$$M_R\tau_R = K_D A_R \tag{4}$$

$$M_I' = K_I A_I' \tag{5}$$

and

$$\frac{K_D}{K_I} = \frac{M_R}{M_I'}\tau_R\frac{A_I'}{A_R} \tag{6}$$

CALCULATION OF τ_D, THE ASSAY OF PRODUCT D IN THE SAMPLE

Combining relation 3 and relation 6, it is possible to determine τ_D, the purity of the product D, by

$$\tau_D = \frac{A_D}{A_I}\frac{A_I'}{A_R}\frac{M_I}{M_E}\frac{M_R}{M_I'}\tau_R \tag{7}$$

Some conditions are required for Eq. 7 to be valid: Areas and weights must be expressed in the same unit system both for analysis and calibration; because precision and accuracy of this method only depend on the precision and accuracy of weighings, they depend neither on the precision and accuracy of the dilutions nor on the injected volume (unlike the external standard method). It requires no preliminary determination of the proportionality coefficients. However, if some points of the sample handling are fully corrected by the use of an internal standard, other difficulties still remain.[2]

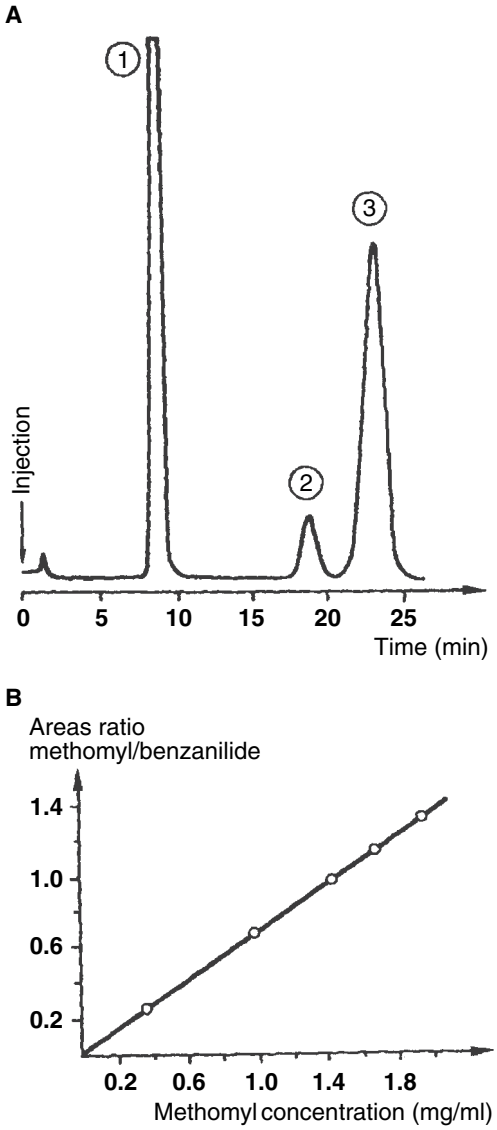

Fig. 1 Insecticide analysis by the internal standard method: (A) chromatogram; (B) calibration curve. 1: Benzanilide (internal standard); 2: methyl-*N*-hydroxythioacetimidate; 3: methomyl.
Source: From Precise quantitative analysis with a stable, high-speed liquid-liquid chromatography column. J. Chromatogr. Sci.[5]

Moreover, this method can quickly become laborious because an internal standard elution which is compatible with the analysis conditions must be found. Conditions that must be fulfilled by the internal standard are its purity must be known and it must be chemically inert toward solutes and mobile phase; on the one hand, its retention time must be different from those of all the constituents present in the sample and, on the other hand, it should be as close as possible as the retention time(s) of the product(s) to be determined. It has also been demonstrated that a necessary correlation was required between chromatographic behaviors of the internal standard and the product to quantify.[3] Otherwise, the use of an internal standard can even degrade the precision of the results. A comparison of the precision of internal and external standard has also been carried out through a liquid chromatography (LC) collaborative study.[4]

The internal standard's coefficient of response for the detector used must be of the same order of magnitude as the one of the product to be determined; in no way can it be present as an impurity in the sample; it must be added at a concentration level that gives a peak area more or less equivalent to the one of the product to be determined. Homologues of the product to be analyzed may be used as internal standards.

The chromatogram given Fig. 1 illustrates the internal standard methodology. Here, methomyl was quantified using benzanilide as the internal standard. Using the calibration curve, the unknown methomyl assay in insecticides is deduced from the area ratio, after the addition to the sample of the same quantity of internal standard as in the calibration steps.

The internal standard method is less often used in LC than in gas chromatography (GC) because injection of repeatable volumes has been made easier by the use of precise and reliable injection systems (loop valves). More generally, gradually, the internal standard method is being abandoned. The external standard method is, nowadays, the most common method and the use of an internal standard seems to be restricted to very specific applications; for example, when preliminary to the chromatographic analysis, the solute of interest must be extracted by means of a complex protocol.

Quantitation by Normalization

J. Vial
A. Jardy
Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

The principle of this method is quite simple. Provided that for each solute, i, the analytical signal lies within the linearity range, the peak area is proportional to the weight of solute having passed through the detector cell, thus, that was present in the injected volume,

$$m_i = K_i A_i \tag{1}$$

where A_i is the peak area of solute i and K_i is the response coefficient. Therefore, the percentage in weight of each analyte is given by

$$\%_i \frac{K_i A_i}{\sum_i K_i A_i} \times 100 \tag{2}$$

DISCUSSION

To apply this method in high-performance liquid chromatography (HPLC), several conditions have to be fullfilled: All the analytes present in the sample to be analyzed must elute from the column (no irreversible retention), with enough resolution and, furthermore, have to be detected. All the response coefficients have to be known, or at least attainable experimentally, which, in turn, implies that all the solutes are available separately in a high degree of purity. This method is unable to determine the percentage of any constituent of the mixture if a response coefficient is missing.

On the other hand, an advantage lies in the fact that there is no need to accurately know the amount of sample injected.

Practically, quantitation by the normalization method is not in as common use in HPLC as it is in gas chromatography (GC). It is highly recommended to avoid its implementation in the case of samples for which the qualitative composition is not known exactly. It is only convenient in routine analysis, as in quality control, when the qualitative composition does not vary.

Moreover, note that, except in very particular cases, the approximation to consider all the K_i equal (Eq. 3) is highly hazardous in HPLC, unlike in GC:

$$\%_i \frac{A_i}{\sum_i A_i} \times 100 \tag{3}$$

A few examples of where it is possible are the following: Use of a refractive index detector, trace analysis of related substances (impurities) in pharmaceutical products, with UV detection at very low wavelength, when the accuracy of the result is of little interest[1] (e.g., when chromatography is used to monitor a chemical reaction), and when a relative value is enough. In this situation, the simplified relationship 3 is sufficient, but the analyst must not forget that the proportions found in this way are not the true proportions.

In conclusion, its efficiency and simplicity make quantitation by normalization a very attractive method that generally requires few injections. Nonetheless, it must be kept in mind that it requires the knowledge of the response coefficients for all the constituents in the mixture. The a priori hypothesis of equality for all response coefficients seldom corresponds to reality and can lead to hazardous results.

Quantitation by Standard Addition

J. Vial
A. Jardy
Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

The principle involved is that, provided the analytical signal is proportional to concentration, the initial analyte content is determined through measurement of this signal before and after the addition of a known amount of the analyte to the analyzed sample. The method of standard addition, also denoted as "spiking," is used when an analyte is to be quantified inside a matrix, the effects of which are likely to affect the chromatographic peak behavior. In this case, the sample itself is used as the calibration matrix.

DISCUSSION

Commonly, the unknown concentration is deduced from the increase in the peak height or the peak area resulting from the addition of known amounts of pure analyte to the sample (at least one or two additions). A comparison of peak height versus peak area for quantitation is given in Ref.[1] A more convenient protocol, which gives information both on the precision and the accuracy of the results, is the following. After each addition, the area of the chromatographic peak is measured. Then, the parameters of the regression line are computed using a least-squares regression method. The analyte quantity in the sample corresponds to the intercept-to-slope ratio, denoted x_0. When the dilution produced by additions cannot be neglected, it is necessary to take it into account. Let A_0 be the peak area of the analyte to be determined on the chromatogram obtained with the unknown sample, A_i be the peak area of the same analyte on the chromatogram obtained after the ith addition, x_i be total quantity of analyte added after the ith addition, and f_i be the dilution factor after the ith addition. Then, a line of the areas corrected by the dilution factor versus the amount of analyte added is plotted (Fig. 1). The expression of the corrected area A_i* is

$$A_i^* = A_0 + (A_i - f_i A_0) \tag{1}$$

If, on the chromatogram, there is another peak other than that of the analyte, well resolved, but close enough, it can be used as a tracer to evaluate f_i. Let A_t be the peak area of the tracer on the chromatogram obtained with the unknown sample and A_{ti} the peak area of tracer on the chromatogram obtained after the ith addition of pure analyte:

$$f_i = \frac{A_{ti}}{A_t} \tag{2}$$

Otherwise, the dilution factor f_i must be evaluated in another way.

Then, the parameters of the calibration curve are computed by mean of a linear least-squares regression:

$$A_i^* = a + bx \tag{3}$$

The result is given by

$$x_0 = \left(\frac{a}{b}\right) \tag{4}$$

The method of standard additions would give the true result if there were no experimental errors. Practically, this is never the case and, so, a weakness of the method appears concerning the reliability of the provided result (unknown concentration). Effectively, the use of extrapolation of a calibration curve is always less conformable and reliable than interpolation, especially concerning the errors on predicted values.[2–4] The problem is even more explicit when the result is expressed along with its confidence interval. Confidence curves of the regression line must, thus, be used. Their expression is

$$A_i^* = a + bx \pm \hat{\sigma}_{y/x} t_{\alpha,(n-2)} \times \left(\frac{1}{n} + \frac{(x-\bar{x})^2}{\sum_i (x_i - \bar{x})^2}\right)^{1/2} \tag{5}$$

In Eq. 5, $\hat{\sigma}_{y/x}$ represents the estimated residual variance of the regression, $t_{\alpha,(n-2)}$ is the limit value that a Student's variable with $n-2$ degrees of freedom has α chances out of 100 not to exceed in module, and n is the number of points used. Confidence limits of the result correspond to the zero of Eq. 5. No exact analytical solutions are available, but either it is possible to solve it numerically or approximate solutions can be

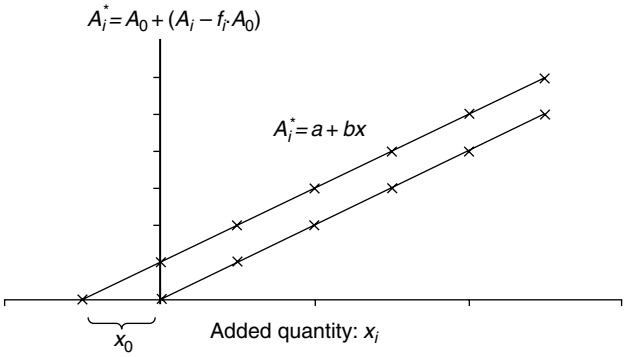

Fig. 1 Visualization of the standard addition methodology. The dotted line represents the calibration line obtained when the analyte of interest is not present in the matrix.

used. An approximate expression of the standard deviation of the result is

$$\hat{\sigma}_{x_0} \simeq \frac{\hat{\sigma}_{y/x}}{b}\left(\frac{1}{n} + \frac{\bar{y}^2}{b^2 \sum_i (x_i - \bar{x})^2}\right)^{1/2} \quad (6)$$

This leads to the following confidence interval (CI) for the unknown concentration:

$$\hat{\sigma}_{x_0} \simeq \frac{\hat{\sigma}_{y/x}}{b}\left(\frac{1}{n} + \frac{\bar{y}^2}{b^2 \sum_i (x_i - \bar{x})^2}\right)^{1/2} \quad (7)$$

To avoid having an excessively large interval, it is strongly advised to take enough points in a relatively widespread range. A compromise must be found for the spacing out of the points. It must be maximum to decrease the error on predicted values, but all the points must, nevertheless, belong to the linear range. An example of an application describing the analysis of 5-hydroxyindolacetic acid in human cerebrospinal fluid is given in Ref.[1]

However, the method of standard addition is not only useful to quantify an analyte present in a matrix, it can also be employed to check if the matrix introduces any proportional error. Similar additions of analyte are made to a blank matrix (the dotted line in Fig. 1) and if there is no proportional error, then the slopes of both regression lines are equal. Therefore, the slope equality has to be tested through a convenient statistical test. To conclude, the method of standard additions is a powerful method that enables to quantify an analyte present in a matrix susceptible to modify its behavior. Nevertheless, this method is somewhat tedious, because it requires many preparations and injections to obtain enough points for a sufficient reliability.

Quantitative Structure-Retention Relationship by TLC

N. Dimov
Chemical Pharmaceutical Research Institute (NIHFI), Bulgarian Pharmaceutical Group Ltd., Sofia, Bulgaria

INTRODUCTION

The retention behavior of a compound in a chromatographic system is governed by three global factors: stationary phase–mobile phase combination, experimental conditions, and the compound's structure. In thin-layer chromatography (TLC), there is a huge choice of combinations: between stationary phases, a much greater choice of mobile-phase components, and less complex experimental conditions. It follows that an optimization strategy is necessary in order to come closer to the wanted separation. Keeping in mind that, for example, with an experimental design, 2^n experiments are necessary, where n is the number of factors, and one has to accept several factors a priori before starting the optimization. Depending on the result achieved, the separation is accepted as satisfactory or the optimization efforts continue. Once the analytical method is established (validated), it is available for application. The new problem became the reference substances necessary for system suitability verification and for identification. Although two difficult-to-separate compounds are enough for the verification, many reference materials are necessary for the identification of all compounds of interest. One of the steps helping to overcome this problem is the so-called quantitative structure–retention relationship (QSRR). It is assumed, in QSRR, that the first two global factors (stationary phase–mobile phase combination and experimental conditions) are already established and the obtained retention depends only on the compound's structure.

DISCUSSION

There is a great number of publications on QSRR in TLC (e.g., Refs.[1–3]). The protocol to be followed in QSRR calculations has, in general, the following steps: (1) composition of the experimental data set, (2) molecular structure entry, (3) structure descriptor calculation, (4) regression between experimental data and descriptors.

The compound's structure is entered using, typically, computer graphics. Each structure is optimized by molecular mechanics, which is followed by molecular orbital calculations. Topological indices, electronic parameters, physicochemical properties, indicator variables, and so forth are used as molecular structure descriptors.

The existing QSRR calculation methods are limited to the ideal case of an isolated molecule; that is, in all cases, the descriptor values are calculated at minimum molecular energy. Thus, it is accepted a priori that the structure of the analyte molecule is rigid enough to maintain its three-dimensional (3D) structure after contacts with the stationary phase. Although such assumption is disputable, this practice continues, because of the lack of knowledge of how the solute molecule is located on the stationary phase, lack of identity of chromatographic contact regions, and the impossibility of calculating the interaction forces developed between them.

To move aside from this impediment, the following have been realized:

- The interaction forces between the solute molecule and chromatographic phases during the chromatographic process release energy higher than the rotational barrier of solute bonds.
- Due to this excess of energy, the solute 3D structure undergoes changes that allow its better location on stationary phase.
- Predicting the exact 3D structure, as it is sorbed on the surface of the stationary phase, is impossible, but presuming several energetically possible structures for one and the same structure allows us to enter into Step 2 several descriptor values for one and the same analyte and use them further in Step 3. It is assumed that one of the calculated descriptor's values could give the "searched best fit" between the experimental and calculated retention values.

If the descriptors used in the most accurate predictive equation are calculated at the minimum heat of formation (CHF), then the analyte has been sorbed as a rigid molecule. If greater accuracy is achieved at higher CHF,

[b]Same plate with *n*-C_7H_{16}–C_6H_6–diethylether = 1 : 2 : 2.

the starting 3D structure has been changed during the chromatographic process.

This assumption will be tested first with the retention data for R_m of 9 benzene derivatives (predominantly rigid structures) and, next, for the R_f of 15 benzodiazepines (versatile structures with many s bonds) separated on silica gel. The data for benzene derivatives were taken from the literature,[4] where several mobile phases had been used. Two mobile phases with different polarities have been chosen.

In the first case, only two from all nine studied benzene derivatives have rotamers (see Fig. 1). From all tested combinations among the calculated descriptors, only one answers both to the accuracy and statistical requirements:

$$R_M = -5.50 \pm 0.22 + (24.57 \pm 0.88)\mathrm{DD}[1] + (4.19 \pm 0.19)Q[6] + (1.26 \pm 0.19)Q[5] \quad (1)$$

for mobile phase I with correlation coefficient $r = 0.9966$, variance $v = 1.96 \times 10^{-4}$, and $F = 483$, and

$$R_M = -7.04 \pm 0.52 + (29.84 \pm 2.08)\mathrm{DD}[1] + (4.51 \pm 0.45)Q[6] + (1.88 \pm 0.44)Q[5] \quad (2)$$

for mobile phase II with correlation coefficient $r = 0.9870$, variance $v = 1.1 \times 10^{-3}$, and $F = 127$. DD[1] stands for the donor delocalization energy of the –O– atom, and $Q[5]$ and $Q[6]$ stand for the charges of the fifth and sixth atoms, respectively. The increased influence of the –O– atom with the most polar mobile phase suggests checking another quantum-chemical local descriptor for the –O– atom. Eq. 3 gives a statistically better prediction of the experimental values of R_M:

$$R_M = -0.93 \pm 0.09 + (10.73 \pm 0.55)\mathrm{AD}[1] + (3.00 \pm 0.31)Q[6] + (1.65 \pm 0.29)Q[5] \quad (3)$$

with $r = 0.9913$, variance $v = 6.4 \times 10^{-4}$, and $F = 267$. AD[1] stands for the acceptor delocalization energy of the –O– atom. The better-fitted rotamers from *o*-ethylphenol and *o*-chlorophenol are with the higher heat of formation. In the above-given final regression, only these rotamers have been included.

The calculated retention is compared with the experimental value in Table 1. From a statistical point of view, the improvement when using the rotamer with better fit is insignificant ($F_{9,9} = 1.26$ and 1.07) and the assumption could be considered as disputable. This can be explained by the small number of compounds that are able to rotate around the s-bond in the total matrix. Independent of the reliability of the assumption, a beneficial conclusion can be drawn from Eqs. ([1–3]). They demonstrate that the

retentions of the studied benzene derivatives are governed in the studied cases only by local descriptors and predominately by the local descriptors for the –O– atom in the hydroxyl group. The connectivity index used in many studies (e.g., Ref.[5]) showed, in the studied case, a correlation coefficient of only 0.285.

The assumption is undoubtedly verified with the retention data for R_f of 15 benzodiazepines separated on silica. The data were taken from the literature[6] because the authors had corrected, graphically, the R_f values to those obtained with reference materials and, hence, more exact values can be expected.

Three statistically equivalent equations have been obtained. One is presented as follows:

$$R_f = -234.9 \pm 43.2 + (47.27 \pm 4.50)\text{EN} + (2918 \pm 350)\text{DD}[5] + (10.7 \pm 1.8)\text{InVNH} \quad (4)$$

with correlation coefficient $r = 0.949$, variance $v = 13$, and $F = 69$. EN represents the electronegativity, DD[5] is the donor delocalization energy of atom 5 (see Fig. 2), and InVNH is an arbitrarily chosen indicator variable, accounting for the presence (value 1) or absence (value 0) of a substituent at the azepine *N* atom. All parameters have statistically insignificant interrelations, r_i. The R_f values calculated with Eq. 4 are given in column 4 of Table 2 and can be compared with the experimental results given in column 3. Although some of the chosen rotamers are identical to the conformers at the lowest molecular energy, the variance obtained when the descriptors were calculated for all molecules at their minimum calculated heats of formation (CHF_{min}) are statistically higher (32.7). Their values are given in column 7 of Table 2. Taking into account the criterion relevant to acceptance of the hypothesis, it is apparent that the accuracy, if a flexible structure approach is assumed, is higher.

Another conclusion from Eq. 4 is that benzodiazepine's retention, again, is governed by local descriptors (about 65% contribution of DD[5]) rather than by global molecular properties (about 35% from EN). The general conclusion is that it seems possible to increase the accuracy of QSRR calculations in TLC, assuming that flexible 3D analyte structures undergo some changes during the process of adsorption onto silica gel. As a result, a better fit between the calculated and experimental retention data can be achieved if several energetically possible structures for one and the same analyte are presumed.

Quantitative Structure-Retention Relationships: TLC Analysis

L. Zhang
Qin-Sun Wang
National Key Laboratory of Elemento-Organic Chemistry, Nankai University, Tianjin, China

INTRODUCTION

The study of quantitative structure–retention relationships (QSRRs) is one of the most important theoretical fields of chromatography; it has become a new investigation branch of chromatographic science.

QSRR studies are widely investigated in high-performance liquid chromatography (HPLC), gas chromatography (GC), and thin-layer chromatography (TLC). Recently, QSRR studies in TLC have attracted more and more researchers.[1] It is known that TLC has some advantages: It is rapid, relatively simple, low cost, and easy to operate, there is a wide choice of adsorbents and solvents, and very small amounts of substance are needed. In this entry, the establishment and application of QSRR studies are reviewed.

ESTABLISHMENT OF QSRR EQUATIONS

Non-specific parameters, physicochemical parameters, and topological indices are the main parameters used in QSRR studies in TLC. The establishment of QSRR equations in TLC are reviewed according to these parameters.

BASED ON NON-SPECIFIC PARAMETERS

Non-specific parameters include the number of carbon atoms in a molecule, molecular volume, solvent-accessible surface, and so forth. This is relatively simple, and the most commonly used non-specific parameter is the number of carbon atoms in the compound.

There is a relationship between the number of carbon atoms and the retention data in HPLC and GC; a similar relationship was also found in TLC. Boyce and Milborrow[2] found that there was a linear relationship between the R_m values and the number of carbon atoms in the R group of *N*-*n*-alkyltritylamines (ph_3 CNHR). Janjic et al.[3] carried out a series of studies on the relationship between transition metal complexes and the number of carbon atoms in the complexes.

Because of their simplicity, non-specific parameters can be obtained relatively conveniently, but it is not very well correlated for complex molecules.

BASED ON PHYSICOCHEMICAL PARAMETERS

Physicochemical parameters are widely used in QSRR studies. Among the many physicochemical parameters, lipophilicity is one of the most widely used parameters in TLC-QSRR studies. As is well known, there is a linear relationship between the R_m [$R_m = \log(1/R_f - 1)$] values and the connection of organic modifier in mobile phase:

$$R_m = R_{m0} + bc$$

where c is the concentration of organic modifier in mobile phase and b is the slope, which is the decrease of R_m values when the concentration of organic modifier in the mobile phase increases 1%. R_m is the intercept of the TLC equation which represents the extrapolated value (i.e., the theoretical value at 0% organic solvent). This linear relationship has been verified by many workers.[2,4]

Pliska and Schmidt[5] first described the theoretical relationship between R_f and P values and presented the details of the computational procedure. At the same time, the relationship between the intercept R_{m0} and the slope b in the TLC equation was also studied by many other researchers. Biagi et al.[4] performed extensive work in this field. They found that R_{m0} values were not dependent on the nature of the organic solvent and that it does not make much difference whether the organic solvent is acetone, methanol, or acetonitrile. In addition, there is a linear relationship between the intercept (R_{m0}) and the slope (b). Biagi et al. considered that the existence of the linear relationship is a reason why the chromatographic method can be used to determine lipophilicity. The intercept of the TLC equation can be considered as a measure of the partitioning of the compounds between a polar mobile phase and a non-polar stationary phase (i.e., as the result of the balance between the interactions with the non-polar phase and the interactions with the polar phase), whereas the slope of the TLC equation indicates the rate at which the solubility of the compound increases in the mobile phase.[4] There are many studies dealing with this aspect.

BASED ON TOPOLOGICAL INDICES

Based on the plot of the suppressed hydrogens of the molecular under study, the calculation methods of molecular connectivity indices was developed. It has been used in many fields, such as the studies of correlation between structure and physicochemical and pharmacological properties, especially the relationship between structure and retention behavior, and the evaluation of the hydrophobicities of organic compounds by chromatographic methods.

The relationship between the retention behavior of benzodiazepine, sulfamides, substituted anilines, barbiturates, a group of natural phenolic derivatives, diethanolamine isomers, amino acids, sulfoether, thioalcohol, 2,4-dinitrophenylhydrazones, and their molecular connectivity indices were studied. All of the results indicate that the R_f or R_m values are highly correlated with molecular connectivity indices.

Pyka[6–8] performed a series of experiments applying topological indices to QSRR studies in TLC. Topological indices, such as Gutman, Randic, and Wiener indices as well as other indices were used. A new optical index (I_{opt}) was proposed,[6] which enables distinction between isomers of D- and L-configuration. Pyka also established a new stereoisomeric topological index (I_{STI}), which enables distinction between stereoisomers with hydroxyl groups in axial and equatorial positions. Using this index, the retention behavior of stereoisomeric menthols and thiol have been studied.

Introducing topological indices to QSRR studies widens the possibility of correlation analysis. Molecular connectivity indices are calculated according to molecular structure; it is relatively objective. Topological indices can be calculated without synthesizing the compound. In addition, using topological indices, the molecular structure can be described by some parameters which have physicochemical significance. However, there is also a limitation in the range of application of topological indices. They can be applied as the sole parameter only when they have been correlated with other features of molecular structure, such as volume, ring size, carbon chain length, and so forth. Generally, they are combined with other parameters that characterize other properties of the compounds of interest.

COMBINATION OF SEVERAL KINDS OF PARAMETERS

As we can see, every kind of parameters have limitations; thus, the combination of several kinds of parameters is advantageous. The combination of several kinds of parameters can often completely reflect the properties of compounds. Wang et al.[9] conducted some studies in this field. They introduced several structural parameters to study the correlation between the molecular structures of *O*-ethyl-*O*-aryl-*N*-isopropyl phosphoroamidothioates, *O*-ethyl, *O*-isopropylphosphoro(thioureido) thioates, and their retention factors in high-performance TLC (HPTLC), respectively.

APPLICATION OF QSRR STUDIES IN TLC

Prediction of Retention and Separation

From the discussion earlier, it can be seen that all the QSRR equations established in the previous part can be used to predict R_f or R_m values of compounds. This goal of QSRR is very easy to comprehend.

Determination of Lipophilicity

Many works[5] have illustrated that there is a linear relationship between R_m values and log P. R_{m0} values also can be used to measure the lipophilicities of chemical substances. In general, the chromatographic method is an excellent alternative to the traditional flask-shaking method for lipophilicity determination. It avoids the difficulties that one may encounter in the flask-shaking method. It is simple and rapid and requires only minute amounts of substances (which need not necessarily be very pure); it does not need quantitative analysis; the nature of the organic modifier does not affect the measurement of the lipophilic character, as the value is not affected by the organic modifier.

Evaluation of Some Physicochemical Parameters of Chemicals

The research on the evaluation physicochemical parameters using the TLC-QSRR equation is very limited. Until now, only the log $E_{T(30)}$ values of some organic solvents[10] and the pK_a values of some substituted phenols[8] have been predicted using this method. In addition, topological indices are introduced to evaluate the pK_a values.

Evaluation of Biological Activities of Compounds

Although, as early as 1965, Boyce and Milborrow[2] studied the relationship between R_m values of *N*-*n*-alkyltritylamines (ph_3 CNHR) and their LD_{50} values, the research on this aspect is limited. When only the R_m values is considered, the activity [log(1/C) or LD_{50}] is correlated with the square of R_m.

Topological indices were also introduced to study the biological activities of compounds. Pyka[7] studied the relationship among R_m values, topological indices, and biological activity [log(1/C)]. All of the equations he obtained show good correlation. There is a good agreement between predicted log(1/C) values and experimental log(1/C) values.

EXPLANATION OF SEPARATION MECHANISM

Theoretically speaking, a good QSRR equation can reflect the most characteristic parameters that influence the retention behavior of compounds. Thus, it can explain the retention mechanism quantitatively and qualitatively, but research on this aspect has made only poor progress until now.

Cserhāti and Forgacs[11,12] did some work on this field which illustrates the high impact of steric interactions on retention. However, until now, some of his hypotheses[12] need further experimental verification to support them.

PROSPECTS

Quantitative structure–retention relationships play a vital role in chromatographic research. The research and application fields of QSRR studies are becoming increasingly broad. Up to now, compounds used in QSRR studied are homologous series. How to establish QSRR equations that fit different kinds of compounds requires much more experimental effort.

From the viewpoint of application, QSRR equations in TLC are mainly used for retention prediction. The explanation of the separation mechanism awaits further investigation. With the application of various statistical methods, it is possible to select the primary retention-effect factors from many solute related factors which will offer explanations of separation mechanisms.

In conclusion, QSRR studies are making excellent progress in recent years, due to increased interest in this field of study. We can anticipate that QSRR studies will become more and more important in the future.

Radiochemical Detection

Eileen Kennedy
Novartis Crop Protection, Inc., Greensboro, North Carolina, U.S.A.

INTRODUCTION

Radiochemical detectors are devices that allow the measurement of low-energy γ-rays or β-particles emitted by radioisotopes. Substances called scintillators absorb the energy that is produced by the radioactive decay and transform it into light. The light from the scintillator, the intensity of which is directly proportional to the energy of the radioisotope emission, can be detected by a photomultiplier to provide an electrically countable pulse. Radiochemical detectors have been developed for various chromatographic techniques, the most common of which is high-performance liquid chromatography (HPLC). In HPLC, the detection of radioisotopes in a column eluate has allowed quantitation of discrete radiolabeled peaks in real time and in a generally non-destructively manner.

DISCUSSION

Gamma-emitters, such as iodine-125, which give off energy in the form of photons rather than particles, are more strongly penetrating than β-emitters. A radiochemical detector for γ-rays is generally composed of a cylindrical block of specially activated sodium iodide enclosed in a thin aluminum shell. One face of the block is optically coupled to a single photomultiplier. The eluate from the HPLC column passes through a coil or U-tube, which is placed in the well of the block. As the eluate passes through the coil, g-radiation is stopped by the very dense sodium iodide, producing light that can be measured by the photomultiplier.

Beta-emitters such as tritium (H-3) or carbon-14 (C-14) are the most commonly used radioisotopes in drug metabolism, agricultural metabolism, and toxicology studies. In HPLC, the radiochemical detector can be off-line or online. Off-line detection requires coupling the chromatograph to a fraction collector. The collected fractions are combined with a suitable liquid scintillation cocktail and then counted by a liquid scintillation counter. This method allows for the control of parameters such as counting time to improve sensitivity, but it suffers from being labor and time intensive. Online or flow-through radiochemical detectors can be homogeneous or heterogeneous. In homogeneous flow through detectors, a scintillation cocktail is added to the column eluate prior to detection in a liquid flow cell. The energy of decay from the b radionuclide is transferred to the scintillation cocktail via a solvent molecule. The liquid flow cell offers the highest sensitivity in online detectors but precludes recovery of the entire sample and requires an additional pump for delivery of the scintillation cocktail. In heterogeneous counting, the column eluate passes directly through a flow cell packed with a suitable solid scintillator such as yttrium silicate, calcium fluoride, or lithium glass. Use of the solid flow cell involves no additional costs for the scintillation cocktail and simplifies waste disposal. However, the solid cells have a lower counting efficiency, particularly with tritium, and can suffer from high backgrounds due to contamination. In both homogeneous and heterogeneous counting, light energy is detected by a pair of photomultiplier tubes located on either side of the flow cell, which is most often composed of a flat coil of thin-wall tubing situated in a transparent case. The photomultiplier tubes are located in fairly close proximity to each other (typically less than in. apart). Most commercially available radiochemical HPLC detectors use coincidence electronics in order to reduce noise pulses. With a coincidence counter, events are only recorded when both photomultiplier tubes are stimulated by light to give a pulse output within 20–50 ns of each other. A multichannel pulse-height analyzer sorts the outputs from the coincidence counter. A computer is then generally used to process data from the radiochemical detector as well as other online detectors and the results are presented either on a monitor or printer.

Unlike other chromatographic measurements such as ultraviolet (UV) absorption, the measurement and quantitation of radioactivity are based on time. Although a known percentage of a radioisotope will decay over a relatively long time, within that time period, the instantaneous rate of decay is not known. Because radioactive decay is a statistical process, the quality of a radioactivity measurement improves as a function of time. In other words, the longer the sample is counted, the more accurate (or statistically relevant) the measurement of the radioactivity. With off-line radiochemical detection, even very small peaks can be counted for a sufficiently long time to allow for a statistically relevant measurement. With online detection, the total flow rate and the cell volume fix the counting time. Online detection of low-level peaks can be improved by either a slower flow rate or by a larger flow cell. For solid flow cells, the total flow rate is equal to the mobile-phase flow rate. For liquid flow cells, the total flow rate is equal

to the mobile-phase flow rate plus the flow rate of the liquid scintillator. The latter is frequently expressed as a ratio of scintillator to mobile phase. As compared to other HPLC detectors, the volume of the flow cell is relatively large in the radiochemical detector. Flow cells typically range from 250 to 500 μl for solid cells and from 1000 to 2000 μl for liquid cells. Upward limits on the size of the flow cell are governed by the possibility of more than one peak being present in the cell at any one given time. However, assuming sufficient resolution, a larger flow cell should allow for a longer counting time and, hence, a more accurate measurement of radioactivity in a given peak. The actual amount of time that the column eluate will remain in the vicinity of the photomultiplier tubes is defined as the residence time. The residence time (R), in seconds, can be calculated as follows:

$$R\frac{V}{F} \times 60$$

where V is the cell volume in microliters and F is the total flow rate in milliliters per minute.

The counts per minute (cpm) can then be calculated for each peak in the sample as follows:

$$\text{cpm} = \frac{N}{R}$$

where N is the total net counts observed in the peak after background subtraction and R is the residence time in minutes.

Disintegrations per minute (dpm) are equal to cpm in the rare cases where the counting efficiency is 100%. Otherwise, dpm can be calculated as follows:

$$\text{dpm} = \frac{\text{cpm}}{E}$$

where E is the counting efficiency expressed as a percentage.

The efficiency of a radiochemical detector can be defined as the number of counts that are detected in the peak after background subtraction divided by the total number of radioactive events that actually occurred in the sample during the counting period. The approximate counting efficiencies that can be achieved with solid flow cells are fairly low for tritium (up to 10%) and significantly better for C-14 (up to 90%). With liquid flow cells, the counting efficiencies are greater than 55% for tritium and greater than 95% for C-14. Under isocratic conditions, the counting efficiency remains constant and can be readily determined by injecting a known amount of activity into an HPLC system, collecting the resultant peak as a single entity and counting it in a liquid scintillation counter. The number of disintegrations in the recovered peak is then compared to the calibrated activity of the standard. With gradient elution, the counting efficiency will generally change as the mobile-phase composition changes. In this situation, an efficiency calibration or quench curve can be obtained by injecting a constant known level of radioactivity during an otherwise blank gradient run. The calibration curve is then used to correct subsequent HPLC runs.

The minimum amount of radioactivity that can be detected by a flow-through radiochemical detector is a subject of continuing debate. It is generally accepted that a fairly sharp peak that contains counts that are at least twice background can be detected. One formula for calculating the minimum detectable activity (MDA) is given by

$$\text{MDA} = \frac{BW}{RE}$$

where B is the background count in cpm, W is the base width of the peak in minutes, R is the residence time in minutes, and E is the counting efficiency expressed as a percentage.

In practical terms, for a 500 dpm peak with a base width of 20 sec, a counting efficiency of 70% and a residence time of 12 sec, we would observe 70 counts, which would be spread out over the peak width, plus the residence time (a total of 32 sec). For a detector that has a 10 cpm background, we would observe 5.3 counts over the same time period of 32 sec. The ratio of the observed peak counts to background would be 13:1 and the peak should be clearly visible. However, under the same conditions, a 50 dpm peak would have a count to background ratio of only 1.3:1 and it is doubtful that this peak could be observed in online counting. In the latter situation, off-line radiochemical detection may be used to clarify the presence or absence of such a low-level peak.

Radiolytic Degradation Products: Monitoring Priority Pollutants

S. Bilal Butt
Rashid Nazir Qureshi
Central Analytical Facility Division, Pakistan Institute of Nuclear Science and Technology, Islamabad, Pakistan

INTRODUCTION

Speedy industrialization has provided much comfort to human beings; however, its adverse effects have emerged in the shape of environmental deterioration.[1] Untreated industrial wastewater has become a great health-risk. It has been found that treated wastewater that is discharged into the water carrying bodies is not free of toxic contaminants, particularly the so-called emerging pollutants.[2] The situation is critical in underdeveloped countries where pollution monitoring systems are not well established. Additionally, the indiscriminate domestic use of synthetic compounds generally known as products of personal care (PPC) has also introduced toxic compounds into the environment.[3] Many of these pollutants from industrial and municipal waste are toxic, persistent, and not readily biodegradable. Also, the current trend of urbanization and increased anthropogenic activity have further deteriorated the already endangered environmental situation. Public health is at risk because of the presence of these toxic pollutants in the environment, particularly in terms of the quality of potable (drinking) water. Industries discharging pollutants into the environment include oil refineries, tanneries, textile plants, and the food, pharmaceutical, paint, and coal processing industries. This entry will focus attention on the contamination of surface, ground, and potable water by industrial and municipal wastewater. The role of chromatography will be highlighted.

MONITORING OF POLLUTION IN POTABLE WATER

Monitoring the concentrations of various pollutants in industrial wastewater, as well as surface and ground water, with precision and accuracy is a difficult task. Wastewater is a complex matrix that normally contains organic pollutants of non-polar to polar nature in addition to bulk inorganic contaminants. Additionally, interferences are likely when handling complex mixtures of compounds. Under these circumstances, chromatography has played an important role and has provided solutions to complex analytical problems. It is extremely important to have an excellent analytical technique that can accurately and precisely monitor the concentrations of pollutants before and after the appropriate treatment process. The strength of chromatography is the fact that it can analyze diverse types of pollutants in water such as PAHs,[4] NO_2–PAHs,[5] and chlorophenols.[6] Emerging contaminants present in potable water are also of great health concern.[3] The elimination of such organic contaminants is key in the production of drinking water and the reuse of water resources. The emerging contaminants most commonly found in raw and wastewater are surfactants,[7] antiseptics,[8] acidic pharmaceuticals/PPC,[2] and polar pesticides.[9] The removal efficiency of these toxic compounds in wastewater treatment plants was found to be low.[10] Therefore, in addition to the untreated wastewater, these sewage effluents are also among the sources of these pollutants and their metabolites in water.

ROLE OF CHROMATOGRAPHY IN MONITORING WATER PURIFICATION EFFICIENCY

Currently, a variety of technologies is incorporated into the processing of industrial and municipal wastewater treatments. The most commonly employed are:

1. Activated Sludge Treatments (AST);
2. Membrane Bioreactors (MBRs);
3. Advanced Oxidation Processes (AOP);
4. Radiolytic Degradation of Contaminants.

The pollutant removal efficiencies of these processes, at different processing stages, are frequently performed by incorporating a variety of chromatographic techniques. For comparison only, AST and radiolytic processes will be considered. AST is a state of the art wastewater treatment process (WWTP) that is preceded by conventional physicochemical pretreatment steps. The level of acidic pharmaceuticals such as carbamazapine, diclofenac, and naproxen in the influent and effluent of an AST facility was monitored by chromatography and the removal efficiency was found to be low.[11]

Chlorinated phenoxy acids are used extensively as herbicides in agriculture, as algaecides in paints, and as coating agents. These are the main sources of their introduction in to the aquatic system. Their removal efficiency using

AST, as monitored by chromatography, is also not satisfactory.[12] Alkylphenol surfactants remain the most widely used non-polar surfactants. The formation of treatment resistance-metabolites out of parent surfactants has been noticed using chromatographic techniques.[13]

Moreover, irrespective of degradation technique chromatography has been used as an effective monitoring tool in the biodegradation of hexachlorocyclohexane (HCH). The potential biodegradation of HCH isomers was evaluated using gas chromatography–mass spectrometry (GC–MS).[14]

IONIZING RADIATION FOR PURIFICATION OF WATER AND WASTEWATER

Ionizing radiation, gamma radiation source or electron beam, is an excellent tool for the purification of polluted water and wastewater.[15] It involves the reaction of primary radiolytic water products, i.e., ($^{\cdot}$OH, e^{-}_{aq}, H) with the pollutants and the formation of secondary short-lived species from the pollutants. The secondary process causes the formation of precipitates that absorb pollutants. The general principal is that radiolytic treatment, in combination with traditional methods such as flotation, coagulations, adsorption, and aeration, is employed for the purification of water and wastewater. Irradiation is used as a facilitating step for the removal of pollutants. In the development of these technologies, chromatography has played a key role in evaluating the efficiency of any process. In this reference, selective wastewater and drinking water treatment processes will be outlined in the context of the important role of chromatography in water purification.

RADIOLYTIC DEGRADATION OF WASTE PETROLEUM PRODUCTS

A process has been studied for the removal of petroleum products, i.e., motor oil, diesel fuels, and residual fuel oil, from wastewater by gamma irradiation. In this regard, the prominent and decisive role of chromatography in this process will be highlighted.

The ^{60}Co γ-source was utilized for studies of water polluted with petroleum products. For this purpose, a heterogeneous system of water–petroleum products was studied. The total concentration of all petroleum products was 150 mg dm^{-3} in the form of an emulsion in bulk water or as a film on the water surface. The removal of petroleum products was studied by monitoring chemical oxygen demand, optical absorbance in the UV–Visible and IR regions, and by

Table 1 Coefficients $K(10)$, $K(15)$, and $K(25)$ for γ-irradiated heterogeneous system (t retention time, X and M mean characteristic and molecular, respectively).

gravimetry and gas chromatography with mass spectrometry.[16] Precipitation was observed when the heterogeneous system was irradiated with γ-rays. After the separation of the precipitate, the remaining petroleum products were extracted in CCl_4 and analysed by GC–MS. The gravimetric analysis showed that 96% of the petroleum products were precipitated at a 25 kGy dose. GC–MS gave in-depth information on the remaining individual components of the petroleum products in the range of 40–500 mAU. The measurements were conducted in the dichloromethane extract from the initial systems (150 mg dm^{-3}) and irradiated once after the precipitate separated. Detailed information about the main compounds, their retention times, characteristic and molecular ions in initial and irradiated systems, and coefficients of the decrease in their concentration upon γ-irradiation to doses of 10, 15, and 25 kGy are given in Table 1.

The data in this table are evidence that chromatography provided information about the removal efficiency of individual compounds and, with that information, it will be easier to assess, decide, and select the type of wastewater purification technology.

DEGRADATION OF ENDOCRINE-DISRUPTING COMPOUNDS

Some chemicals belong to the so-called endocrine disrupting family and their presence in water is of great concern because of their adverse effects on living things. One such compound is *p*-nonylphenol (NPs), which is a by-product of the non-polar surfactant alkylphenoxy polyethoxylate (APE) and has the highest estrogenic activity among synthetic chemicals.[17] This surfactant is mainly used in the textile and paint industries and they are the main sources of its release into the aquatic system.[18] Annual production of NPs and APE is approximately 17,000 and 47,000 tons, respectively, in Japan alone. Around 40,000 tons per year are released into the water environment.[19] NPs degradation with gamma irradiation has been investigated. The concentration of degraded NPs and formation of degradation products have been identified by LC–UV, fluorescence, and LC–MS with atmospheric pressure chemical ionization (APCI) in the negative mode. The concentration of organic acids such as formic and oxalic acid, as final degradation products, was measured by ion chromatography. It is assumed that OH adducts of the NPs are produced during irradiation. LC–MS was used to monitor peak area at a mass to charge ratio of 235 mAU as irradiation products of NPs, at an initial concentration of 1 μg dm^{-3} as a function of dose. Two main irradiation products were detected at 6.3 and 8.5 min retention times. Keeping in view the oxidation of *p*-cresol and 4-ethylphenol, it was proposed that OH adducts of mass 235 are produced from NPs. These masses were assigned to the proposed OH adducts 4-nonylcatechols and 1-(*p*-hydroxyphenyl)-1-non-anols as the degradation products.

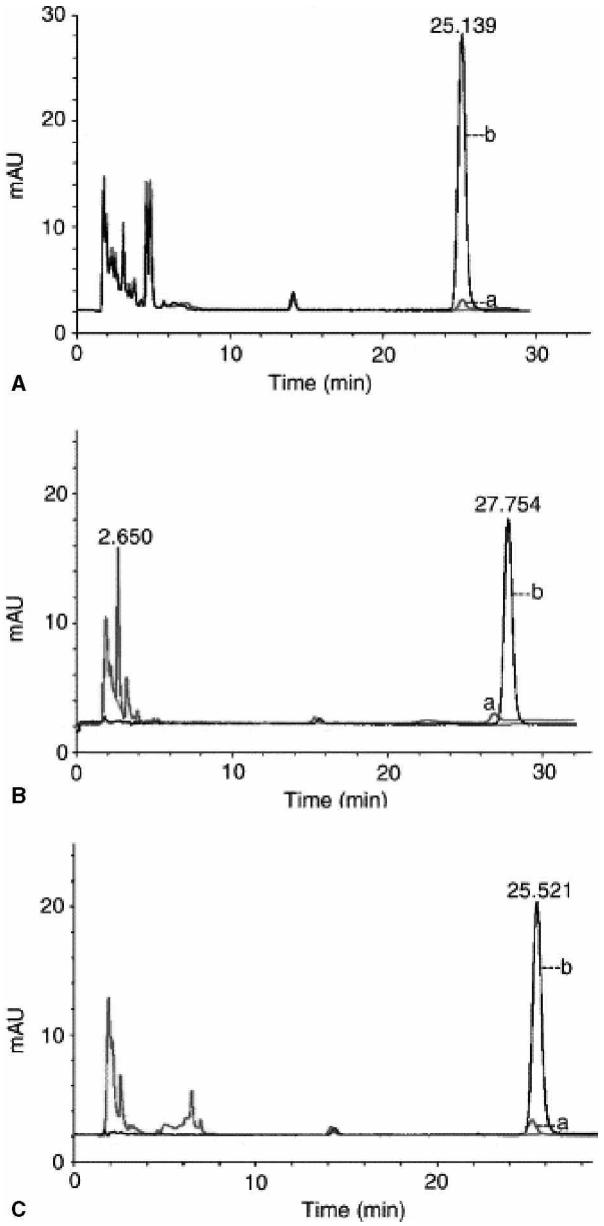

Fig. 1 Chromatographic monitoring of degraded B(*a*)P by 10 kGy γ-irradiation. Column: Discovery C18; mobile phase: methanol: water (80:20); flow rate: 1 ml/min; λ max: 280 nm. [A]: (a) 5 mg dm^{-3} B(*a*)P in methanol, [B]: (a) 2 mg dm^{-3} B(*a*)P in methanol–water [C]: (a) 2 mg dm^{-3} B(*a*)P in methanol–water + surfactant. (b) Doping of each irradiated solution with 1 mg dm^{-3} B(*a*)P.

DEGRADATION OF POLYCYCLIC AROMATIC HYDROCARBONS

The combustion process of fossil fuels and the coal processing industry introduce significant quantities of polycyclic aromatic hydrocarbons (PAHs) into the environment. Sixteen PAHs are known as priority pollutants and are persistent, carcinogenic, and very toxic. The permissible

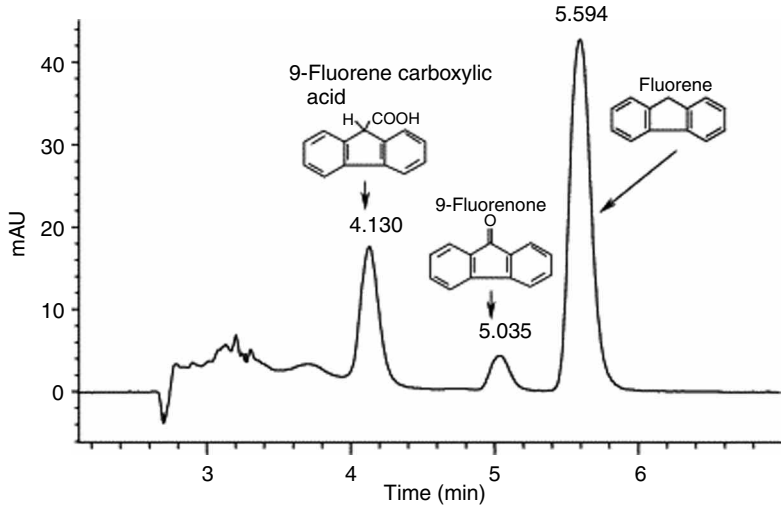

Fig. 2 HPLC chromatogram (column: Zorbax SB-phenyl 4.6 × 250 mm; solvent: 20 vol% H_2O + 80 vol% CH_3OH) of degradation products resulting from 5×10^{-5} mol/L FLU in aerated aqueous solution (pH = 9.6), after γ-rays treatment (0.35 kGy, dose rate: 71 Gy/min). Injection volume: 30 μl. Indication: 2.8–3.95 min mixture of aldehyde and carboxylic acids; 4.13 min 9-FCA; 5.035 min 9-FLE; 5.594 FLU, registered at λ = 260 nm.

limit of two of these PAHs, i.e., benzo(*a*)pyrene [B(*a*)P] and fluorine, in air is 10^{-6} and 2×10^{-3} mg m^{-3}, respectively.[20] The main sources of B(*a*)P are automobile exhaust[21] and the coke oven industry.[4] Its alarming concentration in potable water[22] and urine[23] has been reported. The toxic nature of PAHs, their degradation, and that of B(*a*)P in particular has been investigated using ionizing radiation. The efficiency of the degradation process has been evaluated by various chromatographic techniques. The selected concentrations of B(*a*)P were irradiated in a 50% methanol–water medium with varied doses of γ-rays. The reduction in B(*a*)P concentration was monitored using HPLC–UV, as shown in Fig. 1.[24] It was proposed that degradation products that appear early in the elution order on a reversed phase column are likely to be polar in nature and could be due to the formation of compounds bearing ketonic and carboxylic functional groups. In another study, fluorene degradation was carried out in an aqueous medium as a function of an absorbed radiation dose.[20] The major identified degradation products were 9-fluorenone and 9-fluorene carboxylic acid, in addition to a mixture of aldehydes and carboxylic acids, using HPLC–UV, florescence, and electrochemical detection. The elution behavior of fluorene's degraded products is depicted in Fig. 2.

CONCLUSION

The monitoring of environmental pollutants' degradation and their remediation has emerged as a key issue. In particular, the issue of potable water quality is a great public health concern. The main sources of its pollution are industrial wastewater, municipal waste, and the effluents of wastewater treatment facilities. A number of technologies have been introduced for the purification of polluted water. The efficiency and effectiveness of these processes, i.e., the removal of pollutants, is monitored by incorporating a variety of chromatographic techniques, namely, LC–UV, fluorescence, electrochemical analysis, and gas chromatography with FID and ECD. LC–MS is being used extensively for polar compounds to avoid a derivatization step as exists in gas chromatography.

Radius of Gyration Measurement by GPC/SEC

Raniero Mendichi
Institute of Macromolecular Chemistry, National Research Council (CNR), Milan, Italy

INTRODUCTION

Fundamental properties of macromolecules, such as viscoelasticity and flow behavior, primarily depend on the dimensions and the conformations of macromolecules. Primary biological functions substantially depend on the dimensions of natural macromolecules such as proteins and enzymes. Hence, a primary method to understand the physical properties of macromolecules, synthetic and natural, involves determination of the dimension as a function of the molar mass. A convenient method to fractionate macromolecules is the size-exclusion chromatography (SEC) technique. SEC fractionation is rapid and efficient and requires small amounts of the polymeric sample. A method to measure the dimension of the macromolecules as a function of the molar mass is an online technique to a SEC system.

DISCUSSION

The simplest parameter to quantify the dimension of a macromolecule is the end-to-end distance. The end-to-end distance is the spatial distance between the end groups of a linear chain. Unfortunately, there are no experimental direct methods to measure the end-to-end distance of a macromolecule. Furthermore, the end-to-end distance has no meaning for a chain without end groups (ring) and with many end groups (branched). Instead, the dimension of every type of macromolecule can be always quantified by the gyration radius $\langle s^2 \rangle^{1/2}$.

There are several experimental methods to measure $\langle s^2 \rangle^{1/2}$. Macromolecules can be represented as N segments (monomers, groups) of mass m_i and distance r_i from the center of gravity. The gyration radius $\langle s^2 \rangle^{1/2}$ is defined as the mass average of r_i:

$$\langle s^2 \rangle^{1/2} = \left(\frac{\langle \Sigma m_i r_i^2 \rangle}{\Sigma m_i} \right)^{1/2} \quad (1)$$

Actually, the term "gyration radius" is a misnomer; it originates from the kinematics, but is very popular. More correctly, it should be called "root mean square radius." Non-rigid macromolecules possess conformational mobility; hence, their dimension requires an additional average, $\langle \rangle$, over all the conformations. The dimension of a macromolecule also depends on its long-range interactions, excluded volume, and the polymer-solvent interactions. Therefore, $\langle s_0^2 \rangle^{1/2}$ denotes the dimension of the macromolecules in the unperturbed ideal state and $\langle s^2 \rangle^{1/2}$ denotes the expanse dimension as a consequence of the excluded volume. Finally, macromolecules are generally polydisperse and, by analogy to the molar mass, $\langle s^2 \rangle_n^{1/2}$ denotes the numeric average, $\langle s^2 \rangle_w^{1/2}$ denotes the weight average, and $\langle s^2 \rangle_z^{1/2}$ denotes the z average.[1]

Size-exclusion chromatography fractionation is steric, that is, dimensional. In theory, a SEC system could be calibrated by means of some appropriate standards of known dimensions and, in this way, to measure. SEC fractionation depends on the hydrodynamic radius R_H of the macromolecules: $R_H \propto M[\eta]$ where $[\eta]$ is the intrinsic viscosity. $\langle s^2 \rangle^{1/2}$ and R_H are two different parameters. $\langle s^2 \rangle^{1/2}$ and match is an equilibrium parameter; R_H is a dynamic parameter and depends on the method by which it is obtained. R_H becomes the Stokes radius R_D in diffusion measurements and the Einstein radius R_η in viscosity measurements. Because SEC fractionation depends on R_H, the method is not appropriate for a direct measure of $\langle s^2 \rangle^{1/2}$. Convenient experimental methods to measure $\langle s^2 \rangle^{1/2}$ are scattering techniques.

The $\langle s^2 \rangle^{1/2}$ value of macromolecules usually ranges from 2 to 3 nm (globular proteins) to several hundred nanometers (particles). The range of $\langle s^2 \rangle^{1/2}$ values determines the more appropriate scattering technique. Smaller dimensions of the molecules require shorter wavelengths of the radiation. Light-scattering (LS) wavelengths range from approximately 400 to 700 nm. The minimum $\langle s^2 \rangle^{1/2}$ value that could be measured by LS is 8–10 nm and 5–6 nm in the more favorable case (shorter wavelength). If the dimension of the molecules is small, we need to use other scattering techniques such as x-ray or neutrons.

A modern LS photometer uses coherent light (i.e., laser) with vertical polarization. In our specific case, LS concerns the interaction of the light with matter with a solution of macromolecules. In an LS experiment, we measure the intensity of the scattering. Furthermore, to measure the $\langle s^2 \rangle^{1/2}$ value, we need the angular variation of the scattering. Because we want to measure online to a SEC system, after the fractionation in the columns, we need to measure the angular variation of the scattering instantaneously (i.e., simultaneously) over a wide range of angles. In this case, we need an online multiangle light-scattering (MALS) detector.

Following Zimm,[2,3] the intensity of the scatteringof a solution of macromolecules is in relation to themolar mass of the sample by

$$\frac{Kc}{\Delta R(\theta)} = \frac{1}{MP(\theta)} + 2A_2C + \ldots \quad (2)$$

where $\Delta R(\theta)$ is the scattering excess (Rayleigh factor) at angle θ of the solution with regard to the pure solvent, θ is the angle between the incident light and the detector, M is the molar mass, c is the concentration, A_2 is the second virial coefficient, and K is an optical constant [$K = (4\pi^2 n_0{}^2(dn/dc)^2)/(N_a\lambda_0{}^4)$, where n_0 is the refractive index of the solvent, dn/dc is the refractive index increment of the polymer, λ_0 is the wavelength of the light *in vacuo*, and is Avogadro's number].

The parameter of interest for the measurement of $\langle s^2\rangle^{1/2}$ is the form factor $P(\theta)$. A macromolecule may not be considered as a single point of scattering. In this case, the light scattered from two different points of the same macromolecule will not be in phase: destructive interference. The intensity of the scattering in the presence of the destructive interference is lower for large molecules. The interference depends on the angle of measure of the intensity of the scattering. The interference is absent at 0° angle and highest at 180°. The interference depends on the shape and on the dimension of the molecules. Therefore, there has been introduced a form factor $P(\theta)$ which quantifies the interference. $P(\theta)$ is defined as the ratio between the Rayleigh factor in the presence of interference ($\theta > 0°$) and the Rayleigh factor in the absence of interference ($\theta > 0°$). Thus, by definition,

$$P(\theta) \equiv \frac{R(\theta)}{R(\theta = 0°)} \quad (3)$$

Eq. 3 states that $P(\theta) = 1$ for $\theta = 0°$, independent of the dimension of the molecules, and $P(\theta) < 1$ for $\theta > 0°$ when the dimension of the molecules is comparable with the wavelength l. Fortunately, $P(\theta)$ is a useful method for measuring the dimension of the molecules $\langle s^2\rangle^{1/2}$. Debye[4] showed that the $P(\theta)$ could be expressed independently of the shape and conformation of the macromolecules. Considering the reciprocal of $P(\theta)$ [$P(\theta)^{-1}$], Debye obtained the following equation:

$$P(\theta)^{-1} = 1 + \frac{1}{3}\mu^2\langle s^2\rangle \quad (4)$$

where $\mu = 4\pi/\lambda \sin(\theta/2)$, $\lambda = \lambda_0/n_0$ is the wavelength of the light in the medium. Eq. 4 is valid in the limit $\mu^2\langle s^2\rangle/3 \ll 1$. From the initial slope of the $P(\theta)$ versus $\sin^2(\theta/2)$ plot, we can estimate the gyration radius value $\langle s^2\rangle^{1/2}$.

To estimate M and $\langle s^2\rangle^{1/2}$ values, Eqs. 2 and 4, we need to extrapolate to infinite dilution: $c = 0$. When the MALS detector is used as an online detector in a SEC system to estimate the $\langle s^2\rangle^{1/2}$ of the molecules, we have only a concentration. In a SEC fractionation, it is generally assumed that each instant, slice, contains molecules homogeneous in molar mass and in dimension. In this case, considering the very low concentrations of the macromolecules that elute from the SEC columns, the term ${}_2A_2c$ of Eq. 2 is ignored. However, the exact concentration of each slice has to be known. Thus, the measure of M and $\langle s^2\rangle^{1/2}$ values by a MALS detector requires a concentration detector also, usually a differential refractometer or an ultraviolet (UV) photometer. Combining Eq. 2, deprived of the $2A_2c$ term, with Eq. 4, we obtain

$$\frac{Kc}{\Delta R(\theta)} = \frac{1}{M} + \frac{16\pi^2\langle s^2\rangle}{3\lambda^2 \mathrm{M}}\sin^2\left(\frac{\theta}{2}\right) \quad (5)$$

Using an online dual-detector SEC system, MALS, and concentration from a linear regression of $Kc/\Delta R(\theta)$ on $\sin^2(\theta/2)$, we obtain the molar mass M from the intercept and the dimension of the molecules $\langle s^2\rangle^{1/2}$ from the slope. If the macromolecules are polydisperse, we obtain[3] the averages M_w and $\langle s^2\rangle_z{}^{1/2}$. Fig. 1 shows the $Kc/\Delta R(\theta)$ versus $\sin^2(\theta/2)$ plot of a single slice from a polysaccharide, hyaluronic acid, sample. Fig. 1 shows the classical three parameters that could be obtained at each elution volume: c_i from the concentration detector, M_i and $\langle s^2\rangle_i{}^{1/2}$ from the MALS detector. An accurate measure of $\langle s^2\rangle_i{}^{1/2}$ is not simple. The measurement requires a good signal to-noise ratio, especially at low angles. In addition, if the dimension of the macromolecules is small, the measure of the slope of the $Kc/\Delta R(\theta)$ versus $\sin^2(\theta/2)$ plot is inaccurate. Conversely, if the dimension of the macromolecules is too large, the angular variation of the intensity of the scattering could be not linear. In this case, it is quite difficult to estimate an accurate value of the initial slope of the plot.

Because, for each fraction of the sample, the online MALS detector measures both M_i and $\langle s^2\rangle_i{}^{1/2}$ from a single sample, it is possible to obtain the $\langle s^2\rangle^{1/2} = f(M)$ power law of the polymer. The power law $\langle s^2\rangle^{1/2} = f(M)$ is a very

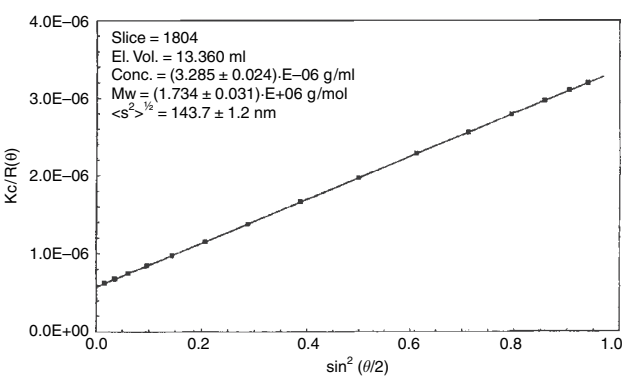

Fig. 1 $Kc/\Delta R(\theta)$ versus $\sin^2(\theta/2)$ plot of a single slice from a hyaluronic acid sample.

important function for understanding the conformation (flexible coils, compact spheres, rigid rods) of the macromolecules. In fact, if the molar mass distribution of the sample is adequately broad, it is possible, from a linear regression of $\log(\langle s^2\rangle^{1/2})$ on $\log(M)$, to estimate the constants K and α of the power law $\langle s^2\rangle^{1/2} = KM^{\alpha}$. Specifically, the slope α of the power law contains fundamental information of the conformation of the macromolecule in solution.

There are several commercially available online MALS detectors. Wyatt Instruments (Santa Barbara, California, U.S.A.) commercializes two MALS detectors: Dawn-DSP (18 angles) and mini-Dawn (3 angles: 45°, 90°, and 135°). Precision Detectors (Franklin, Massachusetts, U.S.A.) commercializes a double-angle LS:15° and 90°. SEC online measurement of $\langle s^2\rangle^{1/2}$ could be performed by other techniques. Viscotek Co. (Houston, Texas, U.S.A.) commercializes an alternative three-detector SEC system, the SEC^3. The SEC^3 system consists of (1) an online viscometer (VISC), (2) an online rightangle LS detector (RALS), and (3) a concentration detector. This three-detector SEC system also measures $\langle s^2\rangle^{1/2}$. More exactly, $\langle s^2\rangle^{1/2}$ is calculated, using an iterative algorithm, from the intrinsic viscosity, by VISC, and the molar mass obtained by the RALS detector. For each instant i, the algorithm is divided into three steps:

- $[\eta]_i$ is measured from VISC; the molar mass is M_i is calculated by RALS using Eq. 2 and $P(\theta) = 1$. In this first step, M is generally underestimated as a consequence of the destructive interference.
- $\langle s^2\rangle^{1/2}$ is calculated by the Flory–Fox equation (Eq. 6). The Ptitsyn–Eizner equation (Eq. 7) considers the expansion of the macromolecules due to the excluded volume. In Eq. 6 and 7, $\phi_0 = 2.86 \times 10^{23}$ and $\varepsilon = (2a - 1)/3$, where a is the slope of the Mark-Houwink–Sakurada equation.

Finally, $P(\theta)$ is calculated by the Debye equation (Eq. 4):

$$\langle s^2\rangle^{1/2} = \frac{1}{\sqrt{6}}\left(\frac{M[\eta]}{\phi(\varepsilon)}\right)^{1/3} \tag{6}$$

$$\phi(\varepsilon) = \phi_0(1 - 2.63\varepsilon + 2.86\varepsilon^2) \tag{7}$$

At this point, the algorithm restarts the first step, with $P(\theta)$ equal to the new calculated value from the previous iteration. The algorithm converges very quickly. A detailed description of the SEC^3 algorithm can be found in Ref. [5]

To measure the dimension of macromolecules is a very delicate task. However, the dimension is a primary parameter needed to understand the physical properties of a macromolecule. We have described two experimental methods, MALS and SEC^3 to measure $\langle s^2\rangle^{1/2}$ online to a SEC system.

Rate Constants: Determination from On-Column Chemical Reactions

Richard Thede
Institute of Chemistry and Biochemistry, University of Greifswald, Greifswald, Germany

INTRODUCTION

The determination of rate constants from chemical reactions occurring simultaneously with the separation process has been studied since the early 1960s. Apparently, the first paper in this field was published by Kallen and Heilbronner,[1] covering the first-order reaction of the dehydrogenation of cyclopropane to cyclopropene on a molecular sieve.

The work done until the early 1970s was summarized by Langer and Patton,[2] who put it under the framework of the ideal chromatographic reactor (ICR) model. The correspondence of the rate constants from first-order irreversible reactions was demonstrated by them as well as by Gil-Av and Herzberg-Minzly.[3]

During the 1980s, the liquid chromatographic reactor[4] got into focus as well as studies on chromatographic reactors with void zones,[5,6] enabling a separate determination of the rate constants in the mobile and the stationary phase.

In the field of determining rate constants through on-column chromatographic reactions, the investigation of reversible first-order reactions got an outstanding position because of their pharmaceutical applications with respect to enantiomers. After the early work of Keller and Giddings,[7] and Cremer and Kramer,[8,9] the methodology was developed mainly by the groups of Trapp, Schoetz, and Schurig,[10] Mannschreck and Kiessl,[11] and Hochmuth and Koenig.[12]

The aforementioned contributions are based on linear partition equilibrium of educts and products. Linear non-equilibrium reactors as well as non-linear reactors—the latter for preparative chromatography—have also been studied largely, but not primarily in the determination of rate constants. There are also methods using stopped or reversed flow of the mobile phase, especially in gas chromatography.[13]

The model of ideal linear non-equilibrium chromatography is sufficient to cover all cases of practical importance, in which rate constants were determined.

In general, the following assumptions were made: isothermal separation column, no radial concentration gradients, constant plug flow of the mobile phase, and linear sorption isotherm.

The mass balance equations for any reactant and product can be written as follows:

$$\frac{\partial c_\mathrm{i}}{\partial t} = -u\frac{\partial c_\mathrm{i}}{\partial x} + \sum \nu_{\mathrm{ij M}} r_\mathrm{jM} - k_\mathrm{fi} q_\mathrm{i} c_\mathrm{i} + k_\mathrm{fi} a_\mathrm{i}$$

$$\frac{\partial a_\mathrm{i}}{\partial t} = \sum \nu_\mathrm{ijs} \frac{v_\mathrm{s}}{v_\mathrm{M}} r_\mathrm{js} + k_\mathrm{fi} q_\mathrm{i} c_\mathrm{i} - k_\mathrm{fi} a_\mathrm{i}$$

Additional simplifications are mostly made:

1. The reactions are not limited by the mass transfer, i.e., $\frac{a_\mathrm{i}}{c_\mathrm{i}} \approx q_\mathrm{i}$ at any x.
2. The chromatographic process produces a certain peak shape, i.e., $c_\mathrm{i} = m_\mathrm{i}(x)\ \Psi_\mathrm{i}(x,t)$ (in the simplest case, $\Psi_\mathrm{i}(x,t)$ represents a Gaussian).
3. Retention times and peak broadening depend linearly on the spatial coordinate.

Assumption (1) permits the development of methods for the determination of first-order irreversible and—with restrictions—also for first-order reversible reactions. It is characteristic for the ICR model.

Assumptions (2) and (3) are required for a realistic modeling of non-first-order irreversible reactions, as well as for the approximation of chromatogram shapes by mathematical–analytical equations. Together with assumption (1) they form the Extended ICR (EICR) model.

RATE CONSTANTS FROM SIMPLE REACTIONS USING PEAK AREAS AND MOMENTS

R → P

The model equations take the form

$$\frac{\partial c_\mathrm{R}}{\partial t} = -u\frac{\partial c_\mathrm{R}}{\partial x} - k_\mathrm{M} c_\mathrm{R} - k_\mathrm{fR} q_\mathrm{R} c_\mathrm{R} + k_\mathrm{fR} a_\mathrm{R}$$

$$\frac{\partial a_\mathrm{R}}{\partial t} = -k_\mathrm{S} a_\mathrm{R} + k_\mathrm{fR} q_\mathrm{R} c_\mathrm{R} - k_\mathrm{fR} a_\mathrm{R}$$

$$\frac{\partial c_\mathrm{P}}{\partial t} = -u\frac{\partial c_\mathrm{P}}{\partial x} + k_\mathrm{M} c_\mathrm{R} - k_\mathrm{fP} q_\mathrm{P} c_\mathrm{P} + k_\mathrm{fP} a_\mathrm{P}$$

$$\frac{\partial a_P}{\partial t} = k_S a_R + k_{fP} q_P c_P - k_{fP} a_P$$

which by the ICR condition (1) can be reduced to

$$\frac{\partial c_R}{\partial t}(1 + q_R) = -u\frac{\partial c_R}{\partial x} - k_a c_R$$

$$\frac{\partial c_P}{\partial t}(1 + q_P) = -u\frac{\partial c_P}{\partial x} + k_a c_R$$

$$k_a = k_M + q_R k_s$$

To get expressions for the peak areas and reaction duration, the following operations are carried out

$$\int_0^\infty \frac{\partial c_R}{\partial t}(1 + q_R)\mathrm{d}t = 0 = \int_0^\infty \left(-u\frac{\partial c_R}{\partial x} - k_a c_R\right)\mathrm{d}t$$
$$= -u\frac{\mathrm{d}m_{R0}}{\mathrm{d}x} - k_a m_{R0}$$

$$\int_0^\infty \frac{\partial c_R}{\partial t}(1 + q_R)t\mathrm{d}t = -(1 + q_R)m_{R0}$$
$$= \int_0^\infty \left(-u\frac{\partial c_R}{\partial x} - k_a c_R\right)t\mathrm{d}t = -u\frac{\mathrm{d}m_{R1}}{\mathrm{d}x} - k_a m_{R1}$$

$$\int_0^\infty \frac{\partial c_P}{\partial t}(1 + q_P)\mathrm{d}t = 0$$
$$= \int_0^\infty \left(-u\frac{\partial c_P}{\partial x} + k_a c_R\right)\mathrm{d}t = -u\frac{\mathrm{d}m_{P0}}{\mathrm{d}x} + k_a m_{R0}$$

The solutions are easily found

$$m_{R0} = m_{R00}\exp(-k_a t_0)$$

$$m_{P0} = m_{R00}[(1 - \exp(-k_a t_0)]$$

$$\mu_{R1} = t_{rR} = \frac{m_{R1}}{m_{R0}} = t_0(1 + q_R)$$

Transforming the solutions for the zeroth moments into expressions for peak areas yields

$$A_R = A_{R0}\exp(-k_a t_0)$$

$$A_P = f_P A_{R0}[1 - \exp(-k_a t_0)]$$

forming the basis of the practical methods[14] to determine the rate constant:

Internal standard method

The inlet peak area is expressed by an internal standard being completely separated from the reaction chromatogram and inert with respect to the reaction. Then $f_S A_S = A_{R0}$, and

$$\ln\frac{A_R}{A_S} = \ln f_S - k_a t_0$$

from which k_a can be evaluated by linear regression from peak areas for varied linear flow rate.

Product–reactant method

Sometimes, the sensitivity factor f_p approaches 1 (i.e., in gas chromatography using the flame ionization detector for reactions in which the number of carbon atoms is not changed or in liquid chromatography using ultraviolet detection for reactions in which the absorption center is not involved).

Then $A_R + A_P = A_{R0}$, and

$$\ln\frac{A_R}{(A_R + A_P)} = -k_a t_0$$

As reactant and product cannot be separated completely—the reaction occurs until the very end of the column—the coelution of product and reactant must be corrected for by diminishing the apparent reactant peak area (v_{int} is the "speed of the recorder")

$$\Delta A_R = v_{int}\int_{t_B}^{t_{min}} h_{min}\int_{t_B}^{t}\frac{1}{\sqrt{2\pi\sigma_R^2}}\exp\left[-\frac{(t-\tau)^2}{2\sigma_R^2}\right]\mathrm{d}\tau\mathrm{d}t$$

This expression can be solved analytically, but the result is quite voluminous and not given here. A typical chromatogram is shown in Fig. 1. The dissociation of dicyclopentadiene is a worked example.[14]

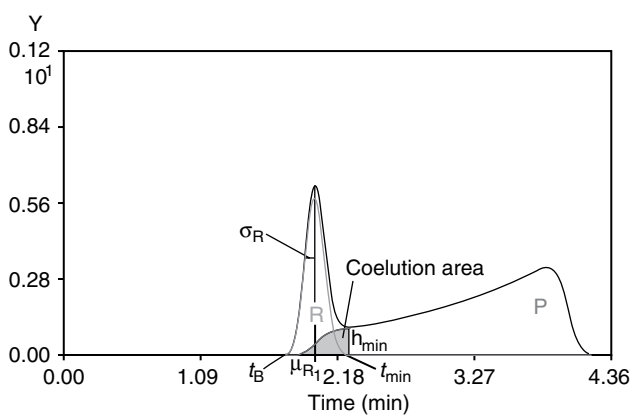

Fig. 1 Typical chromatogram from a first-order reaction with the parameters necessary for the determination of the rate constant. The areas from product and reactant are split at t_{min}.

The correction can be circumvented in case of $f_p \neq 1$ using the total area method

$$\frac{A_{tot}}{A_S} = \frac{(A_{R0} - A_{R0}f_p)}{A_S}\exp\left(-k_a\frac{l}{u}\right) + \frac{A_{R0}f_p}{A_S}$$
$$= C_1\exp(-k_a t_0) + C_2$$

and in case of $f_p \approx 1$ using the total moment method[15,16]

$$\mu_{1tot} = \frac{\int_0^\infty (y_R + y_P)t\mathrm{d}t}{\int_0^\infty (y_R + y_P)\mathrm{d}t}$$
$$= (1 + q_P)t_0 + \frac{(q_R - q_P)}{k_a}[1 - \exp(-k_a t_0)]$$

from which k_a can be obtained by non-linear regression

2R → P

The model equations take the form

$$\frac{\partial c_R}{\partial t} = -u\frac{\partial c_R}{\partial x} - 2k_M c_R^2 - k_{fR}q_R c_R + k_{fR}a_R$$

$$\frac{\partial a_R}{\partial t} = -2k_S a_R c_{sR} + k_{fR}q_R c_R - k_{fR}a_R$$

$$\frac{\partial c_P}{\partial t} = -u\frac{\partial c_P}{\partial x} + k_M c_R^2 - k_{fP}q_P c_P + k_{fP}a_P$$

$$\frac{\partial a_P}{\partial t} = k_S a_R c_{sR} + k_{fP}q_P c_P - k_{fP}a_P$$

Using simplification (1) as well as $K_R = c_{sR}/c_R$ yields

$$\frac{\partial c_R}{\partial t}(1 + q_R) = -u\frac{\partial c_R}{\partial x} - 2k_a c_R^2$$
$$\frac{\partial c_P}{\partial t}(1 + q_P) = -u\frac{\partial c_P}{\partial x} + k_a c_R^2$$

$$k_a = k_M + k_S q_R K_R$$

Using simplification (2) and carrying out the same operations as in the first-order case

$$\int_0^\infty \frac{\partial c_R}{\partial t}(1 + q_R)\mathrm{d}t = 0$$
$$= \int_0^\infty \left(-u\frac{\partial c_R}{\partial x} - 2k_a c_R^2\right)\mathrm{d}t$$
$$= -u\frac{\mathrm{d}m_{R0}}{\mathrm{d}x} - 2k_a m_{R0}^2\int_0^\infty \Psi^2(x,t)\mathrm{d}t$$

$$\int_0^\infty \frac{\partial c_R}{\partial t}(1 + q_R)t\mathrm{d}t = -(1 + q_R)m_{R0}$$
$$= \int_0^\infty \left(-u\frac{\partial c_R}{\partial x} - 2k_a c_R^2\right)t\mathrm{d}t$$
$$= -u\frac{\mathrm{d}m_{R1}}{\mathrm{d}x} - 2k_a m_{R0}^2\int_0^\infty t\Psi^2(x,t)\mathrm{d}t$$
$$= -u\mu_{R1}\frac{\mathrm{d}m_{R0}}{\mathrm{d}x} - um_{R0}\frac{\mathrm{d}\mu_{R1}}{\mathrm{d}x} - 2k_a m_{R0}^2$$
$$\times\int_0^\infty \Psi^2(x,t)\mathrm{d}t\frac{\int_0^\infty t\Psi^2(x,t)\mathrm{d}t}{\int_0^\infty \Psi^2(x,t)\mathrm{d}t}$$

$$\int_0^\infty \frac{\partial c_P}{\partial t}(1 + q_P)\mathrm{d}t = 0$$
$$= \int_0^\infty \left(-u\frac{\partial c_P}{\partial x} + k_a c_R^2\right)\mathrm{d}t$$
$$= -u\frac{\mathrm{d}m_{P0}}{\mathrm{d}x} + k_a m_{R0}^2\int_0^\infty \Psi^2(x,t)\mathrm{d}t$$

From the equations, it follows directly that

$$2m_{P0} + m_{R0} = m_{R00}$$

For *any* symmetric function for the reactant peak shape Ψ

$$\mu_{R1} = t_r = \frac{l}{u}(1 + q_R)$$

For a *Gaussian* reactant peak shape

$$-u\frac{\mathrm{d}m_{R0}}{\mathrm{d}x} = k_a\frac{m_{R0}^2}{\sqrt{\pi}\sigma_R(x)}$$

which can be solved assuming

$$\sigma_R(x) \approx \sigma_R\sqrt{x}$$

(This approximation can be concluded from "numerical experiments.")

The result is[17]

$$\frac{m_{R00}}{m_{R0}} = 1 + \frac{2k_a m_{R00}}{\sqrt{\pi}\sigma_R}t_0$$

The m_{R00} on the right side of the equation must be evaluated from the inlet amount n_{R0} and the volume flow $\dot{v}$

$$m_{R00} = \frac{n_{R0}}{\dot{v}}$$

Methods similar to first order can be used:

Internal standard method

$$\frac{A_S}{A_R} = f_s + f_s \frac{2k_a m_{R00}}{\sqrt{\pi}\sigma_R} t_0$$

Product–reactant method with sensitivity factor $f_p = 2$

$$\frac{A_P + A_R}{A_R} = 1 + \frac{2k_a m_{R00}}{\sqrt{\pi}\sigma_R} t_0$$

The area correction diminishing A_R (v_{int} is the "speed of the recorder")

$$\Delta A_R = v_{int} \int_{t_B}^{t_{min}} h_{min} \int_{t_B}^{t} \frac{1}{\sqrt{\pi\sigma_R^2}} \exp\left[-\frac{(t-\tau)^2}{\sigma_R^2}\right] d\tau dt$$

The characteristic chromatogram can be seen in Fig. 2. A worked example is the aldol-condensation of propanol.[17] The construction of a total area and a total moment method, respectively, are also possible; however, because the reactants' standard deviation must be obtained anyhow, these methods have never been used.

$R_1 + R_2 \rightarrow P$

This reaction can only be carried out under defined conditions, if the faster reactant overtakes the slower reactant. If the faster reactant overtakes the slower one *completely* within the column, the peak areas of the single reactants (without reaction) and the reactants after a reaction can be compared directly (Fig. 3).

Calculations similar to those carried out for the dimerization type lead to the following result

$$\ln\left(\frac{A_{R1}}{A_{R01}}\right) - \ln\left(\frac{A_{R2}}{A_{R02}}\right) = k_a t_0 \frac{(m_{R01} - m_{R02})}{|tr_{R1} - tr_{R2}|}$$

k_a can be found by linear regression, and as in the dimerization type, the zeroth moments in the right side of the equation must be evaluated from the inlet amounts. The addition of tetrachloroterephthaloyl chloride to pyridine has been investigated.[18]

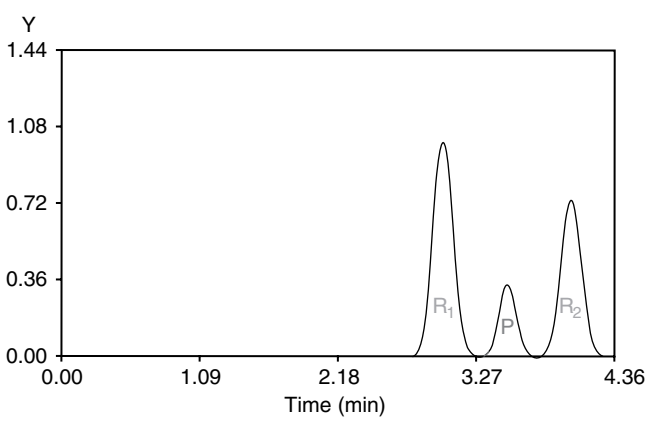

Fig. 3 Typical chromatogram from a second-order reaction (pulse overlay) with complete separation.

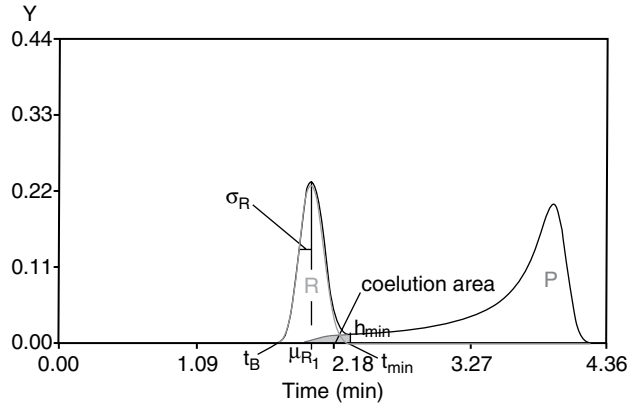

Fig. 2 Typical chromatogram from a second-order reaction (dimerization type).

$R_1 \rightleftarrows R_2$

The area-based determination of rate constants from first-order reversible reactions is possible owing to the fact that molecules of R_1 produced by R_2 do not return under the primary peak of R_1, and vice versa. This means that the area of the primary peaks diminishes like in a simple irreversible reaction. The internal standard method together with the peak area correction gives appropriate results for these reactions too in case of small conversions.[19]

RATE CONSTANTS FROM COMPLEX REACTIONS USING CHROMATOGRAM SHAPES

As can be seen from the chromatograms given for consecutive (Fig. 4)[20] and reversible reactions (Fig. 5), the coelution problem is much more serious than in simple reactions. Moreover, in reversible reactions starting from samples with equilibrium composition, the peak areas are

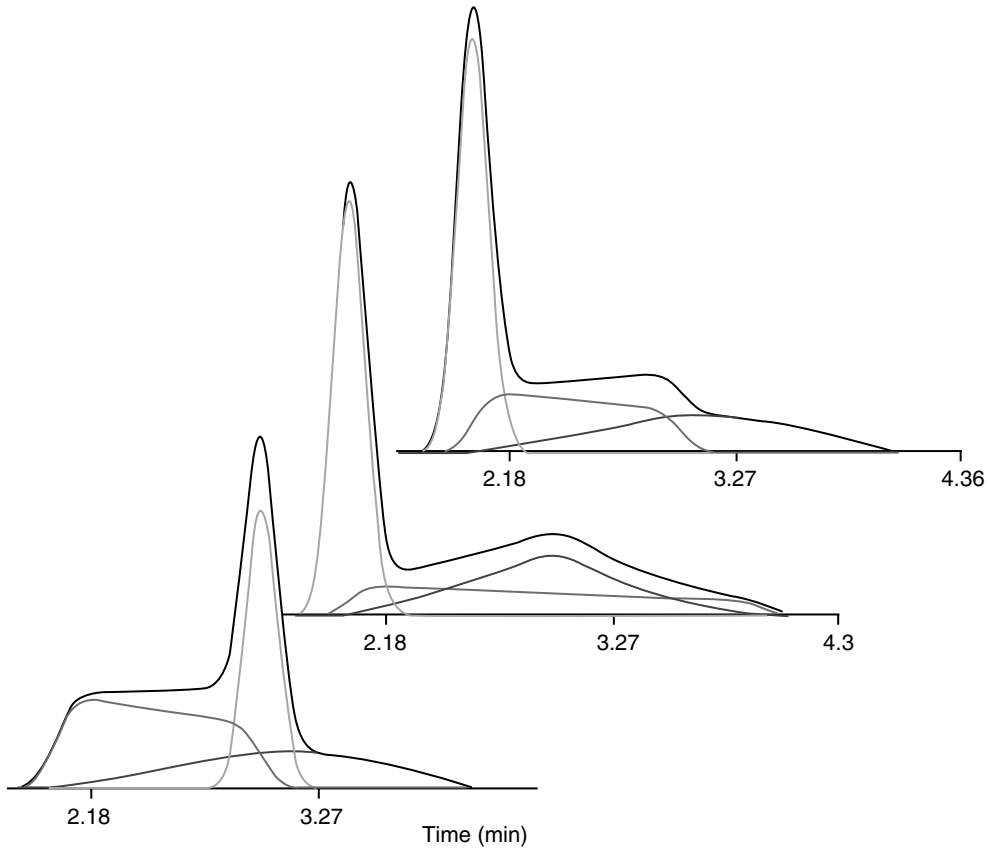

Fig. 4 Chromatograms for the consecutive reaction R → I → P and the elutions orders R, I, P; R, P, I, and I, R, P, respectively.

not changed by the chromatographic reactor owing to the principle of microkinetic reversibility.[21] However, the chromatogram is characteristically shaped by the reaction kinetic processes.

Therefore, fitting of computed chromatograms to the experimental chromatogram is a method of choice in these cases. Such chromatograms were evaluated basing on the discontinuous model (plate model) or on a numerical solution of the balance equations by the finite difference method.[22] Such purely numerical procedures are still quite time consuming, and therefore for rapid calculations mathematical–analytical approximations have been developed on the basis of the Keller–Giddings equation covering the meaningful field of reversible reactions, especially enantiomerizations,[23] and on the basis of the EICR assumptions for differentially small components of the product peaks leading to analytical approximations for all types of the aforementioned reactions.[24]

Recently, Trapp and Schurig[25] published a simplified analytical function for reversible reactions, by the help of which the apparent rate constant of an enantiomerization can be found from the retention times, standard deviations, and maximum heights of the educts, and the maximum height of the interconversion plateau between the educt peaks.

SEPARATE DETERMINATION OF RATE CONSTANTS FOR STATIONARY AND MOBILE PHASE BY SIMULATED RECYCLING VIA VOID ZONES

In general, the rate constants determined by on-column chromatographic methods are a weighed sum of the rate constants within the stationary and the mobile phase, the retention capacity (and in non-first-order reactions also the partition coefficient) being the weighing factor. Certainly, for some catalyzed reactions occurring only within the mobile or the stationary phase, the decomposition is possible, if the dead time is known.

Griffith, Chu, and Langer[5] suggested the application of a simulated recycling of the internal chromatogram, i.e., the substances pass through a chromatographic column, then through an empty capillary, the length of which is sufficient for a residence time similar to that in the mobile phase of the column, and finally through another column of the same type like the first. Then, extra peak(s) is formed, which is only owing to the reaction in the mobile phase.

For irreversible first-order reactions (Fig. 6), the peak area of the extra peaks is sufficient for the separate determination of the mobile phase rate constant, but for complex reactions, the fitting method via numerical or approximate

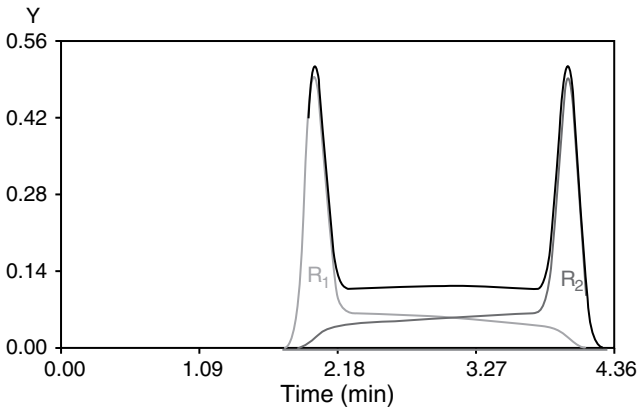

Fig. 5 Chromatogram from a reversible first-order reaction with comparable forward and backward rate constants starting from an equilibrated mixture (i.e., enantiomerizations).

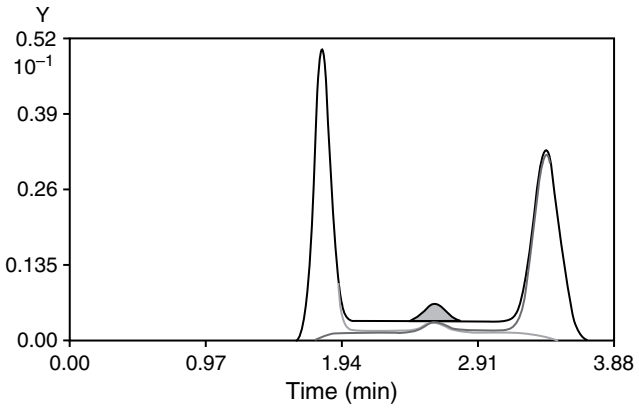

Fig. 7 Extra peak in a chromatogram from a reversible first-order reaction occurring on a system consisting of two identical columns connected by a void capillary (simulated recycling).

analytical computations has to be applied, the latter of which was tested for enantiomerizations (Fig. 7) as well as for isomerizations.[26]

SYMBOLS

A:	Peak area
a:	Stationary phase concentration (including phase ratio)
c:	Mobile phase concentration
f:	Sensitivity factor ($f_P = A_P/A_R$; $f_S = A_S/A_R$ for the *same* inlet amounts)
k:	Rate constants
k_a:	Apparent rate constant (as to be specified for reaction type and order)
k_f:	Mass transfer coefficient
l:	Column length
m_0:	Zeroth moment, concentration-time area
q:	Retention capacity
r:	Rate of reaction
t:	Time
t_0:	Dead time
u:	Linear flow rate
v:	Volume
x:	Spatial coordinate
t_r:	Retention time
Ψ:	Peak shape function
ν:	Stoichiometric coefficient

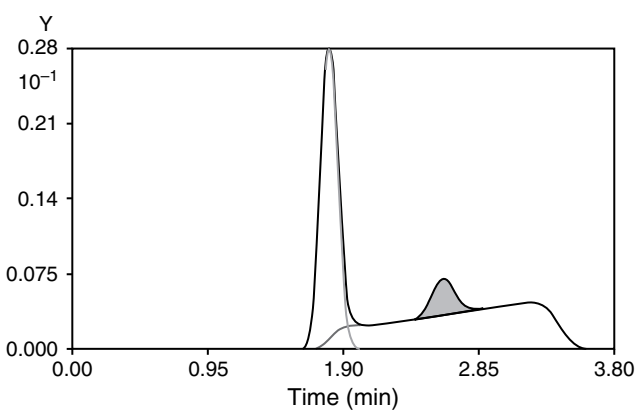

Fig. 6 Extra peak in a chromatogram from a first-order reaction occurring on a system consisting of two identical columns connected by a void capillary (simulated recycling).

INDICES

i:	Substance index
j:	Reaction index
M:	Mobile phase
P:	Product
R:	Reactant
s:	Stationary phase
S:	(Internal) standard
0:	Column inlet

CONCLUSIONS

The determination of rate constants from reactions occurring simultaneously on-column with the separation process has been demonstrated for a variety of first-order reaction types as well as for simple second-order reactions. Assuming retentions times from minutes to hours, sample amounts in the microliter range and conversions in the middle range, first-order rate constants from 10^0–10^{-3}/min and second-order rate constants from 10^4–10^{-1} dm^3/mol/min are accessible, which, however, are in general apparent rate constants, a weighed average of the rate constant in the mobile and the rate constants in the stationary phase. That the latter problem can be solved generally by use of chromatographic reactors

with void zones (simulated recycling) must be proven by further investigations.

Rate Theory in GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The rate theory examines the kinetics of exchange that takes place in a chromatographic system and identifies the factors that control band dispersion. The first explicit height equivalent to a theoretical plate (HETP) equation was developed by Van Deemter et al. in 1956[1] for a packed GC column. Van Deemter et al. considered that four spreading processes were responsible for peak dispersion, namely *multi-path dispersion*, *longitudinal diffusion*, *resistance to mass transfer in the mobile phase*, and *resistance to mass transfer in the stationary phase*.

THE MULTIPATH EFFECT

In a packed column, the individual solute molecules will describe a tortuous path through the interstices between the particles, and some will randomly travel shorter routes than the average and some will travel longer routes. Consequently, those molecules taking the shorter paths will move ahead of the mean and those that take the longer paths lag behind the mean which will result in band dispersion. Van Deemter et al. derived the following function for the multipath variance contribution ($\sigma_M{}^2$) to the overall variance per unit length of the column (σ^2):

$$\sigma_M{}^2 = 2\lambda d_p \tag{1}$$

where d_p is the particle diameter of the packing and λ is a constant that depends on the quality of the packing.

LONGITUDINAL DIFFUSION

Driven by the concentration gradient, solutes naturally diffuse when contained in a fluid. Thus, a discrete solute band will diffuse in a gas or liquid, and because the diffusion process is random, it will produce a concentration curve that is Gaussian in form. This diffusion effect occurs in the mobile phase of both packed gas chromatography (GC) and liquid chromatography (LC) columns. The longer the solute band remains in the column, the greater will be the extent of diffusion. Because the residence time of the solute in the column is inversely proportional to the mobile-phase velocity, the dispersion will also do the same. Van Deemter et al. derived the following expression for the variance contribution by longitudinal diffusion ($\sigma_L{}^2$) to the overall variance per unit length of the column (σ^2):

$$\sigma_L{}^2 = \frac{2\gamma D_m}{u} \tag{2}$$

where D_m is the diffusivity of the solute in the mobile phase, u is the linear velocity of the mobile phase, and γ is a constant that depends on the quality of the packing.

RESISTANCE TO MASS TRANSFER IN THE MOBILE PHASE

During migration through the column, the solute molecules are continually transferring from the mobile phase to the stationary phase and back again. This transfer process is not instantaneous; a finite time is required for the molecules to traverse (by diffusion) through the mobile phase in order to reach the interface and enter the stationary phase. Thus, those molecules close to the stationary phase enter it immediately, whereas those molecules some distance away will find their way to it some time later. However, because the mobile phase is moving, during this time interval, those molecules that remain in the mobile phase will be swept along the column and dispersed away from those molecules that were close and entered the stationary phase immediately. This dispersion is called the resistance to mass transfer in the mobile phase.

Van Deemter derived the following expression for the variance contribution by the resistance to mass transfer in the mobile phase ($\sigma_{\mathrm{RM}}{}^2$) to the overall variance per unit length of the column (σ^2):

$$\sigma_{\mathrm{RM}}{}^2 = \frac{f_1(k')d_p{}^2}{D_m}u \tag{3}$$

where k' is the capacity ratio of the solute and the other symbols have the meaning previously ascribed to them.

RESISTANCE TO MASS TRANSFER IN THE STATIONARY PHASE

Dispersion caused by the resistance to mass transfer in the stationary phase is exactly analogous to that in the mobile phase. Solute molecules close to the surface will leave the

stationary phase and enter the mobile phase before those that have diffused further into the stationary phase and have a longer distance to diffuse back to the surface. Thus, as those molecules that were close to the surface will be swept along in the moving phase, they will be dispersed from those molecules still diffusing to the surface.

Van Deemter derived an expression for the variance from the resistance to mass transfer in the stationary phase ($\sigma_{\mathrm{RS}}{}^2$) which is as follows:

$$\sigma_{\mathrm{RS}}{}^2 = \frac{f_2(k')d_f{}^2}{D_S}u \tag{4}$$

where k' is the capacity ratio of the solute, d_f is the effective film thickness of the stationary phase, D_S is the diffusivity of the solute in the stationary phase, and the other symbols have the meaning previously ascribed to them.

As all the dispersion processes are random, the individual variances can be added to arrive at the total variance of the peak leaving the column:

$$\sigma^2 = \sigma_{\mathrm{M}}{}^2 + \sigma_{\mathrm{L}}{}^2 + \sigma_{\mathrm{RM}}{}^2 + \sigma_{\mathrm{RS}}{}^2 \tag{5}$$

where σ^2 is the total variance/unit length of the column.

Thus, substituting for and from $\sigma_{\mathrm{M}}{}^2$, $\sigma_{\mathrm{L}}{}^2$, $\sigma_{\mathrm{RM}}{}^2$, and $\sigma_{\mathrm{RS}}{}^2$ from Eqs. 1–4, respectively,

$$\sigma^2 = 2\lambda d_p + \frac{2\gamma D_m}{u} + \frac{f_1(k')d_p{}^2}{D_m}u + \frac{f_2(k')d_f{}^2}{D_S}u \tag{6}$$

Now, the variance per unit length of a column is numerically equivalent to ratio of the column length to the column efficiency[2] [i.e., the height of the theoretical plate (H)]; thus,

$$H = 2\gamma d_p + \frac{2\gamma D_m}{u} + \frac{f_1(k')d_p{}^2}{D_m}u + \frac{f_2(k')d_f{}^2}{D_S}u \tag{7}$$

hence the term "HETP equation" for the equation for the variance per unit length of a column. Unfortunately, due to the compressibility of the gaseous mobile phase, neither the linear velocity nor the pressure is constant along the column, and as the diffusivity (D_m) is a function of pressure, the above form of the equation is only approximate. The Van Deemter equation was modified to take into account the compressibility of the carrier gas by Ogan and Scott.[3] The complete HETP equation for a GC column that takes into account the compressibility of the carrier gas will be

$$H = 2\lambda d_p + \frac{2\gamma D_m(o)}{u_o} + \frac{f_1(k')d_p{}^2}{D_{m(o)}}u_o + 2\frac{f_2(k')d_f{}^2}{D_S(\gamma+1)}u_o \tag{8}$$

where u_o is the linear gas velocity at the column outlet, D_m is the diffusivity of the solute measured at the column outlet pressure, and γ is the inlet/outlet column ratio.

It is seen that Eq. 8 is very similar to Eq. 7 except that the velocity used is the *outlet* velocity, *not* the *average* velocity, and that the diffusivity of the solute in the gas phase is taken as that measured at the column outlet pressure (i.e., atmospheric). The shape of the H vs. u curve is hyperbolic; it has a minimum value of $H_{\min}$ at the optimum velocity u_{opt} (i.e., at the optimum velocity, the column will have a maximum efficiency). Expressions for $H_{\min}$ and u_{opt} can be obtained by differentiating Eq. 8 with respect to u and equating to zero, solving for u_{opt} and substituting u_{opt} for u in Eq. 8 to obtain $H_{\min}$.

Refractive Index Detector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The first practical refractive index detector was described by Tiselius and Claesson[1] in 1942 and, despite its limited sensitivity and its use being restricted to separations that are isocratically developed, it is still probably the fifth most popular detector in use today. Its survival has depended on its response, as it can be used to detect any substance that has a refractive index that differs from that of the mobile phase. It follows that it has value for monitoring the separation of such substances as aliphatic alcohols, acids, carbohydrates, and the many substances of biological origin that do not have ultraviolet (UV) chromophores, do not fluoresce, and are non-ionic.

DISCUSSION

When a monochromatic ray of light passes from one isotropic medium (A) to another (B), it changes its wave velocity and direction. The change in direction is called refraction and the relationship between the angle of incidence and the angle of refraction is given by Snell's law of refraction, namely

$$n_B{}' = \frac{n_B}{n_A} = \frac{\sin(i)}{\sin(r)}$$

where i is the angle of incident light in medium A, r is the angle of refractive light in medium B, is the refractive index of medium A, is the refractive index of medium B, and is the refractive index of medium B relative to that of medium A.

The refractive index of a substance is a dimensionless constant that normally decreases with increasing temperature; values are taken at 20°C or 25°C using the mean value taken for the two sodium lines of the spectrum. The optical systems that are used to exploit the refractive index for detection purposes are many and varied. One procedure is to construct a cell in the form of a hollow prism through which the mobile phase can flow. A ray of light is passed through the prism, which will be deviated from its original path, and is then focused onto a photocell. As the refractive index of the mobile phase changes, due to the presence of a solute, the angle of deviation of the transmitted light will also alter and the amount of light falling on the photocell will change. This method of refractive index monitoring is used by many manufacturers in their refractive index detector designs.

Another method evolved from the work of Fresnel. The relationship between the reflectance from an interface between two transparent media and their respective refractive indices is given by Fresnel's equation:

$$R = \frac{1}{2}\left(\frac{\sin^2(i-r)}{\sin^2(i+r)} + \frac{\tan^2(i-r)}{\tan^2(i+r)}\right)$$

where R is the ratio of the intensity of the reflected light to that of the incident light and the other symbols have the meanings previously assigned to them.

Now,

$$\frac{\sin(i)}{\sin(r)} = \frac{n_1}{n_2}$$

where is the refractive index of medium 1, and is the refractive index of medium 2.

Consequently, if medium 2 represents the liquid eluted from the column, then any change in n_2 will result in a change in R, and, thus, the measurement of R could determine changes in n_2 resulting from the presence of a solute. An example of a refractive index detector that functions on the Fresnel principle is shown in Fig. 1. Light from a tungsten lamp is directed through an infrared (IR) filter (to prevent heating the cell) to a magnifying assembly that splits the beam into two beams. The two beams are focused through the sample and reference cells, respectively. Light refracted from the mobile-phase/prism surface passes through the prism assembly and is then focused on two photocells. The prism assembly also reflects light to a user port where the surface of the prism can be observed. The output from the two photocells is electronically processed and either passed to a potentiometric recorder or to a computer data acquisition system. The range of refractive index covered by the instrument for a given prism is limited and, consequently, three different prisms are usually made available to cover the refractive index ranges of 1.35–1.4, 1.31–1.44, and 1.40–1.55, respectively.

Another variant on the refractive index detector arose from the work of Christiansen on crystal filters.[2] If a cell is packed with particulate material having the same refractive index as the mobile phase passing through it, light will pass through the cell with little or no refraction or scattering. If, however, the refractive index of the mobile phase

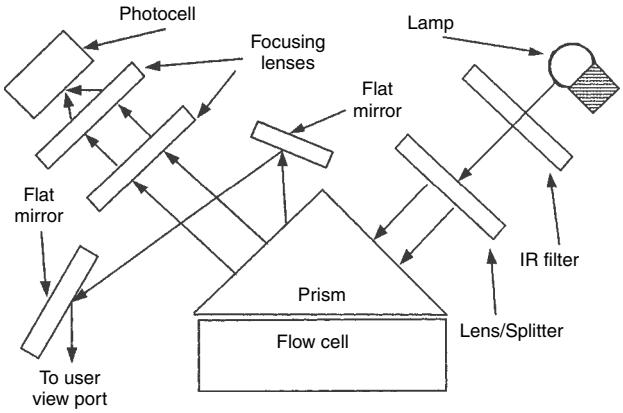

Fig. 1 A diagram of the optical system of a refractive index detector operating on the Fresnel method.
Source: Courtesy of the Perkin Elmer Corporation.

changes, there will be a refractive index difference between the mobile phase and that of the packing. This difference results in light being refracted away from the incident beam, reducing the intensity of the transmitted light. If the transmitted light is focused onto a photocell and the refractive index of the packing and mobile phase initially matched, then any change in refractive index resulting from the elution of a peak will cause light scattering and a reduction in light falling on the sample photocell and, thus, provide a differential output.

In practice, because the optical dispersions of the media are likely to differ, the refractive index will only match at one particular wavelength and, thus, the fully transmitted light will be largely monochromatic. Light of other wavelengths will be proportionally dispersed depending on the their difference from the wavelength at which the two media have the same optical dispersion. It follows that a change in refractive index of the mobile phase will change both the intensity of the transmitted light and its wavelength. This device has been manufactured but was not a commercial success due to its limited sensitivity and the need for different packing for different applications.

Another detector that functions on the change in refractive index of the column eluent is the interferometer detector, which was first developed by Bakken and Stenberg[3] in 1971. The detector responds to the change in the effective path length of a beam of light passing through a cell when the refractive index of its contents changes due to the presence of an eluted solute. If the light transmitted through the cell is focused on a photocell coincident with a reference beam of light from the same source, interference fringes will be produced; the fringes will change as the path length of one light beam changes with reference to the other, and, consequently, as the concentration of solute increases in the sensor cell, a series of electrical pulses will be generated as each fringe passes the photocell. The effective optical path length (d) depends on the change in refractive index (Δn) and the path length (l) of the sensor cell as follows:

$$d = \Delta n l$$

Further, it is possible to calculate the number of fringes (N) (sensitivity) which move past a given point (or the number of cyclic changes of the central portion of the fringe pattern) in relation to the change in refractive index by the equation

$$N = \frac{2\Delta n l}{\lambda}$$

where l is the wavelength of the light employed.

The larger the value of N for a given n, the more sensitive the detector will be. Therefore, l needs to be made as large as possible but will be limited by the dead volume of the column and the dispersion that can be tolerated before chromatographic resolution is impaired. The smallest cell (1.4 μl) (a cell volume that would be suitable for use with microbore columns) is reported to give a sensitivity of about 2×10^{-7} RI units at a signal-to-noise ratio of 2. Consequently, for benzene (RI = 1.501) sensed as a solute in *n*-heptane (RI = 1.388), this sensitivity would represent a minimum detectable concentration of 5.6×10^{-5} g/ml. The alternative 7 μl cell would decrease the minimum detectable concentration to about 1×10^{-6} g/ml, similar to that obtained for other refractive index detectors. However, the cell volume is a little large for modern high-efficiency columns. This type of RI detector has also been made commercially available but is somewhat more expensive with little gain in sensitivity over that obtained from simpler devices.

Another detector based on refractive index change is the thermal lens detector. When a laser is focused on an absorbing substance, the refractive index may be affected in such a way that the medium behaves as a lens. This effect was first reported by Gorden et al.[4] Thermal lens formation results from the absorption of laser light, which may be extremely weak. The excited-state molecules subsequently decay back to ground state and, as a result, localized temperature increases occur in the sample. Because the refractive index of the medium depends on the temperature, the resulting spatial variation of refractive index produces an effect which appears equivalent to the formation of a lens within the medium. The temperature coefficient of refractive index is, for most liquids, negative; consequently, the insertion of a liquid in the laser beam produces a concave lens that results in beam divergence.

The thermal lens effect has been used for LC detection with a small-volume sensor cell. Basically, it consists of a *heating* laser, the light from which is passed directly through the sample, and another laser which passes light through the cell in the opposite direction. When an absorbing solute arrives in the cell, a thermal lens is produced that

causes the probe light to diverge and, consequently, the intensity of the light falling on a photocell is reduced. The cell can be made a few microliters in volume and would thus be suitable for use with microbore columns. A sensitivity of 10^{-6} AU is claimed with a linear dynamic range of about three orders of magnitude. The use of two lasers adds significantly to the cost of the device. Basically, as the thermal lens detector is a special form of the refractive index detector, it can be considered as a type of universal detector. However, like other RI detectors, it cannot be used with gradient elution or flow programing and its sensitivity is no better than, if as good as, other refractive index detectors.

The refractive index detectors are very versatile in that they can detect all substances that have a different refractive index than that of the mobile phase. However, they are also one of the least sensitive detectors ($\sim 1 \times 10^{-6}$ g/ml); they have a linear dynamic range of about two to three orders of magnitude. They are extremely sensitive to flow rate, temperature, and pressure changes and cannot be used with gradient elution. Nevertheless, they are very popular for the detection of certain classes of compounds.

Relaxation Effects in FFF

Athanasia Koliadima
Physical Chemical Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

Field-flow fractionation (FFF) is a reliable technique for separation and characterization of colloids and polymers. It is a dynamic separation technique based on the differential elution of the sample constituents by a laminar flow, in a flat ribbon-like channel, according to their sensitivity to an external field applied in the perpendicular direction to that of the flow. Resolution in the FFF system is a function of the time allowed to equilibrate (or relax) the sample within the channel under the force field, with the mobile phase not flowing prior to fractionation.

RELAXATION EFFECTS IN FFF

Field flow fractionation is an elution method wherein solutes are separated as they are washed through a column. The FFF channel is empty and an external applied force is solely responsible for the fractionation phenomenon. As soon as a solute species enters the FFF channel, the external field begins to force it toward the far wall of the channel. As it begins to concentrate at the wall, however, diffusion counteracts additional concentration. Soon, a thin, steady-state layer is established next to the wall. The distribution of the solute species in this layer is exponential and can be expressed as[1]

$$c = c_0 e^{-x/l} \tag{1}$$

where c is the concentration of solute at distance x (which is the coordinate position above the accumulation wall of the channel) from the lower wall, c_0 the analyte concentration at the accumulation wall, and l the approximate mean thickness of the solute layer (cloud thickness). A finite time is required for the formation of exponential layer under the influence of the field.[2] Until this equilibrium layer is formed, any downstream migration will be accompanied by a decrease in the retention, an increase in the retention parameter, and an increase in the plate height, H. This distortion can be removed by a stop-flow method in which flow is halted after injection for a period adequate to establish the exponential distribution. So the relaxation or equilibrium time, t_r, is the average time of travel under the influence of the field, from the center of the channel, $x = w/2$ to the quasiequilibrium center of gravity, x_{cg}. The latter obeys the equation:[1,2]

$$t_r = \frac{\left[\frac{w}{2} - x_{cg}\right]}{U} \tag{2}$$

where w is the channel thickness and U is the velocity induced by the field on the particles. The velocity U is linked to the field force on each particle as

$$U = \frac{F}{f} \tag{3}$$

where F is the field force to each particle and f is the friction coefficient of an analyte particle.

The x_{cg} is given by the equation:[1]

$$x_{cg} = w\left[\lambda - (e^{1/\lambda} - t)^{-1}\right] \tag{4}$$

where λ is equal to l/w.

So, substitution of this into Eq. 2 yields an equivalent expression of the t_r in terms of the FFF retention parameter, λ:[1,2]

$$t_r = \frac{w^2 \lambda}{D}\left[\frac{1}{2} - \lambda + (e^{1/\lambda} - 1)^{-1}\right] \tag{5}$$

where D is the analyte diffusion coefficient.

The diagrams in Fig. 1 illustrate how the particle concentration profile relaxes in the FFF channel under the influence of a sedimentation force field.[3] Initially, at time zero, particles are homogeneously distributed across the channel. Under the force field (as time progresses), the particle concentration profile is as predicted by the kinetic theory developed by Yau and Kirkland,[3] and the particles are compacted toward the bottom wall. After 5 min relaxation, or longer (in typical operating conditions), as shown in Fig. 1, particle concentration approaches the steady-state or equilibrium condition and will no longer vary with increasing relaxation time.

On the other hand, the velocity of the particles after 5 min relaxation reaches a level that is predicted by the equilibrium theory, after which the unrelaxed particles travel half the length of the channel in higher than predicted velocity streams before they are relaxed to their equilibrium l values. All the above are shown in Fig. 2. As a result of the above, a better resolution can be achieved. Fig. 3 is a composite of fractograms obtained with relaxation times varying from 0 to 20 min and shows

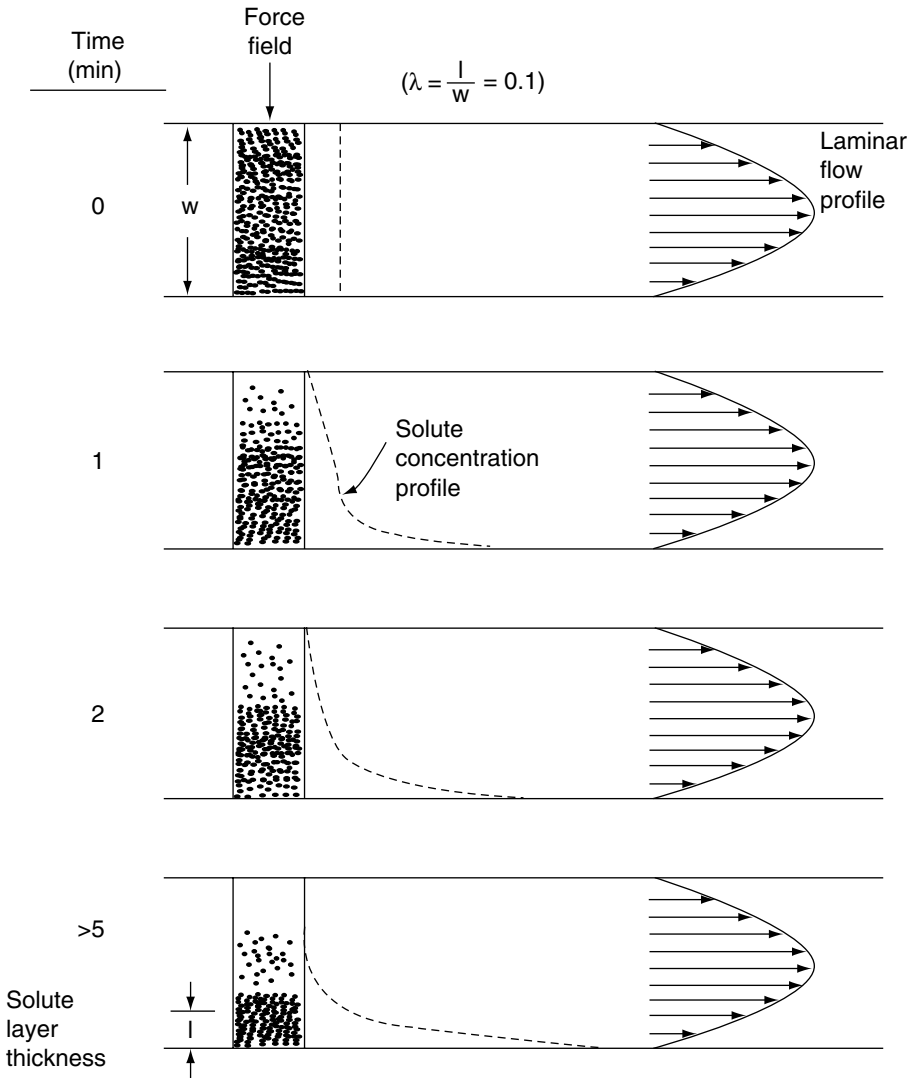

Fig. 1 Relaxation of solute concentration profile under sedimentation force field.
Source: From Nonequilibrium effects in sedimentation field flow fractionation, in Anal. Chem.[3]

how the relaxation time affects resolution.[4] Note that, although there is an optimum relaxation time for better resolution according to the experimental conditions, the resolution volume increases slightly with increasing relaxation time (Fig. 3, dotted line).

Relaxation time is one of the most important contributions to the plate height. The variance of the distribution of the distances traveled by the particles when they all have reached the accumulation wall is calculated by the equation:[2,5]

$$H_r = \frac{17}{140}\frac{w^2\langle v\rangle^2}{L|v|^2} = \frac{17}{140}\frac{1}{L}\left(\frac{\lambda w^2\langle v\rangle}{D}\right)^2 \quad (6)$$

where $\langle v\rangle$ is the mean carrier velocity and L is the column length.

This contribution to H can be relatively important, especially when operating at high-flow rates and for slowly diffusing species, as it is proportional to $(\langle v\rangle/D)$.[2] However, there are some experimental possibilities for considerably reducing this relaxation contribution to H. So, the time, t_p, needed to generate one theoretical plate is given by the equation:[6]

$$t_p = 4\frac{l^2}{D} \quad (7)$$

A separation requiring N plates for resolution requires a time of Nt_p, which is equal to

$$t = 4\frac{N l^2}{D} \quad (8)$$

Eqs. 5 and 8 show that relaxation time can be manipulated by changing the w and l parameters. So, to minimize the relaxation time and, consequently, the total analysis time, we need to reduce the above-mentioned parameters.

Several techniques have been developed to minimize the *l* parameter.[6,7] Various programing methods have been proposed. In the field programing technique, the field force increases and the analyzed particles come into the optimal range, each size effectively taking its turn at optimal migration. One problem with field programing is that, in the course of each particle's wait, during which it has a suboptimal *l*, it may migrate anomalously owing to steric effects or possibly absorb onto the wall. Another problem is that, when the field strength is changed rapidly to get quickly through the particle size range, particles are unable to diffuse enough to steady-state values of *l*. In this technique, the steady-state conditions depend on the secondary relaxation process. Corresponding to each specific value of the field strength, there is an equilibrium or steady-state distribution of particles near the accumulation wall for any type of particle. When the field strength changes from one value to another, a corresponding change occurs in a steady-state distribution. So, the particle cloud requires a finite time to adjust from one steady-state condition to another (secondary relaxation). Although corrections for this secondary relaxation have been developed, this programing technique cannot be applied to complex samples having particles of various densities and shapes.[7,8]

Another programing method alternative to field programing is flow programing,[6] in which the field is held constant while the flow is increased. According to this method, the *l* parameter takes higher values for small particles and, thus, takes a long time, t_p, to generate a plate Eq. 7 and is displaced through the channel slowly to gain adequate plates. Larger particles give small *l*; however, if the largest particles have *l* too small for normal migration, anomalous results will be found. So, flow programing promises to work well over a given range of *l* values, but the practical magnitude of that range is probably limited.

Another way to reduce the *l* parameter could be owing to the increase of the total potential energy of interaction.[9] This could succeed with the variation of the ionic strength of the carrier solution. The increase of the ionic strength decreases the repulsive forces between the particles and the accumulation wall making the van der Waals attractive forces more significant.

The above methods have a main disadvantage that the extreme decrease of the l values leads to several complications, including increasing particle wall interactions and steric effects as the l approaches the particle diameter. Instead of minimizing the l parameter, the channel thickness, w, can be reduced. A common method is to use a thin flow splitter in the inlet region separating two flow ports located at the two walls.[5,6] The sample is introduced into the port near the accumulation wall, while the carrier is introduced into the other one. The effective thickness of the sample stream is controlled by the ratio of these two inlet flows; with this streamlined convergence, the sample would be held in a thin layer near the accumulation wall, requiring little time for relaxation.

CONCLUSIONS

Relaxation in FFF is the main factor for the exponential layer to form under the influence of the external field. The minimizing of relaxation time could lead to reduction of the total analysis time for the separation and characterization of colloidal samples by field flow fractionation. Looking into the future, it is reasonable to expect more experimental and theoretical work for further investigation.

Resin Microspheres as Stationary Phase for Liquid Ligand Exchange Chromatography

Zhikuan Chai
Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, China

INTRODUCTION

Among the separation modes of liquid chromatography (LC), ligand exchange chromatography (LEC) is a particularly useful technique in many applications:

1. Chiral separation of optical isomers in chiral ligand exchange chromatography (CLEC).[1] In this method, complexes of transition metal ions and enantiomeric molecules are formed. Chiral separation is a result of the differences between the free energies of the intermediate diastereomeric complexes formed. For the separation to be successful, the sample molecule must have two polar functional groups with the correct spacing, which can simultaneously act as ligand for the divalent transition metal ion. For this reason, the underivatized racemic amino acids with their amino and carboxyl groups and other similar compounds, such as amino alcohols, hydroxy acids, and diamines, can be resolved with CLEC.

   Chiral separation of racemic drugs is required by the pharmaceutical industry because different optical forms of the drugs often play different roles in their pharmacological action, metabolism, and toxicity. Chiral ligand exchange chromatography plays an important role in this respect.[2]
2. Affinity separation of proteins in immobilized metal ion affinity chromatography (IMAC).[3] The method is based on the fact that some protein molecules, having specific residues on the surface, can form complexes with metal ions immobilized on the sorbent matrix. Retention is determined by the coordination interactions forming the complexes. Immobilized metal ion affinity chromatography can be performed under very mild, non-denaturing conditions with extremely high selectivity; it is particularly suitable for preparative group fractionation of complex extracts and bio-fluids.
3. Separation of organic compounds capable of complexing with transition metal ions through N, S, O, and π-electrons in the molecule. The separation mechanism is similar to IMAC. With its high selectivity, the sample concentration can be low, from 10^{-7} g/ml (amino acids) to 10^{-9} g/ml (fluorides). Ligand exchange is now routinely applied to anion chromatography by using the coordination-unsaturated complex, because such a charged complex is an anion exchange group as well. The corresponding sorbent has specific anion exchange selectivity, originating from their dual capabilities: the normal anion exchange and the ligand exchange capability.[4]

This entry discusses resin microspheres as the stationary phases for LEC. As a detailed review article on the LEC stationary phases was written in 1990,[5] attention is given here to the publications thereafter.

STATIONARY PHASES

Chiral ligand exchange chromatography can be performed either on an achiral stationary phase with a chiral mobile phase or on a chiral stationary phase; IMAC is performed on the metal ion immobilized stationary phase. The latter two stationary phases may be symbolized by the same formula as

M–S–L–Me

where M is the matrix; S, the spacer; L, the ligand; and Me, the metal ion.

The base matrices are divided into two groups. The inorganic matrices are based on silica or zirconia, on which the transition metal ion is complexed with the ligand bonded on the matrix. The inorganic sorbents have high column efficiency but low capacity and low chemical stability. The ligand can also be coated prior to, or during, the experiment, on the octadecylated silica (ODS) reversed phase (RP), which presents the most inexpensive but efficient and selective sorbent for CLEC.

The organic matrices are based on natural or synthetic polymers. This group of stationary phases has high capacity, high chemical stability, but low column efficiency; it is promising for preparative applications.

The spacer connects the matrix with the ligand, which plays a significant role in affinity chromatography, including IMAC. The active site of a biological substance is often located deep within the molecule and the adsorbent prepared by coupling the small ligand directly to the matrix can exhibit low capacities because of the steric interference

between the matrix and the substances binding to the ligand. In these circumstances, a spacer is interposed between the matrix and the ligand to facilitate effective binding. The length of the spacer is critical. If it is too short, the spacer is ineffective and the ligand fails to bind substances in the sample. If it is too long, non-specific effects become pronounced and reduce the selectivity of the separation. $-CH_2CH(OH)CH_2-$ and $-CH_2CH(OH)CH_2-O(CH_2)_4O-CH_2CH(OH)CH_2-$ are the commonly used spacers in IMAC; they are obtained from reactions with epichlorohydrin and butanediol bis(glycidyl) ether, respectively. In CLEC, introducing flexible spacers improves the column efficiency by minimizing the steric constraints for the ligand exchange reactions; introducing long hydrocarbon spacers would increase the retentions of heavy amino acids. $-CH_2-$ and $-CH_2CH(OH)CH_2-$ are the commonly used spacers in CLEC. Methylene groups are introduced by chloromethylation of polystyrene or by the reaction of formaldehyde with an amide. For polyacrylamide, the short spacer of methylene is not stable under acidic and basic conditions, causing significant ligand leakage. The epoxy spacer may influence the elution order of the enantiomers by complexing of the hydroxyl group in the N-substituent of the ligand amino acid with the central metal ion in CLEC.

In CLEC, the ligand is a chiral selector. Out of 35 amino acids tested, the bidentate ligands L-proline and L-hydroxyproline were shown to be the best chiral chelating ligands: Almost all racemic amino acids could be easily and completely resolved into enantiomers on the L-hydroxyproline-modified polystyrene resin with aqueous ammonia solutions as the eluent. The tridentate ligand iminodiacetic acid (IDA) is most widely used in IMAC. The others are aminosalicylic acid, 8-hydroxyquilonine (8HQ), carboxymethylated amino acids, and ethylenediaminetetraacetic acid (EDTA). The ligand content ranges from 10^{-5} to 10^{-3} mol/g of sorbent. It was found that monomeric ligands bonded onto the matrix were less stable, while the polymeric ligands, such as L-proline grafted polystyrene, were stable, even at elevated temperatures.

Depending on the analytes, a variety of transition metal ions are adopted for LEC. For instance, Cu(II), Ni(II), Zn(II), Cd(II), Ag(I), and Hg(II) are chosen for N- and S-containing analytes, Ca(II), Mg(II), Mn(II), Fe(III), Al(III), Ti(IV), and Zr(IV) for O-containing analytes, and Ag(I) and Hg(II) for π-electron-containing analytes. For this reason, Cu(II) is commonly used in CLEC of racemic amino acids, while Cu(II), Zn(II), and Fe(III) are used in IMAC for histidine and tryptophan residues and phosphate residues containing proteins, respectively.

RESIN MICROSPHERE STATIONARY PHASES

Polystyrene

Polystyrene (PS) is of primary importance to LEC. The first LEC experiments were performed with PS beads. In 1961, the Cu(II) form of Chelex 100, a PS resin containing the strongly complexing IDA groupings, was used to selectively isolate the whole range of amino acids from sea water. In 1971, a PS resin modified with L-proline and complexed with Cu(II) was used to separate amino acid racemates. The experimental conditions (pH, ionic strength of the mobile phase, organic modifier, temperature), elution order of enantiomers, and ligands for CLEC were studied with the PS column. It was found that, on the PS–CH_2–L-proline or L-hydroxyproline–Cu(II) column, almost all the L-amino acids eluted ahead of the D-acids, except for the tridentate amino acids histidine, allo-hydroxyproline, aspartic acid, and glutamic acid. Recently, the PS–IDA–Cu(II) particles were used for the separation of aromatic amines with methanol/ammonia as the eluent.[6]

Macronet isoporous PS is a polymer in which pores are formed as a result of homogeneously crosslinking by rigid bridges among linear macromolecules. High ligand loading and high exchange rate are the characteristics of the sorbent. For instance, the matrix containing 11 mol% of crosslinks of diphenylmethane could have a ligand loading capacity of 2.78 mmol/g of dry resin and, as shown in Fig. 1, a glass microcolumn (100 mm × 1 mm I.D.) filled with 5–10 μm microparticles of the polymer with ligand (*R*)-*N*,*N*′-dibenzyl-1,2-propanediamine could have a column efficiency of 3500 theoretical plates, enabling

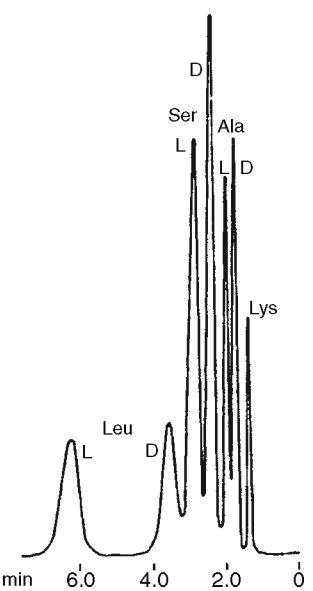

Fig. 1 Chromatogram of a mixture of racemic lysine (Lys), alanine (Ala), serine (Ser), and leucine (Leu) on a glass microcolumn (100 mm × 1 mm I.D.) packed with the chiral diamine resin. Eluent: 0.25 *M* sodium acetate + 1.5×10^{-3} *M* copper (II) acetate, pH 5.2, flow rate 1 ml/hr, room temperature. Attention: The elution time runs from right to left and lysine is not resolved.
Source: From High-performance ligand chromatography of α-amino acids on a polystyrene resin with fixed ligands of the type (*R*)-*N*′,*N*′-dibenzyl-1,2-propanediamine, in Chromatographia.[7]

complete resolution of a mixture of three racemic amino acids into six components under isocratic conditions.[7]

If PS is grafted onto the benzene ring with hydrophobic groups such as *n*- or *tert*-butyl, cyclohexyl, cyclohexylpropyl at the ortho-position of the chiral ligand, the hydrophobic interaction between the group and the enantiomeric molecule influences the stability of the intermediate diastereomeric complex. An increased enantioselectivity with respect to most amino acids was observed for the modified sorbent containing the cyclohexylpropyl group. Thus, modification of polymer skeletons may increase the enantioselectivity in racemate chromatography, as in the case with amino acids containing hydrophobic α-radicals.

The LEC experiment can be performed on ion exchange resins. Sulfonated PS beads were used to absorb the transition metal cation ions. The beads of low-cross-linking (4–8% divinylbenzene) gave narrow and more symmetric chromatographic peaks. A variety of cations, from +1 to +4 valency, were loaded onto the resin; numerous compounds such as phenols, alcohols, sugars, nucleic acids, aromatic acids, sulfur-containing compounds, β-diketones, amine bases, aromatic amines, pyridine derivatives, ethanolamines, aziridines, alkylhydrozines, aliphatic diamines, and unsaturated esters were separated. For instance, the Pb(II) form of Aminex HPX-87P, the Bio-Rad sulfonated PS gel, was used for qualitative and quantitative carbohydrate analysis of fermentation substrates and broths at 85°C with water as the mobile phase; glucose, xylose, galactose, arabinose, and mannose were separated.[8] Phosphorylated PS was used in place of sulfonated PS in LEC because the cation ion exchanger gave similar results but retained metal ions more strongly.

An optically active and electroconductive polymeric sorbent was prepared by coating the PS–L-proline–Cu(II) beads with conducting polymer polypyrrole. Applying a potential difference of ±1.5 V to the column, racemic lysine and aspartic acid were separated according to their charge characteristics and were simultaneously resolved with respect to their optical isomerism.[9]

Polyacrylamide

Contrary to PS, polyacrylamide is a hydrophilic polymer. This may increase the ligand exchange rate, i.e., the column efficiency. Thus on the polyacrylamide–CH_2–L-proline–Cu(II) macroporous microspheres, the enantiomers of valine, threonine, isoleucine, serine, phenylalanine, tyrosine, tryptophan, and asparagine were completely resolved in less than 1 hr with water as the eluent. The efficiency was markedly improved. However, the methylene bridge between the ligand and the matrix was not stable under acidic and basic conditions. The same sorbent, but with a long spacer, $–CH_2CH_2OCH_2CH(OH)CH_2–$, was prepared with L-proline content 1.76 mmol/g of dry polymer.[10] When the polymer was soaked in 0.1 *M* HCl, 0.1 *M* NaOH or 1 *M* NH_3, aqueous solutions, respectively, at room temperature for 1 week, the nitrogen content and Cu(II) capacity of the polymer did not change, indicating that the polymer was stable under moderately acidic and basic conditions. The new sorbent had high enantioselectivity for racemic amino acids.

Polyarylamide beads were also used for IMAC. The Biogel P200–glut–thio–Pt(II) beads were used for separation of biotin-labeled bovine serum albumin (BSA) from their unlabeled counterpart,[11] where Biogel P200 is a commercial product of polyacrylamide, glut—glutaraldehyde, thio—thiourea. At pH 4.8, 73% of BSA–biotin was bound. A 1.0 *M* imidazole–HCl solution, at pH 7, was successfully used to elute the bound BSA–biotin, indicating that binding to immobilized Pt(II) was reversible.

Acrylic Polymer

Separon is a commercial product of poly(hydroxyethyl methacrylate) (PHEMA) resin microspheres. The glycidyl Separon was reacted with L-proline to obtain the chiral sorbent Separon–epoxy–L-proline–Cu(II). The copper content of the resin was 0.3 mmol/g, which probably corresponded to the content of L-proline fixed ligand. The CLEC results showed high enantioselectivities for amino acids with aqueous ammonium carbonate as the eluent and were in good qualitative agreement with the result obtained on a silica gel sorbent having similar chiral ligands. All the sorbents retained the L-enantiomers of amino acids more strongly, the only exception being proline, for which the elution of the L-isomer preceded that of the D-isomer.

Recently, PHEMA microspheres have been more and more extensively used for IMAC. Separon–IDA–Fe(III) or Cu(II) was prepared. It was found that Cu(II) interacted preferentially with histidine and tryptophan residues, while Fe(III) preferred phosphate residues, as demonstrated by the separation of lysozyme, ribonuclease A, myoglobin, and transferrin on the Cu(II) column and ovalbumin on the Fe(III) column, respectively.[12] The PHEMA–Congo Red–Cu(II) and PHEMA–Cibacron Blue F3GA–Zn(II) microspheres were applied for adsorption of BSA.[13] Without incorporating the metal ions, the dyed sorbents were already good stationary phases for affinity chromatography. As shown in Fig. 2, the additional adsorption was attributed to metal–protein complexion, while the nonspecific BSA adsorption on the pure polymer was almost zero.

The weak cation exchange resin can also be used for LEC. Poly(acrylic-methacrylic acid)-type of carboxylic cation exchanger was loaded with blue-green Ni(II)–ammonia complex cations. A diamine, 1,3-diamino-2-hydroxypropane, in a dilute aqueous solution (0.001 *M*) which also contained a 100-fold excess of ammonia, was absorbed on the column and recovered as a sharp effluent band of high concentration (up to 40% w/v) by passing concentrated aqueous ammonia through the column. The weak ion exchanger retained the transition metals stronger

Pump – Reverse

and showed higher efficiency in chromatography of aromatic solutes than the sulfonated PS-type sorbent.

Hydroxylated Polyether

TSK PW is a hydrophilic polymer gel containing the group $–CH_2CH(OH)CH_2O–$ as the main constituent component, which can be readily activated and chemically modified. Other features are high porosity, low specificity in adsorption, high mechanical strength, and chemical stability at pH 2–12. L-Phenylalanine, L-tryptophan, and L-histidine were grafted through epichlorohydrin onto the gel; the Cu(II) form resin was used to resolve neutral, acidic, and aromatic amino acids with fairly good column efficiency.

TSK 5PW–IDA–Cu(II) microspheres (maximum copper loading 18.5 μmol/ml of packed gel) were used for equilibrium binding of histidine-containing cytochrome *c* in IMAC.[14] TSK 5PW–IDA–Zr(IV) microspheres (IDA content 20 μmol/ml of packed gel) were used for the separation of phenols and carboxylic acids. The sorbent was studied as a model to obtain some insight into the retentions on zirconia.[15]

Hydrophilic Vinyl Polymer

TSK Toyopearl is a spherical porous hydrophilic vinyl polymer; it is generally thought that the polymer is poly(vinyl alcohol). TSK Toyopearl–IDA–Zr(IV) microspheres (IDA content 33 μmol/ml gel) were prepared for the separation and preconcentration of fluoride at ng/ml level in a flow system.[16]

The amino-functionalized TSK Toyopearl was further modified as bis(2-pyridylmethyl)-aminated polymer (bpa-P, bpa content 0.43 mmol/g). As the bis(2-pyridylmethyl) amino (bpa) group is a tridentate ligand, and the preferable coordination number of Cu(II) is 4, the formed complex is a charged complex anion exchange group and acts not only as a simple ion exchange group but also as a ligand exchange group originating from its Lewis acidity. The sorbent, thus, showed a special anion exchange property in ion chromatography. Asahipak ODP is an octadecylated poly(vinyl alcohol) porous beads for RP chromatography. When *N*,*N*-bis(2-pyridylmethyl)octadecylamine was coated onto the polymer (bpa-ODP, bpa content 15.2 μmol/ml) for anion chromatography, the column efficiency was greatly improved, as shown in Fig. 3.[4]

Polyvinylamine

L-Proline was grafted onto the hydrophilic polymer via epichlorohydrin; the Cu(II) form resin was used for the CLEC separation of racemic phenylalanine, histidine, and tryptophan.[17]

Table 1 LEC on resin microspheres since 1990.

Polymer matrix	Ligand	Metal ion	Analyte	Refs.
1. CLEC				
Polypyrrole-coated PS	L-proline	Cu(II)	Amino acids	[9]
Polyacrylamide with a long spacer	L-proline	Cu(II)	Amino acids	[10]
Polyvinylamine	L-proline	Cu(II)	Amino acids	[17]
UF	(+)L-2-amino-5-ureidopentanioc acid	Cu(II)	Amino acids	[18]
UF	L-proline	Cu(II)	Amino acids	[19]
Guaran	Borate		Mandelic acid	[22]
2. IMAC				
Polyacrylamide (Biogel P200)	Glut-thio	Pt(II)	Biotin labeled BSA	[11]
PHEMA (Separon)	IDA	Cu(II)	Lysozyme, ribonuclease A, myoglobin, transferrin	[12]
PHEMA (Separon)	IDA	Fe(III)	Ovalbumin	[12]
PHEMA	Congo red	Cu(II)	BSA	[13]
PHEMA	Cibacron blue F3GA	Zn(II)	BSA	[13]
Hydroxylated polyether (TSK PW)	IDA	Cu(II)	Cytochrome *c*	[14]
Sepharose	IDA	Cu(II)	Ovalbumin, lysozyme, LDH	[20]
Sepharose	OPS or 8HQ	Fe(III)	Cytochrome *c*, myoglobin	[21]
3. Other LEC				
PS	IDA	Cu(II)	Aromatic amines	[6]
Sulfonated PS		Pb(II)	Carbohydrate	[8]
Hydroxylated polyether (TSK PW)	IDA	Zr(IV)	Phenols, carboxylic acids	[15]
Hydrophilic vinyl polymer (TSK Toyopearl)	IDA	Zr(IV)	Fluoride	[16]
Hydrophilic vinyl polymer (TSK Toyopearl)	Bpa	Cu(II)	Anion	[4]
Bpa-coated octadecylated poly(vinyl alcohol) (Asahipak ODP-50)	Bpa	Cu (II)	Anion	[4]

PS—polystyrene; UF—urea–formaldehyde resin; glut—glutaraldehyde; thio—thiourea; BSA—bovine serum albumin; PHEMA—poly(hydroxyethyl methacrylate); IDA—iminodiacetic acid; LDH—lactate dehydrogenase; OPS—*O*-phosphoserine; 8HQ—8-hydroxyquinoline; Bpa—bis(2-pyridylmethyl)amine.

Urea–Formaldehyde Resin

Urea–formaldehyde resin (UF) is a hydrophilic condensation polymer. The UF monosized non-porous microspheres were prepared with (+) L-2-amino-5-ureidopentanoic acid as the chiral ligand. The microspheres exhibited exceptional mechanical strength, chemical stability in the pH range 1–13, and low tendency toward swelling in solvents; they were used for the CLEC separation of amino acids.[18] Later, the porous UF microspheres were also prepared and L-proline was grafted via epichlorohydrin onto the polymer (L-proline content 0.28 mmol/g). Eighteen D,L-amino acids were resolved on the sorbent with aqueous ammonia containing 30% acetonitrile; all the D-acids eluted first, except for proline.[19]

Polysaccharides

Polysaccharides are natural polymers including agarose, dextran, cellulose, and guaran.

Sepharose, a commercial product of agarose, is widely used as a good sorbent for IMAC. This is because agarose has a high permeability to large protein molecules and there are no hydrophobic or electrostatically charged groups in the chemical structure. Sepharose–epoxy–IDA–transition metal ion is the standard structure as the sorbent for IMAC. Recently, ovalbumin, lysozyme, and lactate dehydrogenase (LDH) were purified using the Cu(II) form column. The experiments were run in displacement mode with a synthetic copolymer of vinyl imidazole and vinyl caprolactam as the displacer. Vinyl caprolactam renders the copolymer with thermo-sensitivity, i.e., a property

of the copolymer to precipitate nearly quantitatively from aqueous solution on increase of the temperature to 48°C. For the first time, it was clearly demonstrated that a polymer displacer was more efficient than a monomeric displacer (imidazole) of the same chemical nature, probably because of the multipoint interaction of imidazole groups within the same macromolecule with one Cu(II) ion.[20] Besides, Sepharose-*O*-phosphoserine (OPS, OPS content 0.40 mmol/g of dry gel) or 8-hydroxyquinoline (8HQ, 8HQ content 0.52 mmol/g) resins were prepared. The 8HQ–Fe(III) resin had a higher capacity for tuna heart cytochrome *c* than the 8HQ–Al(III) or –Yb(III) resins, while the 8HQ–Cu(II) and 8HQ–Ca(II) resins did not bind this protein. The equivalent IDA chelates showed no binding either. The OPS–Fe(III) resin bound tuna heart cytochrome *c* and horse myoglobin but did not bind hen egg white lysozyme.[21]

Sephadex is a commercial product of dextran. The polymer in Cu(II) form was employed for group separation of amino acids and proteins. Carboxymethylated dextran gel was found useful as a sorbent for LEC of enzymes.

Carboxymethyl-, diethylaminoethyl (DEAE)-, *p*-aminobenzyl-, and phosphate-cellulose, in combination with antimony, cobalt, mercury, and silver ions, were employed in LEC for separation of amines in organic solvents.

Guaran is a polygalactomannan containing *cis*-OH groups. It is well known that the tetrahedral borate ions readily form tetrahedral complexes with the *cis*-OH groups. Thus the borate immobilized polymer (boron content 0.7 mmol/g) was used for enantioseparation of racemates such as 1,2- or 1,3-dihydroxy compounds or α-hydroxy acids.[22] This appears to be the first example of the use of boron as a complexing ion in CLEC.

Glucosamine Polymer

Chitosan is a natural glucosamine polymer obtained from crab shells. The polymer retains Cu(II) more strongly than does cellulose. It was used in LEC of amino acids, peptides, and enzymes.

CONCLUSIONS

Table 1 summarizes the LEC studies since 1990. As a stationary phases for CLEC, the weakness of resin microspheres is in their low column efficiencies. The study of polypyrrole-coated polystyrene microspheres presented an effort to overcome the weakness, where a second electrokinetic interaction was added in addition to the coordination interaction. A high protein adsorption is always needed as a stationary phase for IMAC. The study of PHEMA microspheres modified with dye plus metal ion was interesting, where the protein adsorption was greatly increased by metal complexion plus dye affinity.

ACKNOWLEDGMENT

Resolution in HPLC: Selectivity, Efficiency, and Capacity

J.E. Haky
Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.

INTRODUCTION

Liquid chromatography (LC) involves the analysis of mixtures. The goal of such an analysis is to achieve the greatest possible separation of the components in the mixture in the least amount of time. If performed successfully, the resulting chromatogram can be employed to obtain precise and accurate data describing the concentrations of the components in the mixture being analyzed.

DISCUSSION

The degree of separation of components of a mixture by a liquid chromatographic method is reflected in the resulting chromatogram. For best analytical results, peaks in the chromatogram must be completely resolved from each other, with little or no overlap. The degree of separation of between adjacent chromatographic peaks is a function of the distance between peak maxima and their corresponding peak widths. For Gaussian peaks, this is adequately described by the peak resolution, R_s, defined as the ratio between the difference in the retention times t_1 and t_2 of two peaks and the average of the widths, W_1 and W_2 of the two peaks at their baselines, as shown by

$$R_s = \frac{t_2 - t_1}{0.5(W_1 + W_2)} \tag{1}$$

A resolution of $R_s = 1$ corresponds to about a 4% overlap of two adjacent peaks and is adequate for many chromatographic analyses. Baseline resolution occurs at R_s values of 1.5 or higher.[1]

As shown by Eq. 1 the resolution of components in a liquid chromatographic separation is dependent on: (1) their relative retention on a particular chromatographic system, and (2) their peak widths. To optimize these parameters for maximum resolution, a clear understanding of their nature and the factors that affect them is necessary. Although the retention time of a component adequately describes the amount of time a particular solute takes to elute from a chromatographic system, a more useful parameter describing chromatographic retention is the capacity factor k. This parameter is defined as the ratio of time spent by a solute in the stationary phase to the time it spends in the mobile phase. It can be calculated by Eq. 2, where t_R is the retention time of the peak of interest and t_0 (the "dead-volume time") is the retention time of a solute that is known not to interact with the stationary phase:

$$k = \frac{t_R - t_0}{t_0} \tag{2}$$

Additionally, the relative retention of two peaks in a chromatogram may be defined by the selectivity factor, α, defined by Eq. 3, where k_1 and k_2 are capacity factors of the early- and late-eluting peaks, respectively:

$$\alpha = \frac{k_2}{k_1} \tag{3}$$

The widths of chromatographic peaks are dependent on the degree to which a band of solute molecules spreads out, over the time it spends passing through a chromatographic system. This band spreading is best defined in terms of theoretical plates, N, which can be calculated from Eq. 4, where t_R and W are the retention time and width of the peak of interest, respectively:

$$N = 16\left(\frac{t_R}{W}\right)^2 \tag{4}$$

Higher values of N correspond to lower degrees of band broadening and narrower peaks. On this basis, theoretical plates can be described as a measure of the efficiency of a given chromatographic system.[2]

Chromatographic resolution of any two components in a mixture is dependent on three factors: (1) the overall efficiency of the chromatographic system, as described by the number of theoretical plates N, (2) the inherent selectivity of the system, described by the selectivity factor α, and (3) the degree of retention of each of the components, described by their capacity factors k. For two peaks having approximately equal widths, capacity factors of k_1 and k_2, and a mean theoretical plate number N, the following quantitative relationship can be derived between chromatographic resolution and these parameters[3]:

$$R_s = \left(\frac{N^{1/2}}{4}\right)\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k_2}{1 + k_2}\right) \tag{5}$$

To a first approximation, each of the terms in Eq. 5 can be treated as independent of each other. Therefore, in the

development of a liquid chromatographic method for analysis or isolation of the components of any mixture, experimental conditions can be varied to modify each of these three terms to maximize resolution.

Analysis of Eq. 5 indicates that resolution increases with the square root of the number of theoretical plates in the chromatographic system. Thus, a fourfold increase in N is required to increase the resolution by a factor of 2. Experimentally, N may be increased most directly by (1) increasing the length of the column, (2) reducing the size of the particles of the stationary phase, or (3) using a mobile phase of lower viscosity. However, in modern analytical LC, most of these options are impractical for the following reasons: (1) Increasing the length of the column can increase system back-pressures and the time required to complete the separation to unworkably high levels. (2) Stationary phases with particle sizes below 3 μm are not generally available, owing to excessively high system back-pressures they can cause and their short lifetimes. (3) Because most recommended mobile phases for liquid chromatographic separations are those with low viscosity, there are few alternative mobile phases with lower viscosity available.

For these reasons, attempting to improve resolution by increasing the number of theoretical plates in the chromatographic system is not generally recommended as a first choice in liquid chromatographic method development. Nevertheless, the effect of theoretical plates on overall resolution is important to consider in certain situations, such as in the scaling up of an analytical method to a preparative method, when stationary phases of larger particle sizes are often employed, resulting in lower values of N and poorer resolutions.[1]

Adjusting the selectivity of the chromatographic system, as measured by α, is often a useful technique in improving separations in LC. Such adjustments need to be made with consideration of the second term in Eq. 5, which is $(\alpha - 1)/\alpha$. When $\alpha = 1$, the term is equal to zero, resulting in no resolution. This indicates that the chromatographic system must exhibit some selectivity toward the components of the mixture before any separation is possible. The term rapidly increases as a increases up to about $\alpha = 2$, beyond which only small increases are exhibited.[2] Thus, varying chromatographic conditions to obtain a selectivity factor equal or greater than 2 will often give the best resolutions.

In LC, system selectivity can be modified by a number of techniques, including (1) changing the composition or pH of the mobile phase, (2) changing the column temperature, and (3) changing the type of stationary phase that is employed. Of these, the first method is the easiest to accomplish and is most often the first to be utilized in method development for improving selectivity.

Resolution can often be improved in liquid chromatographic separations simply by changing the retention of the components, which corresponds to changing the capacity factor k of the components to be separated. Rapid increases in the third term in Eq. 5, $k_2/(1 + k_2)$ occur as the capacity factor increases, up to $k_2 = 5$. The term increases only slowly beyond this value.[2] Therefore, in most separations by LC, optimal resolution of mixtures occurs when each component has capacity factor values between 2 and about 10. Increasing k values to higher values results in longer analysis times with minimal improvements in resolution.[2]

The effect of the capacity factor on resolution can be further exhibited by manipulation of Eq. 5 to predict the number of required theoretical plates N_{req} for a given resolution. Eq. 6 enables such predictions:

$$N_{req} = 16R_S^2\left(\frac{\alpha}{\alpha - 1}\right)^2\left(\frac{k_2 + 1}{k_2}\right)^2 \quad (6)$$

Assuming a difficult separation of two components with $\alpha = 1.05$ and a reasonable goal of obtaining a resolution R_s of 1.0, the number of theoretical plates required at various capacity factor values can be calculated. For a capacity factor of 1.0, a minimum of 28,200 plates is required. For a capacity factor of 2.0, the required number of plates drops to 15,880. Because many liquid chromatographic systems usually do not exhibit efficiencies greater than 25,000 theoretical plates, it is evident from these calculations that developing methods for difficult separations should be performed when the capacity factors of the components to be separated are adjusted so they are all greater than 2.

In LC, adjusting capacity factors is most often accomplished by changing the composition of the mobile phase. In reversed-phase chromatography, for example, decreasing the amount of organic component in the mobile phase (e.g., from 80% methanol, 20% water to 50% methanol, 50% water) will generally result in lower capacity factors for all components of the mixture. Empirical models and computer software have been developed which allow the user to predict mobile-phase compositions, which will result in capacity factors of all components in a mixture to be in the optimal range of 2–10. Such programs utilize data obtained from an analysis performed using gradient elution (i.e., continuously varying mobile-phase composition throughout the separation process).[3] In many cases, however, experimental variation of mobile-phase compositions through a trial-and-error process can be equally effective in obtaining a composition giving an optimal capacity factor range for all components.

In summary, resolution in LC is dependent on three factors: (1) the efficiency of the chromatographic system, measured by the theoretical plate value N; (2) the selectivity of the chromatographic system, measured by the selectivity factor α; and (3) the degree of retention of the

components on the chromatographic system, measured by the capacity factor *k*. Although each of these can be independently varied to obtain acceptable separations, most method development in LC is successfully performed through the initial choosing of the proper LC technique (e.g., normal phase, reversed phase, ion exchange) followed by optimizing capacity factors and system selectivity by varying the composition of the mobile phase.

Response Spectrum

Dennis R. Jenke
Technology Resources Division, Baxter Healthcare Corporation, Round Lake, Illinois, U.S.A.

INTRODUCTION

Chromatographic methods are used for a variety of purposes in real-world applications. Chromatography, in its multitude of manifestations, can be used for the purpose of scouting and discovery (i.e., to "uncover" the presence of compounds or entities in samples of unknown composition). In fact, the unique versatility of chromatography as a scouting and discovery tool is based on the almost limitless (or so it seems) combination of separation and detection strategies that can be coupled and brought to bear in investigative situations.

Once an entity has been observed to produce a chromatographic response, chromatographic procedures can be used to either characterize or identify the entity. The characterization/identification processes are facilitated by the chromatographic process, wherein both the elution and the detection properties of the entity provide information that can be useful for these purposes. The chromatographic methods may produce information that can be used to characterize the entity, which ultimately may lead to a proposal for its identity, and/or it may be used to confirm the accuracy of a proposed entity.

Although chromatography is generally considered to be an analytical tool, it also has an important role in process chemistry as a means of isolating and/or purifying substances from complex or dilute mixtures. Preparative chromatographic methods for the generation of laboratory-scale to commercial-scale quantities of pure substances are well documented in the chemical and patent literature.

OVERVIEW

As important as are the three previously mentioned applications of chromatography (Table 1), it is accurate to observe that the primary use of chromatography is for the purpose of establishing the concentration of a known entity (analyte) in a specific sample. As few chromatographic detection strategies are absolute (i.e., their response function can be derived from first scientific principles), the quantitation process includes the characterization of the response function, where the response function is the mathematical relationship that exists between the concentration of an analyte in a standard and the response that is produced by the chromatographic system when such a standard is processed by the chromatographic method.

As shown in Fig. 1, the entire domain or spectrum of a chromatographic method's response extends from the lowest analyte concentration that can be confirmed to reliably produce a chromatographic response (limit of detection, or LOD) to the highest analyte concentration for which an increase in concentration produces an increase in response (limit of range, or LOR). Although the nature of the response function is chromatographic method-specific (although most methods have a response function similar to that shown in Fig. 2), all share, to one degree or another, the spectral characteristics shown in Fig. 1.

It is an interesting aspect of the current state of affairs in chromatographic science that although there is nearly universal agreement among practitioners with respect to the members of the chromatographic response spectrum (e.g., the concept of all methods having a LOD is universally accepted), there is significant discussion among practitioners as to the definition of, and correct method for determining, the various response spectrum members (e.g., how do you determine LOD?). Although various scientific organizations [e.g., International Union of Pure and Applied Chemistry (IUPAC), American Chemical Society (ACS), United States Environmental Protection Agency (USEPA), and International Conference on Harmonization (ICH)] have proposed standard definitions and determination procedures for some of the members of the response spectrum, it is interesting to note that the procedures are not the same, and it is fair to say that not all investigators accept such methods as being scientifically the most valid or rigorous.

The purpose of this entry is to provide an overview of the chromatographic response spectrum and its various members. As a general review, it will not be complete but will strive to be comprehensive and non-judgmental.

THE CHROMATOGRAPHIC RESPONSE SPECTRUM

The chromatographic response spectrum, illustrated in Fig. 1, establishes the boundaries of the response function and breaks the response domain into appropriate categories and regions. The spectrum begins at the lowest analyte concentration that reproducibly produces a discernible analyte response (LOD) and ends at the highest analyte concentration that produces a response that is discernibly different from the response produced at a

Table 1 Application of chromatographic methods.

Nature	Purpose	Desirable response characteristics
Scouting/discovery	"Find" substances present in a sample of unknown composition	Sensitive, specific, with broad scope and range, "universal" response
Identification or characterization	Identify or characterize substance(s) that produce chromatographic responses	Sensitive, specific, "information-rich"
Isolation/purification	Separate a substance from all others in a complex mixture	Sufficient selectivity and specificity
Quantification	Determine the concentration at which a substance is present in a sample	Accurate, precise, specific, sensitive, "universal" response, known response function

lower analyte concentration (LOR). Between the LOD and the LOR are the limit of identification (LOI; the lowest analyte concentration at which the identity of an analyte can be confirmed), the limit of quantitation (LOQ; the lowest analyte concentration at which assay performance meets various standards of accuracy and precision), and the limit of linear range (LOLR; the highest concentration at which the response function is best described by a linear model). Between these limits are various regions of the response spectrum, including the following:

- *Not detected*: Either no response or a response less than that of the LOD.
- *Detected, not identified*: Response between the LOD and the LOI.
- *Detected, identified*: Response between the LOI and the LOQ.
- *Linear dynamic range*: Range of analyte concentrations over which the relationship between the analyte concentration and the method response can be described by a linear model of the form

$$\text{Response} = \text{Slope}\ (\text{concentration}) + \text{Intercept}$$

- *Dynamic range*: Range of analyte concentrations over which the relationship between the analyte concentration and the method response can be described by a mathematical model of the form:

$$\text{Response} = \text{Function}\ (\text{concentration})$$

- *Out of range*: Response is not related to the concentration of the analyte.

THE LIMIT OF DETECTION

Definition

As with many concepts in the analytical sciences, the concept of LOD suffers from the curse of intuition. That is to say that although the concept is, on an intuitive level, clear to all practitioners of the analytical sciences, if one were to ask the practitioners to define the term and describe its determination, one would end up with nearly as many definitions and determination methods as there are practitioners. This is borne out in the scientific literature, which contains literally hundreds of references with the more or less general content of "my (our) definition of the LOD and how I (we) recommend you determine it" (e.g., Table 2). It is borne out by the fact that although several organizations have attempted to unify, or harmonize, the individual definitions, their own results, in fact, are not the same.

Part of the problem is that although the concept is intuitively obvious, it is sufficiently multifaceted that a concise but truly complete and rigorous definition (i.e., one that leaves all questions answered) is difficult to

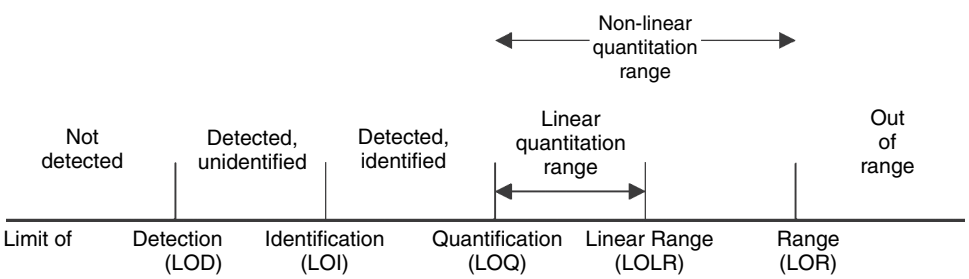

Fig. 1 The response spectrum for chromatographic analysis. The complete response spectrum extends from that analyte concentration at which a chromatographic response can be reliably confirmed to have occurred (LOD) to that concentration above which an increase in concentration no longer produces an increase in chromatographic response (LOR).

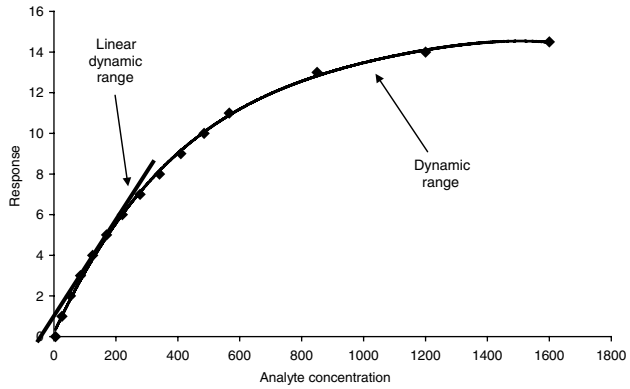

Fig. 2 Typical response function for a chromatographic method. The linear dynamic range and the dynamic range of the method are illustrated.

craft. Another part of the problem is that many definitions seek to define the term in a way that predisposes it to a certain method of determination. It is a simple statement of fact that there is a diversity of opinion on the answers to questions related to the "issues" associated with the subtle aspects of the LOD and that there are numerous mathematical methods that have been devised, which "get at" the essence of the LOD. The challenge is to draft a definition that acknowledges that these differences exist and then handles these differences not by specifying which of literally tens of candidate methods and approaches are correct but rather by requiring that the methods and approaches used be specified as part of reporting the LOD. Such a definition follows:

> The LOD is the lowest concentration of a specified analyte in a sample of specified composition, determined and calculated by specified analytical and mathematical processes, that produces, with a specified consistency, a response for a specified method implemented on a specified instrument system, which one can verify, with a specified level of confidence, is different from the response produced by a sample blank that is known not to contain the analyte.

Whether this definition is the "best" one or not, there is something "troubling" about this definition. The "problem" is that, now, it is "too complicated" to report the LOD. By this definition, it is not enough to just report a number—one must also report the context in which the number is valid. Details about the LOD required by the definition include the following:

1. The analyte's identity.
2. Description of the test sample.
3. Description of the test method (e.g., mobile phase, column, flow rate, injection size, and so on).
4. Description of the instrumentation used.
5. Description of the analytical procedure used to generate the data from which the LOD was determined.
6. Description of the mathematical process by which the LOD was determined.

Methods of Determination

Signal to noise (graphical)

A useful characteristic of a chromatographic analysis is that it results in a pictorial record of the analysis (a chromatogram). This pictorial record can be examined and used to quantify the performance characteristics of the method (and instrument system) used. Performance characteristics useful to a determination of LOD include the magnitude of the analytical signal S for the analyte (e.g., the height of the analyte peak) and the magnitude of the variation in system response when the analyte is not eluting from the system (referred to as the system noise N). These characteristics are illustrated in Fig. 3. It is clear that a comparison of S and N provides a means of establishing detectability. Specifically, a relationship between LOD, S, N, and the analyte concentration that produced the chromatogram being examined (C) can be proposed as follows:

$$\text{LOD} = C[F(N/S)]$$

In this equation, F is a factor that literally can be interpreted as: "How much higher must the peak be than the noise in order for you to be confident that what you are calling a peak is in fact a peak and not just a manifestation of the noise?" Although several values have been proposed for F, it is generally accepted that $F = 3$ is the appropriate choice. However, in the interest of clarity, LOD values obtained by the signal-to-noise method must be footnoted with the value of F used.

Although the signal-to-noise method for determining LOD is conceptually straightforward, its simplicity may lead to issues. Three practical issues of importance are: 1) the analyte level in the sample used to produce the chromatogram from which S and N are obtained; 2) the means of obtaining N; and 3) the number of injections that must be used to obtain the LOD.

Considering these details in somewhat greater detail, it is clear that the calculation of LOD requires that both the signal-to-noise and the peak response be measured effectively. This can be effectively accomplished only over a relatively small range of analyte levels, which themselves are near the LOD. As a general rule of thumb, LOD should be determined from a chromatogram derived from a sample containing an amount of analyte that is from 5–15 times the LOD.

Although the concept of the noise is simple enough, its effective measurement can be quite complicated. As it is desired that the noise measured be representative of the

Table 2 Various definitions for the LOD.

Quantity	Definition	Calculation	Refs.
MDL	MDL = minimum concentration of a substance that can be identified.	$MDL = t_{(n-1,\ 1-\alpha=0.99)} \times S_i$[a]	[1]
Detection limit (C_L)	C_L = lowest concentration of the analyte that can be distinguished with reasonable confidence from a field blank.[b]	$C_L = k \times s_B/S$[c]	[2]
Detection limit (c_L)	c_L = concentration equivalent to the smallest measure that can be detected with reasonable certainty for a given analytical procedure.	$c_L = (x_L - \mu_{b1})/S$[d]	[3]
Detection limit (c_L)	c_L = the number, expressed in units of concentration or amount, that an analyst can determine to be statistically different from an analytical blank.	$c_L = (x - \mu_{b1})/S$[e,f]	[4]
LOD	LOD = lowest concentration of an analyte that the analytical process can reliably detect.	$LOD = k \times s_B/S$[c]	[5]
Detection limit (c_L)	c_L = lowest concentration of an analyte that can be distinguished from a field blank with reasonable statistical confidence.	$c_L = k \times s_B/S$[c,g]	[6]
LOD	LOD = concentration of an analyte that produces a signal that exceeds the signal observed from a blank by an amount equal to three times the standard deviation for replicate measurements on the blank.	—	[7]
LOD	LOD = lowest concentration of an analyte in a sample that can be detected but not necessarily quantitated.[h]	$LOD = 3.3 \times s_B/S$ or $LOD = (F \times C \times N)/S$[i]	[8]
LOD	LOD = lowest analyte concentration that can be detected but not quantified under the stated experimental conditions; LOD = lowest concentration that can be distinguished from the background noise with a certain degree of confidence.	$LOD = (F \times C \times \times \times N)/S$[i,j] or $LOD = F \times s_B$ or $LOD = F \times s_B/S$[k]	[9]
LOD	LOD = concentration derived from the smallest measure that can be detected with a reasonable certainty for a given analytical procedure; LOD = lowest concentration of an analyte that the analytical process can reliably detect.	[l]	[10]

[a] S_i = standard deviation of responses obtained from seven portions of a sample (containing less than 10 × the MDL of the analyte) taken through the entire analytical method.

[b] A field blank is a hypothetical sample that contains zero concentration of the analyte.

[c] k = *A factor that should have at least a value of 3;* s_B = standard deviation of the blank response (based on a minimum of 10 determinations); and S = method's sensitivity.

[d] x_L = Minimum detectable response = $\mu_{b1} + (ks_{b1})$, where μ_{b1} = mean of replicate analyses of a blank (a minimum of 20 is recommended), k = a numerical factor chosen according to the confidence level desired (a value of 3 is strongly recommended); and s_{b1} = the standard deviation of the blank responses. S is the sensitivity of the method.

[e] Use of a value of $k = 3$ is recommended as it allows for a 99.86% level of confidence for a blank signal that follows a normal distribution and an 89% level of confidence for a non-normal distribution.

[f] A more reliable value for c_L is obtained if S (typically determined as the slope of a plot of response vs. concentration) is replaced with a confidence interval $[S \pm (ts_S)]$ reflecting the uncertainty of the slope.

[g] The key features of the LOD analysis are: 1) 16 replicate blank determinations; 2) a blank is devoid of the analyte; and 3) the calibration curve must be generated to calculate the sensitivity (slope).

[h] This definition is attributed to USP, section $< 1225 >$.

[i] C = *Analyte concentration in an analyzed sample,* N = peak-to-peak noise in the sample chromatogram, S = magnitude of analyte signal in the sample chromatogram (peak height), and F = statistical factor (typically 2 or 3).

[j] These authors note that F can vary from 2 to 5.

[k] These authors note that k can have a value of 3.0 or 3.3.

[l] These authors expand the basic relationship $LOD = ks_B/S$ to include: 1) the use of population statistics (vs. sample set statistics); 2) the use of the pooled standard deviation (vs. the blank standard deviation); 3) a consideration of situations where the intercept of the calibration curve is non-zero; and 4) a consideration of the errors in calibration parameters (slope and intercept).

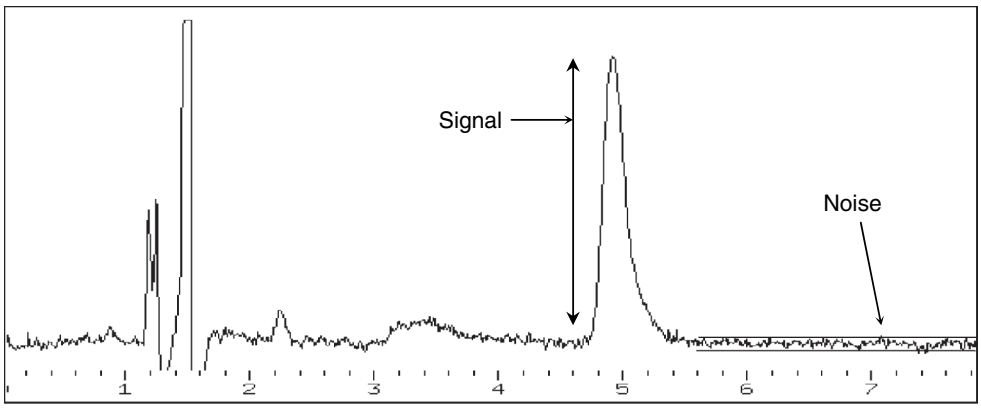

Fig. 3 Signal and noise measurements illustrated. The signal is measured from the apex of the peak to the middle of a straight-line peak base. The noise is measured as the distance between straight lines constructed from the tops and bottoms of the baseline variation. The noise should be measured in a clean portion of the chromatogram and should include a fair representation of the inherent baseline variation.

analytical method and instrumental system, it is anticipated that *N* must be measured over a relatively wide portion of the chromatogram; typical recommendations suggest that a portion equal to 10–20 times the width of the analyte peak be used to measure the signal *S*. It is clear that the portion of the chromatogram used to measure *N* must be clear from analytical responses (such as those produced by other analytes, internal standards, and sample matrix components). Practically speaking, it may be difficult to "find" a chromatographic region that is sufficiently "wide" and "undisturbed" to produce an appropriately representative *N*.

The LOD can be calculated from *S* and *N* obtained from a single chromatogram. However, this may not be an appropriate approach given the large variation in analytical signal that occurs at analyte levels near the LOD. As analytical signals can vary by 20% (or more) from injection to injection at analyte levels near the LOD, it is suggested that LOD be calculated from a minimum of three sample chromatograms and that the reported LOD be the mean of the individual results.

Although the previous discussion implies that the signal and noise are determined from the same chromatogram, other investigators have suggested that it is appropriate to measure the magnitude of the noise in the elution region of the analyte on a chromatogram derived from a sample blank.

Recently, Coleman et al.[11] have observed that although *S*/*N* is a height-based determination, it is most typically the case that peak area is used for analyte quantitation. Thus these authors have proposed a procedure for setting a meaningful lower limit on peak area *S*/*N*.

One of the most common criticisms of the *S*/*N* approach is the subjective nature of the noise measurement. Although it is certainly the case that estimates for the noise may vary from one investigator to the next, such differences tend to be small, certainly well within a factor of 2.

Variation in the method blank (IUPAC/ACS)

In response to the confusion that existed regarding numerous and conflicting data on detection limits, the IUPAC adopted a model for LOD calculations in the 1970s.[3] This standard was reaffirmed by the ACS Subcommittee on Environmental Analytical Chemistry in the early 1980s.[5,12] The IUPAC/ACS procedure is based on two method characteristics: 1) the variation (standard deviation) of multiple blank measurements; and 2) the relationship between the response and the analyte concentration (at concentrations near the LOD). If R_B is the mean blank responses and s_B is the standard deviation of the blank, then the LOD is calculated as:

$$\text{LOD} = R_B + ks_B$$

where k is a numerical constant whose value is chosen in accordance with the confidence level desired. As this calculation of LOD produces a result in response units, the concentration LOD is obtained using the slope S of the method's calibration curve:

$$\text{LOD} = (R_B + ks_B)/S$$

This process is illustrated in Fig. 4.

The analytical procedure used to produce the data from which the LOD is calculated is as follows:

1. A statistically significant number of blank measurements are made. Although at least 10 and as many as 20 replicates have been recommended, 16 measurements are generally selected.
2. The standard deviation of the blank measurements is calculated (in units of response, not concentration).
3. Five standard solutions of varying analyte concentrations (prepared in the blank matrix) are analyzed and a calibration curve of response vs. concentration is

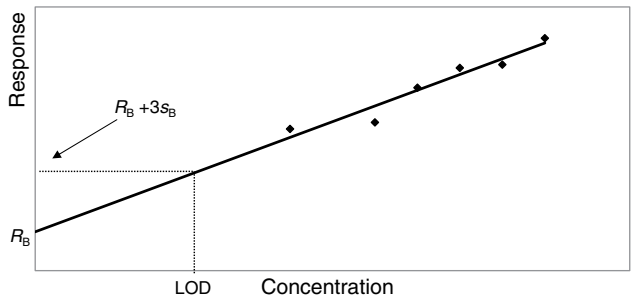

Fig. 4 Calibration graph showing the LOD. This graph illustrates the IUPAC method for determining the LOD. R_B = response of the blank; s_B = standard deviation of multiple determinations of the blank responses.

constructed. If the range of the standard concentrations is appropriately chosen, then the calibration curve is typically linear and its slope can be determined.

4. The LOD is calculated with the generated data per LOD equation. A value of $k = 3$ is strongly recommended.

Numerous authors have proposed modifications of the IUPAC/ACS approach, typically based on a more rigorous statistical analysis of method variation and its contributing factors. Although such approaches are undoubtedly scientifically more rigorous, they typically require more complex computations and their practical significance is open to question.

One significant practical problem with the IUPAC methodology occurs in the situation wherein the blank produces no analytical signal—a circumstance that is commonly encountered in chromatographic analyses. In such circumstances, it may be possible to estimate the "virtual" standard deviation at zero concentration.[13] In this graphical technique (Fig. 5), the standard deviation (in response units) of replicate analyses of successively more dilute samples is plotted vs. the analyte concentration. The *y*-intercept of this plot (S_0) represents the virtual standard deviation at zero concentration. The LOD is calculated by substituting S_0 for s_B in the IUPAC LOD equation.

Another, more practical problem associated with the IUPAC methodology is the time-consuming requirement of 16 replicate analyses (injections for chromatographic analysis) of the blank. To address this issue, the ICH has devised a methodology for the calculation of LOD that is similar in concept to the IUPAC method but is different in its application.[14] By the ICH definition, the LOD is expressed as:

$$\text{LOD} = 3.3(\sigma/S)$$

where σ is the standard deviation of the response and S is the slope of a method's calibration curve. In the ICH

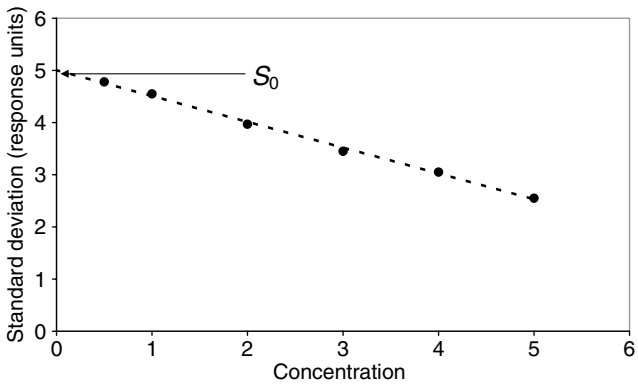

Fig. 5 Determination of LOD based on the projected standard deviation at zero concentration (S_0). The LOD is calculated as the concentration that corresponds to a response three times the value of S_0. Although the relationship between concentration and standard deviation shown here is linear, non-linear relationships between these two variables are likely.

computation, σ can be determined based on one of three data: 1) the standard deviation of the blank; 2) the residual standard deviation of the regression line; or 3) the standard deviation of the *y*-intercepts of regression lines.

95% Confidence intervals around the best-fit line

This graphical method, illustrated in Fig. 6, is a variation of the standard deviation-based approaches discussed previously. In this approach, the 95% confidence bounds are obtained for the best-fit, regression-based, calibration line. The upper 95% confidence bound, extrapolated to zero analyte concentration, reflects the statistical "limit" as it relates to calibration bias and imprecision, and establishes the LOD in terms of response. Mathematically, this response LOD is converted to a concentration LOD by

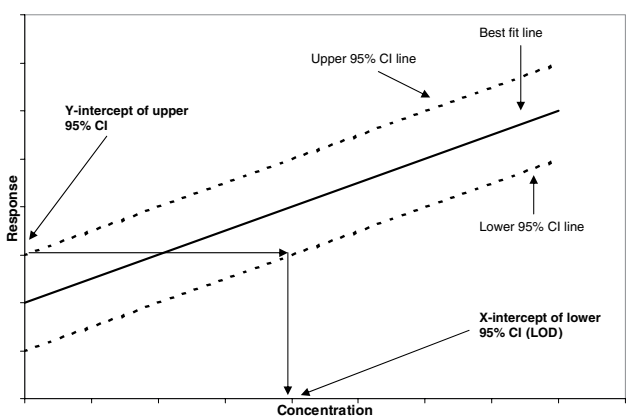

Fig. 6 Graphical determination of the LOD based on the 95% CI lines surrounding the best-fit regression model.

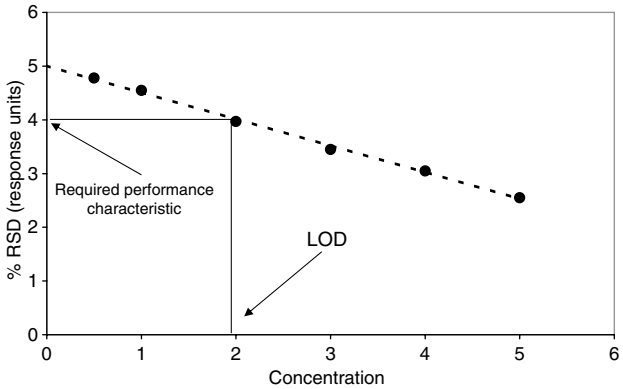

Fig. 7 Determination of LOD based on a specified performance requirement. In this example, the LOD is defined as the lowest analyte concentration with a percent relative standard deviation of not more than 4%. The interpolated value of LOD is approximately two concentration units. Although the relationship between concentration and percent relative standard deviation shown here is linear, non-linear relationships between these two variables are likely.

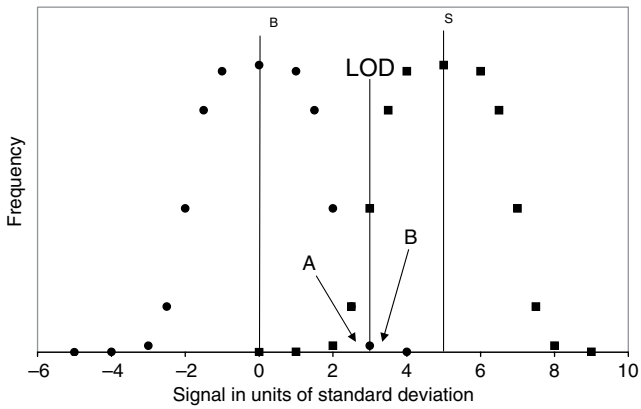

Fig. 8 Normal distribution of responses for the field blank (mean response = μ_B; •) and for the sample (mean response = μ_S; ■). Although the sample has a mean analyte value above the LOD, the potential for a false-negative response (sample analyzed with signal less than the LOD obtained, therefore concluding that the analyte is not present in the sample) exists and its probability is defined by region A in the sample's response distribution. As the sample's mean signal increases, the probability of a false negative decreases. The probability for a false positive (blank producing a signal greater than the LOD, thus concluding that the blank contains the analyte) is defined by region B in the blank's response distribution.

inputting the response LOD into the lower 95% confidence bound and by solving for concentration. Graphically, this can be accomplished as shown in Fig. 6.

Lowest concentration exhibiting required performance

As an alternative to the methodologies based on standard deviation, one can define the LOD (or LOQ) to be the lowest concentration that produces an analytical response that meets predefined quality requirements. For example, one might define the LOD as the lowest analyte concentration that produces a percent relative standard deviation (%RSD) of 10%. The LOD can be determined by performing replicate analyses of successively more dilute samples. The LOD could be estimated if one plots percent relative standard deviation vs. the analyte concentration (Fig. 7).

Minimization of false conclusions

In the context of LOD, false positive and false-negative responses can be defined as follows: false positive—a response for a blank that contains no analyte that falls above the LOD (i.e., a blank that is concluded to contain the analyte); false negative—a response for a sample that contains the analyte that falls below the LOD (therefore it is concluded that the sample does not contain the analyte at detectable levels). False-positive and false-negative responses are possible due to the assay variation (responses for a given sample are represented by a frequency distribution and not a single result). This scenario is illustrated in Fig. 8. To a certain extent, the definition and value for LOD depend on whether it is acceptable to have a false-positive or false-negative response.

Elimination of false positives is accomplished by having the LOD defined and calculated by the IUPAC procedure. With a k value of 3, the possibility of a false positive is less than 0.2% if the data are normally distributed, and less than 11% if hey are not. If greater confidence is required that false positives will not occur, a larger value of k may be necessary in the LOD calculation.

Consideration of false negatives requires that one take into account two response distributions: the response distribution for the blank, and the response distribution for the sample. A false negative will occur in the region where sample and blank response distributions overlap. If the detection limit is defined as that sample concentration for which the response distributions would not overlap (i.e., the LOD is that sample concentration for which a false-negative response cannot be obtained), then clearly the LOD depends on both the standard deviation of the blank and the standard deviation of the sample. Although it is beyond the scope of this manuscript to assess this scenario in a statistically rigorous manner, the following example may serve to illustrate the relationship between LOD and a false negative. In this example, the response populations of the blank and the sample are normally distributed and the standard deviation of both populations is the same. If the means of the blank and the sample populations differ by six times the standard deviation, there is less than a 1% chance that a response within the sample's distribution will also fall in the blank's

distribution (thereby creating a false negative). In such an example, one would be justified in calculating LOD as:

$$\mathrm{LOD} = R_B + 6s_B$$

where R_B and s_B have been defined previously as the mean and standard deviation of the blank response respectively.

Method detection limit

Methods for determining the LOD that are based on the analysis of a field blank that does not contain the analyte of interest are problematic in many real-world applications because either such samples do not exist, or would be impossibly difficult to create. As such a circumstance is frequently encountered in environmental analysis, the USEPA adopted a detection limit procedure, termed the method detection limit (MDL), which focuses on an operational definition of detection limit.[15] Specifically, the MDL is defined as the minimum concentration of a substance that can be measured and reported with 99% confidence that the analyte concentration is greater than zero. The MDL is determined from a replicate analysis of a sample of a specified matrix. Specifically, at least seven aliquots of sample, spiked to contain a concentration of from one to five times the method's estimated MDL, are analyzed. The MDL calculated from these results is statistically tested to determine its "reasonableness." If the result fails the testing, this iterative process begins again with a new estimate of the MDL.

Other methods

The analytical literature abounds with additional methods for the calculation of LOD. Most of these additional methods are variations on the procedures discussed herein, where the variation involves a more rigorous statistical assessment of the various aspects of a method's response function and variation. Although such derivations are mathematically and statistically rigorous, from a practical perspective, it is open to debate whether use of such derivations: 1) clarifies the meaning of the LOD; 2) improves the utility of the LOD; or 3) has the potential to become universally accepted.

Sensitivity vs. Detectability

A frequent error encountered in evaluating the performance of an analytical system is to confuse the concepts of sensitivity and detectability. Although both concepts address facets of a system's response, they are not identical, but rather complementary. Sensitivity relates to the ability of the system to respond to changes in analyte concentration and is most typically reflected as the slope of the method's response function. Detectability, as has been noted previously, is the ability of the method to distinguish between two responses (those responses that arise in the presence and absence of the analyte in the sample matrix of interest). It is possible to have a very sensitive method that has a relatively poor detection limit, especially if the method is very unselective or prone to high blanks. However, an insensitive method is very unlikely to exhibit a low LOD. Thus sensitivity is a necessary—but not sufficient—condition for the achievement of a low LOD.

General Comments

The following observations, relevant to LOD and its determination, are summarized from the various cited references.

A detection limit must be viewed as a temporary limit to current methodology.[1]

The LOD is governed by both instrumental factors (e.g., capability of the analytical instrument and column) and procedural factors (e.g., recovery of the analyte from the sample). It varies with the type of sample, different batches of blank, and type and condition of instrumentation.[16] Factors other than the analytical method itself that can influence the detection limit include the following:[2]

1. The analyst.
2. The analytical environment.
3. The brand of instrumentation used.
4. The quality of reagents.
5. The nature of the samples.
6. The calibration protocol.
7. The use of blank correction.

Column efficiency can affect *S/N* measurements; therefore analysts should account for both the type and the age of the column when determining the LOD. The maintenance status of chromatographic components (e.g., detectors and injectors) will also affect the ability to measure limits.[8] In trace analysis, the LOD is greatly influenced by the recovery of the compound; adsorption to glassware, instability or volatility, incomplete reaction (during derivatization), and poor laboratory technique are some of the causes of sample loss during analysis.[16]

Most paradigms for the calculation of LOD are based on the following simple models of an analytical system:[2]

1. The random error is normally distributed.
2. The population parameters are known.
3. The analytical method is unbiased.
4. The "field blank" is effectively a sample with zero analyte concentration.
5. The variance in the field blank measurement is essentially equal to the variance for samples with very low analyte levels.
6. The matrices of the field blank and samples are effectively identical, so that no unique interference effects are present.

Inherent in the model are the principles that the measured signal consists of an analytical signal (response to the analyte) and a blank signal (background, noise, or measured signal for a blank), and that both the analytical and blank signals fluctuate.[17] Additionally, it is generally assumed that the process has a linear response function.[18]

The calculated LOD can easily vary by an order of magnitude through the use of different statistical approaches.[4]

A value of $k = 3$ is considered minimal because it implies definite risks of 7% for false-positive (concluding that the analyte is present when it is absent) and false-negative (the reverse) decisions.[5]

To a certain extent, the correct calculation of LOD depends on whether greater harm is likely to be caused by false positives or false negatives.[7]

The entire sequence of operations, from procurement of the sample through the final measurement step, ultimately determines the LOD.[7]

Random error, reported as the coefficient of variation, ranges from about 25% to 100% at the LOD.[18]

Numerical values that have been proposed for k in the determination of LOD are summarized in Ref.[17] and range from 1.00 to 20.

It is better to regard the LOD as a useful but approximate guide to an analytical procedure. The value of LOD should be stated with one significant figure only, and duplicate results differing by a factor of less than 2 should not normally be regarded as significantly different.[16]

THE LIMIT OF IDENTIFICATION

As noted in the discussion of LOD, a false negative occurs when a response for a sample that is known to contain the analyte falls below the LOD. In such a case, it would be concluded (falsely) that the sample does not contain the analyte at detectable levels. At some point on the method's response spectrum between the LOD and the LOQ, there is an analyte concentration above which there is a very small chance that a false negative could occur. At this concentration, the vast majority of the responses that make up the sample's response population would fall above the LOD. This concentration is termed the LOI. Thus the LOI is defined as follows:

> The LOI is that analyte concentration at which the probability of obtaining a false-negative response (i.e., a response that is below the LOD) for a sample known to contain the analyte is below a specified value defined by the required level of confidence.

If the response populations of the sample and its associated blank are both normally distributed and if the standard deviations of the populations are similar, the LOI can be calculated as:

$$\mathrm{LOI} = R_B + 6s_B$$

where R_B and s_B have been defined previously as the mean and standard deviation of the blank response, respectively. In such as case, the probability of a false-negative response is 0.13% at the 95% level of confidence. Lack of normality in either response distribution, a greater variation in the response distribution of either the sample or the blank, or a higher required level of confidence would require that the LOI calculation have a multiplier larger than six in the s_B term.

THE LIMIT OF QUANTIFICATION

Definition

If it is an accurate observation that the LOD is a difficult concept to effectively define, the opposite is true for the LOQ. It is generally accepted that the LOQ is linked to method performance expectations including accuracy and precision. Thus a common definition of LOQ is as follows:

> The LOQ is the lowest concentration of the analyte that can be measured with acceptable accuracy and precision under the stated experimental conditions.

Methods of Determination

As LOQ and LOD are related concepts, it is not surprising that the methods suitable for determining LOD are, in most cases, also suited for the determination of LOQ, at least from a conceptual standpoint. Several of the more commonly cited means of determining the LOQ are described as follows.

As a multiple of the LOD

Once a method's LOD has been determined (by any of several methods as noted earlier), the LOQ can be calculated as a simple multiple of the LOD. Although a multiple of 3.3 is commonly cited (where 3.3 is the ratio of 10 : 3), LOQs are routinely calculated as three to five times the LOD.

Signal to noise (graphical)

As was the case with LOD, the LOQ can be calculated from a signal-to-noise evaluation of a chromatogram arising from a field sample known to contain the analyte at a concentration approximately equal to the LOQ. The LOQ is typically calculated as the analyte concentration required

to produce a signal that is 10 times larger than the peak-to-peak noise.

Based on analysis of spiked samples

This approach represents a literal interpretation of the LOQ definition. The LOQ is assessed by analyzing replicates of a field blank spiked with a low level of the analyte (near the LOQ), along with calibration standards. The accuracy (spike recovery) and precision of the replicate analyzes are compared to prespecified performance expectations. If the expectations are met, then the spiked concentration is an estimate of the LOQ. A more accurate determination of the LOQ would involve an iterative process whereby samples containing different levels of the analyte are all repetitively analyzed. The LOQ would fall somewhere between the lowest concentration that meets the performance expectations and the highest concentration that fails to meet the expectations.

Based on standard deviation of the noise

A representative (field) blank is repetitively analyzed and the LOQ is calculated as a multiple (typically 10) of the standard deviation of the blank's responses (divided by the slope of the calibration curve). This is equivalent to the IUPAC/ACS method for determining LOD.

Based on calculated confidence intervals around the calibration curve

Calibration data, obtained at analyte concentrations near the LOQ, are fitted (by an unweighted linear regression) and the confidence intervals (CIs) are calculated. The LOQ is determined as the concentration for which the interval (at a specified level of confidence) does not overlap the CI of the matrix blank (used as a standard).

Based on background interferences and the reproducibility of the response

Responses are obtained from replicate analyses ($n = 4$) of a field blank and the field blank spiked to contain a level of analyte that is close to the LOQ. The means of the obtained responses are tested statistically (with the *t*-test) to determine whether they are statistically different. If the difference is significant, the variability of the response in the spiked sample is evaluated by taking the ratio of its mean response to the response standard deviation. If the ratio is greater than or equal to 3, then the spiked concentration is taken as the LOQ.

Based on confidence intervals

Once again, field blanks and spiked field blanks are repetitively analyzed. The LOQ is determined as the concentration at which the lower confidence level of the mean of the spiked sample responses is at least four times greater than the upper confidence level for the mean blank response.

GENERAL DISCUSSION

It is clear from both the definition of LOQ and several of its methods of determination that a key aspect of establishing an LOQ is defining appropriate performance expectations. Although appropriate performance expectations may vary from method to method and especially from application to application, some general guidance in terms of what level of performance is reasonable to expect at the LOQ is given as follows:

- For bioanalytical LC methods, the accuracy criterion is ± 20% (80–120% of the "known" value) and the RSD should be less than 20%.[9]
- The LOQ is the lowest concentration for which RSD is less than 5%.[13]
- An *S/N* of 10 or less than 10% RSD is a good value as a rule of thumb.[8]
- A recovery of 70–130% and a precision of 10% RSD are required at the LOQ.[19]

A survey of validation data in trace level analyses reported that the following criteria for accuracy, obtained from various references, are pertinent:[20]

1. Below 100 ppb, 60–110% recovery is acceptable; above 100 ppb, 80–100% recovery is acceptable.
2. Below 1 ppm, 70–120% recovery is acceptable.
3. Impurities present at 0.1–10% should produce data within ± 5% of actual.

The linkage of the LOQ to performance expectations clearly differentiates LOQ from LOD. LOD is a calculated result. LOQ is a calculated result compared to a performance expectation. It is the aspect of the performance expectation that makes the link between LOQ and the application more obvious than the link between LOD and the application. Although it is possible for the same method to have two different LOQ values, depending on the needs of different applications, the method will have only one LOD.

It has been previously noted that it has historically been possible to obtain widely different values for LOD and LOQ, depending on the approach used and the statistical "multiplier" applied. As the LOD and LOQ concepts have evolved and have become more standardized and harmonized, obtaining such widely varying results is no longer commonplace. A recent study[13] examined LOD and LOQ values obtained for a multianalyte, gradient, UV-based high-performance liquid chromatography (HPLC) method by four different techniques, including: 1) a performance

Table 3 LOD and LOQ estimated for a gradient LC/UV assay with three analytes.

Analyte	Method 1[a]	Method 2[b]	Method 3[c]	Method 4[d]
LOD (mg/ml)				
A	0.06	0.05	0.02	0.04
B	0.04	0.04	0.02	0.04
C	0.04	0.10	0.05	0.10
LOQ (mg/ml)				
A	0.21	0.09	0.07	0.08
B	0.13	0.09	0.05	0.06
C	0.14	0.13	0.16	0.15

[a]LOQ is the lowest concentration that produces an injection to injection precision of NMT 5%. LOD = 0.3LOQ.
[b]Based on the graphical extrapolation of the plot of standard deviation of replicate injections vs. analyte concentration to zero concentration (to produce S_0, the standard deviation at zero concentration). LOD = concentration that corresponds to $3S_0$, LOQ = concentration that corresponds to $10S_0$. This is the ICH convention (Fig. 4).
[c]The 95% confidence lines are drawn around the best-fit regression plot of peak response vs. analyte concentration. A horizontal line is drawn from the *y*-intercept of the upper 95% CI line to the lower 95% CI line. A vertical line is drawn from the intersection point on the lower 95% CI line to the *x*-axis, yielding the *x*-intercept. The *x*-intercept is the LOD whereas the LOQ is 3.3LOD (Fig. 5).
[d]Based on the chromatographic signal to noise. LOD = $3N/S$; LOQ = $10N/S$ (Fig. 3).
Source: From Determination of LOD and LOQ of an HPLC method using four different techniques, in Pharm. Technol.[13]

expectation of percent relative standard deviation less than 5%; 2) a plot of standard deviation vs. concentration (ICH approach); 3) use of the 95% CI of the best-fit regression line; and 4) signal to noise (graphical). The results of this study are summarized in Table 3. In general, the results obtained via the four methods all agreed to within a factor of 2–3, and the differences between results were distributed randomly (i.e., no method gave consistently lower or higher results). Thus the authors of this study concluded that the four techniques were essentially equivalent and all were suitable for satisfying USP or ICH requirements.

Finally, the following discussion, obtained from Ref.[18] may be a useful and practical means of highlighting the meaning of, and differences between, LOD and LOQ.

Think of the LOQ as a "Beware of Dog" sign posted on the fence around a property, and the LOD as a "Beware of Dog" sign posted in the middle of the fenced yard. One may walk up and touch the first sign fairly safely. However, stay away from that second sign. Do not go into the yard.

A second example is as follows:

> A driver finds himself on an apparently deserted road that extends all the way to the horizon. As a good driver should, he periodically looks to the horizon to check for oncoming traffic. For the longest time, he sees nothing. Then, suddenly, he catches a glimpse (he thinks) of something out there. As he keeps on checking, he is not quite sure; does he see something or not? Is it really something or just a glint off the windshield? At this point, the object is below the driver's LOD. However, as time goes on, the object appears to be there every time he looks up. He is now reasonably confident that there is an object out there. The object has reached its LOD. As the driver and the object continue to move closer, the object grows in size and is more distinguishable from the background. Finally, the driver is virtually 100% confident that the object is out there and, in fact, it appears to be a car (as opposed to a truck or motorcycle). The object has reached its LOI. As time continues and the objects move still closer (with the net result that the car gets bigger and bigger), eventually the driver is able to ascertain that the car is, in fact, a Porsche 914 roadster, containing a driver and her passenger. At this point, the LOQ has been reached.

REPORTING LOW-LEVEL RESULTS

Once the various detectability limits have been defined and established for an analytical method, the question as to the proper format for reporting low-level results arises. To address this question, it is pertinent to observe that the three detectability limits (LOD, LOI, and LOQ) clearly divide the lower end of the response spectrum into finite regions (Figs. 1 and 9). Thus the question of how to report a low-level result boils down to what region of the response spectrum does the result fall in, and what is the appropriate reporting convention for that region.

The lowest response region in the spectrum is that which has the LOD as the upper bound. It is clear that if a response that is smaller than the response associated with the LOD is observed, the analytical result should be reported as "less than the LOD" or "not detected." In either case, the method's LOD must be reported [e.g., "< LOD (= 2 ppm)." It is also appropriate to report the method by which the LOD was determined, although this is done only infrequently.

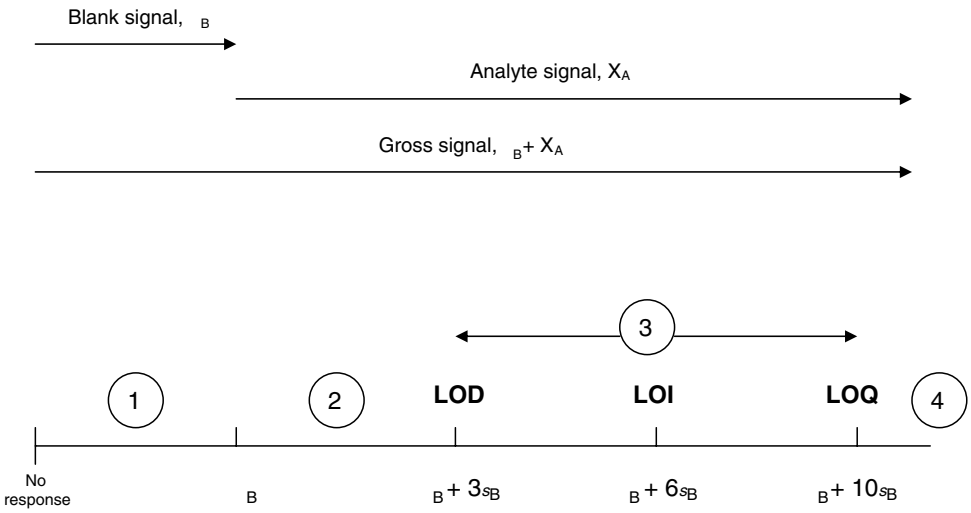

Fig. 9 Diagrammatic representation of various limits and their relationship to the mean blank response (μ_B) and the standard deviation of the blank response (s_B). The numbered regions include: 1) the region of the blank signal (reported as "not detected" and reporting the LOD); (2) the region of the blank variation (reported as "not detected" and reporting the LOD); 3) the region of detection and identification (reported as less than the LOQ and reporting the LOQ); and 4) the region of quantification (reporting the result).

Although the above discussion appears to be straightforward, the circumstance in which no response is observed is a bit more complex. Although there is a temptation to report such a result as a zero concentration, doing so is not correct except in the circumstance that the method's LOD is a single molecule. In all other circumstances, a non-observed response can be produced by an analyte that is either truly not present or an analyte whose level is well below the LOD. Thus as was the case of the response below the LOD, a sample that produces no analytical response is reported as "< LOD" or "not detected," with the LOD and its method of determination being cited.

Moving to higher analyte levels in the sample, the next region in the response spectrum is that region defined by the LOD at the low end and the LOI at the high end. Responses in this region are clearly above the LOD; thus one is confident that the response is "real" (i.e., the response arises from the elution of an analyte from the chromatographic column and into the detector). However, the amount of analyte present is insufficient to allow for its accurate identification. In this case, it is appropriate to report the result as "detected, unidentified" and to cite the method's LOI and its method of generation. Although it is appropriate to note that the analyte concentration in a sample producing a response that falls between the LOD and the LOI is greater than the LOD, this information may or may not be relevant to the interpretation of the result.

The next region one encounters as the response continues to increase is that region which falls between the LOI and the LOQ. As the response is above the LOI, the identity of the compound responsible for the response can be (and presumably is) identified. Thus the compound's identity is noted and the measurement status of the analyte peak is reported as "detected, identified." It is also appropriate to report the concentration of the analyte in such a sample as "< LOQ" and to cite the value of the LOQ and its means of determination. Although it may be tempting to "estimate" the analyte concentration in a sample whose response falls between the LOI and the LOQ, doing so is of limited value as the response function is typically poorly defined in this response region and the response is prone to a high degree of variability.

Although the above directions are clear-cut, there are circumstances where reporting a number is highly desirable (e.g., when the result is part of a data population that is undergoing statistical analysis). In such cases, it may be appropriate to report the analyte's calculated concentration, but care must be taken to ensure that the method's response function in the region of the analyte response is known. Such a result should be termed a concentration estimate and should be reported along with the qualifying notation "< LOQ" and the LOQ should be reported.

It goes without saying that it is appropriate to report the calculated concentration of an analyte whose response is above the LOQ. However, the reader is cautioned to remember that the response region near the LOQ is characterized by a high degree of imprecision and inaccuracy, and that good sense should be exercised in the use of significant figures in the reported value.

THE DYNAMIC RANGE

Because the primary use of chromatography is to establish the concentration of a known entity (analyte) in a specific sample and because few chromatographic detection strategies are absolute (i.e., their response function can be derived from first scientific principles), a useful chromatographic

method must have an analyte concentration region over which a response function can be established. This response function (or calibration curve) is the mathematical relationship that exists between the concentration of an analyte in a standard and the response that is produced when such a standard is processed by the chromatographic method. The dynamic range of a method is that concentration region for which a useful response function can be established. In this context, the term "useful" has three aspects. The first aspect is that the response function must be such that the sensitivity of the method is sufficient for the method's intended application. Although a flat line response function (no change in response produced by a change in analyte concentration) can readily be described mathematically, such a response function would be useless from a quantitative perspective. The second aspect is that the response function must be unique in the sense that every response is produced by a sample containing a single amount of the analyte. Although many chromatographic detectors reach a "flat line" state at high concentration (i.e., no change in response occurs as analyte concentration changes), there are some detectors (e.g., mass spectrometers) whose response actually "bends backward" (i.e., response decreases as concentration both increases and decreases). In such a circumstance, a sample may produce a response that is linked (via the response function) to two analyte concentrations. Inputting a sample's response into a calibration curve and obtaining multiple concentrations is clearly an outcome of limited value. The final aspect is that the response function must adequately "fit" or represent the analytical data from which it is derived. If the fit is poor (i.e., if there is a large difference between the measured response at a specific concentration vs. the response calculated from the regression model), then clearly the response function is not representative of its source data and any calculation based on the response function will be inaccurate.

The terms range and dynamic range are frequently encountered and occasionally incorrectly used interchangeably. The dynamic range is method specific and reflects the largest concentration difference for which a suitable response function can be obtained. The range of a method is application specific and does not necessarily represent the full capability of the method. Thus, for example, the range of an assay used for the purpose of quantifying an active ingredient in a finished pharmaceutical product need be only for 80–120% of the ingredient's nominal concentration in the actual test sample.[21] In many cases, such an application-driven range is just a small portion of the method's true dynamic range.

A subset of the dynamic range is the linear dynamic range. The linear dynamic range is that portion of the range for which the appropriate response function is a linear one. Historically, obtaining a linear calibration model has been the desired outcome of an analytical method development activity and most guidance for analytical method validations include an assessment of linearity (along with the subtle expectation that the desired response function is, in fact, a linear one). As numerous other calibration models exist and can readily be judged in terms of their appropriateness of fit, the desire for a linear response function is truly a throwback to the days when the only regression analysis tools were a pencil and straightedge. In modern chromatographic analysis, there is no underlying need for the response function to be linear and, in fact, there are many fundamental reasons to anticipate that certain detection methods are, by their very nature, non-linear in their response over every practically useful concentration range. It is noted in passing that the entire dynamic range may be made up of numerous smaller concentration regions whose response function is a linear one.

As a general rule of thumb, the LOQ is typically the low point of a method's dynamic range. The concentration at the high end is usually dictated by a lack of sensitivity, which leads to increased uncertainty, and is clearly method-dependent.

It is noted that the apparent dynamic range can be expanded at the high-concentration end via sample dilution provided that the dilution itself does not materially impact the response (e.g., via sample matrix effects). Additionally, a sample preparation process that accomplishes the concentration of the analyte may decrease a method's limit of detectability.

THE LIMIT OF RANGE

The LOR is that analyte concentration at which the method's response function is either no longer useful or no longer determinable. As noted previously, the LOR may reflect that concentration for which:

1. No response function that adequately fits the analytical data can be found.
2. The method exhibits inadequate sensitivity.
3. The method exhibits insufficient accuracy or precision.
4. The response function produces multiple values for a single input quantity.

Although it is typically the case that the LOR is defined by limitations in the detection portion of the analytical system, this is not necessarily the case in chromatographic analysis. Clearly chromatographic performance (such as loss of resolution or poor peak shape) at high analyte concentrations can be the limiting factor in terms of establishing a method's LOR, Additionally, other factors, such as injection-to-injection carryover at high concentration and analyte stability issues in high concentration standard or sample solutions, may represent practical method limitations that ultimately define a method's LOR.

CONCLUSIONS

The response spectrum in chromatographic analysis extends from the lowest analyte concentration that consistently produces a recognizable response to the highest analyte concentration that produces a response that is uniquely different from the response produced at a different analyte concentration. In this manuscript, the response spectrum has been partitioned into several appropriately concise regions via the use of concentration limits that correspond to the functions or purposes of chromatographic analysis (detection, identification, and quantitation). Methods for calculating, using and reporting the various limits were discussed. The position at which a particular response falls on the response spectrum dictates the utility and reliability of the analyte concentration assigned to that response.

Retention Factor: MEKC Separation

Koji Otsuka
Shigeru Terabe
Department of Material Science, Himeji Institute of Technology, Hyogo, Japan

INTRODUCTION

In micellar electrokinetic chromatography (MEKC), an ionic surfactant micelle, such as sodium dodecyl sulfate (SDS), is used as a pseudo-stationary phase that corresponds to the stationary phase in liquid chromatography (LC). Here, the separation principle of MEKC with an anionic micelle (e.g., SDS) under a neutral condition is briefly considered. When high voltage is applied across the whole capillary, the entire solution migrates toward the cathode by electroosmotic flow (EOF) while the SDS micelle is forced toward the anode by electrophoresis. The EOF is stronger than the electrophoretic migration of the SDS micelle and, hence, the micelle migrates toward the cathode at a more retarded velocity than the EOF.

When a neutral analyte is injected into the micellar solution at the anodic end of the capillary, it will be distributed between the micelle and the surrounding aqueous phase. The analyte, which is not incorporated into the micelle at all, migrates toward the cathode at the same velocity as the EOF. The analyte totally incorporated into the micelle migrates at the lowest velocity, or at the same velocity as the micelle, toward the cathode. The more the analyte is incorporated into the micelle, the slower the analyte will migrate. A neutral analyte always migrates at a velocity between the two extremes (i.e., the velocities of the EOF and micelle). The analytes are detected in an increasing order of the distribution coefficients by a detector located at the cathodic end of the capillary. The migration time of the electrically neutral analyte is limited between the two extremes: the migration time of a solute that is not incorporated into the micelle at all, t_0, and that of the micelle, t_{mc}.

Under an acidic condition, however, the absolute value of the velocity of the EOF becomes lower than that of the electrophoretic velocity of the SDS micelle and, therefore, the micelle migrates toward the anode. By contrast, when a cationic surfactant is employed instead of SDS, the direction of the EOF will be reversed or toward the anode, due to the adsorption of the surfactant molecule on the inside wall of the capillary and changing the surface charges.

RETENTION FACTOR

In MEKC, the retention factor, k, for a neutral compound can be defined as n_{mc}/n_{aq} where n_{mc} and n_{aq} are the number of the analyte incorporated into the micelle and in the surrounding aqueous solution, respectively. The retention factor can be related to the migration time of the solute, t_R as

$$k = \frac{t_R - t_0}{t_0(1 - t_R/t_{mc})} \tag{1}$$

or

$$t_R = \left(\frac{1 + k}{1 + (t_0/t_{mc})k}\right)t_0 \tag{2}$$

The reciprocal of t_0/t_{mc} or t_{mc}/t_0 is a parameter representing the migration time window. One should note that when the migration time of the micelle is infinite or the micelle does not migrate in the capillary at all, the value t_0/t_{mc} will be zero; then, Eqs. 1 and 2 become identical to those for conventional LC.

In MEKC, $k = \infty$ means that t_R becomes equal to t_{mc} and the solute migrates at the same velocity as the micelle.

When $t_0 = 0$ or the EOF is completely suppressed, Eq. 2 becomes

$$t_R = \left(1 + \frac{1}{k}\right)t_{mc} \tag{3}$$

Here, the surrounding aqueous phase does not move at all in the capillary and only the micelle migrates toward the anode if an anionic micelle is employed. Note that the EOF is not essential in MEKC.

When the solute has an electrophoretic mobility Eq. 1 will be more complicated, that is, the migration of the ionic solute includes a portion generated by the micelle when the solute is incorporated into the micelle and also the other portion generated by the electrophoresis of the solute itself.

RESOLUTION

Resolution, R_s in MEKC is given as

$$R_s = \left(\frac{N^{1/2}}{4}\right)\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k_2}{1 + k_2}\right)\left(\frac{1 - (t_0/t_{mc})}{1 - (t_0/t_{mc})k_1}\right) \tag{4}$$

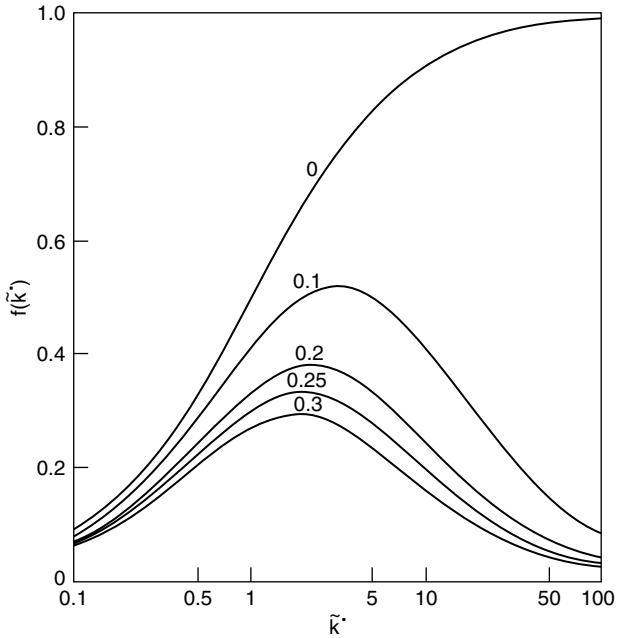

Fig. 1 Dependence of $f(k)$on capacity factor k. The values of are given on each line.
Source: From Electrokinetic chromatography with micellar solution and open-tubular capillary, in Anal. Chem.[4] with permission from the American Chemical Society.

where N is the theoretical plate number, α is the separation factor equal to k_2/k_1 and k_1 and k_2 are the retention factors of analytes 1 and 2, respectively. When $t_0/t_{mc} = 0$, Eq. 4 will be identical to that for conventional LC.

The separation factor α is altered by the combination of the structure of the micelle as the pseudo-stationary phase and the aqueous phase as a solvent of the micelle. Because k is included in the last term of the right-hand side of Eq. 4, the effect of k on R_s in MEKC is different from that in conventional chromatography. The last two terms in Eq. 4 are defined by the function as

$$f(k) = \left(\frac{k_2}{1+k_2}\right)\left(\frac{1-(t_0/t_{mc})}{1-(t_0/t_{mc})k_1}\right) \tag{5}$$

Then, we can calculate the optimum value of the retention factor, k_{opt}, for accomplishing the maximum R_s by differentiating Eq. 5, that is,

$$k_{opt} = \left(\frac{t_{mc}}{t_0}\right)^{1/2} \tag{6}$$

Under a neutral condition, k_{opt} is close to 2 for SDS micelles as the pseudo-stationary phase, as shown in Fig. 1. Practically, the recommended range of k is between 0.5 and 10.

RETENTION FACTOR AND DISTRIBUTION COEFFICIENT

The retention factor can be related to the distribution coefficient, K, between the micelle and aqueous phase by

$$k = K\left(\frac{V_{mc}}{V_{aq}}\right) \tag{7}$$

where V_{mc} and V_{aq} are the volumes of the micelle and aqueous phase, respectively. The value V_{mc}/V_{aq} or the phase ratio, can be written as

$$\frac{V_{mc}}{V_{aq}} = \frac{\bar{\nu}(C_{sf} - CMC)}{1 - \bar{\nu}(C_{sf} - CMC)} \tag{8}$$

where C_{sf}, $\bar{\nu}$, CMC are the concentration of the surfactant, partial specific volume of the micelle, and critical micelle concentration, respectively. At a low micellar concentration, we can arrange Eq. 8 as

$$k \simeq K\bar{\nu}(C_{sf} - CMC) \tag{9}$$

Thus, k can be adjusted by manipulating C_{sf}. Eq. 9 shows that k increases linearly with C_{sf}, and we can calculate K from the slope of this relationship. Also, K remains constant regardless of C_{sf}. The applicability of Eq. 9 under various conditions and for various surfactants has been examined in a number of reports.

Retention Gap Injection Method

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

In GC analysis employing capillary columns, split injections are usually necessary to ensure that a very small sharp sample is placed on the column. This is important for maintaining column efficiency by not overloading the column. However, split injections generally result in an unrepresentative sample being placed on a capillary column (see *Split/Splitless Injector*, p. 2227), and because of this, on-column injection is usually preferred for accurate quantitative analysis. On-column injection requires a relatively large-diameter capillary column to be used to permit the penetration of the injection syringe needle into the column. However, although this procedure ensures that a representative sample is placed onto the column, other problems can arise. On injection, the sample readily separates into droplets that act as separate, individual injections. These separate sample sources can cause widely dispersed peaks and serious loss of resolution and, in the extreme, double or multiple peaks. Grob[1] suggested a solution to this problem which he termed the *retention gap method of injection*.

DISCUSSION

This procedure (Fig. 1) involves removing the internal coating of stationary phase from the first few centimeters of the column. This can be done by heating and volatilizing or burning off the phase. Alternatively, if the stationary phase is sufficiently soluble, it can be removed by a suitable solvent. The sample is then injected into the uncoated section of the column, and although the sample will probably split into droplets, the solvent will still vaporize in the normal way. As there is no stationary phase present, all the components of the mixture will travel at the speed of the mobile phase down the uncoated length of column until they reach a coated section. At this point, they will be absorbed into the stationary phase and all the components of the mixture will accumulate and form a compact sample at the start of the coated portion of the column. This technique is usually practiced in conjunction with temperature programming, the program being started at a fairly low temperature. The relatively low temperature facilitates the accumulation of all the solutes at one point in the column (i.e., where the stationary-phase coating begins). The temperature program is then started, and the solutes are eluted through the column in the normal way. The success of this method depends on there being a significant difference between the boiling points of the sample solvent and those of the components of the sample. In general, however, this procedure does significantly improve the quality of the separation and allows accurate quantitative results to be obtained.

Retention Time and Retention Volume

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The *retention time* of a solute is the elapsed time between the *injection point* and the peak maximum of the solute. The different properties of the chromatogram are shown in Fig. 1. The *volume of mobile phase* that passes through the column between the injection point and the peak maximum is called the *retention volume*. If the mobile phase is incompressible, as in liquid chromatography (LC), the retention volume (as so far defined) will be the simple product of the *exit flow rate* and the *retention time*.

APPLICATION

If the mobile phase is compressible, the simple product of retention time and flow rate will be incorrect, and the *retention volume* must be taken as the product of the *retention time* and the *mean flow rate*. The true *retention volume* has been shown to be given by[1]

$$V_r = V_{r'}\frac{3}{2}\left(\frac{\gamma^2-1}{\gamma^3-1}\right) = Q_0 t_r \frac{3}{2}\left(\frac{\gamma^2-1}{\gamma^3-1}\right)$$

where the symbols have the meanings defined in Fig. 1, and $V_{r'}$ is the retention volume measured at the column exit and γ is the inlet/outlet pressure ratio.

The retention volume V_r will include the dead volume V_0, which, in turn, will include the actual dead volume V_m and the extracolumn volume V_E.

Thus,

$$V_r = V_E + V_m + V_{r'}$$

The retention time can be taken as the product of the distance on the chart between the injection point and the peak maximum and the chart speed, using appropriate units. More accurately, it can be measured with a stopwatch. The most accurate method of measuring V_r for a non-compressible mobile phase, although considered antiquated, is to attach an accurate burette to the detector exit and measure the retention volume in volume units. This is an absolute method of measurement and does not depend on the accurate calibration of the pump, chart speed, or computer acquisition level and processing.

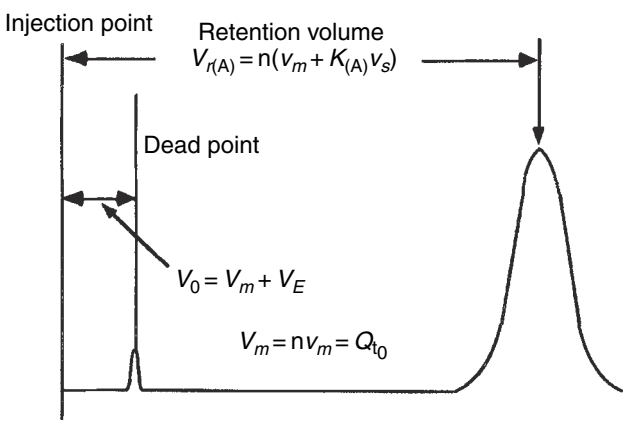

Fig. 1 Diagram depicting the dead point, dead volume, and dead time and retention volume of a chromatogram. V_0 is the total volume passed through the column between the point of injection and the peak maximum of a completely unretained peak, V_m is the total volume of mobile phase in the column, $V_{r(A)}$ is the retention volume of solute A, V_E is the extra column volume of mobile phase, v_m is the volume of the mobile phase per theoretical plate, v_s is the volume of the stationary phase per theoretical plate, K_A is the distribution coefficient of the solute between the two phases, n is the number of theoretical plates in the column, and Q is the column flow rate measured at the exit.

Reversed-Flow GC

Athanasia Koliadima
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

During the last 25 years, a gas flow perturbation technique has been used for physicochemical measurements in homogeneous and heterogeneous systems. This technique is reversed-flow gas chromatography (RF-GC). In this entry, the basic theoretical principles, the experimental setup, and the applications of this technique are reviewed.

REVERSED-FLOW GAS CHROMATOGRAPHY

Reversed Flow Gas Chromatography was introduced in its preliminary form in 1980 by Professor N. A. Katsanos and his colleagues at the University of Patras.[1] Until now, more than on 100 original articles, five reviews, and two books have been published referring to this technique and its applications.

Before dealing with the basic theoretical principals of RF-GC, we have to describe the experimental setup of this technique.

Instrumentation

For applying the RF-GC, a commercial gas chromatograph, slightly modified, is necessary. The modification consists of a T-shaped cell constructed from a glass or stainless steel chromatographic tube inside the chromatographic oven and a four- or six-port gas valve, inside or outside of the oven (Fig. 1).

This cell contains the sampling column which has two branches $l + l'$ and the diffusion column L_1. The diffusion column (20–80 cm × 3–5 mm inner diameter), connected perpendicularly to the sampling column (0.6–2.0 m × 3–5 mm inner diameter) at its midpoint, contains only a stagnant column of the carrier gas, which also flows through the empty sampling column, either from D_1 to D_2 or vice versa. Depending on the system under study, the diffusion column has some differences:

a. An injection port is added at the closed end of the diffusion column when diffusion coefficients in binary gas mixtures are measured.
b. A small glass vessel containing liquid is connected at the end of the diffusion column when physicochemical parameters for the interaction between gases and liquids are calculated.
c. Near the closed end, a small length of the diffusion column is filled with particles of solid when interaction phenomena between gases and solids are investigated.

The sampling column is devoid of any solid or liquid material; for separation purposes, an additional separation column is placed before the detector.

The connection to an appropriate detector flame ionization detector, thermal conductivity detector, flame photometric detector, nitrogen phosphorous detector (FID, TCD, FPD, NPD, etc.) is achieved via the four- or six-port valve being operated manually or electronically. The carrier gas (helium, nitrogen, argon, artificial air, etc.) flows via the valve only through the sampling column, at low flow rates (e.g., 25 cm^3/min) held constant during the experiments.

Procedure

The RF-GC, being a flow perturbation technique, is the change in the direction of flow of the carrier gas and this is done by using the four- or six-port valve. The carrier gas turns to flow in the opposite direction for a short time period t' (10–60 sec), smaller than the gas hold up time in the sections l and l' of the sampling column. Then, it is restored to its original direction of flow. Two questions arise now: why we change the direction of flow of carrier gas and what would we observe by this change?

If a solute is diffused slowly into the stagnant gas column of the carrier gas in the diffusion column, an asymmetric chromatographic signal is obtained, rising rather steeply and falling slowly with time after the maximum. The height of the chromatographic curve, which is obviously proportional to the concentration of the solute at the junction point, $z = 0$ and $x = l'$ of the sampling column; thus, it describes this concentration as a function of time.

This is expected in all of the above three cases (a)–(c) but, in the last two, the asymmetric chromatographic bands are distorted by different physicochemical phenomena, such as adsorption/desorption, possible reaction, etc. occurring between solute and liquid or solid material. The gaseous diffusion still transfers solute to the junction $x = l'$, where it is taken up by the passing carrier gas through the sampling column, but the diffusion rate is now different than before and the chromatographic band looks different. This distortion of the chromatographic band can be used for studying the phenomena mentioned

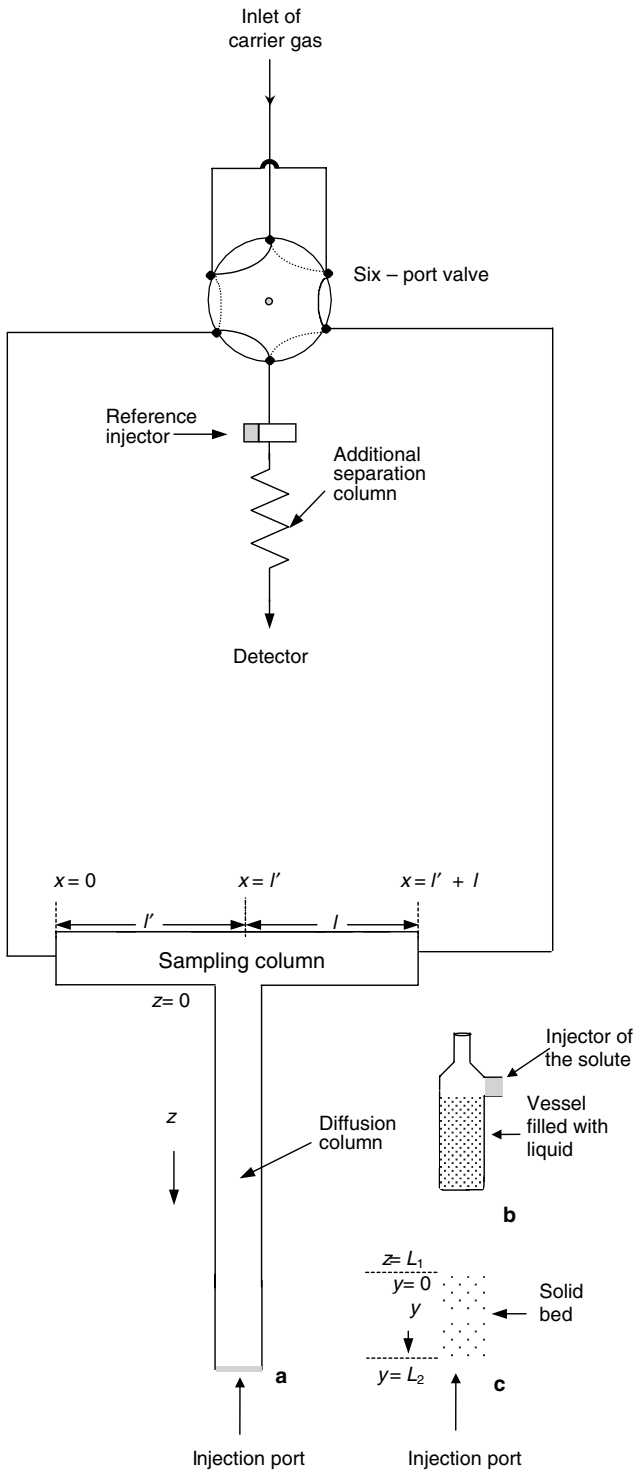

Fig. 1 Schematic representation of columns and gas connections for studying (a) diffusion coefficients in binary gas mixtures, (b) interaction between gases and liquids, and (c) interaction between gases and solids.

above, but many corrections have to be made before use and undesirable difficulties are introduced.

We can overcome the difficulties by applying the flow reversal of the carrier gas. This reversal produces a narrow

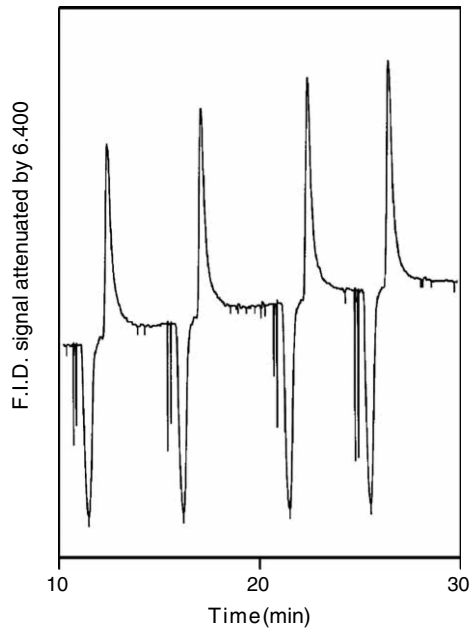

Fig. 2 A reversed-flow chromatogram showing sample peaks for the diffusion of 1-butene into nitrogen (corrected volume flow rate $\dot{V} = 0.33\,\mathrm{cm}^3/\mathrm{sec}$) at 343.2 K and 1 atm.

fairly symmetrical extra chromatographic peak (*sample peak*), which is superimposed on the continuous chromatographic band, and records the concentration of the solute at the junction $x = l'$, at time t when the flow reversal is made. An example of sample peaks is given in Fig. 2.

The sample peak can be made as narrow as we want, since the width at its half-height is equal to the duration t' of the backward flow of the carrier gas through the empty sampling column. The procedure can be repeated many times, giving a long series of sample peaks at various times t.

The sample peak is predicted theoretically by the so-called chromatographic sampling equation[2]:

$$\begin{aligned} c = {} & c_1(l', t_0 + t' + \tau)u(\tau) + c_2(l', t_0 + t' - \tau) \\ & [1 - u(\tau - t')] \times [u(\tau) - u(\tau - t'_M)] + c_3(l', t_0 - t' \\ & + \tau)u(t_0 + \tau - t')\{u(t_0 - t')[1 - u(\tau - t'_M)] \\ & - u(\tau - t')[u(\tau) - u(\tau - t'_M)]\} \end{aligned} \tag{1}$$

where c is the concentration of the solute at the detector, $c_1(l', \ldots)$, $c_2(l', \ldots)$, and $c_3(l', \ldots)$ are concentrations at the point $x = l'$ (cf. Fig. 1), t_0 is the total time from injecting the solute into the system to the last backward flow, t' is the time interval of backward flow, $\tau = t - t_M$, t being the time from the last restoration of the carrier gas, t_M and t'_M are the gas hold times in the sections l and l', respectively and, finally, the various u's are unit step functions for the arguments shown in parentheses.

Eq. 1 describes the concentration-time curve of the sample peaks created by flow reversals, and it has been derived analytically[2,3] using mass balances, rates of

change, etc. and integrating the resulting partial differential equations under given initial and boundary conditions. The concentration of the solute is usually given as the sum of three terms, c_1, c_2, and c_3, all referring to the junction of the sampling and the diffusion column (Fig. 1), but to different values of the time variable. Although Eq. 1 predicts that sample peaks are square, those actually obtained are not square, owing, most probably, to non-ideality.

The area under the curve or the height H from the continuous signal of the sample peak, measured as a function of time, is proportional to the concentration of the substance under study at the junction $x = l'$ of the sampling cell.

Although the experimental arrangement differs a little in the cases mentioned above (a–c), the relationship between the heights of the sample peaks H and the concentration $c(l', t_0)$ in all cases is given by the following equation[2,4]:

$$H^{1/M} = gc(l', t) \tag{2}$$

where M (dimensionless) is the response factor for the detector ($M = 1$ for the linear FID) and g a proportionality constant, having units of cm per mol cm^{-3}.

Diffusion Coefficients in Binary Gas Mixtures

If a small amount of solute A (usually 0.5–10 cm^3 of gas at atmospheric pressure) is injected into the cell through the injection port and, after a certain time during which no signal is noted, an asymmetric concentration-time curve of A is recorded, usually decaying slowly. At a certain known time (from the moment of injection), the flow reversal is started and repeated at various times, t, producing the known sample peaks. By using suitable mathematical analysis, the following equations describing the variation of H with t are derived[2,5,6]:

$$ln(H^{1/M}t^{3/2}) = ln(gN_1) - \frac{L^2}{4D_{AB}}\frac{1}{t} \tag{3}$$

$$ln(H^{1/M}) = ln(gN_2) - \frac{3D_{AB}}{L^2}t \tag{4}$$

where

$$N_1 = \frac{mL}{\dot{V}(\pi D_{AB})^{1/2}} \tag{5}$$

$$N_2 = \frac{\pi m D_{AB}}{\dot{V}L^2} \tag{6}$$

m is the injected amount of solute in moles, D_{AB} the diffusion coefficient of solute A into the carrier gas B, L the length of the diffusion column (cf. Fig. 1), and $\dot{V}$ the volumetric flow-rate in cm^3/sec.

The diffusion coefficient value, D_{AB}, can be calculated by using Eq. 3 or Eq. 4. For short-duration experiments and for long diffusion columns, Eq. 3 is more accurate, while Eq. 4 is more accurate for short diffusion column lengths and for experiments of long duration. Also, the selection of the equation giving the more accurate gaseous diffusion coefficient by RF-GC can be based on the comparison of the two experimental values found from Eqs. 3 and 4 with those given in the literature or calculated from known empirical equations.[7,8]

The same equations can be used for calculating, simultaneously, diffusion coefficients for each substance in multicomponent gas mixtures. This is achieved by using a separation column before the detector (cf. Fig. 1), which can effect the separation of all components of the gas mixture.

Diffusion coefficients of various hydrocarbons into the carrier gases N_2, H_2, and He, determined by RF-GC, can be found in the literature.[3,5,9]

Finally, the dependence of D_{AB} on temperature T is given by the relationship

$$D = AT^n \tag{7}$$

to which all theoretical and semiempirical equations lead. By plotting ln D vs. ln T, one calculates the exponent n of Eq. 7. The various values of n, calculated from diffusion coefficient values obtained by RF-GC, vary between 1.59 and 1.77.[3] These lie between 1.5 and 1.81, values predicted from the literature.[8,10,11]

Physicochemical Parameters for Gas–Liquid Interaction

For calculating physicochemical parameters for the interaction between gas and liquid, a small glass vessel is connected at the end of the diffusion column containing the liquid. A small amount of the solute A is injected at the carrier gas–liquid interface (Fig. 1b). As before, an asymmetric concentration-time curve of A is recorded, but now, it is distorted because of the various phenomena occurring between gas and liquid. Again, the flow reversals at certain times produce sample peaks, the heights of which are proportional to the concentration of solute A at the junction $x = l'$. Using suitable mathematical analysis,[12] the equation which describes the concentration as a function of the time was derived:

$$H/2 = c(l',t) = A_1\exp(B_1t) + A_2\exp(B_2t) + A_3\exp(B_3t) \tag{8}$$

where the pre-exponential coefficients, A_1, A_2, and A_3, can be written as explicit functions of B_1, B_2, and B_3, the geometrical characteristics of the cell and other experimental quantities, but this is not needed for the calculation of the above mentioned physicochemical quantities. The

exponential coefficients of time B_1, B_2, and B_3 are used first for the calculation of the diffusion coefficient of the solute A into the liquid (D_L, cm^2/sec), the partition coefficient of the solute A between the liquid at the interface, and the carrier gas (K, dimensionless) and Henry's law constant for the dissolution of the solute into the liquid (H^+, atm) according to the following equations[12]:

$$X = \frac{9AD_z}{KL_1L_2} + \frac{6D_z}{L_1^2} + \frac{6D_L}{L_2^2} = -(B_1 + B_2 + B_3) \tag{9}$$

$$Y = \frac{18AD_z^2}{KL_1^3L_2} + \frac{18AD_zD_L}{KL_1L_2^3} + \frac{36D_zD_L}{L_1^2L_2^2} = B_1B_2 + B_1B_3 + B_2B_3 \tag{10}$$

$$Z = \frac{36AD_z^2D_L}{KL_1^2L_2^3} = -B_1B_2B_3 \tag{11}$$

$$H^+ = \frac{R_gTd}{KM_L} \tag{12}$$

where X, Y, and Z are auxiliary parameters, A is the ratio of cross-sectional areas in z and y regions, a_z and a_L, respectively (cm^2), L_1 and L_2 are lengths in z and y regions, respectively (cm), d is the density of the liquid, M_L is the molar mass of the liquid, and D_z is the diffusion coefficient of the solute A into carrier gas, which can be determined as previously described.

For the calculation of the other parameters, such as overall mass transfer coefficients of the solute A into the carrier gas (K_G, cm/sec) and in the liquid (K_L, cm/sec) and, from them, gas (k_G, cm/sec) and liquid (k_L, cm/sec) film transfer coefficients, gas (r_G, sec/cm) and liquid (r_L, sec/cm) phase resistances for the transfer of the solute into the liquid, thickness of the stagnant film in the liquid phase (z_L, cm), partition coefficient of the solute between the liquid bulk and the carrier gas (K', dimensionless), and partition coefficient of the solute between the liquid at the interface and the bulk (K'', dimensionless), the following equations are adopted[12]:

$$X_1 = \frac{12D_z/L^2 + 4k/L + k'}{1 + kL/5D_z} = (-B_1 + B_2 + B_3) \tag{13}$$

$$Y_1 = \frac{24D_z^2/L^4 + 24kD_z/L^3 + 12k'D_z/L^2}{1 + kL/5D_z} = B_1B_2 + B_1B_3 + B_2B_3 \tag{14}$$

$$Z_1 = \frac{24k'D_z^2/L^4}{1 + kL/5D_z} = -B_1B_2B_3 \tag{15}$$

$$K_L = k'V_L/a_L; \quad K_G = ka_z/a_L; \quad \frac{1}{K_L} = \frac{1}{k_L} + \frac{K'}{k_G}; \quad z_L = \frac{D_L}{k_L}; \quad K'' = \frac{K}{K'} \tag{16}$$

where X_1, Y_1, and Z_1 have different physicochemical meaning than above X, Y, and Z, $L = L_1$ (gas phase), $k = K_Ga_L/a_z$ and $k' = K_La_L/V_L$ (liquid volume).

All the above calculations can be made by the means of a non-linear regression PC program in GW-BASIC.[12] The only measurable quantities needed for the calculations of all physicochemical quantities are the height H of the extra chromatographic peaks, the time t when these peaks are produced, and the geometrical characteristics of the experimental cell.

The same experimental arrangement, but different mathematical analysis, has been applied for studying homogeneous catalytic reactions in the liquid phase[13] and for calculating mass transfer coefficients for the evaporation of liquids, and diffusion coefficients of vapors by RF-GC.[14]

Physicochemical Parameters for Gas–Solid Interaction

Reversed Flow Gas Chromatography has been used to study the kinetics of various surface-catalyzed reactions, as well as for other physicochemical measurements. The experimental setup is given in Fig. 1c where, near the closed end of the diffusion column, a small amount of solid is placed and the length of this section is denoted as L_2, while the solute A is injected by means of an injection port.

The mathematical analysis for calculating all of the above parameters is described in detail in a recent published book[15] and a review article.[16] Here, only the necessary equations are summarized.

The concentration of the solute at the junction $x = l'$, as a function of time, is given by the following equation:

$$c(l',t) = G\left[A_1^0\exp(B_1t) + A_2^0\exp(B_2t) + A_3^0\exp(B_3t)\right] \tag{17}$$

where

$$A_1^0 = \frac{B_1^2 + kB_1}{(B_1 - B_2)(B_1 - B_3)}; \quad A_2^0 = \frac{B_2^2 + kB_2}{(B_2 - B_1)(B_2 - B_3)}; \quad A_3^0 = \frac{B_2^2 + kB_2}{(B_3 - B_1)(B_3 - B_2)} \tag{18}$$

$$G = \frac{n_Aa_1a_2}{\dot{V}(a_1 + a_2 + a_2Q)}; \quad a_1 = \frac{2D_z}{L_1^2}; \quad a_2 = \frac{2D_y}{L_2^2}; \quad Q = \frac{2a_yL_2}{a_zL_1}; \quad k = k_2 + k_R \tag{19}$$

L_1 and L_2 are the lengths of the sections z and y, respectively (Fig. 1c), a_Z and a_y are the cross sectional areas of the regions z and y, respectively, $\dot{V}$ is the volumetric flow rate

of the carrier gas, n_A is the amount (mol) of the solute introduced as a pulse at $y = L_2$, D_z, and D_y are the diffusion coefficients of the solute into the carrier gas and in the region of the solid bed, respectively, k_R is the rate constant for adsorption/desorption of the solute on the bulk solid, and k_2 is the rate constant of a possible first-order or pseudo-first-order surface reaction of the adsorbed substance.

The height H of the extra chromatographic peaks, obtained by the repeated flow reversals, is again proportional to the gaseous concentration (Eq. 2). This can be combined with Eq. 17, the result being

$$H^{1/M} = gG\sum_{i=1}^{3} A_i^0 \exp(B_i t) = \sum_{i=1}^{3} A_i \exp(B_i t) \tag{20}$$

where $A_i = gGA_i^0$ in cm.

Using a non-linear regression analysis PC program in GW-BASIC,[4] one can calculate the exponential and pre-exponential coefficients from the measured pairs H, t. From these, k_R, k_2, D_y, and the isotherm proportionality constant k_1 of the solute on the solid is carried out. The following—Eqs. 21–23 and Eq. 18—are used:

$$X = \frac{a_1 a_2}{a_1 + a_2 + a_2 Q} + k = -(B_1 + B_2 + B_3) \tag{21}$$

$$Y = \frac{a_1 a_2 k + (a_1 + a_2 Q) k_1 k_R}{a_1 + a_2 + a_2 Q} = B_1 B_2 + B_1 B_3 + B_2 B_3 \tag{22}$$

$$Z = \frac{a_1 + a_2 Q}{a_1 + a_2 + a_2 Q} k_1 k_2 k_R = -B_1 B_2 B_3 \tag{23}$$

where X, Y, and Z are auxiliary parameters.

From the above calculated parameters, through the following Eqs. 24 and 25, the overall deposition velocity (V_d), which is equivalent to an overall mass transfer coefficient of the gaseous solute to the solid surface, corrected for the activated adsorpion/desorption and surface reaction, and the reaction probability γ of the solute with the surface under study, are found:

$$V_d = \frac{k_1 V'_G(\text{empty})\epsilon}{A_S} \cdot \frac{k_2}{k_R + k_2} \tag{24}$$

$$1\gamma = \left(\frac{R_g T}{2\pi M_B}\right)^{1/2} \cdot \frac{1}{V_d} + \frac{1}{2} \tag{25}$$

where A_S is the total surface area of solid, cm^2, V'_G the gaseous volume of the section y of the experimental cell (cf. Fig. 1c), cm^3, R_g the ideal gas constant, J/K/mol, M_B the molar mass of analyte, kg/mol and T the absolute temperature, K.

For calculating adsorption energies, local monolayer capacities, local adsorption isotherms, and probability density functions for the deposition of the injected solute on the solid surface, the height H of the reversed-flow peaks and the physicochemical parameters B_i and A_i are used. The necessary relations are as follows:

The adsorption energy ε is expressed by the next relationship

$$\epsilon = RT \ln\left(\frac{K}{K^0}\right) \tag{26}$$

where K is the Langmuir constant[17] and K^0 is described by statistical mechanics.[18]

The local isotherm θ_t is calculated by the relationship

$$\vartheta_t = \frac{c_s^*}{c_{max}^*} = 1 - \exp(-KR_g T c_y) \tag{27}$$

where is the local adsorbed concentration of the injecting gas in equilibrium with that in the gaseous state, given by Eq. 29 of Ref. 16 c_y is the gaseous concentration of the solute in the gas phase above the solid, obtained by Eq. 28 of Ref. 16, and c^*_{max} is the local with respect to time monolayer capacity.

This capacity c^*_{max} is obtained by the equation:

$$c^*_{max} = \frac{c_s^*}{\vartheta_t} \tag{28}$$

Finally, the probability density function over time for the adsorption energy is given as follows:

$$f(\varepsilon;\ t) = \frac{1}{RT}\left[\frac{KRT(\partial c_s^*/\partial t) + (\partial^2 c_s^*/\partial c_y \partial t)}{\partial(KR_g T)/\partial t} - \frac{\partial c_s^*/\partial c_y}{KR_g T}\right] \tag{29}$$

The expressions for all derivatives, with respect to time in the above relationship, have been given in detail elsewhere.[15]

For studying lateral molecular interactions, the following equation is used:

$$K' = K^0 \exp\left(\frac{\varepsilon}{RT} + \beta\theta_t\right) = K \exp(\beta\theta_t) \tag{30}$$

where $\beta = z\omega/RT$, ω denoting the lateral interaction energy and z the number of neighbors for each adsorption site. Thus, $z\omega\theta_t$ is the added to ε deferential energy of adsorption due to lateral interactions. The $\beta\theta_t$ is the lateral molecular interaction energy and, for its calculation, the height H of sample peaks and the time t, together with some auxiliary physical quantities, are needed, while β is given by the relationship

$$\beta = \frac{1}{c_y}\left[\frac{\exp(KRTc_y) - 1}{KRT} - \frac{c_s^*}{\partial c_s^*/\partial c_y}\right] \quad (31)$$

The surface diffusion coefficient D_s of adsorbate molecules is obtained by the relationship

$$D_s = \frac{D_z\varepsilon_M^2 - D_y}{\partial\vartheta/\partial p} = \frac{D_z\varepsilon_M^2 - D_y}{K^0(1-\vartheta)}\exp\left(-\frac{\varepsilon}{RT}\right) \quad (32)$$

where D_z is the diffusion coefficient of the adsorbate in the carrier gas in the absence of solid, ε_M is the macro void fraction of the bed, D_y is experimentally calculated as described above in Eq. 19 and, finally, θ is given by the Jovanovic isotherm Eq. 22,[16] and the partial derivative of θ with respect to p by Eq. 38 of [16] From the above, it is obvious that only the height H and the time t are necessary for calculating surface diffusion coefficients.

The same data (height and time) used, so far, can be employed to calculate the net adsorption rate as a function of time with lateral molecular interactions, together with the rate constants of adsorption k_α (min^{-1}) and desorption k_d (min^{-1}).

Differentiating Eq. 27 with respect to time, one obtains the rate of θ_t, i.e., the net adsorption rate:

$$\frac{\partial\theta_t}{\partial t} = \left[KRT\frac{\partial c_y}{\partial t + c_y}\frac{\partial(KRT)}{\partial t}\right]\exp(-KRTc_y) \quad (33)$$

The various functions and the derivatives on the right-hand side have already been defined, while $\partial c_y/\partial t$ is given by Eq. 42.[16] If the $\partial\theta_t/\partial t$ calculated by Eq. 3 represents the local net adsorption rate, it can be written in a way analogous to Eqs. 5–22 of Jaroniec and Madey[19]

$$\frac{\partial\theta_t}{\partial t} = k_\alpha c_y RT(1-\theta_t) - k_d\theta_t\ exp(-\beta\theta_t) \quad (34)$$

Setting $K = k_\alpha/k_d$ according to microscopic reversibility, K being calculated from KRT value, and all the other quantities being known, only k_α is unknown in Eq. 34, and both rate constants k_α and k_d, can be found as functions of time and of θ_t.

All above calculations are carried out simultaneously by means of a GW-BASIC program. Also, RF-GC has been applied for measured chemical kinetic properties and surface energies of catalysts.[20]

With the exception of the three cases (a)–(c), which are described in detail, the RF-GC has been applied to determine physicochemical parameters in denuder tubes.[21] This is a special case of the gas–solid interaction where the wall of the diffusion column is covered with a thin layer of the adsorbent, forming a so-called denuder tube. The mathematical analysis in this case assumes a non-steady state condition and a non-zero longitudinal diffusion. The mathematical analysis is given in detail[21] and the same physicochemical quantities as previously can be calculated.

CONCLUSION

As described in detail, RF-GC is a technique which can be applied for studying homogeneous and heterogeneous systems by calculating various physicochemical parameters. The experimental arrangement is quite simple and quantities determined only difficultly by other techniques are easily carried out. These parameters are diffusion coefficients of gases into gases and liquids, rate constants for the adsorption and adsorption/desorption of gases, on and from solid surfaces, deposition velocities and reaction probabilities for the adsorption of gases onto solid surfaces, overall and time-dependent fractional conversions of various reactants into products, under steady- or non-steady-state conditions, activation parameters (energy and entropy) for various physical and chemical processes (adsorption, desorption, heterogeneous reaction, etc.), mass transfer and partition coefficients across gas–solid boundaries, local adsorption isotherms, local adsorbed concentrations, local maximum monolayer capacities, local adsorption energies, lateral molecular interactions of the adsorbed molecules, surface diffusion coefficients of the reactants and products on heterogeneous catalytic surfaces, standard free energies of adsorption, and geometric means of the London surface free energies for adsorption of gases on solid surfaces, adsorption rates on heterogeneous surfaces, effectiveness factors and Thiele-type modulus for catalytic materials.

Reverse-Phase Chromatography

Joseph J. Pesek
Maria T. Matyska
Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

Classical liquid chromatography (LC) is typically practiced in what is referred to as the normal-phase mode; that is, the stationary phase is usually a polar sorbent such as silica and alumina and the mobile phase consists of a non-polar constituent such as hexane modified with a somewhat more polar solvent such as chloroform or ethyl acetate. In this mode, the more polar compounds are preferentially retained. The reversed-phase (RP) mode utilizes the opposite approach for the separation of non-polar analytes or compounds that have some hydrophobic character. In this case, the stationary phase must consist of sorbent that is non-polar in nature and the mobile phase is composed of a primary polar solvent, usually water, that is modified by a more non-polar constituent such as methanol, acetonitrile, or tetrahydrofuran.

DISCUSSION

In order to make RP chromatography a rapid and efficient method, it is necessary to force the mobile phase through the stationary phase using high pressure. Therefore, the stationary phase must be a mechanically stable entity possessing the desired non-polar properties for RP operation. This result is accomplished typically by using particulate silica, which is stable under high pressure, and modifying the surface with a non-polar organic moiety. The modification takes place by reacting the silanol (Si–OH) groups on the silica surface with a suitable reagent, most often an organosilane compound ($X_3Si–R$ or $XR'R'Si–R$, where X is a reactive group such as Cl or methoxy, R' is a small organic group such as methyl, and R is another organic moiety, most often octyl (C_8) or octadecyl (C_{18}), in the RP mode. These silica modifications result in a primarily hydrophobic surface that can preferentially retain the more non-polar compounds in a mixture. The degree of hydrophobicity is controlled by both the length of the alkyl chain and the density of bonded groups on the surface, usually expressed in terms of micromoles per square meter. Due to the fact that original silica material has a high surface area (typically 100–300 m^2/g), the amount of hydrophobic material in the chromatographic column is considerable (from a few to as much as 20% by weight), leading to substantial interactions between solutes and the stationary phase. RP stationary phases are available with a variety of hydrophobic groups on the surface and bonding densities on silica particles of different diameters, surface areas, and pore sizes. In addition to the RP separation materials consisting of silica, some commercial products are also fabricated on other oxides such as alumina or zirconia or consist of polymeric matrices.

The second major component in modern high-performance liquid chromatography (HPLC) is the mobile phase. Since the stationary phase is a non-polar entity, the mobile phase must be more polar to allow retention of the analytes. The most polar solvent for RP-HPLC is water, but the overall polarity of the mobile phase can be adjusted by introducing variable amounts of any of a number of organic solvents. In LC, retention of solutes is a result of its relative affinity for the stationary and mobile phases. This can be described mathematically by the equation

$$k' = \frac{(\text{Amount of analyte})_{\text{SP}}}{(\text{Amount of analyte})_{\text{MP}}}$$

where k' is the equilibrium constant referred to as the capacity factor that relates the amounts of the analyte in the stationary phase (SP) and the mobile phase (MP). Therefore, the mobile phase exerts considerable influence on the retention and, hence, the separation of solutes. This factor makes HPLC a very powerful separation technique in that the mobile phase can be adjusted to accommodate a wide variety of solutes (from large biomolecules to small organic and inorganic compounds) having a range of chemical properties. Simultaneously, the selection of the mobile-phase composition will determine the degree of interaction between the solute and the stationary phase.

Most RP-HPLC separations are done in the isocratic mode (i.e., where the composition of the mobile phase is held constant during the analysis). This approach is suitable when the sample consists of analytes having similar properties or where their hydrophobicities encompass a small or moderate range. Under these conditions, all solutes in the sample will be eluted over a reasonable time span (i.e., not too short to prevent resolution of individual analytes and not too long to result in an inconvenient analysis period). Therefore, proper selection of the mobile-phase composition is essential in the development of any RP separation method. Fortunately, due to the decades of

long practice of RP-HPLC, there exists in the literature and from commercial sources, a wealth of information on suitable mobile-phase compositions for particular types of sample, especially for the C_{18} stationary phase. In addition, the retention of solutes on hydrophobic phases has been modeled mathematically and there exist computer programs for assisting in the optimization of mobile-phase composition in the solution of various separation problems.

A single mobile composition is often not suitable for samples that contain a wide range of chemical properties or hydrophobicities. Under these conditions, an isocratic method may leave the early eluting components unresolved and the analytes having strong retention with inconveniently long elution times. The solution to this problem is to change the mobile-phase composition in a systematic way during the course of the separation. This approach is referred to as gradient elution. In gradient elution, the mobile-phase composition initially is weak (with a large percentage of the most polar component) and becomes increasingly stronger (containing greater amounts of the less polar modifier) as the separation process continues. With this approach, the retention of the less hydrophobic compounds is increased at the beginning of the separation, whereas the retention of the more hydrophobic compounds is diminished at the end of the elution period. The simplest approach to gradient elution is to vary the mobile-phase composition linearly from the beginning to the end of the analysis period. In addition to the rate of change of the mobile-phase composition, the initial and final amounts of the two solvents are also variables that can be changed to improve resolution within the shortest analysis times. Besides linear gradients, other formats have been developed to optimize separations. These gradient methods include a constant composition at the beginning and/or the end of the analysis as C18 well as concave, convex, or step profiles. The main disadvantage of the gradient method is the time required for the column to reequilibrate to the initial mobilephase conditions. This reequilibration time can be from several minutes up to a half-hour or longer. However, modern instrumentation (pumps and pump controllers) has made reproducible gradients relatively easy to achieve.

Another means of controlling eluent strength is the use of ternary or quaternary solvent mixtures instead of the more common binary approach. Each solvent has its own unique properties that can be used to improve the separation of difficult-to-resolve analytes or to shorten the analysis time without sacrificing resolution. Although gradients and more complex solvent matrices are more difficult to model than binary isocratic systems, software exists for such purposes and can assist in method development.

The basic equipment for the RP mode is similar to most other types of HPLC. It consists of solvent reservoirs (one to four), a high-pressure pump, a mixing device that can create any combination of binary solvents or higher order as well as gradients (optional), an injection device, the column, and a detector connected to a data processing device. Ultraviolet (UV) detection is most often used in the RP mode, but fluorescence, refractive index, and electrochemical properties, as well as coupling to a mass spectrometer are also possible. Qualitative information is obtained by comparing the retention times of unknown compounds to those of known standards, whereas quantitative information comes from calibration curves of the peak area vs. concentration. The coupling of LC to mass spectrometers and nuclear magnetic resonance (NMR) spectrometers is becoming more common, which makes positive identification of unknown compounds in a mixture much easier.

APPLICATIONS

One of the primary factors responsible for the development of HPLC was the need to separate mixtures containing hydrophobic compounds that were not sufficiently volatile for analyzing by GC or were thermally unstable after volatilization. Although some compounds that are normally non-volatile can be made volatile by derivatization, this process adds an extra step to the analytical method. However, under any circumstances, a large majority of chemical species, perhaps as much as 70%, cannot be analyzed by GC. Among the most significant of these compounds are ionic species, both organic and inorganic, as well as most biomolecules. With greater demand for the analysis of biologically related samples for medical, pharmaceutical, and biotechnological purposes, the need for reliable RP-HPLC methods continues to increase. Although it is impossible to review all types of sample amenable to RP-HPLC analysis, a few examples will be given to illustrate the breadth of applications possible by this technique.

Because the mechanism of separation is primarily based on differences in hydrophobicity, a simple mixture of aromatic hydrocarbons can be used to illustrate the operation of the RP method. A chromatogram of such a separation is shown in Fig. 1, where the elution times are benzene < toluene < ethylbenzene < isopropylbenzene < *t*-butylbenzene < anthracene. When the RP mechanism is functioning, compounds are eluted in order of increasing hydrophobicity, as illustrated in Fig. 1. By increasing the degree of hydrophobicity either through longer alkyl chains [more saturated or unsaturated (aromatic) hydrocarbon groups] or more alkyl chains (higher bonding density), retention times (larger k' values) become longer under constant mobile-phase conditions. This principle applies to a wide variety of organic compounds. The organic molecules can also have a polar functional group such as an alcohol, ether, amine, or cyano, for example, but the RP method can still be used. In this case, the polar groups may diminish the overall hydrophobicity of the compound, but

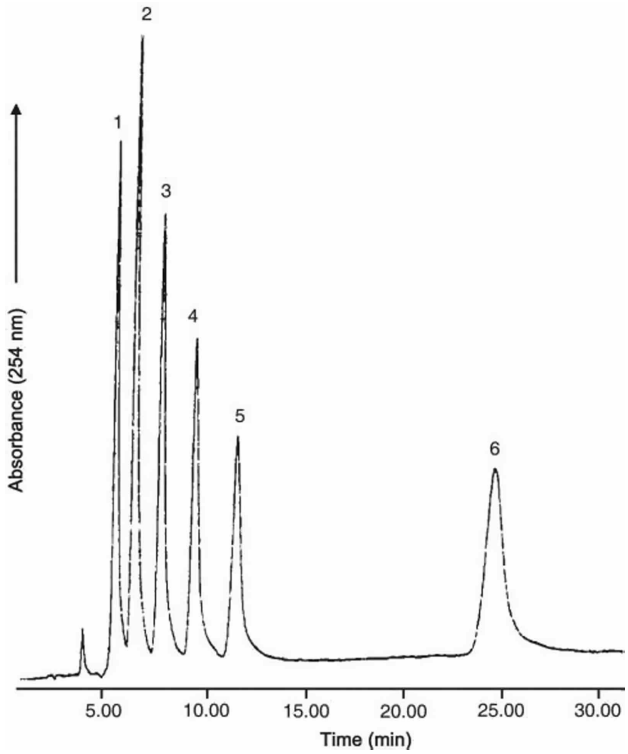

Fig. 1 Separation of RP test mixture on a C_{22} bonded phase. Mobile phase: 50 : 50 acetonitrile–water. Solutes: 1 = benzene; 2 = toluene; 3 = ethylbenzene; 4 = isopropylbenzene; 5 = *t*-butylbenzene; 6 = anthracene.

there will still be some retention on a typical RP stationary phase such as octadecyl (C_{18}). A simple example is benzene and phenol. The addition of a hydroxyl group makes phenol less hydrophobic than benzene, so it will be eluted first.

The above example illustrates the principle of relative retention (i.e., that benzene is retained more strongly than phenol). In order to determine absolute retention, the k' values of each compound must be measured as follows:

$$k' = \frac{t_R - t_0}{t_0}$$

where t_R = the retention time of compound and t_0 is the time to elute an unretained compound. In HPLC, the t_0 is equivalent to measuring the elution time for air in GC. Therefore, selection of a suitable compound that will not be retained is crucial to accurate measurement of k' values. Because retention is based on hydrophobicity, the t_0 marker should be very hydrophilic (i.e., very polar or ionic). Two compounds often selected for this determination are KNO_3 and uracil. They both fulfill the requirement for hydrophilic properties and also have absorbance in the UV, which facilitates detection.

Whereas the overall hydrophobic nature of the stationary phase is the most important factor in determining retention, bonded-phase structure can also influence k' values. This effect can be observed in the separation of polycyclic aromatic hydrocarbons (PAHs). For stationary phases with a high bonding density and/or a high degree of association between adjacent bonded organic moieties, molecules that are more planar are preferentially retained. The National Institute of Standards and Technology (NIST) has developed reference mixtures to measure this effect.

In addition to a wide range of polar and non-polar hydrocarbons that can be analyzed by RP-HPLC, it is also possible to separate ionic species. Because water is used as part of almost all mobile phases, those species which are acids and bases can be neutralized by control of pH. In cases where neutralization is not possible, then the addition of a counterion into the mobile phase so that the analyte will form a neutral complex can be used to enhance RP retention. The same principle can be applied to inorganic species by forming a neutral complex that results in RP retention.

Large biomolecules, while being charged under most aqueous mobile-phase conditions, still have significant hydrophobic portions that interact with the stationary phase. In many complex mixtures of proteins and peptides, the degrees of interaction with the stationary phase (k' values) vary over a broad range. Therefore, gradient elution methods are often required. An example of such a gradient method for the separation of a biochemical mixture is shown in Fig. 2. Finally, although water is used almost exclusively as the weak solvent in RP methods, a few types of sample require the use of other mobile-phase components. For

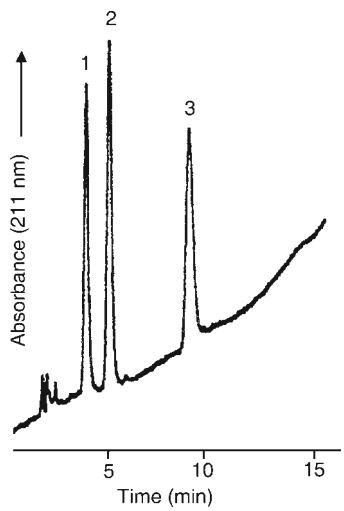

Fig. 2 Gradient separation of peptide mixture on a C_{30} bonded phase. Mobile phase, linear gradient from 25% to 45% A in 15 min. A = 0.1% trifluoroacetic acid (TFA) in 75 : 25 acetonitrile–water and B = 0.1% TFA in water. Solutes: 1 = bradykinin; 2 TFA angiotensin III; 3 = angiotensin I.

example, the separation of triglycerides and fatty acids often utilize acetone as the weak solvent in the RP mode.

Rf

Luciano Lepri
Alessandra Cincinelli
Department of Chemistry, University of Florence (UNIFI), Florence, Italy

Abstract
The R_f value is the fundamental parameter in planar chromatography to describe the position of a spot on a developed chromatogram. R_f values in linear, circular, and anticircular chromatography were defined. Correlations between these types of R_f were evidenced for conversion of linear R_f values in circular and anticircular and unidimensional multiple development. Definition of thermodynamic and relative R_f values were also reported and discussed. In addition, the importance of R_M value, which has a linear relationship with structural elements of the solute and can be used to characterize molecular hydrophobicity in reversed planar chromatography, was evidenced.

INTRODUCTION

The R_f value is the fundamental parameter in planar chromatography and describes, numerically, the position of a spot on a developed chromatogram.

THE R_F VALUE IN LINEAR DEVELOPMENT

The method for determining R_f values is based on the measurement of two lengths in a thin-layer chromatogram and the calculation of their ratio:

$$R_f = \frac{\text{Distance of spot center from start}}{\text{Distance of solvent front from start}}$$

where "start" is the sample application point.

R_f values are between 0 and 1 (solute remains at start or runs with the solvent front, respectively), and the maximum number of significant figures after the decimal point is currently two. R_f values are often multiplied by a factor of 100 (hR_f).

R_f values can be disturbed by side effects or demixing of the multicomponent solvent used. In order to obtain reproducible R_f values, much attention must be paid to the reproducibility of the system.

THE R_F VALUE IN CIRCULAR AND ANTICIRCULAR DEVELOPMENT

Linear R_f values can be transferred to the circular (centrifugal) technique with the equation

$$R_{f\,\text{lin}} = R_f\,\text{circ}^2$$

This equation holds only if the starting line is close to the center of the layer and identical to the solvent entry position. Migration of the mobile phase is radial toward the periphery. Circular R_f values are higher than the linear ones with the exception of $R_f = 0$ and $R_f = 1$. The increase in the circular R_f values is greater in the lower range, and solutes are better resolved in this range with respect to linear development.

In anticircular (centripetal) development, the samples are applied in a circle close to the edges of the plate and the development proceeds from the circle toward the center.

The equation for conversion of linear R_f values is

$$R_{f\,\text{lin}} = 1 - \left(1 - R_{f\,\text{anticirc}}\right)^2$$

and the resolution of the anticircular mode is better in the upper R_f range.[1]

THE R_F VALUE IN UNIDIMENSIONAL MULTIPLE DEVELOPMENT

Unidimensional multiple development is the repeated development of a plate over the same distance with an eluent of constant composition after careful drying between development steps.

The R_f after n identical development steps is

$$R_{f\,n} = 1 - \left(1 - R_f\right)^n$$

where R_f is the retention factor of the solute after a single development.[2]

Since in the second and in all consecutive runs the lower spot migrates before the upper one does, thus reducing ΔR_f with respect to the resolution achieved in the previous run, the resolution-lessening effect is stronger the higher the R_f values are.

DEFINITION OF THERMODYNAMIC R_F VALUE

According to the Martin–Synge model of partition chromatography,[3,4] the thermodynamic R_f value (R_f'), based on the chromatographic equilibrium process of solute distribution between the mobile and stationary phase, can be expressed as the fraction of the relative time spent by a solute molecule in the mobile phase (A) or fraction of solute molecules in the mobile phase (B)

$$R_f' = \underset{\text{(A)}}{\frac{t_m}{t_m + t_s}} = \underset{\text{(B)}}{\frac{n_m}{n_m + n_s}}$$

where the subscripts m and s refer to mobile and stationary phase, respectively.

Because the fractions of solute molecules and respective mole numbers are identical, it is possible to achieve the fundamental relation (1) connecting R_f' value with the distribution coefficient $K_d = C_s/C_m$ and the phase ratio V_s/V_m:

$$R_f' = \frac{m_m}{m_m + m_s} = \frac{C_m V_m}{C_m V_m + C_s V_s} = \frac{1}{1 + K_d\left(\frac{V_s}{V_m}\right)}$$

In the Martin–Synge relationship (1), C_m and C_s are molar concentration of solute in the mobile and stationary phase, while V_s and V_m are the volumes of these two phases. V_s/V_m is numerically equal to A_s/A_m, the ratio of the phase cross-section normal to the direction of the solvent flow, which better describes the local conditions in thin-layer chromatography (TLC). The validity of the equation is limited, since the amount of solvent on the layer decreases toward the solvent front and, therefore, the phase ratio changes.

R_f' values are generally higher than R_f values and can be related to each other by the following experimental relation:

$$R_f' = \xi R_f$$

where ξ is the disturbing factor ($1 \leq \xi \leq 1.6$).[1] Eq. 1 usually holds in the R_f region up to 0.7 since the greatest changes of the solvent front are observed at the end of the chromatogram.

THE R_{ST} NUMBER

Relative R_f values, generally called R_{st} or R_x values, can also be used but are inadequate to render R_f values independent of uncontrolled parameters, since they are dependent on the phase ratio.

$$R_{st} = \frac{(R_f)_i}{(R_f)_{st}} = \frac{\text{Migration distance of substance, i}}{\text{Migration distance of reference substance, st}}$$

These values can be higher than 1.

THE R_M VALUE

Since the R_f value has no linear relationship with structural elements of the solute, R_M values [log $(1 - R_f)/R_f$] of members of a homologous series can be used to show quantitative relations with the number of "homologous structural elements."

In addition R_M value can be used to characterize molecular hydrophobicity in reversed-phase planar chromatography by elution with water–organic solvent mixtures according to the Soczewiński–Wachtmeister equation:[5]

$$R_M = R_{Mo} - S\Phi$$

where R_{Mo} is the R_M factor extrapolated at zero percentage of organic solvent and is usually accepted as a measure of lipophilicity, S is related to the specific surface area of the solute and Φ is the volume fraction of the organic modifier (usually methanol). Lipophilicity is widely used in quantitative structure activity relationship (QSAR) for prediction of the biological activity of substances.[6,7]

Rotation Locular CCC

Kazufusa Shinomiya
College of Pharmacy, Nihon University, Chiba, Japan

INTRODUCTION

Rotation locular countercurrent chromatography (RLCCC) was introduced in the early 1970s[1,2] as a preparative CCC system. In general, the existing CCC systems may be classified into two groups according to the mode of solute partitioning. One is called the hydrostatic equilibrium system (HSES) and the other is called the hydrodynamic equilibrium system (HDES). RLCCC belongs to HSES as does droplet CCC, whereas the high-speed CCC is the most advanced form of HDES, which has been widely used for the separation and purification of natural products.

Although RLCCC is less efficient than high-speed CCC, in terms of resolution and separation times, it has advantages of a large-sample loading capacity and universal application of two-phase solvent systems. Retention of the stationary phase is accomplished simply by adjusting the column rotation speed and flow rate according to physical properties of the solvent system. In addition, RLCCC can be effectively performed with a short column by alternatingly eluting the column with the two solvent phases. This "alternating CCC" method[3,4,5,6] is described later in some detail.

Rotation locular countercurrent chromatography is particularly suitable for the preparative separation of natural products, and the apparatus is commercially available through Tokyo Rikakikai Co., Ltd., Tokyo, Japan.

APPARATUS

Rotation locular countercurrent chromatography uses a separation column containing a series of cylindrical partition units called "locules." This locular column is made by inserting multiple centrally perforated disks into a PTFE (polytetrafluoroethylene) or glass tubing at regular intervals. Multiple column units are connected in series with PTFE tubing and mounted in parallel around the rotary shaft of the apparatus. The column assembly is held at a constant angle from the horizontal plane and rotated at a moderate rate (60–80 rpm). Fig. 1 schematically illustrates the RLCCC apparatus. In each locule, the two phases form a horizontal interface and efficient stirring of each phase is produced by rotation of the column assembly. The system provides the choice of the mobile phase, where the upper phase is eluted in an ascending mode and the lower phase in a descending mode through the inclined column. The solutes present in the sample solution are subjected to an efficient partition process between the two phases, in each locule, and, finally, eluted according to their partition coefficients.

In the early prototype instrument,[1] the columns were fabricated from relatively large-bore PTFE tubing of 4.6 mm inner diameter (I.D.) with PTFE disk inserts having 0.8 mm-diameter holes. These disks were spaced in 3 mm intervals to form 47 locules in each unit. A number of column units were connected in series to provide 5000 locules with a total capacity of 100 ml. The capability of the system was demonstrated with the separation of DNP (dinitrophenyl)–amino acids using a two-phase solvent system composed of chloroform–acetic acid–0.1 *M* HCl at a 2:2:1 volume ratio. In this system, nine DNP–amino acids were resolved within 70 hr at about 3000 theoretical plates.

A commercial RLCCC instrument is equipped with a set of 16 locular column units of 16 mm I.D. and 61 cm in length, containing 37 locules in each unit. The column assembly consists of 592 locules with an 800 ml capacity. At a flow rate of 15–25 ml/hr, the system can yield 250–400 theoretical plates, which corresponds to 2.3–1.5 locules/plate.[7]

SEPARATION PROCEDURE

Each separation is initiated by filling the column with either the upper or lower phase of an equilibrated two-phase solvent system. In order to avoid trapping air bubbles in the column, the solvent should be introduced through the bottom of each column, which is kept in a vertical position. Then, the column assembly is tilted at a desired angle (25–30°) from the horizontal plane. After the sample solution is introduced into the column, the mobile phase is eluted from the column while the apparatus is rotated at a desired rate (60–80 rpm). In order to retain a large volume of the stationary phase, the lower phase is eluted downward from the upper terminus and the upper phase upward from the lower terminus of the column assembly. The effluent from the outlet of the column is continuously monitored with an ultraviolet (UV) monitor and collected into test tubes using a fraction collector.

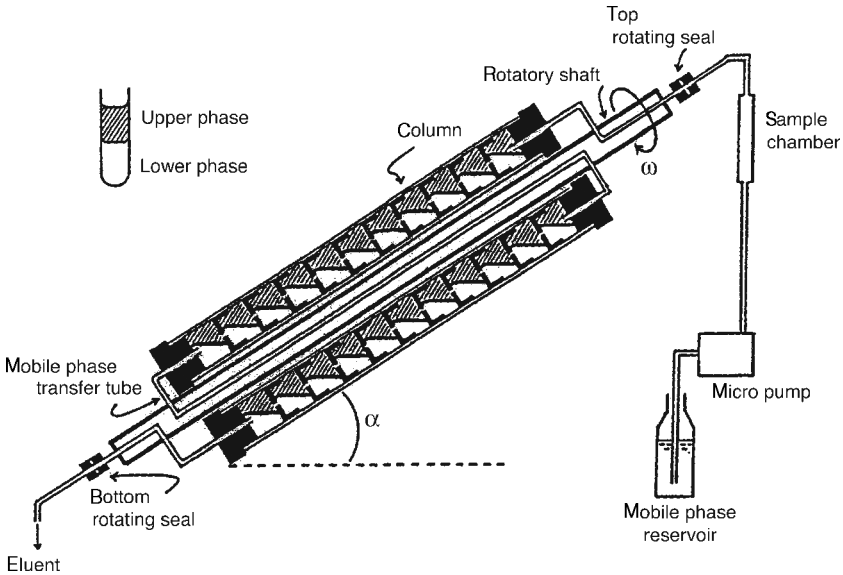

Fig. 1 Rotation locular countercurrent chromatography apparatus.

APPLICATIONS

Because the apparatus became commercially available in the late 1970s, RLCCC has been applied mainly to the preparative separation of natural products, due to its large sample loading capacity. As with other CCC systems, the partition efficiency of the RLCCC system highly depends on the choice of the suitable two-phase solvent system which gives a partition coefficient close to unity ($K \approx 1$) for the targeted compound. The K value can be obtained from a simple spectrophotometric measurement, thin layer chromatography (TLC), or high performance liquid chromatography (HPLC), whichever is appropriate.

SEPARATION OF NATURAL PRODUCTS

Two-phase solvent systems composed of chloroform–methanol–water at various volume ratios are frequently used for the separation of moderately hydrophobic compounds, including flavone aglycones, phenylpropanoids, iridoid glycosides, and so forth.[8]

The separation of more polar compounds, such as glycosides, can be achieved using a polar solvent system composed of ethyl acetate–water with a suitable modifier. Flavonoid glycosides were separated with ethyl acetate–1-propanol–water (2:1:2) and saponins with ethyl acetate–ethanol–water (2:1:2).

CHIRAL SEPARATION

The separation of (±)-norephedrine was first performed by RLCCC using a solvent system composed of 1,2-dichloroethane and 0.5 *M* aqueous sodium hexafluorophosphate (pH 4) containing chiral tartaric acid ester (dinon-5-yl tartrate).[9] This method produced an efficient resolution of enantiomers at purities of over 95% from 200 mg of racemate.

Rotation locular countercurrent chromatography can be applied to the chiral separation with an aqueous–aqueous polymer phase system using bovine serum albumin (BSA) as a chiral selector. In our laboratory, the RLCCC separation of D- and L-enantiomers of kynurenine was achieved from 200 mg of D,L-kynurenine using a solvent system composed of 10% (w/w) polyethylene glycol 8000 and 5% (w/w) disodium hydrogen phosphate containing 6% (w/w) BSA.[10] Because of a long settling time of the polymer phase system under unit gravity, the method required a discontinuous operation as used in the conventional countercurrent distribution apparatus, which consisted of 3 min for mixing, 10 min for settling, and 1 min for transfer of the mobile phase to the next locule at a flow rate of 1.0 ml/min. Using the lower mobile phase, L-kynurenine was eluted first, followed by D-kynurenine, and the separation was completed in 60 h.

ALTERNATING CCC METHOD

In this modified method, upper and lower phases are alternatingly used as the mobile phase by eluting the lower phase in the descending mode and the upper phase in the ascending mode through the respective terminus of a short locular column assembly.

Each separation is initiated by filling the entire column with the upper phase of the equilibrated two phase solvent system. Following the injection of the sample solution, the column is eluted with the lower phase while the apparatus is rotated at 60–70 rpm. After a desired period of elution, when the target compound is about to elute, the mobile phase is switched to the upper phase, which is eluted at the

same flow rate but in an ascending mode in the opposite direction. This alternating elution process with the upper and the lower phases is repeated until the desired component is well resolved.

In our laboratory, this method was applied to the purification of food mono-azo dyes.[3] Amaranth, New Coccine, and Sunset Yellow FCF were purified at 99.7%, 99.5%, and 99.3%, respectively, from 1–2.5 g of commercial dyes. Continued research has led to the purification of impurities present in commercial Sunset Yellow FCF that include RS-SA (trisodium salt of 3-hydroxy-4-[sulfophenyl] azo-2,7-naphthalene disulfonic acid), GS-SA (1-[4-sulfophenyl]azo)-2-naphthol-6,8-disulfonic acid), DONS (disodium salt of 6,6′-oxybis-2-naphthalene sulfonic acid), and 2N-SA (sodium salt of 4-[(2-hydroxy-1-naphthalenyl)azo]benzenesulfonic acid). The method successfully isolated GS-SA from Sunset Yellow FCF.[4,5,6]

Sample Application in TLC

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

This entry describes the general considerations, procedures, and instruments that are important for the correct application of sample and standard zones in thin-layer chromatography (TLC) and high-performance TLC (HPTLC). The application of spots and bands manually and by semiautomated and completely automated instrumental techniques is covered.

GENERAL ASPECTS

Application of small, homogeneous, exactly positioned initial zones of sample and standard solutions having accurate and precise volumes, without damaging the layer surface, is critical for achieving maximum resolution and reliable qualitative and quantitative analysis in TLC and HPTLC. The volumes applied and the method of application depend on the type of analysis to be performed (qualitative or quantitative), the kind of layer used, and the detection limit.

Choice of the Application Solvent

The choice of the solvent for applying standard and sample zones depends mainly on its ability to completely dissolve the analyte(s). Another factor in the choice of the solvent is safety; for example, benzene and chlorinated hydrocarbons should be avoided, if possible. After considering solubility and safety, the chosen solvent should have low viscosity and sufficient volatility to allow complete evaporation from the layer before mobile phase development; it should be as low in chromatographic solvent strength as possible to retard the possibility of "prechromatography" during application, that will increase the developed zone size, and it should wet the layer to provide adequate penetration of the layer by the sample (a problem mostly for non-polar chemically bonded layers and aqueous sample solutions). Weak strength is provided by non-polar solvents for normal phase layers such as silica gel and polar solvents for reversed phase layers such as C_{18} chemically bonded silica gel.

Pretreatment of Samples Prior to Application

Cleanup of samples is not as critical for TLC as it is for column chromatography because plates are not reused. Simple dissolving or liquid–liquid extraction with immiscible solvents and pH control is often sufficient. For more complex samples, cleanup of extracts by column adsorption chromatography or a more modern method such as solid phase extraction, supercritical fluid extraction, or solid phase microextraction is usually applied. Cleanup is not as important in TLC because strongly sorbed matrix components that could irreversibly destroy a high-performance liquid chromatography column or carryover and be detected in later samples can be applied onto the plate if the subsequent development and detection of the analyte are not adversely affected.

Characteristics and Placement of Initial Zones

For high efficiency and resolution of analytes during mobile phase development, initial zone size in the direction of development for round spots should be no greater than 2–6 mm for TLC and 1–2 mm for HPTLC. Volumes leading to these sizes are typically 0.5–5 μl for TLC and 0.1–1 μl for HPTLC; larger volumes of low concentration standards or analytes can be used when applying bands manually using a plate with a preadsorbent zone. The origin line is usually located 1.5–2.5 cm from the bottom of TLC plates, or 1.0 cm for HPTLC plates. The location of the starting point can be marked with a soft pencil on the right and left edges of the plate to aid lineup of the initial zones; more helpful is the use of a commercial application template to guide initial zone positioning in a straight horizontal line, with correct spacing between samples (usually 15 mm for TLC or 5 mm for HPTLC).

In most TLC and HPTLC analyses reported in the literature, no special sequence is stated for location of the initial zones of the standards and unknown samples along the origin line. For example, methods for semiquantitative TLC estimation of drug impurities are contained in various pharmacopeias; it is typically stated that visual comparison should be made of simultaneously chromatographed sample and standard spot intensities, but no special initial zone application locations are suggested.

For quantitative analysis, a special positioning scheme for manual or automatic application called the "data pair method" has often been recommended for reducing systematic errors owing to chromatographic parameters and obtaining the best densitometric results. In this method, all solutions are applied twice, with

duplicates not placed next to each other, but separated by one-half the width of the plate.

Application of Standard Solutions for Quantitative Analysis

It is often stated that it is best to apply samples and standards in the same volume and same solvent to form identical initial zones. This would require applying a fixed volume of a series of standard solutions with increasing concentrations to prepare a calibration graph for quantitative analysis. It is more convenient to apply variable volumes from a single standard solution for calibration, and appropriate volumes of samples to obtain scan areas bracketed within the calibration graph. Accurate and precise results can be obtained with this latter approach by use of the spray-on band application instruments (see the following) or manual application to preadsorbent plates.

Drying the Applied Samples Before Plate Development

The solvent used in sample application must be completely removed before the development stage. This step is carried out with or without heating, depending on the volatility of the sample solvent and the volatilities and thermal stabilities of the analytes. Plates are often dried at room temperature in a horizontal position inside fume hood; a stream of air or nitrogen may be passed over the layer to hasten evaporation. If heat is required, a hair dryer or other type of blower, laboratory oven, or plate heater (Camag Scientific, Inc., Wilmington, Delaware, U.S.A.) is used.

MANUAL INITIAL ZONE APPLICATION

Fully manual application of samples as spots is carried out using disposable fixed volume glass microcapillary pipets, or adjustable volume microdispensers with disposable glass capillaries. Respective examples of these are Drummond (Broomall, Pennsylvania, U.S.A.), Microcaps, which empty by capillary action when touched gently to the layer surface, and Digital Microdispensers, which empty when the plunger is pushed. It is best to keep the capillary tip at a 90° angle to the plate during use. Manual application is used to apply spots directly to the layer or for applying solution aliquots to a preadsorbent for formation of bands. Microcaps are handled in a simple rubber holder similar to the top of an eyedropper; volumes applied are usually 0.5–10 μl, and accuracy of better than 1% can be obtained. Spot size for larger volumes is minimized by applying the sample in small increments on top of each other with complete drying of the solvent after each application, e.g., 20 μl applied in four 5 μl portions; this technique improves resolution, but requires additional time and increases the chances for layer damage. The glass capillaries can be reused without fear of cross-contamination if thorough washing with solvent and next solution is carried out; disposal of the capillaries between different samples is most convenient. Capillaries tend not to fill reproducibly when dipped into certain types of sample solutions [i.e., solvents with high density (e.g., chloroform) or low capillary forces (e.g., hexane); surfactant solutions or viscous liquids] and, in these cases, the use of a syringe type applicator is preferable.

TLC and HPTLC plates with a preadsorbent zone on the bottom simplify and improve manual sample application, especially for larger volumes and crude samples (e.g., biological fluids). Solutions are applied quickly and diffusely to the preadsorbent and are automatically focused into narrow band-shaped initially at the preadsorbent–separation sorbent interface during mobile phase development; this interface serves as the starting point (origin) for calculation of the R_f values of developed zones. The preadsorbent, which is composed of diatomaceous earth or large pore volume silica gel, does not retain or resolve the analytes in samples, but may retain some matrix components to simplify sample pretreatment. Use of preadsorbent plates with lanes or channels facilitates proper positioning of the initial zones and lineup of the measuring slit of a densitometer when scanning chromatograms on the developed plate. Samples are applied as a streak or series of spots down the middle of the preadsorbent area, starting 2 mm below the layer interface, about 5 mm up from the bottom of the plate so that the origin line does not extend into the mobile phase pool in the development chamber, which is normally about 3 mm deep. Large-pore volume silica gel concentrating zones (e.g., on plates from EMD Chemicals, an affiliate of Merck KGaA, Darmstadt, Germany) are thinner and will not tolerate as much applied sample (i.e., they have less sample capacity) compared to diatomaceous earth preadsorbent zones on plates from, e.g., Whatman Inc. (Clifton, New Jersey, U.S.A.) and Analtech Inc. (Newark, Delaware, U.S.A.).

In addition to the use of disposable pipets for manual application, some workers apply samples for HPTLC quantitative determinations by hand in 50–200 nl volumes, using either an adjustable microliter syringe (>50 μl) or fixed-volume platinum–iridium capillary (200 nl) fused into a glass tube. Because these devices are reused, they must be fully rinsed between solutions to eliminate any possible "memory effect" from previous solutions.

INSTRUMENTAL INITIAL ZONE APPLICATION

This section describes a limited selection of available sample application instruments having different degrees of automation. These instruments are representative of others that are commercially available.

Fig. 1 Camag Nanomat 4. The applicator head with attached capillary pipet is lowered onto the layer at the selected position. The capillary touches the layer with constant pressure, which is determined solely by the friction of rest against a permanent magnet. **Source:** Courtesy of Camag.

Camag Nanomat

For TLC or HPTLC, initial zones in the form of spots can be applied from a disposable 0.5, 1, 2, or 5 μl fixed-volume, self-loading glass capillary pipet held in a rocker-type spotting device (the Nanomat 4, Camag) (Fig. 1) that mechanically controls its positioning and brings the capillary tip in gentle and uniform contact with the layer to discharge the solution without damage to the layer. This instrument is relatively of low cost and requires manual filling of the selected capillary held in a holder, placement of the holder on the applicator head, movement to the correct layer positions using a click-stop grid mechanism, and lowering and lifting of the head via a spring mechanism to apply the sample.

Analtech AutoSpotter

The Analtech TLC AutoSpotter (Fig. 2) is a semiautomated device with which up to 18 samples can be applied at one time in the form of spots as the drive bar moves to depress the syringe plungers and dispel the sample solutions. The unit has custom-made syringes with blunt Teflon-tipped needles that minimize sample "creep back" and increase reproducibility. Teflon plunger tips eliminate possible metal-to-glass contamination. Syringes are available in 10, 25, 50, 100, and 250 μl volumes. Samples can be applied at variable rates ranging from 3–30 min, depending on the chosen drive bar speed. An integral heater strip runs beneath the TLC plate at the point of delivery to aid solvent evaporation. The strip temperature and delivery rate are adjustable to give the smallest possible sample zone sizes. Features include digital temperature readout, adjustable needle guide, and alternative syringe templates for use with scored and channeled plates.

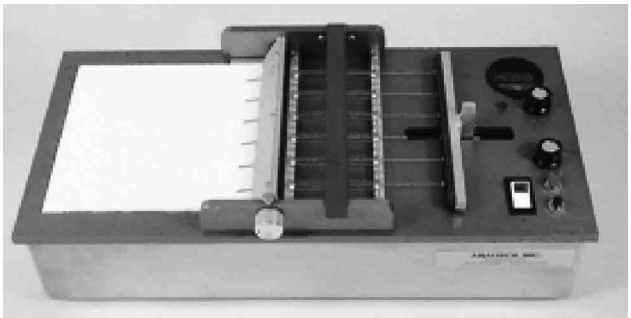

Fig. 2 TLC autospotter.
Source: Courtesy of Analtech.

Desaga TLC Spotter PS 01

The semiautomatic PS 01 from Desaga GmbH (Wiesloch, Germany) applies 10 nl to 10 μl samples to TLC and HPTLC plates as spots for quantitative analysis. Positions of application can be 5, 6, 10, 12, or 15 mm apart and 15 mm from the bottom of TLC plates or 5 mm with HPTLC plates. Solution discharge rate is 100 nl/sec for the 1 μl syringe, or 15 nl/sec using the "L" function. Filling, emptying, and rinsing of the syringe are performed by pressing the appropriate keys on the control panel.

Camag Linomat

Sample application in the form of bands is advantageous for high-resolution separations of complex or multicomponent samples, improved detection limits, and accurate and precise quantitative scanning densitometry. However, fewer samples can be applied per plate in the form of bands, compared to spots. Scanning of bands is done using the aliquot technique, in which the light source measuring slit is set to cover the center 50–75% length of the applied band, or a slit length that covers the entire sample band length can be used; samples applied as spots must be scanned with a slit covering the entire zone.

Narrow, homogeneous sample bands of controlled length [1 mm (spot) to 195 mm] can be applied by use of a semiautomatic spray-on device (the Camag Linomat 5, Fig. 3), in which the plate is mechanically moved right to left in the X-direction beneath a fixed syringe from which 0.1–2000 μl of sample is sprayed by an atomizer operating with a controlled nitrogen gas pressure. The optimum distance of the syringe needle from the precoated layer is usually 1 mm. The rate of application is adjustable to accommodate sample solutions with different volatilities and viscosities. Typical band lengths are 4–10 mm for analytical work and longer bands for preparative-scale separations.

The user fills the syringe with the sample, places the syringe into the instrument, and selects the sample volumes and Y-position via a keypad or by downloading a method from a personal computer (PC). The instrument exactly

Fig. 3 Linomat 5.
Source: Courtesy of Camag.

positions the initial zones, which facilitates automated scanning after chromatogram development. Operation can be in a stand-alone mode or under the control of winCATS software. In the stand-alone mode, up to 10 application methods can be downloaded and stored locally. With the correct choice of application parameters, less volatile and higher strength sample solvents can be tolerated without forming broadened initial zones. The ability to apply larger volumes to an HPTLC plate without loss of resolution lowers the determination limits with respect to the concentration of the solution, which aids in trace analysis. Complex, impure samples can often be successfully quantified only if bands are applied rather than spots.

Camag Automatic TLC Sampler 4

The Camag Automatic TLC Sampler 4 (ATS 4) is an advanced, fully automated, PC-controlled device for sequential application of up to 66 samples from a rack of 2 ml septum-covered vials or 96 samples from well plates (15 05 45 mm height) as spots by contact transfer (0.1–5 μl) or as bands by the spray-on technique (0.5–>50 μl); a motor driven dosing syringe sucks up the sample volume and feeds a steel capillary connected to a capillary atomizer. The speed, volume, and X- and Y-position pattern of application are controllable, and a programmable rinse cycle between the applications can eliminate cross-contamination.

Spraying in the form of rectangles enables application of larger volumes of low concentration samples, or use of higher delivery speeds, without washing away the layer. The spray jet moves back and forth in the Y-direction over the plate, which moves left to right in the X-direction; the sample is applied in a zigzag pattern within a rectangle. Before chromatography, the rectangles are focused into narrow bands by predevelopment with a strong mobile phase. An optional heated spray nozzle allows increased application speed, which is important for aqueous solutions.

Overspotting can be performed (also with the Linomat), in which more than one sample can be applied to a single initial zone position. These samples can include multiple standard reference compounds from different vials to prepare an in situ mixture, sample plus spiking solution, for validation of quantitative analysis by the standard addition method, or sample plus reagent, for in situ prechromatographic derivatization.

Samples applied with the ATS 4 can be positioned for normal, double-sided, or circular chromatographic development. Analyses performed with this applicator, combined with densitometric chromatogram evaluation controlled by the same PC with Windows-based WinCats software, comply with good manufacturing practices/good lab practices (GMP/GLP), installation qualification (IQ)/operational qualification (OQ), and 21 Code of Federal Regulations (CFR) Part 11 (drug analysis) requirements.

Desaga AS30

The AS30 (Desaga) is another software controlled, fully automated band or spot applicator that also works according to a spray-on technique, in which a stream of gas carries the sample from the cannula tip onto the plate. The syringe does not have to be manually filled by the user, as with the Linomat. During the filling process, the dosing syringe is positioned over the tray, which collects rinsing and flushing solvent and excess sample. The sample is injected into the body of the syringe through a lateral opening. After the syringe has been filled, a stepping motor moves the piston downwards to dose the fillport. A second stepping motor moves the tower sideways across the plate. The microprocessor controls both the motors and the gas valve for accurate and precise application in the form of spots or bands, both without layer contact. All parameters for application of up to 30 samples are entered via the keyboard. The user is guided through the clearly structured menu by the two-line LCD display.

Analtech Sample Streaker

The TLC Sample Streaker from Analtech (Fig. 4) is a manual device used to apply large volumes of solution to preparative-layer chromatography (PLC) plates. For PLC, large-volume initial zones are applied in the form of a continuous band across the layer, and this is accomplished with the sample streaker by the mechanical action of

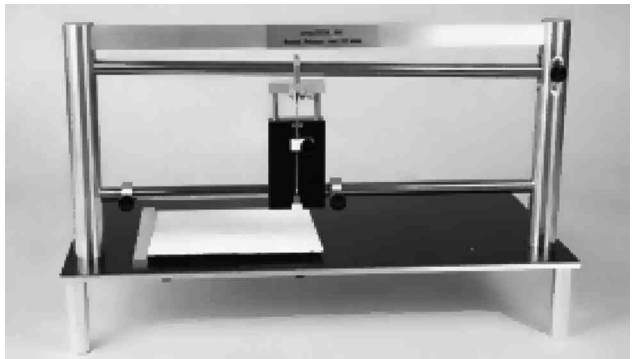

Fig. 4 TLC sample streaker.
Source: Courtesy of Analtech.

pushing the syringe (optional 250 or 500 μl volume) downward as it moves across the sloping stainless steel bar. A 1 mm wide band of sample can be applied to a PLC plate up to 40 cm wide. The device is faster and will apply the sample in a straighter, more homogeneous band than is possible with hand spotting, and the adsorbent will not be scratched during operation.

CONCLUSIONS

The principles, procedures, and instrumentation for application of sample and standard zones in TLC and HPTLC have been described briefly. A reading list is included, which contains references from which more details can be obtained. By using these techniques, the highest quality results possible for qualitative, semiquantitative, and quantitative results will be obtained.

Sample Injectors with Mobile Parts for GC

Piotr Słomkiewicz
Zygfryd Witkiewicz
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

INTRODUCTION

Regardless of the state of matter of the separated mixture, a technique used for introduction of samples into the gas chromatograph has to meet certain criteria, mostly mutually excluding ones. A sample of the possibly lowest volume should be introduced into the chromatographic column to ensure preservation of the internal state of equilibrium. Small sample volume requires application of a high-sensitivity detector and can make interpretation of the chromatographic results difficult, owing to a high level of detector noise. Those contradictory requirements are especially clear in case of chromatographic analyses of environmental samples obtained by extraction with a solvent. In this kind of samples, the substances assayed, also solid ones, can be dissolved in a relatively large amount of a solvent, presenting certain troubles for the analysis, especially using capillary columns. There are methods of dosing of this kind of samples. The methods allow evaporation of excess solvent from the sample. Among others, injectors with mobile parts are designed for this purpose. Possibility of sample concentration through solvent evaporation realized before the sample being introduced into the column is a characteristic feature of those injectors. Principle of those injectors consists of application of diluted sample onto a mobile part of the injector and evaporation of solvent in proper temperature. The solvent is then evacuated with a carrier gas, the mobile element with concentrated sample is transferred to the inlet of a chromatographic column and finally the analytes are introduced into the column.

INJECTOR WITH A MOBILE NEEDLE

Injector with a mobile needle[1,2] is usually utilized for analysis of not highly volatile, mostly solid substances (Fig. 1). It has a form of a glass tube 1 with a glass (or other, e.g., quartz) needle 2 tipped with a steel core 3 placed inside. The needle can be moved with a magnet 4 located on an external wall of the tube. Carrier gas is fed through the inlet 5 into the injector. The gas is either directed into the capillary column, or can be released to the atmosphere through the valve 6 located in the upper part of the tube. Introduction of a sample into the capillary column is realized in the following way: sample-containing needle of a micro-syringe is pierced through a membrane 9 located on the side of the injector and applies the sample of analyzed substances onto the tip of the elevated needle of the injector. The valve 6 is opened and solvent evaporates from the tip of the needle. Solvent vapors and the carrier gas are released through the outlet 7. After the solvent is completely evaporated, the valve 6 is closed, needle 2 lowered into the heated inlet of the column, and sample components are evaporated into the column.

There are some drawbacks connected with the glass injector with mobile needle. They are: complicated service requiring several manipulations while injecting the sample, and difficult application of the sample with a micro-syringe onto the tip of the injector needle; small mechanical resistance of the glass structure, and application of a single stream of carrier gas for feeding the capillary column and for removal of solvent vapors from the injector. Application of a single stream causes that the carrier gas does not flow through the column when vapors are being evacuated, or the flow becomes very limited. This changes column work conditions and interferes with operation of the detector.

TWIN-CHAMBER NEEDLE INJECTOR

Drawbacks of the glass injector with a mobile needle were removed with the twin-chamber needle injector.[3] A set of improvements has been made in this injector. They are easier application of samples with a micro-syringe onto the tip of the injector needle, two independent gas paths utilized: carrier gas for feeding the capillary column and carrier gas for removal of solvent vapors from the needle. Time required for evaporation of solvent from the sample applied onto the needle and the time of analytes evaporation are reduced by usage of two heated chambers.

Fig. 2 shows a scheme of a twin-chamber injector with a needle, during the sample introduction. In this injector, the needle is tipped with sintered quartz 1 in the bottom, and with a steel core 2 in the top. The needle can be moved with a magnet 3 in a quartz tube 4. The tube is fixed with two housings: lower 5 and upper 6, made of acid-resistant steel.

The needle can be introduced into the quartz tube of the injector through a ball valve 7 located in the upper housing. When the needle is lifted, its tip remains in the

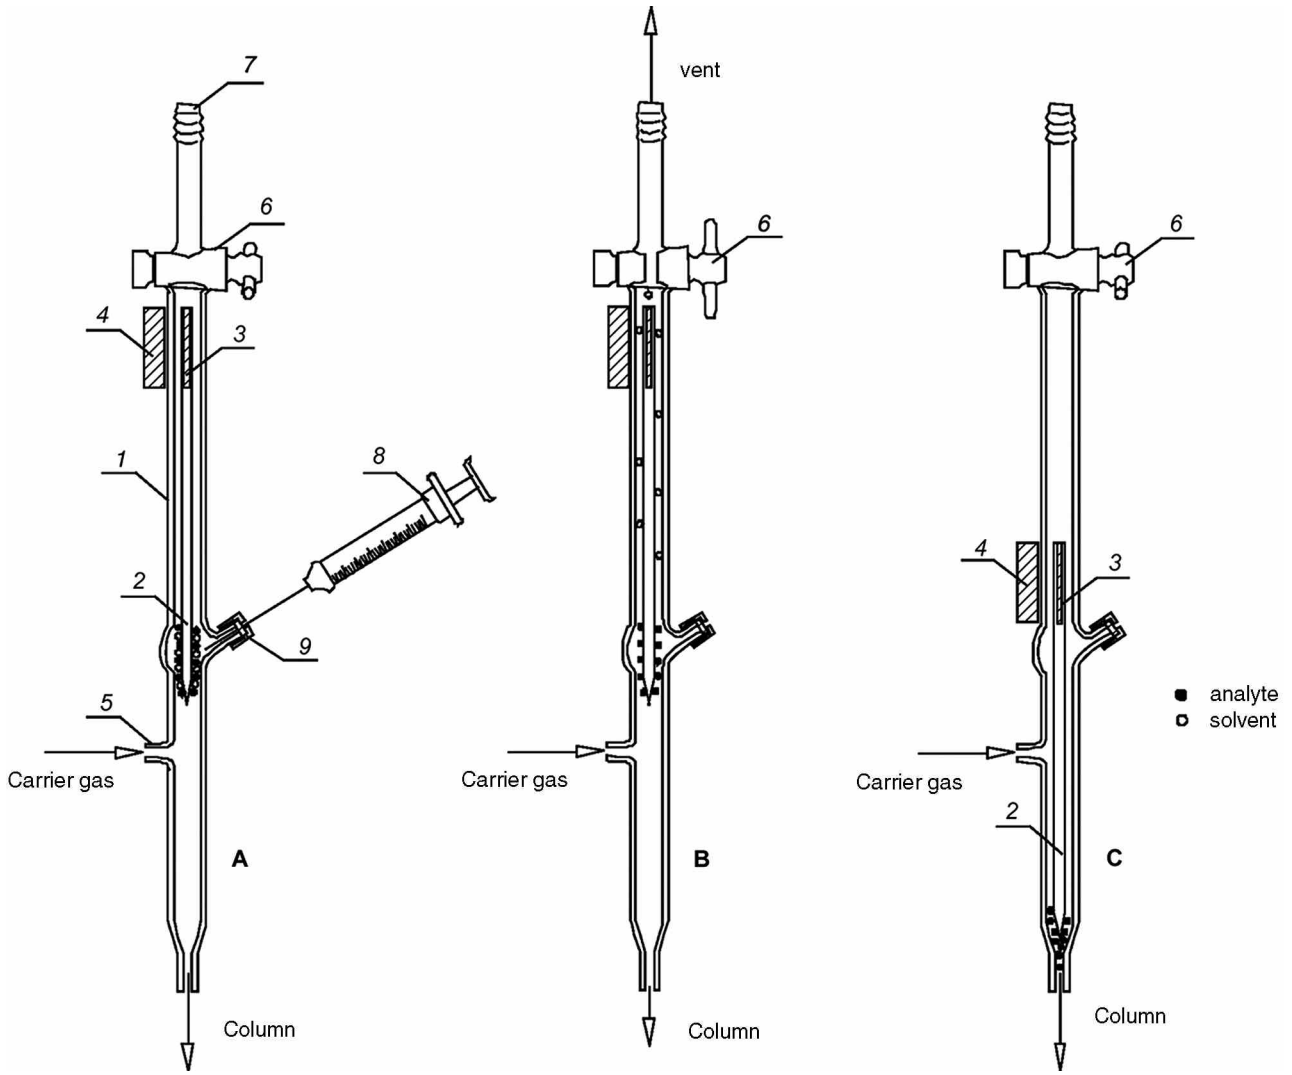

Fig. 1 Diagram of the injector with a mobile needle. 1 – glass tube, 2 – needle, 3 – steel core, 4 – magnet, 5 – carrier gas inlet, 6 – valve, 7 – carrier gas outlet, 8 – micro-syringe, 9 – membrane. Position: A, sample injecting; B, solvent evaporation; and C, analyte injecting into the chromatographic column.

injecting cylinder 8 within the lower housing. The injecting cylinder 8 has glass windows through which application of sample with a micro-syringe onto the sintered tip of the needle can be watched. To make this operation easier, there is an eyepiece with magnifying lens located in front of the front window, and a matt plate is located behind the back window. Below the injecting cylinder 8, there is a heated chamber 9, connected with the injecting cylinder 8 with a ball valve 10. The lower part of the injector is the heated chamber 11, separated from the chamber 9 by a ball valve 12. Chambers 9 and 11 are heated with electric heaters 13 and 14. Constant or variable temperature can be maintained inside the chambers. This is especially true for the chamber 11, in which analytes can be gradually evaporated from the sintered tip of the needle, in order to achieve better separation. Radiators 15, 16, and 17 protect the lower part of the injector and the ball valves 10 and 12 against excessive heat.

The needle with deposited sample is introduced into the heated chamber 9, where solvent evaporates. Then, the needle is transferred into the chamber 11, where temperature is higher, and where the sample becomes evaporated. The sample is thus introduced into the chromatographic column.

Carrier gas and auxiliary gas is supplied to the injector. Carrier gas is separated into two streams. The first stream feeds the chromatographic column. Flow of this stream is turned on with a solenoid valve 19 and the gas flows through the inlet 20 and the chamber 11 to the port 21 of the chromatographic column.

The other stream of carrier gas serves for feeding the chromatographic column when the ball valve 12 is open. In this case, the flow of carrier gas is turned on by the solenoid

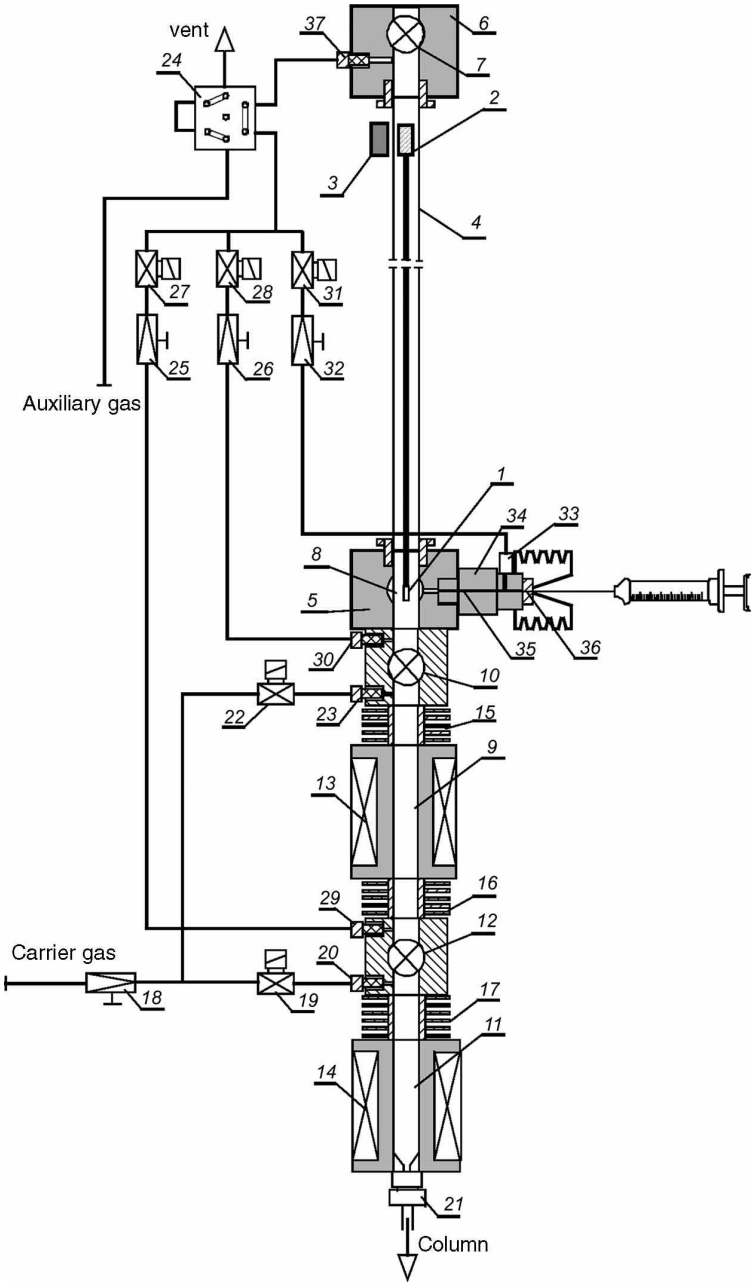

Fig. 2 Diagram of the twin-chamber injector with a needle in position of sample application. 1 – quartz sinter, 2 – steel core, 3 – magnet, 4 – quartz tube, 5, 6 – lower and upper housing, 7, 10, 12 – ball valve, 8 – injecting cylinder, 9 – solvent evaporating chamber, 11 – analyte evaporating chamber, 13, 14 – electric heater, 15, 16, 17 – radiator, 18, 25, 26, 32 – needle valve, 19, 27, 28, 31 – solenoid valve, 20, 23 – carrier gas inlet, 21 – chromatographic column port, 24 – six-way valve, 29, 30, 33 – auxiliary gas inlet, 34 – connector pipe for sample introduction, 35 – micro-syringe needle channel, 36 – membrane, 37 – auxiliary gas outlet.

valve 22 and the gas flows through the inlet 23, chamber 9 and chamber 11 to the port 21 of the chromatographic column.

An auxiliary gas stream is used for evaporation of solvent from the sample applied onto the sintered tip of the needle. The gas flows through the six-way valve 24 to two needle valves 25 and 26, operated by solenoid valves 27 and 28. Part of the auxiliary stream flows through the inlet 29 into the chamber 9.

To evaporate solvent from the sample applied onto the sintered tip of the needle (Fig. 3), flow of the auxiliary gas through the injector is opened by the solenoid valve 27. The stream of gas flows through the inlet 29 into the chamber 9. After the ball valve 10 is opened, the needle of the injector is descended into the chamber 9, where solvent evaporates fast from the sample. Simultaneously, carrier gas flows through the solenoid valve 22 (the solenoid valve 19 is closed).

It is also possible to evaporate solvent from the sample applied onto the needle in the injecting cylinder 8 without descending the needle of the injector into the chamber 9 (Fig. 2). This procedure is possible in the case of solvents characterized with low heat of vaporization. In this case, auxiliary gas flows through the inlet 30 over the ball valve

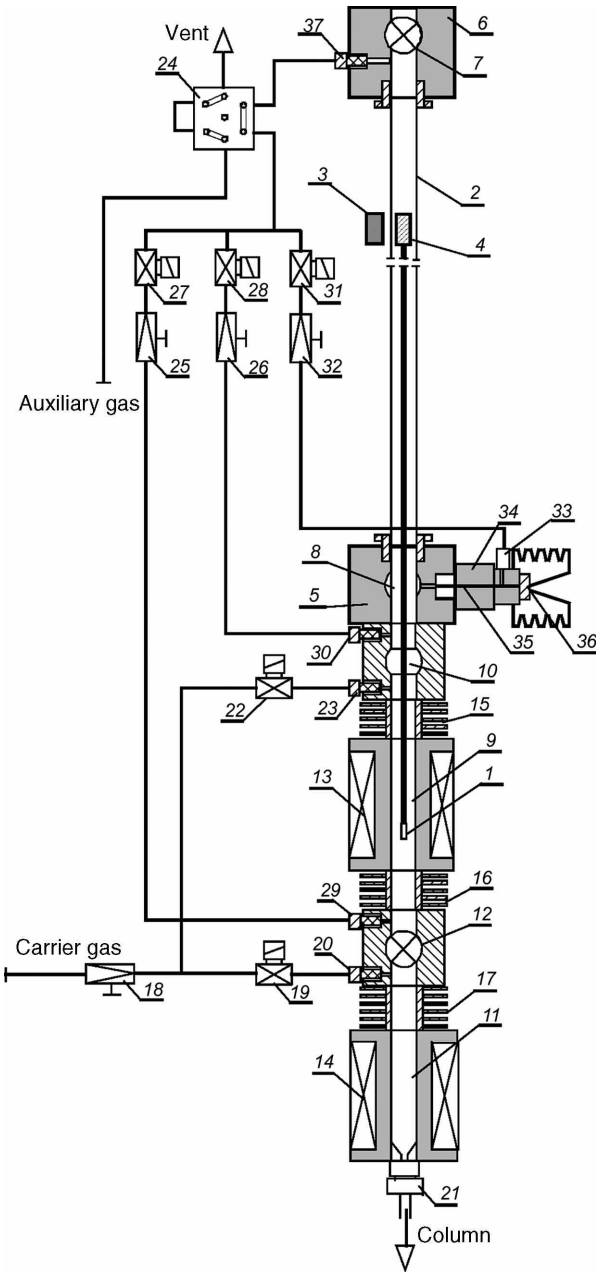

Fig. 3 Diagram of the twin-chamber injector with a needle in position of sample evaporation from the needle inside the first chamber (denotation, as for Fig. 2).

10. Part of the stream, through the solenoid valve 31 and the needle valve 32 is carried to the outlet 33 of the sample connector pipe 34, to wash the channel inside the microsyringe needle 35 and remove possible trace residues of the sample.

Both parts of the auxiliary gas stream unite in the injecting cylinder 8, from which, through the quartz tube 3, they are carried away to the outside of the injector, along with the solvent vapors, through the outlet 37 and the six-way valve 24.

After solvent becomes evaporated, the sample is introduced into the column. The ball valve 12 separates the path of carrier gas introduced into the column from the path of auxiliary gas, and simultaneously protects inlet of the capillary column against accidental drip of the applied sample from the sintered tip of the needle, which could potentially overload the column and would result in necessity of its time-consuming cleaning. After the ball valve 12 is opened, the needle can be descended (Fig. 4) into the chamber 11 and evaporate analytes from the sintered tip, introducing

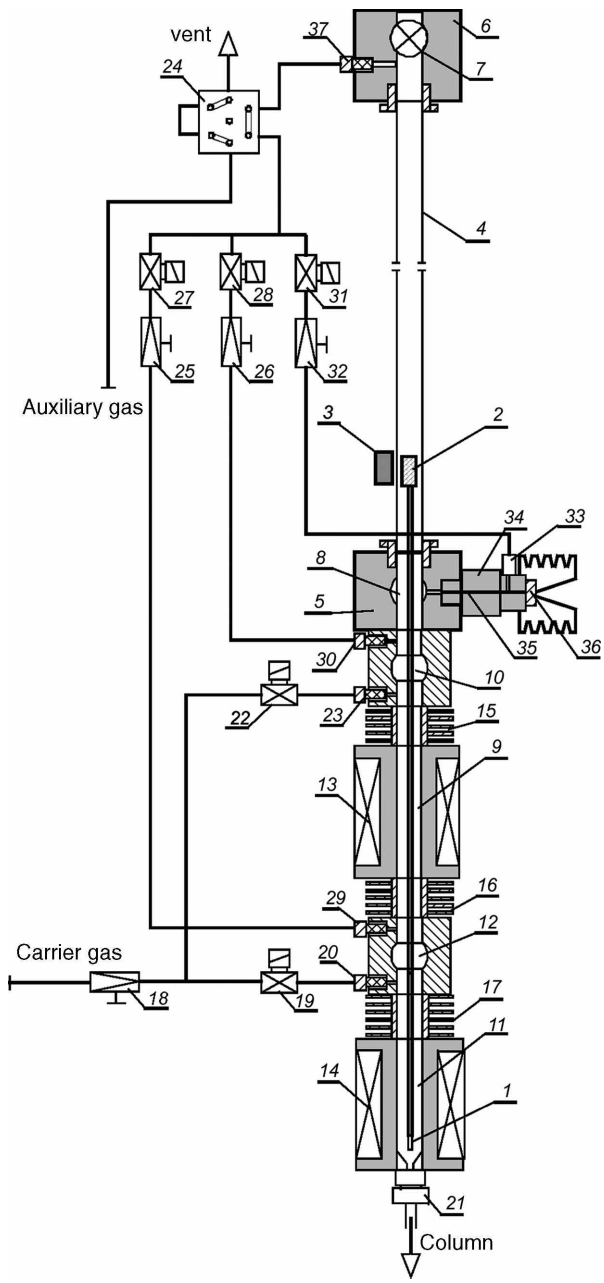

Fig. 4 Diagram of the twin-chamber injector with a needle in position of sample evaporation from the needle inside the second chamber (denotation, as for Fig. 2).

(O – open, C – closed).

them into the chromatographic column. After the injection is over, the needle is elevated, the ball valve 12 is closed, and solenoid valve 19 is opened (the solenoid valve 22 is closed). A list of valve positions during various injector work arrangements is presented in Table 1.

CHROMATOGRAPHIC INJECTOR WITH A MOBILE CONTAINER

An injector with a mobile needle can be improved by replacing the needle with a mobile container for the sample.[4] Compared with the previously described injectors equipped with needles, larger volumes of sample can be introduced into the container. After introducing the sample, the container can be placed in the stream of carrier gas inside a heated chamber. When solvent is evaporated, components of the sample can be transferred from the container into the chromatographic column.

Injector container (Fig. 5) is a quartz tube 1 with a quartz sinter 2 placed inside. There is a packing 3 (glass wool or glass granules) inside the tube. Sample is applied onto that packing. Using the micro-syringe, the sample can be introduced into the container through the openings 4 in its wall. A magnet 5 is located on top of the container.

The container can be moved in the injector tube 7 with a magnet (Fig. 6). For this purpose, a mobile mandrel 6 tipped with steel cores on both ends is used. The tube 7 is fixed in two housings: lower 9 and upper 10, made of acid-resistant steel. The container 1 and the mobile mandrel 6 can be placed inside the quartz tube of the injector after opening the ball valve 11 located within the upper housing 10.

When the injector container is lifted, its side openings 4 (Fig. 5) remain in the injecting cylinder 12 within the lower housing. The cylinder has glass windows through which application of sample with a micro-syringe onto the filling of the container can be watched. To make this

operation easier, there is an eyepiece with magnifying lens located in front of the front window, and a matt plate is located behind the back window. The first electrically heated chamber 13 is connected to the injecting cylinder 12. The second heated chamber 14 is separated from the first one by a ball valve 15. The chambers (13 and 14) can be heated to a constant temperature, or their temperature can be programmed to achieve a preliminary separation of components of the sample applied onto the packing of the container. Radiators 16, 17, and 18 protect the lower part of the injector, the ball valve 15, and the solenoid valve 19 against excessive heat.

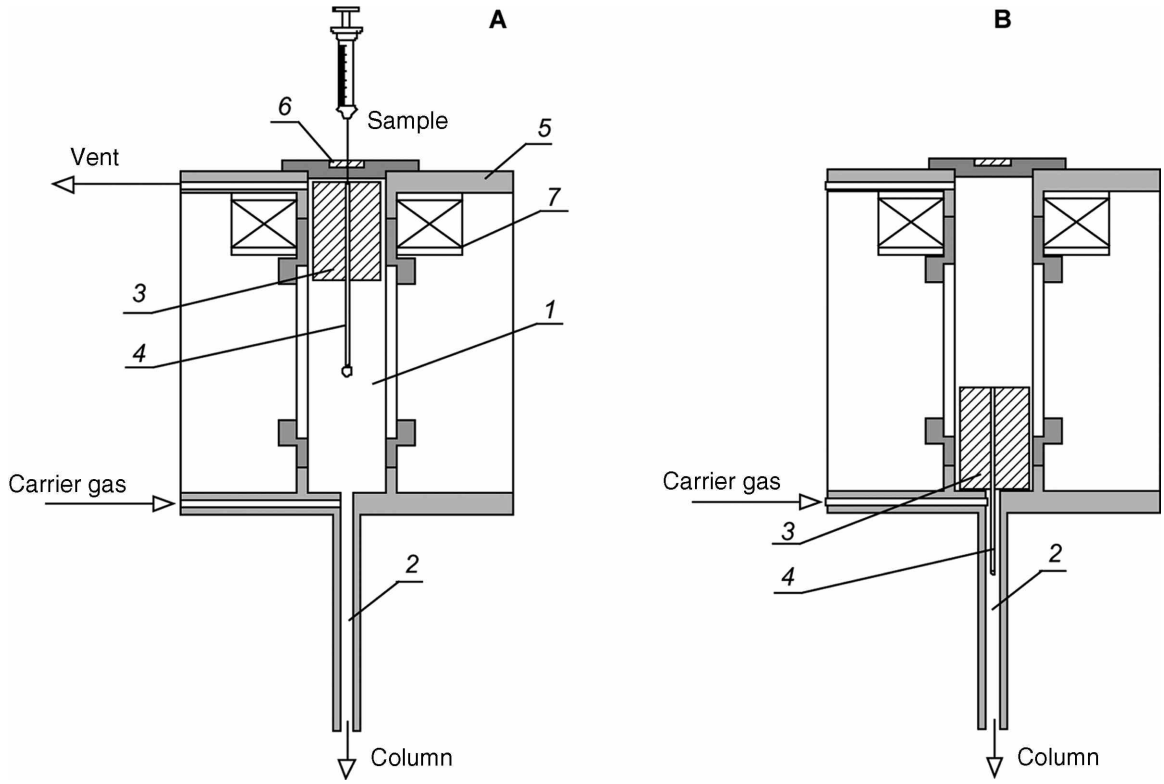

Fig. 9 Automatic injector (A) position of sample application (B) sample injecting position. 1 – evaporating chamber, 2 – injecting chamber, 3 – mobile unit, 4 – wire, 5 – injector body, 6 – membrane, 7 – solenoid.

The injector is supplied with carrier gas and auxiliary gas. Carrier gas is supplied through the solenoid valve 20, inlet 21, chamber 14, and port 22 into the chromatographic column.

After the sample is applied onto the packing of the container, solvent can be evaporated before analytes are transferred into the chromatographic chamber. The procedure consists of lowering the injector container into the heated chamber 13 where solvent is rapidly evaporated from the sample: the ball valve 15 is closed (Fig. 7). Auxiliary gas is used in the container for evaporation of solvent from the sample. The gas flows through the six-way valve 23 into two needle valves 24 and 25 with solenoid valves 26 and 27. Part of the auxiliary gas stream flows through the needle valve 24, through the inlet 28, heated container 1 in the chamber 13, and carrying vapors of solvent flows into the injecting cylinder 12. The other part of the gas stream is supplied through the needle valve 25 into the inlet 29 of the connecting pipe for sample introduction 30, to wash channel of the micro-syringe needle 31 and remove possible remains of the sample. Both parts of the auxiliary gas stream unite in the injecting cylinder 12, from which, through the quartz tube 7, they are carried away to the outside of the injector along with the solvent vapors, through the outlet 33 and the six-way valve 23.

After the solvent is evaporated, the sample can be transferred from the container into the chromatographic column. The procedure (Fig. 8) consists of closing the flow of auxiliary gas through the chamber 13 using the six-way valve 23 (and closing the solenoid valves 26 and 27). Then, the ball valve 15 is opened and the mandrel 6 with the magnet-connected container is lowered into the heated chamber 14. Upon turning the solenoid 19 on, the container becomes immobilized and it is possible to disconnect the mandrel from the container.

After lifting the mandrel 6 up, it is possible to close the ball valve 15 and the sample from the container is introduced into the chromatographic column. An electromagnetic field produced by the solenoid pushes the conical part of the container against the cone-shaped socket in the bottom of chamber 14. This forces the carrier gas to flow through the packing of the container.

After injection is completed, the solenoid is turned off, the ball valve 15 is opened, and the container is taken out from the chamber 14 using the mandrel; the container is moved to the position presented in Fig. 6. The ball valve 15 is closed.

AUTOMATIC SOLID-PHASE INJECTOR

An automatic solid-phase injector[5] is manufactured as a device that can be fitted to the heated block of virtually any gas chromatographic injector available in the market. A diagram of the injector is presented in Fig. 9. The injector

is composed of three principal parts: the evaporation chamber 1, the injection chamber 2 located inside the heated block, and the mobile unit 3 with tungsten wire 4. With a micro-syringe, a sample is applied over the tungsten wire (Fig. 9A). Carrier gas is supplied from the bottom of the injector body 5 and part of it flows through the injecting chamber 2 into the chromatographic column, and the remaining part flows through the evaporation chamber to the outlet located in the upper part of the injector body. Solvent vapors are carried away from the sample placed on the tungsten wire along with the carrier gas flowing through the injecting chamber. After the solvent is removed, the mobile unit 3 is descended with a solenoid 7 to the bottom of the injector body and the tungsten wire 4 is placed in the heated injecting chamber 2 (Fig. 9B). Then, the sample is evaporated and carried by the carrier gas; it is introduced into the chromatographic column. After the injection is over, the mobile unit 3 is moved with a solenoid 7 to the top of the injector body.

The mobile unit of the injector can be equipped with a small crucible or a sorption tube instead of the tungsten wire, depending on the sample matrix.

Sample Introduction Techniques for HPLC

Victor David
Andrei Medvedovici
Department of Analytical Chemistry, University of Bucharest, Bucharest, Romania

Abstract
The content of this entry deals with the first step of the chromatographic process, namely the sample transfer between operator and chromatographic column. The functioning principles, construction and operation of switching valves, automated injection, and selective injectors are widely discussed. Separation efficiency is also influenced by the connecting tubing, and the general relationship between its geometry and chromatographic parameters is analyzed. Some known examples of focusing effects occurring after large volume injection of samples in solvents other than the mobile phase are given. Finally, the main problems related to the malfunction of injectors and their origins are explained, and the qualification of injectors is described.

INTRODUCTION

The injector is an interface that achieves reproducible and accurate transfer of a sample volume between the system operator and the chromatographic column in a front (band) as narrow as possible. Usually, for analysis by high-performance liquid chromatography (HPLC), samples are prepared in a liquid state (as a solution in an appropriate solvent or mixture of solvents, obtained as a result of sample preparation of solid or liquid samples). For practical reasons (avoiding column overloading), even for analytes in a liquid state under ambient conditions, dilution in appropriate solvents is more often used.

The vector transferring a sample from the injector to the head of the chromatographic column is the mobile phase. Thus, injector should be positioned between the mobile-phase delivery system and the chromatographic column (or guard column, if one is used). The requirement that sample transfer takes place as a thin front at the head of the chromatographic column is necessary to minimize, as much as possible, extra-column loss of efficiency. The volume of the connection between the injector and the column should be considered as critical. The lower the injected sample volume and the flow rate, the lower should be the connection volume between the injector and the column. In HPLC, separations are usually driven at a pressure regime higher than ambient and, generally, limited to 400 bar. Pressure limitations are more often imposed by column and/or stationary-phase characteristics (e.g., organic copolymers, or swelled or synthesized stationary phases are used at reduced pressure regime). Therefore, the injectors work under pressurized conditions, and sample transfer has to be realized at ambient pressure without any loss in terms of liquid tightness or serious interruption of the mobile flow in the system.

Usually, injectors are designated for a quantitative transfer of the sample into the column, without any other selective action. However, owing to the increased complexity of the samples, specific injectors have been designed for selective transfer of specific sample constituents. The requirement for continuously decreasing detection limits in chromatographic separations has also led to the development of injectors that enable sample concentration. Insertion of a guard column between the injector and the chromatographic column represents a common approach for acting on the sample matrix to avoid stationary-phase contamination. When the declared aim of the chromatographic process is the assay of some compounds from a sample, the volume accuracy for the injection stage need not be assumed as critical, unless the quantitation limit of the process is affected.

FUNCTIONING PRINCIPLE, CONSTRUCTION, AND OPERATION

Injectors for HPLC are usually called "switching valves" and comprise a stator and a rotor. The stator is used for making connection to the other components of the HPLC system, by means of tubing and the corresponding tightening elements (generally, ferrules and nuts). The rotor is a movable piece that achieves connection between the different ports on the stator. The movement of the rotor from one position to another effects a different set of connections between the ports and, consequently, different liquid flows through the injector. One position of the rotor allows direct connection between the mobile-phase delivery system and the chromatographic column, and a simultaneous connection between the syringe insertion port, the sample loop, and the waste line. This position is known as the LOAD position. The complementary position of the rotor with respect to the LOAD position achieves connection of the mobile-phase delivery system, sample loop, and chromatographic column

on the one hand and the connection of the syringe needle port to the waste line, on the other. This position is generally named the INJECT position. Sample can be loaded into a tubing loop of known and precise internal volume connected to two diametral ports of the stator or directly to the channel from the rotor surface making connection between two vicinal ports on the stator side. The former setup is known as the "external sample loop," while the latter is known as the "internal sample loop" design. The external sample loop design requires six ports on the stator and a 60° rotation of the rotor, while the internal loop device requires only four ports on the stator and a 120° rotation of the rotor. Contact between the rotor and the stator should be tight enough to conserve the pressure regime within the HPLC system but should allow an easy switching movement. The functioning principle is illustrated in Fig. 1. Different constructions of the external and internal sample loop injectors are given in Figs. 2 and 3, respectively.

For external loop injectors, three operation modes are used. First, one supposes that the volume of the sample withdrawn into the syringe is higher than the loop volume, the excess being eliminated via the waste line. This technique is known as the "full loop" mode, which does not require accuracy in the functioning of the sampling syringe as long as the sample volume is larger than that of the loop. The "partial loop" mode imposes the withdrawal of an accurate volume of the sample by means of the syringe. The sample volume is lower compared to the volume of the external loop and, consequently, the sample only partially fills the loop. The "all volume injection" mode requires that the sample (having a considerably lower volume compared to the volume of the external loop) is withdrawn into the syringe needle between two air gaps and a solvent. During the loading operation, the whole sample band is brought within the external loop.

Some examples of commercially available valve supplies are Beckman/Altex, Rheodyne, SSI, Valco, and Waters.

Classification Criteria

Classification criteria applied for injectors used in liquid chromatographic systems are listed in Table 1:

For liquid chromatography (LC) systems micromachined by means of etching of silicon wafers, injection of sample volumes in the range of picoliters up to a few nanoliters is feasible. For such applications, injection is not based on valve switching, but rather on intersection of micromachined channels.

Automated Injection and Selective Injection

Automated injection refers to both automated sample loading and valve switching. Sample volume is user settable and can normally range from 1 to 900 μl. Sample is withdrawn into an external loop having a volume at least equal to the upper limit of the interval, connected between a syringe or stepper pump and a needle. Sample transfer to the column is achieved by means of a six-port rotating valve, often electronically switched, after bringing the needle into the needle seat. Two designs are available. The first setup allows an up and down movement of the needle in the needle seat. Vials are brought from a specific rack by means of a 2-D or 3-D (robotic arm) movement under the needle for sample withdrawal and then put back to their original location. The second technical solution is based on a 3-D movement of the needle from the needle seat to a vial positioned in a fixed rack, followed by sample withdrawal and return to the needle seat. A basic scheme is given in Fig. 4.

Selective injection involves discrimination during the transfer of the analytes to the analytical column, based on some of their physical or chemical properties. In HPLC, selective injection should be considered as being directly related to solid-phase extraction (SPE) or solid-phase microextraction (SPME) processes. However, modules allowing automated off-line SPE or SPME should not be considered as selective injection. An online setup between SPE/SPME

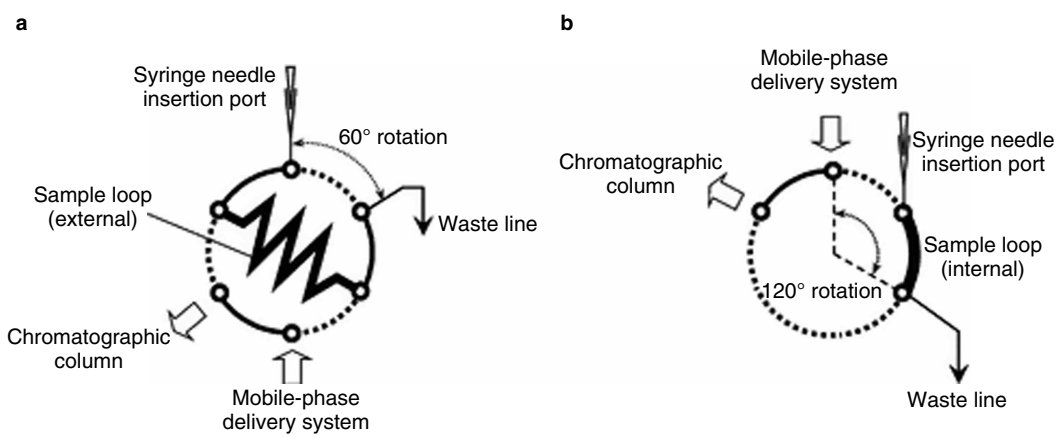

Fig. 1 Injectors for HPLC (a) External sample loop (b) Internal sample loop.

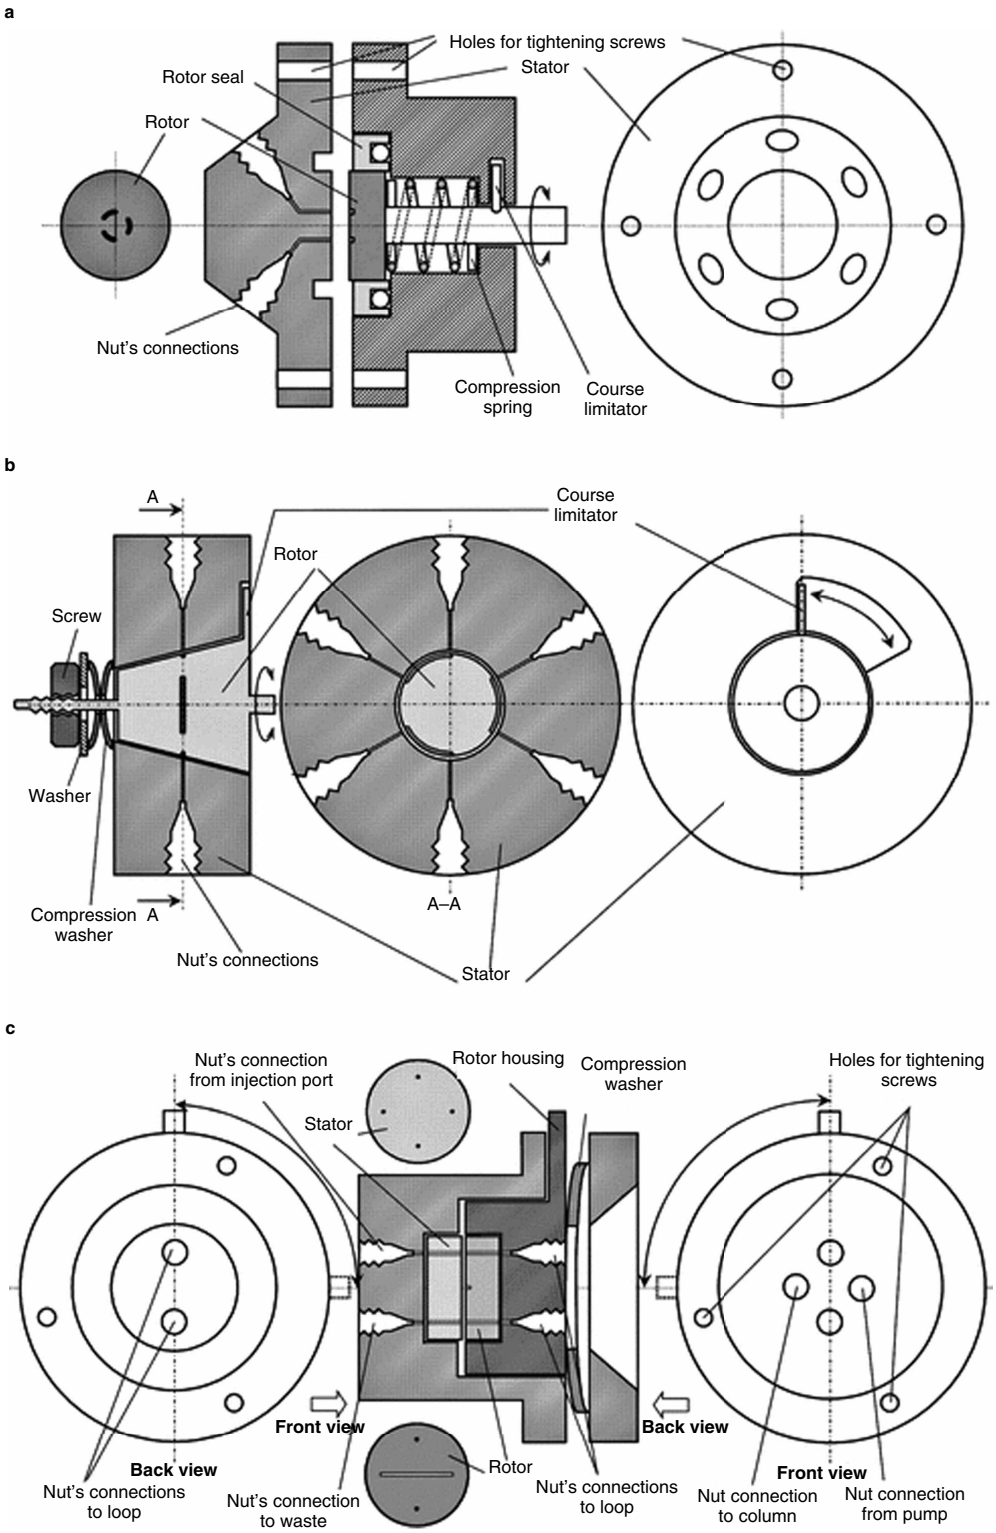

Fig. 2 Different construction types of external sample loop valves: a, Rheodyne; b, Valco; c, Beckman.

and the HPLC system represents a selective injection system. Basically, desorption of the isolated analytes is achieved by means of the mobile phase, usually oriented in a back-flush direction through the extraction cartridge. This basic principle demands a special care on the mobile-phase composition during injection, allowing fast desorption kinetics. A slow release of the analyte from the adsorbent will tremendously affect the efficiency of the separation process (broad band transfer to the column). Basic stages of the SPE process (adsorbent wash, accommodation with the sample solvent,

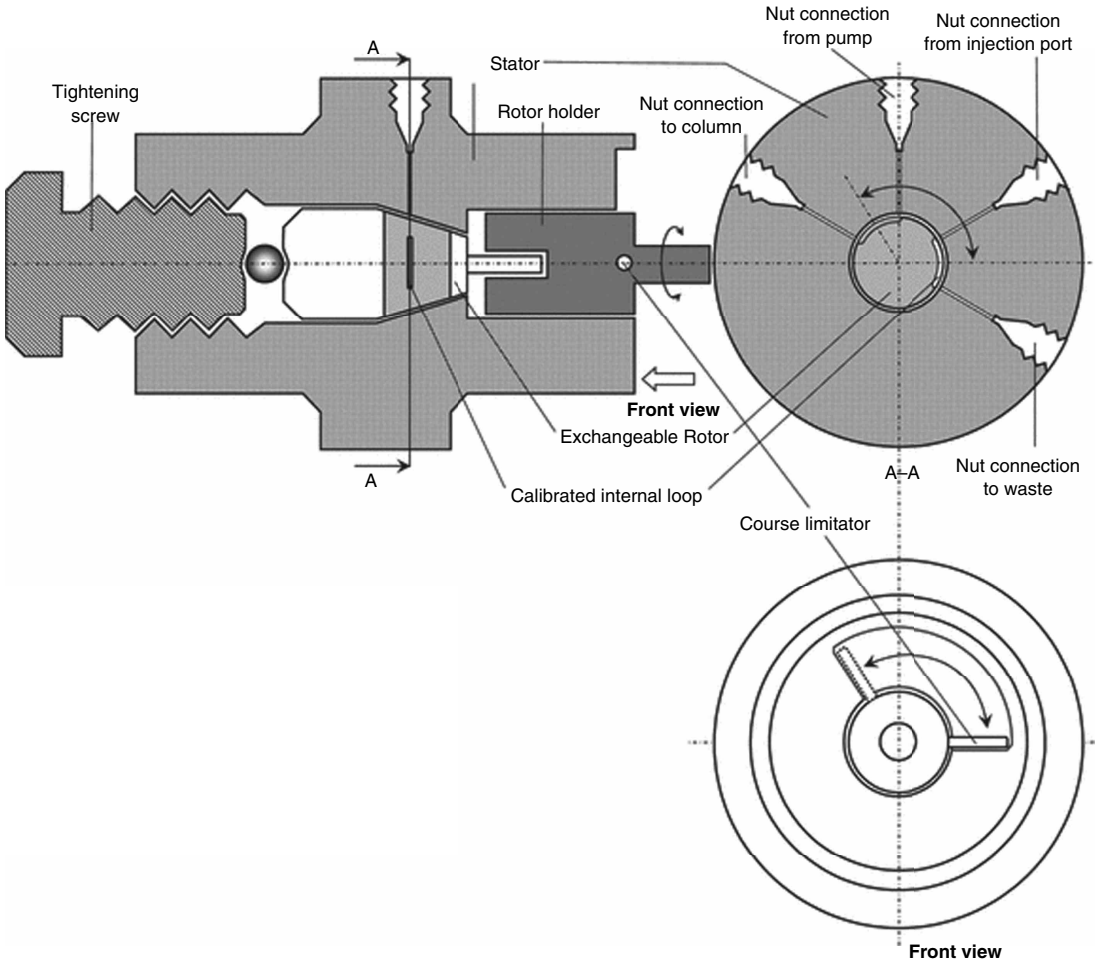

Fig. 3 Construction of an internal sample loop injector.

sample loading, elimination of the remaining matrix, drying the adsorbent and sample desorption) are fulfilled by coupling two six-port rotating valves and a programmable liquid handler (Fig. 5).

Adsorbent wash, accommodation with the sample solvent, sample loading, and elimination of the remaining matrix are processes related to the INJECT position of the valve A and the LOAD position of the valve B.

Table 1 Classification criteria for LC injection systems.

#	Criteria	Type of injection
1	Transferred sample volume	for micro LC applications (injected volumes ranging from 20 to 500 nl) for analytical LC applications (injected volumes ranging from 0.5 to 900 μl) for preparative LC applications (injected volumes ranging from 1 to 10 ml)
2	Sample loop position	internal loop (associated to nano volumes transfer) external loop (associated to analytical and preparative purposes)
3	Way of achieving injection	manual sample loading, manual valve switching manual sample loading, automated valve switching automated sample loading, automated valve switching (autosamplers)
4	Selectivity of injection	unselective selective (associated to sample preparation methods such as derivatization, solid-phase extraction or microextraction, realized off-line or online)
5	Object of the transfer	the sample a fraction resulting from a previous chromatographic separation (multi-dimensional LC interfacing)

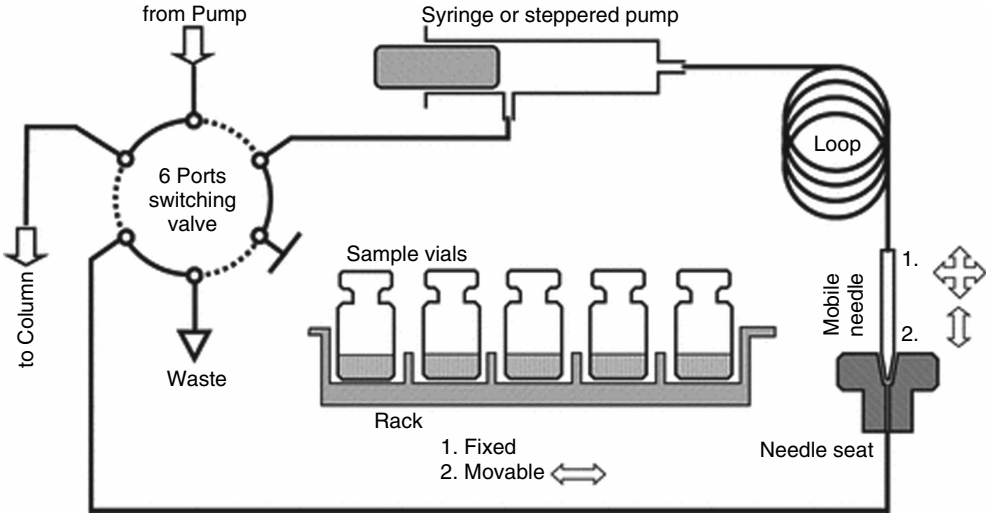

Fig. 4 General setup for an autosampler.

Drying the adsorbent (extremely important when the solvent used for remaining matrix elimination is not fully miscible with the mobile phase) requires the switching of valve A to the LOAD position. Sample desorption is achieved by switching the valve B to the INJECT position.

The SPME hyphenation to HPLC is even simpler. The external loop of a classic injection valve is replaced by a T-adapter, allowing insertion of the SPME needle and pushing out the fiber (Fig. 6). For desorption of the analytes, the valve is moved to the INJECT position. The return to the

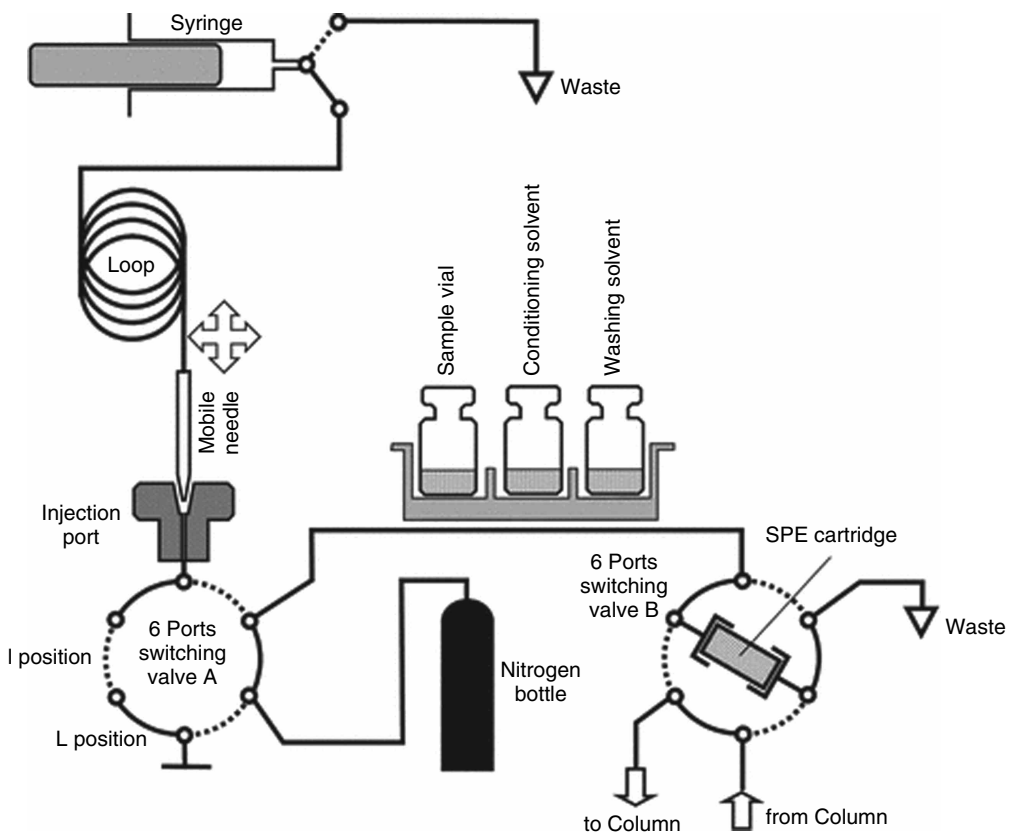

Fig. 5 Online coupling between SPE and liquid chromatography resulting in a selective injection configuration.

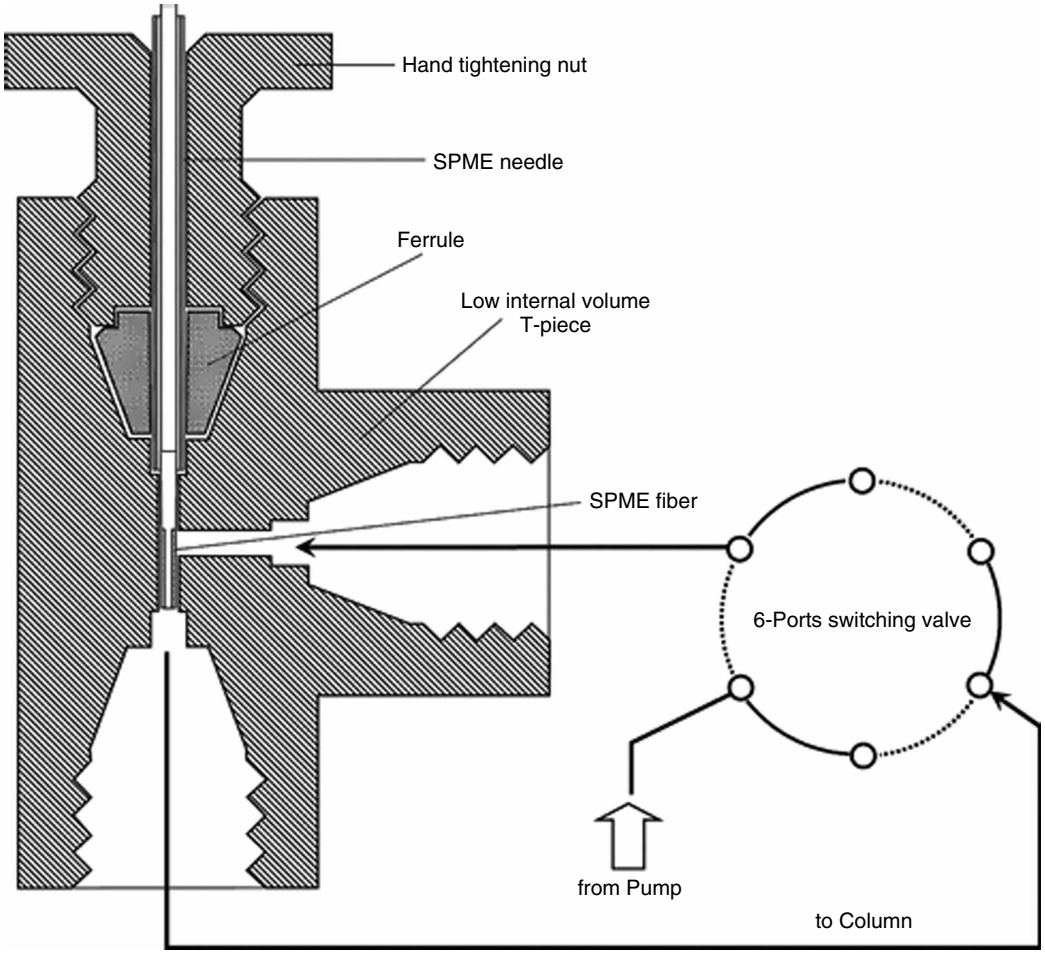

Fig. 6 Selective injection in LC by adapting SPME technique to the online desorption.

LOAD position of the valve isolates, again, the T-adapter and allows retraction of the fiber and withdrawal of the SPME needle. Special attention should be given to the compatibility of the fiber with the mobile phase, to eliminate risks associated with fiber material swelling.

A separate discussion relates to the automated off-line precolumn derivatization of the analytes, achievable by means of an autosampler. Derivatization brings a selective character to the injection process. Sample, reagents, and buffers can be transferred from vials to the loop or to an empty vial. Operations such as mixing of the reaction media, repetitive dilutions, and even sample concentration are possible.

Phenomena Related to Injection

Once the valve is switched for injection, the sample front is transferred to the column via the connecting tubing. Immediately after injection, the sample occupies a cylindrical zone in the transfer tubing. The length of the cylindrical zone depends upon the relative compressibility coefficients of the mobile phase and the sample solvent. When the injected zone moves toward the column, two phenomena occur simultaneously: the first relates to frictional forces to the tubing walls, resulting in a hyperbolic profile of the laminar flow, while the second relates to longitudinal diffusion of the analytes and the sample solvent within the mobile phase. Frictional forces are directly related to flow rate, viscosity of the sample solvent, and smoothness of the inner tubing walls, and are inversely related to the internal diameter of the tubing. Longitudinal diffusion is directly related to diffusivity of the analytes and sample solvent within the mobile phase and is inversely related to flow rate, tubing cross section (contact surfaces between zones), volume of the sample (initial cylinder length), and concentration of analytes. This is illustrated qualitatively in the Fig. 7.

The contribution of connecting tubing to extra-column effects has been already discussed in the literature. All parameters have been studied experimentally to obtain a mathematical relationship describing their mutual dependence. Such an equation is given below, where the band broadening in a chromatographic system is considered to be inversely affected by the flow rate

$$L = \frac{40 \times V_R^2 \times D_M}{\pi \times F \times \mathrm{id}^4 \times N} \quad (1)$$

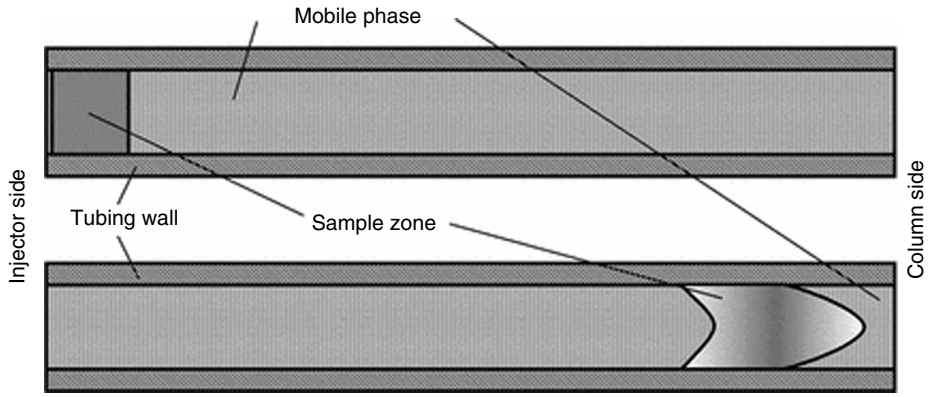

Fig. 7 Sample front during transfer from the injector to the chromatographic column.

where L is the column length (cm), V_R is the retention volume (ml), I.D. is the column internal diameter (cm), F is the flow rate (ml/sec), D_M is the diffusivity of the solute in the mobile phase (cm^2/sec), and N is the peak efficiency (theoretical plates).

Eq. 1 can be rewritten if we consider the following relationships:

$$N = \frac{L}{H} \tag{2}$$

$$V_R = t_R \times F \tag{3}$$

$$t_R = t_0 \times (1 + k') \tag{4}$$

$$V_0 = t_0 \times F \tag{5}$$

where H is the height equivalent to the theoretical plate (cm), t_R is the retention time of the solute (sec), t_0 is the column dead time (sec), k' is the capacity factor of the solute, and V_0 is the volume of the mobile phase within the column, or void volume (ml).

Eq. 6 results after making the above substitutions:

$$H = \frac{\pi \times \mathrm{id}^4 \times L^2 \times F}{40 \times V_0^2 \times D_M \times (1 + k')^2} \tag{6}$$

As the band broadening associated with the injector (H_{inj}) may be considered as the ratio between the length of the connection tubing between the injector and the column (L_{tub}) and the corresponding equivalent efficiency loss N_{tub}, i.e.,

$$H_{inj} = \frac{L_{tub}}{N_{tub}} \tag{7}$$

it clearly follows that

$$L_{tub} = \frac{\pi \times L^2 \times \mathrm{id}^4 \times F \times N_{tub}}{40 \times V_0^2 \times (1 + k')^2 \times D_M} \tag{8}$$

According to Eq. 8, it is possible to calculate the length of the connection tubing having an internal diameter of 0.127 mm (red lines), 0.178 mm (green lines), or 0.254 mm (blue lines), generating 5% loss in efficiency for a solute characterized by a capacity factor of 1 and a diffusion coefficient of 10^{-5} cm^2/sec, separated under a flow rate of 1 ml/min (Fig. 8).

Briefly discussing the results from Fig. 8, it can be inferred that connection tubing between the injector and the column having an internal diameter of 0.127 or 0.178 mm and a length below 50 cm should induce no major loss in terms of peak broadening for chromatographic columns having their void volumes below 2 ml. However, it is important to note that tubing with low internal diameter and significant length will generate a significant pressure drop in the LC system, especially for applications based on higher flow rates.

The effect of injection in the resulting chromatogram can usually be observed as a negative peak, owing to valve switching, which generates a short interruption in the mobile-phase flow through the chromatographic system. If the sample solvent is different from the mobile phase and is

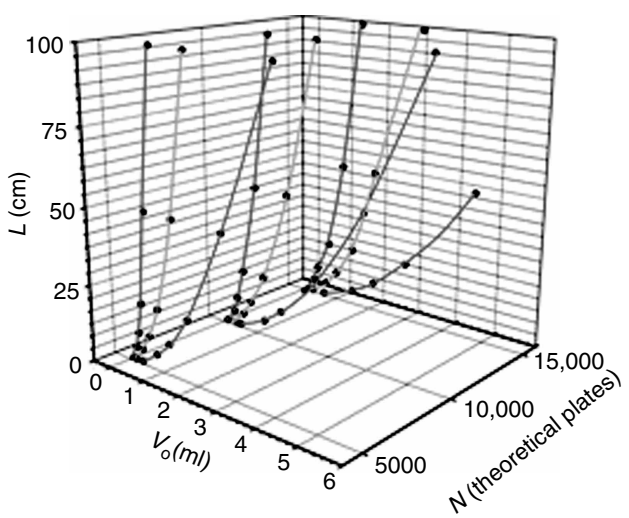

Fig. 8 The approximate length of connection tubing that causes a 5% loss of observed efficiency. Particular conditions are given in the text.

detectable, then the corresponding peak may get overlaid onto the injection pattern. This effect can be used as an indicator of the dead time (t_0) of the chromatographic process.

Focusing Effects on Injection

It is generally accepted that injection volumes less than 5 μl do not induce observable effects on the overall efficiency, retention, and shape of the chromatographic peaks owing to the influence of sample solvent. It is also assumed that, on using the mobile phase as the sample solvent, injection volume does not represent a critical parameter (no influence on efficiency, retention, and peak shape is observed) for the separation process. However, if an analyte is consistently more soluble in the sample solvent than in the mobile phase, and the injection volume exceeds a given limit, focusing of the analyte in the sample solvent occurs on injection, drastically affecting peak shape, retention, and efficiency. This may be explained as follows: the analyte remains dissolved in the plug created by the front of the injected sample volume in the mobile-phase flow. In this case, the distribution constant (K) between the stationary phase and the sample solvent is significantly lower than that corresponding to the partition between the stationary phase and the mobile phase. Obviously, the molecules of the analyte will be carried on by the sample solvent plug along the chromatographic column. Simultaneously, the longitudinal diffusion at the interface between sample solvent front and the mobile phase will give rise to a population of the analyte molecules transferred to the mobile phase, which will obey the "correct" partition mechanism. Therefore, the retention is drastically reduced for a significant number of analyte molecules, whereas for the diffusing molecules the retention will have the true value. Peak

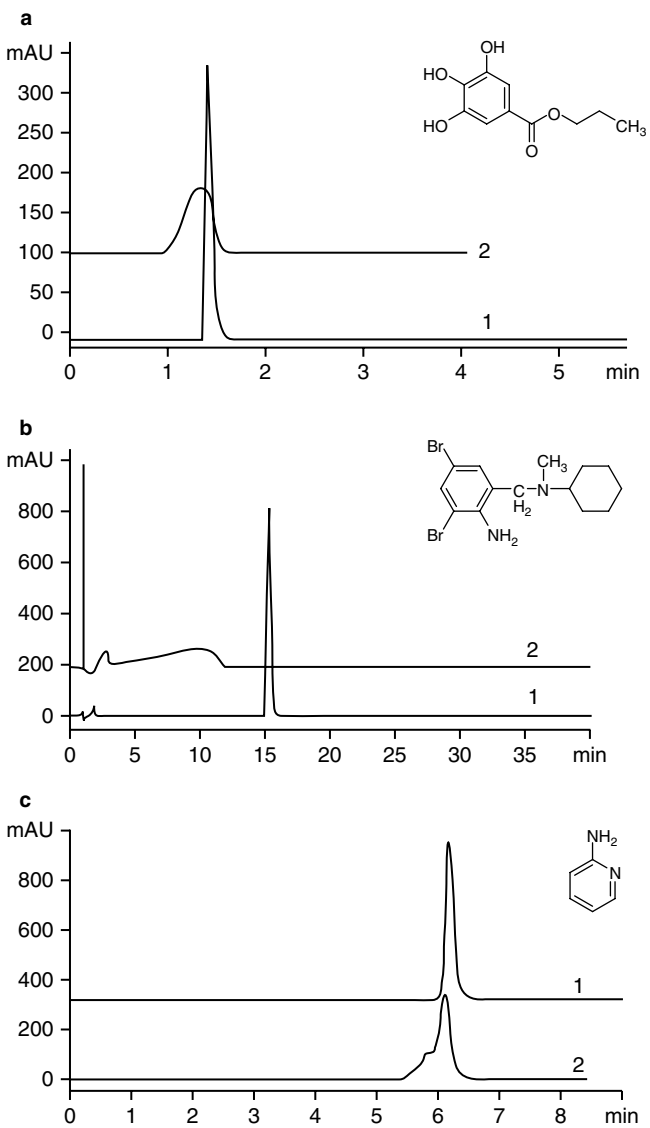

Fig. 9 Focusing of the analyte in the sample solvent on injection **a**, Assay of propyl gallate. Chromatographic column: Chromolith Performance RP-18e, 10 cm × 4.6 mm I.D. × 5 μm d.p., Temperature: 25°C, Flow rate: 2 ml/min, Mobile phase: MeOH/ACN/aq. 0.1% H_3PO_4 = 12/24/64 v/v/v, λ = 273 nm, Injection volume: 100 μl, Sample concentration: 10 mg/L [1] sample solvent is the mobile phase, [2] sample solvent is MeOH/ACN/aq. 0.1% H_3PO_4 = 20/40/40 v/v/v; b, Assay of bromehexine. Chromatographic column: Hypersil BDS 3–C18, 10 cm × 4.6 mm I.D. × 3 μm d.p., Temperature: 25°C, Flow rate: 1 ml/min, Mobile phase: ACN/aq. 0.1% H_3PO_4 brought to a pH of 7 with triethylamine = 75/25 v/v, Detection wavelength λ: 240 nm, Injection volume: 5 μl, Sample concentration: 5 g/L [1] sample solvent is the mobile phase, [2] sample solvent is ACN/aq. 3% HCl = 75/25 v/v; **c**, Assay of 2-aminopyridine. Chromatographic column: Purosphere Star—C18, 12.5 cm × 4 mm I.D. × 5 μm d.p., Temperature: 25°C, Flow rate: 0.7 ml/min, Mobile phase: ACN/aq. 80 mM sodium octane sulfonate brought to a pH of 2.8 with H_3PO_4 = 20/80 v/v, Detection wavelength λ: 290 nm, Injection volume: 50 μl, Sample concentration: 28 mg/L [1] sample solvent is the mobile phase, [2] sample solvent is ACN/water brought to a pH of 2.8 with H_3PO_4 = 20/80 v/v.

shape is, thus, seriously affected, resulting in splitting of bands for the same analyte (as can be seen in Fig. 9a).

Conversely, if the solubility of the analyte in the sample solvent is much lower than that in the mobile phase, large-volume injection may be allowed without any risk in terms of peak shape alteration, erratic retention, and efficiency loss. In this case, soon after coming into contact with the stationary phase in the head of the chromatographic column, the molecules of the analyte are readily distributed to it. The plug of the sample solvent runs through the column, but the molecules of the analyte are free to participate in the correct partition process between the stationary phase and the mobile phase. The focusing of the analyte in stationary phase now comes into effect, resulting in the preservation of the elution properties. Among chromatographers, the following rule sums up the above-mentioned circumstances: high volume injection is allowed in LC without any risk of affecting the elution results, if the elutropic strength of the sample solvent is lower than that of the mobile phase at the beginning of separation.

Focusing of analytes in the sample solvent can get extended by "subtle" effects. As illustrated in Fig. 9b, such phenomena affecting retention, efficiency, and peak shape may occur when the pH of the sample front is widely different from the pH of the mobile phase and the buffering capacity of the mobile phase is exceeded. In the given example, the analyte is forced into a protonated form within the injection front of the sample, while the separation process assumes a non-protonated form. Fig. 9c illustrates almost the same effect appearing in ion-pairing separation mechanism. Injection of high volumes of the sample in solvents which do not contain the ion-pairing agent, keeps the analyte in unassociated form, strongly reducing partition toward the stationary phase and focusing the molecules in the injection front. The retention, peak shape, and efficiency are again strongly affected.

Recently, it has been proved in some applications that large volume injection of samples in hydrophobic solvents (*n*-hexane, *n*-pentane, *i*-octane) is possible, with a gradual reduction of retention and a relatively small loss in terms of peak efficiency. Two conditions are, however, necessary to apply such an injection approach: the solutes must be soluble in hydrophobic solvents and, meanwhile, they have to be less hydrophobic than the sample solvent to avoid competition with solvent molecules in partitioning between the mobile phase and the stationary phase.

Troubleshooting

The main problems related to the malfunctioning of the injectors in LC are summarized in Table 2. More often, defective injection will introduce major problems related to precision of the analytical method and will tremendously affect quantitation. Malfunctions generally originate from inadequate tightness between stator and rotor surfaces in the switching valve or needle and needle seat, respectively (for auto samplers). Accuracy problems are related to the syringe or defective stepping pump operation and/or tightness.

Qualification of LC Injectors

Manual injectors are operationally qualified for repeatability and carryover. Autosamplers are additionally checked for accuracy. Injection systems are qualified after the solvent delivery system and the detector. To eliminate "subjective" effects, the chromatographic column is excluded from the setup for qualifying injectors. The column is replaced by a low internal diameter, significant length stainless steel tubing, generating a pressure drop similar to that in a packed column (about 100 bar).

Table 2 Troubleshooting injectors (major malfunctions events).

Observed malfunctions	Origin / Location
Overpressure in the LC system	Blocked channels on the rotor face or blocked loop; Blocked needle or needle seat; Incomplete switching of the valve.
Leakage, pressure drop	Lack of tightness between rotor and stator surface; Lack of tightness between needle and needle seat; Lack of tightness located to the piston of the syringe/steppering pump; Inadequate connections with fittings on the stator.
Low precision on injection	Accidental scratches made between channels on the rotor surface (usually generated by the use of improper needles tips of the injection syringe); Specific adsorption of the analytes on the rotor surface or within the loop (should be considered in relation to mobile-phase composition and/or sample solvent); Lack of tightness within injection port on the syringe needle walls.
Ghost peaks generated within chromatogram	Lack of inertness of some parts of the injector in direct contact with the mobile phase and/or sample solvents; Contamination of the needle from a previous injection process.
Peak broadening effect	High void volume of the connection tubing between injector and column; Improper connection of the ferrule on the tubing resulting in a void volume generated in the stator port.
Erratic sample injection	Defective movement of the needle or the vials in the autosampler.

Repeatability

A solution of a standard reference compound is obtained in a suitable solvent. This solution is repeatedly injected into the system, recording the chromatograms. After peak area integration, the mean value, standard deviation, and relative standard deviation (RSD) are estimated. Acceptance criteria refer, generally, to an RSD% value below 1%, if the injection volume is lower than 10 μl and 0.5% for higher injection volumes. Usually, for statistical computation, a series of 10 determinations are required. Plotting the integrated peak areas against the serial number of the injection process may represent an efficient way for evaluating a trend. A random distribution of the integrated peak area around the mean value should be observed. Continuously increasing or decreasing peak area values reflects a trend and should be investigated as an abnormal phenomenon.

Carryover

The carryover test checks for residual memory effects. Basically, it measures the residual peak area of the target compound in the chromatogram of a blank sample injected immediately after injection of a concentrated solution of the compound (e.g., 1000 mg/L). The carryover effect is evaluated as the percentage of the residual peak area in the blank chromatogram with respect to the peak area of the analyte after the injection of the concentrated solution. Limits of 0.1–0.2% could be considered as acceptable.

Accuracy

The accuracy test should be conducted especially for autosamplers. It consists of systematically increasing the injection volume from a solution of a reference standard compound. Set volumes should cover the whole working volume interval of the given autosampler module. The plot of the integrated peak areas against the nominal value of the injection volume must be linear and characterized by a correlation coefficient higher than 0.99. The correlation coefficient may be calculated according to the following relationship:

$$r_{xy} = \frac{\sum x_i y_i - \frac{1}{n}\sum x_i \sum y_i}{\sqrt{\sum x_i^2 - \frac{1}{n}\left(\sum x_i\right)^2} \times \sqrt{\sum y_i^2 - \frac{1}{n}\left(\sum y_i\right)^2}} \quad (9)$$

where x_i are set injection volumes, y_i are the integrated peak areas, $i = 1, \ldots, n$ is the serial number of the injections carried out for different volumes.

For the accuracy test it is important that the absolute amount of the target analyte for the lower injected volume is at least equal to the limit of quantitation (LOQ) and the corresponding amount of the compound at the higher injected volume does not exceed the linearity domain.

CONCLUSIONS

This entry deals with modern approaches used for introducing samples from the operator to the chromatographic column.

Sample Preparation

W. Jeffrey Hurst
Hershey Foods Technical Center, Hershey, Pennsylvania, U.S.A.

INTRODUCTION

Before any sample can be subjected to chromatography, some type of sample preparation is required, which can be as simple as filtration or an involved solid-phase extraction protocol. Sample preparation is that activity or those activities necessary to prepare a sample for analysis. The ultimate goal of sample preparation is to provide the component of interest in solution, free from interferences, and at a concentration appropriate for detection. Sample preparation can be divided into a number of classes of activities: solvent extraction, sorbent extraction and compound isolation, headspace, and membrane separations, with each of these areas further divided into techniques that apply to the category of activities.

SAMPLE EXTRACTION

Should the sample be solid, the first step would involve the extraction of the sample with an appropriate solution that would solubilize the compound of interest and remove as few interfering compounds as possible. This operation is sometimes conducted using a blender or other mixer to provide as homogeneous extract an as possible. Alternatively, one could use a Soxhlet or similar apparatus to extract the sample.

The standard methods that one would use in sample preparation for chromatography include filtration, sedimentation, centrifugation, liquid–liquid extraction (LLE), open-column chromatography, and concentration/evaporation. Filtration for sample preparation may be performed on numerous occasions in a sample preparation protocol, with the first filtration being used to separate large-particulate matter from solvent. The final filtration before chromatography likely uses a 0.45 μm or smaller disposable filter unit to prevent small-particulate matter from contaminating the chromatographic system. Other methods to prepare a sample for analysis through extraction include supercritical fluid extraction (SFE), pressurized fluid extraction (PFE), and microwave-assisted solvent extraction (MASE). There will continue to be additions to this list, as techniques evolve and modifications of the more standard techniques are made.

When SFE was initially introduced, it was thought that it might be the panacea for sample extraction because it used a very innocuous solvent, CO_2. The operator varied pressure, temperature, flow rate, and extraction time, with some extraction protocols requiring the use of small amounts of polar modifiers. All of these variables affected the solvating power of the carbon dioxide. In addition to the carbon dioxide, other supercritical fluids have been used to vary the extraction selectivity.

In MASE, the sample and solvent are heated directly, in contrast to more conventional schemes, where the vessel is heated to extract the sample. The MASE technique uses a combination of microwave energy and a pressurized environment to enhance the extraction efficiency of some species. The energy adsorbed in a microwave is based on two complementary phenomena: molecular dipole rotation and ionic conductance. The sample solvents are placed in a closed vessel that absorbs microwaves. This facilitates the extraction of the samples of interest and has been applied to a variety of sample types and matrixes, with one of the most notable successes being its use in the automation of sample preparation of environmental samples. Conversely, open vessel microwave heating can be used to reduce solvent volumes and concentrate samples for subsequent analysis.

PFE uses standard solvents at elevated temperatures and pressures to increase extraction efficiency. The technique uses standard laboratory solvents that would be used to extract the compound of interest, but PFE techniques use solvent near supercritical temperatures. The high pressure does not allow the solvent to boil, hence increasing its penetration, while the high temperature increases solvent viscosity. Samples are placed in stainless-steel extraction vessels that are loaded into the device, which has been programmed for the extraction protocol. Instruments are available from a variety of manufacturers who allow extraction of either a single or multiple samples. In a variant of the technique, sometimes different solid-phase sorbents are placed in the extraction vessel to allow for a more selective extraction using PFE.

SORBENT EXTRACTION AND COMPOUND ISOLATION

One of the techniques that is increasingly used and has replaced more of the traditional methods of sample preparation is solid-phase extraction (SPE). SPE, introduced in the early 1970s, offers the possibility of, if not eliminating, at least reducing the tedium in sample

preparation. SPE has been called "digital chromatography," where samples can be introduced onto a device, interferences removed, and the analyte of interest eluted in a small amount of solvent. Conversely, the SPE device can be used as a flow-through cleanup device. The method can be used on many occasions as a substitute for LLE.

There is a wide diversity in not only SPE packing types but also SPE formats. The packing types parallel those used in open-column chromatography and HPLC. Second-generation-type supports such as Water's OASIS and the Varian NEXUS are seen as universal supports for many sample types, with other similar supports unique for SPE in continual development. Although the early SPE devices were cartridge or syringe barrel based, the formats have evolved to support the growing demands in drug discovery through the development of microtiter plate formats to support high-throughput screening (HTS) activities. In addition to columns, there has also been a growth in disk-based SPE devices, with exciting developments in the application of molecular imprinted polymers (MIPs), where imprints of molecules are formed on plastic supports. The initial success in the application of these devices has been in drug discovery and development. In addition to the large number of general supports, there are an increasing number of special purpose supports for specific applications such as dinitrophenylhydrazine (DNPH) columns for the determination of aldehydes and ketones, columns for explosive analysis, and columns for the analysis of samples for proteomic studies. Finally, there are a number of solid-phase devices that incorporate some sort of filter material into the unit. One can also purchase filter devices that work in conjunction with microtiter plate devices or as standalone units for applications such as protein precipitation.

Solid-phase microextraction (SPME) was developed as an alternative to many other sample preparation methods because it uses virtually no solvents or complicated equipment. It is an adsorption/desorption method where the compounds of interest are adsorbed onto a coated fused silica fiber. After a given time, the fiber is placed in a gas chromatography (GC), where the compounds are thermally desorbed. SPME has recently been adapted for use in HPLC, where compounds that are adsorbed are desorbed using an appropriate solvent.

A related technique that has come into use in recent years and is similar to SPME is stir-bar sorptive extraction (SBSE). Like SPME, it is a solventless technique allowing not only extraction but also concentration of the analyte of interest. In this technique, a stir bar is coated with a relatively thick layer of polydimethylsiloxane film that is placed in the solution containing the compound of interest, where the compound is adsorbed onto the film. The technique initially has been applied to the extraction and isolation of organic compounds from aqueous systems. An additional advantage is that the thicker film used with SBSE allows for the extraction and isolation of larger masses of analytes, thereby allowing an increased concentration of material to be available for analysis. The analytes can be desorbed thermally or by the use of an appropriate solvent.

Matrix solid-phase dispersion (MSPD) is an SPE variant where samples are ground and mixed with a support. In the initial application, samples were placed in a disposable column previously packed with Florisil, which trapped the fat from the sample and allowed the compounds of interest to be eluted. This has successfully been applied to the determination of lipophilic pesticides from both fatty and non-fatty matrixes. Recently, an orthogonal technique, dispersive solid-phase extraction, for the isolation and analysis of a variety of pesticides on numerous food matrixes has been introduced. The technique is called QuEChERS, which stands for quick, easy, cheap, effective, rugged, and safe. The technique offers advantages in time and solvent usage since it uses approximately 10 ml of solvent per sample when compared to the potentially hundreds of milliliters of solvent used for more standard extraction and isolation protocols. It uses a combination of $MgSO_4$ and primary secondary amine (PSA) sorbent not only to remove water and non-target compounds, but also isolate the compounds of interest.

HEADSPACE

This term can be applied to a number of techniques including static headspace, purge and trap, and thermal desorption. All of these techniques involve the extraction of a gaseous component from a solid or liquid sample. Static headspace is usually a one step technique where the component of interest is extracted from the sample held in a closed vessel usually at elevated temperatures and then injected onto the GC. Purge and trap is a multistep technique where the compound of interest is extracted into a matrix and then thermally desorbed onto the GC for analysis. SPME used in conjunction with GC analysis could be considered a purge and trap technique. In thermal desorption, the sample is heated rapidly and isolated using a cryogenic trap with the compounds isolated thermally desorbed.

MEMBRANE SEPARATION

Two additional techniques that are used in sample preparation protocols are ultrafiltration and microdialysis. In ultrafiltration, pressure is applied to a membrane and those molecules smaller than the molecular-weight cutoff can pass through while molecules larger are retained. This technique can be used as a way of sample concentration or as a way to eliminate higher-molecular-weight compounds from an analytical scheme. Membranes are available with cutoffs ranging from 300 to 300,000 daltons. Microdialysis differs from the other techniques because it is in vivo sampling and has been applied to the

determination of drugs and other biomolecules from tissues, organs, and biological fluids. In microdialysis, molecules can diffuse across a membrane, resulting in either direct or reverse dialysis.

AUTOMATION

Finally, no discussion of this topic would be complete without mention of the place of automation in sample preparation and its impact on this activity. Laboratory robotics' initial focus was on the automation of sample preparation and it is used in that way in many laboratories, but "islands of automation" have developed within certain organizations where certain portions of sample preparation such as SPE are automated. This initial automation used cartridge-based sorbents, but current applications involved the use of microtiter-based formats.

CONCLUSIONS

As sample preparation evolves, there is going to be not only growth in the variety of techniques, but also the use of a combination of techniques, such as the SPE/PFE example mentioned earlier. Sample preparation is an extremely broad subject, because there are techniques that are more likely used by those in different industry segments. This entry has provided an overview of some of the methods of sample preparation that are widely used. The reader is referred to the Bibliography for in-depth discussion on these topics.

Sample Preparation and Stacking for CE

Zak K. Shihabi
Department of Pathology, Wake Forest University, Winston-Salem, North Carolina, U.S.A.

Abstract
The sample matrix affects the separation in capillary electrophoresis (CE) much more than it does in high-performance liquid chromatography (HPLC). It affects the resolution, quantification, and precision through effects on the current conductance and through effects on the capillary walls. Proteins tend to bind to the capillary wall and change the analysis unpredictably. Samples of biological or industrial origin and those with low concentration require special preparation and thoughtful planning for separation in order to avoid the deleterious effects of the sample. Emphasis on simple stacking and concentration methods is presented to overcome the poor detection limits of CE and to bring it closer to HPLC.

INTRODUCTION

Unlike in high-performance liquid chromatography (HPLC), the composition (matrix) of the sample itself greatly affects several aspects of the separation in capillary electrophoresis (CE): migration, resolution, quantification, sensitivity, detection, and precision. Although the sample, in most instances, constitutes a very small portion of the overall volume in the capillary once injected (0.5–5%), the matrix of the sample has profound effects on the migration of analytes in CE. This is due to two main factors: the contribution of the sample to the total current conductance and its interaction with the capillary walls (especially proteins). The conductance is related to the voltages, the current, and the field strength, all of which affect the migration (velocity) of the analytes and also the peak shape obtained for the analytes.

As CE has a relatively low sensitivity, owing to the short light pathway of the capillary, there is a tendency to inject large volumes of sample to enhance detection. However, as the sample size or its ionic strength increases, the matrix effects and the contribution to the current conductance become much more significant. Also, as the ionic strength of the separation buffer is decreased to speed up the analysis, the matrix effects become more significant.

It is not well appreciated that in CE there is a relationship, or an interaction, between the sample matrix, the buffer, and the capillary wash between the samples. Because of the large surface area to the capillary volume, the sample matrix affects the charges on the capillary wall. Samples obtained from clean sources, or pure standards, generally do not require much or any preparation, while those from biological fluids, foods, and industrial sources often have a complex matrix (excess of ions and proteins), which necessitates special or clever manipulation not just of the sample but also of the separation buffer and the degree of capillary wash. This depends on the concentration of the analytes relative to the contaminants. For example, we routinely analyze cryoglobulins for diagnosis of vasculitis.[1] These proteins being cationic in nature precipitate and bind easily to the capillary walls, ruining the separation. Capillary wash between samples with the traditional sodium hydroxide of 0.2 mol/L is not sufficient. In order to deal with such a problem, a special wash between samples with high concentration (10%) of phosphoric acid was critical. This explains why a method described in the literature based on pure standards needs further modification for its successful use in routine analysis.

Sample preparation in CE requires careful thinking and strategy to obtain a good analysis. There is also a relationship between the sample matrix and the separation buffer. Based on how the sample is prepared and how the separation buffer is selected, sample matrix effects can be either favorable or detrimental to the analysis. In other words, it can lead to improved separation, with concentration of the analytes on the capillary (stacking) or to poor separation with band broadening. Matrix effects in capillary zone electrophoresis (CZE) are different from those observed in micellar electrokinetic chromatography (MEKC). Also, the matrix effects are different in electroinjection compared to hydrodynamic injection. These facts can be highly discouraging for a researcher new to this technique. However, understanding the basics of matrix effects is very important for avoiding poor separation or poor peak shape.[2] The two most common techniques in CE are CZE and MEKC. Other techniques such as size separation, nonaqueous CE, and isoelectric focusing are less utilized, and furthermore, they are quite specialized techniques. Hence, we focus here on sample preparation for CZE and MEKC. The aim of this entry is to offer the reader both basic and practical information on how to overcome deleterious sample matrix effects and how to turn them around to be favorable for the overall analysis.

EFFECT OF SAMPLE MATRIX IN CAPILLARY ZONE ELECTROPHORESIS

The most important elements encountered as matrix in the sample affecting the CE are the different ions, proteins, pH, and diluents. These constituent factors can vary widely between different samples, which can affect greatly the separation in CE. Often, when the sample matrix is different from that of the standards, erroneous quantification resulting from changes in the peak shape (especially for peak height) and, consequently, poor recovery is observed. If there is an interaction between the sample and the capillary walls or changes in the charge on the surface of the capillary, precision suffers greatly due to changes in electro-osmotic flow (EOF).

Sample Ionic Strength

Ions are very important in electrophoresis. They carry, or conduct, current. A sufficient ionic strength is important for the solubility of some compounds such as proteins. However, there is an inverse relationship between electrophoretic mobility and ionic concentration. In the hydrodynamic injection mode, when some of the analyte ions migrate from a high-conductivity region in the sample to a low-conductivity area in the buffer, they accelerate, resulting in non-symmetrical multiple peaks, or band spreading. In the electrokinetic injection mode, the excess ions in the sample decrease the migration or transfer of the analytes into the capillary, leading to a diminished detector signal. Pure standards prepared in water compared to those added to serum or diluted in saline solutions show differences in peak shape and a large difference in the detector signal, causing the quantification to be difficult. In other words, an excess of ions in the sample, especially with large sample volumes, ruins both the separation and the quantification in CE, with the effects being more pronounced in electroinjection.

Proteins

At low concentrations and under appropriate conditions, proteins have little effect on separation in CE. However, at high concentrations in the sample together with low ionic strength in the buffer, many proteins, especially the cationic ones, tend to be adsorbed preferentially onto the inlet side of untreated capillary walls, changing the zeta potential, which in turn affects the EOF. Even the slightest variation in the EOF along the capillary length causes an increase in band spreading and a decrease in peak symmetry, leading to very poor reproducibility. An excess of proteins in the samples causes poor reproducibility, especially of migration time; thus, the capillary requires a more thorough wash between injections. In our experience, even small amounts of some types of paraproteins present in serum ruin the capillary after a single injection unless a thorough wash is employed. Fortunately, untreated capillaries are not that expensive to replace.

pH

The ionization and net charge of the sample components are affected significantly by changes in the pH of the sample. As a result, the migration rate, the solubility, the theoretical plate number, and the peak height could all get affected. Proper dilution of the sample with an appropriate buffer is the first step in separation. Usually, the sample is diluted with the same solvent used as the electrophoresis buffer; however, in some instances, a pH of the sample different from that of the buffer is selected to concentrate the sample on the capillary (stacking).

Diluent Type

In most cases, the sample is dissolved in aqueous buffers similar to the electrophoresis buffer, but at a higher dilution. However, as discussed later, using some organic solvents (especially acetonitrile and acetone) as sample

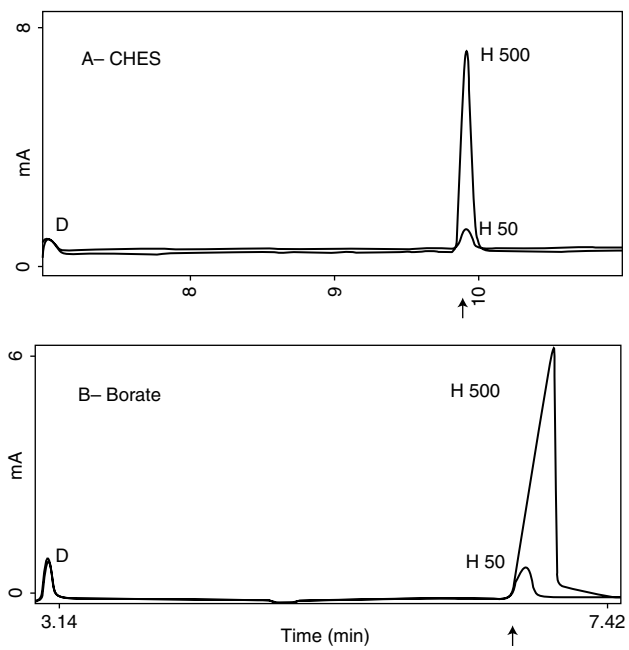

Fig. 1 Effect of both sample concentration and buffer type on migration time for hippuric acid (H): A, Symmetrical peak shape with separation buffer CHES 150 mmol/L, pH 9.0, 214 nm; hippuric acid 500 mg/L (top peak) and 50 mg/L(lower peak) and B, Distorted peak shape using separation buffer borate 150 mmol/L, pH 9.0, 214 nm; hippuric acid 500 mg/L (top peak) and 50 mg/L (lower peak) (D = DMSO; arrow indicates common or constant migration time).

Source: With permission from Effect of sample composition on electrophoretic migration: Application to hemoglobin analysis by capillary electrophoresis and agarose electrophoresis, in J. Chromatogr. A.[2]

diluent can yield much better separation due to the stacking effect.

Analyte Concentration in the Sample

Some unexpected factors can affect the peak shape and migration in CE. For example, concentration of the analyte itself in the sample can have an effect on the peak shape, which can be remedied by dilution or by using a different buffer as illustrated in Fig. 1.[2] In this figure, hippuric acid at low concentrations shows a good peak shape in CE using borate or *N*-cyclohexyl-2-aminoethanesulfonic acid (CHES) buffer. However, when the concentration is increased tenfold, the peak shape deteriorates in the borate but not in the CHES buffer.

Migration can also get affected by the concentration of the analyte in the sample. This is much better observed in gel electrophoresis where multiple samples are applied to the gel and the same analytes align exactly with respect to each other. However, this does not happen all the time. For example, hemoglobin (Hb)F in the presence of large amounts of HbS changes its migration depending on its concentration. As the ratio HbF:HbS decreases, the migration time of HbF decreases too (see Fig. 2).[2]

MATRIX EFFECTS IN MEKC

MEKC is often used for separating neutral and hydrophobic molecules. The effect of sample matrix in MEKC is less dramatic than in CZE. The surfactants in MEKC offer a great advantage for samples with high protein content. They solubilize the proteins and decrease wall interactions, thereby eliminating the need for extraction or deproteinization, and allow direct sample injection, provided the proteins do not interfere with the detection of the analytes of interest.

Surfactants in the Sample

Surfactants are sometimes added to the sample to solubilize the analytes. In general, a low concentration of the surfactant in the sample favors peak height. A surfactant in the sample different from that in the running buffer can give a slightly better peak height.

Surfactant in the Buffer

A high sodium dodecyl sulfate (SDS) concentration in the running buffer causes an increase in peak height. However, at the same time, high SDS concentrations result in excessive current generation and long migration times. Peaks with higher capacity factors (k') are more affected by the surfactants in the buffer.

Organic Solvents in the Sample

MEKC is often employed in the separation of non-polar compounds. The addition of an organic solvent to the sample to solubilize the analyte, especially with large sample injection, decreases peak height as well as resolution. Thus, the concentration of these solvents needs to be kept to the minimum.

SAMPLE VOLUME AND STACKING

Concentrating the sample in the capillary is called stacking. It is a very simple method to perform in routine analysis. Because of the relatively low sensitivity of detection in CE, a high sample volume is very desirable to improve the signal-to-noise ratio. Unfortunately, a simple increase in the sample volume, under continuous buffer separation (the same buffer in the sample, capillary, anode, and cathode), leads to sample overloading. The theoretical plate number in CE drops considerably with an increase in the sample (volume). For example, the theoretical plate number dropped from 800,000 to less than 10,000 when the injection time was increased from 0.2 to 15 sec.[3] Low sample volume offers very high theoretical plate numbers, but at the same time yields very small detector signals. The rule of thumb is to keep the sample plug, under non-stacking conditions, at less than 1% of the capillary length.[4]

The general idea behind most of the stacking methods is to inject a very large sample and induce the same

molecules in different regions of the injection plug to migrate with different velocities, so that the two edges of the sample come closer to each other before the electrophoresis step. Discontinuity in the capillary buffer with regard to concentration, pH, ions, or conductivity is the key to induce differences in molecular migration. This discontinuity can be introduced in the capillary simply by dissolving the sample in a buffer or diluent different from the electrophoresis buffer. Some of the stacking methods are applicable for the majority of the analytes, while others are limited to a very few or certain compounds.

Stacking in CZE

A large sample volume is injected and the two edges of the sample are induced to migrate toward each other. This mechanism leads to enhanced sensitivity, higher plate numbers, and better separations. Stacking in CZE can be brought about by various manipulations of the sample. Further, a combination of two different methods can give a higher concentration factor.

Low Ionic Strength in the Sample

Most often CE analyses employ this simple method. Here, the sample is dissolved in the same solvent used as the electrophoresis buffer but at a 10 times lower concentration. This causes the sample resistance and the field strength in the sample plug to increase. In turn, this causes the ions to migrate rapidly until they are slowed at the interface of the separation buffer. They stack as a sharp band at the boundary between the sample plug and the separation buffer with the positive ions lining up in front of the negative ions before entering the separation buffer. As a result of this simple manipulation, the sample can be concentrated up to 10 times.[5] This stacking effect can be utilized with both pressure and electrokinetic injections (field amplification injection). A similar stacking can also be accomplished by injecting a very short plug of water into the capillary before injecting the sample.

pH Adjustment

Stacking based on adjusting the pH for samples with multiple charges has been described. Peptides can be concentrated by dissolving the sample in buffer 2 pH units above the net p*I*, so that they are negatively charged. As the potential is turned on, the peptides initially migrate toward the anode until they are stopped by the interface of the separation buffer, where they concentrate. After the short pH gradient of the sample dissipates in the separation buffer, the peptides become positively charged. Thus, they migrate toward the cathode as a sharp zone. Catecholamines were concentrated based on the same principle at acidic conditions in the sample.

Transient Isotachophoresis

One of the earliest methods for ion separation (later used for sample concentration on the capillary) is isotachophoresis (ITP) based on the work of Kohlrausch. This method concentrates dilute samples using buffers that are discontinuous with respect to the ions, all of which have to migrate at the same velocity, regardless of their mobility, during the electrophoresis. A fast-mobility ion at a high concentration is used as a leading ion while a slow-mobility ion is used as a terminating ion. The sample ions have intermediate mobility. At equilibrium, samples of low concentration and intermediate ion mobility change their field strength, by adjusting their concentration, to keep pace with the velocity of the leading ion. The electric field strength is inversely proportional to the ion mobility in that region. If a few sample ions accidentally enter the leading zone, they encounter lower field strength, so that they slow down. However, if some sample ions slow down in the terminating ion region, they are exposed to higher field strength and speed up, catching up with their own segment. Thus, the difference in field strength between terminating and leading zones dictates the stacking. ITP is often considered a concentration and purification method. It can concentrate a sample ten- to thousandfold. The concentrated segments can be coupled to CZE by several methods using a single capillary or separate capillaries for further separation and quantification.

As the velocities of the ions are affected by factors such as the charge, pH, concentration, and coions, successful ITP requires careful attention to all these details, which makes it difficult to use in practice. A simpler form of ITP is transient ITP (t-ITP), which is easier to couple to CZE (in the same capillary).[6–8] Under appropriate conditions, a concentration step due to a brief ITP can occur before the sample enters the separation buffer. In many instances, the t-ITP step occurs accidentally in samples containing high concentrations of salts (self-stacking) or it can be induced by the addition of an appropriate leading/terminating ion to samples with a complex matrix. The method can concentrate both small and large molecules.

Karger et al.[9,10] have described two strategies for coupling ITP to CZE. The first method uses on-column t-ITP. After the sample is injected, a leading or terminating electrolyte is chosen based on the mobility of both the analyte and the coion of the background electrolyte. This method gives an approximate fiftyfold increase in sensitivity. In the second method, a second CZE column is coupled to the ITP column. This involves a more complicated system, but it yields up to a thousandfold increase in sensitivity.[10] Karger et al. have also shown the advantages of coupling t-ITP with CZE for concentration of several model proteins such as cytochrome *c*, lactoglobulin, ribonuclease, and lysozyme for both UV and mass spectrometric detection.[10]

Transient Pseudo-isotachophoresis (Acetonitrile Stacking)

Many biological samples such as serum contain close to 70,000 mg/L of proteins that can adsorb, denature on the inlet, and clog the small pores of the column in HPLC or bind to the walls of the capillary. To analyze drugs and endogenous small molecules present in serum, these compounds have to be extracted either by liquid or by solid phase. Both extraction methods avoid the proteins, concentrate the analytes, and yield clean chromatograms, but they are laborious procedures especially for routine analysis. A more common procedure for drug analysis in serum involves removal of proteins by the addition of 2 volumes of acetonitrile and occasionally by the addition of acids or heavy metal salts.[4] Acetonitrile is a common reagent for deproteinization in both HPLC and CE. It requires 2 volumes of acetonitrile to 1 volume of serum to completely remove serum proteins.[4,11] The advantages here are the simplicity and speed of deproteinization by acetonitrile. However there is an opposite effect of acetonitrile in HPLC vs. that in CE.

Effect of acetonitrile in HPLC: When the recovery of small molecules analyzed in serum is calculated based on the peak height of aqueous standards also treated by acetonitrile similar to serum, a high recovery is obtained. However, when the calculation is based on aqueous standards diluted in the mobile phase (pump solvent) a low recovery is obtained. In analyses of drugs in serum, acetonitrile in the sample decreases the peak height and limits the amount of sample to be injected on the column due to the formation of a short gradient leading to a nonsymmetrical peak shape with a decrease in the plate number.[12] Alternative deproteinizing mixtures for acetonitrile in HPLC have been proposed.[12]

Effect of acetonitrile in CE: When acetonitrile is present in the sample at a concentration of ~60–80% together with a low concentration of ~1% of sodium chloride (normally present in serum), stacking occurs. In practice, the biological samples (1 volume) are deproteinated by mixing with 2 volumes of acetonitrile and injecting the supernatant after centrifugation directly into the CE apparatus. Acetonitrile can be used to remove the excess of proteins; however, it has several additional advantages in CE. It reverses the harmful effects of ions present in serum, allows larger volumes of sample (about a third of the capillary volume) to be injected, and solubilizes many analytes better. The overall effect is an approximate twentyfold increase in sensitivity (Fig. 3). This is a general stacking method applicable for many compounds. Anionic compounds are easy to stack by this method. Cationic compounds stack better in acetonitrile using a high concentration of zwitterionic buffers (Fig. 4). Two different mechanisms are behind this stacking. Acetonitrile in the absence of salts has low conductivity and hence causes stacking by high field strength. However, acetonitrile in the presence of salts causes stacking by another

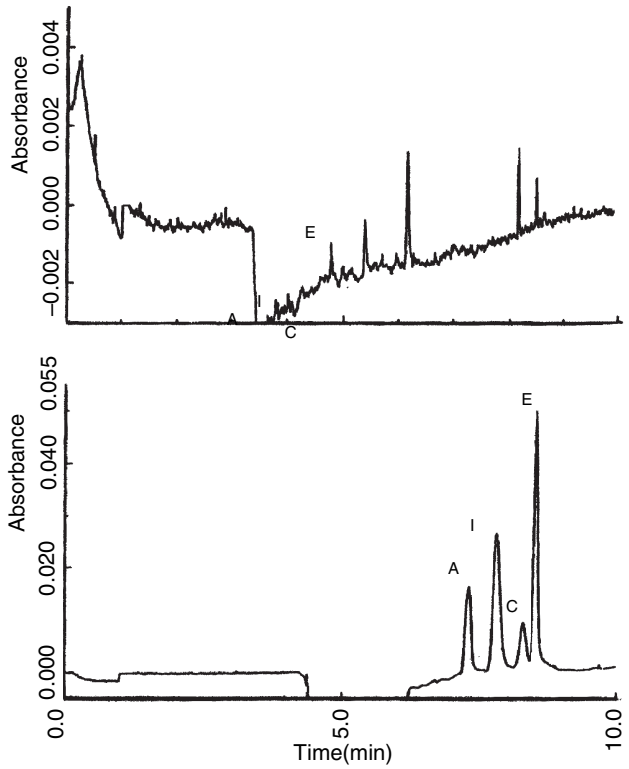

Fig. 3 Separation and stacking of some natural peptides (A = angiotensin, I = insulin B chain, C = impurity in the insulin B chain, and E = Leu-enkephalin). Top: at 1.5% loading of the capillary; bottom: at 30% loading of the capillary.
Source: With permission from Peptide stacking by acetonitrile-salt mixtures for capillary zone electrophoresis, in J. Chromatogr. A.[26]

mechanism, transient pseudo-ITP.[13–16] The salts act as leading ions, while acetonitrile acts as a pseudoterminating ion (i.e., it provides the high field strength for stacking). Short-chain alcohols and acetone can also accomplish the same effect.[13] Optimum conditions for stacking by this method have been described.[15] Further, this method has been extended for the stacking of enantiomers.[16]

Stacking in MEKC

Stacking in MEKC is more difficult than in CZE. It requires controlling of several parameters, and it works for certain compounds better than it does for others, e.g., a higher efficiency of stacking is achieved with highly retained analytes. Also, polarity reversal, which is required in some procedures, is not easily accomplished on some CE instruments.

Several strategies have been devised by Quirino and Terabe for stacking in MEKC.[17,18] The main principles involved are low conductivity in the sample, removing the bulk of the sample buffer, reversed micelle migration, and sweeping (or interaction of) the analytes into the micelles. In the normal stacking mode, the neutral molecules are

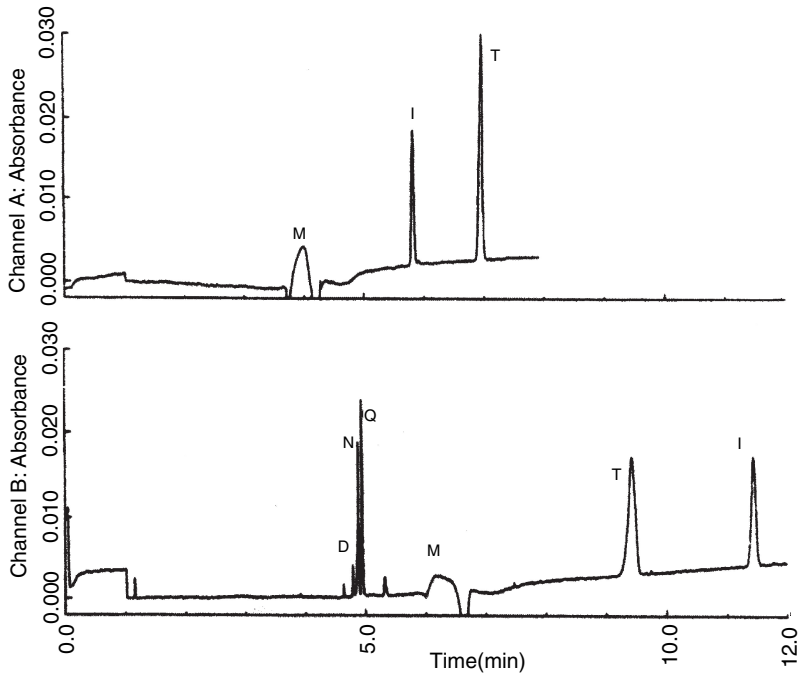

Fig. 4 Effect of the separation buffer type on stacking at a sample loading of 12% of the capillary volume. Top: Borate buffer 210 m*M*, pH 8.6; bottom: triethanolamine 160 m*M*, tricine 50 m*M*, pH 8.6 containing 10% acetonitrile. Separation of a mixture of weakly cationic and weakly anionic compounds in the same run: doxepin (D, 50 mg/L), *N*-acetylprocainamide (N, 50 mg/L), quinine (Q, 20 mg/L), theophylline (T, 50 mg/L) and iothalamic acid (I, 20 mg/L) at 14 kV, 254 nm; (M = Electro-osmotic flow).
Source: With permission from Stacking of weakly cationic compounds by acetonitrile for capillary electrophoresis, in J. Chromatogr. A.[27]

solubilized in a low-conductivity medium, e.g., in water or a very low concentration of micelles, to accelerate their migration. Another approach is to use reversed-migration micelles for stacking. Samples are prepared in low-conductivity matrices and injected as long plugs into the capillary. The polarity of the applied voltage is initially negative to facilitate stacking of the analytes and also the removal of the bulk of the sample matrix. Samples therefore stack as concentrated zones in the boundary between the sample and the separation zones. Once the current reaches 97–99% of the predetermined value, the polarity is switched to positive to enable the separation and detection of the stacked zones.[17] To avoid changes in polarity, the micelles can be prepared in acidic buffer with negative polarity, so that the micelles have a higher electrophoretic velocity than the EOF. The micelles from the cathodic vessel enter the neutral sample zone and cause the stacking, followed by the separation step.[18] Stacking here is mainly dependent on analyte retention factors and the nature of the pseudostationary phases.

Quirino and Terabe have also devised the "sweeping" concept, in which the sample itself has no additives or complexation reagents. These additives are added to the separation buffer. The analyte, the pseudostationary phase, or both should have electrophoretic velocities when an electric field is applied. The extent of preconcentration is dictated by the strength of the interaction between the analyte and the pseudophase.[19] A mixed mode for further stacking is one in which the sample is concentrated first by field-amplified injection under non-micellar conditions. The buffers are changed and the polarity is reversed to induce sweeping of the analytes into a micellar SDS solution, giving a great increase in sensitivity for some cations.

A different approach for stacking introduced by Palmer et al.[20] involves a high-conductivity sample matrix invoked to transfer field amplification from the sample zone to the separation buffer. This causes the micellar carrier in the separation buffer to stack before it enters the sample zone. Micelle stacking is induced by simply adding a salt to the sample matrix to achieve a two- to threefold increase in conductivity as compared to that of the separation buffer. Neutral analytes moving out of the sample zone with EOF are efficiently concentrated at the micelle front.[20] Stacking of neutral analytes based on electrokinetic injection of high-salt sample matrixes by EOF, occurring simultaneously with the injection procedure, has also been described.[20]

SAMPLE BAND BROADENING AND DESTACKING

Band broadening can occur due to many factors in CE. Often it occurs when the sample size is increased greatly in the continuous buffer mode or when the conductivity of the sample increases over that of the separation buffer. It can occur due to thermal effects or band spreading in the connection assemblies. Higher conductivity can accidentally arise from extra salts in the sample or just from a very high concentration of the sample. These effects can lead to non-symmetrical peaks too. Non-symmetrical peaks can appear as migration times (in CE) or migration distances (in agarose electrophoresis), not matching well with those of the standards (Figs. 1 and 2).[2]

METHODS OF SAMPLE PREPARATION FOR CE

Sample extraction and purification yield clean samples suitable for separation by CE. Unfortunately, they require time and extra steps. In the previous section, different simple maneuvers that avoid these extra steps were discussed. However, if the sample analytes are too low in concentration and are present in an unusually complex matrix, sample extraction and purification become necessary as the last resort. Here, several methods used for sample preparation suitable for CE are described. Some of the described methods are applicable to different or several kinds of analytes, while others are more suited for specific ones.

Dilution and Direct Sample Injection

One of the main advantages of CE for routine analysis in industrial and clinical settings is the simplicity of sample introduction. If the compound of interest has a strong absorbance and/or is present in a high concentration relative to that of the interfering compounds, it can be injected directly without any sample preparation or with simple dilution with an appropriate solvent.

To tolerate extra ions in the sample, the ionic strength of the buffer should be as high as possible. Many separations of pure standards utilize very low-ionic-strength buffers so as to apply high voltages and thus accomplish the separation in a short period of time. However, this approach does not work well for biological and industrial samples, where the samples have many components and contain high salts and proteins. In these cases, high-ionic-strength buffers are needed for the separation, which dictate low voltages and thus result in slow separations. High-ionic-strength buffers also favor stacking.

MEKC has the advantage of tolerating small concentrations of proteins without ruining the capillary. The surfactants used for the micelles solubilize the proteins and release the bound drugs (or small molecules). However, the wavelength and the separation conditions have to be chosen in such a way that the proteins do not interfere with or mask the compounds of interest. Several drugs have been successfully analyzed with direct serum or urine injection, especially by MEKC, where the micelles solubilize the proteins.[21]

Extraction with Direct Injection from Organic Solvent

Some analytes can be extracted with organic solvents nonmiscible in water, such as chloroform or methylene dichloride, and injected directly as illustrated in Fig. 5. The advantages include eliminating both the matrix effects and the tedious step of evaporation. However, this will be restricted to compounds highly soluble in the organic solvents and/or present in relatively high concentration.[22]

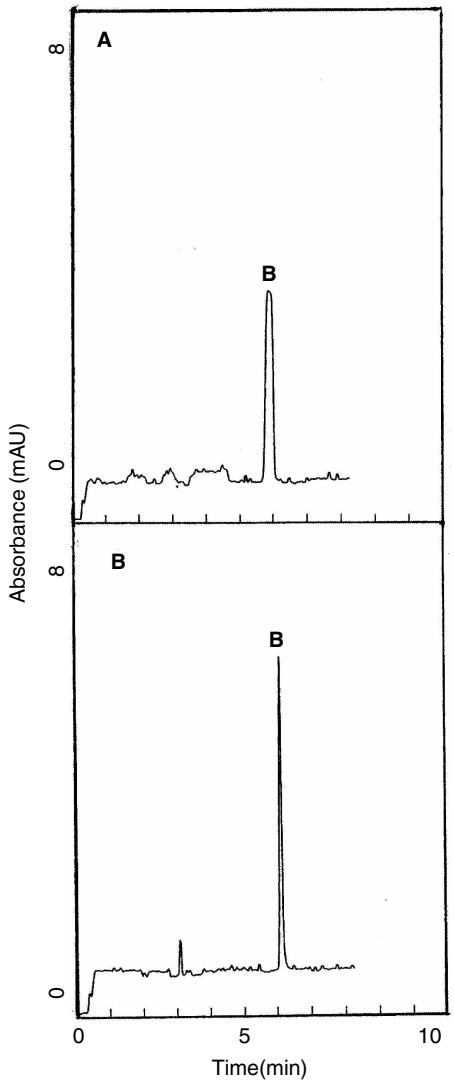

Fig. 5 Extraction of analytes with organic solvents (A) Benzoic acid standard 30 mg/L in the electrophoresis buffer (separation under non-stacking) and (B) Benzoic acid 30 mg/L in 10 mmol/L HCl extracted with chloroform (containing 10% methanol) with direct chloroform injection for 40 sec on a capillary 50 μm × 40 cm, 214 nm, and 12 kV. Separation buffer: boric acid 400 mg, sodium carbonate 200 mg, polyethylene glycol 200 mg in 100 ml water. (B = benzoic acid.)

Extraction and Precipitation

If the analyte is present at very low concentrations in the presence of overwhelming interfering compounds, cleanup and concentration steps become necessary. Solvent extraction procedures similar to those of chromatographic techniques are often used for sample

preparation for drugs and many other small molecules. Solid-phase methods are very popular because of the wide choice of packing material. Sample extraction methods offer two other main advantages in CE, namely, sample concentration and elimination of both sample ions and proteins. Double solvent extraction is very useful for electrokinetic injection, especially for basic compounds. It eliminates the variability resulting from matrix effects in electrokinetic injection. Some compounds such as proteins can be precipitated preferentially with organic solvents and reconstituted.

In the last few years, there has been an interest in new microextraction methods, which are more suitable for CE, especially because this technique does not require large volumes of the sample.[23]

1. *Solid-phase microextraction* (SPME) is a solvent-free sample preparation technique commercially available using a thin coating, such as of polymethylsiloxane, polyacrylate, or carbowax, of varying thicknesses attached to the surface of a fused fiber (e.g., silica) as the extraction medium. The fiber is dipped first into the sample for a certain period of time, then into the eluting solvent, e.g., organic solvent, and injected directly. Initially, this technique was applied for the analysis of organic compounds by gas chromatography (GC) in the field of environmental sciences; however, it has been successfully extended to the analysis of a wide variety of compounds such as naproxen and tricyclic drugs by CE and liquid chromatography (LC). Extraction yield depends on optimizing the pH, salt, temperature, and time.
2. *Molecular imprints*: A template is prepared in such a way that certain selected compounds interact with it, based on steric and chemical memory. They are analogous to antibodies in immunoassays, where they can also be used in competitive assays. Molecular imprints have been used in LC and CE.
3. *Membranes*: In this technique, different membrane types such as microporous, homogenous, ion exchange, and asymmetric have been employed for sample preparation for GC, HPLC, and CE. The extraction in this technique can be further automated.
4. *Immunoaffinity solid-phase extraction*: An antibody attached to a solid material is used to bind the compounds of interest. Optimization of the binding and elution and miniaturization of this type of sample cleaning have been applied for CE and LC.
5. *Homogeneous liquid–liquid extraction*: This uses the phase separation phenomenon from homogeneous solutions as salting effect or cloud point extraction, with the target solute being extracted into a small volume of a separate phase. This method can give high concentration and is suited for CE.

Sometimes extraction does not yield a sufficiently concentrated sample for the desired sensitivity. In such cases, dissolving the sample in an appropriate solvent can give a further concentration based on stacking especially if used in a long and a wide capillary.[24] The importance of sample extraction and concentration together with stacking for CE has been emphasized by dedicating a special issue of *Journal of Chromatography A* to this subject.[23]

Dialysis

Dialysis is one of the simplest techniques for the desalting and purification of proteins; however, it is a slow process. Large molecules can be separated from small ones through special dialysis membranes, which are available with different molecular weight cutoff points. However, the use of small commercial dialysis cells or blocks is more suitable for CE than the use of traditional bags.

Filtration and Ultrafiltration

Small volumes can also be filtered rapidly through special filtration devices in a microfuge at 15,000 × *g*. As in dialysis, the filtration membranes come with different cutoff pores for different molecular weights. Both sides of the filtration chambers can be used for CE analysis based on whether the compound of interest has a high or low molecular weight.

Organic Solvent Deproteinization

In HPLC, alcohols and especially acetonitrile are often added to the biological samples to remove (serum) proteins. In CE, in addition to the removal of proteins, the presence of acetonitrile and small-chain alcohols in the sample leads to stacking, as discussed earlier. Protein removal can also be accomplished by alcohols such as ethanol and by acids such as trichloroacetic acid. In CE, precipitation with acids is less desirable than the precipitation with organic solvents, as it increases the salt load. Following precipitation, proteins can also be dissolved in the appropriate buffers and assayed by CE.

Desalting

Desalting is a difficult procedure to perform in routine assays. There are several methods for desalting, such as: 1) dialysis, as described earlier; 2) using ion exchangers, e.g., Chelax 100 and AG 50X2; and 3) reversing the polarity during CE. Organic solvent extraction is another simple method for eliminating ions. In general, the use of high-ionic-strength running buffers enables the direct analysis of samples containing relatively high salt concentration, eliminating in many instances the need for desalting.

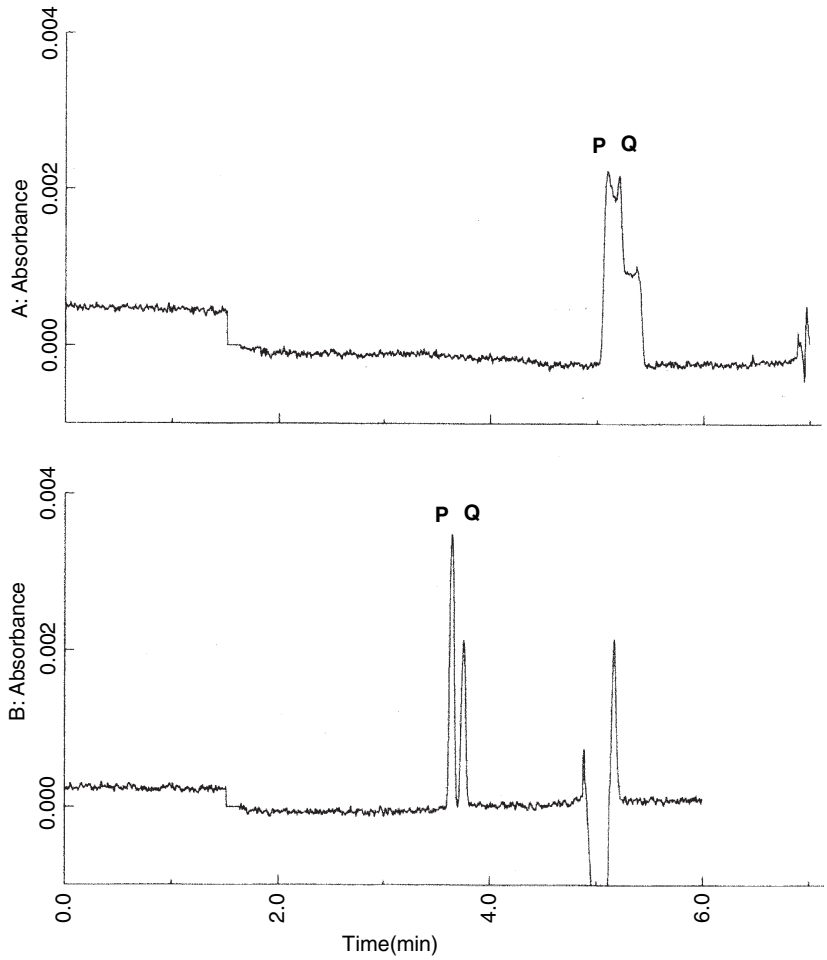

Fig. 6 Comparison of pressure injection vs. electroinjection. Propranolol (P, 10 mg/L) and quinine (Q, 10 mg/L) in serum deproteinated with 2 volumes of acetonitrile. Top: Pressure injection 30 sec; bottom: Electromigration injection at 2 kV for 30 sec. Electrophoresis buffer: 90 mmol/L phosphate buffer, pH 6.2.

Gel Filtration

This technique can be used to purify proteins of different sizes and also for desalting.

Solid-phase ligands binding/antibodies bound to inert beads: The recent interest in proteomics placed great emphasis on analyzing proteins and peptides from biological fluids that are present in very low concentration among numerous different proteins (~10,000), some with very high concentration (such as albumin, globulins, and transferrin). If the abundant proteins are not removed first, they make the analysis very difficult by overloading the capillary. Several methods can be used to remove these proteins and enrich those of interest; some are commercially available as kits. In general, several separation or binding steps are used to remove or enrich these proteins e.g., size exclusion, anion exchange chromatography, hydrophobic chromatography, and especially antibodies bound to inert beads or solid-phase ligands. Several of the purification methods discussed above have been compared for protein purification and analysis by CE.[25]

MATRIX EFFECTS IN ELECTROINJECTION VS. HYDRODYNAMIC INJECTION

The common mode of sample introduction on the capillary is hydrodynamic injection making use of low pressure, vacuum, or height. Electrokinetic injection (or electromigration) is less frequently used. The latter method shows bias in the peaks when multiple components are present in the sample. Early peaks tend to be taller because the more positive components migrate faster. This method is also more susceptible to matrix effects. Small ions, including H^+ present in the sample, decrease the peak height of the analytes, i.e., decrease transfer of the sample to the capillary through a decrease in field strength in the sample. Thus, this method is excellent when dealing with pure samples prepared in water or pure standards.

On the other hand, under appropriate conditions, electroinjection can yield better stacking and better separation than hydrodynamic injection. It has been observed that just by dissolving the sample in acetonitrile, in place of water or an aqueous buffer, 2 to 10 times better stacking can be obtained by electroinjection (due to the high field

amplified injection) as compared to pressure injection (Fig. 6), or as compared to samples prepared in water. As the analytes concentrate at the inlet of the capillary, the whole capillary is left for better separation action. Other organic solvents enhance the sensitivity of electroinjection to different degrees. These solvents offer the added advantage of removing proteins from the sample.

CONCLUSIONS

Unlike in HPLC, the sample matrix is very important in CE. The sample matrix affects resolution, quantification, and precision through its influence on the current conductance and effects on the capillary walls. The sample matrix tends to ruin the separation; however, under appropriate conditions, it can improve separation. Samples with a clean matrix can be injected directly without treatment on the capillary. However, samples from biological or industrial origin and those with low concentration require special preparation or thoughtful planning for separation to avoid the deleterious effects of the sample matrix. In addition, these samples also require special buffers with specific ionic strength, special washing solutions, and steps for the capillary between samples. Different strategies to improve the separation for both hydrodynamic and electroinjection in CE through different methods of sample preparation and buffer manipulation have been presented.

Sample Preparation for HPLC

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Among the various steps of a sample analysis, from sample collection to the final report of the results, the most tedious and time-consuming one is the *sample preparation*, which requires almost two-thirds of the total analysis time. It is also the most error-prone part of the process, as it contributes about 30% in the sources of errors, impacting on the precision and the accuracy of the overall analysis.

An effective sample preparation helps the analytical chemists to cope with today's increasing demands in the laboratory. No matter how sophisticated the available analytical equipment is, the limits of the analytes' detectability in any analytical procedure eventually depend on the effectiveness of the sample preparation.

OVERVIEW

The main objectives of sample preparation are as follows:

1. Matrix modification in order to:
   a. Prepare the sample for introduction (injection) onto chromatographic column.
   b. Render the solvent suitable for the analytical technique to be used.
   c. Prolong the instrument's lifetime (e.g., column lifetime).
2. Clean-up purification in order to:
   a. Remove impurities and obtain the required analytical performance and selectivity.
   b. Reduce matrix interference.
3. Analyte enrichment (preconcentration) in order to improve the method sensitivity (reduction of the limits of detection and quantification).

The sample, prior to high-performance liquid chromatography (HPLC) analysis, has to be in a liquid state. By contacting the sample with a solvent, the analytes are extracted. Then, the solvent is separated from solid residue by means of decantation, filtration, or centrifugation. Furthermore, it can be concentrated by evaporation.

Typical traditional and modern approaches of sample preparation techniques for liquid and solid samples are summarized in Table 1. These techniques are further discussed under the respective paragraphs.

SELECTION OF THE SUITABLE SAMPLE PREPARATION TECHNIQUE

The term sample preparation may refer to the various stages of the analysis procedure, as shown in Fig. 1. An ideal sample pretreatment technique should have the following characteristics:

1. Simplicity and rapidity.
2. High extraction efficiency with quantitative and reproducible analyte recoveries.
3. Specificity for the analytes.
4. High sample throughput.
5. Fewer manipulation steps to minimize the analyte losses.
6. Amenability to automation.
7. Use of the minimum amount of solvent, compatible with many analytical techniques.
8. Low cost regarding reagents and equipment.

As no ideal sample preparation technique exists, each technique has to be considered according to its own advantages and disadvantages. The analyst may choose the most suitable one when developing a method, depending on several parameters such as sample matrix, nature, physical and chemical properties of analytes, concentration, and analytical technique that is to be applied.

Automation is one issue of paramount importance, as the biggest problem with sample preparation is time. The benefits of automation, apart from the obvious economic one, include the reduced manual operations and laboratory materials required, the increased sample throughput and productivity per instrument, and the higher precision with minimal risk regarding the handling of contagious or radioactive samples.

PRELIMINARY SAMPLE PREPARATION PROCEDURES

Frequently, intermediate stages may be required prior to the extraction techniques for sample preparation. These are to minimize the analyte solubility in the matrix and to maximize the selective isolation for a quantitative, rapid extraction of the analyte of interest (e.g., changing of pH or ionic strength). Proteins must be removed prior to extraction by denaturation with organic solvents or chaotropic agents, precipitation with acid (pH modification), addition of a compound that competes for binding sites, or use of restricted-access media. Conjugated components may need to be hydrolyzed to release the free compound. Lipids may be extracted into a non-polar organic solvent.

Once transferred into a liquid phase, the sample can either be directly injected or treated further using the steps outlined in Table 2.

TRADITIONAL LIQUID SAMPLE PREPARATION TECHNIQUES

Liquid–Liquid Extraction

Sample dilution can occasionally be applied if the analyte is present in such a high concentration that the analyte is still detectable, although this is rarely efficient. For the major part of the analyses, the analyte has to be isolated from the sample by using an extraction technique.

For many years, liquid–liquid extraction (LLE) was the classical technique for the preparation of liquid samples. In spite of several drawbacks, it was widely used in all fields of analysis. It usually involves mixing of an aqueous sample solution with an equal volume of immiscible organic solvent for a period of time, and then allowing these two liquid phases to interact so that the analytes of interest are extracted from the aqueous layer into the organic layer, as the organic solvent has a larger affinity for them. The selectivity and efficiency of the extraction process are governed by the choice of the two immiscible liquids. The more hydrophilic compounds prefer the aqueous phase, and the more hydrophobic compounds will be found in the organic solvent, as

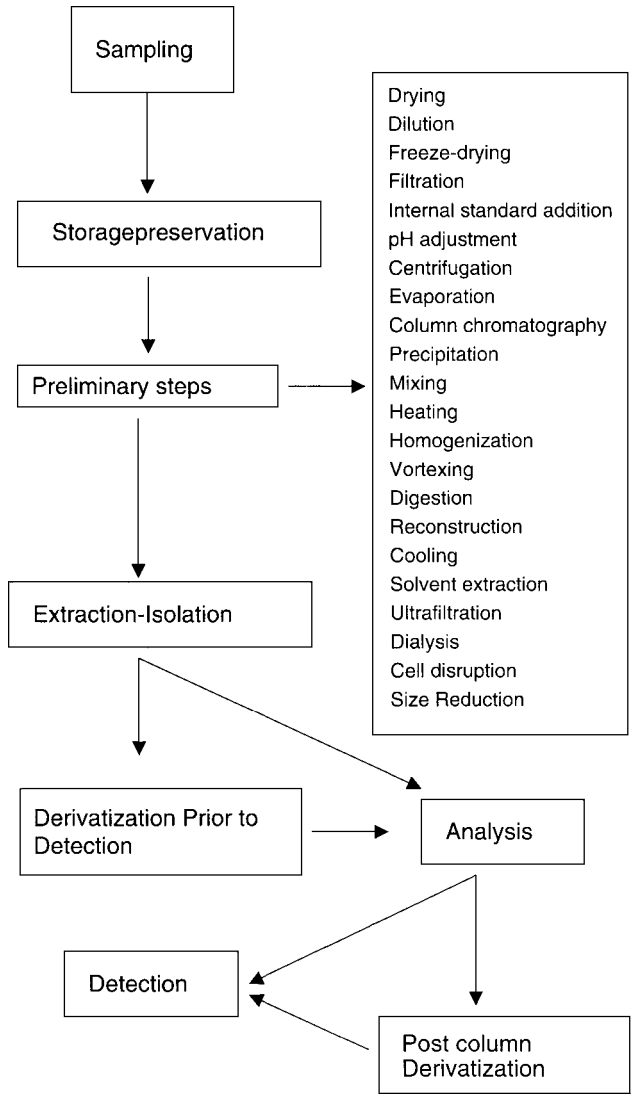

Fig. 1 Stages of sample preparation.

Table 2 Further treatment requirements for a sample in liquid phase before analysis.

- Dilution to the appropriate concentration ranges with a compatible solvent in case it is too concentrated.
- Concentration by LLE, SPE, evaporation, or lyophilization.
- Derivatization to stabilize, freeze-drying, and storage at 4°C, far from light or air exposition, in case it is reactive or thermally or hydrolytically unstable.
- Removal of unwanted high-molecular-weight substances by size exclusion chromatography, dialysis, ultrafiltration, precipitation, and use of supported liquid membrane.
- Removal of particulate matter by filtration, centrifugation, or sedimentation.
- Solvent exchange if the solvent is not compatible with the analytical method.
- Solvent can be removed by evaporation, lyophilization, or distillation, and the analytes can be reconstituted in a solvent and at a concentration suitable for the technique that will be used for analysis.
- Addition of internal standard.

"like" dissolves "like." Organic solvents such as methylene chloride, chloroform, ethyl acetate, and diethyl ethers are preferred as they can be easily removed by evaporation. Chelating and other complexing agents, ion pairing, and chiral reagents may also be used. After the immiscible liquids are separated, the layer containing the extracted analytes is removed, concentrated to dryness, and reconstituted in an appropriate solvent that is compatible with the analytical system (e.g., the HPLC mobile phase).

A limitation of this technique is that polar, water-miscible solvents cannot be used for the extraction. Other drawbacks of this technique are:

1. The use of large quantities of organic solvents, leading to a considerable cost for their acquisition and disposal.
2. The formation of emulsions during the mixing procedure.
3. Evaporation of the solvent is time-consuming.
4. The coextraction of other matrix-interfering components with similar properties.
5. It is difficult to be automated in its classical form (using a separation funnel or similar apparatus), although a number of flow-system LLE approaches have been presented, applying the principle of flow injection analysis.

In the latter approach, a chemical reaction or complexation takes place in a mixing-reaction coil, resulting in an extractable component segmented with an organic immiscible solvent steam at the phase segmenter, where small reproducible droplets of one phase are formed in the other. The phase containing the analytes of interest can be monitored by a flow-through detector, and the unwanted phase is directed to waste.

Automation in LLE has been also introduced using an instrumentation that can automate all or part of the extraction and concentration process. A number of autosamplers and workstations for HPLC and gas chromatography (GC) can perform LLE. Robotic systems can be used to handle larger-volume LLE.

Column Extraction–Liquid–Liquid Extraction

Column extraction based on the theory of LLE is a widely used technique in biochemistry, toxicology, pharmaceutical analysis, and other fields. Extrelut by Merck (Darmstadt, Germany) and Extube by Varian (Harbor City, California, USA) are commercially available prepacked columns used in these applications (Fig. 2A). Extraction is performed by fixing an aqueous solution or suspension to a supporting material (stationary phase) and allowing the other immiscible solvents (mobile phase) to pass over it. The two phases are in contact, thus permitting a continuous and multistep extraction to occur. This technique can replace the conventional LLE in a separating funnel, and thus it becomes more efficient and practical as no emulsions can be formed, less solvent volumes are used, and preparation time is reduced. Body fluids (e.g., urine) are the best example for the application of in-column LLE.

MODERN LIQUID SAMPLE PREPARATION TECHNIQUES

Solid-Phase Extraction

Solid-phase extraction (SPE) is a particularly attractive, fast, and effective technique for the isolation and preconcentration of target analytes that avoids or eliminates the disadvantages of LLE, tending to replace it in many applications.

The principle of SPE involves a partitioning of analytes to be extracted between two phases: a solid phase, the sorbent, and a liquid phase, the matrix, which contains possible interferences. Analytes must have a greater affinity for the solid phase than for the sample matrix (retention or adsorption step), and they are subsequently removed by eluting with a solvent that has a greater affinity for the analytes (elution or desorption step). The different mechanisms of retention or elution are a result of intermolecular forces among three components: the analyte, the active sites on the surface of the sorbent, and the liquid phase or matrix.

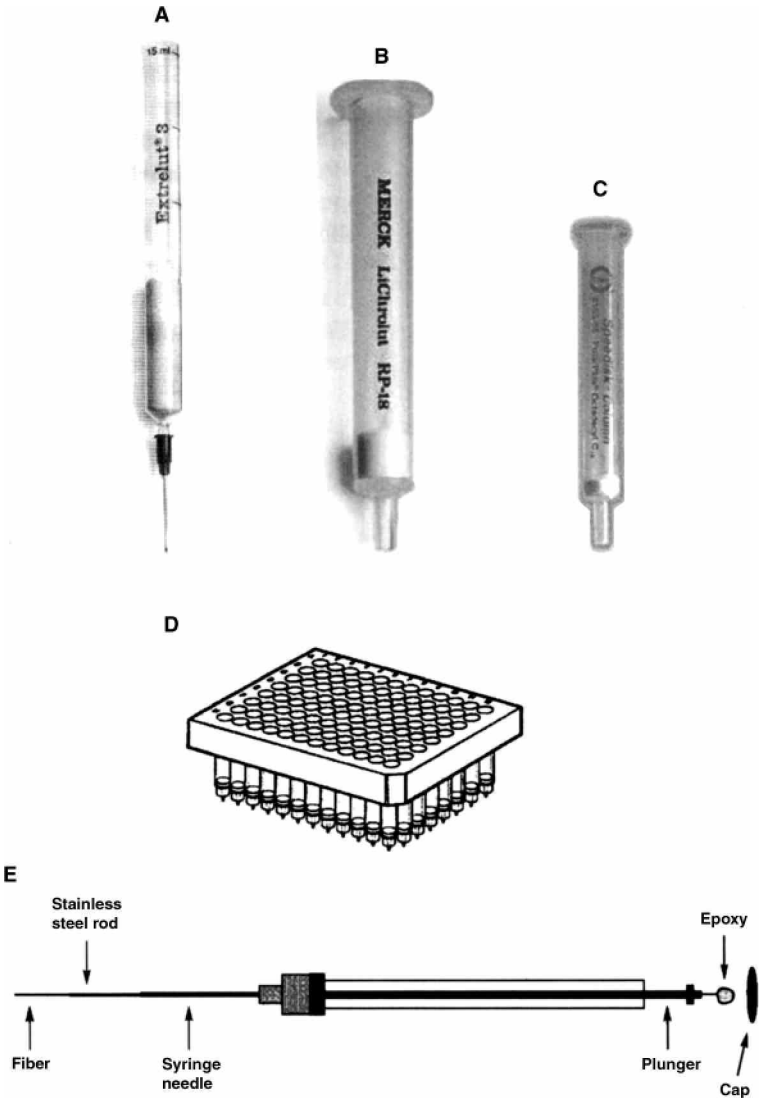

Fig. 2 (A) Extrelut column for LLE; (B) SPE cartridge; (C) SPE cartridge, disk format; (D) 96-well extraction plate; and (E) SPME device.

Solid-phase extraction objectives, apart from the removal of interfering compounds and the preconcentration of the sample, include:

1. The fractionation of the sample into different compounds or groups of compounds as in classical column chromatography.
2. The storage of analytes that are unstable in a liquid medium or with relatively high volatility.
3. The derivatization by reactions between the reactive groups of the analyte(s) and those on the adsorbent surface.

The major types of commercially available SPE product configurations are:

1. Syringe barrel columns.
2. Cartridges.
3. 96-Well plates.
4. Disk membranes.
5. Solid-phase extraction vacuum manifolds for simultaneous processing of 10, 12, 20, and 24 SPE tubes.

Fig. 2 illustrates the typical commercially available SPE formats.

Solid-phase extraction cartridges are available in a wide variety of sizes, with packing capacities ranging from 20 mg to 10 g and with reservoir volumes as large as 30 ml. In this configuration, extraction is carried out by a disposable cartridge of polypropylene, in a shape similar to an injection syringe without plunger and without injection needle. The column is filled with the sorbent (particle size of 40 μm) fixed between two frits (pore size of 20 μm) of polypropylene. The upper part of the barrel serves as a sample reservoir. The column can be connected to extraction systems by Luer fittings.

Although gravity can facilitate the flow of most organic solvents through the columns, samples and more viscous

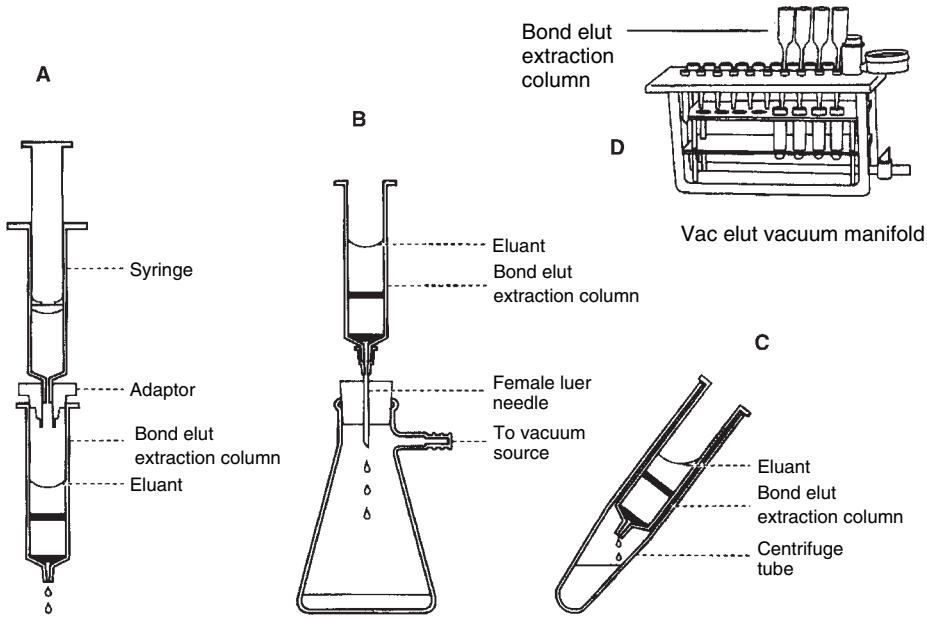

Fig. 3 Different ways of SPE process. (A) Positive pressure; (B) vacuum; (C) centrifugation; and (D) vacuum manifold.

solvents must be drawn by vacuum applied to the column outlet, by positive pressure applied to the column inlet (gas pressure from a syringe), or by centrifugation (Fig. 3). The typical flow rate ranges between 0.2 and 1.5 ml/sec.

All sample types are amenable to SPE with suitable handling: solids, liquids, semisolids, etc. Solid-phase extraction is extensively used in sample preparation, as it offers a fast, safe, and convenient means for subsequent analysis by chromatographic techniques [HPLC, thin-layer chromatography (TLC), GC, etc.]. The major benefit is that it requires less solvent than conventional LLE methods. Impurities are removed and the analytes are concentrated, leading to a higher sensitivity in subsequent analysis. The SPE process can be carried out either online or off-line.

Solid-phase extraction is performed according to the following steps:

1. Conditioning of the sorbent (i.e., solvation; activation of functional groups) and preparation of the sorbent to interact with the sample.
2. Sample loading. The sample, optionally containing the internal standard, is forced through the sorbent of the cartridge. The component of interest and some undesired compounds are adsorbed by the sorbent. In this step, the interaction between the analyte and the sorbent should be predominant. The most effective sorbent facilitates the interaction between the functional groups and the analyte. To enhance the retention of the analyte, the sample can be diluted with water, so that the polarity of the environment of the analyte is increased.
3. Washing to remove the undesired polar matrix constituents. A solvent of low elution strength is chosen as a washing solvent (water or a buffer) so that the analyte is not eluted from the sorbent. Only after the completion of this step may some air pass through the column.
4. Sorbent drying. This may be necessary to remove water if the elution solvent is immiscible with it. Drying can be performed by vacuum aspiration, nitrogen flow, or centrifugation. Analytes in a purified form are now present on the column.
5. Elution or extraction process. This aims for the quantitative recovery of the analyte that is achieved by selective desorption of the compounds of interest from the sorbent with a suitable solvent and collects the cartridge effluent. The interaction between the analyte and the elution solvent should be so strong that the interaction between analyte and sorbent will be overcome.
6. Solvent evaporation. The extract is directly injected or evaporated under a gentle stream of nitrogen and reconstituted in the mobile phase or after the addition of internal standard.

The optimization of SPE must be executed in each of these steps for best performance. Two different approaches can be chosen:

1. The analyte is retained on the sorbent while components pass through to waste. The analyte will be eluted later from the sorbent, with a suitable solvent, to be analyzed.
2. The matrix components are adsorbed while the analyte is evacuated.

The first approach is generally preferred as less sorbent is required and isolate preconcentration is possible. The

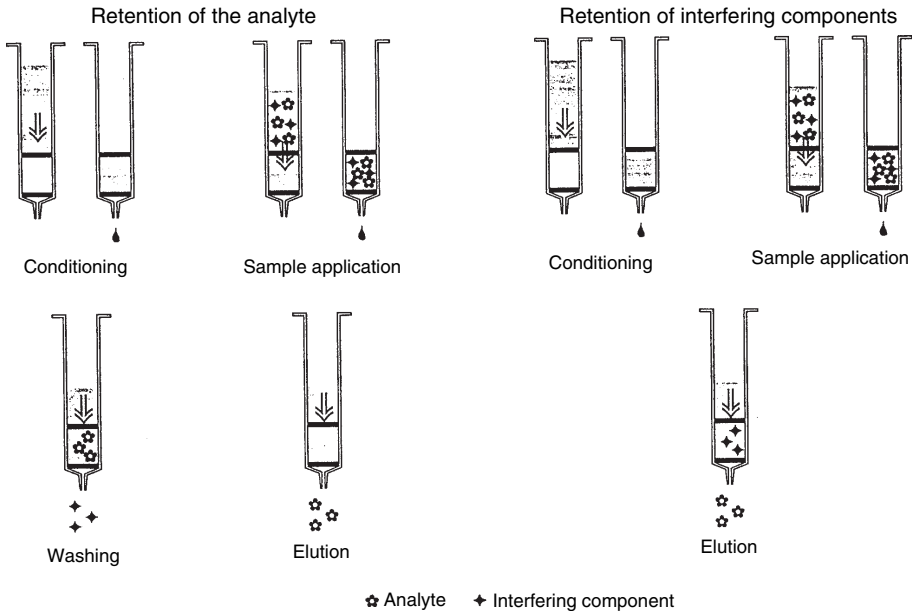

Fig. 4 The steps of solid-phase extraction technique.

second approach is selected when interferences are present but the concentration of analytes is not required (Fig. 4).

Solid-Phase Extraction Sorbents

Several SPE sorbents have been developed. These can be classified according to the primary interaction possibilities of the functional groups of the sorbents, mostly non-polar, polar, or ionic. Ionic groups consist of cation exchange and anion exchange sorbents and contain functional moieties that can act as ion exchangers. Silica-based sorbents include the following: reversed phase (RP)—highly hydrophobic octadecyl (C_{18}), octadecyl (C_{18}), octyl (C_8), ethyl (C_2), cyclohexyl, and phenyl; wide-pore RP—butyl (C_4); normal phase—silica modified by cyano (–CN), amino ($–NH_2$), and diols; adsorption, silica gel, fluorisil, and alumina; and ion exchangers, amino ($–NH_2$), quaternary amine (N^+), carboxylic acid (–COOH), and aromatic sulfonic acid ($ArSO_2OH$). Other sorbents with a wide variety of specifications are also introduced in SPE: polymeric sorbents are polystyrene–divinylbenzene (PS–DVB) resins that overcome many of the limitations of the silica-based phases. The broader range of pH stability increases the range of method development and flexibility, providing greater analyte retention of polar compounds than C_{18} sorbents. However, a conditioning step with a wetting solvent is still required.

Hydrophilic–lipophilic polymeric sorbents have been recently introduced, claiming that no conditioning step is required as the sorbent preserves analyte retention, even if the bed dries out. Commercially available products include Oasis by Waters and Abselut by Varian. These are copolymers of polyvinyl pyrrolidone (a hydrogen acceptor, which increases the water wettability of the polymer) and a cross-linked PS–DVB resin that provides the RP retention necessary to retain analytes. These are designed to extract an extensive spectrum of analytes: lipophilic, hydrophilic, acidic, basic, and neutral. They exhibit greater pH stability and enhanced retention over C_{18}-bonded silica.

Mixed-mode sorbents contain both non-polar and strong ion (cation and/or anion) exchange functional groups, targeted for the extraction of basic drugs.

Affinity sorbents such as the *restricted-access matrix* sorbents, *immunosorbents*, or *molecularly imprinted polymers* (MIPs) have been introduced as well. These are based upon molecular recognition using antibodies with a high degree of selectivity or with molecularly imprinted polymer.

Graphitized carbon: Porous graphitic carbon, similar to the liquid chromatography (LC)-grade Hypercarb, is available in SPE cartridges. This is characterized by a highly homogenous and ordered structure, made of large graphitic sheets with a specific area approximately 120 m^2/g. Compounds are retained by both hydrophobic and electronic interactions so that non-polar analytes, and also very polar analytes, can be retained from aqueous matrices. Owing to the different retention mechanism, acetonitrile and methanol can be inefficient, and it is preferable to use methylene chloride or tetrahydrofuran.

Column selection is based on the nature of the analytes, the nature of the sample matrix, the degree of purity required, the nature of the major contaminants, and the analytical technique applied.

Sorbent–Isolate Interaction

The most common chemical interactions between sorbent and isolates are non-polar (van der Waals forces or

dispersion forces), polar (hydrogen bonding, dipole–dipole, and induced dipole–dipole), ion exchange (ionic), and covalent interactions.

Non-polar interactions are the weakest interactions, which are exerted between the CH bonds of the analyte and those of the sorbent, usually C_{18}. Because these are facilitated by a polar solvent environment, they play a crucial role in the bioanalysis of blood, plasma, serum, and urine.

Isolated compounds include alkyl, aromatic, alicyclic, or functional groups with significant hydrocarbon structure. All isolates have a potential for non-polar interaction (except inorganic ions and compounds with polar groups, e.g., carbohydrates). Because of this fact, the non-polar interactions are non-selective and allow the extraction of groups of compounds with different structures. Retention is facilitated by a polar solvent, while elution is facilitated by an organic solvent with sufficient non-polar character (MeOH, ACN, etc.). A wash solvent should be more polar than that used for elution.

Polar interactions occur between a polar group of the sorbent and a polar group of the isolate. Silica is the typical adsorbent. Examples of groups that exhibit polar interactions are carbonyl, carboxyl, hydroxyl, sulfhydryl, and amine groups; rings with hetero atoms and with unequal electron distributions; as well as groups with π-electrons, such as aromatic rings and double or triple bonds. Hydrogen bonding is one of the most significant polar interactions. Polar interactions are stronger than non-polar ones. Although they provide greater selectivity, they have the disadvantage of being facilitated by a non-polar environment. Highly polar solvent facilitates elution, while wash solvent should be less polar than those used for elution.

Ionic interactions are exhibited between two groups (of analyte and sorbent) with opposite charge. These are the strongest interactions that can be seen between an analyte and a sorbent. Because few compounds possess either a cationic or an anionic group, the selectivity is high. Ionic interactions can only be effected in a polar environment. For an actual ionic interaction, it is necessary that the respective functional groups of sorbent and analyte are both ionized. Analytes can be eluted in two ways:

1. By using an elution solvent of such a pH that the respective functional groups of either the sorbent or the analyte are neutralized.
2. By using an elution buffer with a high concentration of a counterion (an ion of a charge opposite to that of the functional group of the sorbent), which will compete for the active sites of the sorbent with the analyte. Evidently, a combination of both elution ways is possible.

Applications of SPE include clinical analysis, pharmaceuticals, food analysis, environmental analysis, agrochemicals, forensic samples, etc.

Solid-Phase Extraction Disk Technology

Solid-phase extraction in disk format has been designed to overcome the limitations of the conventional packed-bed SPE columns. Disks exhibit minimal channeling, have small void volumes, do not require frits, have low capacity for interference (cleaner extracts are provided), and capture analytes of interest very effectively. They require lower solvent volumes, providing a faster sample processing and an increased throughput. Disk products include rigid disk, flexible disk, and thin packed beds of small particles between two retained screens.

A typical extraction sequence is similar to the traditional SPE, although 500 μl of the appropriate solvent is sufficient for disk conditioning and extraction of the analytes. Several types of disk extraction media are commercially available in different dimensions depending on the application and sample volume. The most prevalent are paper-based, membrane-based, glass fiber-based, and polytetrafluoroethylene (PTFE)-based products. Commercially available products are Speediscs by Baker, Empore by 3M, Novo Clean by Alltech, and SPEC by Ansys Technol.

AUTOMATED SOLID-PHASE EXTRACTION SYSTEMS

Solid-phase extraction automation is accomplished off-line and online. In off-line automation, SPE cartridges are not directly connected to the high-pressure flow stream of the analytical instrument. In online SPE, the solid-phase device is inserted into, and becomes part of, the liquid or gas flow stream. Obviously, the hardware interfacing requirements for the two approaches differ. In the manual mode, a simple vacuum is used to pull the liquids through the cartridge. However, in the automated mode, positive gas or liquid pressure is more commonly used to push liquids through the cartridge. Off-line automated SPE usually involves some form of robotic manipulation using flexible robotic arms and semiflexible modified *x–y–z* liquid handling devices. Most of these systems are controlled by dedicated personal computers.

The benefits of the automated solid-phase extraction are:

1. Analysts can redirect their time to other tasks.
2. Automated systems can provide a higher sample throughput with higher accuracy and precision because of minimized systematic errors than do manual systems.

Early automated systems processed individual samples *in series*. The next sample in the series was not started until

the preceding sample had been completed or was on its way. However, this approach was slower than manual systems. Automated *parallel processing* SPE, where numerous samples are extracted simultaneously with significantly improved throughput, seems to be more practical. Such automated systems can achieve treatment of up to 400 samples per hour.

Autosamplers offer at some level sample preparation functions such as dilution, internal standard addition, and calibration standard preparation. In addition, some automated liquid handling devices have built-in heating, cooling, SPE, and other functions for performing automated sample preparation. These operations are controlled by a computer system.

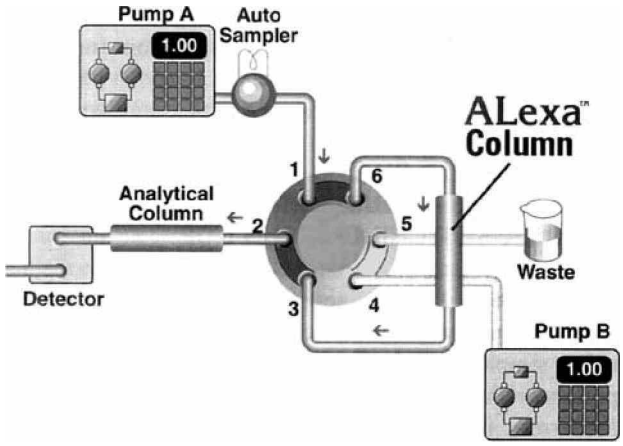

Fig. 5 Online SPE–LC column-switching technique.

ONLINE SOLID-PHASE EXTRACTION–LIQUID CHROMATOGRAPHY COLUMN-SWITCHING TECHNIQUE

Online SPE–LC utilizes the principle of *column switching*. A typical online arrangement is performed using simple electrically or pneumatically driven (six-port) switching valves and commercial precolumns and holders. A fresh disposable precolumn is used for every sample, and extraction is carried out in a way similar to the off-line sequence. A solvent delivery unit provides the solvent necessary to purge, wash, and activate the precolumn, and to apply the required volume of sample. High-pressure switching valves are used to couple two or more columns that trap either defined volumes or the collected samples, usually in a loop, and direct them to a second, usually the analytical, column. Valve configuration can be used for conventional HPLC analysis, and it can perform more advanced functions such as diverting the mobile phase containing the desired solutes from the first column to the second column for defined periods of time, a process called *heart-cutting* or *on-column concentration* (trace enrichment). Additionally, it can perform "backflushing" of specific sample components from one column to waste, which leaves only the peak of interest on the second column and front-cutting and end-cutting when needed. Selecting the appropriate valve and actuating it at the correct time cause different fractions of the sample to follow different paths through the column network.

In the most common case, the pretreated biofluid is injected onto the cartridge or precolumn, which retains the target molecules. Interfering sample constituents are flushed into waste. The analytes retained on the bonded phase of the cartridge or precolumn are eluted, online, via the switching valve onto the analytical column. Simultaneously to the analytical separation, an exchange of the cartridge or reconditioning of the precolumn takes place (Fig. 5).

The separation of the sample occurs not only by chromatographic means, but also by physical means that are under the control of the analyst and unrelated to the chemical properties of the analyte, thus resulting in very efficient separations.

Column-switching techniques have been used to analyze a sample directly, without any pretreatment stages, with the advantage of easy automation. The increase in safety and the improved analytical speed and accuracy often make up for the initial cost of the additional equipment that is required. Automating the column-switching systems can usually be accomplished using the timed-event tables included with HPLC instrument-control software; this enables a simpler and a more accurate control of complex column networks with minimal contamination and loss.

The limitation of column switching includes restricted sample enrichment. Another limitation is that the sample throughput using this approach probably will not be as high as for the other methods. Finally, it is considered too complicated to be practical, although modern instruments make these procedures relatively straightforward.

SOLID-PHASE MICROEXTRACTION

Solvent-free sample preparation techniques attract widespread attention to reduce the use of toxic organic solvents. Solid-phase microextraction (SPME) is a *solvent-free* technique for sample preparation that can integrate sampling, extraction, concentration, and sample introduction into single step, resulting in high sample throughput.

Generally, the term *microextraction* refers to an extraction technique where the volume of the extracting phase is very small in relation to the volume of the sample, and the extraction of the analytes is not exhaustive. The fraction of the initial analyte extracted depends on the partitioning of the analyte between the sample matrix and the extraction phase. The higher the affinity of the analyte for the extraction phase, the greater the amount of analyte is extracted.

Once sufficient extraction time has been reached and equilibrium has been established, further increases in extraction time do not affect the amount of analyte extracted.

Solid-phase microextraction is an adsorption/desorption technique used to analyze the volatile and non-volatile compounds in both liquid and gaseous samples used as an alternative to the headspace, purge-and-trap, solid-phase extraction, or simultaneous distillation/extraction techniques. Analytes are thermally desorbed and directly introduced into any gas chromatograph or GC/mass spectrometry (MS) system. When coupled to HPLC with the proper interface, the analytes are washed out of the fiber by the mobile phase.

The SPME device, shown in Fig. 2E, consists of a 1 cm length of narrow diameter fused silica optical fiber, coated on the outer surface with a thin film of stationary phase and bonded to a stainless steel plunger, and a holder such as a modified microsyringe. The fused silica fiber can be drawn into a hollow needle by using the plunger on the fiber holder. The fiber assembly consists of an outer protective septum-piercing needle and an inner fiber attachment needle to which the fiber is epoxied. The septum flange prevents GC or HPLC mobile phase from escaping when injecting. When not in use or during transfer, the fiber retracts into the needle. The SPME processing steps include:

1. Penetration of the syringe through the septum of the sample vial.
2. Extension of the fiber into the sample or in the headspace. Organic analytes partition into the stationary phase of the fiber until equilibrium is reached.
3. Retraction of the fiber into the syringe needle and, once the equilibrium is reached, withdrawal of the syringe from the sample vial.
4. Insertion/introduction of the needle into the GC port, depression of the plunger, and thermal desorption of the analytes. Alternatively, the analytes are washed out of the fiber by the HPLC mobile phase via a modified HPLC six-port injection valve and a desorption chamber that replaces the injection loop in the HPLC system. The SPME fiber is introduced into the desorption chamber, under ambient pressure, when the injection valve is in the load position. The SPME/HPLC interface enables mobile phase to contact the SPME fiber, remove the adsorbed analytes, and deliver them to the separation column. Analytes can be removed via a stream of mobile phase (dynamic desorption) or, when the analytes are more strongly adsorbed to the fiber, the fiber can be soaked in mobile phase or another stronger solvent for a specific period of time (e.g., 1 min) before the material is injected onto the column (static desorption) (Fig. 6).
5. Removal of the syringe from the injection port. It is now ready for resampling. The thermal or solvent treatment of the coated fiber in the injection port ensures that the fiber is free from interferences or residual compounds.

With solid or dirty matrices, such as sludge and biological fluids, the technique can be operated in the headspace mode as the fiber is exposed to the gas phase above the sample. Agitation by stirring or sonication of the sample matrix improves the transport of analytes from the bulk sample phase to the vicinity of the fiber. Other parameters that influence the partition equilibrium are the sample matrix, temperature, and properties of the coating and analyte (e.g., the thickness of the coating and the distribution constant for the analyte). An equilibrium time of 30–60 min is usually enough for direct immersion SPME. Full equilibrium is not necessary for high accuracy and precision from SPME, but consistent sampling time and other sampling parameters are essential. The vial size, the sample volume, and, when using liquid samples, the depth that the fiber is immersed into the sample should be consistent. The desorption of an analyte from an SPME fiber depends on the boiling point of the analyte, the thickness of the coating on the fiber, and the temperature of the injection port. As with any other extraction/concentration technique, it is best to use multiple internal standards, and to treat the standards and the analytes in an identical manner.

The equilibrium conditions can be described as:

$$n = K_{fs}V_fV_sC_0/K_{fs}V_f + V_s \quad (1)$$

where n is the number of moles extracted by the coating, K_{fs} is a fiber coating/sample matrix distribution constant, V_f is the fiber coating volume, V_s is the sample volume, and C_0 is the initial concentration of a given analyte in the sample.

As indicated by Eq. 1, after equilibrium has been reached, there is a direct proportional relationship between the sample concentration and the amount of analyte extracted.

Complete extraction can be achieved for small sample volumes when distribution constants are reasonably high. When the sample volume is very large, Eq. 1 can be simplified to:

$$n = K_{fs}V_fC_0 \quad (2)$$

In this equation, the amount of extracted analyte is independent of the volume of the sample. In practice, there is no need to collect a defined sample prior to analysis, as the fiber can be exposed directly to the ambient air, water, production steam, etc.

The commercially available fibers include polydimethylsiloxane (PDMS; 100, 30, and 7 μm), PDMS–divinylbenzene (PDMS–DVB; 65 μm), polyacrylate (PA; 85 μm), carboxen–PDMS (CAR–PDMS; 75 and

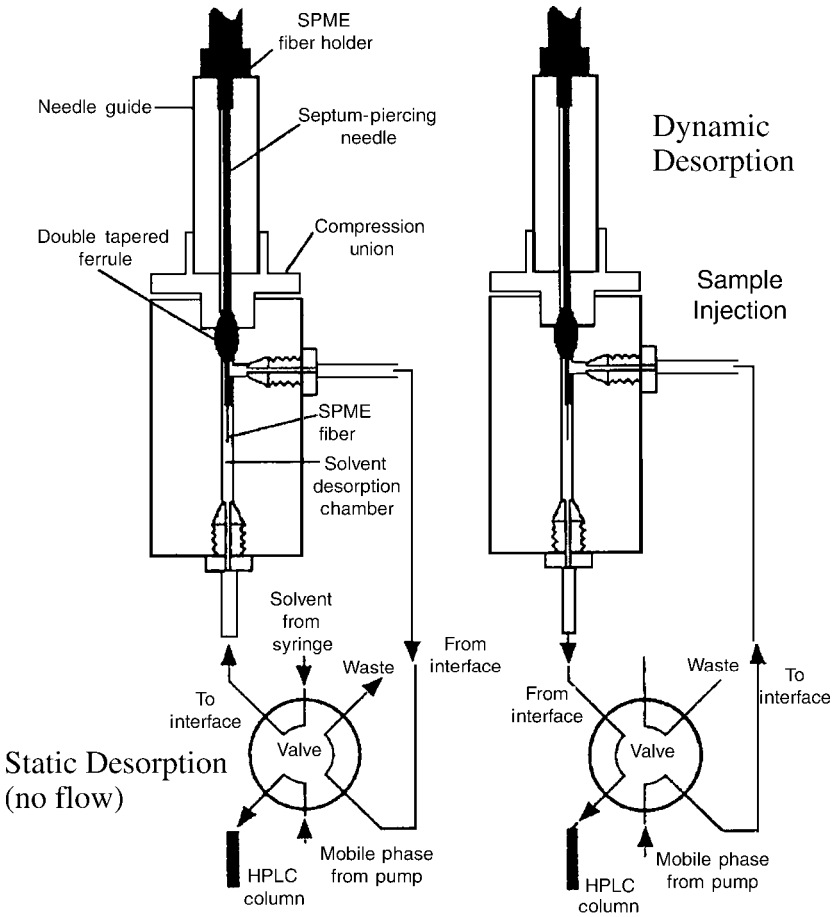

Fig. 6 SPME/HPLC interface.

85thinsp;μm), Carbowax–DVB (CW–DVB; 65 and 75 μm), Carbowax-templated resin (CW-TPR; 50 μm), and DVB–CAR–PDMS (50/30 μm). The type of fiber used affects the selectivity of extraction. In general, polar fibers are used for polar analytes, and non-polar types are used for non-polar analytes. Selectivity toward target analytes and interferences can be enhanced by surfaces common to affinity chromatography. Fibers can be reused up to 100 analyses or more depending on the sample matrix, on the care of the analyst, and on the applications for which used.

MEMBRANE-BASED SEPARATIONS

There are a number of different membrane techniques which have been suggested as alternatives to the SPE and LLE techniques. It is necessary to distinguish between porous and non-porous membranes, as they have different characteristics and fields of application. In porous membrane techniques, the liquids on each side of the membrane are physically connected through the pores. These membranes are used in Donnan dialysis to separate low-molecular-mass analytes from high-molecular-mass matrix components, leading to an efficient cleanup, but no discrimination between different small molecules. No enrichment of the small molecules is possible; instead, the mass transfer process is a simple concentration difference over the membrane. Non-porous membranes are used for extraction techniques.

The introduction of membranes in the field of sample preparation contributes to minimal organic solvent use, minimal contamination and exposure to toxic or dangerous samples, automation, and effective cleanup and analyte isolation.

Membranes in Sample Filtration

Membrane filters are used to remove particulates from samples and solvents prior to HPLC analysis and also for the preparation of liquid samples, where no solvent is used. Typical materials of construction for membrane filters are usually synthetic polymeric materials, although natural substances, such as cellulose, and inorganic materials, such as glass fibers, are also used: acrylic copolymer, aluminum oxide, cellulose acetate, glass fiber, mixed cellulose esters, nitrocellulose, nylon, polycarbonate, polyester, polyether sulfone, polypropylene polysulfone, PTFE, PVC, etc. The compatibility of the polymeric material with the solvents used must be a great concern of their different chemical properties.

Membranes are available in sheet, roll, disk, capsule, cartridge, and hollow-fiber formats. For sample filtration, disk-format membranes are the most popular devices. Disks are sold in loose form or packed in disposable syringe filters or cartridges; common diameters commercially available are 3, 7, 13, 25, 47, and 96 mm, or even larger. Samples are filtered by manually applying a positive pressure or in a vacuum manifold.

DIALYSIS AND MICRODIALYSIS

Dialysis is a membrane barrier separation process in which differential concentration forces one or more sample analytes to transfer from one fluid to another through a membrane. In dialysis, the solution containing the analyte of interest (whose concentration is depleted) is called the "feed" and the fluid receiving the analyte is called the "dialysate." Dialysis is used to remove salts and low-molecular-weight substances from solutions or to remove high-molecular-weight interferences (e.g., proteins) and to allow the measurement of small molecules.

Other variations of the porous membrane techniques include microdialysis and electrodialysis, where a membrane promotes selective transport of charged compounds.

Microdialysis is a technique for in vivo sampling of living tissues or animals, where sampling is performed by means of a probe containing the semipermeable membrane. It is used for medical applications and for online monitoring of extracellular chemical events in living tissues. The membrane is placed at the end of a small piece of a small-diameter, fused silica tubing that is inserted into the tissue of an animal, being in direct contact with the interstitial space. A flowing fluid that can be void of substances of interest, or include physiologically or pharmacologically active substances, is used on the other side of the membrane. The concentration gradient across the membrane enables the diffusion of substances from the interstitial space into the dialysis probe. Usually, the probe is held in place mechanically so the animal can move freely. The outlet of the probe is connected to a collection vial or, in some cases, an HPLC microvalve that enables online analysis using a microbore column. Microdialysis has the advantages of easy operation, rapid isolation of components of interest from complicated and dirty matrices, and lower consumption of organic solvents. Pharmacokinetic studies can also be executed.

Dialysis can also be used as an online sample preparation technique for the deproteinization of biological samples prior to HPLC. Selecting the appropriate semipermeable membrane for the dialyzer can prevent interference from large macromolecules. Samples are introduced into the feed (or donor) chamber, and solvent is pumped through the lower acceptor (or recipient) chamber. The smaller molecules diffuse through the membrane to the acceptor chamber and are directed to an HPLC valve for injection. In case of low concentrations of compounds of interest, a trace enrichment step may be required; this is accomplished with a column placed downstream of the dialyzer that will retain the analyte until the concentration is sufficient for detection. After this step, the analyte can be backflushed into the HPLC system. The technique is useful for blood studies as sampling can be achieved continuously without blood withdrawal. A commercial online system, such as Asted from Gilson, used for both cleanup and enrichment by a combination of dialysis with SPE, is shown in Fig. 7.

Membranes in Extraction

Non-porous membranes are used, as already mentioned, in membrane extraction techniques. A non-porous membrane is a liquid or a solid (e.g., polymeric) phase that is placed between the two phases, usually liquid but sometimes gaseous. This arrangement permits the versatile chemistry of LLE to be used and extended, thus providing a highly effective cleanup as well as a high enrichment factor, and technical realizations can easily be automated. In most cases, there is no, or insignificant, use of organic solvents. The technique is known as *supported liquid membrane*. An advantage of the membrane techniques is that they are amenable to automation and connection to chromatographic instruments.

AFFINITY TECHNIQUES—IMMUNOAFFINITY EXTRACTION

A high degree of molecular selectivity can be achieved with affinity chromatography and affinity extractions. These techniques are based on *molecular recognition* (antigen–antibody interactions). Because the antibodies are highly selective toward the analyte used to initiate the immune response, the corresponding immunosorbent may extract and isolate this analyte from complex matrices in a single step, thus eliminating matrix interference.

Immunosorbents are used in medical and biological fields because they are available for large molecules and are easily obtained, while obtaining selective antibodies for small-size molecules is more difficult. The first step in making an immunosorbent is to develop antibodies with the ability to recognize the desired analytes. Then immunosorbents are obtained by immobilizing the antibodies on solid supports by covalent bonding, adsorption, or encapsulation. The sorbent must be chemically and biologically inert, easily activated, and hydrophilic to avoid non-specific interactions. The common choices are activated silica, Sepharose, agarose gel, etc.

The immunoextraction procedure may be "off-line" or "on-line." In the off-line approach, the immunosorbent is

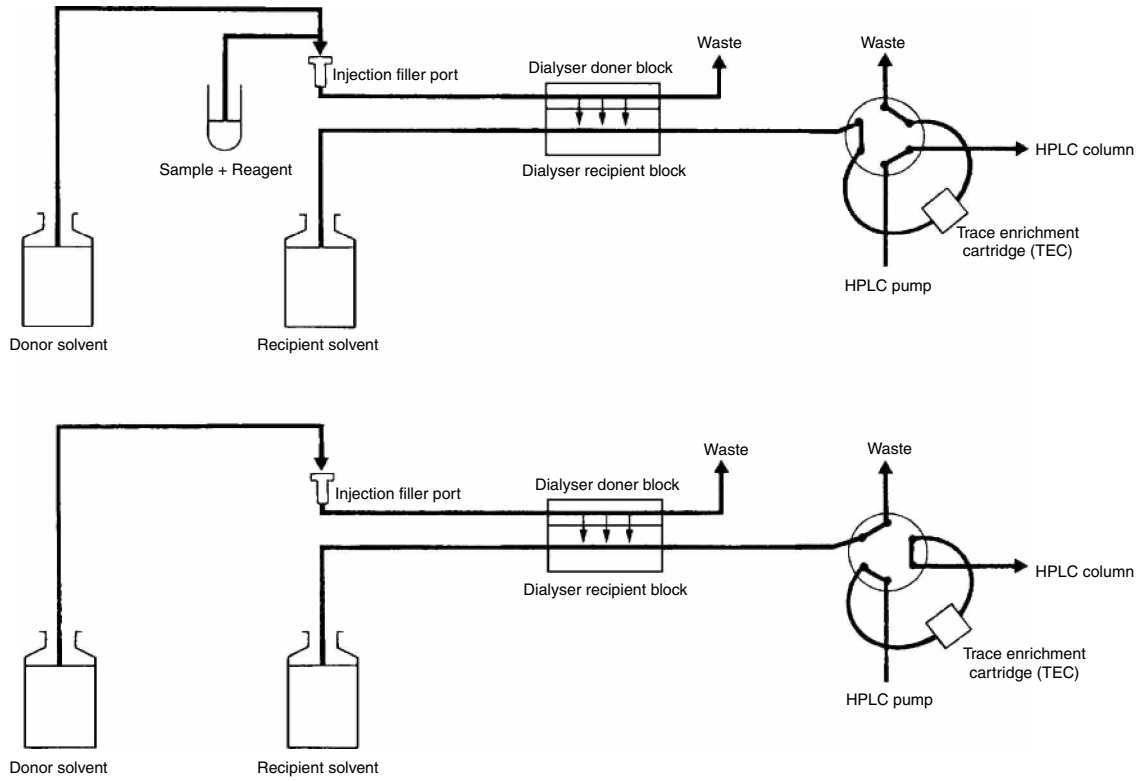

Fig. 7 Online sample preparation by dialysis.

packed into a disposable cartridge. A typical SPE sequence is followed. The sorbent is first conditioned, then the sample is applied, washed to eliminate interference, and analytes of interest are desorbed by the appropriate eluent system, which may be a displacer agent, a chaotropic agent, an aqueous–organic solvent mixture, or a solution that alters pH. With the online approach, the immunosorbent is packed into a precolumn incorporated in a six-port switching valve, where the immunoextraction is performed at the load position, while desorption is achieved at the inject position.

MOLECULARLY IMPRINTED POLYMERS

One approach to synthesize the antibody mimics has been the development of MIP. These involve the preparation of polymers with specific recognition sites for certain molecules. The desired affinity can be introduced by adding an amount of the compound of interest to the polymerization reaction. This "pattern" (template) chemical may be removed after polymerization, leaving vacant sites of a specific size and shape, suitable for binding the same chemical again, from an unknown sample. Like immunosorbent, the recognition is a result of shape and a mixture of hydrogen, hydrophobic, and electronic interactions. Molecularly imprinted polymers have the advantage to be prepared more rapidly and easily, using well-defined methods, and to be stable at high temperatures over a large pH range and in organic solvents. They have found applications in LC, as normal and chiral stationary phases, and in areas where they can be substitutes of natural antibodies (i.e., immunoassays, sensors, and SPE). Noncovalent imprinting protocols are the most commonly used for preparing MIPs using acrylic or methacrylic monomers—often, with methacrylic acid and ethylene glycol dimethylacrylate as cross-linkers. A problem related to the use of MIPs in SPE is the difficulty in removing all the template analytes, even after extensive washing, and the difficulty in establishing a quantitative and rapid desorption as a result of the high greed of the MIP for the analytes.

RESTRICTED-ACCESS MATERIALS

Special sorbents possessing restricted-access properties have been developed to allow the direct injection of biological matrices into the online SPE–LC systems. These sorbents, the so-called *restricted-access materials*, combine the size exclusion of proteins and other high-molecular-mass matrix components that are prohibited from entering the pores of the packing, and they are not well retained by the column. Therapeutic drugs and other small molecules permeate the pores of the column packing material where they partition and are retained by

conventional retention mechanics, such as hydrophobic, ionic, or affinity interactions at the inner pore surface. They are suitable for handling biological samples because they prevent the access of proteins, thus allowing online cleanup and trace enrichment for the determination of several drugs and their metabolites in various biological fluids in the same step.

TRADITIONAL APPROACHES OF SOLID SAMPLE PREPARATION

Solid samples such as biological tissues may be prepared for extraction by a stepwise process that begins with the disruption of the gross architecture of the sample. This modifies the physical state of the sample and provides the extracting medium with a greater surface area per unit mass. Methods reducing the sample particle size include homogenizing, cutting, milling, mincing, blending, macerating, pulverizing, chopping, grinding, sieving, and crushing. Additionally, samples may be frozen in liquid nitrogen or by exposure to dry ice, or they may be freeze-dried to produce a material that can be mechanically pulverized. The finely divided powder that is produced may then be extracted.

Dissolution is the predominant process that takes place before solid samples are injected into HPLC in order to be converted into a liquid state. This is accomplished either by dissolving the entire sample matrix, or by leaching the analytes from the solid matrix using a suitable solvent.

For many years, the *traditional sample preparation* methods, such as the Soxhlet extraction, were applied. Most of these methods have been used for more than 100 years, and they mostly require large amounts of organic solvents. These methods were tested during those times, and the analysts were familiar with the processes and protocols required. However, the trends in recent years are automation, short extraction times, and reduced organic solvent consumption. Modern approaches in solid sample preparation include microwave-assisted solvent extraction (MASE), pressurized liquid extraction, accelerated solvent extraction (ASE), matrix solid-phase dispersion (MSPD), automated Soxhlet extraction, supercritical fluid extraction (SFE), gas-phase extraction, etc.

Solid–liquid extraction (SLE) refers to the classic extraction technology that is achieved by using the appropriate solvent that selectively dissolves the analyte of interest. The most common form of SLE is the "shake-filter" method that involves the addition of an organic solvent for organic compounds or dilute acid or base for inorganic compounds to the sample, and also agitation to allow the analytes to dissolve into the surrounding liquid until they have completely migrated. Heating or refluxing the sample in hot solvent may speed up the extraction process. The insoluble substances are subsequently removed by filtration or centrifugation. A faster and more complete extraction is achieved by *sonication*, where the sample is immersed into a solvent within a vessel that is placed in an ultrasonication bath. The ultrasonic agitation allows more intimate solid–liquid contact, and the gentle heating generated during sonication can aid the extraction process. The extract can either be directly injected, or treated further according to the procedures described under "Preliminary Sample Preparation Procedures."

SOXHLET EXTRACTION

In this technique, the solid sample is placed in a "thimble" that is a disposable, porous container made of stiffened filter paper or Pyrex glass. The thimble is placed in the Soxhlet apparatus designed to repeatedly siphon the solvent with the extracted components, after the inner chamber that holds the thimble is filled to a specific volume with solution. The siphoned solution containing the dissolved analytes is returned to the boiling flask, and the process is repeated until the analyte is successfully removed from the solid matrix. Soxhlet extractions are usually slow, often requiring 24 hr or more. However, it requires little operator involvement after the sample is loaded, and refluxing proceeds until the termination of the extraction. Rows of Soxhlet extractors may be used usually under fume hoods, when the technique is integrated into routine analysis. In relation to modern extraction techniques, it is a low-cost method. The Soxhlet extraction glassware is rather inexpensive; however, the cost is elevated by the large solvent volumes required. Small-volume Soxhlet extractors and thimbles can accommodate sample amounts of a few milligrams. Method development involves the choice of the suitable solvent or solvent mixture (azeotrope) of high volatility, so that it is easily removed and has a high affinity for the analyte but a low affinity toward the solid sample matrix.

A fully automated Soxhlet extraction has been patented as Soxtec by Foss Tecator (Sweden) based on a four-step solvent extraction technique. The sample is rapidly dissolved during the first step in boiling solvent. The remaining soluble matter is efficiently removed at the second step, while distilled solvent is collected at the third step. In the fourth step, the sample cup lifts off the hot plate, utilizing residual heat to predry while eliminating boil-dry risk.

FORCED-FLOW LEACHING

Forced-flow leaching is an extraction technique that can provide a nearly quantitative recovery of many organic compounds. In this technique, the sample of interest is packed into a 20 cm × 4 mm stainless steel column. An extraction solvent is pumped under a gas pressure of 2.5 kg/cm^2 through the column, which is heated close to

the solvent's boiling point. The results are comparable to Soxhlet extraction, but the extraction time is reduced from 24 to 0.5 hr using the forced-flow technique. An advantage of this method is that the sample is subjected continuously to fresh, hot solvent, and the effluent from the column can be collected easily for further treatment.

MODERN APPROACHES OF SOLID SAMPLE PREPARATION

Supercritical Fluid Extraction

Supercritical fluid extraction is a modern sample preparation technique of great interest and utility for complex matrices, primarily considered as an alternative for Soxhlet and sonication extraction for solid and semisolid matrices.

A *supercritical fluid* is defined as a substance above its critical temperature and pressure, which means that it does not condense or evaporate to form a liquid or a gas, but is a fluid with intermediate properties. These properties change from gas-like to liquid-like as the pressure is increased.

A typical supercritical fluid extractor includes a supercritical fluid (most often CO_2 or CO_2 with an organic modifier) source, a means of pressurizing the fluid, a pumping system (for the liquid CO_2), an extraction thimble, a device to depressurize the supercritical fluid (flow restrictor), an analyte collection device, temperature-control systems for several zones, and an overall system controller.

The CO_2 remains a liquid throughout the pumping or compression zones and passes through small-diameter metal tubing as it approaches the extraction thimble itself. The fluid then passes through the extraction thimble at a flow rate and a time period predetermined at the method development stage. The supercritical fluid containing extracted analytes flows through additional capillary tubings until it reaches the restrictor zone.

Applications of SFE include the extraction of salts, proteins, carbohydrates, peptides, amino acids, and other interfering polar compounds in a biological matrix. It shows its best advantage for extracting the analytes from solids and semisolids, rather than from liquids and fluids, mainly because of the extraction thimble's design. The extraction thimbles and associated pieces are made of porous materials such as nickel, chlorofluorocarbon compounds, and stainless steel materials that are very similar to the frits used in HPLC columns. To extract a liquid sample by SFE successfully, it has to be first mixed with a solid material such as diatomaceous earth or alumina, so that the sample is no longer in a liquid state. An SPE filter bed medium may also be used while passing a liquid sample through this first.

A drawback of this technique is a clear need for SFE to be carried out on reference materials of known composition determined by an alternative technique. The advantages of SFE in comparison to LLE are:

1. Less organic solvent is used in reduced time (extraction times can be less than 0.5 hr).
2. Carbon dioxide as an extraction solvent has the advantage of low critical temperature; additionally, it is cheap, non-toxic, and non-explosive. It is classified as a non-polar solvent that can be modified to more polar solvent by the addition of organic solvents (modifiers) such as lower alcohols (e.g., methanol).
3. Online and off-line analytical scale SFE can be applied. In the former, the coupling step (i.e., the transfer and collection of extracted analytes from the SFE to the chromatographic system) is of great importance.

PRESSURIZED SOLVENT EXTRACTION–ACCELERATED SOLVENT EXTRACTION

As an alternative to SFE with carbon dioxide or other supercritical fluids, it was proposed that heating the organic solvents under pressure above their boiling point, but below their supercritical point, would enhance the speed of reaction and solvent strength. This technique, known as the *pressurized solvent extraction* (PSE), provides an easy method for extraction, reducing the amount of solvent required and speeding up the process. The system is marketed as ASE by Dionex Corporation (Sunnyvale, California, U.S.A.). Because PSE represented an extension of existing methods, it attracted attention and is often adopted by official organizations.

MATRIX SOLID-PHASE DISPERSION

Matrix solid-phase dispersion handles viscous solid, solid, or semisolid samples directly by blending with a solid-phase support, such as silica or bonded silica, similar to those used in SPE columns. This is performed by placing a small quantity ($\sim$ 0.5 g) of the sample into a glass mortar and blending it with a glass or agate pestle. The bonded phase acts as a lipophilic binding solvent that assists in sample factorization. The best ratio of sample-to-solid support-bonded phase is 1:4 (or other, depending on the application). The isolation of polar analytes from biological samples is assisted by the use of polar solid support phases and less polar analytes by the less polar phase. The sample components dissolve and disperse into the bound organic phase on the surface of the particle, leading to the complete disruption of the sample and its dispersion over the surface.

The conditioning of the material to be used for MSPD can greatly enhance the analyte recovery. Once the MSPD blending process is completed, the material is transferred to a column constructed from a syringe barrel or other appropriate device containing a frit that retains the entire sample, which is compressed to form column packing by using a modified syringe plunger. A second frit is placed on top of the material, which is compressed so that no channels are formed. The addition of eluting solvent to the column may be preceded by the use of some or all of the solvent to backwash the mortar and pestle. Approximately 8–10 ml of solvent is used to perform the elution. However, most target analytes are eluted in the first 4 ml.

Because the entire sample is present in the column, it is possible to perform multiple or sequential elutions, which can be conducted by gravity flow, by application of pressure to the head of the column, or by placing the columns on a vacuum manifold and applying suction.

If the eluate from an MSPD column is not adequately clean for direct injection, additional steps may be necessary to remove the coeluted matrix components, either by using other solid-phase material packed at the bottom of the MSPD column, or by eluting the analytes from the MSPD column directly onto a second SPE column for sample cleanup and analyte concentration. Sorbents similar to SPE can be used. The ionic state of the sample components is sometimes necessary to be modified to assure that certain interactions occur between the solid support and the eluting solvent. This may be accomplished by adding acids, bases, salts, chelating or dechelating agents, antioxidants, etc. at the time of the sample blending and/or as an additive to the eluting solvent.

Matrix solid-phase dispersion provides results equivalent to older official methods. However, it generally requires 95% less solvent and 90% less time than classical methods. Matrix solid-phase dispersion has been applied to the isolation of drugs, herbicides, patricides, and other pollutants from animal tissue.

DERIVATIZATION IN HPLC

In some cases, the enhancement of detectability is required in trace analysis, when the analytes do not possess a UV-absorbing, fluorescent, or electroactive functionality; therefore derivatization is necessary. A reaction with a fluorotag will produce a highly fluorescing derivative of the compound of interest; thus very low concentrations are detectable. An improvement of UV detectability can also be obtained by a reaction with a chromotag.

The derivatization for HPLC is performed either "off-line" (pre-column) before injection into the column, or "on-line" (post-column) by mixing the reagent with the column effluent.

Precolumn derivatization offers some advantages vs. postcolumn derivatization, as it involves less reaction restrictions, simpler equipment, and no time limitation regarding kinetics, provided that all species are stable. It can be performed either manually or automated. However, there are several drawbacks such as the introduction of contaminants, a possible loss of analyte as a result of side reactions, adsorption, degradation, and incomplete reactions.

By postcolumn derivatization, the analyte is derivatized after the separation and before the detection by using a reaction detector. The simplest way is to add a reagent solution to the column effluent with an extra pump. After the mixing T-piece, a reactor with a suitable holdup volume is inserted to allow reaction to take place. The benefits of this approach are that chromatographic separation is not affected and reaction is not required to be complete.

The most common *fluorotags* (fluorescent reagents) are dansyl chloride and *o*-phthalaldehyde (OPA). *Chromotags* include *p*-bromophenacyl bromide (PBPB) for derivatization of carboxylic acids (K-salts) with a crown ether catalyst, ninhydrin for primary amines forming complexes that have their adsorption maxima at about 570 nm, and dansyl chloride for primary and secondary amines, including amino acids, thiols, imidazoles, phenols, and aliphatic alcohols.

Chiral derivatization can be applied to improve the separation of enantiomers.

CONCLUSIONS

The analytical process typically consists of several discrete stages, such as sampling, preparation, instrumental analysis, quantification, data reporting, and interpretation; each step is critical in obtaining accurate and reproducible results.

A sample preparation step is often necessary to isolate the components of interest from a sample matrix, as well as to purify and to concentrate the analytes. The quality of sample preparation is pivotal in the overall quality of the analysis. Despite the advances in instrumentation and computer technology, many sample preparation practices are based on the 19th century technologies (e.g., the commonly used Soxhlet extraction that was developed more than 100 years ago).

An ideal sample preparation technique should be solvent-free, simple, inexpensive, efficient, selective, amenable to automation, and compatible with a wide range of separation methods and applications. It should also allow for the simultaneous separation and concentration of the components.

There is no universal sample preparation method, as sample preparation depends strongly on the analytical demands, as well as the size and nature of the sample. What is beyond any doubt is the continuously increasing

demand for improved selectivity, sensitivity, reliability, and rapidity in the process of sample preparation.

Among the previously discussed sample preparation techniques, SPE offers a fast, safe, and convenient means for subsequent analysis by chromatographic techniques (HPLC, TLC, GC, etc.). The major benefit is that it requires less solvent than conventional LLE methods. Impurities are removed and the analytes are concentrated, leading to a higher sensitivity in subsequent analysis.

Modern techniques are currently driving out conventional approaches because of their many advantages, including speed, use of less environmentally hazardous solvents, better facilitation for the control of the extraction, as well as automation and online combination of the extraction with other analytical techniques. A major concern when developing techniques for sample preparation is the possibility for automating the entire analytical process, which might lead to increased sample throughput and reduced manual operations with obvious economic benefits, as well as higher accuracy and precision.

Miniaturization has become a dominant trend in analytical chemistry. The development of techniques such as micro-LLE (in-vial extraction), ambient static headspace, disk cartridge SPE, SPME, MSPD, and MASE, which use smaller sample size, minimize solvent use, and are amenable to automation, is a positive sign for analytical science. The combination of modern sample preparation techniques may result in more cost-effective and faster analysis, higher sample throughput, lower solvent consumption, and less manpower, while maintaining, or even improving, sensitivity. Speed in sample preparation is a prerequisite in any analytical method. The future in sample preparation depends on new sorbents and new formats developed for SPE or SPME that exhibit higher selectivity and greater convenience for method development.

Sample Preparation for Ion Chromatography

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

INTRODUCTION

Separation methods, such as gas and liquid chromatography, can provide high resolution of complex mixtures of almost every matrix, from gases to biological macromolecules, and detection limits down to femtograms or even lower. Sample preparation is often a neglected area, which over the years has received much less attention and research than the chromatographic separation or detection stages.

The entire advanced analytical process can be invalidated if any unsuitable sample preparation method has been employed before the sample reaches the chromatograph.[1] In general, sample preparation methods are based on converting a real, complex matrix into a sample in a format that is suitable for analysis by a specific analytical technique. They have a common aim, such as the following:

- Removal of potential interferences from the sample, thus increasing the selectivity of the method
- Increasing the concentration of the analyte(s) and, thus, the sensitivity of the determination
- Converting the analyte into a more suitable form, if necessary
- Providing a robust and reproducible method that is independent of variations in the sample matrix

In modern analytical chemistry and, particularly, in trace analysis, sample preparation is usually more important than the determination method itself for the accuracy and reproducibility of the results.[2] Adequate sample preparation is becoming more important because it allows full exploitation of all of the potential chromatographic methods, including ion chromatography.

SAMPLE PREPARATION METHODS FOR ION CHROMATOGRAPHY

Ion chromatography is well established as a regulatory method for the analysis of anions and cations in environmental samples, as there are few alternative methods that can determine multiple ions in a single analysis. Ion chromatography offers an enormous range of possibilities for the selection of stationary and mobile phases and, in combination with different detection techniques, usually is able to solve even difficult separation problems.

The most important fields of ion chromatography applications are for water and waste water analysis, in the food and beverages industry, and for the semiconductor, clinical, and pharmaceutical sectors.[3–5]

Ion chromatography has reached a high stage of development; the only deficits remaining to be found are in the sample preparation area, which is necessary when an analytical method cannot provide good separation and quantification due to interferences from sample matrix components. Sample matrix effects can include shortened retention times, poor peak efficiency, poor resolution, poor reproducibility, and irregular baseline.

Sample treatment before analysis is necessary to protect expensive analytical columns and increase their lifetimes. Columns used for ion chromatography require absolutely particle-free sample solutions. Unfiltered solutions can cause increased column back pressures and, therefore, in some cases, results in vastly reduced column life.

In practice, real samples whose compositions may vary significantly, can only be analyzed after a more or less complicated sample preparation procedures. The most important practical reasons when and why sample preparation is necessary include:

- Analyte concentration is too high or too low
- Analyte concentrations differ essentially
- The presence of components that may cause interference by peak overlapping
- Samples containing particles
- Solid samples
- Gaseous samples

Sample preparation methods for the wide range of problems to be solved with ion chromatography methods are very numerous and the apparatus and time required for sample preparation vary considerably. The choice of the sample preparation method depends on the physical state and the composition of the sample. The crucial criteria are the choice of the separation mode and analytical conditions, as well as availability of apparatus configurations.[6]

The performance of the separation column, with regard to its resolution, capacity, pH, stability, and compatibility with organic solvents can also be decisive for the basic need for sample preparation or for type of sample pretreatment that is finally chosen.

The most important sample preparation methods for chromatographic analyses (including ion chromatography), taking into consideration the sample form (liquid, solid or gaseous) are:[7]

1. Liquid samples (filtration, dilution, pH adjustment, standard addition, derivatisation, liquid–liquid extraction, solid-phase extraction, distillation, microdiffusion, and membrane separation)
2. Solid samples (drying, homogenization, dissolution, extraction/leaching, digestion, ashing, and combustion)
3. Gaseous samples (absorption in liquids, adsorption on solid phases, membrane sampling, and chemical conversion)

Water samples for analysis by ion chromatography should be collected in plastic containers, such as polytetrafluoroethylene (PTFE), polypropylene (PP), polystyrene (PS), or high-density polyethylene (HDPE). Glass bottles can contribute ionic contamination when performing trace analysis. Polyvinylchloride (PVC) should absolutely be avoided.

The majority of water samples collected for ion chromatography analysis require little or no sample pretreatment. Drinking water samples usually require no pretreatment other than filtration through a 0.45 μm filter to remove particulates. Most waste water often requires only dilution and filtration to bring the analytes of interest into the working range of the method.

Filtration using membrane filters with a pore size of 0.45 μm is the most common sample pretreatment procedure for ion chromatography. For biologically active samples, the use of sterile filters with a pore size of 0.2 μm is strongly advisable. Filters are made either from PTFE, polyvinyldienedifluoride (PVDF), or similar material. Cellulose filters are generally unsuitable. Filter materials differ in pore size, porosity, filtration speed, compatibility with acids, abuse, and organic solvents, as well as in their adsorption properties and blank values.

Recently, membrane separation techniques have achieved great importance in technical applications for separating substances. The variety of available membranes allows one to take advantage of very different separation mechanisms.[8]

Classical filtration and microfiltration are not normally regarded as being membrane techniques, but are directly linked to ultrafiltration with regard to their aims and their procedures. Ultrafiltration is a filtration technique in which the membranes have pore sizes that are much smaller than those used in membrane filtration.

The combination of dialysis with ion chromatography was first published by Nordmayer and Hansen.[9] However, its commercialization by Metrohm has established it as a very versatile, efficient, user-friendly, and automated sample preparation technique.[10]

The term "dialysis" covers separation methods that are based on the transport of molecules or ions through a semipermeable membrane. A differentiation is made between various types of dialysis (passive dialysis, Donnan dialysis, and electrodialysis), according to the driving force and the type of separation membrane that is used.[11]

Active Donnan dialysis is employed most commonly with ion chromatography and is useful for clean-up of sample solutions at extreme pHs.[12] Electrodialysis can be used with ion chromatography for the off-line analysis of strongly alkaline samples containing trace amounts of common inorganic anions.[13]

Liquid–liquid extraction is of little importance in the context of ion chromatographic analysis.[14] Separation via the gas phase is a method with a comparatively high degree of selectivity, as only a few of the analytes that can be determined by ion chromatography can be converted to a volatile form.

For the isolation and preconcentration of analyte ions, as well as separation of interfering matrix components, the various versions of solid-phase extraction are suitable. This involves passing the sample solution through a small column (solid-phase cartridge) that is filled with a suitable sorbent material which either retains the analyte ions or the interfering matrix components. The versatility of solid-phase extraction allows this technique to be used for purification, preconcentration, solvent exchange, desalting, derivatisation, as well as, for sample fractionation.

For the practical performance of solid-phase extraction, many manufactures offer ready-to-use cartridges filled with sorbent materials, as well as devices for passing the sample solution through the sorbent bed, either manually, semi-automatically, or fully automatically.[15]

Solid-phase systems are available commercially, both in column and cartridge form, and also in the format of extraction discs.[16]

Depending on the properties of the components to be preconcentrated or purified, and of the matrix, there is a large number of sorbent available, such as:[17]

- Nonpolar, reversed phase (e.g., octadecyl C_{18}, octyl C_8, ethyl, phenyl, graphite carbon, styrene/divinylbenzene copolymers)
- Polar, normal phases (e.g., cyano, amino, diol, silica gel, florisil, alumina)
- Ion exchangers (e.g., quaternary amine, carboxylic acid, sulfonic acid, cation exchanger, anion exchanger)

Polyvinylpyrrolidine has been shown to be very suitable as the sorbent for the separation of humic materials, tannins, lignins, as well as organic dye compounds, phenolic materials, aldehydes, and aromatic acids.[18] Non-polar solid-phase extraction can be used for the preconcentration of heavy metals as complex compounds and their subsequent determination by cation-exchange chromatography.

Many environmental samples (e.g., sea water, waste water, and brines) contain high concentrations of chloride, sulfate, and sodium ions. Matrix removal of chloride and sulfate is based on the precipitation of these anions with counterions from sulfonated resins. Fully sulfonated cation exchange resins are available with a variety of counterions. The most commonly used counterions are: Ag^+, Ba^{2+}, and H^+, for matrix elimination of chloride, sulfate and general cations, respectively.

Many of the sample preparation techniques for ion chromatography can also be performed using online instrumentation, which can be easily automated and is less time-consuming than off-line techniques.[19]

Automated matrix elimination can also be performed using "heart-cut" techniques.[20]

A novel solution to the problem of performing ion chromatography separation on high ionic strength samples has been the usage of the dominant matrix ion as eluent ("matrix elimination ion chromatography").

In the field of ion chromatography, solid-phase extraction is frequently used for the preconcentration of analytes from samples with an organic matrix, e.g., solvents, fruit juices, body fluids, or for the determination of nitrate and nitrite in meat products.[21]

Solid Sample Treatment for Ion Chromatography

The determination of ionic substances, or substances that can be converted into ionic form from solid samples, is an important field of application of ion chromatography. This includes the analysis of soils, sediments, dusts, geological materials, various industrial products, as well as biological samples and all types of foodstuffs. The sample preparation methods for solid substances can be classified according to whether treatment with a liquid, fusion, ashing, or combustion of the dry sample is necessary.

The analysis of solids by ion chromatography requires either the transfer of the whole sample, or at least the ions of interest, into an aqueous phase. This can be carried out in different ways, depending on the solubility of the analyzed substance and the ionic content to be determined.[22] Dissolution of the sample or extraction of the ions to be determined is normally carried out at room temperature, but can also be accelerated by gentle warming or by heating the solvent up to the boiling point. Solvent extraction which employs, basically, the principles of traditional solvent extraction, but with a higher temperature and pressure, shows better extraction properties.

The choice of extracting solution is dependent on both the sample matrix and upon the nature of the determined ions. Water is preferred, in order to avoid introducing extraneous peaks into the final chromatogram. Sometimes, water combined with a miscible solvent such as methanol, solutions of dilute acid or base, dilute salt solutions, or even the eluent, can be used.

If an aqueous extraction is not sufficient, it may be necessary to consider a wet chemical digestion. Open digestions can be carried out relatively simply in heat resistant vessels on a hotplate. Digestions under pressure require special vessels and the necessary safety precautions must be observed.

Acid digestion with concentrated mineral acids is basically inappropriate for ion chromatography because the excess of the acid coanion can lead to the appearance of a large, interfering peak in the final chromatogram and can also cause column overloading. If mineral acids such as HCl, H_2SO_4, or HNO_3 have to be used, the difference in retention times between the sample anions and the solvent anion should be as large as possible.

For acid extraction followed by the determination of the standard anions (Cl^-, NO_2^-, NO_3^-, PO_4^{3-}, SO_4^{2-}) by ion chromatography with direct conductivity measurement, tartaric acid, perchloric acid, and/or formic acid can be used. For chemical suppression ion chromatography, acetic acid, or formic acid can be used for determining the standard anions.

In general, acid digestion is better suited to preparing samples which are to be analyzed for cations (e.g., transition metals and rare earth elements) using ion chromatography with post column reaction detection.[23]

An alternative to the acid digestion of solid samples is fusion under alkaline conditions. The procedure is usually very labor intensive, takes a long time, and involves a high risk of errors from contamination and loss of analyte. This method can be used for the determination of fluoride and chloride in geological materials after fusion with sodium carbonate and subsequent injection into an ion chromatography column.

Other possible ways of solid sample preparation for ion chromatographic analysis are dry ashing using air as the oxidizing agent or combustion in an atmosphere of pure oxygen. With ashing, the dry and homogenized sample is mineralized in a combustion boat by heating it in a muffle furnace for several hours at temperatures of, typically, 300–800°C. Then, the ashes are dissolved in water or, if necessary, in a dilute mineral acid.

Combustion techniques are very useful for preparation of samples in which heteroatoms can be converted to ionic species suitable for determination by ion chromatography. Combustion is, therefore, used frequently for the analysis of biological samples, pharmaceutical preparations, polymerized substances, coal and other fuels, as well as foodstuffs and other samples with a very high organic matrix content.[24] Generally, conventional ion chromatographic methods for solid samples are:

1. Fusion methods
   - Alkaline with NaOH, KOH, Na_2CO_3, K_2CO_3
   - Acidic with $KHSO_4$, $K_2S_2O_7$
   - Fluorination, chlorination, sulfurization

2. Combustion methods

   – Burning the sample in air/oxygen
   – Oxygen bomb, calorimeter bomb
   – Combustion in a stream of oxygen
   – Combustion in an oxyhydrogen flame

3. Wet chemical digestions

   – Open acid digestion with reflux
   – Pressure digestion
   – UV pyrolysis

The determination of substances present in gaseous form by ion chromatography is usually preceded by preconcentration through absorption into a suitable liquid or absorption of the component on a solid sorbent material or on a reagent impregnated filter. The composition of the absorption solution plays an important role with the regard to the completeness of the gas separation and conversion. Only in very few cases can the separation of several gaseous substances take place simultaneously. Gases such as HF, NO_x, SO_2, SO_3, or NH_3 are absorbed in ultrapure water (possible with addition of H_2O_2 to oxidize sulfite to sulfate), dilute bases, or sodium carbonate solutions. Gases, such as NH_3, are absorbed in acidic solutions, e.g., sulfuric acid.

Diffusion denuders are a possible future example of diffusion-controlled gas sampling. All these methods are batch methods involving many manual work steps and offer a relatively poor temporal resolution. By the use of membrane-supported gas sampling (permeation denuders, wet-effluent scrubbers), continuous sampling and determination can be realized; it is also easy to automate.[25]

CONCLUSIONS

Sample preparation is a growing and developing area of ion chromatography in recent years. The variety of sample preparation methods is great, yet it is not always easy to find a suitable method for the specific problem to be solved. For a single problem, there are often several potential versions; the user has to make a selection based on various criteria.

Future development in ion chromatography might include the development of new stationary phases offering different separation selectivities and detection modes to those that are currently available; the increased usage of ion chromatography in hyphenated techniques and further advances in sample treatment which allow extension of the application of ion chromatography to more complex samples.

Sample Preparation for TLC

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

This entry describes the classical and modern sample preparation methods that have been used prior to qualitative and quantitative analysis by thin-layer chromatography (TLC) and high-performance (HP) TLC. Extraction and cleanup methods that are covered include classical methods such as liquid–liquid extraction (LLE) and Soxhlet extraction, as well as modern methods such as solid-phase extraction (SPE), pressurized liquid extraction (PLE), and supercritical fluid extraction (SFE). Modern methods have not been as widely applied in TLC as for other modes of chromatography, e.g., column high-performance liquid chromatography (HPLC).

OVERVIEW

After collection of a representative sample, sample preparation is the first step in a TLC analysis, followed by application of initial zones of samples and corresponding standards to the layer (plate); development of the layer with the mobile phase to achieve the separation; detection of the zones by their color, ultraviolet (UV) absorbance, or fluorescence, either natural or induced by postchromatographic derivatization with a detection reagent; documentation of the chromatograms using a system with a CCD (charged couple device) camera (videodensitometer), digital camera, or flatbed scanner; identification of unknown zones in sample chromatograms; quantification of the analyte by densitometry; and validation of the results. The later steps will not provide a correct result unless sample preparation is carried out properly.

Extraction procedures should recover essentially all of the analyte from the sample and leave behind as many of the impurities as possible. Cleanup procedures are designed to reduce matrix interferences while not losing any of the analyte and increasing its concentration as much as possible. General, practical aspects of modern sample preparation methods have been described in earlier articles,[1,2] but not their use in TLC. The purpose of this entry is to review the procedures used prior to TLC analysis and illustrate analytes and samples for which each has been applied successfully; details of the TLC methods after sample preparation will not be given but can be found in the cited references.

Sample preparation requirements are not as strict for TLC because the layer is used only once, instead of repeated injection of samples onto an HPLC column. The presence of strongly-sorbed impurities, even solid particles, in samples is of no concern if the subsequent development and zone detection are not adversely affected. These materials can build up on an HPLC column and destroy its performance. In TLC, every sample is separated on fresh stationary phase, without carryover or cross-contamination. Therefore, TLC can require fewer cleanup steps during sample preparation, saving effort, time, and expense. This advantage allows many kinds of liquid samples to be applied directly to a plate with no sample preparation except to remove any carbonation, e.g., beverages analyzed for Sucralose,[3] caffeine,[4] or aspartame[5] content using TLC-densitometry. Direct application is facilitated by use of plates with a preadsorbent zone, which may retain certain impurities at the origin during mobile-phase development.

TRADITIONAL LIQUID EXTRACTION

As stated above, cleanup of samples is not as critical for TLC as it is for column chromatography because plates are not reused. Simple dissolving or LLE with immiscible solvents and pH control is often sufficient. For more complex samples, cleanup of extracts by column adsorption chromatography, or a more modern method, such as SPE, is usually applied.

As an example of liquid sample extraction with an immiscible solvent in which the analyte is highly soluble, phenolic compounds in Croatian red wine were determined by LLE with diethyl ether at pH 2.0.[6]

One of the most used solvent partitioning methods involves chloroform–methanol (2:1) extraction followed by washing the organic phase with 0.88% KCl and filtering out and solid residue by passing through glass wool (the Folch procedure). This method has been especially successful with biological samples, e.g., for the recovery of lipids and phospholipids from snail tissue, hemolymph, and shells and from medicinal leeches.[7] A modified Folch procedure, with reextraction of the upper phase with water-saturated butanol, was described for recovering lipids from human normal and pathological tissues.[8]

When extract cleanup is needed, an adsorbent column can be used. For example, sample preparation for

determination of polycyclic aromatic hydrocarbons in sugar beet included saponification of the sample, several LLEs, and a silica gel column cleanup.[9]

SOXHLET EXTRACTION

This is a reflux-type extraction technique in which a solid sample is put in a thick, stiff paper thimble, in which solvent repeatedly fills and siphons. The analyte is exhaustively extracted, usually over a period of hours, without operator intervention. Soxhlet extraction was used in the TLC determination of the main alkaloid, tetrandrine, of *Stephania tetrandra* (methanol-5% conc. ammonia solvent);[10] lipids from grain sorghum DDG (*n*-hexane solvent);[11] and secondary amines from some Nigerian foodstuffs (petroleum ether, 60–90°C, solvent).[12]

ULTRASONIC EXTRACTION

Ultrasonic extraction of the pesticides atrazine, propham, chlorpropham, diflubenzuron, alpha-cypermethrin, and tetramethrin from soil was optimized in terms of the solvent (acetone), duration of sonication, and number of extraction steps. Comparisons with shake-flask and Soxhlet extractions made using reversed-phase (RP) TLC on C-18 plates showed advantages in extraction efficiencies, simplicity of use, and low-solvent consumption for ultrasonic extraction.[13]

EXTRELUT COLUMN LIQUID EXTRACTION

Extrelut columns (Merck, Darmstadt, Germany) can be used to perform LLE in place of a separatory funnel. The tube is packed with diatomaceous earth, and an aqueous sample is poured in. When a suitable organic solvent is then passed through, the analyte is eluted, while water and polar compounds in the sample are retained on the column. Applications are illustrated by the use of Extrelut extraction prior to TLC for the determination of nicotine and its metabolite cotinine in urine samples of children of smoking parents[14] and of caffeine in coffee.[15]

DIALYSIS

Dialysis is a cleanup method in which the analyte passes from one solution to another through a membrane while impurities do not transfer. The process can be set up to remove either low-molecular-weight or high-molecular-weight interferences. As examples, dialysis was used to extract the mycotoxin patulin from apple juice using ethyl acetate in a diphasic system,[16] and to remove low-molecular-weight constituents from bark extracts prior to carbohydrate and phenol analysis.[17]

SPE

SPE cleanup is carried out by passing sample extracts through a conditioned cartridge packed with a sorbent. A series of solvents is passed through to elute various analytes in different fractions prior to TLC. Impurities are eluted in separate fractions and discarded or remain on the column after elution of the analytes. SPE is also carried out in disks, but cartridges have been mostly used for TLC applications. In many analyses, cleanup by both LLE and SPE are carried out.

The following SPE sorbents have been reported for sample preparation prior to TLC analyses: C_8 chemically bonded silica gel in the TLC profiling of impurities in MDMA synthesis from piperonal;[18] amino-bonded silica for fractionation of lipid classes[19] and recovery of lipids from Gaucher and Krabbe's disease patient tissue;[8] C_{18} silica gel for drugs in river water,[20] resveratrol and piceid in wine,[21] and evolved alachlor collected in ethylene glycol;[22] $AgNO_3$-modified silica gel for determination of docosahexaenoic acid in bovine milk;[23] SBD-1 (styrene divinyl benzene) for organophosphorus pesticides in water;[24] and Florisil for two oxycholesterols in raw and cooked meat.[25]

SPE was coupled online between HPLC and TLC for the quantitative determination of 4(5)-methylimidazole in caramel.[26]

MICROWAVE-ASSISTED EXTRACTION

A prototype extractor based on conventional Soxhlet principles, but assisted in the cartridge zone by focused microwaves, was shown to accelerate the extraction of lipids from sausage products.[27]

PLE

In PLE, solvent is pumped into an extraction vessel containing the sample and is heated (e.g., 60–200°C) and pressurized (3.5–20.0 MPa). The method is also termed pressurized solvent extraction (PSE) and accelerated solvent extraction (ASE). Solvent consumption and extraction time are reduced by increasing the solubility of the analyte in the solvent and increasing the kinetic rate of desorption of the analyte from the sample matrix.

An extract containing caretenoids, phenolic compounds, and degradation products of chlorophylls was obtained from microalga using an optimized PLE procedure with ethanol at 115°C for 15 min, followed by silica gel TLC analysis of the extract.[28] PLE extracts

from a selection of herbs were compared using TLC analysis with extracts obtained according to Pharmacopoeia monographs; PLE was found to give equivalent or higher extraction yields and was faster and required less solvent.[29] The fat content of homogenized poultry meat samples was analyzed using PLE, TLC, and capillary gas chromatography (CGC); two different solvent mixtures (chloroform–methanol and *n*-hexane–isopropanol) were tested at various temperatures and pressures for PLC.[30] Lipids were extracted with pentane–hexane or dichloromethane and determined by Iatroscan rod TLC with a flame ionization detector (TLC–FID) in the analysis of a wide array of marine biota tissues.[31] PLE of yew twigs with methanol at 100°C was found to give the best yield of taxoids when compared with methanol maceration and methanol ultrasonic extraction; the crude extracts were purified by alumina column SPE followed by zonal micropreparative silica gel TLC, and quantification was by C-18 column HPLC.[32]

SFE

SFE involves extraction of the analyte from a sample using a supercritical fluid, a substance above its critical temperature and pressure. The extractant used most often is CO_2 plus an organic modifier such as 1–10% methanol. Solvating power can be adjusted by changing the fluid and/or its modifier, temperature, or pressure. SFE increases the recovery rate in many cases compared to liquid extraction and eliminates the cost of purchase and problems of storage and disposal of organic solvents.

The following are examples of TLC analyses in which SFE was the method used for sample preparation: lipids in wool (analysis by TLC–FID);[33,34] lipids in fish feed (TLC–FID);[35] the pesticide chlorpyrifos and its degradation products in soil;[36] hydrocarbons in heavy petroleum products (TLC–FID);[37] aromatic and aliphatic hydroperoxides in solid matrices (online sample transfer to TLC plates);[38] colored fractions from a Mediterranean brown alga;[39] essential oil in foods;[40] and cyanazine from soil (silica gel TLC-densitometry at 220 nm).[41]

IMMUNOAFFINITY EXTRACTION AND CLEANUP

Immunoaffinity (IA) methods are based on the principle of molecular recognition via very selective antigen–antibody interactions. Their use for sample preparation prior to TLC has been mostly for determination of toxins. The following are selected examples: the steroid animal drug trenbolone and its metabolite in bovine urine;[42] fumonisin B1 in corn with methanol–water (80:20) extraction followed by IA column cleanup;[43] aflatoxins B1, B2, G1, and G2 in foods regulated within the European Community using methanol extraction, IA column cleanup, and densitometric quantification;[44] deoxynivalenol (vomatoxin) in wheat flour and malt by extraction with water and polyethylene glycol, IA column cleanup, and HPTLC-fluorescence densitometry;[45] and ochratoxin A in green coffee using extraction with methanol-aq. $NaHCO_3$, IA column cleanup, and normal or RP TLC-densitometry.[46]

PRE–TLC DERIVATIZATION

The major method of zone detection for compounds that are not naturally colored, UV-absorbing, or fluorescent is to apply a postchromatographic dip or spray reagent, often followed by heating the layer to complete the reaction. However, samples are sometimes derivatized prechromatography[47] if the derivative is more readily separated and/or detected by TLC. Derivatives can be formed in solution and then applied to the layer, or the reaction can be carried out in situ at the origin by overspotting the reagent after applying the underivatized sample.

Reagents for the pre-TLC formation of sensitively detected fluorescent derivatives have been most successfully used, usually with fluorodensitometric quantification after separation. The following are examples of reagents used in this approach: monodansylpiperazine and monodansylcadaverine for fatty acids (automated gradient multiple development);[48] monodansylcadaverine for carboxylic acids (densitometric quantification at 10–210 pmol/zone);[49] monodansylcadaverine and *N*,*N*′-dicyclohexylcarboimide for C_{20} fatty acids in rat placenta (C_{18} silica gel layers);[50] dansyl chloride and sodium carbonate for putrescine, spermidine, spermine, and histamine on alumina plates;[51] dansyl chloride for morphine and 6-monoacetyl morphine as its marker in urine (200–400 pg/zone);[52] dansyl chloride for 20 beta-blockers (0.2 ng detection limit);[53] and 6% mercuric acetate solution for dipalmitoylphosphatidylcholine and 1-palmitoyl-2-oleylphosphatidylcholine, with visualization by dipping into cupric sulfate solution and densitometry at 365 nm.[54]

CONCLUSION

The methods used for sample preparation prior to TLC and HPTLC analysis are described. Included are traditional and modern procedures for extraction, cleanup, and derivatization. The references cited contain details of the sample preparation, as well as the following chromatographic methods. Only by use of optimized techniques, such as those given, can high quality results be obtained for qualitative and quantitative analysis.

INTRODUCTION

There are few processes that can be predictably scaled up from laboratory to production scale without difficulties. Preparative high-performance liquid chromatography (HPLC), for example, is not a linear scale up; it is expensive and uses large volumes of solvents. The product can become hydrolyzed by or react with the column, which can induce chemical/steric/chiral conformation changes and often requires significant prepurification with further risk of degradation.

Countercurrent chromatography (CCC)[1,2] is a process that avoids these difficulties. It is a form of liquid–liquid chromatography without a solid support, which separates soluble natural product substances on their partition, or differential solubility, between two immiscible solvents. The principle of separation (partition) is the same in both the laboratory and the production plant and is generic in that it can be applied to an extremely broad range of purification problems in many industries. Furthermore, because there is no solid support, there is 100% sample recovery and no need for any prepurification.

BACKGROUND INFORMATION

A recent review on CCC as a preparative tool[3] described an extremely useful comparison of four different CCC approaches and concluded that "the real future belongs to the new generation of centrifugal instruments." They concluded that more reliable designs were required, that there was a need to accommodate higher loads on the 100 g to 1 kg scale, and that truly preparative instruments needed to be developed. They called for a better understanding of the mechanisms of separation in order to achieve this.

Ito's work[4] on pH zone refining makes a valuable contribution to the scale-up scenario. It offers a method of operating existing instruments preparatively when purifying ionizable compounds with the ability of achieving sample loadings two orders of magnitude higher than normal. Sutherland et al.[5] demonstrate that preparative gram-quantity separations of crude plant extracts use one-tenth the volume of solvents compared to the equivalent prep-HPLC. Sandlin and Ito[6] have shown that CCC is feasible using a "J"-type coil planet centrifuge with tubing bore up to 5.5 mm internal diameter and have successfully demonstrated fractionations in 750 ml coils, but at relatively low flow, speed, and β value. They have also investigated the effect on resolution of increasing sample volume and sample concentration.[7] Ito and colleagues[7–9] have described unit-gravity (non-centrifugal) slowly rotating coil devices, which would be suitable for large-scale CCC separations.

PARAMETERS AFFECTING SCALE-UP

The main parameters affecting scale-up have been analyzed in detail by Sutherland et al.[10] For scale-up of CCC to be successful, they recommended that two measures or responses had to be maintained as the process was scaled up: retention of the stationary phase and resolution of the sample components. It was emphasized that even if it was possible to retain phases as the tubing bore increased, it was possible that the hydrodynamics of the mixing and settling zones may not work as well, as the bulk volume to surface area ratio increased.

They studied three "J"-type coil planet centrifuges with different coil sizes: analytical ($d = 0.76$ mm), lab prep ($d = 1.6$ mm),and process ($d = 3.68$ mm). By constructing the coils from stainless steel, they were able to increase flow considerably without risk of bursting the tubing or causing the tubing to work loose under the action of high cyclic forces, which can be a common problem (see later). They first showed that there was no difference in retention between coils made with stainless steel or polytetrafluoroethylene (PTFE). This was an important experiment that showed that retention was a hydrodynamic process and not governed by the surface properties of the tubing-wall material.

THE EFFECT OF THESE SCALE-UP PARAMETERS ON RETENTION

Fig. 1 shows Sutherland et al.'s plot of retention against flow for the three CCC units with different bore sizes. It clearly shows how increasing the tubing bore not only allows higher throughput but also shows that retention with larger bores is far more tolerant or stable when flow is increased, a very important discovery for industrial scale-up. They went on to demonstrate that increasing speed allowed even higher retention and linear flows of the mobile phase and that the mean Reynold's

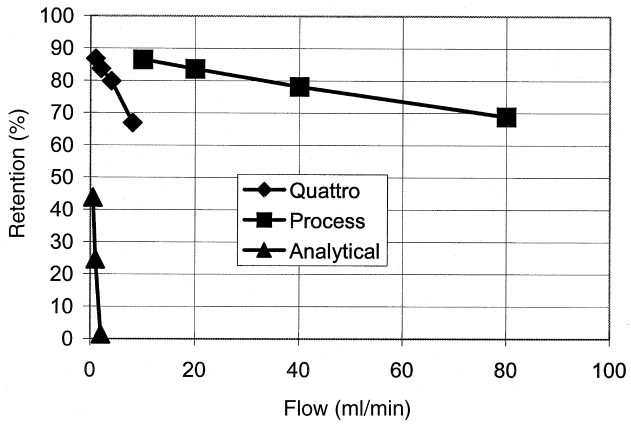

Fig. 1 Variation of retention with flow for different tubing bores: an analytical CCC (0.76 mm), a Bunel CCC (1.6 mm), and a process CCC (3.68 mm).

numbers of the mobile-phase flow were still well within the laminar flow region.

They concluded that increasing two of the three major variables affecting scale-up, speed and tubing bore, actually improved retention. The third, flow, decreased retention as flow increased but less so as the bore increased. Tubing material and retention of the stationary phase therefore are no barrier to the industrial scale-up of CCC.

THE RETENTION BEHAVIOR OF DIFFERENT PHASE SYSTEMS

Du et al.[11] have shown that there is a linear relationship between retention and the square root of flow. The negative gradient of this line gives an indication of the stability of the retention process for a given phase system: The shallower the negative gradient, the more stable the process and the higher the flow possible for a given retention. Tables 1 and 2 give the linear regressions for the phase systems tested on the process-scale CCC[10] at 800 and 1200 rpm, respectively. In all cases, the lower phase is the mobile phase pumping from head (center) to tail (periphery). Retention was measured at four different flow rates: 10, 20, 40, and 80 ml/min, except for the butyl alcohol–acetic acid–water (4:1:5) phase system where only flows of 10 and 20 ml/min were tested before retention dropped below 50%. A range of two-phase solvent systems are listed across the polarity range. In the case of hydrophilic low interfacial tension phase systems like butyl alcohol–acetic acid–water (4:1:5), a high speed of rotation was required to achieve a reasonably high retention.

THE EFFECT OF THESE SCALE-UP PARAMETERS ON RESOLUTION

There has not been any significant change in resolution detected[10] as the bore size increases, provided the sample volume injected maintains the same ratio of coil volume. This is a significant finding, as in most chromatography processes, resolution reduces as the process is scaled up. Resolution was found to increase with increasing speed of rotation as would be expected due to the increased number of mixing and settling cycles per unit time.

The effect of flow on resolution is shown in Fig. 2 for the process CCC[10] running at 1200 rpm. The resolution is between benzyl alcohol and phenyl ethanol resolved using the heptane–ethyl acetate–methanol–water (1.4:0.1:0.5:1.0) phase system. Resolution drops off with increasing flow as would be expected, as the sample will have experienced fewer mixing and settling steps before it elutes and the retention is lower. However, the increased flow appears to improve mixing, as it can be seen that this drop off is only gradual. Doubling flow does not halve resolution and so it would appear advantageous to increase flow as much as possible in the scale-up process.

ENGINEERING CHALLENGES OF SCALE-UP

Sutherland et al.[10] and, earlier, Sandlin and Ito[6] have shown that scale-up is feasible. It can be seen that over 60% retention has been achieved for a broad range of phase systems with flows of 0.1 L/min in a 1 L capacity coil. This leads to the solvent front ($k = 0$) eluting in 4 min and the $k = 1$ point in 10 min with sample volumes of at least 0.1 L possible. All this adds up to sample process

Table 1 Regression analysis between retention (S_f) ($\sqrt{F}$) and the square root of flow for phase systems tested on the process CCC at 800 rpm.

Solvent system	Linear regression	Correlation
Heptane–ethyl acetate–methanol–water (1.4:0.1:0.5:1.0)	$S_f = 97.27 - 3.1341\sqrt{F}$	0.9936
Heptane–ethyl acetate–methanol–water (1.4:0.6:1.0:1.0)	$S_f = 95.73 - 3.3658\sqrt{F}$	0.9988
Heptane–ethyl acetate–methanol–water (1.4:2.0:2.0:1.0)	$S_f = 102.02 - 6.0416\sqrt{F}$	0.9950
Iso–hexane–acetonitrile (1:1)	$S_f = 106.74 - 6.9389\sqrt{F}$	0.9994

Table 2 Regression analysis between retention (S_f) and the square root of flow ($\sqrt{F}$) for phase systems tested on the process CCC at 1200 rpm.

Solvent system	Linear regression	Correlation
Heptane–ethyl acetate–methanol–water (1.4:0.1:0.5:1.0)	$S_f = 97.724 - 2.3506\sqrt{F}$	0.9991
Heptane–ethyl acetate–methanol–water (1.4:0.6:1.0:1.0)	$S_f = 100.41 - 3.107\sqrt{F}$	0.9877
Heptane–ethyl acetate–methanol–water (1.4:2.0:2.0:1.0)	$S_f = 103.63 - 5.2379\sqrt{F}$	0.9996

Butyl alcohol–acetic acid–water (4:1:5)	$S_f = 100.65 - 11.484\sqrt{F}$	1.0

throughputs of up to 1 L/hr or in weight terms as much as 1 kg/day.

However, before this can be realized, the engineering of the coil planet centrifuge will have to be made more reliable. The cyclical forces that produce the unique mixing and settling zones within the coiled tubes can cause them to shake apart and loosen. Janaway et al.[12] have solved this problem by developing new techniques for winding coils. As the scale increases, the volumes of samples being pumped through become extremely high; therefore, designing flying leads that can be guaranteed to not leak becomes paramount. The coil planet centrifuge is a rotating piece of equipment and bearings can wear out. With such high cyclical forces, the reliable engineering of larger CCC units will not be trivial.

So far, Sutherland et al.[10] have only been working with 110 mm radius coil planet centrifuge (CPC) rotors with a capacity of 1 L, which can be operated in a conventional laboratory. Sandlin and Ito[6] have gone as high as 150 mm with capacities of 0.75 L but with a lower speed and b value. The engineering challenge will be to build the next generation of process units at larger rotor radius with capacities of tens or hundreds of liters, but they would need to be installed in hazards plants using intrinsically safe manufacturing practices.

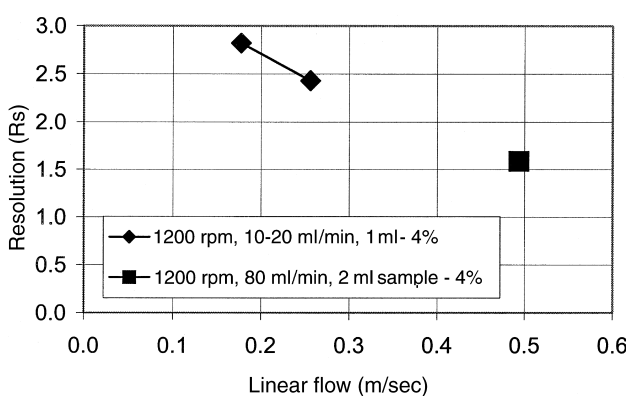

Fig. 2 Variation of resolution with flow for benzyl alcohol and phenyl ethanol in a heptane–ethyl acetate–methanol–water (1.4:0.1:0.5:1.0) phase system.

CONCLUSIONS

The chromatographic scale-up of countercurrent chromatography appears feasible, but there are engineering challenges ahead which will need to be solved before this promising new technology can be realized.

ACKNOWLEDGMENTS

Some of the work presented was undertaken as part of a BBSRC/DTI LINK Consortium study on the "Industrial Scale up of Countercurrent Chromatography." The author would like thank both the BBSRC and the DTI for their financial support and the members of the consortium[10] who have also contributed toward progressing the scale-up of countercurrent chromatography near to reality.

SEC with On-Line Triple Detection: Light Scattering, Viscometry, and Refractive Index

Susan V. Greene
Ethyl Petroleum Additives Corp., Richmond, Virginia, U.S.A.

INTRODUCTION

During the 1980s, accurate molecular weights (M) and molecular-weight distributions (MWDs) could be obtained by size-exclusion chromatography (SEC) in conjunction with multiangle light scattering (LS), SEC using conventional calibration, or SEC in combination with viscometry (VISC) using universal calibration (UC). In addition to generating M and MWD, the viscometer with UC yields conformational and branching information. The impetus to combine the two advanced detector technologies of LS and VISC into a single, efficient, and accurate SEC method has been fueled by a growing interest to characterize both natural polymers and the increasing array of synthetic polymers.[1,2]

New electronics and improved computer data acquisition capabilities have permitted the development of SEC with online triple detection using LS, VISC, and refractometry. Online triple detection is known as size-exclusion chromatography cubed (SEC^3) with the three dimensions being defined by the three detectors.[3] The use of eliminates the requirement for column calibration, unlike conventional and universal calibration, where a premium is put on control of variables such as flow rate, temperature, and column resolution. SEC^3 can offer advantages in polymer production quality control as well as in research and development of new polymers.

THEORY

The schematic for one possible configuration of SEC^3 hardware is shown in Fig. 1. When polymer molecules exit from the SEC column(s), they are simultaneously monitored in real time by three online detectors: right-angle laser LS,[4] VISC, and refractive index (RI). The following simplified equations illustrate the variables that relate to the responses of the three detectors:

$$(M)\left(\frac{dn}{dc}\right)^2(C) \rightarrow \text{LS} \tag{1}$$

$$([\eta])(C) \rightarrow \text{VISC} \tag{2}$$

$$\left(\frac{dn}{dc}\right)(C) \rightarrow \text{RI} \tag{3}$$

The term dn/dc refers to the change in RI of a polymer relative to its concentration. The LS detector responds to M, the VISC detector responds to the intrinsic viscosity ($[\eta]$), which is inversely proportional to molecular density, and the RI detector monitors concentration (C). A single narrow standard is used to determine the offset constants related to the interdetector volume for a given three-detector system.[5] Either C or dn/dc of a polymer sample must be known a priori in order to calculate the other variable using the RI detector (Eq. 3). Once both dn/dc and C are known, the LS and VISC (Eqs. 1 and 2) can be solved to determine M and $[\eta]$, respectively, for a polymer sample.[3] Structural information, such as chain flexibility, branching, and intramolecular interactions are all related to $[\eta]$. Several key polymer properties related to $[\eta]$ are as follows:

- *Chain Length*. As the chain length increases, $[\eta]$ increases and the density decreases. This behavior can be fitted to the well-known Mark–Houwink (M-H) equation (Eq. 4) relating M (approximate chain length) to $[\eta]$. The M-H constant a is the slope of the double-logarithmic plot of $[\eta]$ vs. M, and log K is its intercept.

$$[\eta] = KM^a \tag{4}$$

- *Conformation*. If a polymer molecule is folded onto itself, instead of keeping the fully extended chain, the density will be higher resulting in a lower $[\eta]$. This can be induced either by strong intramolecular attractions (e.g., hydrogen-bonding) or by a poor solvent. The Flory–Fox equation[3] calculates $[\eta]$ for a linear flexible coil molecule in solution, relating $[\eta]$ to radius of gyration, R_g. Eq. 5 shows this linear flexible coil example, where ϕ is the Flory-Fox constant.

$$[\eta]M = 6^{2/3}\phi {R_g}^3 \tag{5}$$

- *Chain Flexibility*. If two polymers have the same M, the stiff chain one will produce a coil of lesser density and greater $[\eta]$, compared with its flexible coil counterpart.

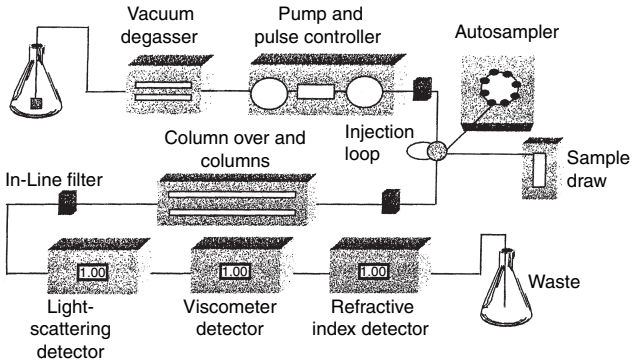

Fig. 1 Hardware schematic for a typical SEC^3 triple online detector configuration.

- *Chain Branching*. A branched molecule is more compact, having greater density and lower $[\eta]$ than its linear counterpart. The Zimm–Stockmayer theory defines the g factor for a polymer as the ratio of $[\eta]$ for the branched polymer to $[\eta]$ of the linear polymer, at the same molecular weight, with ε being the shape factor ($\sim$0.75).

$$g = \left(\frac{[\eta]_{\text{branched}}}{[\eta]_{\text{linear}}} \right)^{1/\varepsilon} \tag{6}$$

  Once g is determined, the branching number B_n (number of branches per molecule), the branching frequency λ (number of branches per arbitrarily selected repeat unit of molecular weight), and f (number of arms for a star) can be calculated. Determinations of B_n, λ and f require equations specific to the type of branching for that polymer.[6]
- *Aggregation*. Colloidal suspension particles are aggregates, which are formed due to poorly dissolved molecules. Aggregates are more dense and have a lower $[\eta]$ than their non-aggregated counterparts. The LS detector responds strongly to such aggregates. When a low VISC response is coupled with a high LS response, the presence of an aggregate is confirmed.

Thus, the SEC^3 data obtained from its LS detector determine the MWD, whereas the VISC detector characterizes conformation and branching. The efficiency of SEC^3 is a consequence of no column calibration requirement for the determination of M and MWD. The precision of the system is limited only by the signal-to-noise ratios of the LS and RI detectors, not by chromatographic variables such as flow rate and column retention. Sophisticated software is required to display the SEC^3 picture of molecular structure.

APPLICATIONS

Four examples of polymer characterization by SEC^3 will be discussed: a dextran sample with branching transitions, a pair of brominated polystyrene (PS) samples, aggregation in chitosan, and a PS star polymer. SEC^3 numerical results for dextran, chitosan, and star-branced PS are listed in the corresponding figure captions.

Dextran is a randomly branched polysaccharide with both long- and short-chain branching. The overlay of the traces generated by the three detectors in Fig. 2 shows a large shift toward a higher M for the LS detector, compared to the other two detectors. This indicates polydispersity within the sample, especially in the high-molecular-weight region of the MWD. Because long-chain branching decreases $[\eta]$ more than short-chain branching, the M-H plot indicates a transition from short- to long-chain

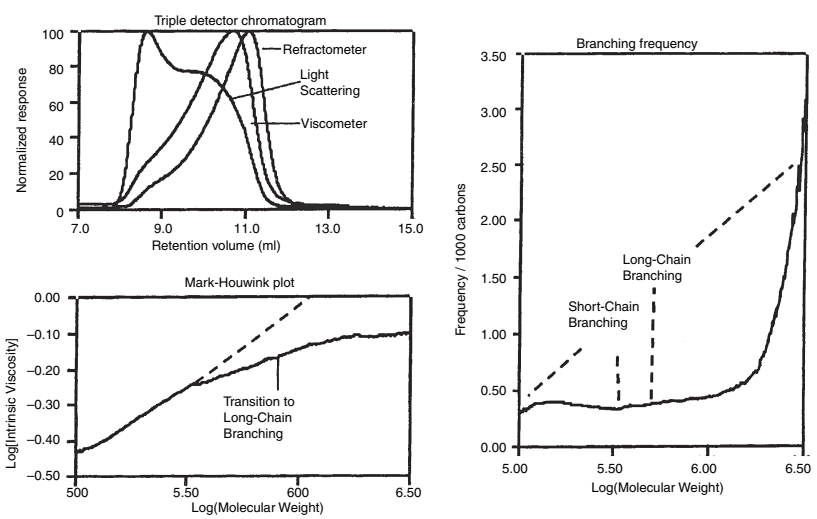

Fig. 2 In the triple-detector overlay of dextran, the shift of the LS detector toward a higher M indicates polydispersity. Both the M-H and branching frequency plots show a randomly branched polysaccharide, with both short- and long-chain branching. $M_n = 230{,}000$, $M_w = 540{,}000$, $M_z = 1{,}160{,}000$, $[\eta] = 0.54$ dl/g, $B_n = 26.6$, $\lambda = 0.43$, $dn/dc = 0.142$, $a = 0.287$, $\log K = -1.852$.

branching at $\log(M) = 5.5$, where the plot deviates from linearity. The branching frequency plot is another visual presentation of the transition from short- to long-chain branching within dextran's MWD. Again, the slope of the curve change indicates a branching transition.

An overlay of the MWDs of two samples of brominated PS is shown in Fig. 3. From the MWD overlay, it is not clear if the MWD difference is a result of two PS samples of the same M_w brominated at different levels, or two PS samples with different M_w brominated at the same level. The M-H plot, which also includes linear PS without bromination, shows that the plots of the two samples in question lie on top of each other. The superposition of the two graphs shows that two PS samples of different were brominated to the same level. The M-H plots of these two samples would be parallel to each other if PS samples of the same M_w were brominated at different levels.

Chitosan is a stiff-chain polysaccharide that has a tendency to aggregate in aqueous solution. Aggregation is indicated when a low VISC response is coupled with a high response from the LS detector. Examples of chitosan with and without aggregation are shown in Fig. 4. Note the close similarity between the non-aggregated chromatograms of the VISC and LS detectors' responses,

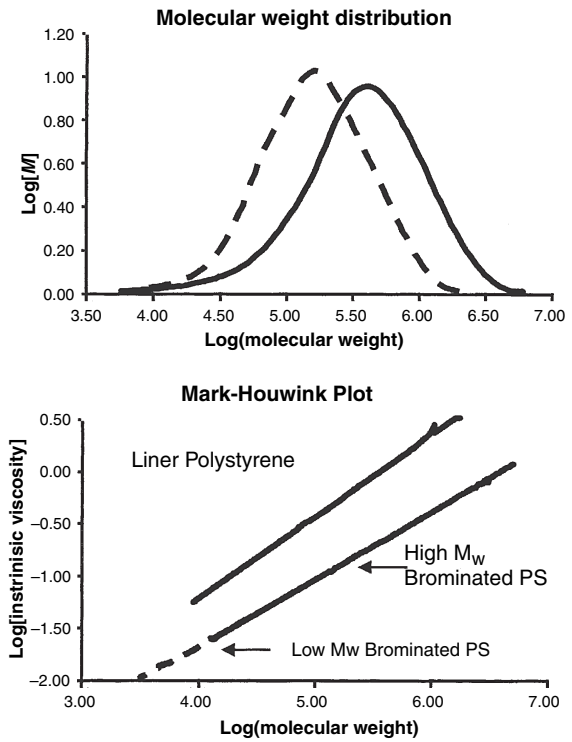

Fig. 3 Two polystyrene (PS) samples with different MWDs are compared in the upper chromatogram. In the lower graph, M-H plots of these same two samples lie on top of each other, indicating they have the same $[\eta]$ across their MWDs. It can be concluded that two PS samples of different M_w were brominated at the same level. A linear PS sample is included in the M-H plot for the purpose of comparison.

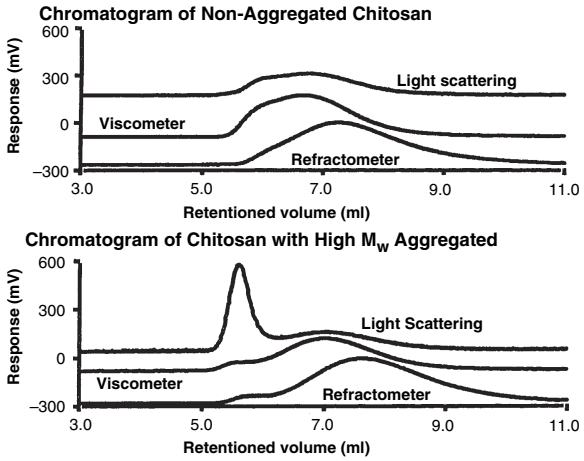

Fig. 4 Triple-detector chromatograms of non-aggregated and aggregated chitosan are compared. For the non-aggregated sample, both the LS and VISC detectors respond similarly. Aggregation in chitosan is indicated in the lower chromatogram, where the VISC response is low and the LS response is high. Non-aggregated chitosan: $M_n = 75{,}000$, $M_w = 260{,}000$, $M_z = 1{,}100{,}000$, $[\eta] = 7.9$ dl/g. Aggregated chitosan: $M_n = 90{,}000$, $M_w = 780{,}000$, $M_z = 3{,}000{,}000$, $[\eta] = 6.8$ dl/g.

respectively. For the aggregated sample, the LS response is much greater than that for the viscometer.

Star polymers are created when long-polymer chains are grouped covalently to a center core. The resulting polymer

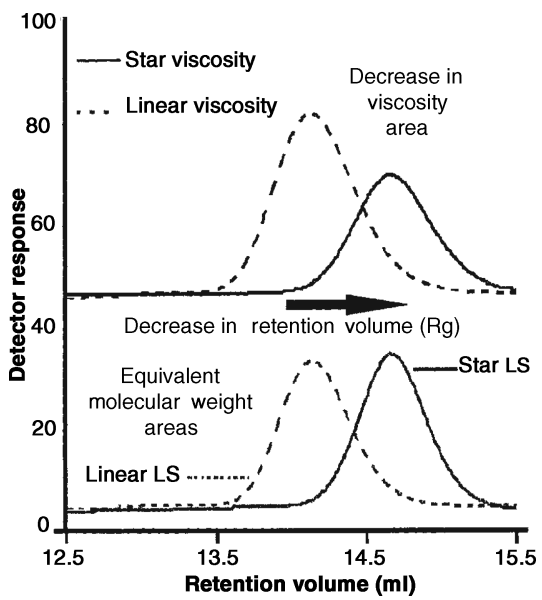

Fig. 5 The VISC traces (upper chromatogram) and the LS traces (lower chromatogram) are overlayed for a linear and a star-branched polymer with the same M. Star-branching creates a denser polymer with lower $[\eta]$ and a smaller R_g. Linear PS: $M_w = 100{,}000$, $[\eta] = 0.495$ dl/g, $R_g = 14$ nm. PS-star: $M_w = 100{,}000$, $[\eta] = 0.318$ dl/g, $R_g = 10$ nm, $f = 5$.

is denser with decreased [η], compared with a linear polymer of the same *M*. Fig. 5 compares VISC and LS detector chromatograms obtained for linear and star-branched PS, both with the same *M*. The difference in [η] is demonstrated by the area difference between the viscometer peaks of the two samples. The areas of the LS detector response are the same for both samples, but the delay elution of the star polymer confirms the star's increased density and smaller in accordance with Eq. 5.

CONCLUSIONS

Three capture its ability to reveal qualitative structural information in a visual format. The applications discussed show how peak displacement of the triple-detector chromatograms reflects polymer polydispersity (dextran), how detector response can relate to aggregation (chitosan), and how peak area differences can indicate a change in polymer chemical composition (PS vs. PS-star). The M-H plots (dextran, brominated PS) give information about polymer conformational changes, structural differences, and branching distributions.[7]

The SEC^3 technique has been in existence for 10 years. It is a relative newcomer to the analytical arena. The amount of information (molecular weight, conformational, and branching) produced, given the ease with which it can be generated, makes SEC^3 a very attractive technique. Recently, the triple detector system has been used in conjunction with temperature rising elution fractionation (TREF) to expand fundamental understanding of polymer structure–property relationships.[8]

SEC: High Speed Methods

Peter Kilz
Polymer Standards Service GmbH, Mainz, Germany

INTRODUCTION

Size-exclusion chromatography (SEC) is the established method to determine macromolecular properties in solution. It is the only technique that allows efficient measurement of property distributions for a wide range of applications. Recent trends in industrial laboratories and research institutes have been focused on increasing the analytical throughput in order to increase productivity. Quality control and combinatorial chemistry demand the optimization of high-throughput methods. Increased analytical throughput can also save time and resources (e.g., instrumentation) in production-related fields. In combinatorial research, high-throughput analytical techniques are a bare necessity, because of the huge numbers of samples being synthesized;[1,2] and references therein. In either situation, the slowest step in the process will determine the overall turnaround time. The importance of high-speed analytical techniques becomes obvious when research companies synthesize over 500 targets per day, but only about 100 samples can be analyzed. The potential of new synthetic methods and in-line production control cannot be fully utilized until the typical SEC run times of 40 min are substantially reduced.

METHODS FOR FAST SEC ANALYSES

There have been several approaches to overcome the traditionally slow SEC separations, which are caused by the diffusion processes in SEC columns. Most of them are column-related (see the sections "High-Speed SEC Columns," "Small Particle Technology," and "Smaller SEC Column Dimensions" below); one utilizes the column void volume (see the section "Overlaid Injections"), while another replaces separation with simplified sample preparation (see the section "Flow Injection Analysis"). Cloning existing methods and instrumentation is also reviewed with respect to the potential time gain (see the section "Cloning of SEC Systems"). Benefits and limitations of each method are summarized in Table 1.

High-Speed SEC Columns

The pore volume of the column packing has been shown to be one of the major factors influencing peak resolution in SEC. True high-speed separations, with good resolution, requires special high-speed columns, which allow fast flow rates, possess high separation volumes, and allow solutes to easily access the pores.[3] PSS GmbH is currently the only vendor of high-speed columns for SEC. Their high-speed columns replace conventional columns one to one, which allows for a trouble-free method transfer from an existing conventional application to a high-speed application. High-speed SEC can be performed in about 1 min, cutting down analysis time by about 10%, with similar resolution on existing instrumentation.[4] Fig. 1 shows a comparison of an SEC separation of polystyrene standards in THF on a conventional column and on a high-speed column, analyzed on the same instrument.

Precision and accuracy of high-speed separations have been investigated for various applications. Both the accuracy of molar mass results and the reproducibility have been comparable to results from conventional columns.[3]

Fig. 2 shows the overlay of 10 out of 60 repeats of a commercial polycarbonate sample analyzed in tetrahydrofurane (THF). They overlap almost perfectly. Each run took about 2.5 min, and the total run time for 60 repeats was about 2 hr.

The overall time savings can even be larger when taking the complete analytical process into account. The total run time of an instrument consists of the preparation and equilibration time, the time needed for running the calibration standards, and the run times for the unknown samples. If 10 individual standards are used for calibration and 10 samples are run, the total run time on a conventional system will be about 2 days. The same work carried out on a high-speed system will only require about 3 hr, and can be easily performed in a single day.[4]

The cost-saving aspects of high-throughput SEC techniques can be substantial and have been evaluated for different scenarios.[5]

Polyolefins, other synthetic polymers, and water-soluble macromolecules have been investigated in high-speed SEC systems. High-speed SEC can be a major time saver in two-dimensional chromatography applications, which require about 10 hr analysis time for cross-fractionation.[6] This can be reduced by a factor of 10, to about 1 hr, which makes it much more interesting for many laboratories. Details on these and additional high-speed applications can be found in Ref.[4]

Small Particle Technology

Reducing particle size of the SEC column packings reduces the time requirements in SEC because of the increased mass transfer and resultant separation efficiency.

Table 1 Synopsis of methods for increased SEC throughput.

Approach	Advantages	Disadvantages	Beneficial for...
Instrument cloning	No method change Easy to implement No additional training	High investment cost High maintenance Higher operating cost More people More space Limited throughput gain	Sample increase of up to 3 ×
High-speed column	No method change Uses existing equipment 1 : 1 application transfer No additional training Minimizes investment (column only) SEC separations in 1 min Time gain ~10 × No additional shear High efficiency Runs with conventional software	No eluent savings	QC/QA Increased throughput (10 ×) Use with exiting methods
FIA	Uses existing equipment Saves eluent	No separation Limited time gain Not applicable for copolymers/blends Requires molar mass sensitive detectors Only primary information (conc., Mw, IV) Needs method change Needs special software	Samples difficult to separate Utilize existing instruments
Overlaid injections	No method change Uses existing equipment No additional training Low cost	Needs overlaid injection-ready software	QC/QA known samples
Small columns	Uses existing equipment Minimizes investment Saves eluent Runs with current software	Limited time savings Needs method adaption Optimization of: injection volumes detection systems Shear degradation Low efficiency	Low-resolution applications Low-time-saving requirements Single detector applications
Needs training			
Limited throughput increase			

Hence, columns can become smaller in dimensions while maintaining resolution. This approach has been used for many years. Column bank lengths dropped from several meters to now typically 60 cm with current SEC column particle sizes of 5 μm as compared with about 100 μm in the early 1960s. During the same period, time requirements dropped from about 6 hr to less than 1 hr.

Unfortunately, this approach is very limited now because of the high shear rates in columns packed with small particles (less than 5 μm), which can cause polymer degradation.

Smaller SEC Column Dimensions

The reduction of column dimensions can, in theory, substantially reduce the time requirements of the separation. However, several limitations predicted by chromatographic theory have to be considered.[7,8] A study of the influence of column dimensions on fast SEC separations has been published in Ref.[4] It has been found difficult to optimize and transfer existing methods and, in many cases, new equipment had to be purchased.

Overlaid Injections

This approach has also been used when SEC separations required hours; it can cut down analysis time by a factor of 2. It utilizes the fact that about 50% of the SEC elution time is needed to transport the solutes through the interstitial volume of the columns. This allows us to inject another sample before the current one is already totally eluted. The

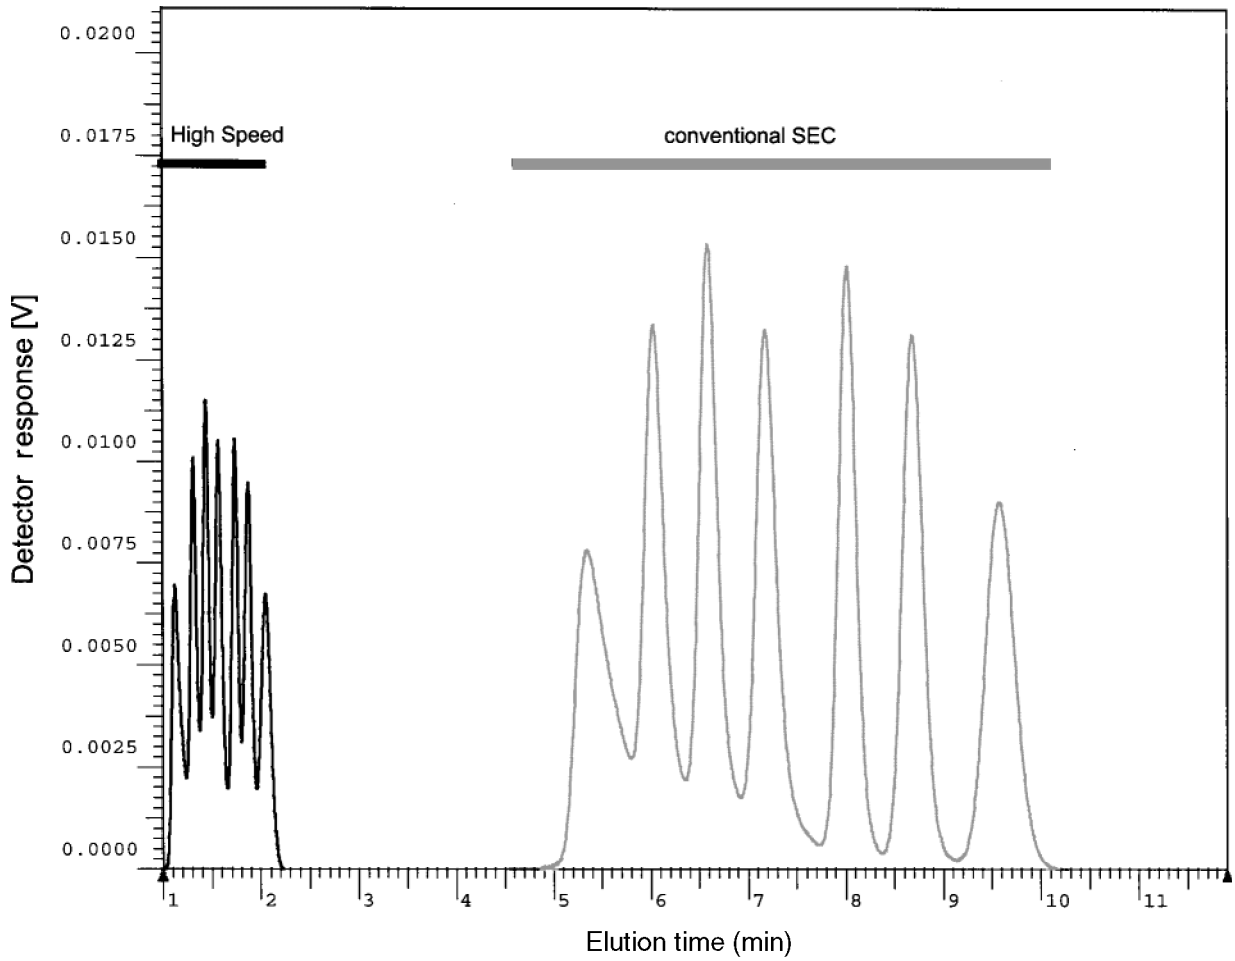

Fig. 1 Chromatogram of conventional SEC column (right part) compared to high-speed SEC column (left part); tested on identical instrument with polystyrene standards, in THF.

optimum injection interval, Δt_{min}, can be calculated from the separation properties of the instrument:

$$t_{min} = (V_t - V_0)/F$$

where V_t is the total penetration volume of column(s), V_0 is the total exclusion volume of column(s), and F is the volumetric flow rate.

The required parameters are easily determined from a molar mass calibration curve.

Today, this method can be combined with appropriate software to automate data acquisition and data processing. It is easy to use, requires no additional investment, and no method modifications are necessary.

Flow Injection Analysis (FIA)

Another approach to cut down on analysis time is to avoid separation and inject samples directly into detector cells. FIA has received some attention recently and is, therefore, mentioned in this review. Because it does not rely on any separation, advantages and limitations will be summarized only.

This method uses the HPLC equipment for sample handling and requires molar mass sensitive detectors (such as light scattering and/or viscometry) to obtain a mean property values from each detector (Mw and/or IV, respectively). The FIA result from a concentration detector yields polymer content in a sample, which can also be determined with other well-established methods. The FIA approach requires expensive and well-maintained equipment, and will not save much time or solvent; furthermore, no distribution information is available.

Cloning of SEC Systems

The number of processed samples can be increased proportionally by increasing the number identical systems. The time and analytical requirements for each sample are not changed, but the number of samples per hour can be increased. Because no change in analytical methods is necessary, cloning SEC instruments and methods is straightforward and can be carried out in most environments.

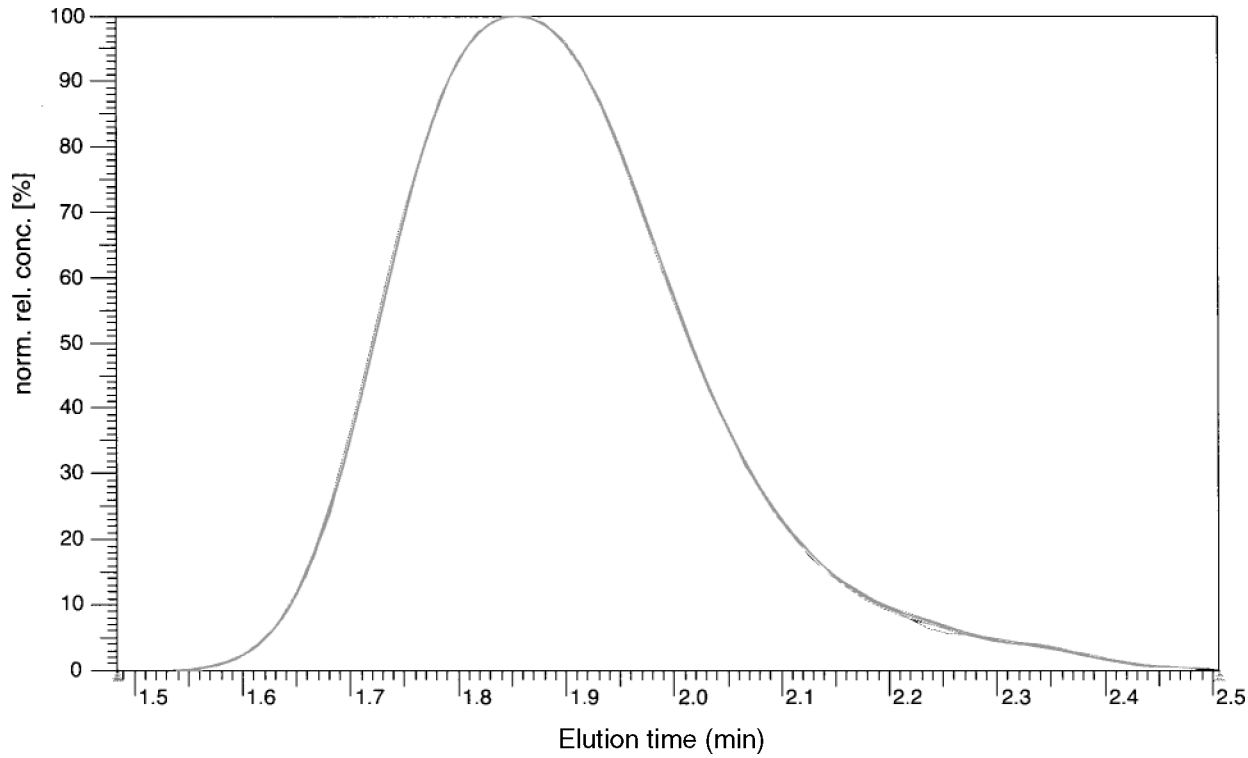

Fig. 2 Overlay of 10 out of 60 repeats of a commercial polycarbonate analysis, in THF, on PSS SDV 5 μm high speed 10^3, 10^5 Å column; measured Mw = (29,610 ± 150) g/mol (nominal sample molar mass by producer: 30,000 g/mol).

This approach, however, is clearly limited by the availability of important resources such as laboratory space, operators, instrumentation, and software licenses. Cloning systems can become very costly; time and effort for instrument maintenance and operation increases proportionally.

True parallelization of analytical processes has, so far, not been very successful. In such set-ups, only the separation module (in general the column) is set up in parallel, while solvent delivery, injection, detection, and data processing are multiplexed. These systems will no longer be as simple in operation and maintenance as the cloned systems.

CONCLUSIONS

Time requirements of SEC experiments can be reduced substantially by using high-speed SEC columns. The availability of high-speed columns allows an increase in SEC separations by a factor of 10 and run times of 1 min are possible. Precision and accuracy of results are comparable with existing methods. Existing methods and instrumentation can still be used with high-speed columns.

The time gain of high-speed columns can open up SEC methodology for

a. Monitoring and controlling processes online;
b. Using SEC methods routinely in QC labs;
c. Allowing high-throughput screening for new materials design;
d. Being a useful tool in combinatorial chemistry; and
e. Studying monitoring time-critical processes.

Sedimentation FFF: Surface Phenomena

George Karaiskakis
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

The study of the interfacial phenomena between the channel wall and the colloidal suspension under study in sedimentation field-flow fractionation (SdFFF) is of great significance in investigating the resolution of the SdFFF separation method and its accuracy in determining particles' physicochemical quantities. The particle–wall interactions in SdFFF affect the exponential transversal distribution of the analyte and the parabolic flow profile, leading to deviations from the classical retention theory, thus influencing the accuracy of analyte quantities measured by SdFFF. Among the various particle–wall interactions, our discussion focuses on the van der Waals' attractive and electrostatic repulsion forces, which play dominant roles in SdFFF surface phenomena.

SEDIMENTATION FIELD-FLOW FRACTIONATION

By the expression "surface phenomena" in SdFFF, we mean all the forces that are active when a particle approaches the channel wall. These include the van der Waals attractive and electrostatic repulsive forces, as well as the Born repulsive and solvent restructuring forces. Additionally, hydrodynamic forces due to shear near the SdFFF wall will be important for larger particles, especially at high-flow rates. Our discussion focuses on the first two forces (van der Waals' attractive and electrostatic repulsive), which exert a dominating effect on retention behavior in SdFFF.

When the colloidal particles under study do not interact with the sedimentation FFF channel wall, the potential energy of a spherical particle, $\varphi(x)$, is given by the relation:[1,2]

$$\varphi(x) = \frac{1}{6}\pi d^3 \Delta\rho G x \tag{1}$$

where d is the particle diameter, $\Delta\rho$ the density difference between the particle and the carrier liquid, G the sedimentation field expressed in acceleration, and x the coordinate position of the center of particle mass.

In the case when surface phenomena are present in SdFFF, which means that the colloidal particles interact with the channel wall, the potential energy given by Eq. 1 must be corrected so as to include the potential energy of interaction, which can be estimated by the classical DLVO theory. It involves estimations of the repulsive energy, φ_R, due to overlap of electric double layers and the London–van der Waals' attractive energy, φ_A, in terms of the particle–wall distance h and their summation to give the total interaction energy, φ_{tot}, in terms of the distance h.

The φ_R particle–wall repulsive energy can be represented in terms of the distance $h = x - d/2$, the gap width between the wall and the particle's closest surface, by the following relation:[1–6]

$$\varphi_R = 8\varepsilon d\left(\frac{kT}{e}\right)^2 \tanh\left(\frac{e\psi_1}{4kT}\right)\tanh\left(\frac{e\psi_2}{4kT}\right) e^{-\kappa h} \tag{2}$$

where ε is the dielectric constant of the medium, e is the electronic charge, ψ_1 and ψ_2 are the surface potentials of the particles and the wall plane, respectively, and κ is the reciprocal double-layer thickness given by the expression:

$$\kappa = \left(\frac{2e^2 I}{\varepsilon kT}\right)^{1/2} = \left(\frac{8\pi e^2 N_A I}{1000 ekT}\right)^{1/2} \tag{3}$$

where I is the ionic strength of the suspending medium. In order for Eq. 2 to be valid, the distance $1/\kappa$ must be small enough compared to d and h, so $\kappa d \gg 1$ and $\kappa x \gg 1$.

The van der Waals' attractive potential energy between the particles and the channel wall, φ_A, is given by the elation:[1–6]

$$\varphi_A = +\frac{A_{132}}{6}\left[\ln\left(\frac{x + d/2}{x - d/2}\right) - \frac{dx}{(x + d/2)(x - d/2)}\right] \tag{4}$$

where A_{132} is the effective Hamaker constant, which depends not only on the molecular properties of the particles and the wall material, but also on the suspending medium. Subscripts 1 and 3 refer to the particle and the wall material, respectively, while subscript 2 represents the medium.

Eq. 4, when $h \ll d/2$, approaches:

$$\varphi_A = -\frac{A_{132} d}{12(x - d/2)} \tag{5}$$

When the van der Waals' force is dominated by the dispersion interactions, A_{132} can be approximated by:[1,4]

$$A_{132} \approx \pm\sqrt{A_{131}A_{232}} \approx \left(\sqrt{A_{11}} - \sqrt{A_{33}}\right) \times\left(\sqrt{A_{22}} - \sqrt{A_{33}}\right) \quad (6)$$

where A_{ii} and A_{iji} are Hamaker constants for two bodies of material i interacting in vacuum and in suspending medium j, respectively.

Hamaker constants, which for some materials are given in the literature,[4] can be calculated on the basis of the Lifshitz theory as presented in Eq. 7 below,where n_1, n_2, and n_3 are the refractive indices of the three media, ε_1, ε_2, and ε_3 are the corresponding static dielectric constants, and v_e is the mean value of the absorption frequency of the three media.

The Hamaker constants A_{ii} can also be determined experimentally by measuring the corresponding surface tensions, since:[1,7]

$$A_{ii} \approx 2.1 \times 10^{-21}\gamma_{ii} \quad (8)$$

where γ_{ii} is in mJ m^{-2} and A_{ii} in J.

From Eqs. 2–4 and 8, and the potential curves, which express the variation of φ_R, φ_A, and φ_{tot} with the distance h, the following conclusions can be drawn:

1. The particle–wall repulsive energy (φ_R) is a function of the surface potentials of the particle (ψ_1) and the wall (ψ_2), the dielectric constant of the medium (ε), the electronic charge (e), the particle diameter (d), and the ionic strength of the suspending medium (I), as the reciprocal double-layer thickness is immediately related to I. φ_R decreases by a decrease in the particle diameter, surface potential of the particle and the wall, and the dielectric constant of the medium, as well as by an increase in the ionic strength of the dispersing medium and the temperature. Of all of the above quantities that affect φ_R, none is as accessible to empirical adjustment as κ. This quantity depends on both the concentration and valence of the indifferent electrolyte. Another way of decreasing φ_R is the variation of the surface potential of the particles by changing the suspension's pH.
2. The particle–wall attractive energy (φ_A) is a function of the effective Hamaker constant (A_{132}), of the particle diameter, and the separation distance between the particle and the channel wall. The Hamaker constant can be easily varied by adding, to the suspending medium, various amounts of detergent to change the medium's surface tension, which, as Eq. 8 shows, affects A.
3. The net potential energy of interaction between the colloidal particles and the SdFFF channel wall, $\varphi_{tot} = \varphi_R + \varphi_A$, which is the resultant of the repulsive and the attractive components, vs. their separation distance, h, shows a maximum and two minima, although some of these features may be masked if one contribution greatly exceeds the other [cf. Fig. 12.12 of Ref.[7]]. The height of the maximum above $\varphi_{tot} = 0$ is the energy barrier, while the deeper minimum is the primary minimum, and the more shallow one the secondary minimum. If no barrier is present, or if the height of the barrier is negligible compared to thermal energy, then the net potential energy of attraction will pull the particles close to the channel surface into the primary minimum, after which partial or total adhesion of the particles on the channel wall occurs, which may be reversible or not. In case the potential energy barrier is appreciable compared to thermal energy, the colloidal particles under investigation are prevented from adhering in the primary minimum. If the depth of the secondary minimum is small enough compared to thermal energy, then the particles will simply diffuse away from the channel wall, the system will be stable, and no surface phenomena are present in SdFFF. It must also be pointed out that adhesion of the particles on the channel wall may occur in the secondary minimum but, in that case, the adsorption may be reversible.

General Comments

1. The larger the Hamaker constant, the larger is the attraction between the particles and the channel wall.
2. The higher the surface potential of the particles, the larger will be the repulsion between the particles and the SdFFF wall.
3. The lower the concentration of the electrolyte, the longer is the distance of the particle from the SdFFF channel wall before the repulsion drops significantly.

Perturbations in Retention Ratio

The retention ratio with particle–wall interaction, R_p, may be smaller or larger than that of the classical theory, depending on whether the attractive or the repulsive force

$$A_{132} \approx \frac{3hv_e}{8\sqrt{2}} \cdot \frac{\left(n_1^2 - n_3^2\right)\left(n_2^2 - n_3^2\right)}{\left(n_1^2 + n_3^2\right)^{1/2}\left(n_2^2 + n_3^2\right)^{1/2}\left[\left(n_1^2 + n_3^2\right)^{1/2} + \left(n_2^2 + n_3^2\right)^{1/2}\right]} + \frac{3}{4}kT\left(\frac{\varepsilon_1 - \varepsilon_3}{\varepsilon_1 + \varepsilon_3}\right)\left(\frac{\varepsilon_2 - \varepsilon_3}{\varepsilon_2 + \varepsilon_3}\right) \quad (7)$$

dominates in the total interaction energy between particles and the SdFFF channel wall.

When $\varphi_A = \varphi_R$, the surface phenomena do not influence the retention ratio and the resultant solute's quantities do not need any correction.

When $\varphi_A > \varphi_R$, the larger is the retention volume, and the smaller will be the experimental retention ratio, R_p. The latter leads to a particle size higher than that expected, making necessary its correction.

In the case when $\varphi_A < \varphi_R$, the larger is the R_p value and the smaller will be the particle size, also making necessary the relative correction.

When $\varphi_A \gg \varphi_R$, the particle–wall interaction leads to partial or total adhesion of particles on the SdFFF channel wall.

Correction of Particle Size in SdFFF Due to Particle–Wall Interaction

Perturbations to retention ratios due to particle–wall interactions may be described in terms of the semiempirical parameter δ_w having units of length.[8,9] A measure of δ_w, which is independent of field strength, may be obtained with the aid of a simple plot of determined experimental retention data, over a range of field strength, via the equation:[8]

$$\frac{R_p - 6\alpha}{6\lambda} = 1 + \frac{\delta_w}{l} \tag{9}$$

where R_p represents the perturbed retention ratio due to interactive forces between particles and the accumulation wall, $\lambda = l/w$ (l is the thickness of the particle cloud and w the thickness of the channel) and $a = d/2w$.

Eq. 9 shows that a plot of $(R_p - 6a)/6\lambda$ vs. $1/l$ should be a straight line with intercept 1 and slope δ_w. The δ_w value so determined can be used in the modified steric retention equation:[8]

$$R_p = 6(a - a^2) + 6\lambda(1 - 2\alpha - 2\lambda)\left(1 + \frac{\delta_w}{\lambda w}\right) \tag{10}$$

from which the corrected particle radius can be calculated. δ_w is a universal constant for a given carrier liquid, channel wall material, and particle material system.[8,9]

In the case of a positive δ_w, the repulsive particle–wall interaction predominates and the experimental particle diameter is smaller than the real one while, when δ_w is negative, the attractive component of interaction predominates, leading to particle diameters larger than those expected.

Partial Adhesion of Particles on the SdFFF Channel Wall

Partial adhesion on the SdFFF channel wall was achieved by using monodisperse spherical particles of polymethyl methacrylate (PMMA) with nominal diameter 0.358 μm.[10] The extent of the PMMA particles' adhesion and detachment on and from the channel wall depends on the concentration of the indifferent electrolyte $Ba(NO_3)_2$ added to the suspending medium to influence the total potential energy of interaction between the PMMA particles and the channel wall. When the concentration of the electrolyte exceeds a given value, which is called critical electrolyte concentration (*CEC*), total adhesion of the colloidal particles occurs at the beginning of the SdFFF channel wall.

While the addition of indifferent electrolytes to the carrier solution at concentrations lower than the CEC value does not influence the retention volume and, hence, the Stokes diameter of the particles under study in SdFFF, the same addition strongly influences the recovery of the colloidal particles, as it is dependent on the interaction energy between the particles and the channel wall.

At concentrations higher than the CEC, in which total adhesion of the colloidal particles occurs at the beginning of the SdFFF channel wall, the recovery is zero. At intermediate electrolyte concentrations, partial adhesion of the particles occurs and the recovery values vary between 0 and 100. It must be pointed out that the total recovery of the particles injected into the column after their detachment was verified by the fact that the area under the curve of the eluted peak, after the detachment of the adhered particles, was exactly the same as that obtained by SdFFF using a carrier solution in which the particles are not adhering to the channel wall.

Total Adhesion of Particles on the SdFFF Channel Wall

Total adhesion of particles on the SdFFF channel wall was achieved[11] with the following model samples:

Table 1 Debye's lengths for the adhesion ($\lambda^{adh.}$) and detachment ($\lambda^{det.}$) of the particles as a function of the corresponding ionic strengths $I^{adh.}$ and $I^{det.}$ of the suspending medium.

Sample	d (μm)	$I^{adh.}$	$I^{det.}$	$\lambda^{adh.}$ (nm)	$\lambda^{det.}$ (nm)
a-Fe_2O_3(I)	0.146	8.1×10^{-2}	—	1.08	—
		—	2.0×10^{-3}	—	6.87
a-Fe_2O_3(II)	0.258	3.1×10^{-2}	—	1.74	—
		—	2.0×10^{-3}	—	6.87
TiO_2	0.310	3.1×10^{-2}		1.74	—
		—	2.0×10^{-3}	—	6.87

Table 2 Collection of parameters used in the calculation of particle–wall interaction energies in SdFFF.

Material	Hamaker constant ($10^{20} \times A$/J)	Surface potential (mV)	Refs.
a-Fe_2O_3(I)	$A_{22} = 6.2$	−15.6	[1,12]
a-Fe_2O_3(II)	$A_{22} = 6.2$	−15.6	[1,12]
TiO_2	$A_{22} = 6.2$	−45.7	[1,12]
H_2O	$A_{33} = 4.4$	—	[1,12]
Stainless steel (SS)	$A_{22} = 22.0$	−24.0	[15,12]
SS-H_2O-I.O.[a]	$A_{132} = 1.02$	—	[1,12]

[a]I.O. = inorganic oxide [a-Fe_2O_3(I), a-Fe_2O_3(II), TiO_2].

1) hematite monodisperse spherical particles of two sizes [a-Fe_2O_3(I) with $d = 0.146$ μm and a-Fe_2O_3(II) with $d = 0.258$ μm], and 2) titanium dioxide (TiO_2) monodisperse spherical particles with $d = 0.310$ μm. Variation of the suspension ionic strength and, consequently, variation of Debye's length, by adding to the suspending medium [triply distilled water containing 0.5% (v/v) of detergent FL-70 and 0.02% (w/w) sodium azide as bacteriocide] various amounts of KNO_3, leads to total adhesion and/or to complete release of the particles under study.[11]

The critical ionic strengths of the dispersing medium with the corresponding Debye's lengths for the adhesion and detachment processes for the samples under study are compiled in Table 1. In all cases, the adhesion Debye's length is much smaller than the detachment one. Furthermore, there is a critical value of the λ parameter where the profile of the potential of the particle–wall interaction changes form, and the particles are totally adhered at the SdFFF channel wall. As λ is immediately related to the closest distance of separation of the particles from the substrate, h, the calculation of the φ_{tot} as a function of h, at various ionic strengths, I, of the suspension medium for the samples under study is of great significance. The necessary quantities for these calculations are summarized in Table 2, while the resultant maximum, φ_{max}, and secondary minimum, φ_{mn1}, energies for the adhesion and detachment of the particles used on and from the SdFFF channel wall, are compiled in Table 3, from which the following conclusions can be drawn:

1. The height of the barrier is enormous ($\sim 10^9$ kT), but independent of the ionic strength, as is the same for both conditions of adhesion and detachment. It is also dependent on the size and the chemical nature of the colloidal particles.
2. The depth of the secondary minimum is dependent on the suspension's ionic strength, as it is different for the conditions under which adhesion and detachment take place. The secondary minimum of the interaction profile becomes more prominent as the ionic strength and particle size increases. Thus, particle adhesion in the secondary minimum explains their reversible adsorption in SdFFF, even though the energy barrier is sufficient to prevent attachment in the primary minimum of the interaction energy curve.

Potential-Barrier Field-Flow Fractionation

The presence of surface phenomena in SdFFF, except for being a main source of error in calculating physicochemical quantities, could also be a basis for a new separation method called *Potential-Barrier Field-Flow Fractionation*, which can separate colloidal particles of different size or of any physicochemical parameter involved in the potential energy of interaction between the particles and the FFF channel wall.[1,2,10,11] The same method can be also used for the *concentration* and analysis of *dilute* colloidal samples, such as those of natural water, where particles are present in low concentration.[13]

CONCLUSIONS

The surface phenomena in SdFFF are the main factors influencing the accuracy of colloidal properties measured by field-flow fractionation. It is, therefore, important to point out the interactions between the colloidal particles and the SdFFF channel wall in order to correct the separation resolution and/or the analyte characterization.

Table 3 Maximum, φ_{max}, and secondary minimum, φ_{mn1}, energies for the adhesion and detachment of the particles used on and from the SdFFF channel wall.

Sample	d (μm)	Adhesion		Detachment	
		φ_{max} (kT)	φ_{mn1} (kT)	φ_{max} (kT)	φ_{mn1} (kT)

Selectivity

Hassan Y. Aboul-Enein

Ibrahim A. Al-Duraibi
Pharmaceutical Analysis Laboratory, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

INTRODUCTION

The selectivity *a*, also known as the relative retention, the separation factor, or chemistry factor, of a chromatographic column is a function of thermodynamic of the mass-transfer process and can be measured in terms of the relative separation of the peaks:

$$\alpha = \frac{t_{R2} - t_0}{t_{R1} - t_0} = \frac{k_2'}{k_1'} = \frac{K_2}{K_1}$$

where t_{R2} and t_{R1} are the retention times of compounds 2 and 1, respectively, t_0 is the retention time of unretained compounds, k_2' and k_1' are the capacity factors of compounds 2 and 1, respectively, and K_2 and K_1 correspond to the distribution coefficients of compounds 2 and 1, respectively.

So, the selectivity of the chromatographic system is a measure of the difference in retention times (or volume) between two given peaks and describes how effectively a chromatographic system can separate two compounds with slight variations in structure or molecular weight. For compounds with the same molecular weight, the structure difference may involve no more than compounds that are mirror images (i.e., optical isomers resulting from the presence of one or more asymmetric atoms). Therefore, when components interact with a column and are retained, they will be separated if their degrees of retention are not identical. Two components with identical retentions would have $\alpha = 1$, or no separation. For effective separation, an $\alpha = 1.5$ is desired.

OPTIMIZING THE SELECTIVITY

Separation problems become substantially more difficult as the number of components increases much above 10. Such complexity is often characteristic of environmental and biological samples. Different chromatographic modes offer potentially unlimited selectivity, but the conditions for optimal selectivity are correspondingly more difficult to find. A systematic basis for the combining of independent selectivity mechanism can provide a major boost to the overall selectivity. The overall effect is multiplicative, based on the separating power, or peak capacity, of each of the steps. The serial implementation of multiple origins of selectivity is the most practical approach at present.

The net retention of a particular solute depends on all the solute–solute, solute–mobile phase, solute–stationary phase, and stationary phase–mobile-phase interactions that contribute to the retention, which, consequently, affect the selectivity.

The selectivity is dependent on the temperature and the chemistry of the components that make up the chromatographic system (i.e., column, solvent, and the sample). So, it is necessary to understand the physicochemical basis of retention and the retention mechanism involved in high-performance liquid chromatography (HPLC) separation.

THE SAMPLE OR SOLUTE

The basic structure and number of functional groups in the solute molecule largely determine chromatographic retention. The functional group must be able to interact with the stationary-phase surface. Moreover, the strength of the retention is increased by the introduction of a second functional group. In addition, the type of functional group determines the elution order. Therefore, changing the chemical nature of the sample compounds or altering the functional group by chemical derivatization of an analyte should lead to compounds that can be will separated with higher α, because it will alter the chromatographic properties and the solubility of the analytes. Furthermore, the quantity of injected sample could affect k' values and column efficiency.

STATIONARY PHASE

Selectivity enhancement through choice of stationary phase can be a simplifying approach for difficult

separations, where interest is in certain critical pairs and where practical capacity is deemed important.

The nature of the stationary phase plays an important role in the improvement of the selectivity of a chromatographic system. Therefore, changing the chemical composition of the column from very non-polar to a higher polarity will cause the non-polar compounds to elute faster. Also, some phases have an affinity toward some compounds; therefore, selecting the ideal phase will improve the selectivity. For instance, the chromatographic selectivity in electron-acceptor and electron-donor stationary phase depends on the ability of the stationary phase to form complexes with solutes. The selectivity depends not only on the number and mutual position of electron-accepting substituents attached to aromatic skeleton but also on the nature of the spacer connecting the ligand with the silica surface. Also, in liquid–solid chromatography (LSQ), the sample retention is governed by adsorption to the stationary phase. For retention to occur, a sample molecule must displace one or more solvents from the stationary phase. In addition to this displacement effect, polar solvent or sample molecules can exhibit very strong interactions with particular sites on the stationary phase. The separation of enantiomers using a chiral mobile phase is possible only if transient diastereomeric complexes are formed in the stationary phase. For this to happen, the stationary phase must be chiral.

Another way to improve selectivity is by using column switching, which is, in its simplest form, the use of a number, *N*, of different chromatographic mechanisms in sequence, which will expand the overall selectivity of a liquid chromatography system by the *N*th power of that obtained from a single selectivity mechanism. Column switching can create tremendous separating power, but it is a requirement that each one in the sequence of selectivity mechanism not be redundant.

TEMPERATURE

Temperature is the first of the variables affecting selectivity. Increased temperature decreases retention time on the column, sharpens peaks, and produces a change in selectivity. However, temperature is generally limited, by solvent vapor pressures, to an effective range of 20–60°C; also important is the effect temperature has on the column packing.

Temperature affects sample solubility, solute diffusion, and mobile-phase viscosity in liquid chromatography (LC). With increasing temperature, the solute diffusion coefficient tends to increase while the mobile phase viscosity decreases, producing a favorable influence on the selectivity. The change in selectivity with temperature appears more pronounced in ion-pair chromatography than other HPLC methods. Therefore, temperature may be an important variable for optimizing selectivity in certain applications of ion-pair chromatography.

MOBILE PHASE

The most powerful approach to increase a is to change the composition of the mobile phase. If changing the concentration of the components in the mobile phase provides insufficient change, altering the chemical nature of one of the components will often be sufficient. Also, we can produce other a changes by adding mobile-phase modifiers to the mobile phase. The shifts in selectivity under certain circumstances have been attributed to the change in mobile-phase composition rather than to the stationary phase. Also, selectivity arises from the combined action of mobile phase and stationary phase. Change in mobile phase can result in significant differences in selectivity for various sample analytes which can be obtained when the relative importance of the various intermolecular interactions between solvent and solute molecules is markedly changed. It is frequently preferable to use mixtures of solvents, rather than a single, pure solvent, as the mobile phase. However, in many cases, selecting a mobile phase is still a trial-and-error procedure. Moreover, pH has a prominence as a tool to affect the separation of some compound solutes. Likewise, an impressive separation of optically active compounds has been demonstrated through the use of chiral reagents that induce a ligand-exchange mechanism. Therefore, it should be recognized that the harnessing of liquid-phase composition to control HPLC selectivity provides a major corridor for achieving separation in an increasingly systematic manner.

The difficulty in eliminating the silanol groups from the silica substrate make it necessary to neutralize them using additives in the mobile phase. Also, solvent strength generally increases with the volume percent of organic modifier. Its effect is most important when hydrophobic mechanisms contribute significantly to retention. In this case, changing the organic modifier can be used to adjust solvent selectivity, as normally practiced in reversed-phase chromatography. Mobile-phase additives (in normal phase), which are very polar, influence the adsorption of substances strikingly, even in the very low concentration range, because they are adsorbed preferentially. On the other hand, the stationary-phase selectivity can be altered for some phases by the addition of some compounds or metallic complexes to the mobile phase.

HPLC offers options to control selectivity through the mobile phase. Therefore, it is important to improve the practical understanding of liquid-phase compositions needed to achieve chemical selectivity.

Selectivity Tuning

Ján Krupcik
Eva Benicka
Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia

INTRODUCTION

A very important quality criterion of an analytical method is its capability to deliver signals that are free from interferences. The ability to discriminate between the analyte and interfering components has, for many years, been expressed as the "selectivity" of a method and/or measurement system. This leads to a definition: *Selectivity of a method refers to the extent to which it can determine particular analyte(s) in a complex mixture without interference from other components in the mixture*.[1] In current analytical chemistry, selectivities based on multistage separation and detection principles are frequently used. In all these methods, the analytical tools are chosen in relation to the analytes in such a selective way that the tools give preference for the target analyte to be appropriately analyzed, either qualitatively or quantitatively. Techniques such as chromatography, electrophoresis, and membrane separations for all types of species tend to rely on selectivity in a separation process, exhibit *separation selectivity*. Hyphenated techniques like column gas or liquid chromatography–mass spectrometry (LC–MS), in which *separation and detection selectivities* are combined, are often required in legal situations when positive and non-biased identification is needed. In analytical methods, various kinds of interactions are utilized in discrimination processes. They can be based on, for example, chemical reactions, associate formation, adsorption to surfaces, inclusion phenomena, absorption of radiation, and biochemical (immunochemical or enzymatic) or electrochemical (redox) principles. To cope with overlap in responses to the useful interactions, modern methods usually rely on several *selectivity* generating steps (stages) to reduce the effects of interfering interactions. In the current analytical chemical literature, *selectivity* is very often expressed in combination with words such as *adjustment*, *tuning*, and *optimization*. In the separation methods, various terms are used to clarify the selectivity as, for example, *stereoselectivity*, *enantioselectivity*, and *shape selectivity*.[1]

RETENTION AND SELECTIVITY IN COLUMN CHROMATOGRAPHY

A separation is achieved in a chromatographic system by moving the solute zones apart and constraining their dispersion so that peaks are eluted discretely. To move the zones apart, each solute must be retained to a different (*selective*) extent, which means that their distribution coefficients must differ or they must interact with different volumes of stationary phase. Regulating the magnitude of the apparent distribution coefficients or modifying the quantity of stationary phase available to each solute, therefore, controls retention. The former is employed in interaction chromatography and the latter in exclusion chromatography. In practice, it is rare that either procedure is exclusive in any given separation, as both retentive processes are usually present to some extent. Interaction and exclusion processes, when they do occur together, act independently.[2]

Retention in chromatography can be, for an analyte i, expressed, e.g., by retention factor, k_i, using the following equation:

$$k_i = K_{\mathrm{D},i}\frac{V_\mathrm{s}}{V_\mathrm{m}} \tag{1}$$

where $K_{\mathrm{D},i}$ is a distribution coefficient, V_s and V_m are volumes of stationary, s, and mobile, m, phases in the column, respectively.

Distribution coefficient, $K_{\mathrm{D},i}$, can be calculated from an equation:

$$K_{\mathrm{D},i} = \frac{\bar{c}_{i,\mathrm{s}}}{\bar{c}_{i,\mathrm{m}}} \tag{2}$$

where average concentrations, $\bar{c}_i$, of a solute, i, in the mobile and stationary phases can be found from equations:

$$\bar{c}_{i,\mathrm{m}} = n_{i,\mathrm{m}}/V_\mathrm{m} \tag{3a}$$

$$\bar{c}_{i,\mathrm{s}} = n_{i,\mathrm{s}}/V_\mathrm{s} \tag{3b}$$

where $n_{i,\mathrm{m}}$ and $n_{i,\mathrm{s}}$ represents number of moles present in the mobile and stationary phases, respectively.

Distribution coefficient, $K_{\mathrm{D},i}$, can be used to calculate the Gibbs free energy difference, ($\Delta G_i^{\#}$), which characterizes overall interactions of the solute in the stationary and mobile phases as follows from equation:

$$\left(\Delta G_i^{\#}\right) = -RT \ln K_{D,i} \tag{4}$$

Evaluation of interactions of a solute with stationary and mobile phase may, however, be too complex for organic molecules containing various functional groups differing in polarity and interactive characteristics. This problem has been solved assuming that each group, *j*, of the molecule is associated with its own unique change in interaction energy, $\Delta G_{i,j}^{\#}$, independently, when transferred between phases. Thus, the overall interaction energy, $\Delta G_i^{\#}$, for an analyte *i*, can be approximated as the sum of its parts:

$$\Delta G_i^{\#} = \sum \Delta G_{i,j}^{\#} \tag{5}$$

Thus, the *separation selectivity* of the chromatographic system can be tuned by any parameter, which influences the interaction of an analyte with stationary and mobile phase.[3]

The *separation selectivity* may be tuned by the modification of both enthalpic and entropic terms:

$$\Delta G^{\#} = \Delta H^{\#} - T\Delta S^{\#} \tag{6}$$

SEPARATION SELECTIVITY CRITERIA IN COLUMN CHROMATOGRAPHY

In column chromatography, *the separation selectivity* is often expressed by *selectivity factor*, α, of a critical pair of sample components:

$$\alpha = \frac{k_j}{k_i} \tag{7}$$

where *k* is retention factor of compounds *i* and *j* and usually $k_j > k_i$ (see Fig. 1).

The number of adjacent peaks, *m*, in which *selectivity factor* is higher than a threshold value, $\alpha > \alpha_{thres}$, may be used to express overall *separation selectivity* of the chromatographic system for multicomponent sample separation:

$$m = 1 + \sum_{1}^{n-1} k_q \tag{8}$$

where $k_q = 1$ for those adjacent peaks for which $k_j/k_i \geq \alpha_{thres}$ otherwise $k_i = 0$.[4]

Selectivity coefficient in ion-exchange chromatography $k_{A/B}$ characterizes the ability of an ion-exchanger to select one of two ions present in the same solution.[5] *Selectivity coefficient* describing exchange of cations:

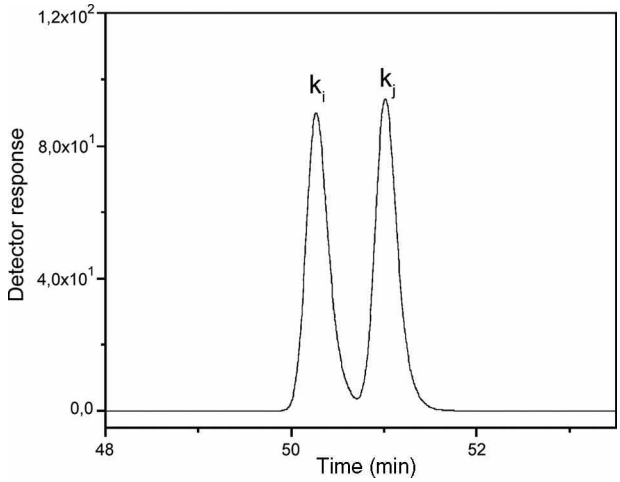

Fig. 1 Column chromatographic separation of two components.

$$Mg_S^{2+} + Ca_M^{2+} = Mg_M^{2+} + Ca_S^{2+}$$

is calculated from the equation:

$$k_{Mg/Ca} = \frac{[Mg^{2+}]_M \cdot [Ca^{2+}]_S}{[Mg^{2+}]_S \cdot [Ca^{2+}]_M} \tag{9}$$

and anions:

$$Cl_S^- + OH_M^- = Cl_M^- + OH_S^-$$

is calculated from the similar equation:

$$k_{Cl/OH} = \frac{[Cl^-]_M \cdot [OH^-]_S}{[Cl^-]_S \cdot [OH^-]_M} \tag{10}$$

where $[Mg^{2+}]$, $[Ca^{2+}]$, $[Cl^-]$, and $[OH^-]$ are equilibrium concentrations. Subscript S refers to the ion-exchanger ("stationary phase") and M to the external solution ("mobile phase"). Ions involved in the exchange are specified as subscripts. For exchanges of ions differing in charges, the numerical value of $k_{A/B}$ depends on the choice of the concentration scales of the ion-exchanger and the external solution. Concentration units must be, therefore, clearly stated for an exchange of ions differing in charges. The *corrected selectivity coefficient* ($k_{a,\ A/B}$) is calculated in a way identical to the calculation of *selectivity coefficient*, except that the concentrations are replaced by activities.[5]

SEPARATION SELECTIVITY TUNING IN COLUMN CHROMATOGRAPHY

Separation *selectivity* in column chromatography can be tuned in: (i) one column, and (ii) two or more columns coupled in series.

Single Column Separation Selectivity Tuning

For a given sample and separation mechanism, the *separation selectivity* of the chromatographic system depends on the nature of both mobile as well as stationary phase. Interactions of solute with mobile and stationary phases may include a mixture of non-polar dispersive and various polar forces. The terms "polar" and "non-polar" have been commonly used to describe a property of both the solute, as well as mobile and stationary phases. These terms, however, should not be confused with *selectivity*. The *separation selectivity* of a stationary phase can be changed discontinuously by selection of a proper column packing (by its polarity or other parameters), or tuned continuously, synthesizing tailor-made phases or mixing stationary phases differing in polarity.[6]

Tailor-made stationary phases

Tailor-made phases are specially synthesized materials to perform required *separation selectivity*. Thus, for example, in gas chromatography (GC), polyethylene glycol (PEG) may be acid-terminated to form a free fatty acid phase (FFAP) for the separation of non-esterified fatty acids. Tailor-made stationary phases are often used for the separation of isomers. This was instructively shown by synthesis of four tailored high-performance liquid chromatography (HPLC) stationary phases containing different functional groups, such as: C_{18}, C_{30}, alkylamide, and cholesterolic, for simultaneous HPLC separation of β- and γ-isomers of tocopherol.[7] It was pointed out that *separation selectivity* of each stationary phase has been a result of modulation in the mass transfer and set of unspecific interactions in the tertiary system comprising analyte, stationary, and mobile-phase interactions. Differences in observed retention and selectivity of tocopherols, together with the stationary-phase structure investigations, indicated that a spatial organization changing chemically bonded ligands as predominantly a solvation consequence. Molecular modeling studies were used to explain some of these complicated supramolecular phenomena, which caused cholesterolic stationary phase to offer beneficial performance in screening of tocopherols by HPLC and biomimetic studies of not completely recognized interactions of tocopherol isomers and biological membranes.[7]

Mixed stationary phases

Specialty columns are prepared to optimize *separation selectivity* for specified or standard analyses by mixing relative amounts of two or more distinct stationary phases.

Solute partition coefficient of an analyte, *i*, in a column consisting of two stationary phases differing in polarities, $K_{Di,AB}$, may be described by equation:

$$K_{Di,AB} = \Phi_A K_{Di,A} + \Phi_B K_{Di,B} \quad (11)$$

where $K_{Di,A}$ and $K_{Di,B}$ are corresponding partition coefficients in pure stationary phase *A* and *B* columns, respectively, and Φ_A and Φ_B are their volume fractions. This equation and its consequences also establish criteria for the analytical usefulness of mixed phases in column chromatography. For solutes and stationary phases for which the above equation is valid, it is also possible to predict an optimum composition at which the required separation selectivity is obtained.[8–10]

Main factors influencing separation selectivity in single column chromatography

Separation selectivity, in principle, may be tuned by thermodynamic parameters (temperature and pressure) and/or by polarity of stationary and mobile phase. The *separation selectivity* for a given sample is usually "optimized" by a trial-and-error approach on a column chosen by chromatographer.

The change of temperature under the isocratic, as well as programing, conditions is often used to *tune separation selectivity* in gas chromatographic separations. Temperature has not been very actively utilized in HPLC, mainly because of reported stability problems of the most commonly used stationary phases. However, more interest in the application of temperature for retention control has come nowadays because of the trend of miniaturization in chromatography and the availability of temperature-stable stationary phases.[11]

The column pressure practically does not influence the *separation selectivity* in gas and liquid chromatography. It, however, substantially influences the *separation selectivity* in supercritical fluid chromatography (SFC).[12]

Usually, the simplest *separation selectivity* tuning in HPLC is performed by tuning the composition of mobile phase polarity, mixing two or more solvents (under isocratic or gradient conditions), adding the concentration of the organic modifier and setting a proper pH for separation of given sample on a selected column at the laboratory temperature. The most effective way is to vary several parameters simultaneously.[13–15]

Separation Selectivity Tuning in Column Series

Columns of different polarities may be coupled in series under the conditions of dual column chromatography, two-dimensional chromatography, or comprehensive two-dimensional chromatography. In this part, only the *separation selectivity tuning* in dual column chromatography will be illustrated with some examples.

The *separation selectivity* of dual column HPLC, GC, and SFC coupled in series may be tuned by changing thermodynamic parameters and/or contribution of individual column polarities.[16–21] In analytical praxis, it is convenient to keep constant the entire column parameters

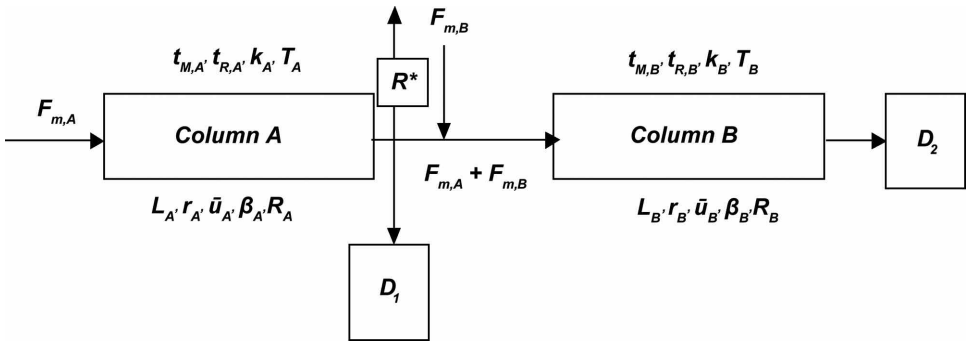

Fig. 2 Schematic of two chromatographic columns coupled in series. F_m – mobile-phase flow, t_M – mobile-phase hold-up time, t_R – retention time, k – retention factor, T – temperature, L – column length, r – column inner diameter, u – mobile-phase-flow rate, β – column phase ratio, R – column pneumatic resistance, R^* – pneumatic resistance, D – detector.

depicted in Fig. 2, except for mobile-phase flows ($F_{m,A}$, $F_{m,B}$) and/or temperatures (T_A, T_B) in individual columns. The selectivity factor of compounds i and j in a column series can then be calculated from the formula:

$$\alpha = \frac{k_{AB,j}\left(T_A, T_B, F_{m,A}, F_{m,B}\right)}{k_{AB,i}\left(T_A, T_B, F_{m,A}, F_{m,B}\right)} \tag{12}$$

where $k_{i,AB}(T_A, T_B, F_{m,A}, F_{m,B})$ is the retention factor of a compound, i, in the column AB series, T is the temperature, and F_m is the mobile-phase flow in individual A, B columns.

The retention factor of a solute in a coupled column series, $k_{i,AB}$, can, for equal column temperatures ($T_A = T_B$), be calculated from the following equation:

$$k_{i,AB} = x_A \cdot k_{i,A} + x_B \cdot k_{i,B} \tag{13}$$

where x_A and x_B are weight (retentivity) factor, calculated from the following equations:

$$x_A = \frac{t_{M,A}}{t_{M,AB}} = \frac{L_A \cdot F_{m,B}}{L_A \cdot F_{m,B} + L_B \cdot F_{m,A}} \tag{14}$$

$$x_B = \frac{t_{M,B}}{t_{M,AB}} = \frac{L_B \cdot F_{m,A}}{L_A \cdot F_{m,B} + L_B \cdot F_{m,A}} \tag{15}$$

where t_M is the mobile-phase hold-up time and L is column length.

From Eqs. (12–15), it follows that the *separation selectivity* of a column series can, for example, be tuned by changing the mobile-phase flows in individual columns.

Modification of Eq. 13 leads to a linear relationship of overall selectivity factor, $k_{i,AB}$, on weight (retentivity) factor, x_B:

$$k_{i,AB} = k_{i,A} + x_B\left(k_{i,B} - k_{i,A}\right) \tag{16}$$

The *separation selectivity tuning* in dual column chromatography may be illustrated by HPLC separation of the enantiomers of *N*-3,5-dinitrobenzoyl derivatives of some amino acids in two chiral β-cyclodextrin columns of opposite separation selectivity coupled in series. Fig. 3 shows

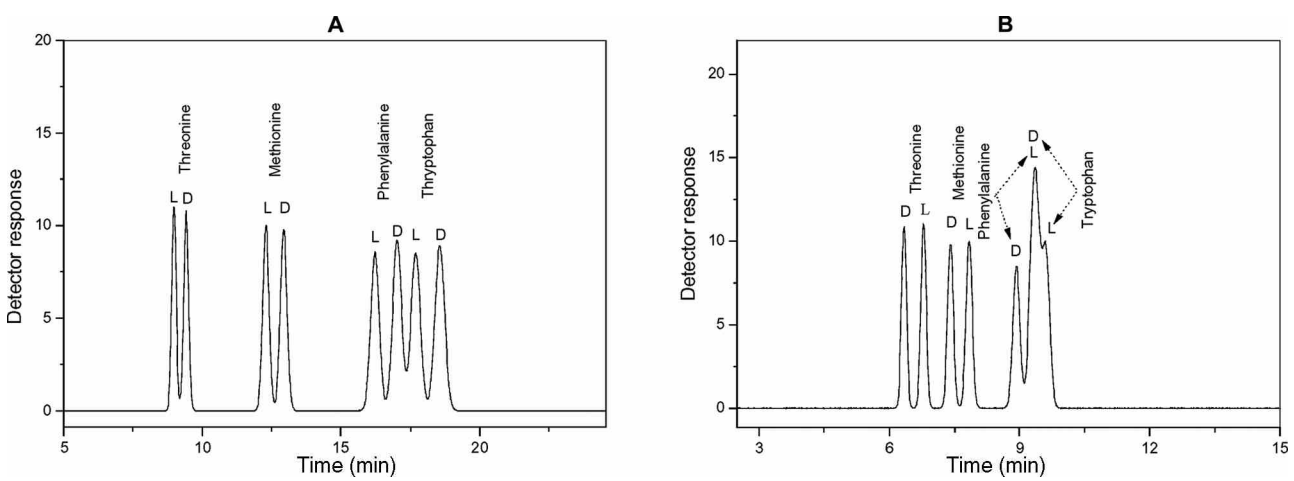

Fig. 3 HPLC separation of enantiomers of *N*-3,5-dinitrobenzoyl derivatives of threonine, methionine, phenylalanine, and tryptophan on individual Cyclobond 2000 SN (A) and 2000 RN (B) columns. Mobile phase consisted of 50% ACN and 50% water solution of TEAA-buffer at pH 2.

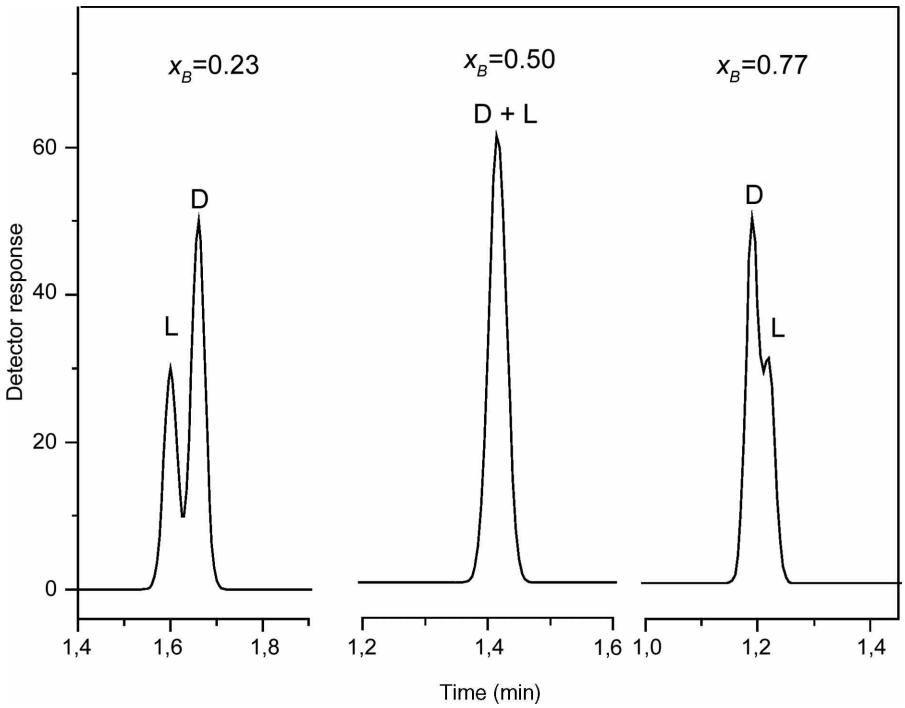

Fig. 4 Dependence of retention order of *N*-3,5-dinitrobenzoyl threonine enantiomers on retentivity factor, X_B.

the separation of enantiomers of the *N*-3,5-dinitrobenzoyl derivatives of tryptophan, phenylalanine, methionine, and threonine on individual columns. The flows of mobile phase in individual columns ($F_{m,A}$, $F_{m,B}$) were selected as variables in the column series. Fig. 4 depicts the dependence of the retention order of *N*-3,5-dinitrobenzoyl threonine enantiomers on retentivity factor, x_{RN}. Retention (k) and *separation selectivity* ($\alpha = k_L/k_D$) factors of enantiomers found by HPLC on individual Cyclobond 2000 SN (A) and 2000 RN (B) columns for *N*-3,5-dinitrobenzoyl derivatives of the studied amino acids listed in Table 1 were used to construct the dependence depicted in Fig. 5. This figure shows, in correspondence with Eq. 16, that the *separation selectivity* of two columns coupled in series may be used for optimization separation selectivity purposes.

COMPUTER-ASSISTED OPTIMIZATION OF SEPARATION SELECTIVITY IN COLUMN CHROMATOGRAPHY

After selecting a stationary phase and the mobile-phase components, several isocratic experiments are required to build a retention model. A computer-assisted multivariate procedure is often used to find the best combination of the working parameters.[22] *Separation selectivity* is often monitored by maximum resolvable components in the shortest time at separation of multicomponent samples.[4]

Various computer-assisted chromatographic optimization methods have been developed to optimize *separation selectivity*.[23–28] It should be pointed out that most of the method development strategies, as well as many types of chromatography softwares, have been focused on

Table 1 Retention (k) and selectivity ($\alpha = k_L/k_D$) factors found by HPLC on Cyclobond 2000 SN and 2000 RN columns* for *N*-3,5-dinitrobenzoyl derivatives of listed amino acids.

No.	*N*-3,5-dinitrobenzoyl derivative of	k_{SN}	α	k_{RN}	α
2	L-Tryptophan	4.29	0.97	2.09	1.09
1	D-	4.42		1.92	
4	L-Phenylalanine	3.82	0.92	1.89	1.05
3	D-	4.17		1.80	
6	L-Methionine	2.77	0.95	1.40	1.06
5	D-	2.91		1.32	
8	L-Threonine	1.77	0.95	1.06	1.07
7	D-	1.86		0.99	

*Cyclobond columns were purchased from ASTEC (http://www.astecusa.com/index.htm).

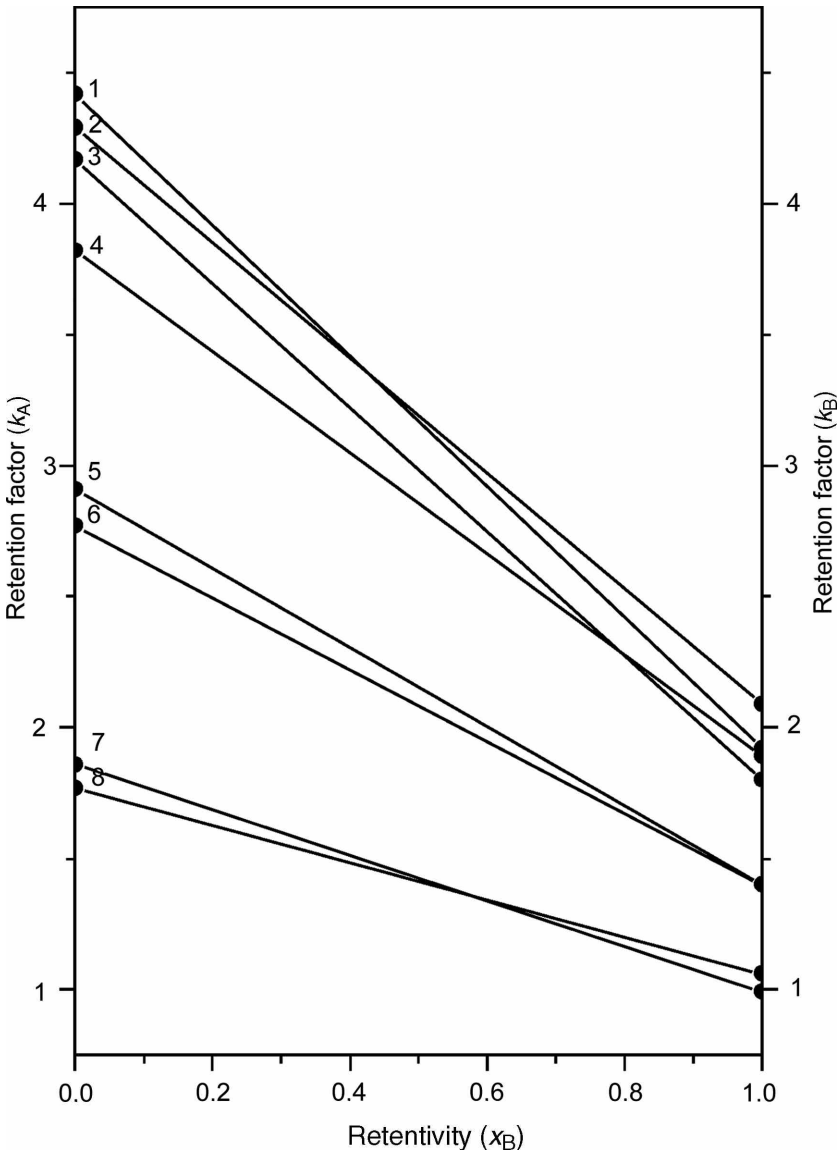

Fig. 5 Dependence of retention factor $k_{i,AB}$ of enantiomers of *N*-3,5-dinitrobenzoyl derivatives of studied amino acids on retentivity factor, X_B. For the identification of lines, compare numbers of lines with that listed in Table 1.

achieving the optimized *separation selectivity* of a complex mixture. This is an important milestone in the development of chromatographic method but, in addition to *separation selectivity*, there are many other method parameters that need to be optimized, as well.[29]

CONCLUSION

The selectivity tuning in chromatography, in general, encompasses all the discrete or continuous adjustments of separation procedure, materials, and conditions, leading to distinguishing of target compound, or group of similar compounds, from all other compounds present in a sample. The strategies utilized for selectivity tuning in particular case emerge from comprehension of chromatographic separation processes and their consequences for analysis of a compound in a sample. The optimization of separation selectivity, together with optimization of separation efficiency, may lead to resulting effect of full resolution of compounds subjected to chromatographic analysis.

Selectivity: Factors Affecting, in SFC

Kenneth G. Furton
Department of Chemistry, International Forensic Research Institute (IFRI), Miami, Florida, U.S.A.

INTRODUCTION

Retention and selectivity in supercritical fluid chromatography (SFC) are a complex function of many experimental variables and are not as easily rationalized as in the case of gas and liquid chromatography. Retention in SFC is dependent on temperature, density (and pressure drop), stationary-phase composition, and the mobile-phase composition. Many of these variables are interactive and do not change in a simple or easily predicted manner.[1]

EFFECT OF TEMPERATURE

Changes in retention at constant density are predictable from van't Hoff plots.The logarithm of the capacity factors is a linear function of the reciprocal of the column temperature, even down to subcritical conditions.[1] Analysis of the thermodynamics of the temperature-driven selectivity shifts in capillary SFC, at a constant mobile-phase fluid density, demonstrates the importance of stationary-phase polymer swelling. The other thermodynamic derivative contributing to temperature-driven selectivity shifts is the thermal pressure coefficient of the mobile-phase fluid.[2] Usually, temperature programing in SFC is done by increasing the temperature during a pressure, density, or eluent program, although negative temperature programs can also be employed to increase density. Although density conditions are the same either by decreasing temperature at constant pressure or by increasing pressure at constant temperature, the latter is preferable, as the higher diffusion coefficients at the higher constant temperature provide more favorable mass-transport properties.

EFFECT OF PRESSURE DROP (DENSITY DROP)

Selectivity is almost independent of pressure in high-performance liquid chromatography (HPLC) and gas chromatography (GC), whereas pressure (and corresponding density) is a very important parameter controlling selectivity in SFC, particularly if a significant pressure or density drop occurs along the column. In general, pressure drops are low when open-tubular columns are used, but they are significantly higher with packed columns and, therefore, have a significant effect on chromatographic resolution with packed column systems.[3] The observed selectivity, can be described by $\alpha_{obs}=e^{(B-mD)} \times (e^{bwL}-1)/mwL$, where the values for the constants B, m, and b will vary depending on the compound types being separated, the mobile phase, the stationary phase, and the temperature. D is the density of the mobile phase at the head of the column, w is the rate at which the density changes along the column, and L is the total column length. Because wL is simply the density change, $\Delta\rho$, across the column, the net result is that observed SFC selectivity changes caused by a linear density change along a column are only dependent on the total density drop which occurs. Therefore, in order to maintain constant selectivity as the density drop is increased, the density at the head of the column must be increased. Alternatively, if the density at the head of the column is kept constant while $\Delta\rho$ is increased, both selectivity and retention will increase.[4] Figure 1 demonstrates the effects of the density drop across a column for *n*-alkanes in carbon dioxide (data from Ref.[4]). Some general conclusions include that, on average, α_{obs} changes by 0.001 per 10% density drop up to a 30% density drop. Also, selectivity decreases more rapidly as density drops become larger and that selectivity increases at larger k' values where the mobile-phase density is lower.

EFFECT OF OVERALL DENSITY (PRESSURE AT CONSTANT TEMPERATURE)

The overall density of the mobile phase is one of the most important parameters used to optimize separations in SFC with density programing as common in SFC as temperature programing in GC and eluent composition in HPLC.[5] Capacity ratios, k', decrease roughly linearly at higher densities with different slopes for different classes of compounds, thereby affording changes in selectivity.[5] A similar effect is seen for the supercritical fluid elution of analytes from octadecylsilica sorbents, as seen in Fig. 2.[6]

Effect of Stationary Phase

In SFC, both packed and capillary columns are used, each with their specific advantages and disadvantages. Packed columns in SFC are very similar to those used in HPLC, with the most often used stationary phases being modified silicas. Column selectivity follows the same rules as it does in HPLC with aromatic hydrocarbons (e.g., more retained on octadecyl silica column than on bare silica).[5] A great variety

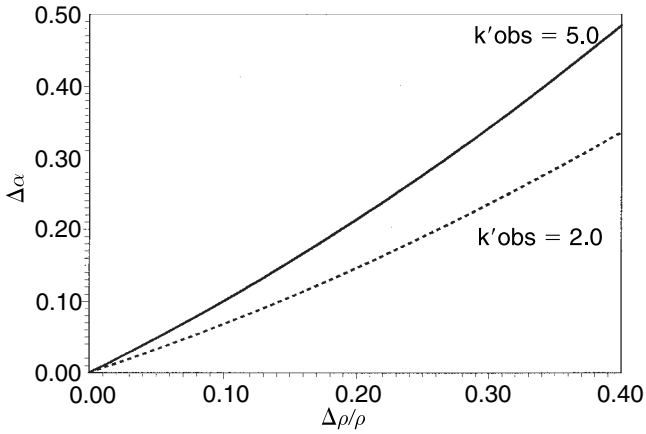

Fig. 1 Density drop effects on α at different k's for *n*-alkanes in carbon dioxide.

of different selective stationary phases have been used in packed column SFC. For example, racemic *N*-acetylamino acid *t*-butyl esters have been resolved on chiral (*N*-formyl-L-valylamino)propylsilica using methanol-modified carbon dioxide.[5] The most often used stationary phases for open-tubular SFC are immobilized films of polymeric materials—most commonly, polysiloxanes common to GC. Selecting a suitable stationary phase follows the same rules as in GC or HPLC, bearing in mind the frequently used carbon dioxide is a relatively non-polar eluent. For example, non-polar substrates such as hydrocarbons are strongly retained on a dimethyl column, whereas free carboxylic acids are more retained on a cyanopropyl column.

EFFECT OF MOBILE-PHASE COMPOSITION (POLARITY MODIFIERS)

Carbon dioxide is the most commonly used mobile phase in SFC, due to its low cost, low expense, low toxicity, and low-critical temperature and pressure. However, using the classification scheme of eluents by Snyder, carbon dioxide shows a polarity similar to that of hexane.[5] Therefore, the solvent power of eluents used in SFC is generally enhanced by adding small amounts of a second eluent modifier. Selection of the optimum solvents can be achieved in much the same way that selections are made for HPLC solvents, namely utilizing a solvent polarity/selectivity scheme. To be useful, a solvent characterization scheme must efficiently determine the solvent strength or polarity and the solvent selectivity. The polarity of non-electolytes is the capacity of the solvent for all intermolecular interactions (primarily dispersion, induction, orientation, and proton donor–acceptor interactions). Solvent selectivity is a measure of the relative capacity to enter into each specific interaction. The three primary specific interactions evaluated in all solvent characterization schemes are orientation (dipolar interaction), proton-donor (acidity), and proton-acceptor (basicity) interactions. One of the most widely used schemes is the solvent triangle introduced by Snyder and reevaluated over the years.[7] In Snyder's approach, solvent selectivity factors (using nitromethane), (using ethanol), and (using dioxane) are used to characterize the relative importance of orientation, proton acceptor (basicity) and proton donor (acidity), respectively. When these three terms are graphed against one another for the common solvents, a so-called selectivity triangle is generated where solvents with similar selectivities are clustered into eight major selectivity "groups." Additionally, a solvent polarity index, P', is calculated to provide a measure of the relative polarity of each solvent. Values for the various polarity/selectivity terms and critical constants are summarized in Table 1 for some common polarity/selectivity modifier solvents.[7,8] The most recent data for Snyder's terms from Ref.[3] have been included where available. Popular alternative schemes have utilized solvatochromic parameters based on the concept of linear solvation energy relationships to quantitatively probe-specific chemical interactions such as polarizability, hydrophobicity, and hydrogen-bonding interactions.

Solvatochromic descriptors described by Abraham are summarized in Table 1 , including the overall or summation hydrogen-bond acidity scale ($\sum\alpha_2^H$) basicity scale ($\sum\beta_2^H$) and dipolarity/polarizability descriptor ($\sum\pi_2^H$).[9] It has been shown that olvatochromic parameters may be successfully used to predict retention near the critical point in packed column SFC and may be useful in controlling selectivity of chiral separations.[10] Supercritical fluid selectivities are comparable to subcritical selectivities with minor differences attributable to the physical nature of modifier behavior under near-critical conditions where binary mobile phases may exhibit gross compositional hererogeneity at interfaces.[10] When organic modifiers are increasingly added to the mobile phase at constant pressure (density) and temperature, the retention of analytes increases or decreases, depending on whether the supercritical analytes are more or less soluble in the modifier compared to the supercritical fluid, provided that the column activity remains the same.[1]

MISCELLANEOUS AND COMBINED EFFECTS

Temperature, pressure, and density may also influence SFC selectivity in other ways. For example, water solubility in supercritical fluids generally increases with temperature, causing a shift the equilibrium of the number of water-deactivated silanol groups to carbon-dioxide-deactivated groups.[1] Therefore, the solubility of analytes in the mobile phases increases but so does retention for polar analytes due to increased stationary-phase activity.

Abstract
Molecular ordering through self-assembling of organic stationary phase is very useful for increasing selectivity in high-performance liquid chromatography (HPLC). Herein, we introduce comb-shaped polymers as self-assembled organic stationary phase for HPLC so that the selectivity can be robustly enhanced by increasing polymer chain rigidity as well as grafting density. For example, comb-shaped poly(octadecyl acrylate)-grafted silica (prepared by *grafting-to* and *grafting-from* methods) columns showed very high selectivity toward polycyclic aromatic hydrocarbon (PAH) solutes with regard to grafting technique onto silica. A comparison of the results obtained with synthetic columns and with commercial octadecylsilylated silica (ODS) revealed the effectiveness of tailor-made columns. Potential application of polypeptide lipid-grafted type stationary phases for molecular recognition has also been described.

INTRODUCTION

Liquid chromatography has become an indispensable tool for both routine analysis and research in the pharmaceutical, biomedical, and biotechnology industries. On an analytical level reversed-phase high-performance liquid chromatography (RP-HPLC) is the most widespread technique, probably owing to the broad applicability of that mode of separation to a wide range of compounds and sample matrices. The majority of bonded phases employed in RP-HPLC are still of the reversed-phase *n*-alkyl type, mostly octadecylsilylated silica (ODS) or C18 and C8. The development of new chemically bonded stationary phases for reversed-phase liquid chromatography (RPLC), engineered for solving specific separation problems, has led to improved analyses of a broad range of compounds. Refinements in approaches used to characterize chemically modified surfaces have resulted in increased understanding of stationary-phase morphology, which in turn has permitted development of novel stationary phases with properties tailored for specific applications. Usually, retention and selectivity of solutes increases with increasing grafting density of the organic phase on silica.[1,2] Molecular ordering of the organic phase also increases the selectivity.[3,4] On the basis of these viewpoints, polymeric phases are reasonable tools as organic stationary phases, and polymer immobilization process can also play an important role in increasing the grafting density as well as improving molecular ordering. Generally, the surfaces of inorganic materials are functionalized with polymer chains by using either the *grafting-to* or the *grafting-from* method. *Grafting-to* method has some limitations while there are distinct advantages in the control of polymerization degree; a polymer with a terminal reactive group can be obtained by one-step telomerization, and usual spectroscopy is applicable for determination of the chemical structure before immobilization onto silica. The main disadvantage of this method is low grafting densities resulting from steric crowding of the reactive sites.[5] On the other hand, the *grafting-from* technique results in significantly higher grafting density because the steric barrier to incoming polymers imposed by the in situ grafted chains does not limit the access of smaller monomer molecules to the active initiation sites.[6–8] Though *grafting-to* is still a good method for the preparation of HPLC stationary phases, increasing attention has been devoted to *grafting-from* techniques, especially for high retentivity and selectivity.[9–11] One of the most extensively used *grafting-from* method is atom transfer radical polymerization (ATRP)[12,13] from initiator-grafted inorganic particle surface. In this entry, we introduce high-density polymeric organic phases with π-electron-containing moieties as stationary phases for selectivity enhancement using surface-initiated ATRP *(grafting-from*) technique. Further, it is also described how the concentration of carbonyl π-electrons, through peptide-derived low

molecular compounds and polymers, brings about extremely high selectivity enhancement in HPLC.

SELF-ASSEMBLED PHASES FOR MOLECULAR RECOGNITION

Biological organisms are constructed by molecular building blocks, and these molecules are assembled spontaneously through various intermolecular interactions.[14,15] Self-assembling systems provide supramolecular functions further than those of unit segment molecules in a solution state such as lipid membranes, proteins, and nucleic acids. For instance, self-assembled systems such as lipid membrane aggregates can provide a highly ordered microenvironment leading to a unique host–guest chemistry exceeding the functions of the original lipid. Thus, there are many reports on biomimetic approaches to reproduce lipid membrane functions with totally synthetic lipids.[16–18] One of the successful results is seen in L-glutamide-derived amphiphiles. For example, dialkyl L-glutamide-derived amphiphilic lipids form nanotubes,[19] nanohelices,[20] and nanofibers[21] based on bilayer structures in water and on the fact that intermolecular hydrogen bonding among the amide moieties not only contributes self-assembly[20] but also shows a very unique secondary chirality with extremely strong circular dichroism (CD) signals.[20] Another unique self-organization has been realized by lipophilic derivatives of L-glutamide even in organic solvents.[22] These low-molecular compounds can form nanofibrillar aggregates in organic solvents to make a gel through a three-dimensional (3-D) network formation. Hence, this phenomenon is often called as "molecular gelation," but the functions are rather more similar to those of lipid bilayer membranes than to those of conventional polymer gels.

This knowledge encourages us to apply biomimetic membranes for molecular recognition systems such as HPLC. However, lipid membrane systems suffer from a serious problem owing to their instability in organic solvents. To overcome this problem, we have reported the use of poly(octadecyl acrylate)-grafted silica (Sil-ODA$_n$) as a lipid membrane analogue for stationary phases in RP-HPLC.[23] Poly(octadecyl acrylate) cannot form bilayer structures in water but forms "*nanogels*" which undergo temperature-responsive phase transition between ordered and disordered structures like lipid membrane systems. Sil-ODA$_n$ showed unique separation behaviors with ordered-to-disordered phase transitions of long alkyl chains. In particular, very high selectivity toward polycyclic aromatic hydrocarbons (PAHs) was observed in the ordered (crystalline) state.[24,25] Detailed investigations showed that the highly ordered structure in Sil-ODA$_n$ induced the orientation of carbonyl groups that work as a π–π interaction source with solute molecules. We have also found that the aligned carbonyl groups are effective for recognition of length and planarity of PAHs through multiple π–π interactions.[26,27]

GRAFTING OF COMB-SHAPED POLYMER AS AN ORDERED ORGANIC PHASE

Polymer grafting onto a silica surface is a very useful approach to introduce highly ordered organic phases. Three main routes are usually reported for chemically attaching a polymer to a surface: 1) the *grafting-to* method, where end functionalized polymers react with appropriate surface sites; 2) the *grafting-from* method, where chains grow in situ from preformed surface-grafted initiators; and 3) surface copolymerization through a covalently linked monomer.

Polymer *Grafting-to* Method

Single-anchor grafting

A comb-shaped polymer as a lipid membrane analogue is readily prepared by radical telomerization of octadecyl acrylate. By using 3-mercaptopropyl trimethoxysilane (MPS) as a telogen, not only the degree of polymerization (n) can be controlled by adjusting the initial molar ratio of the monomer to telogen, but also the reactive terminal group can be introduced at one end of the polymer main chain. Thus, poly(octadecyl acrylate)-grafted silica (Sil-ODA$_n$) is prepared by mixing the polymer with appropriate porous silica gels (Fig. 1).[27]

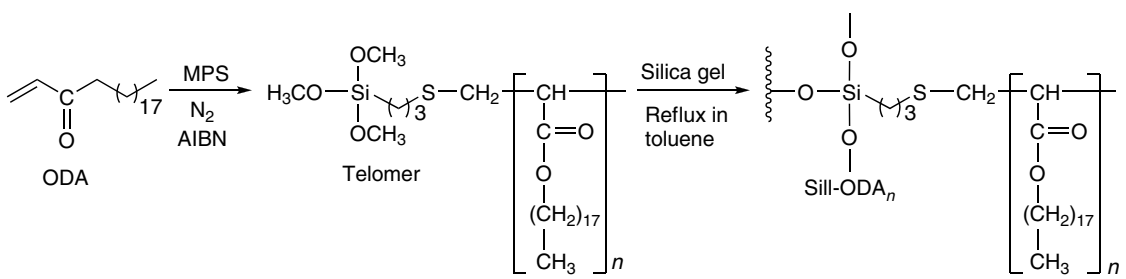

Fig. 1 Synthesis process for polymeric organic phase by one-step telomerization followed by immobilization onto silica through the terminal methoxysilyl group (grafting-to method).

The average degree of polymerization (n) is estimated by the proton ratio, based on the terminal methoxy group using proton nuclear magnetic resonance (H-NMR) spectroscopy. Immobilization of ODA_n is usually carried out by mixing with silica at reflux temperature for 72 hr in toluene. Silica gels with different pore sizes and diameters can be employed for the grafting process. Usually, silica gels with an average diameter of 5 μm, a pore size of 120 Å, and a specific surface area of 300 m^2/g are considered to be suitable for HPLC. The resultant polymer-grafted silicas indicate a distinct phase transition that can be assigned to a crystal-to-isotropic transition (Fig. 2a). This phase transition temperature is observed even in methanol, ethanol, and acetonitrile, and in their aqueous mixtures acting as usual mobile phases in RP-HPLC, although the peak-top temperature (T_c) somewhat decreases owing to solvation.[28]

The column packed with Sil-ODA_n shows very unique separation in RP-HPLC. Especially the uniqueness is emphasized when the solutes are PAHs. An extremely high separation factor, as compared with conventional ODS columns, is observed at temperatures below T_c: e.g., the separation factor $\alpha_{pentacene/chrysene}$ is 17.6 and 1.6 for Sil-ODA_n and conventional ODS columns respectively. To explain this unusual selectivity, we have proposed the multiple π–π interaction mechanism between PAHs and carbonyl groups of acrylate moieties in the ordered state.[27] This interaction is quite possible according to our previous calculations and experiments: 1) Fig. 3a shows the temperature dependencies of the separation factor α for geometrical isomers of stilbene. The poly(methyl acrylate) phase is less hydrophobic than Sil-ODA_n and ODS, as well as in a disordered state because of the absence of any long-chain alkyl groups, but the selectivity is distinctly higher than that in ODS. 2) A carbonyl-π–benzene-π interaction was simulated by the ab initio study.

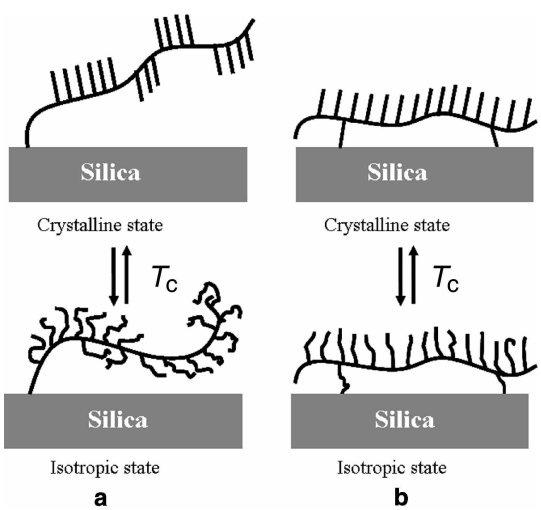

Fig. 2 Schematic illustrations of the phase transition behavior of silica-supported organic phases (a) Sil-ODA_n (single-anchor) (b) Sil-co-ODA_n (multianchor).

When HCHO and benzene was chosen as a model complex, the potential-energy curves indicated that the binding energy in HCHO–benzene was much larger (1.87 kcal/mol)[28–30] than that in benzene–benzene (0.49 kcal/mol) in plane-to-plane stacking.[31] 3) The selectivity with geometrical isomers from various substituted azobenzene compounds was investigated.[26] As a result, it was found that the separation factor between the *trans*- and *cis*-isomers was remarkably dependent on the electron-donating property of the substituent group. This strongly suggests that bonded ODA_n works as an electron-acceptor and a π–π interaction is brought about by a carbonyl-π moiety in ODA_n. This estimation was confirmed by the observation that addition of acetone as a carbonyl group-containing solvent to a mobile phase reduced the selectivity remarkably, whereas the presence of 2-propanol had almost no effect. Acetone works as a sort of an inhibitor for ODA_n–PAHs interactions.

These observations prompt us to propose multiple π–π interactions between carbonyl groups and PAHs. ODA_n, which is in an ordered state, interacts better with planar and slender PAHs such as *trans*-stilbene,[32] naphthacene, and pentacene[27] than with non-planar and bulky substances such as *cis*-stilbene[32] and *o*-terphenyl,[23] and less slender substances such as triphenylene[23] and coronene.[33] However, these unique selectivities distinctly decrease when ODA_n is in a disordered state, but rather similar to that of ODS. As shown in Fig. 3b, it is highly probable that multiple π–π interactions are more effective both in an ordered state and for planar and slender substances, but not in a disordered state.

Multianchor grafting

A reduction in the molecular mobility of a polymer chain as an organic stationary phase would lead to an increase in the selectivity in HPLC. Porphyrin derivative-bonded phases show a unique shape selectivity by retaining planar PAHs.[34] Similar molecular-planarity selectivity is also observed in cholesteryl-10-undecenoate-[35] and 4,4′-dipentyldiphenyl-bonded phases.[36] These phases contain rigid structures, and hence the limited mobility in their organic phases contributes to the shape selectivity. Similar phenomenon of selectivity increase can be observed in the comparison of the retention behaviors of polymeric and monomeric ODSs.[37]

From this viewpoint, poly(octadecyl acrylate) having the plural reactive groups in the side chain has been synthesized and immobilized onto silica (Fig. 2b). The polymer is obtained by a one-step cotelomerization with ODA and methacryloxypropyl trimethoxysilane (MAPTS). The monomer composition of the resultant copolymer is readily adjusted by the initial molar ratio and then estimated by ^{1}H-NMR spectroscopy. Sil-co-ODA_n prepared by multi-anchoring showed remarkably higher selectivity for PAHs with different molecular planarity (thickness) than for the corresponding Sil-ODA_n prepared by single anchoring although no significant difference was detected for planar

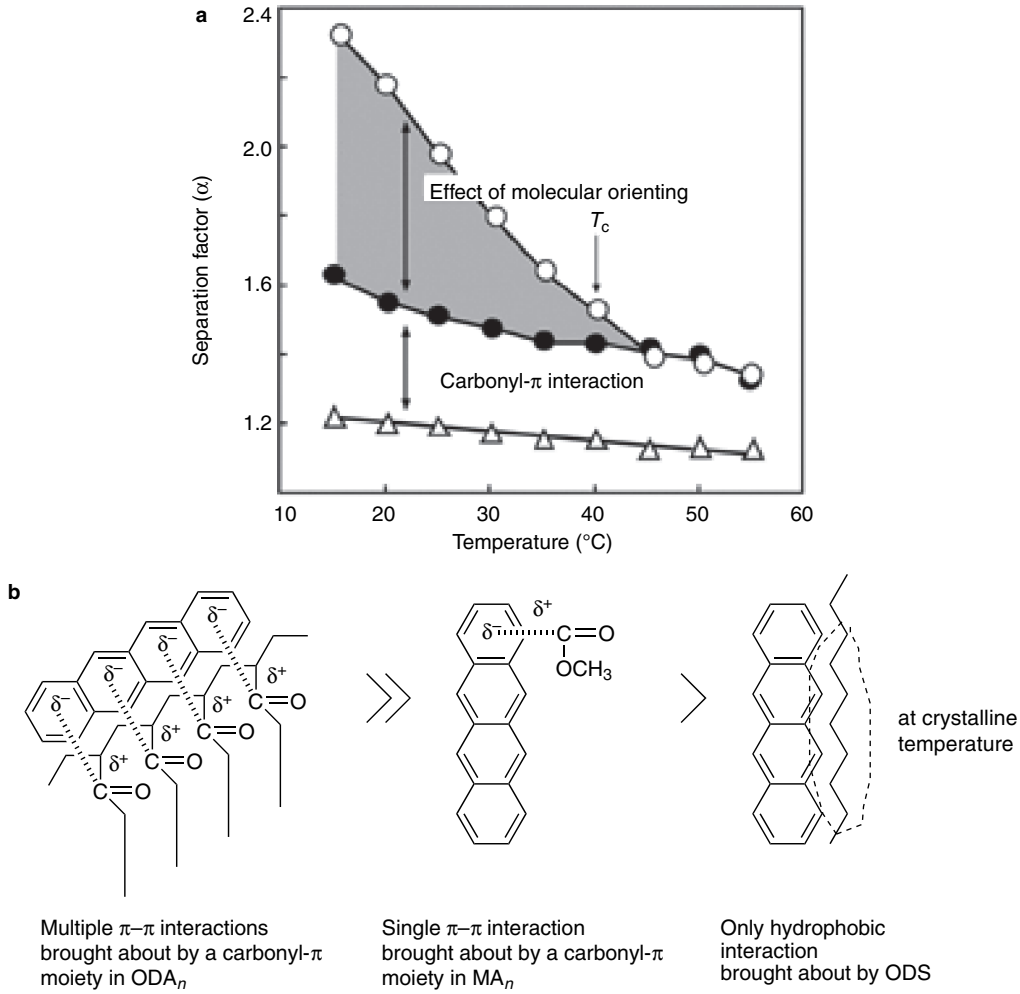

Fig. 3 (a) Temperature dependencies of the separation factors of *cis*- and *trans*-stilbene with columns: Sil-ODA$_n$ (open circles), Sil-MA$_n$ (solid circles), and ODS (open triangles). Mobile phase: methanol:water (70:30). Sil-MA$_n$: poly(methyl acrylate)-grafted silica. (b) Schematic illustrations of interaction mechanism between solutes and stationary phases.

PAHs.[32] This cannot be explained only by the increase of side-chain ordering, because it seems that there is no significant difference in the phase transition behavior between Sil-ODA$_n$ and Sil-co-ODA$_n$ in the mobile phase, as detected by differential scanning calorimetry (DSC) and suspension-state ^{1}H-NMR.[32] Therefore, we focus on the rigidity of the polymer main chain in Sil-co-ODA$_n$. It is certain that the mobility of the polymer main chain is relatively restricted by multianchoring effect in co-ODA$_n$ (Fig. 2b). This must be accompanied also by suppression of the mobility around the carbonyl groups for main interaction sites with PAHs. Therefore, it is estimated that the higher selectivity of Sil-co-ODA$_n$ can be attributed to the carbonyl groups on the rigid main chain, which are immobilized by both molecular ordering of the long-chain alkyl groups and multianchoring effect. Especially, the rigidity in Sil-co-ODA$_n$ reduces the interaction with bulky PAHs such as *cis*-stilbene and *o*-terphenyl. Based on these facts it is concluded that the molecular-shape selectivity observed with Sil-ODA$_n$ is derived from multiple carbonyl-π interactions, which is promoted by the ordering of the octadecyl groups in ODA$_n$ at temperatures below the phase transition temperature (T_c). In the same way, this interaction would be included as a main driving force in the shape selectivity observed with Sil-co-ODA$_n$.

Grafting-from Method for High-Density Polymeric Phase

The grafting-from technique involves the immobilization of initiators onto the substrate followed by in situ surface-initiated polymerization to generate a tethered polymeric phase. This approach has generally become the most attractive way to prepare thick, covalently tethered polymer brushes with a high grafting density. A variety of synthesis methods such as radical chain transfer reaction,[38] reverse ATRP,[39] living anionic surface-initiated polymerization,[40] ATRP,[41,42] dispersion polymerization,[43] and

reversible addition fragmentation chain transfer (RAFT) polymerization have been proposed for the preparation of polymer brushes. ATRP is one of the well-developed controlled living radical polymerization, and has been attracting much attention as a new route to well-defined polymers with low polydispersities and high grafting density.

As we have mentioned, the main limitation of telomerization followed by grafting, or the grafting-to method, is the low grafting densities owing to steric crowding of reactive sites during grafting process.[5] To overcome the limitations of the grafting-to technique, it is reasonable to use the grafting-from method to prepare poly(octadecyl acrylate)-grafted silica (Sil-gf-ODA$_n$) for HPLC packing material.[10] In the surface-initiated ATRP process (grafting-from) the polymer chains grow from the initiators that have been previously anchored onto the inorganic particle surface. Consequently, the grafted chains do not hinder the diffusion of the small monomers to the reaction sites, so that well-defined polymer chains with higher graft density can be obtained.[6,7,44]

The synthesis procedure for Sil-gf-ODA$_n$ is as follows: the ATRP initiator is synthesized from 2-bromo-2-methyl propionic acid undecyl ester by hydrosilation with trichlorosilane and then immobilized onto porous silica gel. The reaction between a trichlorosilane anchoring group and a surface OH group of silica results in the formation of a self-assembled monolayer on silica surface. The surface-initiated polymerization of ODA is carried out from the initiator-grafted silica using copper(I)bromide and *N*,*N*,*N*′,*N*″*N*‴-pentamethyldiethylenetriamine (PMDETA) as catalyst precursors (Fig. 4). The polymer-grafted stationary phase was characterized by diffuse reflectance infrared Fourier transform (DRIFT), elemental analysis, suspension-state ^{1}H-NMR, solid-state ^{13}C cross-polarization/magic angle spinning-nuclear magnetic resonance (CP/MAS-NMR), and DSC measurements. The surface coverage of ATRP polymerized ODA, Sil-gf-ODA$_n$, was calculated on the basis of elemental analysis results according to our previously reported method.[45] The grafting density of polymer chains on Sil-gf-ODA$_n$ is 3.75 μmol/m^2 which is significantly higher than that obtained from Sil-ODA$_n$ prepared by the grafting-to method (2.63 μmol/m^2).[10]

Characteristic features of high-density polymeric phase

The DSC thermogram of polymeric ODA (ODA$_n$) shows a sharp endothermic peak (T_c) in both the heating and the cooling processes. ODA$_n$ provided an endothermic peak at 47°C (T_{c2}, peak-top temperature) with a shoulder at around 42°C (T_{c1}) in the heating process (Fig. 5). By polarization microscopic analysis T_{c1} and T_{c2} can be assigned as crystalline-to-liquid crystalline and liquid crystalline-to-isotropic phase transitions, respectively, as mentioned above. Similar phase transitions were also observed even after immobilization on silica (Sil-ODA$_n$), as in methanol where the peak-top temperature (phase transition temperature) decreased from 47°C to 38°C,[45] which indicated that silica perturbs the molecular ordering. However, high-density Sil-gf-ODA$_n$ yields less reduction in peak-top temperature which is in the range from 47°C to 43°C (Fig. 5). These results indicate that the polymer side chains in high-density Sil-gf-ODA$_n$ remain ordered structures at higher temperatures, as compared to those in Sil-ODA$_n$.

Solid-state ^{13}C CP/MAS-NMR spectroscopy is a powerful tool for evaluation of the chemical composition and conformational properties of chemically modified surfaces. It is reported that the ^{13}C signal for $(CH_2)_n$ groups are observed at two resonances: One is at 32.6 ppm

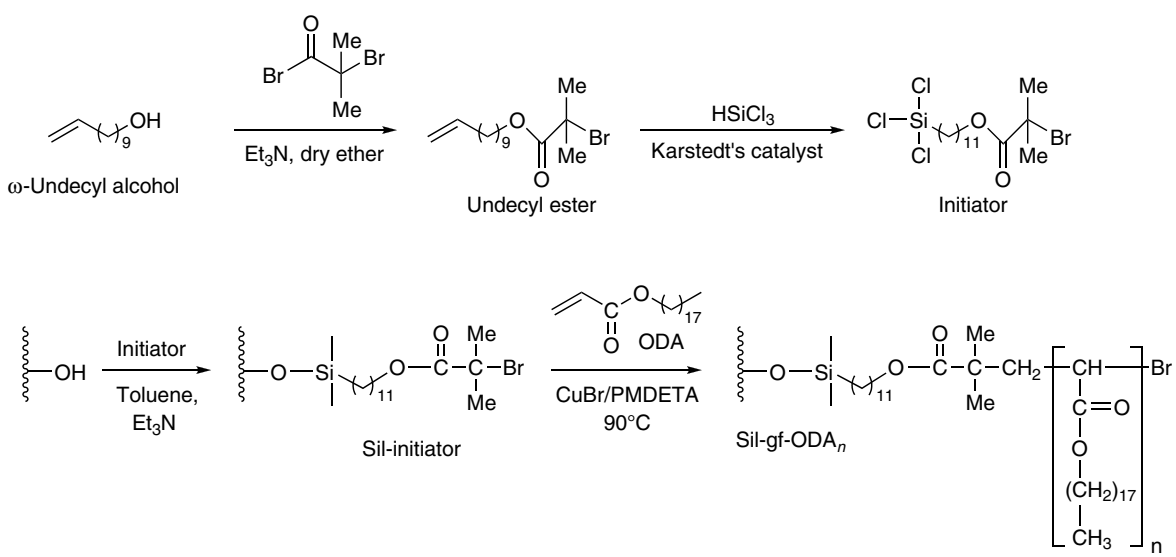

Fig. 4 Synthesis process of preparing polymeric organic phase by surface-initiated atom transfer radical polymerization (grafting-from method).

attributed to a *trans* conformation, indicating a crystalline and rigid state, and the other is at 30.0 ppm attributed to a *gauche* conformation, indicating disordered and mobile state.[46,47] Solid-state ^{13}C CP/MAS-NMR measurements were carried out at different temperatures from 25°C to 50°C for Sil-gf-ODA$_n$ and Sil-ODA$_n$ (Fig. 5). Fig. 6 shows transformation of $(CH_2)_n$ chains from ordered to disordered states (*trans* to *gauche*) as the temperature is increased. However, comparing the two approaches, Sil-gf-ODA$_n$ is more dominated by *trans* conformation than Sil-ODA$_n$ immobilized by the grafting-to method (Fig. 6A). The above result of improved order and rigidity of alkyl chains in Sil-gf-ODA$_n$ than in Sil-ODA$_n$ agrees with the DSC observation, and it is an important characteristic to understand the separation behavior of organic layers grafted onto the silica surface.

Retention mechanism

As discussed in the section "Single-anchor grafting," in high-density ODA$_n$ prepared by the grafting-from method, a main interaction source for molecular recognition is derived from a carbonyl-π moiety and not from molecular hydrophobicity. Fig. 7 shows the correlation between log *k* and log *P* for Sil-gf-ODA$_n$, Sil-ODA$_n$, and polymeric ODS (ODS-p) phases. These results indicate that Sil-gf-ODA$_n$ and Sil-ODA$_n$ have a retention mode in RP-HPLC similar to that of an ODS-p phase. Plots of log *k* vs. log *P* for alkylbenzenes and PAHs almost superimpose each other for ODS-p; however, a significant deviation is observed for PAHs and alkylbenzenes for Sil-ODA$_n$ and Sil-gf-ODA$_n$ demonstrating the existence of other possible interaction sites besides molecular hydrophobicity, which can be attributed to π–π interaction between a solute and a stationary phase. This is the most important feature of ODA$_n$-grafted silica. Furthermore, it is observed that Sil-gf-ODA$_n$ showed higher retention for PAHs as compared to alkylbenzenes. For example, log *P* of naphthacene (5.71) is smaller than that of octylbenzene (6.30), while log *k* of naphthacene (1.53) is higher than that of octylbenzene (0.93). The increase of log *k* for PAHs is accompanied by selectivity enhancement which provides specific interactive sites for PAHs that can recognize aromaticity besides molecular hydrophobicity. For instance, $\alpha_{naphthacene/benzene} = 33.0$ for Sil-gf-ODA$_n$, whereas Sil-ODA$_n$ and ODS-p yielded values of 26.8 and 10.8, respectively (Fig. 8).

Molecular-shape selectivity

Table 1 shows selectivity results for a series of PAHs on ODA$_n$-grafted silicas prepared from two different grafting

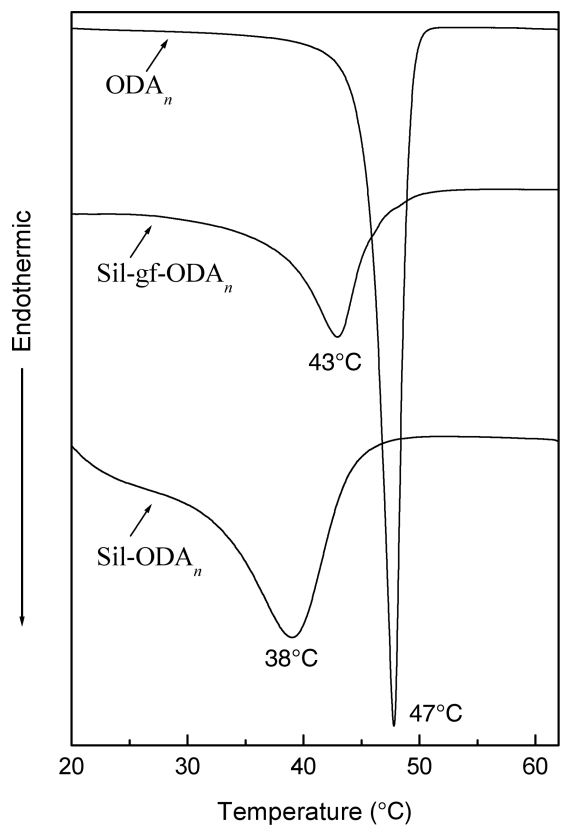

Fig. 5 Differential scanning calorimetry (DSC) thermograms of polymeric ODA (ODA$_n$), Sil-gf-ODA$_n$ (grafting-from), and Sil-ODA$_n$ (grafting-to).

Eluates: a, benzene; b, toluene; c, ethylbenzene; d, butylbenzene; e, hexylbenzene; f, octylbenzene; g, decylbenzene; h, dodecylbenzene; i, naphthalene; j, anthracene; k, naphthacene. Mobile phase: methanol:water (90:10); Column temperature: 30°C; Flow rate: 1.00 ml/min.

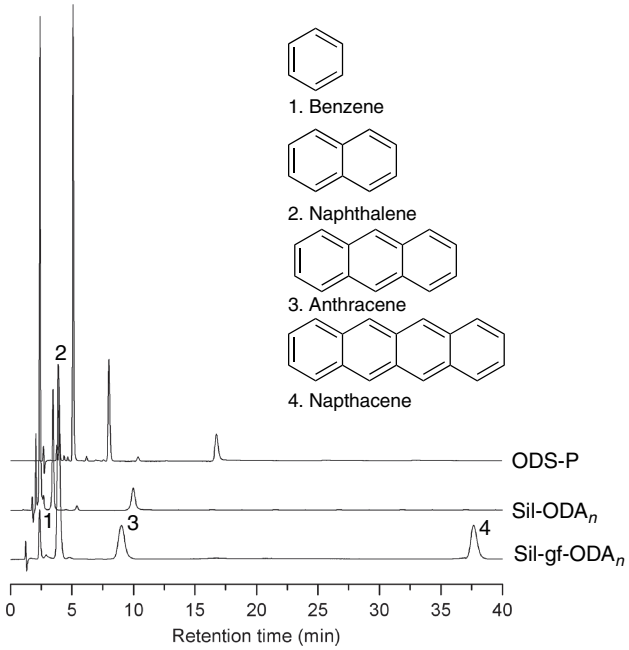

Fig. 8 Chromatograms for a mixture of benzene, naphthalene, anthracene, and naphthacene with Sil-gf-ODA$_n$, Sil-ODA$_n$, and ODS-p. Mobile phase: methanol:water (90:10); Column temperature: 30°C; Flow rate: 1.00 ml/min.

approaches, as well as for ODS-p. The selectivity in ODA$_n$ is discussed focusing on molecular planarity and length in PAHs.

Cis- and *trans*-stilbenes as geometrical isomers are good candidates for the evaluation of molecular-shape selectivity in HPLC. They have the same carbon number per molecule, and, thus, their molecular hydrophobicities are similar but the molecular planarities are absolutely different. The selectivity at 15°C is 1.33, 2.41, and 4.32 for ODS-p, Sil-ODA$_n$, and Sil-gf-ODA$_n$, respectively, clearly indicating higher selectivity by ODA$_n$-grafted silica prepared by *grafting-from* method; however, *grafting-to* approach also yielded a higher selectivity than that of ODS-p.

Another good example is the isomers of *o*-, *m*- and *p*-terphenyls. *o*-Terphenyl is bulky, and *p*-isomer is nearly planar. As summarized in Table 1, Sil-ODA$_n$ shows a better selectivity than that of ODS-p, and the selectivity is further enhanced in a high-density type, Sil-gf-ODA$_n$, although its

Table 1 Retention and separation factors of PAHs for Sil-gf-ODA$_n$, Sil-ODA$_n$, and ODS-p stationary phases at 15°C.

Solute	C_nH_n	Sil-gf-ODA$_n$		Sil-ODA$_n$		ODS-p	
		k	α	k	α	k	α

			4.3		**3.0**		**1.7**
Naphthacene	$C_{18}H_{12}$	41.4		10.7		11.4	
O-Terphenyl	$C_{18}H_{14}$	1.19		0.72		2.46	
			4.0		**1.9**		**1.7**
m-Terphenyl	$C_{18}H_{14}$	4.49		1.36		4.24	
			7.7		**3.9**		**2.2**
p-Terphenyl	$C_{18}H_{14}$	8.82		2.82		5.53	

Mobile phase: methanol:water (90:10); Column temperature: 15°C; Flow rate: 1.0 ml/min.

selectivity decreases remarkably at higher temperatures such as 60°C to be similar to those of ODS-p. These results indicate that the ODA$_n$ phase in a highly ordered state recognizes molecular planarity much better than ODS-p does; it should be noted that the organic phase in polymeric ODS has higher density than in conventional ODS.

To evaluate the planarity recognition capability of ODS phases, Tanaka et al.[48] has introduced the separation for a special mixture composed of two homologous alkylbenzenes and non-planar and planar PAHs. As shown in Fig. 9, it is observed that all compounds are resolved better for Sil-gf-ODA$_n$ than for ODS-p.

In addition, the ODA$_n$ phase shows better selectivity for molecular slenderness (length). In Table 1, this is distinctly seen in the selectivity of a mixture of benz[a]anthracene, chrysene, and naphthacene, which are completely planar compounds but different in their molecular lengths. The selectivity is much higher in Sil-gf-ODA$_n$, ($\alpha_{\text{naphthacene/chrysene}} = 3.32$) than in ODS-p ($\alpha_{\text{naphthacene/chrysene}} = 1.60$).

As mentioned above, the ODA$_n$ phase has a temperature-dependent ordered-to-disordered phase transition. Fig. 10 shows the selectivity for a planar triphenylene and a non-planar *o*-terphenyl in Sil-gf-ODA$_n$, Sil-ODA$_n$, and ODS-p. It shows that the effect of temperature is very low for ODS-p, while Sil-gf-ODA$_n$ and Sil-ODA$_n$ both showed remarkable temperature dependence with distinctly higher selectivity in Sil-gf-ODA$_n$ than in Sil-ODA$_n$ below the phase transition temperature, which is attributed to the ordered/disordered state of the ODA$_n$ moiety.

PEPTIDE LIPID-GRAFTED TYPES

In recent years, there has been renewed attention in synthetic polypeptides because of their potential application as biodegradable and biomedical polymers, as well as their ability to form highly ordered hierarchical structures through non-covalent forces such as hydrogen bonding. Incorporation of a high degree of amino acid functionality and chirality in the polymer chains can enhance the potential to form secondary structures (α-helix and β-sheet) and higher ordered structures. On the other hand, it is known that special kinds of peptide-derived lipids can form highly ordered structures such as lipid bilayer membranes.[21] In these cases, mostly hydrogen bonding interactions with peptide (amide) bonds play an important role in molecular assembling. One of the successful examples is an L-glutamic acid-derived lipid which can produce not only nanofibrillar aggregates such as helical and tubular structures but also show supramolecular functions on the base of chirally-ordered structures.[21] Therefore, the application of these self-assembling system is of great interest to scientists dealing with the preparation of new packing materials for HPLC.

With this background, we have done direct immobilization of a dialkyl L-glutamide-derived lipid (Glu-1) onto porous silica (Fig. 11).[33] Extremely enhanced selectivity was obtained for shape-constrained solutes, e.g., PAHs, aromatic positional isomers, and nucleic acid constituents. This finding encouraged us to develop polymeric peptide lipid type stationary phases.

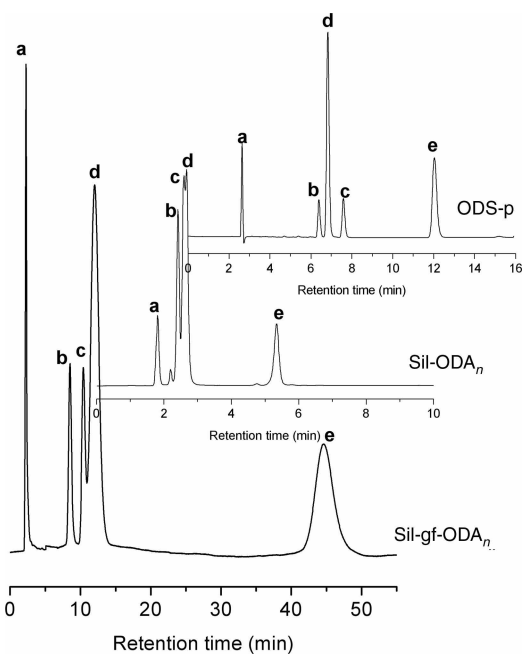

Fig. 9 Chromatograms for the Tanaka test mixture with Sil-gf-ODA$_n$, Sil-ODA$_n$, and ODS-p. Eluates: a, uracil; b, butylbenzene; c, pentylbenzene; d, *o*-terphenyl; e, triphenylene. Mobile phase: methanol:water (90:10); Column temperature: 30°C; Flow rate: 1.0 ml/min.

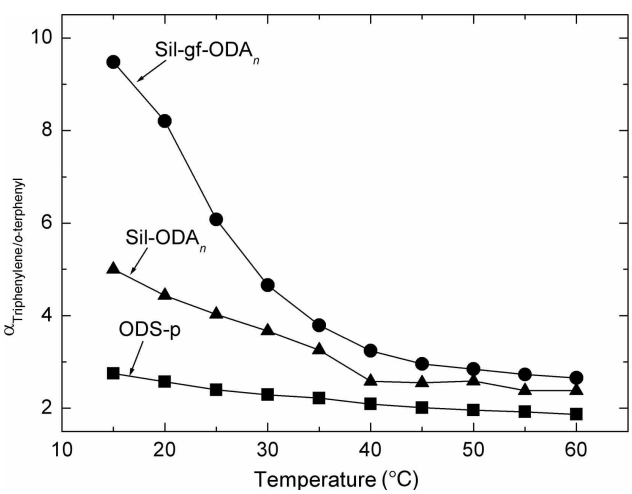

Fig. 10 Temperature dependencies of the separation factors between triphenylene and *o*-terphenyl with Sil-gf-ODA$_n$, Sil-ODA$_n$, and ODS-p. Mobile phase: methanol:water (90:10); Flow rate: 1.0 ml/min.

Silica-supported polymeric type stationary phases (Sil-Phe-1 and Sil-Phe-2) have also been synthesized from polymerizable group-introduced L-alanine lipids such as *N*′-octadecyl-N^{α}-[(*N*-acryloyl)-β-alanyl]- L-phenylalanine amide (Phe-1) and *N*′-octadecyl-N^{α}-(4-vinyl)benzoyl- L-phenylalanine amide (Phe-2) (Fig. 11). Telomerizations of Phe-1 and Phe-2 with silane coupling agent MPS were carried out, followed by immobilization onto silica.[49,50] These polymeric stationary phases showed remarkably enhanced molecular-shape selectivity as compared to ODS-p. Our detailed investigations showed that multiple π–π interactions played a key role in the recognition of molecular-shape of guest molecules. On the other hand, molecular-recognition ability of these polymeric-type peptide lipids are lower than those of monomeric type lipids.[33,49,50] In Glu-1, as compared to the L-phenylalanine–derivative lipid type, carbonyl groups (π–π interaction source) are more highly concentrated on a molecular unit. More functionality is one of the driving forces for multiple π–π interaction as well as molecular recognition in HPLC system.

CONCLUSIONS

In this entry, several kinds of comb-shaped polymers with highly ordered side chains have been introduced as attractive organic phases for RP-HPLC. Poly(octadecyl acrylate), ODA_n, is one of the simplest comb-shaped polymers, and its grafting for introduction onto silica surface is done by a one-step telomerization with 3-mercaptopropyl trimethoxysilane followed by immobilization with the terminal trimethoxysilyl group (*grafting-to* method). The chromatographic results are summarized as follows:

1. Extremely high separation ability is observed in π-electron substances such as PAHs. This is owing to the facts that carbonyl groups of ODA work as π–π interaction sources and that highly ordered state of the side chains promotes multiple π–π interaction with π-electron–containing solutes. Therefore, this selectivity is emphasized for molecular shapes such as planarity, bulkiness, and slenderness.
2. The immobilization of a polymer on a support material influences the resultant molecular-shape selectivity. For example, poly(octadecyl acrylate) having plural trimethoxysilyl groups in the side chain (co-ODA_n) was rigidly immobilized onto silica to observe the multianchoring effect of Sil-co-ODA_n. Compared with Sil-ODA_n, which is immobilized through a single terminal group at one end of the polymer main chain, Sil-co-ODA_n showed better selectivity: e.g., 1.4 times higher selectivity for the separation of triphenylene and *o*-terphenyl.
3. The *grafting-from* method is applicable for the immobilization of ODA_n onto silica. The advantage with this method is that it increases the density of polymeric phase on silica. An initiator-modified silica is prepared in advance, and then, surface-initiated ATRP is carried out with ODA. The resultant polymer-grafted silica (Sil-gf-ODA_n) shows higher surface coverage as well as molecular ordering. Consequently significant increase in the retention time and selectivity for PAHs are observed as compared to those in Sil-ODA_n prepared by the *grafting-to* method.

The use of peptide-derived lipids (Glu-1, Phe-1, and Phe-2) as organic stationary phases also has been described in this entry. These lipids not only have high potential ability as a self-assembling system but also are attractive as a carbonyl π-electron source. As a result, double-alkylated L-glutamide-derived stationary phase has been developed and extremely high selectivity is detected in HPLC as predicted. Polymeric types of peptide-derived lipids were also considered and developed, but their selectivity could not exceed that of the monomeric type lipids. This is probably due to the fact that radical polymerization of peptide-derived monomers disturb the stereoregularity of the resultant polymer main chain, and thus, sufficient molecular ordering is not obtained to increase the selectivity (multiple π–π interaction). Finally, it is concluded that subsidiary weak interactions, such as π–π interaction, can

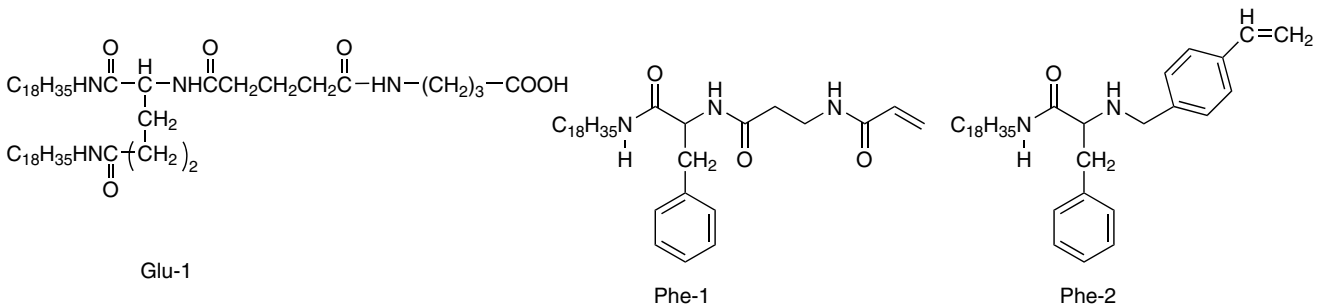

Fig. 11 Chemical structures of peptide lipids.

be remarkably enhanced by molecular ordering, and this concept leads us to highly selective HPLC.

Separation Ratio

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The *separation ratio* between two solutes has two uses. The first is to help identify a solute or confirm its identity. The second is to help calculate the minimum efficiency required to achieve a given separation (this aspect of the separation ratio will be discussed under resolution). The first chromatographic parameter to be used for solute identification, other than the corrected retention volume, is the capacity ratio of the solute.

DISCUSSION

The capacity ratio of a solute (k') was defined as the ratio of the distribution coefficient (K) of the solute to the phase ratio (a) of the column. In turn, the phase ratio of the column was defined as the ratio of the volume of mobile phase in the column (V_m) to the volume of stationary phase in the column (V_s); that is,

$$a = \frac{V_m}{V_s}$$

and, as

$$V_r' = KV_s$$

Thus,

$$k' = \frac{K}{a} = \frac{KV_s}{V_m} \quad \text{and} \quad k' = \frac{V_r'}{V_m}$$

where V_r' is the corrected retention volume of the solute.

As the measurement of k' does not depend on flow rate, it is unaffected by flow changes and is, thus, a more reliable measurement than corrected retention volume for solute identification.

Unfortunately, both V_m and V_s will vary between different columns and, due to the partial exclusion that can occur with porous supports and stationary phases, may vary between different solutes. For this reason, the separation ratio (a) was introduced as an identification parameter. For two solutes, (A and B), the separation ratio is defined as

$$\alpha_{A/B} = \frac{V'_{r(A)}}{V'_{r(B)}} = \frac{K_A V_s}{K_B V_s} = \frac{K_A}{K_B}$$

It is seen that the separation ratio is independent of all column parameters and depends only on the nature of the two phases and the temperature. Thus, comparing data from two different columns, providing that the same phase system is used in each, and the columns operated at the same temperature, then any two solutes will have the same separation ratio on both systems. Thus, the separation ratio will be *independent of the phase ratios* of the two columns and the *flow rates*. It follows that the separation ratio of a solute can be used more reliably as a means of solute identification.

In practice, a standard substance is often added to a mixture and the separation ratio of the substance of interest to the standard is used for identification purposes. The separation ratio is taken as the ratio of the distances in centimeters between the dead point and the maximum of each peak, or if data processing is employed and the flow rate is constant, chart distances can be replaced by the corresponding retention times.

INTRODUCTION

All of the samples analyzed using a chromatographic technique need special preparation before they are introduced into the column. This process is laborious, not reliable enough, and often expensive. There are several steps involved in sample preparation: dialysis, dilution, extraction (selective extraction or concentration), and derivatization. Sometimes, the derivatization step is part of the extraction process. The expenses refer to the reagents and solvents of chromatographic purity grade. The sample preparation will become easier and not so expensive by automation.

Sequential injection analysis (SIA), introduced in 1990,[1,2] is a technique with a high potential for online process measurements. It is simple and convenient because sample manipulation can be automated. Furthermore, it consumes low volumes of reagents and solvents. Up to now, all the necessary steps done manually before introduction of the sample into the high-performance liquid chromatography (HPLC) were separately introduced in SIA systems. By including SIA in sample preparation, it became faster, more accurate, and precise. Contamination is reduced substantially and the objectivity of the analysis increased. The main advantages of the coupling of SIA with HPLC are high precision of sample injection into the column, low contamination, low consumption of sample, reagents, and solvents, and the short time of preparation that decreases the time of analysis.

DIALYSIS

For online measurements, the dialysis step is very important because, through dialysis, the solid particles can be retained, the solution can be purified, and also some of the interference can be eliminated. The main disadvantages of dialysis are the slow speed involved and the low recovery of analyte. These parameters can be improved by introducing the dialyser into the conduits of a SIA system.[3]

With the incorporation of a passive, neutral, semipermeable dialysis membrane into the conduits of the sequential injection system, the contact time of the sample zone with the membrane had much influence on the quantity of analyte that dialyzed through the membrane. It is necessary to determine, first, the time necessary to propel the entire sample zone over the membrane. After the propelling of the sample zone over the membrane, the flow direction is reversed and the sample zone is drawn back into the holding coil for fixed periods of time; usually these periods of time can vary from 2 to 60 sec. By increasing of the dialysis time, the sensitivity of dialysis and, finally, the sensitivity of the analytical information are increased. A long dialysis time is also not good to consider, because this increases the dispersion of the dialyzed sample (situated below the membrane) due to a longer time delay before it is drawn in the specific holding coil for analysis.

To increase the percentage of dialysis, as well as the dialysis time, multiple flow reversals with a time of 20 sec between each flow reversal is selected. Similar results are obtained by using a sequential injection system with the stopped-flow period around 150 sec. The advantage of utilizing the stopped-flow mode over multiple flow reversals in the sequential injection analysis systems is that it needs less programming and, also, it reduces the strain on the pump.

DILUTION

It is well known that HPLC techniques are performed at low concentration ranges. Sometimes, the sample is too concentrated in the analyte to be determined, and a dilution step is absolutely necessary. When a SIA system containing a dialyzer is utilized for sampling before a HPLC, the sample is already diluted. If the dilution is still not enough, a special step must be adopted in the program of the SIA system. The next step, when the analyte is extracted into a solvent, can also be considered a dilution.

There are two methods that can be adopted for a dilution in SIA: by using a dilution coil and by using a dilution step.[4,5] The easier dilution technique in SIA is by using a dilution step which can also be accomplished in a shorter time. There are three types of volumes that can control the dilution: the sample volume (the volume of sample or standard that is drawn into the holding coil via the sample

port), the transfer volume (the volume of sample plus accompanying wash in the holding coil and tubing that is transferred into the dilution conduit from the holding coil), and the analysis volume (the volume taken from the dilution conduit to the holding coil).[4]

CONCENTRATION

The concentration step is very easy to implement in sequential injection analysis. The system is very simple and the results are reproducible. Most of the time, this step is not necessary for HPLC. When it is necessary, it can easily be done in the same time with the extraction step.

EXTRACTION

There are two types of extraction that can be used in sampling. The first one involves a chemical reaction before the extraction, and the other one is just a simple extraction of analyte(s) from the solution. When a chemical reaction is involved, the derivatization step that may be necessary is included in the extraction step.

Extraction techniques that involve a chemical reaction can be classified as non-selective extraction or concentration, when more than one analyte is extracted from the solution by using the organic collectors (e.g., 8-hydroxyquinoline and dithizone derivatives) and selective extraction or separation. The first step in such an extraction technique is the formation of the complex by adding the reagent(s) to the solution of analyte, and after the extraction of the complex in an organic solvent. The problem that can arise in a SIA system with these types of extraction is the precipitate that is formed, and this can contaminate the other sample and also can block the tubing. To avoid these problems, it is necessary either to dilute the sample in such a way that the precipitation equilibria will not be reached and that all the complex will remain dissolved in the solution, or by derivatization of the ligands to make the complexes soluble in the aqueous olution by introducing hydrophilic groups into their structures (e.g., in the place of 8-hydroxyquinoline, the 7-iodo, 8-hydroxyquinoline, 5-sulfonic acid can be used).

Three types of SIA system were proposed in coupling with the extraction technique: The first one is based on the introduction of bubbles into the system,[6] the second system is based on wetting film that is formed on a Teflon tube wall,[7] and the third one is based on solid-phase extraction.[8] The most utilized system is the one based on bubbles. The most reliable is the one based on a Teflon tube wall, and the principle of functioning of this system is as follows. The aqueous sample is propelled through the segment of organic solvent whose flow is impeded due to hydrophobic interactions with the walls of Teflon extraction coil. This wall drag allows the faster moving aqueous sample to penetrate through and ultimately separate from the organic solvent. These steps are repeated with a reextraction into a second aqueous segment that is collected and which is going to the analyzer.[9]

DERIVATIZATION

This step can be included in the extraction techniques because, in most of the cases of extraction, the analytes are being transformed. This step is only necessary for analytes that cannot be determined directly in the form that they already exist in solution. In the SIA system, the derivatization process can be assimilated with a reaction between analyte(s) and reagent with the optimum parameters for both the reaction and SIA system;[8,10] the difference is that the product of the reaction is not channeled to the detector, but is channeled to the chromatograph.

SIA/HPLC SYSTEMS

Sequential injection is the perfect vehicle for HPLC, which, in turn, enhances sequential injection by eliminating the problem of dialysis, dilution, or concentration, extraction, and mixing reactants during the loading process. HPLC can be carried out in different modes: affinity chromatography, ion chromatography, extraction chromatography, and so forth.

Most of the SIA/HPLC systems have been applied for the separation and assay of radionuclides. The reason for selecting such a system is the potential radiation and contamination of an operator during the sampling process. By using SIA/HPLC systems, all steps are automated and the contact of the operator with them is minimal. Grate and Egorov[11] reviewed the 2 Sequential Injection Analysis in HPLC radiometric separation and gave to SIA/HPLC systems the main place between automatic analytical separation in radiochemistry. They found that the type of chromatography suitable for coupling with SIA is extraction chromatography. For radiochemical separation, a wide-bore holding coil, in combination with air segmentation and sequential loading and delivery of solutions, instead of zone stacking in the holding coil, is proposed.

Enzymes and antibody–antigen systems have been used to measure a large number of analytes in relation to SIA/HPLC systems.[12] A very interesting application of these systems is given when the HPLC is carried out in the bead injection (BI) form.[13] As BI is presently restricted to relatively short columns, it is focused on separations based on mobile-phase changes, rather than relying on the separating power provided by a large number of theoretical plates. The SIA/BI system has also been

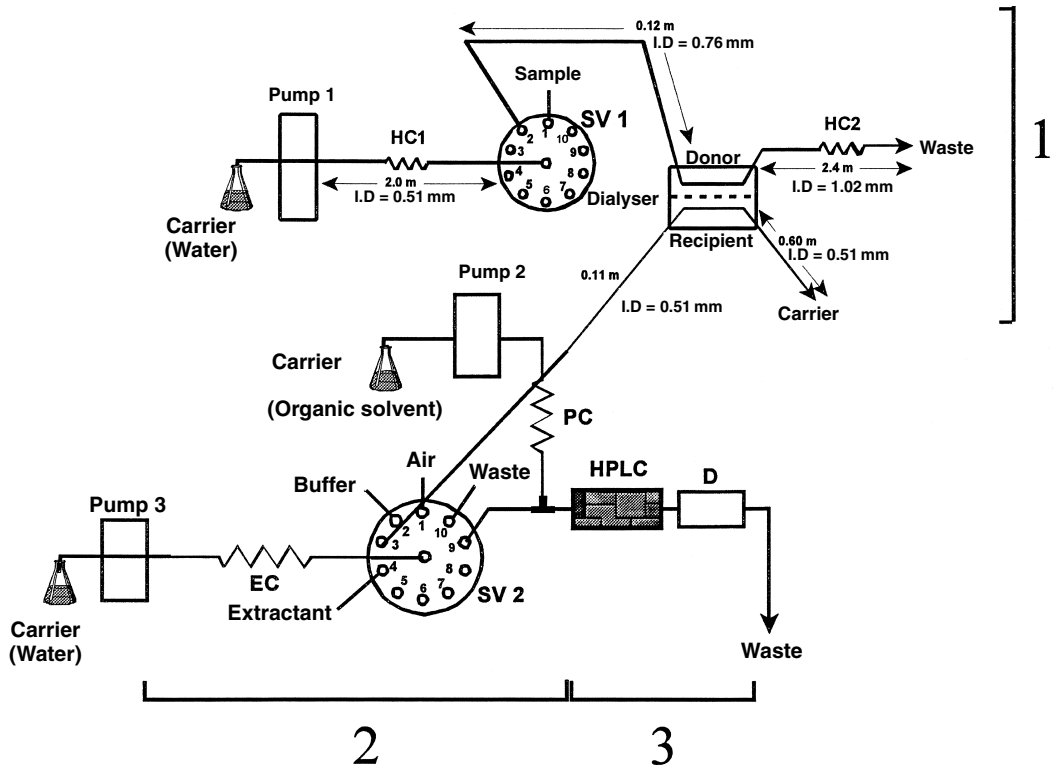

Fig. 1 Schematic representation of SIA/HPLC–detector system: 1: the dialysis unit; 2: the extraction (dilution, concentration, derivatization) unit; 3: the HPLC–D unit. SV is the selection valve; EC is the extraction coil; D is the detector.

applied with very good results for the separation of radionuclides.

An automated sequential trace enrichment dialyzer and gradient HPLC system is proposed for pharmacokinetic studies of drugs and their metabolites.[14] The dialyzer is essential in the determination of pharmaceutical compounds from tablets and biological fluids (e.g., blood). By its incorporation into the conduits of a SIA system and coupling with the HPLC, the objectivity and reproducibility of the measurements were increased.

FEATURES FOR SIA/HPLC SYSTEMS

The ideal system for sample preparation in a chromatographic method is that the operation of all the steps between sample dissolution and chromatography is done through a SIA technique (Fig. 1).The first part of the system will consist of a sample dialysis (unit 1) and the outlet will be channeled into the second unit consisting of concentration or dilution steps and extraction of the analyte. It is always assumed that the concentration, dilution, and derivatization steps can be done by extraction—in most cases, it is absolutely necessary.

The proposed SIA/HPLC (Fig. 1) system operates by a well-programmed computer which will be able to analyze all types of sample: from environment, from the food industry, from the pharmaceutical industry, and also biological samples.

CONCLUSIONS

The utilization of sequential injection analysis coupled with HPLC systems increases the reliability of an HPLC analysis considerably because the primary factor that contributes to the increasing uncertainty is the sample preparation. It is always necessary to look to the most reliable methods for sample preparation, because only these methods will give the best results after the automation by using sequential injection analysis. The best coupling must be concerned with the selectivity and sensitivity assured by a sequential analysis system and by the selectivity and sensitivity of the HPLC technique. The introduction of bead injection considerably improves the reliability of the discussed system.

INTRODUCTION

A phase diagram, as shown in Fig. 1, can describe the physical stage of a substance of fixed composition. In this pressure–temperature diagram for CO_2, there are three lines describing the sublimation, melting, and boiling processes. These lines also define the regions corresponding to the gas, liquid, and solid states. Points along the lines (between the phases) define the equilibrium between two of the phases. The vapor pressure (boiling) starts at the triple point (Tp) and ends at the critical point (Cp). The critical region has its origin at the Cp. At this point, we can define a supercritical fluid (SF) as any substance that is above its critical temperature (T_c) and critical pressure (P_c). The T_c is, therefore, the highest temperature at which a gas can be converted to a liquid by an increase in pressure. The P_c is the highest pressure at which a liquid can be converted to a traditional gas by an increase in the liquid temperature. In the so-called critical region, there is only one phase and it possesses some of the properties of both a gas and liquid. Subcritical (liquid) CO_2 is found in the triangular region formed by the melting curve, the boiling curve, and the line that defines the P_c.[1]

DISCUSSION

Supercritical fluids begin to exhibit significant solvent strength when they are compressed to liquidlike densities. This makes physical sense intuitively because it is known that gases are not considered as good solvents.

The density of a pure solvent changes in the region of its Cp. For a reduced temperature ($T_r = T/T_c$) in the range 0.9–1.2°C, the reduced solvent density ($\rho_r = \rho/\rho_c$) can increase from gaslike values of 0.1 to liquidlike values of 2.5 as the reduced pressure ($P_r = P/P_c$) is increased to values higher than ~1.0 atm. However, as T_r is increased to 1.55, the SF becomes more expanded and reduced pressures greater than 10 are needed to obtain liquidlike densities. By operating in the critical region, the pressure and the temperature can be used to regulate density, which regulates the solvent power of a SF.[2]

The viscosity changes rapidly in the critical region; even at the high-pressure levels of 300–400 bar, it is only about 0.09 Cp, an order of magnitude below typical viscosities of liquid organic solvents.

The properties of gaslike diffusivity and viscosity, zero surface tension, coupled with liquidlike density, combined with the pressure-dependent solvating power of SF have provided the impetus for applying SF technology to analytical separation problems.

SUPERCRITICAL FLUID CHROMATOGRAPHY (SFC): AN INTRODUCTION

The first reported observation of the occurrence of a supercritical phase was made by Baron Cagniard de la Tour in 1822.[3] He noted visually that the gas/liquid boundary disappeared when heating each of them in a closed glass container increased the temperature of certain materials. From these early experiments, the critical point of a substance was first discovered. The first workers to demonstrate the solvating power of supercritical fluids for solids were Hannay and Hogarth in 1879.[4] They studied the solubility of cobalt(II) chloride, iron(III) chloride, potassium bromide, and potassium iodide in supercritical ethanol ($T_c = 243$°C, $P_c = 63$ atm).

Klesper et al. first demonstrated, in 1962, SFC by the separation of nickel porphyrins using supercritical chlorofluoromethanes as mobile phases.[5] Sie and Rijnders[6] and Giddings,[7] in 1966, developed the technique further, both practically and theoretically, as well as many applications. A few years later, Gouw and Jentof reviewed the general aspects of SFC, including different mobile phases, solute retention, selectivity, and applications.[8]

Until the beginning of the 1980s, SFC was characterized by the utilization of packed columns, in the so-called "LC-like SFC".[9] The introduction in 1981 of capillary open columns with small internal diameters and immobilized stationary phases has opened perspectives to the "GC-like SFC," or c-SFC (capillary supercritical fluid chromatography), with the great advantage of the high-resolution power of capillary columns. The combination of these columns with detectors traditionally utilized in gas chromatography (GC) allows the analysis of compounds with lower volatility and/or higher molecular weight than those in GC.[10]

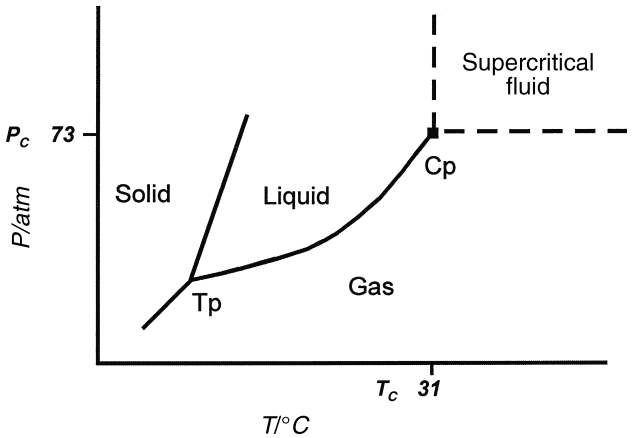

Fig. 1 Phase diagram for CO_2. P_c = critical pressure; T_c = critical temperature; Cp = critical point; Tp = triple point.

INSTRUMENTATION IN SFC

A schematic drawing of the main parts of the SFC system is shown in Fig. 2. It consists of a high-pressure pump for pressurizing and delivering the solvent, usually CO_2 connected to an oven, generally a modified gas chromatography used as the temperature controller for the SFC column. The injector should introduce small sample volumes into the column and a restrictor is placed between the end of the column and the detector to maintain the mobile phase in the supercritical state. A detailed description of each part of the system follows.

Mobile Phase

Pure CO_2 has been the preferred solvent due to its favorable properties. The CO_2 is used in siphoned cylinders to assist the transference of the solvent to the pump. CO_2 passes through a cooling system to increase its density before being inserted in the heating system. When required, a vessel containing a modifier can be added to the system in a way similar to that already well known in supercritical fluid extraction (SFE).

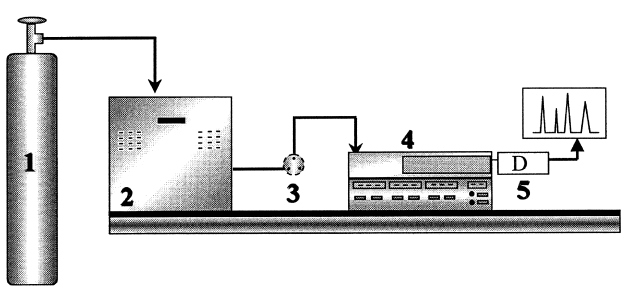

Fig. 2 Schematic drawing of a SFC apparatus. 1: CO_2 tank, 2: high-pressure pump, 3: injection valve, 4: oven (containing the column and restrictor), 5: detector (D).

Pump

Although several high-pressure pumps have been used in SFC, the syringe-type pump has been the preferred to deliver CO_2 into the system. This choice is made due to the absence of pulses of syringe pumps and the possibility of flow rate and pressure control.

Sample Introduction

Samples are usually injected through a high-pressure injection valve fitted with a small internal loop.

Temperature Control

To control and maintain the critical temperature of the mobile phase (CO_2), the column is installed in an oven, similar to those used for GC or high-performance liquid chromatography (HPLC), depending on the type of column used (Fig. 2).

Columns

Two types of columns are used in SFC: packed columns containing solid particles of small inner diameter or wall-coated open-tubular columns (WCOT), usually called just capillary columns. Packed columns have been preferred when capacity is the most relevant issue; capillary columns are selected when efficiency is the goal.

Restrictor

In order to maintain the desired SF mobile-phase conditions, the end of the column is connected to a restrictor. Although several types of restrictor are available,[11] the most popular is the linear restrictor, which consists of a small piece (~10 cm) of a fused silica or metal tube of small inner diameter (50 μm or less).

Detectors

One of the attractions of SFC is that it can use both GC- and LC-like detectors, including the almost universal flame ionization detector (FID) for non-volatile and volatile analytes after separation on either capillary or packed columns. Selective responses could be also obtained from a number of detectors as NPD, ECD, FPD, ultraviolet, Fourier transform infrared, nuclear magnetic resonance, and mass spectrometry (MS).

APPLICATION

An important field of application of analytical chemistry involves the isolation, identification, and quantification of

components in complex samples. Chromatography is one of the most used techniques, because modern chromatographic methods have an excellent separation power, are versatile, and can be used with several detection techniques.

During the last 15 years, the applications of supercritical fluids (SFC and SFE) have shown a fast advance; among others, from a historical perspective, SFC was developed after GC was well established and when HPLC was starting. The interest for SFC has grown with the GC and HPLC development and technological innovations that had occurred independently of SFC research, but surely allowed that commercial SFC instruments could be introduced in the 1980s.

SFC has been applied to environmental analyses, chemical foods, polymers, pharmaceutical, and agro-industry research. This process generates quite complex products, which has been analyzed by different chromatographic approaches, including SFC. Considering the complexity of these samples, a high-resolution technique is required. Even considering that packed column SFC has some advantages in certain cases, capillary columns coated with polymeric phases presents more efficiency (N) per column, being more adequate for complex samples.

As an example, in natural product analysis, SFC offers perspectives in the analysis of several classes of compounds that present difficulties in either conventional liquid chromatography (LC) or GC. In this area, it is very common that the analytes do not have chromophore groups, thus making difficult the detection through UV–Vis, the most popular HPLC detector. At the same time, several of them are not volatile enough to be analyzed by GC. In this case, the use of SFC with capillary columns and FID detection is a valuable tool. Fig. 3 shows a chromatogram of a mixture of triterpenes containing–COOH a functional group (betulinic acid, oleanolic acid, ursolic acid, and polpunonic acid).[12] These compounds are a good example of a class of compounds that presents biological activities and are difficult to be analyzed by either GC or HPLC without an additional derivatization step.

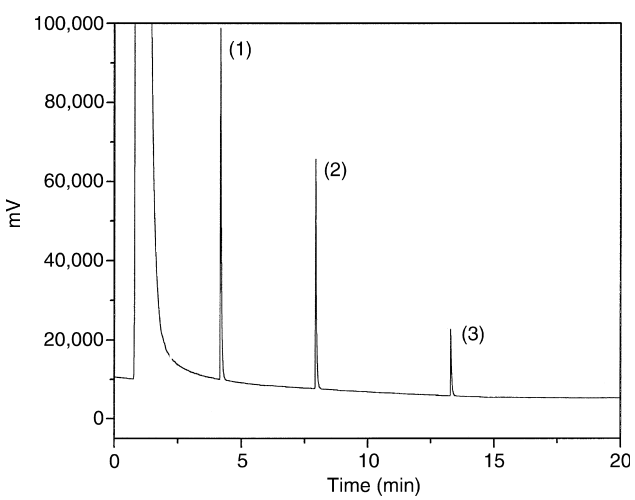

Fig. 3 c-SFC chromatogram of a mixture of triterpenic acids: (1) oleanolic acid, (2) ursolic acid, (3) polpulnonic acid. Column: 20 m × 100 μm × 0.20 μm (5% phenyl, 95% methyl polysiloxane cross-linked); $T = 80°C$; $P = 120$ atm.

CONCLUSIONS

SFC is a very important chromatographic technique still underestimated and underutilized. It presents characteristics similar to both GC and HPLC, although having its own characteristics. Whereas the column temperature control is the way to achieve a good separation in GC and the solvating power of the mobile phase is controlling factor in HPLC, in SFC the density of the fluid is the major factor to be optimized. Both packed (LC-like) and capillary (GC-like) columns have been used in this technique, which has found applications in practically all areas in which GC or HPLC has shown to be the selected separation technique.

SFC: MS Detection

Manuel C. Ventura
Pfizer Global Research and Development, Pfizer Inc., La Jolla, California, U.S.A.

INTRODUCTION

In recent years, supercritical fluid chromatography (SFC) has been exploited as an alternative to high-performance liquid chromatography (HPLC) because of its superior speed and enhanced selectivity for a wide range of organic compounds, with the exception of highly polar species. The higher diffusion coefficient and lower viscosity of the SFC mobile phase, primarily consisting of condensed CO_2, permit faster run times than HPLC with longer columns and thus higher plate counts. These properties combined with the advantages of mass spectrometry (MS) instrumentation used as chromatographic detectors gave rise to interest in coupling SFC with MS. When one considers chromatographic and mass spectrometric advantages available with this interface, SFC/MS is an attractive alternative to liquid chromatography (LC/MS) for many applications. The coupling of SFC with an increasing variety of MS sources and analyzers in recent years has enabled many new applications and enhancements to existing applications.

HISTORICAL DEVELOPMENT

Vacuum ionization sources such as electron impact (EI) or chemical ionization (CI), commonly used for GC/MS, were initially used when the first SFC/MS interfaces were assembled. In either EI or CI, more than a minimal gas load on the source is not tolerable. For SFC/MS with EI or CI, low source pressure is maintained using a low flow rate or split-flow direct fluid introduction (DFI), sometimes termed direct liquid introduction (DLI).[1] Alternatively, differential pumping of the effluent from a restrictive nozzle is feasible as used with the molecular beam interface employed in some early SFC/MS experiments.[2] Performance of such systems is compromised by adverse effects of gradient conditions on ionization and ion transmission. Increased pressure in the ion source resulting from high flow rates reduces ionization efficiency by EI and CI, thus limiting such experiments to low polarity species, which do not require high levels of polar organic modifier to elute by SFC.

Complex interfaces were also designed to eliminate the gas load on the mass spectrometer from the SFC effluent. Particle beam[3] and moving-belt[4] interfaces originally used for LC/MS were employed with some success, due to their capacity to limit the effect of the mobile phase on the MS analysis. In both cases, sensitivity is compromised due to inefficient mass transport and thermal degradation.

Thermospray interfaces, originally designed for constant vapor pressure conditions, have nonetheless been utilized for SFC/MS by several researchers.[5] Column effluent is vaporized in a heated fixed restrictor probe in which solutes are ionized by mobile-phase-mediated CI (e.g., with ammonium acetate) producing CI-like spectra (prevalent in MH^+ or MH^- ions). The popularity of simple atmospheric pressure ionization (API) sources has slowed further improvements to the thermospray interface.

RECENT DEVELOPMENTS

The recent success of SFC/MS using API sources has contributed to an overall decline in the use of many interface designs described earlier. API sources include electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization (APPI). Along with providing usually unambiguous mass spectral identification (MH^+ or MH^- signals predominate), API sources for SFC/MS provide attractive advantages for the analytical chemist. Many commercially available interfaces originally designed for LC/MS require minimal modification to effectively couple an SFC to API-MS systems. Another advantage of API interfaces in SFC is the "self-volatilizing effect" of CO_2 in nebulization of the mobile-phase solutes.

Electrospray ionization occurs in the solution phase prior to vaporization at atmospheric pressure in the mass spectrometer source. Ions are desolvated in the strong electric potential gradient from the needle tip to the inlet of the mass analyzer. In the early period of SFC/ESI-MS development, Sadoun, Virelizier, and Arpino[6] constructed an interface using a 25–30 cm long fused silica restrictor (25 or 60 μm I.D.) with one end attached to the outlet of a packed column and the other end to the source (Fig. 1A). The last 10 cm of silica was coated with a layer of conductive nickel paint to simulate an electrospray needle. Employing a gradient with methanol/water as the polar modifier, detection limits in the low picogram range were reported; however, ionization efficiency was significantly affected by the mobile-phase composition, and severe tailing for low volatility compounds was observed. Some of these deficiencies were addressed by Pinkston and Baker[7]

using a sheath liquid of methanol/water/ammonium acetate with an ionspray (or pneumatically assisted electrospray) interface for open tubular or packed column SFC/MS. In the latter application, a syringe pump supplied methanol through a tee between the mobile-phase outlet and the transfer line to provide backpressure regulation without a variable restrictor valve (Fig. 1A). Advantages of this interface included reduced tailing and lowered modifier composition requirements in the gradient, allowing for higher flow rates and shorter retention times. Sjöberg and Markides described a similar sheath liquid-type ESI interface also convertible to an APCI interface.[8]

Atmospheric pressure chemical ionization is similar to ESI in that both ionization processes occur at atmospheric pressure. Ionization by APCI is fundamentally different, however, in that nebulized solute molecules encounter a plasma of protons, ions, and electrons generated by the corona discharge ionization of background N_2, H_2O, or methanol, and ionize either by proton transfer or charge exchange. The proton transfer agents, usually water or methanol, are supplied by saturating the N_2 nebulizing gas or using the SFC mobile-phase polar modifier, again usually methanol. The first report of packed column SFC with APCI by Huang, Henion, and Covey[9] described an interface in which the backpressure regulator was bypassed and the restrictor was a 20 μm I.D. stainless steel pinhole diaphragm. The effectiveness of this interface was limited by inadequate heating in the nebulization region resulting in chromatographic tailing for more involatile substances. This problem was addressed by the interface designed by Tyrefors, Moulder, and Markides.[10] This interface was constructed to maintain the temperature of the mobile phase in the column up to the tip of the restrictor and provide consistent intense vaporization conditions somewhat independent of flow rate. The outer tube was actively insulated with a heating coil, while a coaxial nebulizing gas flowed around the restrictor tube into which a fine heating wire was inserted. Other interface styles more popular in recent years include those reported by Morgan, Harbol, and Kitrinos[11] and Ventura et al.[12] In the former, the mobile phase exits the backpressure regulator through transfer tubing directly into the nebulizer of the APCI source. In the latter, a split from the compressed mobile-phase region through an ~1 m length of 50 μm capillary upstream of the backpressure regulator is directly adapted to the source (Fig. 1B).

Another API technique gaining popularity of late is APPI. This recently developed ionization mode[13,14] utilizes photons emitted from a lamp beam directed into the aerosol emitted from the nebulizer, typically of the same construction as an APCI nebulizer, to ionize solute molecules. Krypton lamps have been most commonly applied in LC/MS APPI research, as its photons' energies (10.0 and 10.6 eV) exceed the ionization potential (IP) of the majority of organic analytes while they are insufficiently energetic to ionize most mobile-phase solvents. Conveniently for SFC, CO_2 and methanol have higher IP than krypton photons, producing higher signal-to-noise than other API techniques for various types of ionizable solutes. This high signal-to-noise benefit, particularly in the non-polar range, is seeing increased utility especially in pharmaceutical applications.[15,16]

An unmodified APCI source can be further employed for the ionization technique coordination ion spray (CIS), which

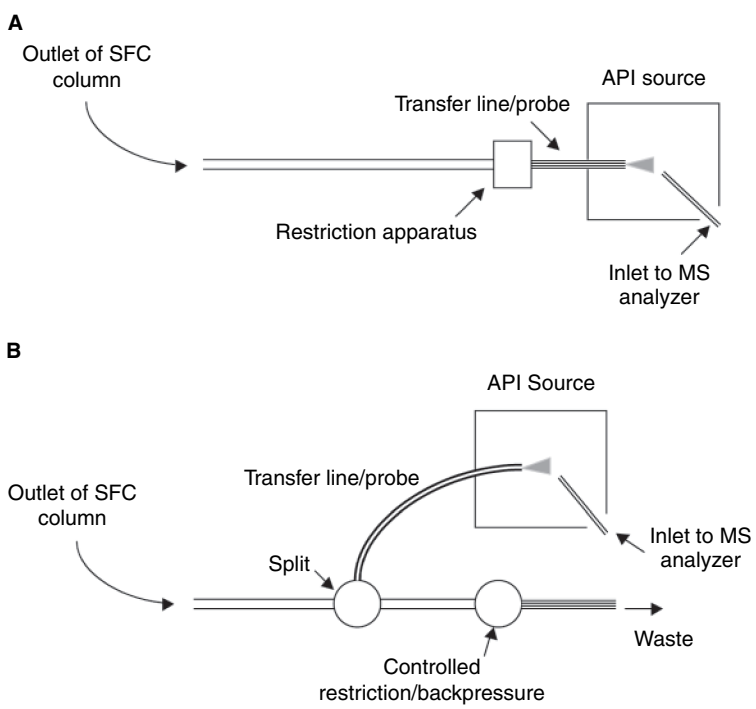

Fig. 1 Two general styles for interfacing SFC to API sources are depicted. In (A), the SFC column effluent is directed entirely into the API source. In some systems, the restriction apparatus is a simple transfer tube restriction used for low flow experiments. In others, a variable restrictor or backpressure regulator is used between the outlet and the source. In the configuration used by Pinkston and Baker,[7] the restriction apparatus is a series of tees to add a coaxial flow of nebulizing gas, an electrospray buffer sheath flow, and another to introduce liquid from a syringe pump to regulate mobile phase pressure. In (B), a direct interface is shown in which a split directs a fraction of the mobile phase flow toward the API source, while the remainder is sent to waste through a backpressure regulator or some controlled restriction to maintain system pressure.

is beneficial for detection of species that are difficult to ionize by standard API methods.[17,18] This technique, which relies on the introduction of a metal cation (such as Ag^+) solution upstream of the ESI or APCI nebulizer, was used with SI-SFC (silver ion SFC) as described by Sandra et al.[19] for the analysis of triglycerides in vegetable oil that are otherwise very difficult to ionize. The researchers showed that CIS-ESI-MS was able to produce intense molecular ion signals (as $[M + Ag^+]$) relative to APCI-MS for saturated triglycerides in SI-SFC separated oil samples.

Though SFC interfacing in an online fashion with an matrix assisted laser desorption ionization (MALDI) source has not yet been reported, the analysis of fractions from an SFC separation has been facilitated by the recent design of an online sample desorption device for MALDI.[20] In this device, the end of the column is connected to an integral restrictor positioned over a spot of C18 sorbent saturated with an appropriate sample matrix such as α-cyano-4-hydroxycinnamic acid. The technique was applied to the separation of a silicone oil. MALDI-MS elucidated the polymer distributions corresponding to fractions deposited over a range of SFC retention times.

Recent advances in MS technologies are being exploited by scientists simultaneously utilizing the separation characteristics offered by SFC. Accurate mass measurements afforded by high resolution time-of-flight (TOF) analyzers permit identification of unknown metabolites and new chemical species.[21] The TOF analyzer's fast spectral acquisition rate is beneficial for chromatographic integrity when coupled with SFC that can generate very narrow peaks.[22] SFC with tandem mass spectrometry (SFC-MS/MS) has also been shown useful for the enantioselective detection of trace level drugs in biological matrices.[23]

The inherent lower viscosity of the SFC mobile phase relative to HPLC yields significant advantages for chiral separation applications.[24] Indeed, preparative SFC is experiencing an increase in utilization in the pharmaceutical industry for chiral purification for a wide range of scales. Now, mass-directed purification technology has been incorporated with SFC for both chiral and achiral purification applications,[25] and commercial prep-SFC/MS systems are currently in development.

CONCLUSIONS

SFC/MS is now entering a more mature phase of development due to scientists' increasing experience with the technology. As system robustness and the well-known utilities of SFC/MS for many applications increase, the user base will continue to see growth. The community utilizing SFC and SFC/MS has driven the vendor market to produce ever more robust and fully integrated systems. Going forward, these technologies will not be avoided as before for such reasons as user unfamiliarity, hardware unavailability, or fragility. SFC/MS technology has now reached a rightful scientific position wherein the principal of the system will dictate that it be used in the many situations in which it is advantageous.

Silica Capillaries: Chemical Derivatization

Joseph J. Pesek
Maria T. Matyska
Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

Capillaries for capillary electrophoresis (CE) are made of fused silica that has been drawn to precise internal and external diameters. Virtually all fused-silica capillaries used in CE, whether for home-made instruments or for commercial systems, have an external diameter of approximately 375 mm. Internal diameters vary over a wider range but generally lie between 50 and 100 mm. Smaller-diameter capillaries generally lead to detection problems, especially if spectroscopic methods are used, because the optical path length becomes too short. Larger-diameter capillaries dissipate heat inefficiently and can lead to band-broadening at higher applied voltages. All capillaries are covered externally with a polyimide coating for protection against breakage and to provide flexibility in fitting the typical column (50–100 cm) into the instrument.

BACKGROUND INFORMATION

Fused silica has surface properties that are similar to the porous particulate matter used as a support material in high-performance liquid chromatography (HPLC) packings. The most important features are the presence of silanol (Si—OH) groups that are polar and ionizable and siloxane linkages (Si—O—Si) that have a hydrophobic character. It is generally recognized that the silanols are the most influential in determining the surface properties of silica. For CE, the Si—OH moieties contribute in at least three ways to the overall performance of the electrophoretic experiment. The presence of silanols on silica surfaces can be considered as a result of the formation of a polymer during condensation of silicic acid. When the polymer cross-links, all four bond sites on each silicon atom do not form siloxane linkages, leaving a hydroxyl group in one position. Because the silanols are acidic groups, they can dissociate in the presence of aqueous solution and behave as any weak acid. The of this moiety is near 5 but can vary depending on the purity of the silica material. Therefore, when the pH of the solution in contact with the inner wall of the capillary is approximately 3 or less, the sites will be fully protonated and the surface will be polar. If the pH is 7 or greater, then the silanols will be fully ionized. The acidic nature of the silanols leads to two of the salient features of the fused-silica surface with respect to electrophoretic experiments. Upon ionization of at least some of the silanols, a double layer is created at the surface when a voltage is applied to a capillary filled with aqueous buffer. This double layer is responsible for electro-osmotic flow (EOF), the movement of solvent toward the cathode. Because of the acidic nature of the silanols, there also is a strong tendency to adsorb basic compounds when these groups are ionized. Finally, the silanol moiety can be considered a reactive group on the surface and it functions as the site for chemical modification of the inner wall. This property will be discussed in more detail later.

Because the first two properties of the silanol, creation of EOF and strong affinity for bases, can often be regarded as undesirable, the third property, the possibility of chemical modification, is used to eliminate these unwanted effects. The presence of EOF diminishes the ability of the CE experiment to separate solutes with very similar electrophoretic mobilities. For basic solutes, the acidic nature of the silanol can result in irreversible adsorption on the surface, which leads to either a complete loss of or greatly reduced detectability. When the silanol group has been modified with an organic moiety, the EOF is greatly diminished and the strong affinity for bases is significantly reduced or eliminated. In addition to chemical derivatization of the surface through a reaction at the silanol, it is also possible to modify the inner wall by adsorption of various compounds that masks the effect of the Si—OH group.

WALL COATING THROUGH CHEMICAL MODIFICATION

Chemical modification of the inner wall of fused-silica capillaries and the surfaces of porous silica supports for HPLC utilize the same reactions. The most common method is based on organosilanization. Within this general reaction scheme, there are two possible approaches, as shown in Table 1. The first possibility involves the use of an organosilane reagent ($RR'R'SiX$) with only a single reactive group (X). The substituents on the

Table 1 Types of reactions for modifying capillary walls.

Reaction type	Reaction	Surface linkages
Organosilane	a) $Si-OH + X-SiR'_2R \rightarrow Si-O-SiR'_2R + HX$ or b) 	Si — O — Si — C
Chlorination followed by reaction of Grignard regents or organolithium compounds	$Si-OH + SOCl_2 \xrightarrow{\text{Toluene}} Si-Cl + SO_2 + HCl$ a) $Si-Cl + BrMgR \rightarrow Si-R + MgClBr$ or b) $Si-Cl + Li-R \rightarrow Si-R + LiCl$	Si — C
TES silanization		Si — H monolayer
Hydrosilation	$Si-H + CH_2=CH-R \xrightarrow{\text{Catalyst}} Si-CH_2-CH_2-R$	Si — C

silicon atom are as follows: X = halide most often Cl; R = the organic moiety giving the surface the desired properties (i.e., hydrophobic, hydrophilic, ionic, etc.); R′ = a small organic group typically methyl. This reaction leads to a single siloxane bond between the reagent and the surface. Because of the single point of attachment of the reagent, the resulting bonded material is referred to as a monomeric phase. The second approach to organosilanization involves a reagent with the general formula The substituents on the silicon atom in this reagent are defined earlier. The basic difference between the approaches as shown in Table 1 is that the reagent with three reactive groups results in bonding to the surface as well as cross-linking among adjacent bonded moieties and is referred to as a polymeric phase. This cross-linking effect provides extra stability to the bonded moiety but is less reproducible than the monomeric method. The one-step organosilanization procedure is relatively easy and the modification of the surface can be done by forcing the reagent continuously through the capillary or simply filling the capillary with the organosilane solution. The capillary is heated for about 1–2 hr and then rinsed with a solvent such as toluene to remove the excess reagent. As is the case with the production of stationary phases for HPLC, organosilanization accounts for virtually all of the commercially available chemically modified capillaries.

A second modification scheme that has been reported for the modification of capillaries is based on a chlorination/organometalation two-step reaction sequence. This process is also depicted in Table 1. In the first step, the silanols on the surface are converted to chlorides via a reaction with thionyl chloride. This step must be done under extremely dry conditions because the presence of any water results in the reversal of the reaction with hydroxyl replacing the chloride (Si—Cl), resulting in the regeneration of silanols (Si—OH). If the chlorinated surface can be preserved, then an organic group can be attached to the surface via a Grignard reaction or an organolithium reaction. The main advantage of this process is that it results in a very stable

silicon–carbon linkage at the surface. However, the stringent reaction conditions for the first step and the possibility of forming salts as by-products in the second reaction have resulted in relatively little commercial use of this process.

The third method reported for the modification of capillary inner walls involves first silanization of the silica surface followed by attachment of the organic group through a hydrosilation reaction. The process is also depicted in Table 1. In the first step, the use of triethoxysilane under controlled conditions results in a monolayer of the cross-linked reagent being deposited on the surface. This reaction results in the replacement of hydroxides by hydrides. In the second step, an organic moiety is attached to the surface via the hydride moiety in a catalyzed hydrosilation reaction. The catalyst is usually hexachloroplatinic acid (Speier's catalyst) but can be other transition metal complexes or a free-radical initiator. This process also results in a silicon–carbon bond at the surface, does not required dry conditions (water is required as a catalyst in the first step), and is applicable to a variety of unsaturated functional groups in the hydrosilation reaction, although terminal olefins are the most common. The silanization/hydrosilation method also has seen limited commercial utilization to date.

The result of all three of the chemical modification schemes described here is to eliminate or drastically reduce EOF. In some cases, the EOF can be reversed by the attachment of a positively charged group, such as $R—NH_3^+$ to the surface. Whether the EOF is diminished, eliminated, or reversed, separation is improved because electrophoretic mobility differences are enhanced. The replacement of silanols by various organic moieties also has beneficial effects with respect to the separation of basic compounds. An example of the difference in peak shapes seen for bare and modified capillaries is shown in Fig. 1. In some cases, the tailing observed for highly basic compounds is more severe than shown in the figure and in the worst cases irreversible adsorption results in the complete absence of a peak in the electropherogram.

Once a reaction scheme has been selected, then a choice must be made as to the type of surface that is suitable for a particular separation. The surface properties are controlled by the "R" group of the reactions shown in Table 1. Hydrophobic coatings can be achieved by using organic moieties that are common in reversed-phase (RP) HPLC. The most common would be either octadecyl (C_{18}) or (C_8) octyl In general, hydrophobic coatings are used for small molecule separations where the main concern is the suppression of EOF and the elimination of possible adsorption at the silanol sites. However, for the separation of proteins, peptides and DNA related species that have considerable hydrophobic character, it is more desirable to

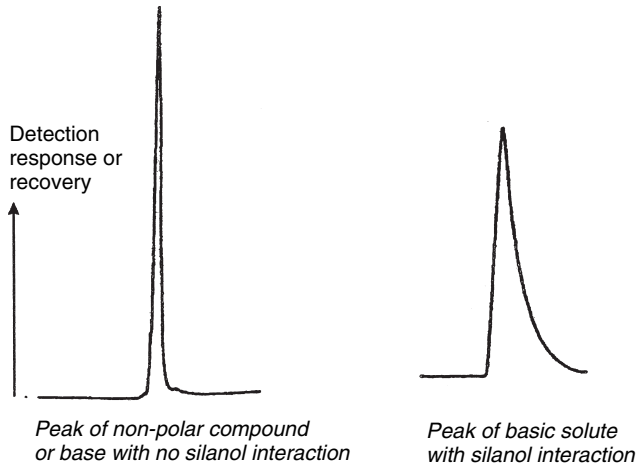

Fig. 1 Comparison of peak shapes for modified and bare capillaries.

have a hydrophilic coating. The presence of any neutral bonded group will reduce or eliminate the EOF and a hydrophilic species will prevent strong interactions with the surface that would occur if the coating was hydrophobic. Because of the importance of CE in the separation of biomolecules, considerable effort has been devoted to the development of hydrophilic wall coatings. By far, the most extensively used hydrophilic coating is polyacrylamide. The surface is first modified with a linker such as 3-methacryloxypropyltriethoxysilane having a double bond available as a site for acrylamide to attach and polymerize. Derivatives of polyacrylamide have also been bonded which result in increased stability at high pH. Other polymers such as polyethylene glycol, cellulose, and poly(vinyl alcohol) have also been used in order to achieve a hydrophilic surface. The presence of any polymer on the capillary usually results in a reasonably thick layer that shields the surface and drastically lowers or eliminates EOF. Polymers containing cationic or anionic species can also be useful in preventing adsorption of hydrophobic compounds on the surface as well as controlling EOF. The type charge on the polymer controls the direction of the EOF. For negatively charged groups (sulfonic acid), the direction is cathodic, and for positively charged groups (quaternary amine), the direction is anodic.

WALL COATING THROUGH BUFFER ADDITIVES

Another approach to reducing the EOF as well as wall adsorption is to add a compound to the running buffer that will compete with the solute for the silanol sites on the surface. These materials must have some affinity for the charged or polar sites on the inner wall and so they must, themselves, be hydrophilic or charged. Non-ionic

surfactants are hydrophilic to prevent solute adsorption on the wall and block the silanols in order to reduce the EOF. The use of cationic polymers in the buffer results in a reversal of EOF to the anodic direction, whereas the use of anionic polymers preserves the cationic direction but tends to stabilize the flow in comparison to a bare capillary. Other additives such as diaminoalkanes and polyvinylalcohol result in reduced EOF and less solute adsorption on the wall.

Column technology is one of the most rapidly developing areas of CE. The capillary is the key to separation, so it is likely that numerous column formats will be established to meet specific separation needs similar to stationary-phase development in HPLC.

Silica Capillaries: Epoxy Coating

James J. Bao
Advanced Medicine Inc., San Francisco, California, U.S.A.

INTRODUCTION

Capillary electrophoresis (CE) has proven to be one of the best possible techniques available for the separation of proteins. However, CE separation of proteins is often complicated by the interaction between the analytes and the silanol groups on the inner surface of the capillary. This interaction often results in broad asymmetrical peaks, poor efficiency, altered electro-osmotic flow (EOF), reduced protein recovery, and poor reproducibility. Attempts have been made to reduce this interaction by chemically modifying the surface with a layer of chemical coating. Capillary coating has the advantage of allowing analysts to freely modify the composition of the buffer to optimize the separation. Different coatings have been made and each of them has unique characteristics. For protein separations, the most commonly used capillary coatings are hydrophilic coatings.[1–6] For example, epoxy coating is one of these hydrophilic coatings; various protein samples have been separated successfully on this coating.

PREPARATION OF EPOXY COATING

A typical procedure for preparing epoxy coating can be found in the literature.[7,8] Basically, a fused-silica capillary is activated with 1.0 *M* NaOH solution for 10–20 min and then washed with dilute HCl and water for another 20 min each. The washed capillary is then heated in an oven for 3 hr at 120°C with N_2 slowly passing through. A γ-glycidoxypropyltrimethoxysilane (GOX) in CH_2Cl_2 is pushed into the pretreated capillary and heated for 3 hr. Next, a solution of ethyleneglycol diglycidyl ether (EGDE) and 1,4-diazabicyclo-[2.2.2]-octane (DABCO) is forced through the column and allowed to react at 120°C for at least 3 hr. Finally, the capillary is washed with methanol at room temperature.

SEPARATION OF PROTEINS ON THE EPOXY COATING

Epoxy coating is a hydrophilic coating due to the high content of ether and hydroxyl groups. It is expected that this hydrophilic surface will reduce protein adsorption and, thus, is suited for protein separations.

SEPARATION OF MODEL PROTEINS AT NEUTRAL pH

The usefulness of this epoxy coating for protein separation can be demonstrated with the separation of various model proteins using 10–50 m*M* phosphate buffer near pH 7. The model proteins are lysozyme (p*I* 11), cytochrome-*c* (p*I* 10.2), ribonuclease-A (p*I* 9.3), α-chymotrypsinogen (p*I* 8.8), trypsinogen (p*I* 8.7), α-chymotrypsin (p*I* 8.4, 8.8), and myoglobin (horse heart, p*I* 7.3). They are all positively charged at pH 7 and have high tendency to adsorb onto the negatively charged walls of uncoated capillaries. Therefore, very poor separation is seen with an uncoated capillary. However, a good separation of these proteins can be achieved on the epoxytreated surface. Fig. 1 shows that all five proteins are baseline resolved with a high separation efficiency.

Coating the inner surface of capillary reduces the amount of surface silanol groups and, thus, the EOF in the capillary. The epoxy coating retains about one-third of the EOF of an uncoated capillary at pH 7. This EOF is critical for the separation and detection of samples containing neutral to slightly negatively charged proteins. For example, α-chymotrypsin, myoglobin (whale, p*I* 6.9), conalbumin (p*I* 6.3), carbonic anhydrase (p*I* 6.1), and α-amylase (p*I* 5.9) can also be separated at pH 7.

SEPARATION OF MODEL PROTEINS AT OTHER pHs

One of the major advantages of coating the inner surface of the capillary is that it allows the buffer pH to be freely adjustable to achieve the best separation. Coating reduces the effect of pH on EOF, electrophoretic mobility, and protein separation. For example, the EOF in the coated capillary has less than half (from 0 to 3×10^{-4} cm^2/VS) the variation as seen in the uncoated capillary (from 1×10^{-4} to 8×10^{-4} cm^2/VS) between pH 3 and 11.

The five positive model proteins as shown in Fig. 1 can also be separated at various other pHs (pH 4–10).[7] However, the migration times of these individual proteins vary with pH change differently. Although the electrophoretic mobility of these proteins changes accordingly with pH, the overall effect of pH on both EOF and electrophoretic mobility varies at different pH values. This

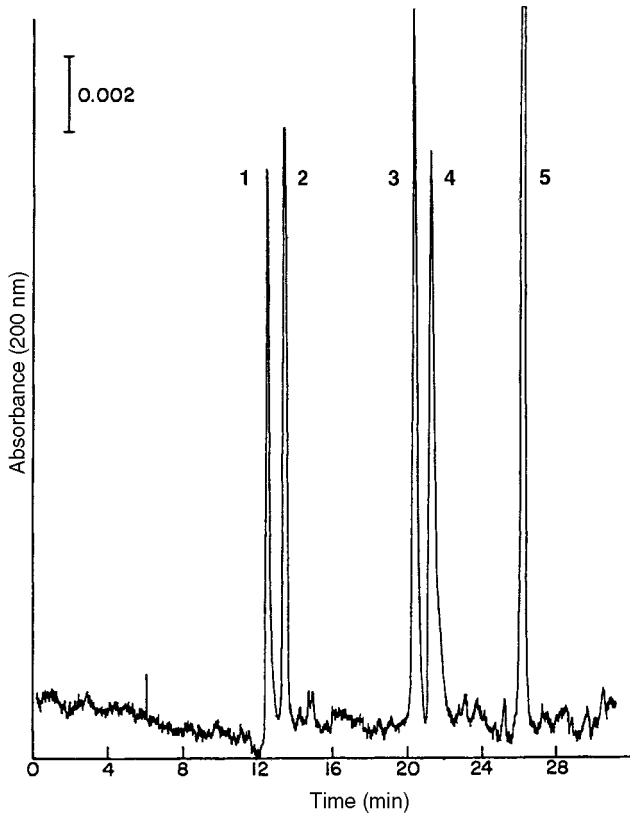

Fig. 1 CE separation of five basic model proteins in an epoxy-coated capillary. Experimental condition: 65 cm separation length, inner diameter/outer diameter 50/363 μm, 0.01 *M* phosphate buffer, pH 7, 300 V/cm, 17 μA. Peaks: (1) lysozyme, (2) cytochrome-*c*, (3) ribonuclease A, (4) α-chymotrypsonagen, and (5) myoglobin (horse heart).

variation provides a basis for optimizing pH for the separation of these proteins.

The theoretical plate number for the separation of these model proteins has a maximal value at pH 7. However, the peak capacity increases with pH because the separation window between lysozyme and myoglobin increases with pH, whereas the peak width does not change significantly. The resolution between the two pairs of proteins, ribonuclease A and α-chymotrypsinogen, and α-chymotrypsinogen and myoglobin, increases with the pH. However, the resolution between lysozyme and cytochrome-*c* increases slightly from pH 5 to 7, drops to zero at pH 8 (no separation at all), and then increases again as the pH is increased.

PROTEIN RECOVERIES

In general, the efficiency of protein separation in CE should be directly proportional to the separation length (i.e., $N = L/H$), where N is the theoretical plate number, L is the separation length, and H is the height-equivalent theoretical plate. Results obtained by locating two detectors at 20 and 65 cm from the injection end show that longer separation length gave much better separation. Much higher than expected separation efficiency is obtained from the 65 cm separation length segment than that from the 20 cm separation length. Therefore, a long capillary should be used when better resolution and higher efficiency are desired. However, no significant improvement in separation efficiency can be achieved when the capillary length exceeds 1 m. On the other hand, a short capillary is preferred when separation time is of major concern.

The adsorption of positive proteins onto the epoxy capillary surface can be quantitatively evaluated by using the two online detector design. From the responses of the two detectors, it is possible to determine the adsorption of proteins on the surface between the two detectors. Zero-percent recoveries have been reported on an uncoated capillary at pH 7 for lysozyme, cytochrome-*c*, ribonuclease A, and α-chymotrypsinogen. However, most of these proteins had recoveries between 84.4% and 95%, except for lysozyme (55.5%), on an epoxy-coated capillary. Therefore, coating does reduce protein adsorption significantly.

REPRODUCIBILITY AND STABILITY

The reproducibility of protein separation from run to run, day to day, segment to segment, column to column, and chemist to chemist is very high. From run to run, the % relative standard deviation (RSD) ($n = 5$) of migration times for neutral marker (MO) and lysozyme are 0.94 and 0.71, respectively. The % RSD in EOF for day to day ($n = 5$) and segment to segment ($n = 6$) are 2% and 3.5%, respectively. For column to column, the EOF at pH 7 varied from 0.5×10^{-4} to 2×10^{-4} with an average of 1.14×10^{-4} for nine columns coated over a 3-month period.

The major challenge to capillary coatings, especially hydrophilic coatings, is the stability. Adding a hydrophobic moiety into the coating may increase coating stability but interfere with protein separations. Epoxy coating provides a balance between hydrophilicity and stability. Epoxy is well known for its chemical and mechanical stability. The epoxy is covalently bound to the silica surface and is cross-linked to generate a stable surface. This coating has shown to be suitable for protein separations at pH 4–10. When stored at room temperature, this column is stable for at least several months.

SEPARATION OF CYTOCHROME-*c* VARIANTS

The separation of cytochrome-*c* variants was challenging because of their similarity in structure. Each of them differs

by only a few amino acids in their sequences. When five cytochrome-*c* variants were injected, only four peaks were obtained, with the horse and dog variants migrating together. Varying the experimental conditions still did not help the separation of the horse and dog variants. Very reproducible separations were obtained at pH 6–8.[8]

SEPARATION OF RECOMBINANT PROTEINS

BMP-2 is a recombinant protein which has the potential to develop into a biotech drug. Previous experiments with an uncoated capillary and a commercially available hydrophilic-coated column (Celect P150) failed to separate the BMP-2 components with reproducible results. By using the epoxy coating, the various BMP-2 components were separated. IL-11 is another recombinant protein under investigation. Using this epoxy coating, a CE method was developed to monitor the stability of IL-11 at different storage conditions. The results showed that there were some significant differences in the CE profiles of the three IL-11 samples stored at different temperatures for different periods of time.[8]

CONCLUSIONS

Epoxy coating is well suited for the separation of proteins in CE. This coating is easy to prepare and can be used for a broad range of pHs. High recoveries of proteins prove that this epoxy modified surface has reduced the protein adsorption significantly.

Silica Capillaries: Polymeric Coating for CE

Xi-Chun Zhou

Lifeng Zhang
Environmental Technology Institute, Innovation Centre (NTU), Singapore

INTRODUCTION

The performance of capillary electrophoresis (CE) with an unmodified fused-silica capillary is dependent on the chemical properties of the silica surface. The residuals Si–OH groups on the surface lead to *electro-osmotic flow* (EOF), which contributes to solute migration. For cationic solutes moving toward the negative electrode, the EOF will diminish the resolution, because it contributes toward migration in this direction and reduces the overall migration time. For anionic solutes, EOF is necessary for migration toward the negative electrode or it retards the movement toward the positive electrode and enhances resolution. Therefore, when cationic solutes are the analytes, it is often desirable to diminish the EOF in order to enhance resolution and, therefore, a bare capillary may not be the best choice for a column in this situation.

Another drawback of the unmodified capillary is that the silanols are potential sites for adsorption of certain solutes, especially high-molecular-weight proteins, which leads to poor recovery of the analyte and variable migration times due to the decrease in EOF.

POLYMERIC COATINGS

Capillary columns modified with polymeric coatings are a desirable approach for controlling EOF and adsorption of solutes on the wall. In general, for a coating to be successful in CE, the polymers should be able to: (a) modify or suppress the EOF, (b) be stable for a long period (many injections) in the presence of aqueous buffer solutions so that migration times remain constant and good quantitative determinations are possible, and (c) suppress strong, or even irreversible, adsorption of analyte molecules (e.g., proteins).

According to the way polymers are attached to the column surfaces, the polymeric coatings can be differentiated between those substances that are covalently attached to the capillary surface and those coatings that are not covalently attached but are adsorbed to the surface by physical or ionic forces. Comparatively, adsorbed coatings are simpler to prepare, whereas covalent bonded coatings require elaborate chemical reactions. With regard to the mechanism by which prevention of adsorption of proteins occurs and the properties that they render to the coated surfaces, the compounds currently used as adsorbed coatings belong mainly to two categories: aminated or cationic polymers and hydroxylic or neutral polymers. Aminated polymers, such as polybrene, are adsorbed to the silica wall by Coulombic attraction.

The mechanism for which wall interactions are minimized is primarily due to the ionic repulsion of proteins and peptides at a pH below their p*I*. These polymers generate a positively charged layer at the surface of the silica wall and, therefore, lead to an anodal EOF. These polymer coatings are very stable and are useful over a wide pH range. Hydroxylic or neutral polymers are attached onto the silica wall by weaker interactions such as hydrogen-bonding. The mechanism for which wall interactions are minimized is described as a shielding of the silanol groups. Because these polymers are not charged, the EOF is, in most cases, suppressed. The working pH range is narrower and is limited to the acidic pH regime. Coating procedures may be varied to generate the coating thickness and homogeneity. Most commonly, the reagent is simply passed through the capillary in a suitable buffer. In the case of hydroxylic polymers, thermal immobilization is usually required. Prior to electrophoresis, the unbonded reagent is flushed from the capillary. The main limitation of adsorbed coatings is their instability under basic conditions.

A polymeric coating which is covalently bonded to the surface of capillary wall is the most significant approach among the surface deactivation methods. This method provides a more flexible approach in preventing adsorption of analytes and, at the same time, permits manipulation of separation parameters to optimize selectivity and efficiency. The silanization of the silica surface is an elegant method which enables the production of a large variety of polymer coatings that are chemically bonded to the capillary column surface. In general, polymers are attached to the silica surface by an Si–O–Si linkage or Si–C linkage. Many different mono-, di-, or tri-functional silanization reagents are commercially available or can be easily synthesized. The capillary coated with polymers via Si–C linkage show better stability under alkaline conditions and improved reproducibility of the separation than that of the Si–O–Si linkage.

Among the bonded materials described in the literature, polyacrylamide is one of the most popular and successful for achieving good protein separations. Initial studies were based on the bonding of the linker 3-methacryloxyptopyltriethoxysilane between the surface and the polymerized,

and in some cases cross-linked, acrylamide. The main drawback of this type of wall coating is its long-term stability. In order to overcome this effect, the surface silanization agent was replaced with 7-oct-1-enyltrimethoxysilane. Improvement in stability, as well as efficiency and reproducibility of migration times, in comparison to the columns with linear polyacrylamide bonded by the conventional method, was achieved. However, at the high pH range, the amido bonds in polyacrylamide are possibly hydrolyzed, leading to degradation of the attached polymer and a loss of column performance. In order to overcome this effect, N-substituted acrylamide monomers can be used which provide steric protection to the amido bond. Poly-(acryoylaminoethoxyethanol) was shown to have dramatically improved stability over polyacrylamide at a high pH. Poly-(*N*-(acroylaminoethoxy) ethyl-β-D-glucopyranose was demonstrated to be even more stable. In addition to the improved stability of the amido bond, the linkage of polymer to the capillary surface via a Si–C bond made through a silanization/hydrosilation process contributed greatly toward the length of coating's service.

Various types of polyethers and diol moieties are also effective hydrophilic coating, which often function in a manner similar to polyacrylamide. Different combinations of polyether with triethoxysilane groups or anchored poly(ethylene glycol)s have resulted in low EOF and low adsorptive coatings. It has also been possible to combine the characteristics of the two most common hydrophilic coatings by linking a polyvinylmethylsiloxanediol to linear polyacrylamide. As combining cellulose, functionalized polyethyleneimine and polyether in various proportions thus allows the control of EOF that is independent of pH. The mixed phase from ethylene glycol diglycidyl ether and glycidol also exhibits low EOF and protein adsorption. Polysiloxanes are another type of capillary coating used in the formation of mixed materials to produce surfaces more conducive to electrophoretic conditions.

Other types of polymers have also been attached to the inner walls of fused-silica capillaries through different linking agents. A common approach involves the bonding of a methacryl group via standard organosilane chemistry. Then, bonding of another species to the linker takes place by a double-bond reaction and polymerization. For example, in the case of a cellulose coating, the species attached to the linker can be allyl methylcellulose. Other polymers include cross-linked dextrin, triblock poly(ethylene oxide)–poly(propylene oxide) and poly(vinyl alcohol).

Charged polymeric coatings are also bonded to the column surface to control the adsorption and EOF, especially in the analysis of oppositely charged species in a single run, or for fast separation of analytes with sufficient differences in electromobilities. One effective approach is the cryptand-containing polymer coating, which generates a switchable EOF depending on the pH of the running buffer. Other charged coatings can be synthesized with sulfonic acid or quaternary ammonia groups that provide more stable EOF over a fixed buffer pH range.

Capillaries with chiral polymer coatings have been applied in CE for resolution of enantiomers. Possibly because of its inclusive effect, cyclodextrin seems to be an effective chiral selective agent when bonded to a fused-silica capillary surface. In this case, the purpose of the modification is to induce interactions with the chiral material on the surface. Certainly, the cyclodextrin moiety lowers EOF like other wall modifications because it diminishes the number of silanols. The lower EOF allows for slower migration of the solute through the column and, hence, more time for interaction with the chiral selector. The diminished number of silanols also results in less nonspecific interactions with the fused-silica surface, which would tend to degrade the enantiomeric separation.

Capillaries bonded with polymeric coatings are also applied to capillary electrochromatography (CEC) for separation of neutral molecules. In this case, the polymeric coating participate to solute–bonded phases interaction in a manner similar to open-tubular LC. Most polymeric coating preparations have followed the procedures typically used in open-tubular LC and GC.

Polymer-coated columns offer advantages in the respect that the surface is generally well shielded from the solutes as they migrate through the system. Most polymer procedures involve a multistep process that can often be time-consuming and/or experimentally difficult. Recently, it has been demonstrated that polymer coatings can be produced in a single step by mixing the polymer, a surface-derivatizing agent, and a cross-linking agent in a solvent that is then placed in the capillary. The coated capillary is then heat-treated, which removes the solvent and immobilizes the polymer film on the surface. A number of polymers were tested and higher efficiencies obtained for basic protein separation. The formation of organic–inorganic polymeric coatings by the sol–gel technique has also been reported to be a simpler way.

Further development in the preparation of polymeric coatings with more reproducible reaction conditions and better reagents will make the CE a more challenging separation technique.

Size Separations by CE

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

Abstract
Size separations by capillary electrophoresis (CE) are performed using low viscosity and replaceable linear polymer solutions. The technique was employed for DNA sequencing during the Human Genome Project, which was completed in 2000. Current applications involve many modes of DNA separation as well as those involving sodium dodecyl sulfate (SDS) proteins. The purity of recombinant monoclonal antibodies is often determined using CE.

INTRODUCTION

Electrophoretic separation based on molecular size is the predominant technique for the separation of large biomolecules.[1] When using the traditional slab-gel, a rigid anticonvective gel is required to provide mechanical stability for the separation. These gels are designed for a single use at relatively low electric field strengths.

During the early days of high-performance capillary electrophoresis (HPCE), rigid gels were polymerized in situ within the capillary. These gel-filled capillaries were used for multiple runs at high field strengths. The capillaries were prone to failure and proved too unreliable for routine use. It was soon discovered that low-viscosity pumpable media was capable of defining molecular pores required for size separation. In the capillary format, the walls of the tube provide the requisite mechanical stability, so high-viscosity gels are unnecessary. These solutions are known as polymer networks, entangled polymers, or physical gels. When polymer networks are used for size separations, a fresh matrix is employed for each run. Through the use of high-pressure pumping systems, polymer networks suitable for DNA sequencing can be pumped in and out of the capillary.

This technology has facilitated the development of instruments containing arrays of 96 capillaries for high-throughput applications such as DNA sequencing. Other high-throughput DNA applications that will eventually incorporate this technique include genetic analysis and human identification. Ultimately, microfabricated devices may be used for many of these applications.

SEPARATION MECHANISM

Several mechanisms for the migration of macromolecules through polymer networks have been described. The Ogston model considers the molecule as a non-deformable sphere. The speed of migration is based on the mobility of the solute in free solution modified by the probability of an encounter with a restricting pore. This mechanism is operative when the radius of gyration of the macromolecule is less than or equal to the average pore size of the polymer network. Separation of sodium dodecyl sulfate (SDS) proteins is believed to occur following this mechanism.

Large biopolymers, such as DNA and oligosaccharides, do not follow the Ogston model. These molecules can deform during transit through the porous network. Instead, a strand of DNA can move through the polymer matrix in a snake-like manner known as reptation. It is also known that fragment resolution decreases as the length of the macromolecule increases. The molecules align with the electric field in a size-dependent manner. This process is known as biased reptation. This effect limits the size of DNA molecules that can be separated using conventional slab-gel techniques. The high electric field strength used in capillary electrophoresis (CE) further limits the separation. Beyond 20,000 base pairs (bp), separations become poor and pulsed-field techniques must be employed.[2] Equipment based on this technique is not available for commercial CE instrumentation.

Further masking a full understanding of the separation mechanism is the interaction of the macromolecule with the polymer network reagents. Separations have been reported in polymer concentrations far below what is required to define pores.[3]

DENATURATION OF MACROMOLECULES

Because separations occur based on molecular size, the macromolecule must be denatured to ensure that all solutes have the same charge-to-mass ratio. DNA and RNA are denatured by heating in formamide at 90°C for a few

minutes. This improves both the separation and the sizing accuracy.

To denature proteins, the disulfide bonds must be reduced and the molecule must be unfolded. Heating to 90–95°C for a few minutes in a solution composed of 0.1% SDS and a reducing agent, β-mercaptoethanol or dithiothreitol (DTT), is sufficient to denature most proteins. When the molecular weight of a protein is less than 10 kDa, the SDS binding stoichiometry may change, resulting in errors in the calculation of molecular weight.[4]

MATERIALS FOR POLYMER NETWORKS

A wide variety of polymeric materials can be employed for size separations. It appears that the molecular weight and concentration of the polymer is more important than the polymer type itself. Once the polymer concentration is greater than the overlap threshold, the porous matrix is defined and reproducible. Best results are obtained if the polymer does not interact with the macromolecules being separated.

Among the materials used as polymer network reagents are linear polyacrylamide (LPA), dimethylpolacrylamide, methylcellulose derivatives, poly(ethylene oxide), and others. The appropriate molecular weight of the polymer is important. Sometimes, blends of different molecular weight are used. For example, the mixture of 2% LPA (MW = 9 mDa) and 0.5% LPA (MW = 50 kDa) is used to separate DNA sequencing reaction products of up to 1000 bases in less than 1 hr, as shown in Fig. 1.[5] The viscosity of this polymer is 30,000 cps. The solution exhibits non-Newtonian properties as the viscosity drops upon the initiation of flow. The use of 2% LPA (MW = 16 mDa) and 0.5% LPA (MW = 250 kDa) at 125 V/cm extends the read length to 1300 bases in 2 hr.[6]

INJECTION

Electrokinetic injection provides the highest efficiency separations. If the salt concentration of the sample is greater than 50 m*M*, hydrodynamic injection gives better results. It is better to desalt the sample by dialysis, precipitation, or ultracentrifugation.

DETECTION

For SDS proteins, low-ultraviolet (UV) detection at 200 or 220 nm is used depending on the UV transparency of the polymer network. For oligonucleotides, UV detection at 260 nm is employed. When performing DNA sequencing, short tandem repeat or genetic analysis, laser-induced fluorescence (LIF) is the method of choice. Intercalating dyes such as YOYO or YO-PRO fluorescence when complexed in between the DNA strands are sometimes added to the background electrolyte when monitoring polymerase chain reaction (PCR) products and restriction digests and for genetic analysis. For DNA sequencing, the fluorescent tag is incorporated in the chain-terminating dideoxynucleotide reagent. When separating short tandem repeats for human identification, the PCR primers can incorporate the fluorescent tag.

APPLICATIONS

DNA applications, in particular DNA sequencing, human identification, and genetic analysis, dominate the field. Other DNA applications including oligonucleotides, antisense DNA, restriction fragments, plasmids, PCR products, hydridization (DNA probe), and RNA have also been demonstrated.[7,8]

DNA testing is rapidly becoming the predominant technique for human identification. The restriction fragment length polymorphism (RFLP) method requires large amounts of DNA (20–100 ng) and is extremely time-consuming and labor-intensive.

A PCR method employing short tandem repeats (STR) is now the method of choice. STRs are sequences where two to seven nucleotides of DNA are constantly repeated. Unlike the DNA of a gene, STRs are prone to DNA replication errors. The lengths of these fragments vary from one person to the next, thereby providing the potential for DNA fingerprinting. The use of PCR and LIF detection provides high sensitivity, so very little DNA is required. The need for higher specificity is addressed with multiplex PCR, where several dye-labeled primers simultaneously amplify multiple locations throughout the genome.

The most widely used genetic screening technique, PCR–RFLP, detects a mutation at a specific restriction endonuclease cleavage site at the mutation locus.[9] The products from other techniques such as amplification refractory mutation system (ARMS), single-strand conformational polymorphism (SSCP), heteroduplex polymorphism (HPA), constant denaturant capillary electrophoresis (CDCE), and PCR are usually separable using polymer networks.

PCR is particularly useful for genetic analysis because both amplification and primer-specific isolation of gene fragments occur simultaneously. Allele-specific amplification can be employed to detect a single-base-pair mutation through the use of a specially designed primer that is complementary to the mutated DNA.[10] PCR amplification takes place only if mutation is present. Fig. 2 illustrates the separation of multiplex PCR fragments in this case,

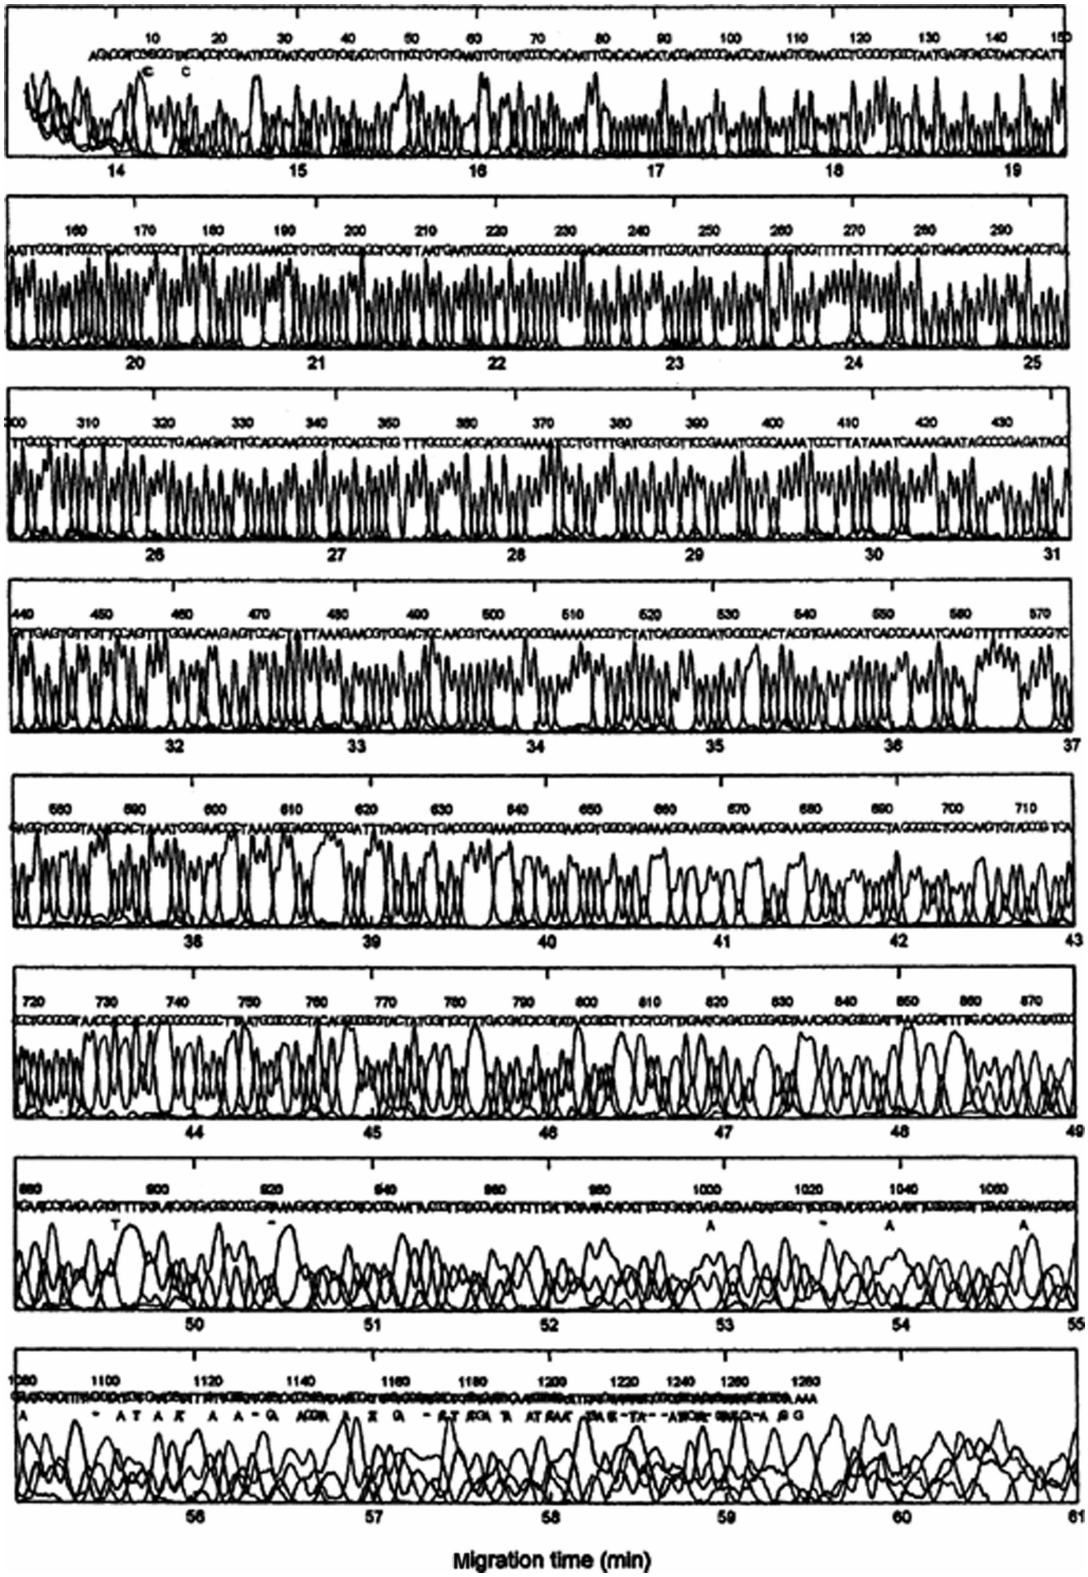

Fig. 1 Separation of DNA sequencing fragments. Conditions: capillary, 30 cm (45 cm total length) × 75 μm I.D., coated with poly(vinyl alcohol); background electrolyte, 2% linear polyacrylamide (LPA), 9 mDa and 0.5% LPA, 50 kDa in 7 *M* urea and 500 m*M* Tris/500 m*M* TAPS/20 m*M* EDTA; buffer, 50 m*M* Tris/50 m*M* TAPS/2 m*M* EDTA with urea in catholyte; injection, 25 V/cm for 10 sec; field strength, 200 V/cm; temperature, 60°C; detection, laser-induced fluorescence.

searching for specific deletions in the dystrophin gene believed to result in Duchenne muscular dystrophy. The deletion is indicated by the arrow. Size separations for SDS proteins have become important in the biopharmaceutical industry, particularly for the separation of impurities in reduced and non-reduced monoclonal antibodies.

MICROCHIP ELECTROPHORESIS SYSTEMS

Instrumentation based on microfabricated chips is now widely available from multiple sources. Advances in many forms of DNA separations continue to appear in the literature. Sequencing of 600 bases in 6.5 min is the modern speed record for electrophoretic separations.[11] It is likely that alternative sequencing technology will displace electrophoretic sequencing. Microfabricated capillary array electrophoresis has been studied for human identification via STRs.[13] Genetic analysis by PCR has been reported for prenatal diagnosis of beta-thalassemia.[14] Microchip devices can automate the complete DNA analytical process, including DNA extraction, cleanup, PCR, and size separation.[15]

CONCLUSIONS

The sequencing of the human genome is one of the most complex analytical projects ever accomplished. While DNA sequencing may move to other technologies such as pyrosequencing, the fields of human identification and genetic analysis will continue to be performed in capillaries and ultimately in microfabricated systems. SDS proteins will continue to be separated using capillaries until the resolution of the microfabricated systems is improved.

Slow Rotary CCC

Qizhen Du
Institute of Food and Biological Engineering, Zhejiang Gongshang University, Hangzhou, China

INTRODUCTION

When the mobile phase of a two-phase solvent system is pumped into a rotating coil column around its horizontal axis, filled with the stationary phase, a satisfactory retention of the stationary phase can be obtained at three rotating speed ranges: below 10 rpm, from 20 to 150 rpm, and over 300 rpm. But only at a speed in the range of 20–150 rpm the two phases in the coil column can thoroughly mix to meet the requirement of partition chromatography.[1,2] Ito and Bowman[3] initially reported separations of a series of dinitrophenyl (DNP) derivatives of amino acids and peptides with this mode. Later, Ito and Bhatnagar[4,5] developed an apparatus equipped with an assembled column composed of ten small columns of 90 ml capacity. Further, Ito studied the hydrodynamic distribution of the two immiscible solvent phases in the slowly rotating column.[6] But this countercurrent mode was neglected because high-speed countercurrent chromatography (HSCCC), which adopted a planetary centrifugal mode, had been popularised since the 1980s. However, the utilization of HSCCC for industrial separations is limited because the apparatus possesses some disadvantages due to the planetary rotational mode, which causes three problems: (i) the operation should be attended carefully because of the high-speed rotation column; (ii) balancing is difficult due to the diversification of two phase solvents in the column; and (iii) inlet and outlet tubes are easily broken while the column rotates under high speed. In recent years, Du and Ito have developed a separation method using a slow rotary mode.[7,8] In contrast to HSCCC, this method is called slow rotary countercurrent chromatography (SRCCC).

APPARATUS

Fig. 1 shows a simplified cross-sectional view through the central axis of the apparatus equipped with an assembling column. The motor drives a rotary frame that consists of three aluminium arms rigidly bridged together with links. The frame holds two rotary elements: the countershaft and the centrally located column holder assembly. The countershaft is equipped with a toothed pulley at one end and a gear at the other end. The pulley of the countershaft is coupled with a toothed belt to an identical stationary pulley mounted on the stationary wall member of the apparatus. The coupling causes a counter-rotation of the countershaft on the rotary frame. This motion is further conveyed to the central column holder assembly by a 1:1 gear coupling. As a result, the column holder assembly rotates around its own axis at a rate twice that of the rotary frame, in the same direction. This particular design offers a great advantage in that the scheme allows flows in and out of the rotary column without the use of rotary seals. The assembling column provides an eccentric motion of each coil and allows the column to comprise more coils. But this mode does not show better retention of stationary phase than a single column with a larger coil diameter rotating around the axis itself. The later apparatus design for SRCCC introduced the design shown in Fig. 2. The apparatus horizontally holds a cylindrical column holder that can rotate around its axis, and the frame is similar to that shown in Fig. 1. Polytetrafluoroethylene (PTFE) tubing is directly wound around the holder hub, forming either a single-layer or a multilayer coil separation column. The coil column, made of tubes with larger inner diameters, permits a higher flow rate with satisfactory retention of the stationary phase, and the convoluted tube column gives higher retention of the stationary phase than standard wall tubes.[9]

To scale up the column for industrial separations, the chromatographic parameters using a convoluted PTFE tubing with an average I.D. (inner diameter) of 15 mm for developing a large chromatographic column were tested. The results showed that 1.5 cm I.D. convoluted PTFE tubing provides the following advantages: (i) it provides excellent retention of the stationary phase for many solvent systems, even at a high-flow rate of the mobile phase; (ii) it produces good mixing of the two phases, thus enabling efficient partitioning; (iii) increased sample size yields relatively low peak broadening; and (iv) increase in peak width and resolution using longer columns is predictable.[9] Therefore, a long holder with larger inner tubes can be used to make a column of up to 100 L in volume. In this case, a pair of rotary seals can be used as inlet and outlet (Fig. 3). Suitable rotary seals may be obtained commercially from Johnson-Fluiten, Milano, Italy.

SOLVENT SYSTEMS AND OPTIMUM ROTATIONAL SPEEDS

A suitable solvent system is the key to successful separation with countercurrent chromatography. But for some solvent systems, the retention of stationary phase would become insufficient, possibly caused by low interfacial

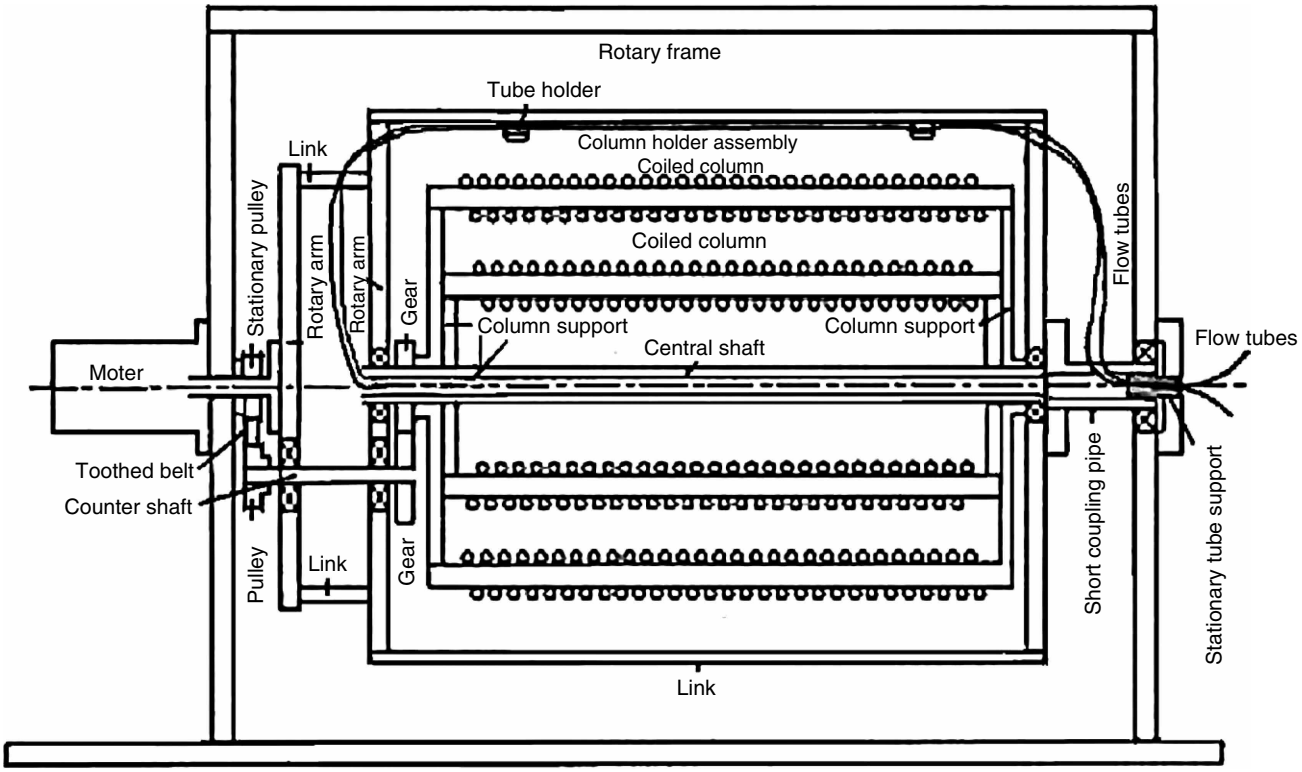

Fig. 1 Illustration of a seal-free flow-through rotary device.
Source: From Preparative counter-current chromatography with a rotating coil assembly, in J. Chromatogr.[4]

tension. Also, every solvent system possesses a critical rotational speed that gives optimum retention of the stationary phase. Therefore, more and more feasible solvent systems are expected to be reported for practical separations. Table 1 lists the optimum rotational speeds and retention rates of stationary phases of the reported solvent systems.

APPLICATION

One gram of DNP amino acids, composed of 500 mg DNP-glu and 500 mg DNP-ala, was separated with the solvent system composed of chloroform, acetic acid, and water (2:2:1). The apparatus was equipped with a 900 ml separation column consisting of ten units of glass coiled tube (0.5 cm I.D., 2.5 cm core diameter), connected in series with PTFE tubing. The separation yielded a peak resolution of about 1.7.[3]

Thirty grams of prepurified extract from the root of *P. lobata*, containing puerarin at a level of 60%, was separated using an apparatus equipped with a 10 L column with a two-phase solvent system composed of *n*-hexane, ethyl acetate, *n*-butanol, water, and acetic acid (1:1:2:6:0.2, v/v) at a flow rate of 5 ml/min at 21 rpm. The 10 L capacity column was prepared by winding 200 m, 8.5 mm I.D.

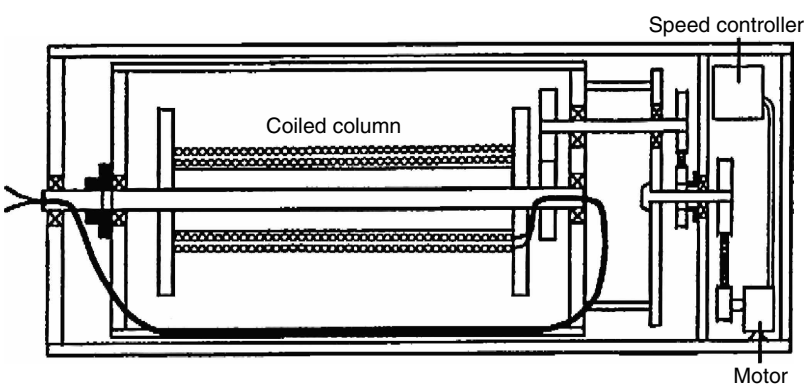

Fig. 2 Cross-sectional view of seal-free slow rotary countercurrent chromatography (SRCCC) instrument equipped with a large convoluted multilayer coil.

Source: From Low-speed rotary countercurrent chromatography using converted multilayer helical tube for industrial separation, in Anal. Chem.[7]

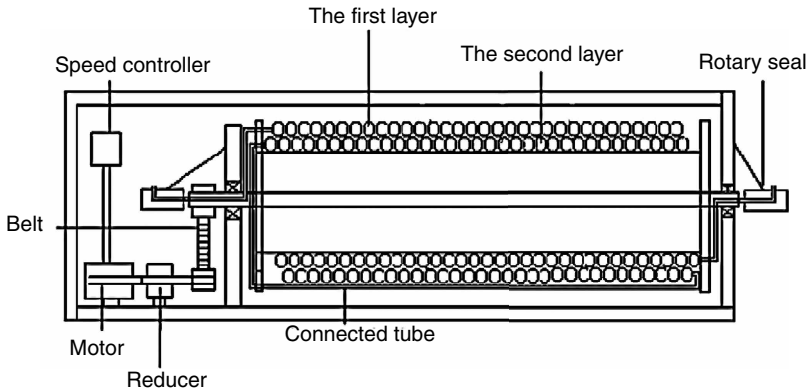

Fig. 3 Sketch of a slow rotary countercurrent chromatograph equipped with a pair of rotary seals.

convoluted tubing onto a 9 cm O.D. (outer diameter) column holder hub, making seven layers each consisting of 60 loops. The total elution time was 43 hr, and 38% of the stationary phase was retained when measured at the end of the run. Two major components, puerarin and 3′-methoxypuerarin, were resolved with a minimal overlapping zone. This separation yielded 16.7 g of puerarin at 91.2% purity, which corresponds to a recovery rate of 84.6%. Also, 150 g of dried extract of tea leaves containing epigallocatechin gallate (EGCG) at 30% was separated using the same apparatus with a two-phase solvent system composed of *n*-hexane, ethyl acetate, *n*-butanol, water, and acetic acid (0.5:1:2:6:0.2, v/v) at a flow rate of 5 ml/min at 21 rpm. The separation ran 72 hr, and retention of the stationary phase was 33%. In this separation, 40.05 g of EGCG was obtained at 92.8% purity, which corresponds to an 82.6% recovery rate.[7]

Nearly a kilogram (0.9 kg) of tea polyphenols containing 60% EGCG was separated using an apparatus equipped with a 40 L column. The 40 L column was made of 185 m of 17 mm average I.D. convoluted PTFE tubing wound onto a 2.4 m wide and 15 cm O.D. coil holder. The separation was performed at a 40 ml/min flow rate of the mobile phase to give a satisfactory result.[10] The apparatus was further used for isolation of salicin from the bark extract of *S. alba* and amygdalin from the fruit extract of *Semen armeniacae*. A 500 g amount of crude extract containing salicin at 13.5% was separated to yield 63.5 g of salicin at 95.3% purity in 20 hr using methyl *tert*-butyl ether–1-butanol (1:3) saturated by methanol–water (1:5) as a stationary phase and methanol–water (1:5) saturated by methyl *tert*-butyl ether–1-butanol (1:3) as a mobile phase. A 400 g amount of crude extract containing amygdalin at 55.3% was separated to yield 221.2 g of amygdalin at

Table 1 The optimum rotation speeds and retention rates of stationary phases of the reported solvent systems.

Solvent system	Optimum rotary speed (rpm)	Percent retention of stationary
n-BuOH–*n*-hexane–EtOAc–H_2O (2:2:1:6)	22	39.2
n-BuOH–*n*-hexane–EtOAc–H_2O–AcOH (2:1:0.5:6:0.2)	21	35.2
n-BuOH–*t*BME–CH_3CN–H_2O (2:2:1:5)	12	63.3
EtOAc–H_2O (1:1)	40	25.9
EtOAc–*n*-BuOH–H_2O (1:1:2)	20	51.4
EtOAc–AcOH–H_2O (3:1:3)	20	56.8
EtOAc–*n*-hexane–AcOH–H_2O (3:1:1:3)	20	60.0
n-Hexane–H_2O (1:1)	30	22.7
n-Hexane–MeOH (1:1)	30	50.0
n-Hexane–MeOH–H_2O (6:5:3)	60	75.5
n-Hexane–MeOH–EtOAc–H_2O (1:1:1:1)	40	60.0
$CHCl_3$–H_2O (1:1)	100	83.0
$CHCl_3$–MeOH–H_2O (4:3:2)	10	60.5
$CHCl_3$–MeOH–AcOH–H_2O (5:3:4:1)	100	85.0
$CHCl_3$–AcOH–H_2O (2:2:1)	100	79.5

Source: From Retention of stationary phase and partition efficiency of multilayer helical column rotated around its horizontal axis, in J. Liquid Chromatogr. Relat Technol.[2]

94.1% purity in 12 hr using ethyl acetate–1-butanol (1:2) saturated by water as a stationary phase and water saturated by ethyl acetate–1-butanol (1:2) as a mobile phase. The flow rate of the mobile phase was 50 ml/min.[11]

CONCLUSION

Slow rotary countercurrent chromatography possesses excellent separation efficiency, which is demonstrated by the above separations. The simplicity of the SRCCC system provides ease of scale-up, and its slow rotation column permits the system to be left unattended during the separation. Therefore, SRCCC is a promising CCC technology in the utilization of industrial separations.

Solute Focusing Injection Method

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

In capillary-column gas chromatography (GC), split injections are necessary to ensure that a very small, compact sample is placed on the column. However, split injections generally result in an unrepresentative sample being placed on a capillary column; thus, on-column injection is usually preferred for accurate quantitative analysis.

DISCUSSION

On-column injection demands the use of large-diameter tubes to permit the penetration of the injection syringe needle into the column. However, this procedure also causes other problems to arise. On injection, the sample readily separates into droplets which act as separate, and individual, injections that cause widely dispensed peaks and serious loss of resolution. In the extreme, double or multiple peaks are formed. Grob[1] suggested two solutions to this problem: the retention gap method of injection and the solute focusing method.

The solute focusing method is claimed to be more effective than the retention gap method, but the technique requires more complicated equipment. In the solute focusing method, the injector is designed so that there are two consecutive, independently heated and cooled column zones, located at the beginning of the column. A diagram of the solute focusing system and its mode of action is shown in Fig. 1. Initially, both zones are cooled and the sample is injected onto the first zone, where immediate sample splitting almost inevitably occurs. The carrier gas is then allowed to preferentially remove the solvent by eluting it through the column, leaving the contents of the sample dispersed along the cooled section of the tube. The selective removal of the solvent occurs because the solvent components are significantly more volatile than the components of the sample, even at the reduced temperature. The first zone is then heated and the second zone is continued to be kept cool. The solutes in the first zone progressively elute through the zone at the higher temperature until they meet the cooled zone. The movement of all the components is now significantly slowed down and they begin to accumulate at the beginning of the cooled second zone. The net effect is that the entire sample is now focused at the beginning of the cooled portion of the column. The temperature of the second zone is now programmed to the appropriate rate and the separation developed in the usual manner. This technique has more flexibility than the retention gap method, but the apparatus and the procedure is more complex and expensive. It should be pointed out that sample splitting does not occur in packed columns. It follows that if the sample is amenable to separation on such columns, then the packed column may be the column of choice if high accuracy and precision are required.

Solute Identification in TLC

Gabriela Cimpan
Sirius Analytical Instruments Ltd., East Sussex, U.K.

INTRODUCTION

Solute identification means qualitative analysis. Various methods are used today to identify a separated substance on a thin-layer chromatography (TLC) plate. Of all chromatographic methods, TLC provides a unique simultaneous separation of up to 70 samples on the same plate; therefore the reproducibility of the experimental conditions is not an issue because the experimental conditions are the same for all samples. This, together with the advantage of separating compounds with very different polarity and the possibility of using different detection methods for the same spot or for adjacent spots on the same plate, is the power of TLC.

UV–VIS DETECTION

Observing a substance in UV or visible light is the simplest way of detection and identification of the substance in TLC. If the substance is fluorescent, the identification is most reliable. However, many substances show similar behavior in UV light or have similar colors in visible light. Therefore a more accurate way of identification is required.

Often, the R_f value of the separated substances is compared with the R_f values of references. Not a long time ago, this information, together with the similar color, was usually enough to identify a substance. Today, modern densitometers are capable of measuring, more accurately, migration distances (therefore the R_f value) and to scan the in situ UV–Vis spectrum of the spot.

The majority of substances do not provide enough information based on their UV–Vis spectra; therefore a derivatization reaction should be applied to enhance the identification range. The derivatization is a chemical reaction designed to selectively improve the spectral characteristics of the separated substances and can be performed before or after the chromatographic separation. The prechromatographic derivatization can be performed during sample preparation or directly at the starting zone on the TLC plate. A preconcentration zone is recommended for the in situ prechromatographic derivatization reaction because all the formed substances will be concentrated at the starting point before the chromatographic separation. Postchromatographic derivatization can be non-destructive or destructive, and it is performed by covering the TLC plate with a homogenous layer of reagent, either by spraying or dipping. Sometimes, heating the plate is necessary for reaction completion.

If the substance is colored, the visible spectrum of the separated substance is recorded and compared with the reference spectrum. If the substance is not colored, but is active in UV light, there are two ways of identifying it, i.e., by fluorescence quenching, when the substance quenches the layer fluorescence, or by measuring the native fluorescence of the substance (before and/or after derivatization). UV–Vis fluorescence covers more than a third of the total methods of identification used in TLC, while the derivatization technique represents a similar percentage. All derivatization reactions are specific for chemical groups. The rest of about 20% consist of other methods of identification used in TLC: infra red (IR), mass spectrometry (MS), etc.

INFRARED DETECTION

The online technique for coupling high-performance thin--layer chromatography (HPTLC) with Fourier transform infrared spectroscopy (FTIR) has provided a powerful tool of using IR spectra and the rich information for the compound identification in TLC. The information contained in a UV–Vis spectrum is poor compared with IR, and only the chromophores can be identified by the former method. TLC was first coupled with FTIR in 1989, thereby providing a powerful tool for in situ measurement of separated compounds, with applications in the pharmaceutical, biological, environmental, and related sciences. Even the substances which do not absorb in UV have an IR spectrum; thus the method is universal. However, the strong IR absorption of the conventional stationary phases used in planar chromatography is a serious drawback of online coupling of HPTLC/FTIR.

The FTIR spectrometer is connected to the external unit by an interface mirror which diverts the beam to the spot on the plate. The reflected beam is then collected by using another set of mirrors and directed to a mercury cadmium telluride (MCT) narrow-band detector. This instrument can be used even with the strong absorbing layers used in TLC.

Various classes of drugs can be identified from complex mixtures by this method. UV–Vis spectra can help to recognize different structural groups; then, FTIR can further identify the compounds. All the spectra can be included in UV–Vis or IR spectral libraries and can be used as references for further assays.

The HPTLC/FTIR online coupling has been used for analyzing compounds from complex biological matrices where the number of compounds can be very high and the polarities very different; gradient development often has to be applied to obtain a separation.

Further development in obtaining and interpreting the data in this method will allow the identification and quantitation of separated unknown compounds.

RAMAN SPECTROSCOPY

Raman spectroscopy is the measurement of the wavelength and intensity of inelastically scattered light from molecules. The Raman scattered light occurs at wavelengths that are shifted from the incident light by the energies of molecular vibrations. The mechanism of Raman scattering is different from that of infrared absorption, and Raman and IR spectra provide complementary information. Typical applications are in structure determination, multicomponent qualitative analysis, and quantitative analysis. The most common light source in Raman spectroscopy is an Ar-ion laser. Because Raman scattering is a weak process, a key requirement to obtain Raman spectra is that the spectrometer should provide a high rejection of scattered laser light. New methods, such as very narrow rejection filters and Fourier-transform techniques, are becoming more widespread.

Special HPTLC plates allow direct Raman spectroscopy to be run after the separation without removal from the plate. They are made of a special 3–5 μm spherical silica gel on a 10 × 10 cm plate. The thickness is 0.1 mm to allow more of the compound to reside on the surface for this analysis.

Modern Raman spectrometers allow scanning of a surface up to A4 size, with XY translation stage and fine spatial adjustment to allow the operator to align the laser probe onto samples as small as 5 μm in diameter. Sample selection is assisted by the use of an integral video microscope with a rotating turret that can be fitted with up to four objective lenses to provide on-screen magnification of up to 500×.

Surface-enhanced resonance Raman scattering (SERRS) is a very sensitive technique with many applications, especially in forensic analysis. SERRS was successful in differentiating the majority of the 26 inks examined in an experiment designed to show that the method is less invasive than TLC and can be used coupled with an HPTLC plate.

MS DETECTION

The online coupling between TLC and MS provides a powerful combination for the detection and identification of substances separated by a planar chromatographic method. The online coupling between these two methods has to overcome the problem of vaporizing and introducing the sample into the mass spectrometer. Different methods are reported in the literature, but the analytical principle is the same: the sample is ionized from the layer surface by means of a laser beam, under vacuum, and in the presence of an energy-buffering matrix. Once the ions are transferred into the mass spectrometer, more sophisticated methods can be applied for data analysis and interpretation, e.g., MS/MS.

In planar chromatography, the sample is fixed on the layer and can be found in three-dimensional space. The interface between the layer and MS must separate the compound molecules from the layer molecules and must present a way to transport them into the MS, either via a liquid or a gaseous phase. The main difference between MS and the spectroscopic methods is that MS is a destructive method, consuming the sample, while the others are non-destructive.

The samples can be removed from the layer-by-laser desorption or matrix-assisted laser-desorption ionization (MALDI) which can be coupled with a time-of-flight (TOF), ion trap, or Fourier-transform mass spectrometer. MS/MS can also be an option for further analysis. The electron or chemical ionization methods are most commonly used to break the sample molecules into fragments (ions) in the gaseous phase. The obtained spectra can be used for sample identification by comparison with a spectral library. The laser desorption ionization assisted by a matrix (MALDI and SALDI techniques) uses the ionization of the sample at the surface of the thin layer, and the matrix plays a role of energy buffer. Electrospray ionization is another method of transferring the sample to the MS by spraying organic solvents containing the molecules of the sample.

The presence of the layer material, together with the sample, raises many problems in designing an appropriate interface for TLC/MS. More details can be found in the bibliographic references.

The instrumentation for TLC/MS is not as widespread as for other chromatographic methods (e.g., GC/MS and LC/MS) mainly because of the complexity of the interface involved.

IMAGE ANALYSIS

Image analysis has brought new possibilities to compound detection, identification, and quantitation in TLC; it takes advantage of the main benefit of planar chromatography, i.e., the possibility of separating and analyzing up to 70 samples on a single plate. The image can be obtained by charge-coupled device (CCD) cameras, digital camcorders, or flatbed scanners and can be further processed with a computer. The power of image-analysis systems relies on good resolution and contrast and the capacity to minimize the distortion and the perspective errors from a lens. The

settings of the factors for obtaining a good image can be different from sample to sample. Although the colored image is more similar to the real chromatographic plate, the black and white image, with shades of gray, can be interpreted better by the human eye, as it is more sensitive to small changes in black and white than are colors.

Charge-coupled devices have been used as detectors in planar chromatography, although more applications have been found in quantitative analysis. Videodensitometers have been used to measure the absorption or the fluorescence of a separated spot on a TLC plate.

The miniaturization of the TLC technique will be a challenge for image analysis, but, probably, this will be the technique for creating image libraries for compounds or for complex mixtures such as plant extracts.

PHOTOACOUSTIC DETECTION

Non-uniformity of the layer or of the sample distribution in the layer and light scattering are some of the difficulties that an online spectroscopic detection method has to overcome.

Photoacoustic detection measures the pressure variation caused by the heating of a gas in the vicinity of the sample. If the sample is enclosed in a photoacoustic cell equipped with a microphone, the modulated signal can be interpreted as a function of temperature, pressure, and the quantity of the sample.

Since photoacoustic spectroscopy (PAS) was first reported in 1975, the method was gradually improved, and now, nanograms to picograms of substances can be successfully detected and quantified on TLC plates. When the method was first developed, the separated spot had to be scratched from the plate and introduced into the PAS cell for the measurements; but now, the PAS cell can be fixed directly onto the layer surface. Other instruments can be laser-based densitometers with signal enhancement at a resonant frequency of the cell. The detection limit is very low in this case, and the linearity of the quantitative determination is over 3 orders of magnitude. Moreover, FTIR can be used in combination with the PAS technique for in situ measurements. The presence of helium might be necessary to prevent high background noise, which is mainly produced by the silica-based layer.

FLAME IONIZATION DETECTION

TLC coupled with online flame ionization detection (TLC/FID) has been developed for the analysis of organic substances which show no UV absorption and no fluorescence and which present difficulties by GC analysis.

Planar chromatography is usually performed on a quartz rod (Chromarod®) coated with a thin layer of silica or alumina onto which the sample is developed and separated. The rod is advanced at a constant speed through the flame of the FID, and the substances are ionized through energy obtained from the hydrogen flame. Influenced by the electric field applied to the poles of the FID, the ions generate electric current with an intensity proportional to the amount of each organic substance entering the flame. Spotting of the sample is performed with a specially designed application system; the rods are further developed in special development tanks, then the rods are scanned through the hydrogen flame.

Applications have been reported in many areas including analysis of lipids, oils, fatty acids, polymers, asphalt, and surfactants. The advantages of this method are high throughput, low cost per sample, easy quantitation using standard chromatography software, and simple method development analogous to standard TLC.

The quantitation of samples using Chromarods is not very linear, as the rods are not uniform, but nevertheless, the method remains a very useful tool for difficult samples.

DIGITAL AUTORADIOGRAPHY

Digital autoradiography (DAR) can be used in combination with TLC for the analysis of radiolabeled compounds, most frequently ^{3}H and ^{14}C. The method is simple and requires reasonably priced instrumentation; therefore it is widely used for biochemical and pharmacological applications. The instrumentation for TLC–DAR can scan a 20×20 cm area, the radioactivity bands are visualized with a digital radiograph, and the digital data are processed with a high-capacity computer.

The analysis of samples in biological matrices is extremely powerful compared with drawbacks such as narrow concentration range for quantitative measurements and long time required for spot detection. Digital autoradiography can be used in hyphenated off-line and online methods. A powerful example is TLC/DAR/FABMS/MS with applications in in vitro and in vivo metabolism studies.

BIOAUTOGRAPHY

Bioautography is a method developed for the study and analysis of biologically active substances from simple samples to complex biological matrices. Antimicrobial activity is the monitored parameter, and it can be either growth-inhibiting or growth-promoting.

The screening of biological activity can be performed by diffusion method, dilution method, and bioautography.

The diffusion method uses an agar layer impregnated with the organism being tested; a filter paper disk containing the sample is placed on top. After an appropriate incubation time, the paper disk is removed and the average diameter of each zone of growth inhibition is measured.

In the dilution method, the sample is mixed with a suitable medium which has been previously impregnated with the organism being tested. After the incubation time, the growth of microorganisms can be determined by comparing the test culture with a control culture.

Bioautographic methods involve a chromatographic layer containing the biologically active compound which migrates, by diffusion, to an inoculated agar plate. The inhibition zones can be easily visualized by specific reagents. In direct bioautography, the microorganisms grow directly on the TLC plate and further analysis steps are performed on the plate. Silica gel and cellulose plates produce good results, while polyamide and aluminum oxide are not recommended for this type of assay. Bioautography is an additional method for the screening of biologically active compounds and provides good selective postchromatographic detection.

Solvent Systems: Systematic Selection for HSCCC

Hisao Oka
Food-Related Chemistry, Laboratory of Chemistry, Aichi Prefectural Institute of Public Health, Nagoya, Japan

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

High-speed countercurrent chromatography (HSCCC) produces highly efficient chromatographic separations of solutes without the use of solid supports.[1–3] Thus the method eliminates all complications caused by the solid support, such as adsorptive loss and deactivation of samples, tailing of solute peaks, contamination, etc. As with other CCC schemes, HSCCC utilizes two immiscible solvent phases, one as a stationary phase and the other as a mobile phase, and the separation is highly dependent on the partition coefficient values of the solutes, i.e., the ratio of the solute concentration between the mobile and stationary phases. Therefore the successful separation necessitates a careful search for the suitable two-phase solvent system that provides an ideal range of the partition coefficient values for the applied sample.

In the past, the search for suitable two-phase solvent systems entirely relied on a laborious and time-consuming trial-and-error method that has often discouraged the users of HSCCC, while the method for systematic solvent search has not been reported. In this entry, we introduce a method for the systematic selection of suitable two-phase solvent systems for HSCCC and its application to the separation of antibiotics and dyes.

HOW TO SELECT SUITABLE SOLVENT SYSTEM

In addition to the basic requirements of stability and solubility of the sample, the two-phase solvent system should satisfy the following.

1. For ensuring the satisfactory retention of the stationary phase, the settling time of the solvent system should be considerably shorter than 30 sec.

   Using the equilibrated two-phase solvent system, the settling time is measured as follows: A 2 ml volume of each phase (the total volume is 4 ml) is delivered into a 5 ml-capacity graduated glass cylinder, which is then sealed with a glass stopper. The solvent in the cylinder is gently mixed by inverting the cylinder five times and the cylinder is immediately placed on a flat table in an upright position. Then, the time required for the solvent mixture to settle into two clear layers is measured. The experiment is repeated several times to obtain the mean value.
2. For efficient separation, the partition coefficient (K) of the target compound(s) should be close to 1, and the separation factor (α) between the components should be greater than 1.5. If $K < 1$, the solutes are eluted close together near the solvent front, resulting in a loss of peak resolution, and, if $K > 1$, the solutes are eluted in excessively broad peaks and require a long elution time. The minimum α value of 1.5 is required for the baseline separation in a semipreparative CCC equipment providing a moderate partition efficiency of around 800 theoretical plates.

   The K value is determined simply by measuring the ultraviolet (UV) absorbance of the solute in each of the two phases after partitioning in the equilibrated two-phase solvent system and dividing the solute concentration in the upper phase by that in the lower phase. However, when the sample is a mixture of various components, the precise K values of each component cannot be determined by this method. In such a case, a mixture is partitioned with a two-phase solvent system as described above and the resulting upper and lower phases are analyzed by HPLC. Each K value is determined by dividing the corresponding peak area of the upper phase by that of the lower phase.
3. In addition to the above two major requirements, it is desirable that the solvent system provides nearly equal volumes of each phase to avoid excessive waste of the solvent.
4. It is also convenient to use a volatile solvent system: The pure compound is obtained simply by evaporating the collected fractions.

By keeping the above in mind, the following three series of solvent systems can provide an ideal range of the K values for a variety of samples: *n*-hexane/ethyl acetate/*n*-butanol/methanol/water,

Table 1 *n*-Hexane/ethyl acetate/*n*-butanol/methanol/water system.

0	0	5	0	5 (hydrophilic)

chloroform/methanol/water, and *tert*-butyl methyl ether/butanol/acetonitorile/water.

In each solvent series,[4] the partition coefficient of the sample can be finely adjusted by modifying the volume ratio of the components. The first series covers a broad range in both hydrophobicity and polarity continuously from *n*-hexane/methanol/water to *n*-butanol/water. The second series of chloroform/methanol/water provides moderate hydrophobicity and the third series of *tert*-butyl methyl ether/*n*-butanol/acetonitorile/water is suitable for hydrophilic compounds. Most of these two-phase solvent systems provide near 1 : 1 volume ratios of the upper/lower phases, together with the reasonable range of settling times in 30 sec or less, so that they can be efficiently applied to HSCCC and other centrifugal CCC schemes.

For the sample mixture with an unknown composition, the search for the suitable two-phase solvent system may be initiated with the partition coefficient measurement with *n*-hexane/ethyl acetate/*n*-butanol/methanol/water (5 : 5 : 0 : 5 : 5) (Table 1), chloroform/methanol/water (10 : 3 : 7) (Table 2) or *tert*-butyl methyl ether/butanol/acetonitorile/water (6 : 0 : 3 : 8) (Table 3). If the $K_{(org/aq)}$ value is too large, the search should be directed toward the more hydrophobic solvent systems and, if the K value is too small, the search should be directed toward the more hydrophilic solvent systems until the proper K values are obtained.

Table 2 Chloroform/methanol/water system.

Chloroform	Methanol	Water
10	0	10 (hydrophobic)
10	1	9
10	2	8
10	3	7
10	4	6
10	5	5
10	6	4
10	7	3 (hydrophilic)

Table 3 *tert*-Butyl methyl ether/*n*-butanol/acetonitrile/water system.

tert-Butyl methyl ether	*n*-Butanol	Acetonitrile	Water
1	0	0	1 (hydrophobic)
4	0	1	5
6	0	3	8
2	0	2	3
4	2	3	8
2	2	1	5 (hydrophilic)

If the above solvent search reaches the solvent system of *n*-hexane/methanol/water (2 : 1 : 1), which is suitable for the most hydrophobic compounds, and a more hydrophobic solvent system is required, one may reduce the amount of water from the above solvent system and/or replace methanol with ethanol. Some useful solvent systems for the extremely hydrophobic compounds are *n*-hexane/ethanol/water (6 : 5 : 2) and *n*-hexane/methanol (2 : 1). On the other hand, if the solvent search reaches the solvent systems of *n*-butanol/water or *tert*-butyl methyl ether/butanol/acetonitorile/water (2 : 2 : 1 : 5), which are suitable for the most hydrophilic compounds, and a still more hydrophilic solvent system is required, the above solvent system may be modified by the addition of acid or salt; trifluoroacetic acid (TFA) or ammonium acetate has been successfully used.

APPLICATION TO THE SEPARATION OF ANTIBIOTICS AND DYES

Separation of Bacitracin Components

Bacitracins (BCs) are peptide antibiotics produced by *Bacillus subtilis* and *Bacillus licheniformis*.[5] They exhibit an inhibitory activity against Gram-positive bacteria and are most commonly used as animal feed additives for domestic animals, such as calf and swine, for preventing bacterial infection and/or improving feed conversion efficiency. Over

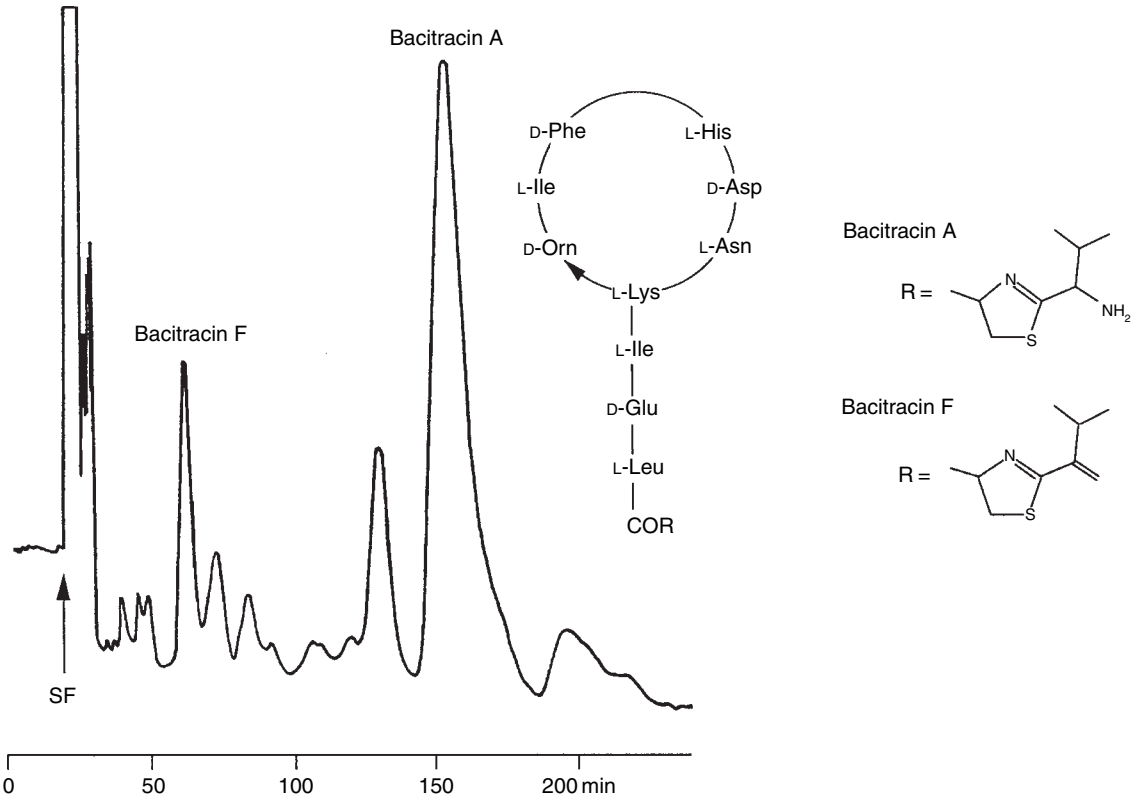

Fig. 1 HSCCC separation of bacitracin components. Solvent system: chloroform/ethanol/methanol/water (5 : 3 : 3 : 4); mobile phase: lower phase; flow rate: 3 ml/min; detection: 254 nm.

20 components are contained in the bacitracin complex, among which BC-A is the major antimicrobial component and BC-F is a degradation product having nephrotoxicity.

We tested three groups of two-phase solvent systems containing *n*-butanol, ethyl acetate, or chloroform as a major organic solvent, and ethanol and/or methanol as a modifier against water in each group. The most promising *K* values were obtained from the chloroform, ethanol, and/or methanol, water system. Among all combinations for the solvent volume ratio, chloroform/ethanol/methanol/water (5 : 3 : 3 : 4) yielded the most desirable *K* values, and the α values between the adjacent components are all greater than 1.5.

Fig. 1 shows a countercurrent chromatogram of bacitracin components using the chloroform/ethanol/methanol/water (5 : 3 : 3 : 4) system. A 50 mg amount of the bacitracin complex was loaded into the HSCCC column. The retention of the stationary phase was 72.7% and the elution time was about 3 hr. All components were eluted in an increasing order of their partition coefficients, yielding 5.5 mg of pure BC-A and 1.5 mg of pure BC-F.

Separation of Colistin Components

Colistin (CL) is a peptide antibiotic produced by *Bacillus polimyxa* var. *Colistinus*; it inhibits the growth of Gram-negative organisms. Colistin is a mixture of many components, among which the two main components are colistin A (CL-A) and colistin B (CL-B).[6] As in the case of bacitracin, CL is used as a feed additive.

CL is soluble in water, slightly soluble in alcohols, but insoluble in non-polar solvents such as hexane and chloroform. Based on these properties, we selected *n*-butanol and water as a basic solvent system. However, this combination was not suitable by itself, because the CL components were entirely partitioned into the lower aqueous phase. In order to partition the CL components partly into the *n*-butanol phase, various salts (sodium chloride and sodium sulfate) or acids (hydrochloric acid, sulfuric acid and TFA) were added as a modifier. A desirable effect was obtained by the addition of TFA, where the partition coefficients of CL components rose as the concentration of TFA in the solvent system was increased. As TFA forms an ion pair with amino groups in the molecule of CL, the hydrophobicity of CL components increases with the concentration of TFA, resulting in the partition of components toward the organic phase. In order to determine the optimal concentration of TFA in the solvent system, *K* values were measured at various TFA concentrations. The *K* value of each component increases with the TFA concentration and, at 40 m*M* TFA concentration, the *K* values of CL-A and CL-B reach 1.5 and 0.6, respectively. At this TFA concentration, the α values between the adjacent peaks are all greater than 1.5,

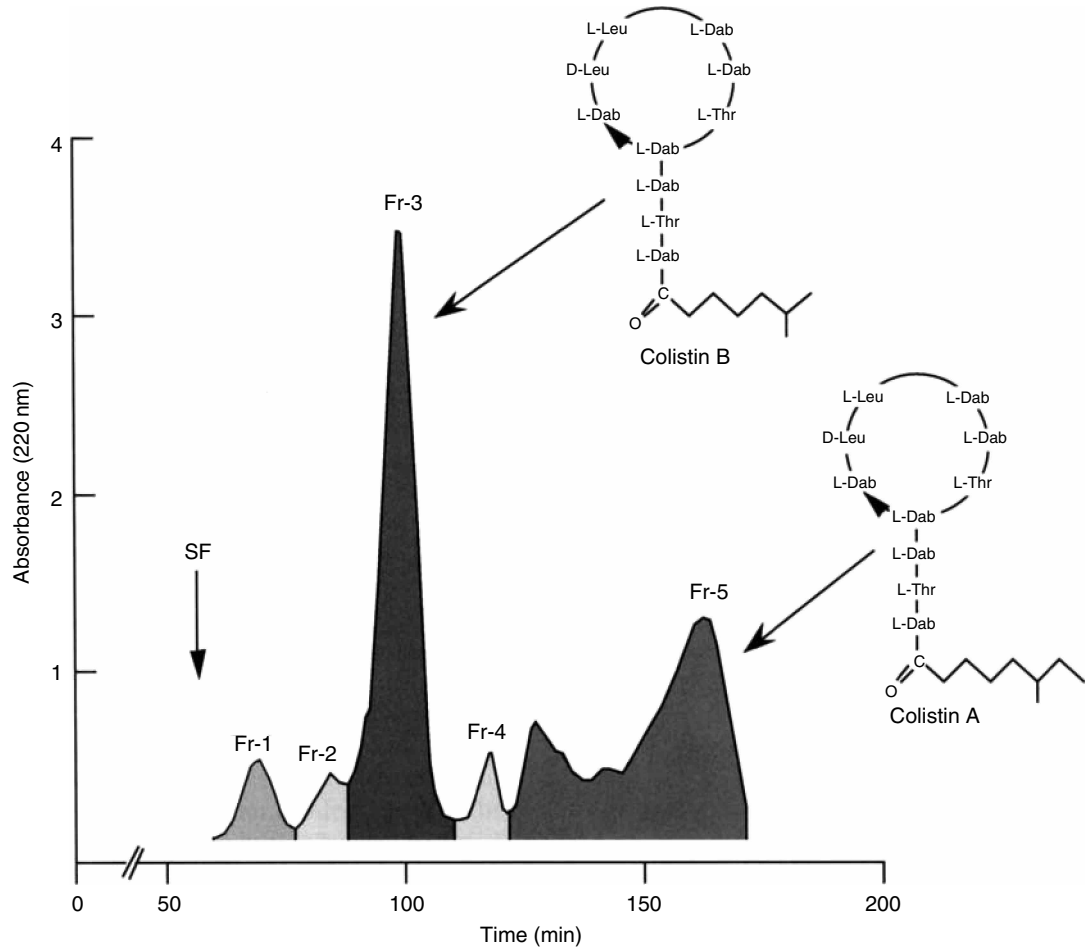

Fig. 2 HSCCC separation of colistin components. Solvent system: *n*-butanol/0.04 *M* trifluoroacetic acid (1 : 1); mobile phase: lower phase; flow rate: 2 ml/min; detection: 220 nm.

promising a good separation for all components. The settling time of the solvent system was 28 sec, which is within an acceptable range. Therefore we selected a solvent system of *n*-butanol/40 m*M* TFA aqueous solution (1 : 1) for the HSCCC separation of CL components.

Using the above solvent system, a 20 mg portion of commercial CL was separated by HSCCC. The retention of the stationary phase was 45%. The elution curve, monitored at 220 nm, is shown in Fig. 2. The yields of CL-A and CL-B were 9 mg each, and those of the other minor components were 0.5–1.0 mg. From HPLC analysis, the fractions of CL-A and CL-B each produced almost a single peak with a high purity of over 90%.

Separation of Ivermectin Components

Ivermectins B1 are broad-spectrum antiparasitic agents widely used for food-producing animals such as cattle, swine, and horse.[7] They are derived from avermectins B1, the natural fermentation products of *Streptomyces avermitilis*.

We have selected a two-phase solvent system composed of *n*-hexane, ethyl acetate, methanol, and water. As described above, this solvent system is conveniently used for the separation of components with a broad range of hydrophobicity by modifying the volume ratio between the four solvents. In the *n*-hexane/ethyl acetate/methanol/water (8 : 2 : 5 : 5) system first examined, the *K* values of the components were 0, 0.46, 0.61 (avermectin B1a); ∞, 1.86 (ivermectin B1b); 3.06 (ivermectin B1a); and 4.38, respectively. This indicates that the component corresponding to ivermectin B1a is mostly partitioned in the upper organic phase. Although the *n*-hexane/ethyl acetate/methanol/water (9 : 1 : 5 : 5) system somewhat improved the *K* value of ivermectin B1b to 2.31, it was still too large. Finally, a slightly less polar solvent mixture at the volume ratio of 19 : 1 : 10 : 10 yielded the best *K* values: 0, 0, 0.18 (avermectin B1a); 0.48, 0.79 (ivermectin B1b); 1.36 (ivermectin B1a); and 2.83, with desirable α values of over 1.5 for all components. The settling time of this solvent system was 7 sec, promising excellent retention of the stationary phase. In addition, the volume ratio between the two phases is nearly 1, indicating that either phase can be used as the mobile phase without wasting the solvents. Therefore the above solvent system was selected for the separation of ivermectin components.

	R	–C_{22}–X–C_{23}–
Ivermectin Bla	C_2H_5	–CH_2–CH_2–
Ivermectin Blb	CH_3	–CH_2–CH_2–
Avermectin Bla	C_2H_5	–CH=CH–
Avermectin Blb	CH_3	–CH=CH–

Fig. 3 HSCCC separation of ivermectin components. Solvent system: *n*-hexane/ethyl acetate/methanol/water (19 : 1 : 10 : 10); mobile phase: lower phase; flow rate: 2 ml/min; detection: 245 nm.

A 25 mg quantity of crude ivermectin was separated using the above solvent system at a flow rate of 2 ml/min. The retention of the stationary phase was 67.6% and the total separation time was 4.0 hr. The HSCCC elution curve of the ivermectin components, monitored at 245 nm, is shown in Fig. 3, where all components are separated into three peaks. This separation yielded 18.7 mg of 99.0% pure ivermectin B1a (Fig. 3), 1.0 mg of 96.0% pure ivermectin B1b (Fig. 3), and 0.3 mg of 98.0% pure avermectin B1a.

Separation of Lac Dye Components

Lac dye is a natural food additive extracted from a stick lac, which is a secretion of the insect Coccus laccae (*Laccifer lacca* Kerr), and is widely used for coloring food.[8] It is known that its red color is derived from water-soluble pigments including laccaic acids A, B, C, and E.

Laccaic acids have two or three carboxyl groups, five or six hydroxyl groups, and/or one amino group, and are freely soluble in water, but only slightly soluble in organic solvents such as chloroform and ethyl acetate. Based on these physicochemical properties of laccaic acids, we selected a two-phase solvent system composed of *tert*-butyl methyl ether/*n*-butanol/acetonitrile/water, which has been frequently used as the solvent system for the separation of hydrophilic compounds as described earlier. In the *tert*-butyl methyl ether/*n*-butanol/acetonitrile/water (4 : 2 : 3 : 8) system first examined, the *K* values of the components were 0.08, 0.10 (laccaic acid C), 0.19, 2.00, 0.84 (laccaic acid B), and 0.60 (laccaic acid A), respectively. This indicates that the first component (*K* value: 0.08) and laccaic acid C (*K* value: 0.10) would be eluted together near the solvent front because of their small *K* values. A more polar solvent composition of *tert*-butyl methyl ether/*n*-butanol/acetonitrile/water (2 : 2 : 1 : 5) yielded the best *K* values, with desirable α values of over 1.5 for all components. The settling time of this solvent system is less than 30 sec, which ensures a satisfactory retention of the stationary phase in HSCCC as described before. Therefore we selected this solvent system for the separation of the lac dye components.

A 25 mg quantity of lac dye was separated using the above solvent system at a flow rate of 1 ml/min. The retention of the stationary phase was 83.6%. The total separation time was 8.3 hr. The absorbance of effluents in every tube was measured at 495 nm to draw the elution curve (Fig. 4). In the HPLC analysis of the original sample, laccaic acids A, B, and C constituted about 37.1%, 18.0%, and 35.5% of the total peak area at 280 nm, respectively. After only one-step operation by HSCCC, the purities of the above three components were increased to 98.1% (laccaic acid A), 98.2% (laccaic acid

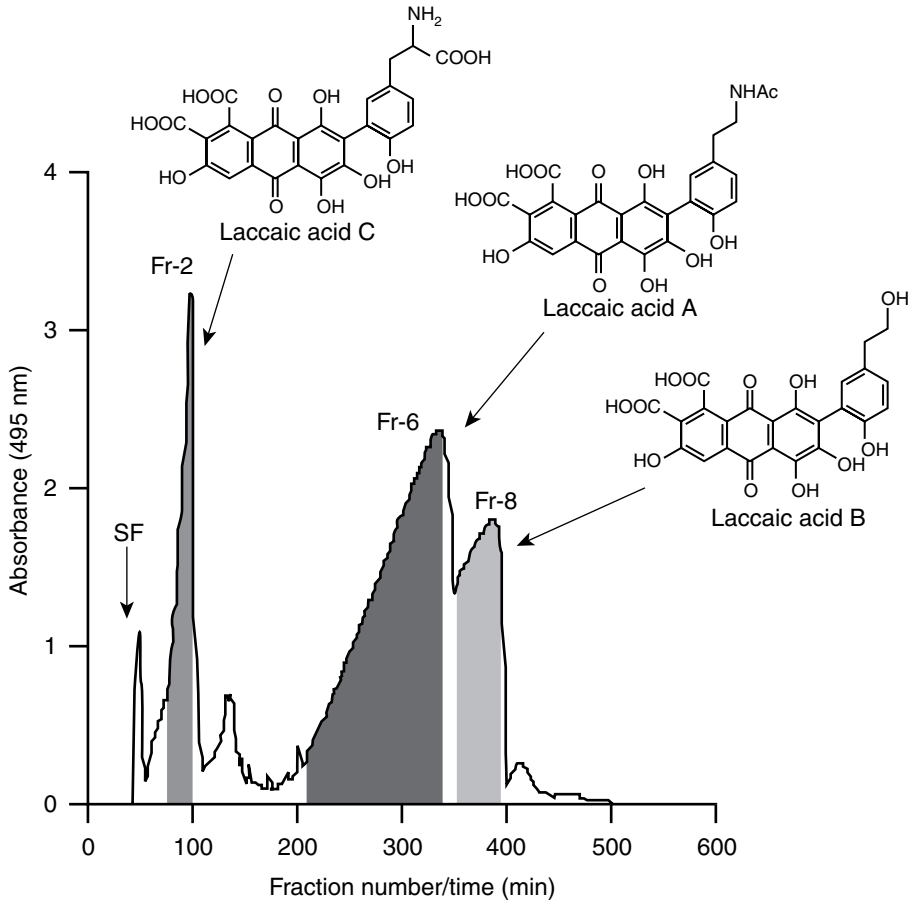

Fig. 4 HSCCC separation of lac dye components. Solvent system: *tert*-butyl methyl ether/*n*-butanol/acetonitrile/water (2 : 2 : 1 : 5); mobile phase: lower phase; flow rate: 1 ml/min; detection: 495 nm.

B), and 97.2% (laccaic acid C), respectively. These results demonstrate the high resolving power of HSCCC achieved by the careful selection of the proper solvent system.

CONCLUSIONS

Because of a support-free partition system, HSCCC provides an important advantage over other chromatographic methods by eliminating various complications, such as adsorptive loss and deactivation of samples, as well as contamination from the solid support. As shown by our examples, HSCCC can isolate various components from a complex mixture of natural products by carefully selecting the two-phase solvent system to optimize the partition coefficient (K) of the target component(s). The HSCCC system can also be applied to microanalytical-scale separations without excessive dilution of samples. We believe that HSCCC is an ideal method for the separation and purification of natural products.

Sorbents in TLC

Luciano Lepri
Alessandra Cincinelli
Department of Chemistry, University of Florence (UNIFI), Florence, Italy

Abstract
A review of all sorbents used as stationary phases in thin-layer chromatography (TLC) is reported. The specific application field of all sorbents is described according to their relative chemical–physical properties. New materials have been developed for the high-performance thin-layer chromatography (HPTLC) technique to offer both high-efficiency separations and high-sensibility analysis. In particular, silanized silica gel has been extensively used as stationary phase in reversed-phase (RP) chromatography for its hydrophobic properties.

INTRODUCTION

Since the introduction of commercial precoated plates in the mid-1960s, continual developments with regard to the increase of selectivity and the improvement of separation efficiency have been pursued [e.g., ready-to-use layers suitable for high-performance thin-layer chromatography (HPTLC) and overpressured layer chromatography (OPLC), polar and hydrophobic bonded phases, impregnated layers, and plates with concentrating zones]. A wide variety of thin-layer chromatography (TLC) and HPTLC precoated plates, which give reproducible results, are commercially available today, even if it is possible to prepare these plates in the laboratory. Homemade plates can allow access to stationary phases that are not otherwise available.

The average particle size and the range of particle sizes are smaller on HPTLC layers than on TLC layers (i.e., 2–10 and 5–17 μm, respectively, for Macherey-Nagel HPTLC and TLC silica plates), and a marked fall in theoretical plate heights is observed (about one order of magnitude smaller than on standard silica layers). Consequently, smaller plate sizes (from 20 × 20 to 10 × 10 cm) and sample volumes (from 1–3 to 0.1–0.2 μl) and shorter migration distances (from 10–16 to 3–8 cm) can be used. A rational classification system of commonly used sorbents in TLC is shown in Table 1.

HYDROPHILIC UNMODIFIED SORBENTS

Silica, Silica Gel, or Silicic Acid

These products are by far the most frequently used sorbents in TLC and are prepared by the dehydration of aqueous silicic acid generated by the addition of a strong acid to a silicate solution. Chemically, each silicon atom is surrounded by four oxygen atoms in the form of a tetrahedron. The surface of silica contains: 1) siloxane groups (Si–O–Si); 2) silanol groups (Si–OH); 3) water hydrogen bonded to the silanol groups; and 4) also non-sorbed "capillary" or bulk water. The silanol groups (about 8 μmol/m^2) represent adsorption-active surface centers that are able to interact with solvent and solute molecules during the separation process. The silanol active centers can differ slightly depending on whether they occur as isolated, vicinal, or geminal silanols.

Surface energy and surface extension together characterize the activity of silica ("activity" is the surface property of the adsorbent), and the size of the surface is reduced when covered with molecules such as water and glycol, which deactivate the surface of the sorbent. An increase in the surface activity results in lower R_f values, which, therefore, depend on silica porosity and humidity changes. The water content of the layer can be checked by measuring the absorption values of Reichardt's dye at 500 nm; the color of the dye changes from violet to pink with increasing silica gel humidity.[1] The surface pore diameter can vary over a wide range; TLC sorbents have pores of 40, 60, 80, and 100 Å. Pores of about 40 Å are termed "small," those major of 100 Å "large," and those of 60–80 Å "medium." Most sorbents for TLC have medium and large pores. The specific surface area of silica gel ranges from 200 to more than 800 m^2/g.

Activation by heating at 150–200°C removes the physically bound water. Water content of silica can be controlled by storing TLC plates at known humidity. The assumption that one silica is most suitable for adsorption and another for liquid–liquid partition chromatography is questionable and, moreover, irrelevant, because pure adsorption or partition retention mechanisms generally do not occur. Thin-layer

Table 1 Classification of the most used TLC sorbents.

General class	Sorbents
Polar inorganics (hydrophilic)	Silica gel, alumina, diatomaceous earth (kieselguhr), magnesium silicate (Florisil®)
Polar organics	Cellulose, starch, chitin, polyamide 6 or 11
Polar bonded phases	3-Aminopropyl, 3-cyanopropyl, and diol-modified silica
Hydrophobic bonded phases	C_2, C_8, C_{18}, C_{30}, and phenyl-modified silica; C_8-modified alumina; cellulose triacetate
Ion exchangers	
Inorganic	Zirconium(IV) phosphate, tungstate, and molybdate; titanium(IV) silicate; ammonium molybdophosphate and tungstophosphate; hydrous oxides
Organic	Polystyrene-based anion and cation exchangers, polymethacrylic acid; cellulose-based anion and cation exchangers; substance-specific complexing ligands
Impregnated layers	Silica impregnated with saturated and unsaturated hydrocarbons (squalene, paraffin oil); silicone and plant oils; complexing agents (silver ions, boric acid, and borates; carbohydrates; unsaturated and aromatic compounds); chelating compounds [ethylene diamine tetra-acetic acid (EDTA), digitonin]; transition metal salt; synthetic peptides; 18-crown-6 and ammonium sulfate; silanized silica gel impregnated with anionic and cationic surfactants
Gel filtration media	Cross-linked, polymeric dextran gels (Sephadex)
Chiral phases	Cellulose, cellulose triacetate, tribenzoate, and triphenylcarbamate; silanized silica gel impregnated with the copper(II) complex of (2*S*,4*R*,2′*RS*)-*N*-(2′-hydroxydodecyl)-4-hydroxyproline (CHIRALPLATE, HPTLC CHIR); molecular imprinting polymers (MIPs)

chromatographic silica gels have specific pore volumes ranging from 0.5 to 2.0 ml/g, and sorbents with the highest values are preferred for partition chromatography. Typical applications of silica gel in TLC separation of classes of organic compounds are listed in Table 2.

Alumina

The sorbents for TLC are obtained by thermal removal of water from hydrated aluminum hydroxide preparations at 200–600°C; the specific surface area of these aluminas ranges from 50 to 350 m^2/g. The aluminas for TLC have mean pore diameters of 60, 90, or 150 Å and specific pore volumes between 0.1 and 0.4 ml/g. The most frequently used crystalline form is γ-Al_2O_3 (specific surface 100–200 m^2/g). Aluminum cations, hydroxyl groups, and oxide ions are present on the surface, and the oxide ions are responsible for the basic properties of the sorbent. The use of gypsum (calcium sulfate hemihydrate) as a binder neutralizes the alumina surface. Aluminas with pH values of 9–10, 7–8, and 4–4.5 are designated basic, neutral, and acidic in character, respectively. Owing to the high density of hydroxyl groups (about 13 μmol/m^2), alumina tends to adsorb water and becomes deactivated. For this reason, the activation of aluminum oxide-precoated layers, before use, by heating for 10 min at 120°C is recommended.

Aluminas are of notable selectivity in adsorption chromatography of aromatic hydrocarbons; examples of separations of organic and inorganic compounds by adsorption and partition chromatography on layers of alumina are presented in Table 2.

Cellulose

Cellulose is formed by long chains of β-glucopyranose units connected one to another at the 1–4 positions. TLC sorbents are native fibrous cellulose and microcrystalline cellulose AVICEL. The polymerization degree of native cellulose ranges from 400 to 500 glucose units, and the fibers are shorter (2–20 μm) than those in paper chromatography, preventing the instantaneous spreading of solutes. The specific surface area is about 2 m^2/g. High-purity fibrous cellulose, obtained by washing under very mild acidic conditions and, successively, with organic solvents, is also used in TLC. AVICEL is formed by dissolving the amorphous part of native cellulose by hydrolysis with hydrochloric acid.

Partition chromatographic mechanisms operate on cellulose thin layers even if adsorption effects cannot be excluded (for separation of substance classes, see Table 2). Celluloses are naturally occurring chiral adsorbents and can be used for chiral separation of optically active amino acids and dipeptides.

Polyamides

Synthetic organic resins used in TLC are polyamide 6 (nylon 6) and polyamide 11, which consist of polymeric caprolactam and undecanamide, respectively. Therefore, polyamide 6 is more hydrophilic than polyamide 11, owing to the shorter hydrophobic chain of its monomeric unit.

Polyamide-precoated plates are currently used for the separation of phenols and phenolic compounds (i.e., anthocyanins, anthoxanthins, anthraquinone derivatives, and

Table 2 Application in normal and RP-TLC.

Sorbent	Substance class
Silica gel	Aflatoxins, alkaloids, anabolic compounds, barbiturates, benzodiazepines, bile acids, carbohydrates, etheric oil components, fatty acids, flavanoids, glycosides, lipids, mycotoxins, natural pigments, synthetic dyes, nitroanilines, nucleotides, peptides, pesticides, steroids, sulfonamides, surfactants, sweeteners, tetracyclines, vitamins
Alumina	Aromatic hydrocarbons, carbonyl compounds (DNPH derivatives), herbicides, hydrazines, insecticides, metal ions, fat-soluble vitamins, lipids, lipophilic dyes, polycyclic aromatic hydrocarbons (PAHs)
Cellulose	Amines, amino acids, antibiotics, artificial sweeteners, carbohydrates, catechols, chiral amino acids and dipeptides, flavanoids, PAHs, peptides
Alkyl- and aryl-bonded phases	Alkaloids, amides, amines, amino acids, amino phenols, antibiotics, antioxidants, barbiturates, fatty acids, indole derivatives, nucleobases, oligopeptides, optical brighteners, PAHs, peptides, phenols phthalates, porphyrins, preservatives, steroids, surfactants, tetracyclines
Amino-modified silica gel	Barbiturates, monosaccharides, nucleosides, nucleotides, pesticides, phenols, purine derivatives, steroids, vitamins
Cyano-modified silica gel	Alkaloids, amino acid derivatives, analgesics, antibiotics, benzodiazepines, carboxylic acids, carotenoids, pesticides, phenols, preservatives, steroids
Diol-modified silica gel	Digital glycosides, nucleosides, pesticides, pharmaceuticals, phospholipids, steroids
Cellulose-based ion exchangers	DNA adducts, DNA and RNA fragments, dyes for food, inorganic ions, steroids
Polystyrene-based ion exchangers	Amines, amino acids, inorganic ions, peptides, purine and pyrimidine derivatives
Ammonium tungstophosphate	Amines, amino acids, indole derivatives, oligopeptides, polyamines, sulfonamides
Silica gel impregnated with paraffin, silicon, and plant oils	Barbiturates, carboxylic acid esters, fatty acid derivatives, nitrophenols, polychlorobiphenyls (PCBs), peptides, pesticides, phenols, steroids, surfactants, triazines
Silanized silica gel impregnated with anionic and cationic surfactants	Aliphatic and aromatic amines, alkaloids, amino acids, amino sugars, carboxylic and sulfanilic acids, indole derivatives, nucleobases, nucleosides, nucleotides, peptides, dipeptides, polypeptides, phenols, phenothiazine bases, steroids, sulfonamides, water-soluble food dyes
Silver-impregnated silica gel	*cis*-Monoenoic esters, *cis*/*trans*- and *trans*/*trans*-dienoic esters, fatty acid cholesteryl esters, positional and geometric isomers of fatty acid methyl esters, terpenoids, prostaglandins
Polyamides	Amino acids and their derivatives, phenolic compounds, preservatives
Silanized silica gel impregnated with *N*-(2′-hydroxydodecyl)-4-hydroxyproline	Chiral α-amino acids, α-methyl amino acids and aliphatic or aromatic α-hydroxycarboxylic acids, chiral *N*-alkyl, *N*-carbamyl, and *N*-formyl amino acids, dipeptides and heterocyclic compounds

phenolic acids) using solvents of different elution strength [*N*,*N*-dimethyl formamide (DMF) > formamide > acetone > methanol > water]. Such eluents and solutes compete with the peptide groups of the polyamide for the hydrogen bonds.

Owing to the medium polarity of polyamide 6, the sorbent can be made more or less hydrophobic than the mobile phase by selecting appropriate polar and non-polar eluents; therefore, normal- and reversed-phase (RP) chromatography and also two-dimensional techniques can be developed.

POLAR AND HYDROPHOBIC BONDED PHASES

A variation of chromatographic selectivity in TLC has been obtained using surface-modified silica gel or cellulose.

ALKYL- AND ARYL-BONDED SILICA PLATES

These materials are suitable for RP-TLC owing to their lipophilic properties. The commonly used RP layers consist of dimethyl-(RP-2), octyl-(RP-8), octadecyl-(RP-18), and phenyl-bonded silica gel, type 60, with different mean particle sizes and particle size distributions. Recently, C_{30}-modified silica gel was proposed for the separation of tocopherol homologues.

The lipophilic character of the sorbent increases from RP-2 to RP-18, but it is also determined by the surface density of hydrophobic residues. Consequently, silicas are reacted to a different degree, either totally (100%) or partially (i.e., 50% of the reactive silanol groups), in order to obtain materials of various hydrophobicity and wettability.

Because aqueous–organic mixtures are commonly used as eluents, it should be noted that RP-18 plates can be developed with solvents containing a maximum water content of approximately 60% (v/v), whereas on 50% modified

silica layers, water percentages as high as 80% can be used. Wettable RP-18W plates for normal-phase and RP chromatography can be eluted with purely organic and aqueous–organic solvents as well as with purely aqueous eluents.

Hydrolytic cleavage of alkyl ligands from the silica surface depends on: 1) the pH of the mobile phase (although these phases are stable in the pH range from 3 to 9 only, hydrolytic cleavage usually occurs far more readily in an acidic rather than basic environment); and 2) the length of the chemical bonded ligands (long aliphatic chains prevent access of the mobile phase to the bonds, which anchor them to the silica matrix, more than short chains).[2]

Typical applications of RP chromatography are shown in Table 2. Beyond analytical applications, RP-TLC on bonded phases is also a tool for physicochemical measurements, particularly for molecular lipophilicity determination of biologically active compounds.

AMINO-, CYANO-, AND DIOL-MODIFIED PRECOATED SILICA LAYERS

These sorbents possess as functional groups cyano, amino, and diol residues bonded by short-chain hydrophobic spacers to the silica matrix. With regard to polarity, hydrophilic modified silicas range between unmodified silica and the non-polar alkyl- or aryl-bonded phases:

Silica > diol – silica > amino – silica > cyano – silica > RP material

In the case of NH_2 and CN plates, the functional groups are bonded through a trimethylene chain to the silica gel. The hydrophilic modified layers are wetted by all solvents, including water, and are useful for the separation of polar substances, which can cause problems with silica or alumina (see Table 2). The NH_2 ready-to-use plates can act as weak basic ion exchangers.

CELLULOSE- AND POLYSTYRENE-BASED ION EXCHANGERS

Several functional groups have been used to obtain cellulose anion exchangers [aminoethyl (AE), diethylaminoethyl (DEAE)] or cation exchangers [carboxymethyl (CM), phosphate (P)] for TLC. Polyethyleneimine (PEI) cellulose is not a chemically modified cellulose, but a complex of cellulose with PEI. These cellulose exchangers are particularly useful for the separation of proteins, amino acids, enzymes, nucleobases, nucleosides, nucleotides, and nucleic acids (Table 2).

Plates coated with a mixture of silica and cation- or anion-exchange resin are commercially available. These polystyrene-based ion exchangers are suited for separation of inorganic ions and organic compounds with ionic groups (Table 2).

The large surface area of cellulose exchangers causes a large number of functional groups to be close to the surface. The distances of the active groups are longer than on exchange resins (about 50 and 10 Å, respectively), but cellulose ion exchangers, despite their smaller exchange capacity compared with polystyrene-based exchangers, can be easily penetrated by large hydrophilic molecules, such as proteins, enzymes, and nucleic acids, which, therefore, interact with all the active groups. In contrast, the majority of ionic substituents of exchange resins do not participate in the reaction because they are located inside the synthetic resin matrix, which hydrophilic molecules cannot penetrate.

IMPREGNATED LAYERS

The selectivity of sorbents can be easily improved by their impregnation with suitable organic and inorganic substances. The impregnating agent can be added to the sorbent suspension before plate preparation or, alternatively, the precoated layers may be dipped into an appropriate solution containing the impregnating agent.

Ready-to-use impregnated plates are also commercially available [e.g., caffeine- or ammonium sulfate-impregnated silica for the separation of polycyclic aromatic hydrocarbons (PAHs) and surfactants, respectively]. A large number of impregnating agents have been tested, the ones most frequently used in TLC being silver nitrate, metal ions, cationic and anionic surfactants, silicone, and paraffin oil. Boric acid-impregnated silica gel layers are suitable for the resolution of carbohydrates and lipids (see Table 2).

Argentation chromatography, in which silver is used as a π complexing metal on a silica gel support, is usually employed for the separation of organic compounds with electron-donor properties because of the presence of unsaturated groups in the molecule of the analytes. TLC is particularly appropriate for applying silver complexation techniques because the instability of silver causes severe limitations to column lifetime and, therefore, to HPLC methods.

The first investigation on alkyl-bonded silica layers impregnated with anionic and cationic surfactants was carried out by Lepri, Desideri, and Heimler.[3] The optimal concentration of the alcoholic solution of the impregnating agent was found to be 4%. With regard to the layers, ready-to-use alkyl-bonded silica plates were found to have many advantages over the previously used homemade plates. An appropriate term proposed for this chromatographic technique is surely “dynamic ion-exchange chromatography.” The method can be applied to separation of a wide variety of ionic compounds and classes of compounds (see Table 2).

DEXTRAN GELS

Polymeric, cross-linked dextran gels, called Sephadex®, are used in size-exclusion TLC. Sephadex gels, which are available in coarse (100–300 μm), medium (50–150 μm), fine (20–80 μm), and superfine (10–40 μm) particle size distributions, must be applied in a total swollen condition as chromatographic sorbents and eluted with the aid of continuous development techniques. A typical application in TLC is the determination of molecular weights of proteins.[4]

LAYERS FOR CHIRAL CHROMATOGRAPHY

Only cellulose, modified cellulose (cellulose triacetate, tribenzoate, and triphenylcarbamate), and silanized silica gel impregnated with the copper(II) salt of derivatized L-hydroxyproline have been used as chiral stationary phases for the separation of enantiomeric solutes.

Spiral Column Assembly for HSCCC

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

Abstract
Retention of the stationary phase in the standard multilayer coil for high-speed countercurrent chromatography (HSCCC) entirely depends on the Archimedean screw effect. However, it fails to retain a satisfactory amount of the stationary phase for the highly polar solvent systems such as polymer phase systems which are useful for separation of proteins and other macromolecules and cell particles. In order to improve the retention of the stationary phase, spiral column assemblies have been introduced, which can additionally utilize the radially acting centrifugal force to retain the heavier phase in the periphery and the lighter phase in the proximal portion of the spiral channel. Two different types of spiral columns were devised: the spiral disk assembly consists of a stack of multiple disks each having a spiral groove and the spiral tube assembly, which is made by inserting plastic tubing along the spiral groove of spiral tube support and forms multiple spiral layers. Performance of each system was examined using two different types of polar solvent systems, 1-butanol–acetic acid–water (4:1:5, v/v) and 12.5% (w/w) of polyethylene glycol (PEG)-1000 and 12.5% (w/w) of dibasic potassium phosphate in water each with suitable test samples. The results clearly demonstrate the useful application of spiral column countercurrent chromatography (CCC) for separation of polar compounds.

INTRODUCTION

The high-speed countercurrent chromatography (HSCCC) centrifuge uses a multilayer coil as a separation column, which produces high-efficiency separation with good retention of the stationary phase with a variety of two-phase solvent systems.[1,2] However, the method often fails to retain a satisfactory amount of the stationary phase for highly viscous, low interfacial solvent systems such as polymer phase systems, which are useful for the separation of macromolecules and particulates. Retention of the stationary phase in the conventional multilayer coiled column in the HSCCC system totally relies on the Archimedean screw force generated by the planetary motion of the column. However, this force is often too weak to retain the stationary phase for some polar solvent systems, such as aqueous–aqueous polymer phase systems, resulting in carryover of the stationary phase from the column.

The new spiral column designs described below improve the retention of the stationary phase by modifying the configuration of the column from a coil to a spiral, so that the centrifugal force gradient produced by the spiral pitch helps to distribute the heavier phase in the periphery and the lighter phase in the proximal portion of the column. This effect can be enhanced by increasing the pitch of the spiral. Although a spiral column can be prepared simply by winding the tubing into a flat spiral configuration,[3,4] it can provide a limited spiral pitch [outer diameter (O.D.) of the tubing]; additionally, the connection between the neighboring spiral columns is rather difficult. Two new column designs termed "spiral disk assembly"[5–10] and "spiral tube assembly,"[11,12] described below, solve these problems and provide a universal application of two-phase solvent systems including the polymer phase systems for HSCCC.

SPIRAL DISK ASSEMBLY

In this design, the separation column consists of a set of solid disks each with a single or plural spiral channel(s). In the first model, a single spiral channel is engraved in a plastic disk, which can be serially connected by stacking multiple disks sandwiched with Teflon sheet septa. In the second model, four spiral channels are incorporated in a single disk, symmetrically around the center, so that the spiral pitch increases four times that of the single spiral channel without losing column space. Connection between the neighboring spiral channels is formed by a short straight channel situated radially on the other side of the disk. A set of these disks can be serially connected by spacing a Teflon sheet between the neighboring disks, so that the column provides a large capacity that is somewhat comparable to that of the multilayer coil. The separation disk with a single spiral will serve as a control to evaluate the effect of pitch on partition efficiency.

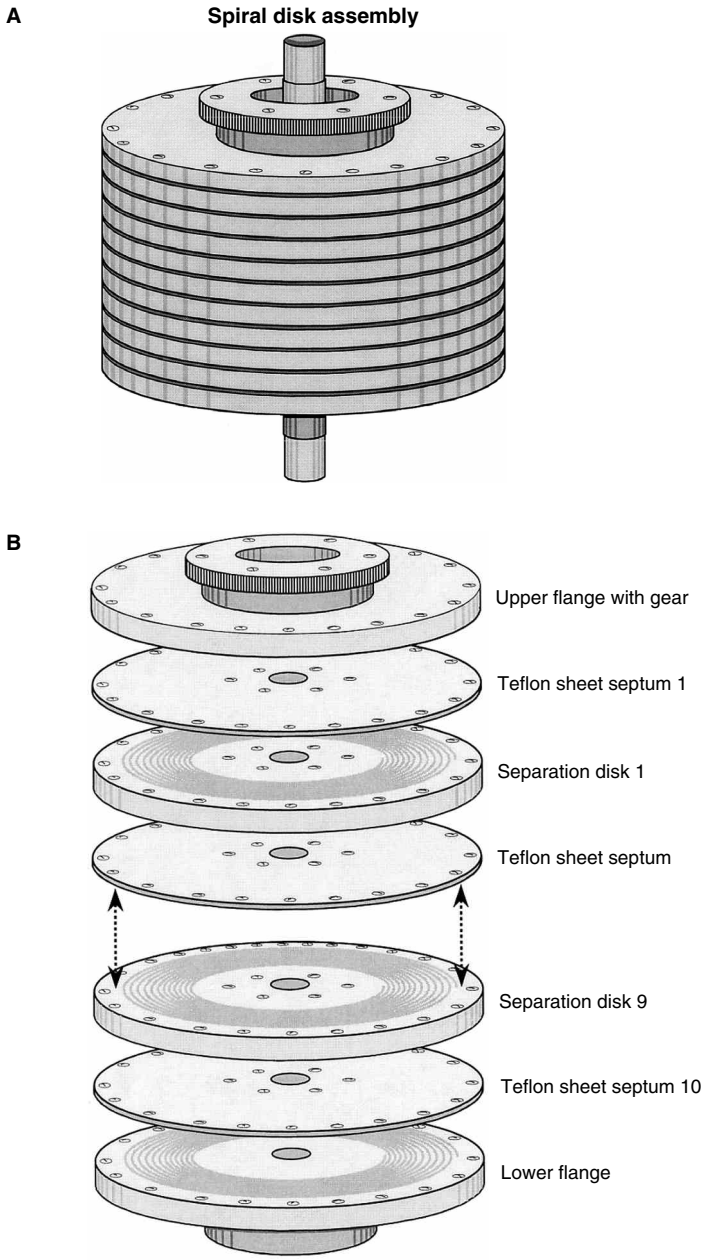

Fig. 1 Schematic illustration of the spiral disk assembly. A, Whole view and B, exploded view showing each component.

The design of the spiral column assembly is shown in Fig. 1. Fig. 1A shows a full view of the column assembly, which can be mounted on a type-J multilayer coil planet centrifuge (P.C., Inc., Potomac, Maryland, U.S.A.). The column components are illustrated in Fig. 1B. The column consists of a pair of flanges (one equipped with a gear), nine disks with spiral grooves, and 10 Teflon sheet septa. The design and dimensions of each component are illustrated in Fig. 2A–E.

The design of the individual separation disk with one spiral channel (diameter of 17.5 cm, thickness of 3 mm, with a 1.9 cm diameter center hole) is shown in Fig. 2A. The channel is 2.6 mm wide, 2 mm deep, with 1 mm ridge width, which gives a spiral pitch of 4 mm. The total channel length is about 4 m, comprising 12 spiral turns, with a total capacity of about 23 ml. The channel starts at the internal inlet (23 mm from the center) and extends to the external outlet (75 mm from the center), which is connected to the radial channel on the other side through a hole about 1 mm diameter. The performance of this single spiral column may be compared to that of the following four-channel spiral column, by using a polar butanol solvent system and polymer phase systems.

Design of the individual separation disk with four separate spiral channels is shown in Fig. 2B. A plastic

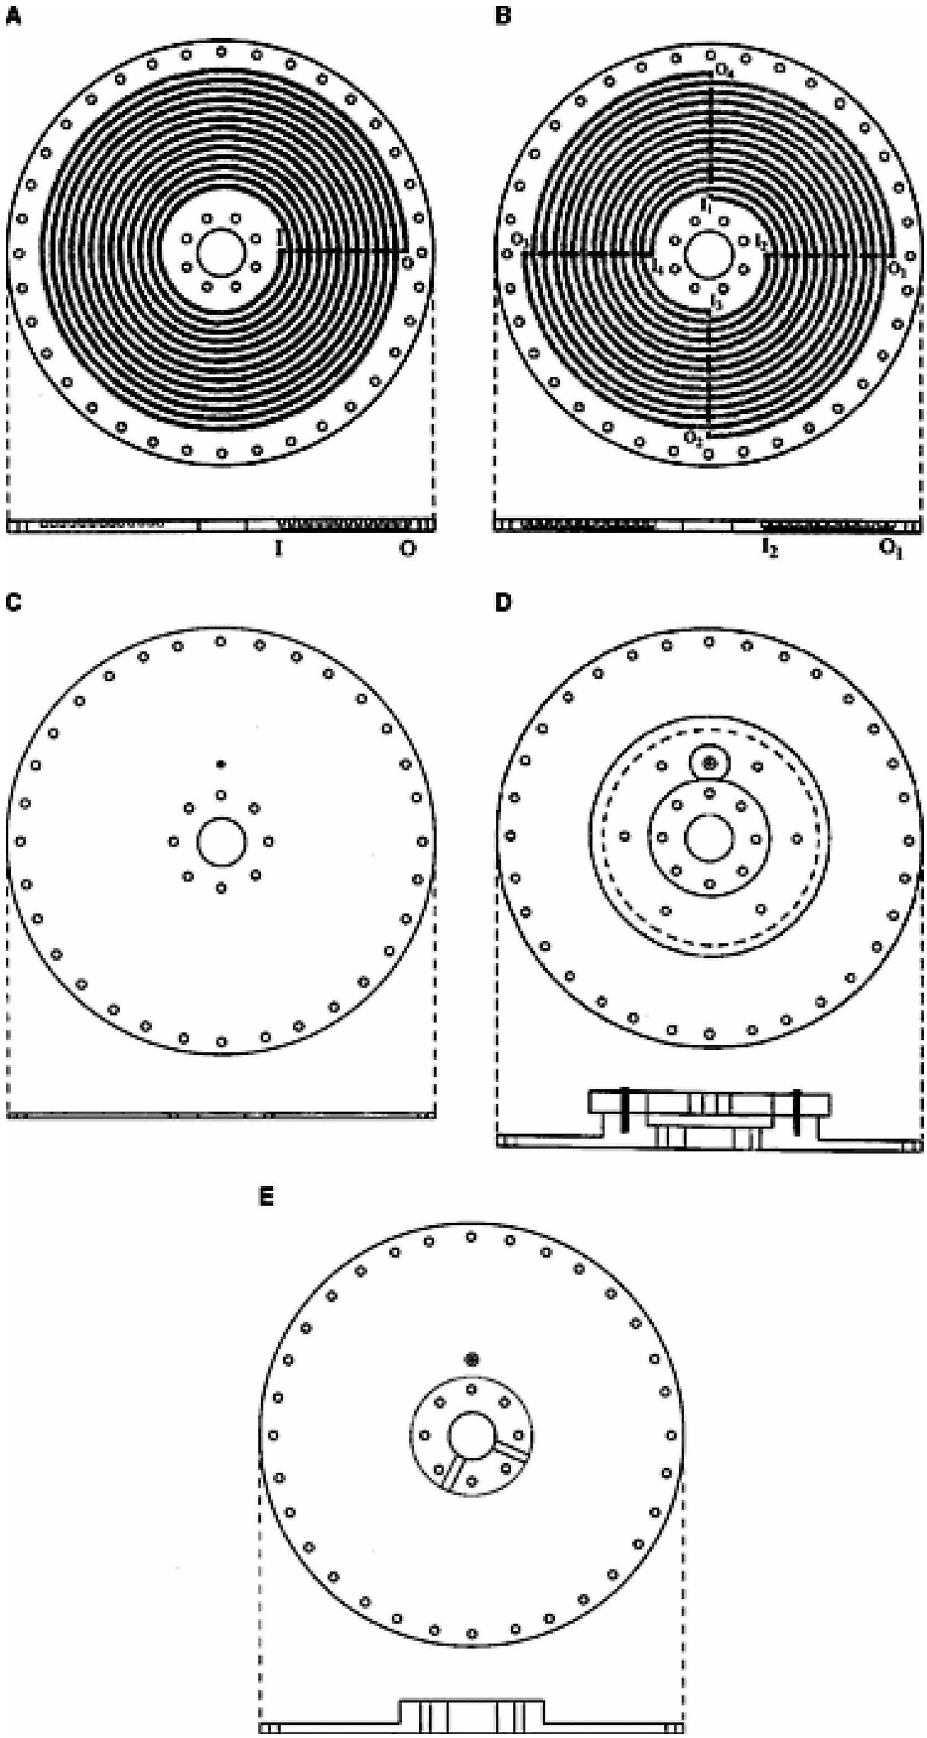

Fig. 2 Drawing of each component of the spiral disk assembly. A, Disk with a single spiral; B, disk with four spirals; C, Teflon sheet septum; D, upper flange equipped with a plastic gear; and E, lower flange.

disk (17.5 cm diameter and 4 mm thick, high-density polyethylene or polymonochlorotrifluoroethylene) has four spiral channels (grooves), each 2.6 mm wide, 2 mm deep, and about 1 m long, with a capacity of about 6 ml. The ridge between each groove is 1 mm and, therefore, the pitch of each spiral becomes as large as 16 mm (four times that of the single spiral channel). Each channel starts at the inner end (I_1, I_2, I_3, and I_4) to reach the outer end (O_1, O_2, O_3, and O_4, respectively). As shown in the diagram, each channel forms 3.25 spiral turns so that the outer end of channel 1 (O_1) radially coincides with the inner end of channel 2 (I_2), and those of channels 2, 3, and 4 (O_2, O_3, and O_4) similarly coincide with the inner ends of channels 3, 4, and 1 (I_3, I_4, and I_1), respectively. Each end of the channel (except for O_1) has a hole (about 1 mm diameter) through the disk to reach the other side, where a radial channel (dotted line) leads to the next spiral channel through another hole. The outer end of channel 4 (O_4) is connected to a similar radial channel that leads to channel 1 (I_1) of the next disk, or the column outlet, through an opening in the Teflon septum (Fig. 2C).

All disks have screw holes (clearing an 8–32 screw) at both inner and outer edges, at regular intervals (10° for the outer edge and 45° for the inner edge). Similar holes are also made in both the Teflon sheets and the flanges.

The design of the flanges is shown in Fig. 2D and E. The upper flange (Fig. 2D) is equipped with a plastic gear (9 mm thick, 10 cm pitch diameter), which engages with an identical stationary gear on the HSCCC centrifuge. Fig. 2E shows the lower flange, which has two screw holes (90° apart) for tightly fixing the column assembly against the column holder shaft (1.9 cm O.D.). The upper and lower flanges each have an inlet hole, which fits into an adapter with a 1/4–28 screw thread. They also have a set of screw holes (clearing an 8–32 screw) around the outer and inner edges as in the separation disks and the Teflon septa. The column assembly is mounted on the rotary frame of a multilayer coil centrifuge and counterbalanced with brass blocks. A pair of flow tubes from the column assembly is led downward through the center hole of the column holder shaft and passed through the hollow central pipe to exit the centrifuge at the center hole of the top plate, where it is tightly fixed with a pair of clamps. These tubes are protected with a sheath of Tygon tubing to prevent direct contact with metal parts.

EXPERIMENTAL PROCEDURE

Each two-phase solvent system is thoroughly equilibrated in a separatory funnel at room temperature, and the two phases are separated before use. The sample solution is prepared by dissolving the sample in an appropriate volume (1–5 ml) of the upper and/or lower phase of the solvent system. In each experiment, first the column is entirely filled with the stationary phase (upper or lower phase), followed by sample injection through the sample port. Next, the apparatus is rotated at 800 rpm, while the mobile phase is eluted through the column at the desired flow rate. The separation may be repeated by changing the direction of the revolution and/or the elution mode (head to tail and tail to head), although it is expected that the best result would be obtained by eluting either the lower phase from the internal terminal toward the external terminal of the spiral channel, in a tail-to-head elution mode, or the upper phase in the opposite direction in a head-to-tail mode. The effluent from the outlet of the column is continuously monitored through an ultraviolet (UV) detector.

BASIC STUDIES WITH SINGLE DISKS

Using a single disk with each channel design, a series of experiments were performed to evaluate the performance of the disk in terms of partition efficiency and retention of the stationary phase, by using three different types of two-phase solvent systems: 1-butanol–acetic acid–water (4:1:5, v/v/v) for separation of dipeptides; 12.5% (w/w) polyethylene glycol (PEG)-1000, 12.5% (w/w) dibasic potassium phosphate in water for protein separations; and 4% (w/w) PEG-8000, 5% (w/w) dextran T500 in water for measuring the retention of the stationary phase. The experiments were performed at various flow rates of the mobile phase, using four different elution modes: L–I–T (lower phase eluted from the inner terminal at the tail); L–I–H (lower phase eluted from the inter terminal at the head); U–O–T (upper phase eluted from the outer terminal at the tail); U–O–H (upper phase eluted from the outer terminal at the head). Four other reversed elution modes, including L–O–T, L–O–H, U–I–T, and U–I–H, showed considerably less retention of the stationary phase, compared with their counterparts, because of the adverse effect of the radial centrifugal force gradient. The dimensions of these four spiral channels are given in Table 1.

1-BUTANOL–ACETIC ACID–WATER (4:1:5) SYSTEM

Fig. 3A–D shows the separation of a standard sample mixture of trp–tyr (0.5 mg) and val–tyr (2 mg) with a two-phase solvent system composed of 1-butanol–acetic acid–water (4:1:5), by using a set of four different spiral columns (columns I–IV in Table 1).

Table 1 Dimensions of the four spiral channels used in the present studies.

Disk no.	Number of spirals	Width[a] (mm)	Depth[a] (mm)	Pitch (mm)	Capacity (ml)
Column I	1	2.6	2.0	4	23
Column II	1	1.5	3.7	4	21
Column III	4	2.6	2.0	16	23
Column IV	4	1.5	3.7	16	21

[a]The width of the spiral groove becomes the depth of the channel and the depth becomes the width of the channel when assembled.

In each chromatogram, the UV absorbance (280 nm) was plotted against the elution time together with the percent retention volume of the stationary phase relative to the total column capacity. In each group, a set of chromatograms is arranged according to the four different elution modes, i.e., L–I–T, L–I–H, U–O–T, and U–O–H, where L and U indicate the lower phase mobile and upper phase mobile, I and O denote eluting from internal terminal and external terminal of the spiral, and T and H represent "tail-to-head" and "head-to-tail" elution mode, each under various flow rates of the mobile phase.

In column I (Fig. 3A), the elution with upper phase from the head of the spiral (U–O–H) produces the best peak resolution and the highest percent retention of the stationary phase. The elution with the lower phase from the head of the spiral (L–I–T) also shows a good peak resolution up to a flow rate of 5 ml/min, in spite of low retention of the stationary phase. Elution of the lower phase from the head (L–I–H) retains a satisfactory amount of the stationary phase at the flow rate of 0.5–2 ml/min, while the peak resolution is much lower than that of its counterpart (L–I–T). The elution of the upper phase from the tail (U–O–T) shows no retention of the stationary phase, even at a low flow rate of 0.5 ml/min. These elution trends are also observed in column II (Fig. 3B), except that the peak resolution is much reduced in the elution of the lower phase from the tail (L–I–T), for a similar retention level of the stationary phase.

Fig. 3C and D shows the chromatograms obtained from the four-spiral disks under otherwise identical experimental conditions. It clearly indicates that the retention of the stationary phase is much improved in all elution modes. Although the peak resolution of the two dipeptides was substantially reduced, the flow rate could be increased up to 10 ml/min to yield a moderate degree of peak resolution, as emphasized by column IV (Fig. 3D). This suggests that if one uses a multichannel spiral disk with a large pitch, the separation of peptides might be achieved in a very short elution time.

PEG-1000–DIBASIC POTASSIUM PHOSPHATE POLYMER PHASE SYSTEM

Fig. 4A–D similarly illustrates the peak resolution between two protein samples (lysozyme and myoglobin, 10 mg each) in the PEG–phosphate system obtained from the four different spiral disks. In the single-spiral disks (Fig. 4A and B), the best results were obtained by eluting the upper PEG-rich mobile phase from the head end of the outer terminal (U–O–H); other modes resulted in low resolution. Except for L–I–T and I–O–T in column II, all groups show a satisfactory level of stationary phase retention with a flow rate of 0.5 ml/min, indicating that mixing of two phases in the spiral column is inefficient. This tendency is more pronounced in the four-spiral disks (Fig. 4C and D), which show much higher retention of the stationary phase (over 60%), but without any peak resolution. Corresponding columns in Fig. 4A and B show the latter to yield somewhat higher peak resolution, which is probably the result of the shallow channel with respect to the centrifugal force that facilitates mass transfer between the two phases. This suggests that the separation might be further improved by reducing the width of the spiral groove.

PEG-8000–DEXTRAN T500 POLYMER PHASE SYSTEM

A series of experiments was performed to examine the retention of the PEG–dextran polymer phase system without samples. Results are shown in Table 2, where percent retention of the stationary phase is indicated at the flow rates of 0.5–1 or 2 ml/min for each spiral column. The results indicate that, among the single-spiral disks (I and II), column I with a deep channel retained over 60% of the lower dextran-rich stationary phase (U–O–H and U–O–T) at a low flow rate of 0.5 ml/min while, under other conditions, the retention was substantially less than 50% of the total column capacity. In contrast, the four-spiral disks (columns III and IV) attained remarkably improved retention of over 50% for all elution modes, at 0.5 ml/min flow rate. Again, the results indicate the effect of the greater spiral pitch, which favors the retention of the stationary phase.

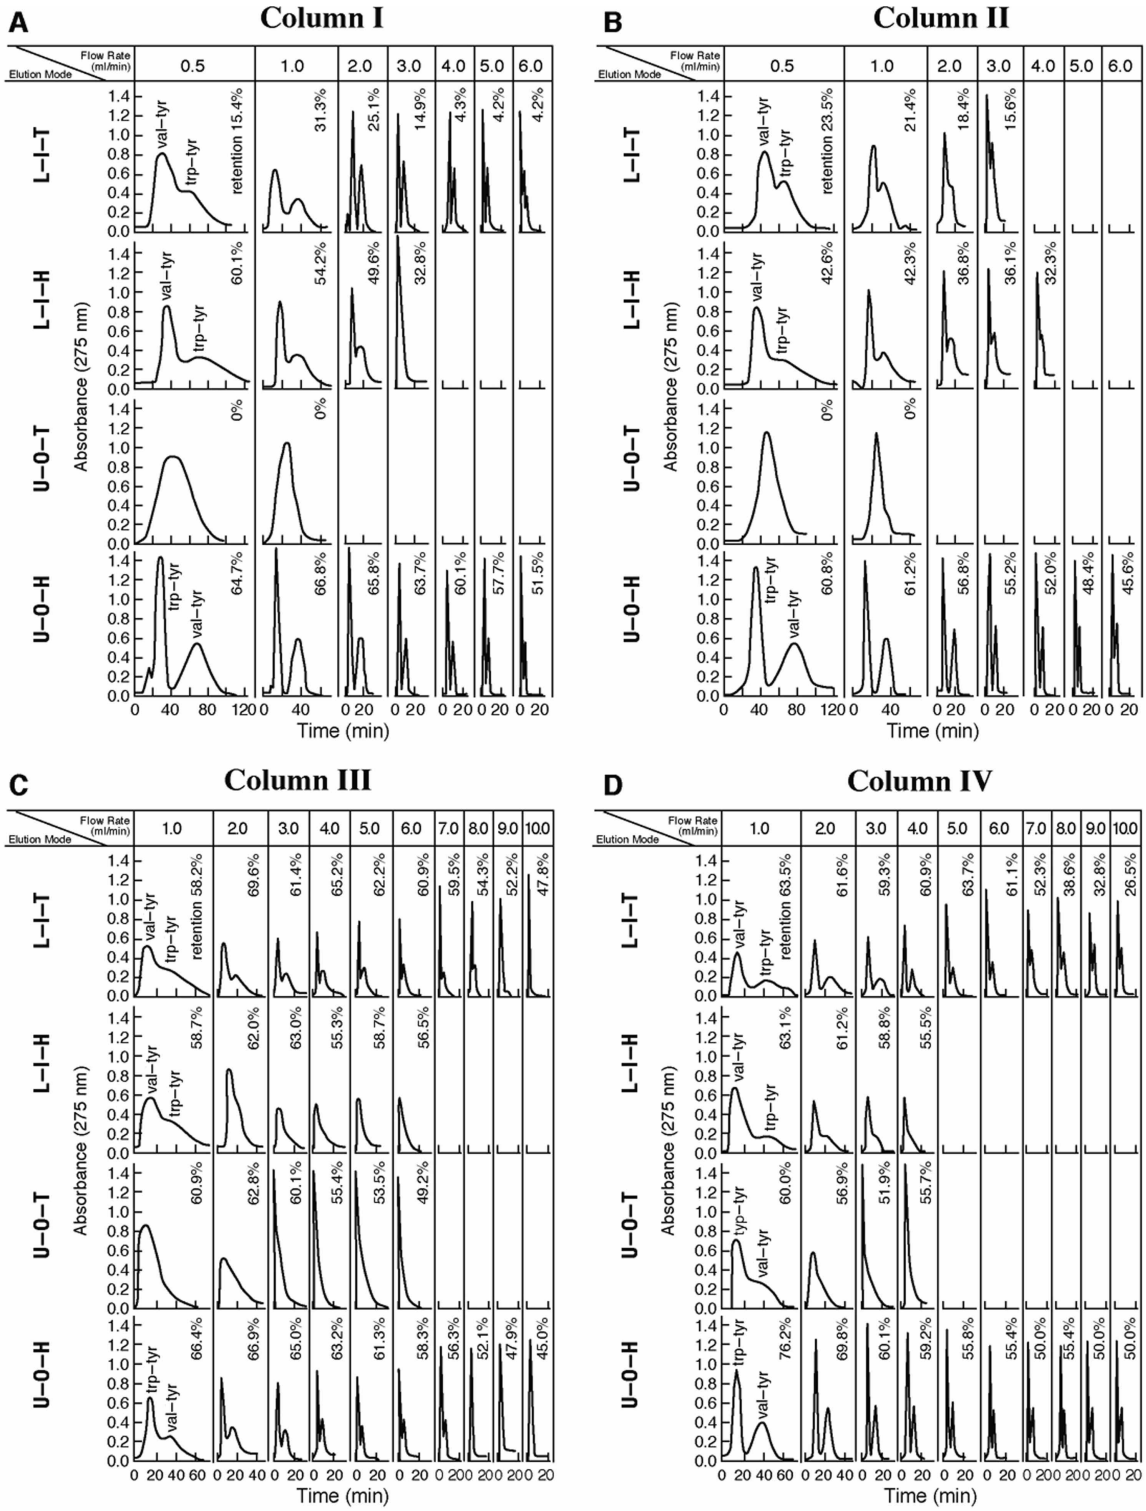

Fig. 3 Separation of peptides with a set of four single disks. A) Column I, B) column II, C) column III, and D) column IV (dimensions of the channels are listed in Table 1). Experimental conditions are as follows: apparatus: a type-J coil planet centrifuge with 10 cm revolution radius; sample: trp–tyr (0.5 mg), val–tyr (2 mg) in 1 ml of upper phase; solvent system: 1-butanol–acetic acid–water (4:1:5); elution modes: L–I–T, lower phase from the inner terminal at tail, L–I–H, lower phase from the inner terminal at head, U–O–T, upper phase from the outer terminal at tail, and U–O–H, upper phase from the outer terminal at head; flow rate: 0.5–10 ml/min as indicated; rpm: 800; stationary phase retention as indicated in the figure.

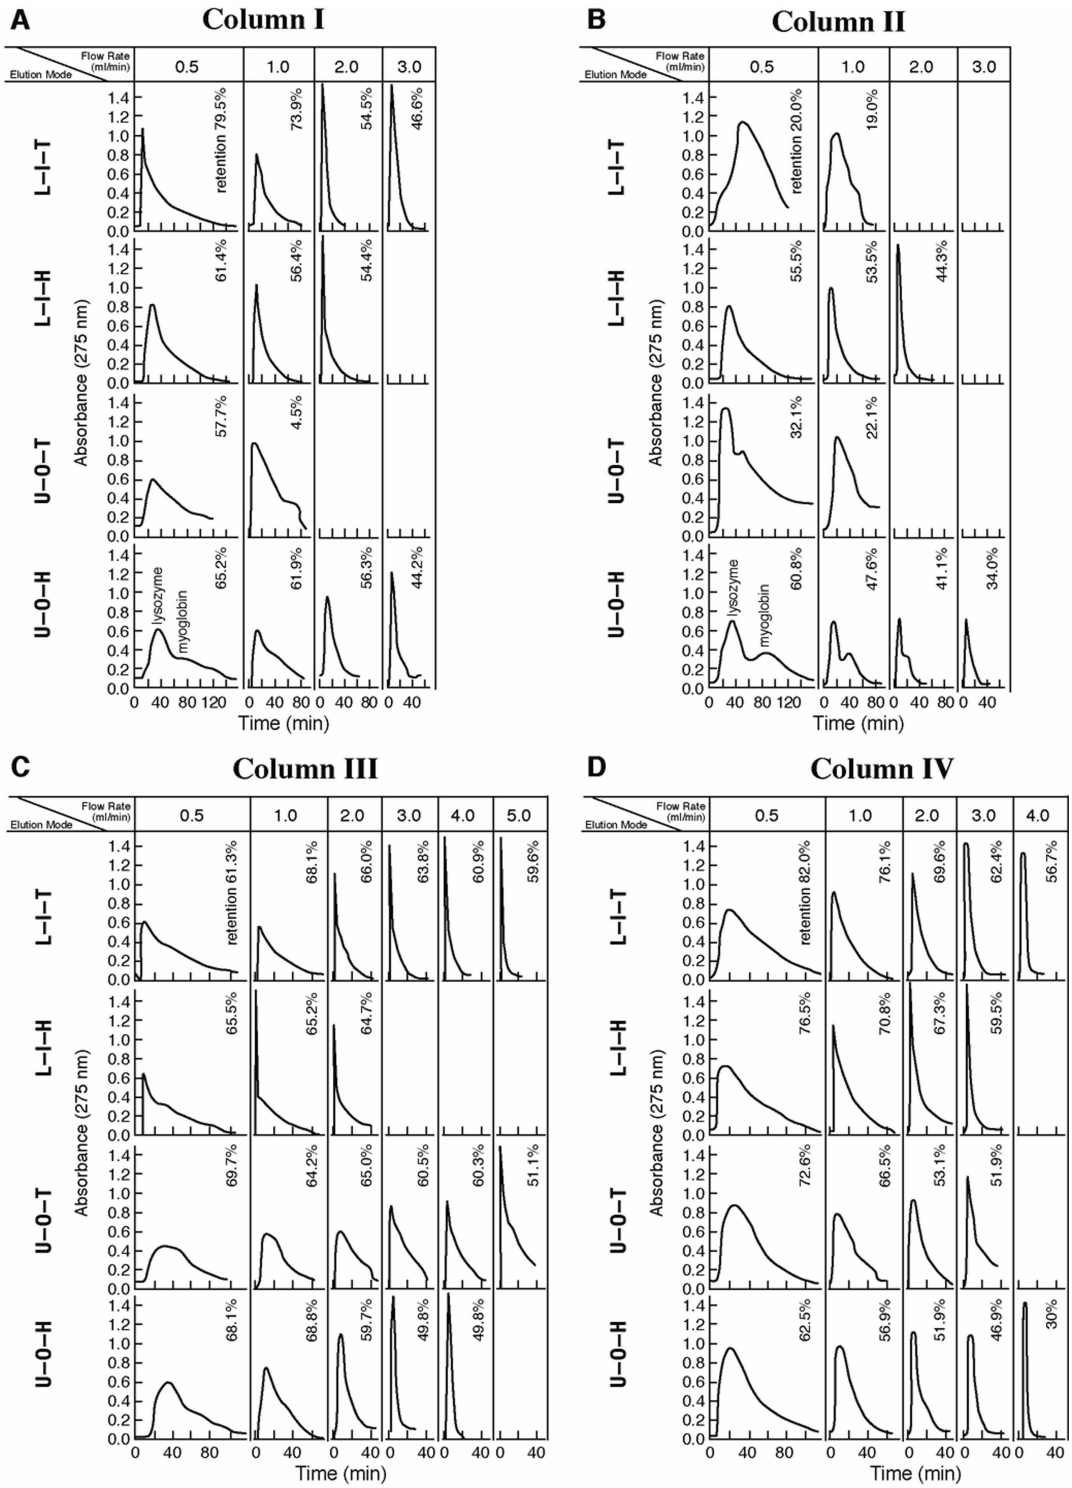

Fig. 4 Separation of proteins with a set of four single disks. A) Column I, B) Column II, C) Column III, and D) Column IV (dimensions of the channels are listed in Table 1). Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; sample: lysozyme and myoglobin each 5 mg in 1 ml of upper phase; solvent system: 12.5% (w/w) PEG-1000 and 12.5% (w/w) potassium diphosphate in water; elution modes: L–I–T, lower phase from the inner terminal at tail, L–I–H, lower phase from the inner terminal at head, U–O–T, upper phase from the outer terminal at tail, and U–O–H, upper phase from the outer terminal at head; flow rate: 0.5–5 ml/min as indicated; rpm: 800; stationary phase retention as indicated in the figure.

Table 2 Percent retention of 4% PEG-8000–5% Dextran T500 in 10 m*M* Na_2HPO_4 system.

Column	I	II	III	IV
Flow rate (ml/min)	0.5–1.0	0.5–1.0	0.5–1.0–2.0	0.5–1.0–2.0
L–I–T	40.0–14.8	14.3–3.3	61.1–50.0–14.3	55.6–33.3–4.0

PRELIMINARY SEPARATION WITH A MULTILAYER SPIRAL DISK ASSEMBLY

The performance of the present column design was examined by using a spiral disk assembly consisting of eight units of column I, with a total capacity of 165 ml. Results are shown in Fig. 5A and B. In Fig. 5A, a mixture of five dipeptides was well resolved and was completely eluted in 2 hr. The upper organic phase of the 1-butanol solvent system was eluted at a flow rate of 4 ml/min. Similar separations were shown with the standard multilayer coils in HSCCC, but only with more stable butanol solvent systems.[1]

Fig. 5B shows the separation of two stable proteins (lysozyme and myoglobin) by using a PEG-1000/K_2HPO_4 polymer phase system at a flow rate of 1 ml/min, where they were well resolved in slightly over 5 hr. As suggested by basic studies, the separation may be substantially improved by using the column II disk assembly, which provides a shallower channel to facilitate mass transfer in viscous polymer phases.

MIXER-SETTLER SYSTEM

The present system allows modification of the channel configuration and/or placing suitable inserts into the channel to improve the partition efficiency. Fig. 6 shows two spiral disks, each with a modified channel. In the locular disk (Fig. 6A) the spiral channels consist of multiple compartments called locules connected with a narrow duct and in the barricaded disk (Fig. 6B) barricades are made at the middle of the channel at regular intervals to divide the channel into multiple sections. Each system allows performing mixer-settler partitioning by placing a glass bead

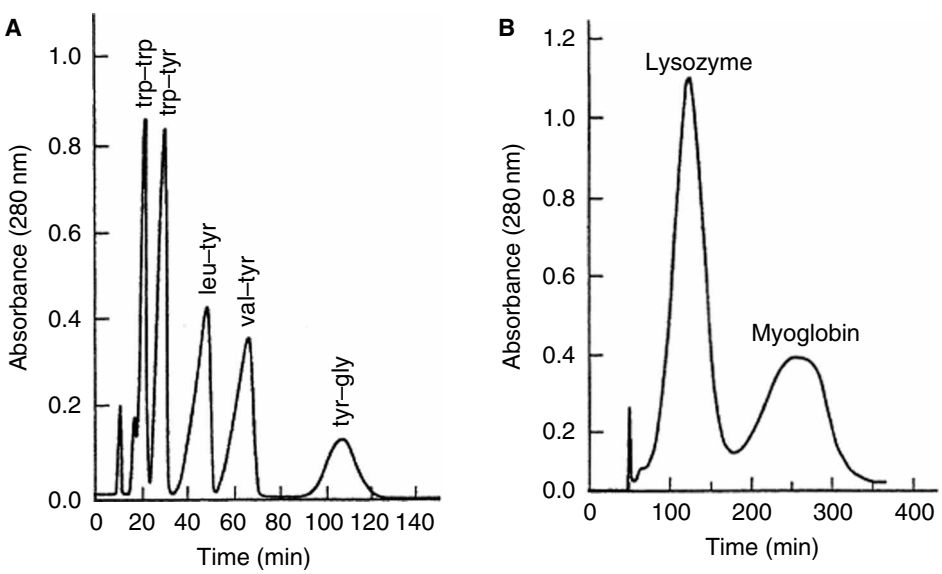

Fig. 5 Preliminary separation of peptides and proteins by a spiral disk assembly. A, Separation of a set of dipeptides and B, separation of lysozyme and myoglobin. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; column: spiral disk assembly consisting of 8 disks (column I) with a total capacity of about 165 ml; sample: A, trp–trp (1.25 mg), trp–tyr (2.5 mg), leu–tyr (l0 mg), val–tyr (l0 mg), tyr–gly (10 mg) in 5 ml upper phase; B, lysozyme and myoglobin each 50 mg in 5 ml lower phase; solvent system: A, 1-butanol–acetic acid–water (4:5:1) B, 12.5% (w/w) PEG-1000, 12.5% (w/w) K_2HPO_4 in water; mobile phase: A, upper organic phase; B, upper PEG-rich phase; flow rate: A, 4 ml/min, B, 0.5 ml/min; elution mode: A, U–O–H; B, U–O–H; rpm: 800; retention of stationary phase: A) 60% and B) 77.4%.

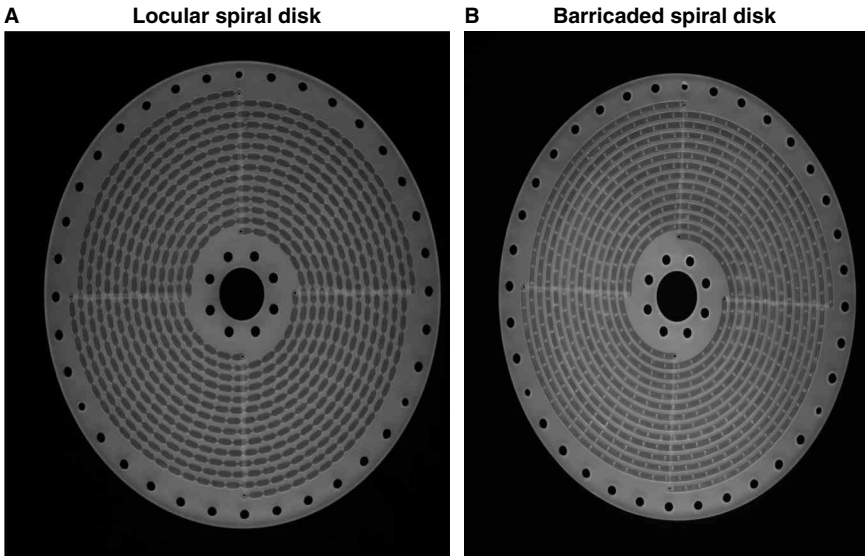

Fig. 6 Photograph of the four-spiral disks with modified channel configuration. A, locular spiral disk and B, barricaded spiral disk.

in every other compartment. The mechanism of this mixer-settler system is illustrated in Fig. 7. In the upper figure, under a fluctuating centrifugal force field the two phases are vigorously mixed by a vibrating glass bead in the mixing locule and they are separated in the next empty settling locule. Although this system gives excellent peak resolution of proteins, it tends to gradually lose the stationary phase from the mixing locule. This problem is solved by a barricaded spiral disk where two phases can freely countercurrent through the opening on the top and bottom of the barricade to maintain the stationary phase retention in the channel.

Fig. 8 illustrates comparison in protein separation between four different spiral disks at 800 rpm. The left panel shows the original spiral disk, which gives poor peak resolution. In the locular disk, the separation is improved, but the best separation was obtained from the mixer-settler spiral disks on the right. The chromatogram in Fig. 9 shows separation of five proteins obtained by mixer-settler countercurrent chromatography (CCC) using a barricaded spiral disk assembly consisting of eight disks. In Fig. 9A four proteins were well resolved while the fifth was still retained in the column. This may be the best protein separation ever achieved with the polymer phase system. However, this mixer-settler system is only useful for separation with polymer phase systems.

SPIRAL TUBE ASSEMBLY

This new column design uses the spiral tube support to make multiple spiral tube layers from a single piece of

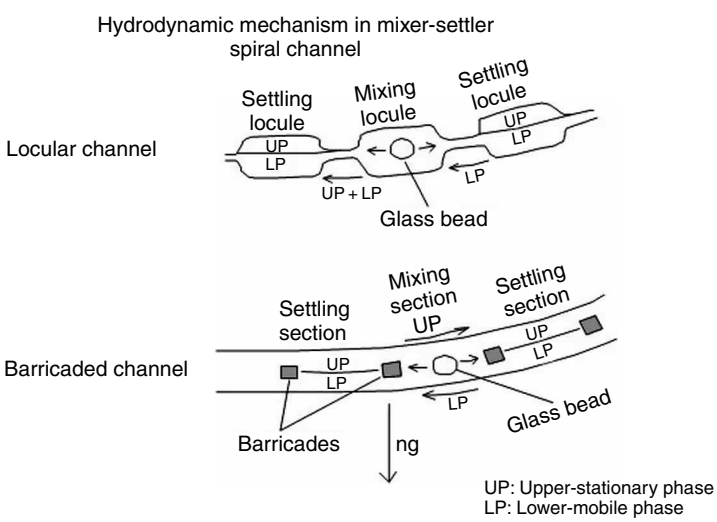

Fig. 7 Mechanism of mixer-settler HSCCC. In the locular channel disk (upper diagram), mixing locule receives the lower mobile phase, which it releases as a mixture of two phases through a narrow opening, resulting in a gradual loss of the stationary phase in the mixing locule. In the barricaded-channel disk (lower diagram), the two phases freely countercurrent through the opening at the top and bottom of the barricade to maintain the stationary phase retention in the channel.

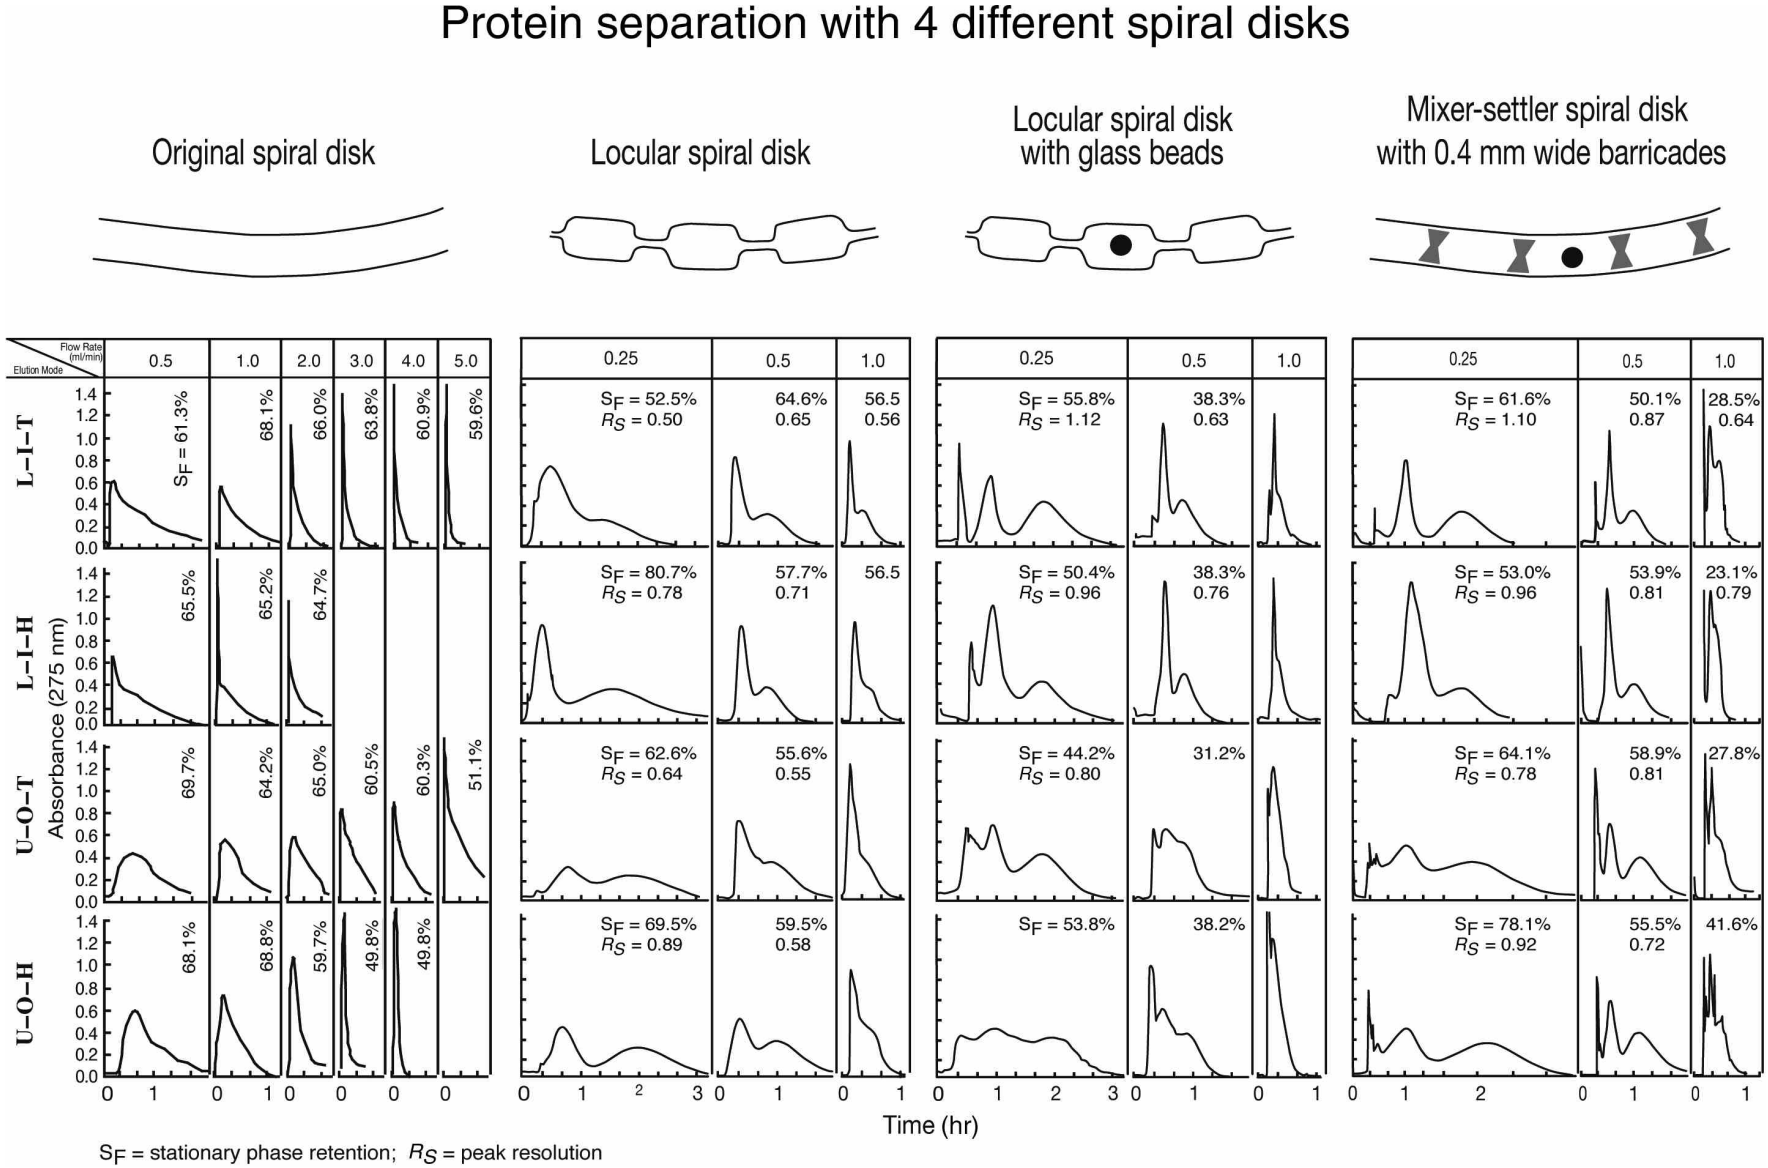

Fig. 8 Comparison of protein separation between four different spiral disks. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; sample: lysozyme and myoglobin each 50 mg in 5 ml of upper phase; solvent system: 12.5% (w/w) PEG-1000 and 12.5% (w/w) K_2HPO_4 in water; rpm: 800.

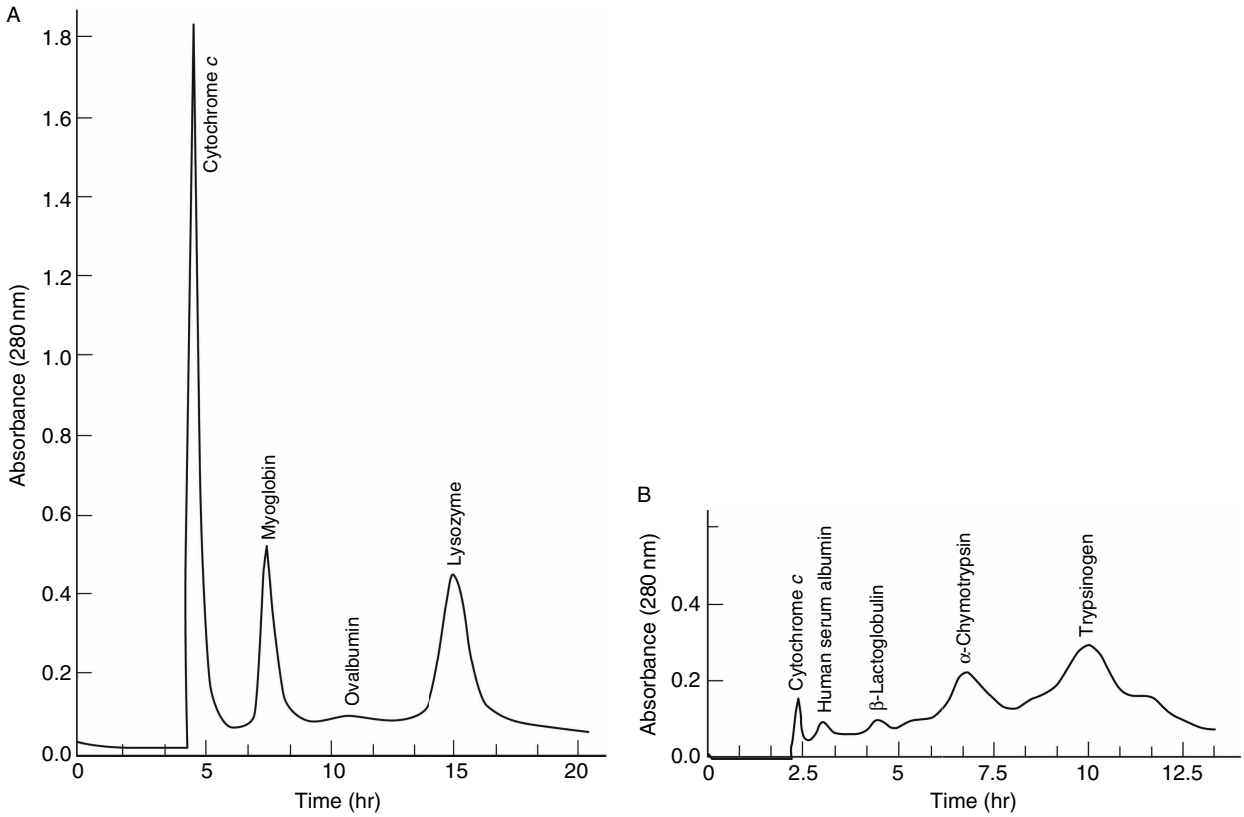

Fig. 9 Separations of five standard protein samples by mixer-settler HSCCC. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; column: a mixer-settler spiral disk assembly consisting of eight barricaded disks with a 160 ml capacity; A, solvent system: 12.5% (w/w) PEG-1000 and 12.5% (w/w) K_2HPO_4; mobile phase: lower phase; sample: five proteins each 5–6 mg in 1 ml of each phase, cytochrome *c* ($K = 0.02$), myoglobin ($K = 0.59$), ovalbumin ($K = 1.26$), lysozyme ($K = 1.69$), and bovine serum albumin ($K = 1.95$); flow rate: 0.25 ml/min; rpm: 800; detection: 280 nm; stationary phase retention: 52%; B, solvent system: PEG1000/K_2HPO_4/KH_2PO_4/H_2O (16:8.3:4.2:71.5, w/w); sample: cytochrome *c* (5 mg, $K = 0.035$), human serum albumin (20 mg, $K = 0.4$), β-lactoglobulin (20 mg, $K = 0.69$), α-chymotrypsin (20 mg, $K = 1.2$), and trypsinogen (20 mg, $K = 2.1$) in 2 ml of each phase; flow rate: 0.5 ml/min; rpm: 1000; stationary phase retention: 53.6%.

tubing so that there is no risk of leakage of solvent through the junction. Fig. 10 shows two different designs for the spiral tube support. The first design shown on the left has an open slot at each terminal of the deep spiral grooves through which the tube is led to the other side of the disk and run along the radial groove toward the center, and finally returned to the upper side through the central hole to start the next spiral. One problem of this design is that a long tube must be passed through the central hole of the disk for winding each spiral. Another problem is that, as the number of spiral layers is increased, the length of the transfer tube and the dead space also increase.

These problems are solved in the second system shown on the right. The major improvement in the design is achieved by making the radial transfer grooves on the upper side of the disk. This avoids the necessity of passing the tube through the central hole, and the length of the transfer tube is kept minimum. In this system the transfer tubes are sandwiched between the spiral layers, limiting the column capacity. However, this problem is largely eliminated by a special process described later, and this system has been chosen for developing the spiral tube HSCCC.

Fig. 11 shows a photograph of the spiral tube support (aluminum) made at the NIH Machine Shop. It has four spiral grooves. The diameter of the support is about 16 cm and the depth of the spiral groove is about 5 cm. Later, the sharp bend at each end of the radial transfer grooves is rounded to prevent kinking of the tube. It accommodates about 40 m of 1.6 mm I.D. tube in nine spiral layers with a total capacity of about 100 ml.

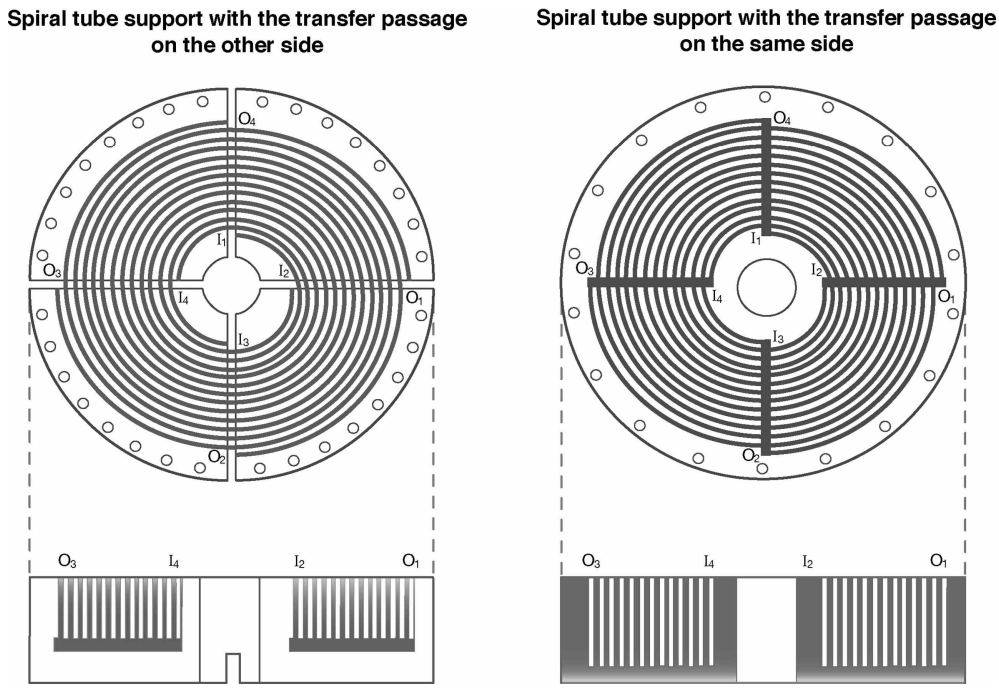

Fig. 10 Two different designs for spiral tube support.

The performance of this spiral tube assembly was tested for separating dipeptide samples, tryptophyl–tyrosine and valyl–tyrosine, with a two-phase solvent system composed of 1-butanol–acetic acid–water at a volume ratio of 4:1:5 at 800 rpm (Fig. 12). The best results were obtained by L–I–T and U–O–H elution modes where the two peptides were resolved within 30 min at a high flow rate of 5 ml/min (Fig. 12).

However, the separation of proteins is inefficient as expected from the results obtained from the spiral disk assembly described earlier. Improvement in protein separation in the present system can be achieved by changing the shape of the tube. When the tube is perpendicularly pressed at 1 cm intervals with a pair of pliers, the peak resolution in protein separation was improved remarkably from 0.68 to 1.10, as shown in Fig. 13. The separation of the dipeptides was also improved in spite of the reduced column capacity from 103 to 95 ml.

Fig. 14 shows protein separations with this cross-pressed spiral tube assembly consisting of nine spiral layers of a 1.6 mm I.D. tube with a total capacity of 95 ml at 800 rpm. The protein peaks were resolved even at a relatively high flow rate of 2 ml/min.

As mentioned earlier, the column capacity of this spiral tube assembly is limited by the transfer tubes

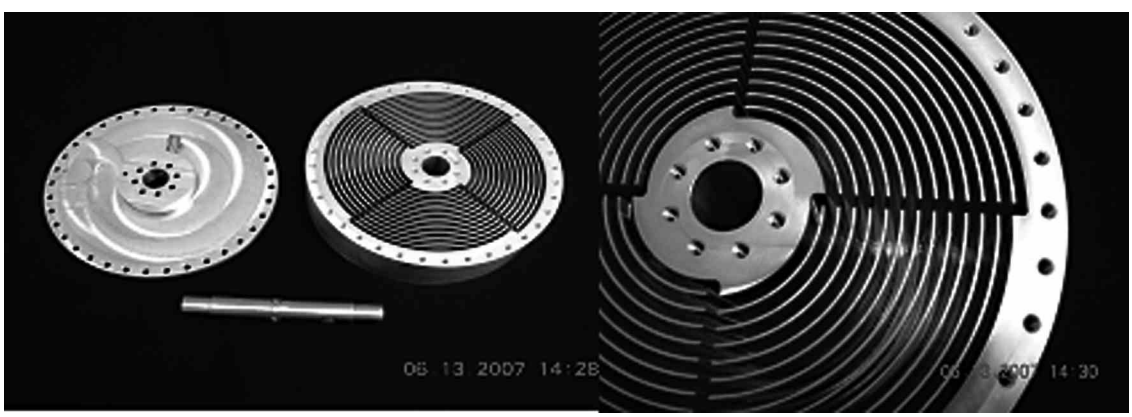

Fig. 11 Photograph of spiral tube support.

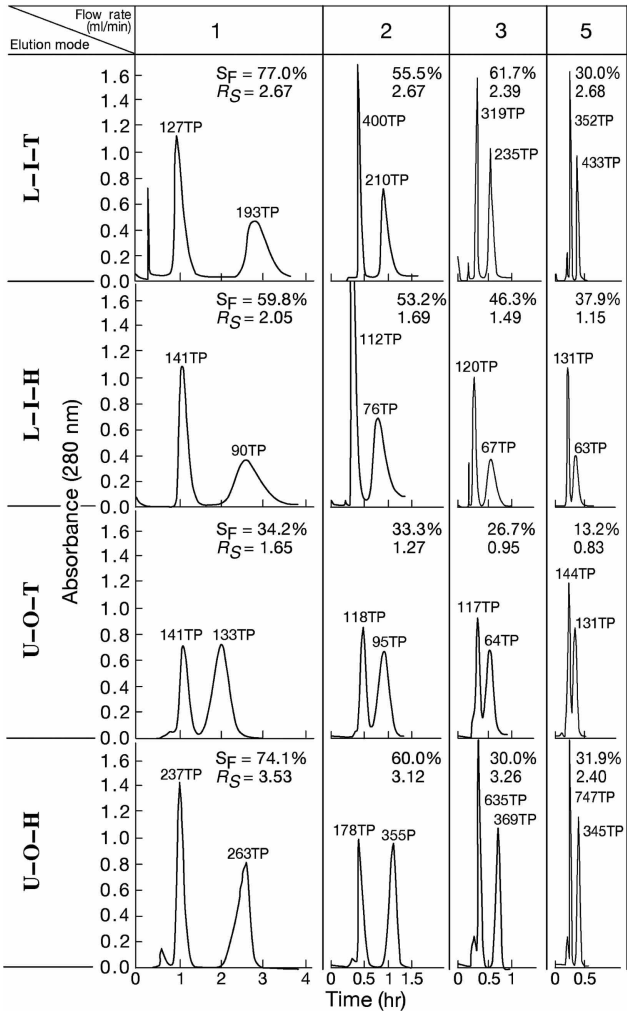

Fig. 12 Separation of dipeptides by spiral tube assembly at 800 rpm. Experimental conditions are as follows: apparatus: spiral tube with 1.6 mm I.D. and about 36 m long forming nine spiral layers with a total capacity of about 100 ml; solvent system: 1-butanol–acetic acid–water (4:1:5, v/v/v); Sample: trp–tyr (1.25 mg) and val–tyr (5 mg) in 0.5 ml of upper phase; monitoring system: Uvicord IIS at 280 nm; elution mode: L–I–T, lower phase pumped from the inner tail terminal of the spiral tube, L–I–H, lower phase pumped from the inner head terminal of the spiral tube, U–O–T, upper phase pumped from the outer tail terminal of the spiral tube, U–O–H, upper phase pumped from the outer head terminal of the spiral tube.

sandwiched between the spiral layers. This problem may be largely alleviated by compressing the four radial grooves using a specially made tool with rectangular teeth that fit to the radial grooves. This process gives three major advantages for the separation: first, the number of spiral layers is increased; second, the dead space in the transfer tubes is reduced; and, third, laminar flow of the two phases is interrupted as in the cross-pressed spiral tube.

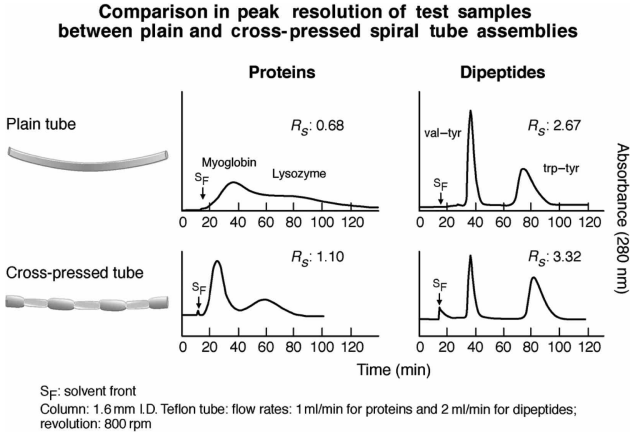

Fig. 13 Separation of proteins and dipeptides by plain spiral tube and cross-pressed tube assemblies. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; separation column: plain spiral tube assembly: nine spiral layers about 40 m long, 1.6 mm I.D. FEP tube with a total capacity of 103 ml; cross-pressed spiral tube assembly: nine spiral layers about 40 m long, 1.6 mm I.D. FEP tubing cross-pressed at 1 cm interval with 95 ml capacity; solvent system: 12.5% (w/w) PEG-1000 and 12.5% (w/w) dibasic potassium phosphate in water (for protein separation); sample: lysozyme and myoglobin, each 5 mg in 1 ml of upper phase (for protein seperation), trp–tyr (1.25 mg) and val–tyr (5 mg) in 0.5 ml of upper phase (for dipeptide separation); elution mode: L–I–T; flow rate: 1 ml/min (for protein separation), 2 ml/min (for dipeptide separation); detection: 280 nm; rpm: 800.

Fig. 15 shows protein separation obtained by the spiral tube assembly with these two tube modifications of cross-pressing and radial groove compression. The column is made from a slightly smaller tube of 1.35 mm I.D. making 15 spiral layers with a total capacity of about 85 ml. The protein separation was performed in the L–I–T elution mode under various revolution speeds ranging from 600 to 1200 rpm. As the revolution speed is increased, the separation of the two peaks steadily improves and at 1200 rpm two protein peaks are well resolved. The separation is completed in 90 min at a high flow rate of 2 ml/min.

The spiral tube assembly can be successfully applied to the separation of dipeptides and proteins using highly polar solvent systems with sufficient stationary phase retention. Although a plain spiral tube assembly can be used for the separation of peptides, the partition efficiency is remarkably increased by modifying the tube configuration in two steps: cross-pressing and radial groove compression especially for protein separation with a polymer phase system. As the present system allows a high flow rate with high retention of the stationary phase, good peak resolution is obtained in a short elution time. This improved spiral tube assembly can be efficiently applied to all two-phase solvent systems for HSCCC.

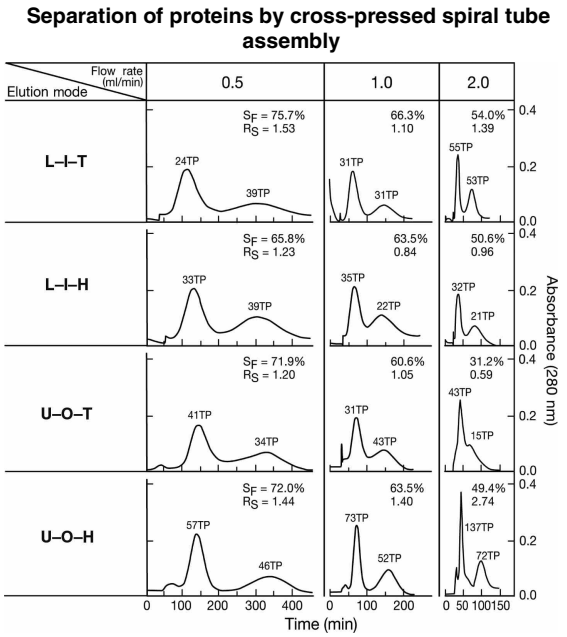

Fig. 14 Protein separation by cross-pressed spiral tube assembly at 800 rpm. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with 10 cm revolution radius; separation column: nine spiral layers about 40 m long, 1.6 mm I.D. polytetrafluoroethylene (PTFE) tubing cross-pressed at 1 cm interval with a 95 ml capacity; solvent system: 1.25% (w/w) dibasic PEG-1000 and 1.25% (w/w) potassium phosphate in water; sample: lysozyme and myoglobin, each 5 mg in 1 ml of upper phase; detection: 280 nm; rpm: 800.

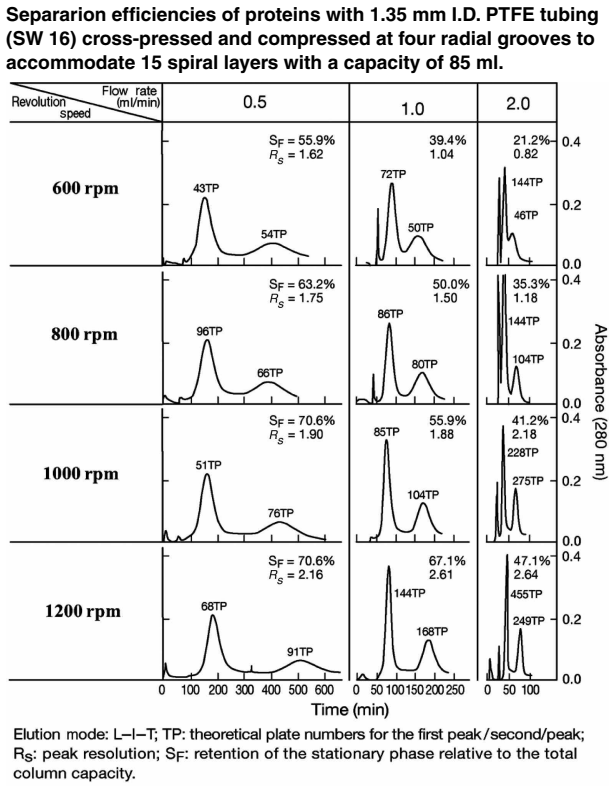

Fig. 15 Protein separation by cross-pressed and radial groove-compressed spiral tube assembly at various revolution speeds and flow rates. Experimental conditions are as follows: apparatus: type-J coil planet centrifuge with a 10 cm revolution radius; solvent system: 12.5% (w/w) PEG-1000 and 12.5% (w/w) dibasic potassium phosphate in water; sample: lysozyme and myoglobin, each 5 mg in 1 ml of upper phase; elution mode: L–I–T; detection: 280 nm.

Spiral Disk Assembly: Column Design for HSCCC

Yoichiro Ito
Fuquan Yang
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

The high-speed countercurrent chromatography (HSCCC) centrifuge uses a multilayer coil as a separation column which produces high-efficiency separation with good retention of the stationary phase with a variety of two-phase solvent systems.[1,2] However, the method often fails to retain a satisfactory amount of the stationary phase for highly viscous, low interfacial solvent systems such as polymer phase systems, which are useful for the separation of macromolecules and particulates. A new column design called "spiral disk assembly," described below, provides a universal application of solvent systems, including the polymer phase systems for HSCCC.

PRINCIPLE

Retention of the stationary phase in the coiled column of the HSCCC system totally relies on the Archimedean screw force generated by the planetary motion of the column. However, this force is often too weak to retain the stationary phase for some polar solvent systems, such as aqueous–aqueous polymer phase systems, resulting in carryover of the stationary phase from the column.

The new spiral column design improves the retention of the stationary phase by modifying the configuration of the column from a coil to a spiral, so that the centrifugal force gradient produced by the spiral pitch helps to distribute the heavier phase in the periphery and the lighter phase in the proximal portion of the column. This effect can be enhanced by increasing the pitch of the spiral. Although a spiral column can be prepared simply by winding the tubing into a flat spiral configuration,[3,4] it can provide a limited spiral pitch [outer diameter (O.D.) of the tubing] and, additionally, the connection between the neighboring spiral columns is rather difficult.

These problems can be solved by making a single or plural spiral channel(s) in a solid disk. In the first model, a single spiral channel is made in a plastic disk, which can be serially connected by stacking multiple disks sandwiched with Teflon sheet septa. In the second model, four spiral channels are incorporated in a single disk, symmetrically around the center, so that the spiral pitch is increased by four times that of the above single spiral channel without losing the column sptace. Connection between the neighboring spiral channels is formed by a short straight channel situated radially on the other side of the disk. A set of these disks can be serially connected by spacing a Teflon sheet between the neighboring disks, so that the column provides a large capacity that is somewhat comparable to that of the multilayer coil. The separation disk with a single spiral will serve as a control to evaluate the effect of the pitch on the partition efficiency.

DESIGN OF THE SPIRAL DISK

The design of the spiral column assembly is shown in Fig. 1. Fig. 1a shows a full view of the column assembly, which can be mounted on the type-J multilayer coil planet centrifuge (P.C., Inc., Potomac, Maryland, U.S.A.). The column components are illustrated in Fig. 1b. The column consists of a pair of flanges (one equipped with a gear), nine disks with spiral grooves, and ten Teflon sheet septa. The drawing, and dimensions for each component are illustrated in Fig. 2a–e.

The design of the individual separation disk with one spiral channel (diameter: 17.5 cm, thickness: 3 mm, with a 1.25 cm diameter center hole) is shown in Fig. 2a. The dimensions of the channel are 2.6 mm wide, 2 mm deep, with 1 mm ridge width, which gives a spiral pitch of 4 mm. The total channel length is about 4 m, comprising 12 spiral turns, with a total capacity of ~23 ml. The channel starts at the internal inlet (23 mm from the center) and extends to the external outlet (75 mm from the center), which is connected to the radial channel on the other side through a hole of ~1 mm diameter. The performance of this single spiral column may be compared to that of the following four-channel spiral column, by using a polar butanol solvent system and polymer phase systems.

Design of the individual separation disk for four separate spiral channels is shown in Fig. 2b. A plastic disk (17.5 cm diameter and 4 mm thick, high-density polyethylene) has four spiral channels (grooves), each 2.6 mm wide, 2 mm deep, and ~1 m long, with a capacity of about 6 ml. The ridge between each groove is 1 mm and, therefore, the pitch of each spiral becomes as large as 16 mm (four times that of

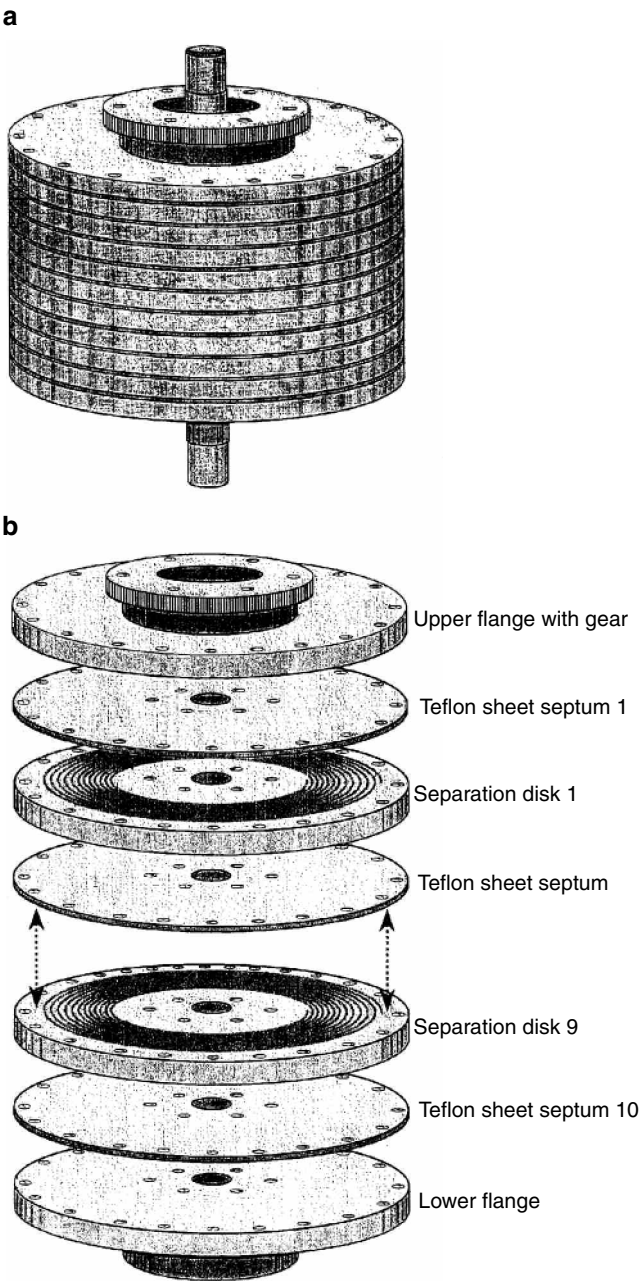

Fig. 1 Schematic illustration of the spiral disk assembly. a, Whole view. b, Exploded view showing each component.

the single spiral channel). Each channel starts at the inner end (I_1, I_2, I_3, and I_4) to reach the outer end (O_1, O_2, O_3, and O_4, respectively). As shown in the diagram, each channel forms 3.25 spiral turns so that the outer end of channel 1 (O_1) radially coincides with the inner end of channel 2 (I_2), and those of channels 2, 3, and 4 ($O_{2,3,4}$) similarly coincide with the inner ends of channels 3, 4, and 1 ($I_{3,4,1}$), respectively. Each end of the channel (except for O_1) has a hole (~1 mm diameter) through the disk to reach the other side, where a radial channel (dotted line) leads to the next spiral channel through another hole. The outer end of channel 4 (O_4) is connected to a similar radial channel which leads to channel 1 (I_1) of the next disk, or the column outlet, through an opening in the Teflon septum (Fig. 2c).

All disks have screw holes (clearing an 8–32 screw) at both inner and outer edges, at regular intervals (10° for the outer edge and 45° for the inner edge). Similar holes are also made in both the Teflon sheets and the flanges.

The design of the flanges is shown in Fig. 2d and e. The upper flange (Fig. 2d) is equipped with a plastic gear (9 mm thick, 10 cm pitch diameter), which engages with an identical stationary gear on the high-speed CCC centrifuge. Fig. 2e shows the lower flange, which has two screw holes (90° apart), for tightly fixing the column assembly against the column holder shaft (0.9 in. diameter). Both upper and lower flanges each have an inlet hole which fits into an adapter with a 1/4–28 screw thread. They also have a set of screw holes (clearing an 8–32 screw) around the outer and inner edges as in the separation disks and Teflon septa. The column assembly is mounted on the rotary frame of the multilayer coil centrifuge and counterbalanced with brass blocks. A pair of flow tubes from the column assembly is led downward through the center hole of the column holder shaft and passed through the hollow central pipe to exit the centrifuge at the center hole of the top plate, where it is tightly fixed with a pair of clamps. These tubes are protected with a sheath of Tygon tubing to prevent direct contact with metal parts.

EXPERIMENTAL PROCEDURE

Each two-phase solvent system is thoroughly equilibrated in a separatory funnel at room temperature and the two phases are separated before use. The sample solution is prepared by dissolving the sample in an appropriate volume (1–5 ml) of the upper and/or lower phase of the solvent system. In each experiment, the column is first entirely filled with the stationary phase (upper or lower phase), followed by sample injection through the sample port. Next, the apparatus is rotated at 800 rpm, while the mobile phase is eluted through the column at the desired flow rate. The separation may be repeated by changing the direction of the revolutions and/or elution mode (head to tail and tail to head), although it is expected that the best result would be obtained by eluting either the lower phase from the internal terminal toward the external terminal of the spiral channel, in a tail-to-head elution mode, or the upper phase in the opposite direction in a head-to-tail mode. The effluent from the outlet of the column is continuously monitored through an ultraviolet (UV) detector.

BASIC STUDIES WITH SINGLE DISKS

Using a single disk with each channel design, a series of experiments was performed to evaluate the performance of

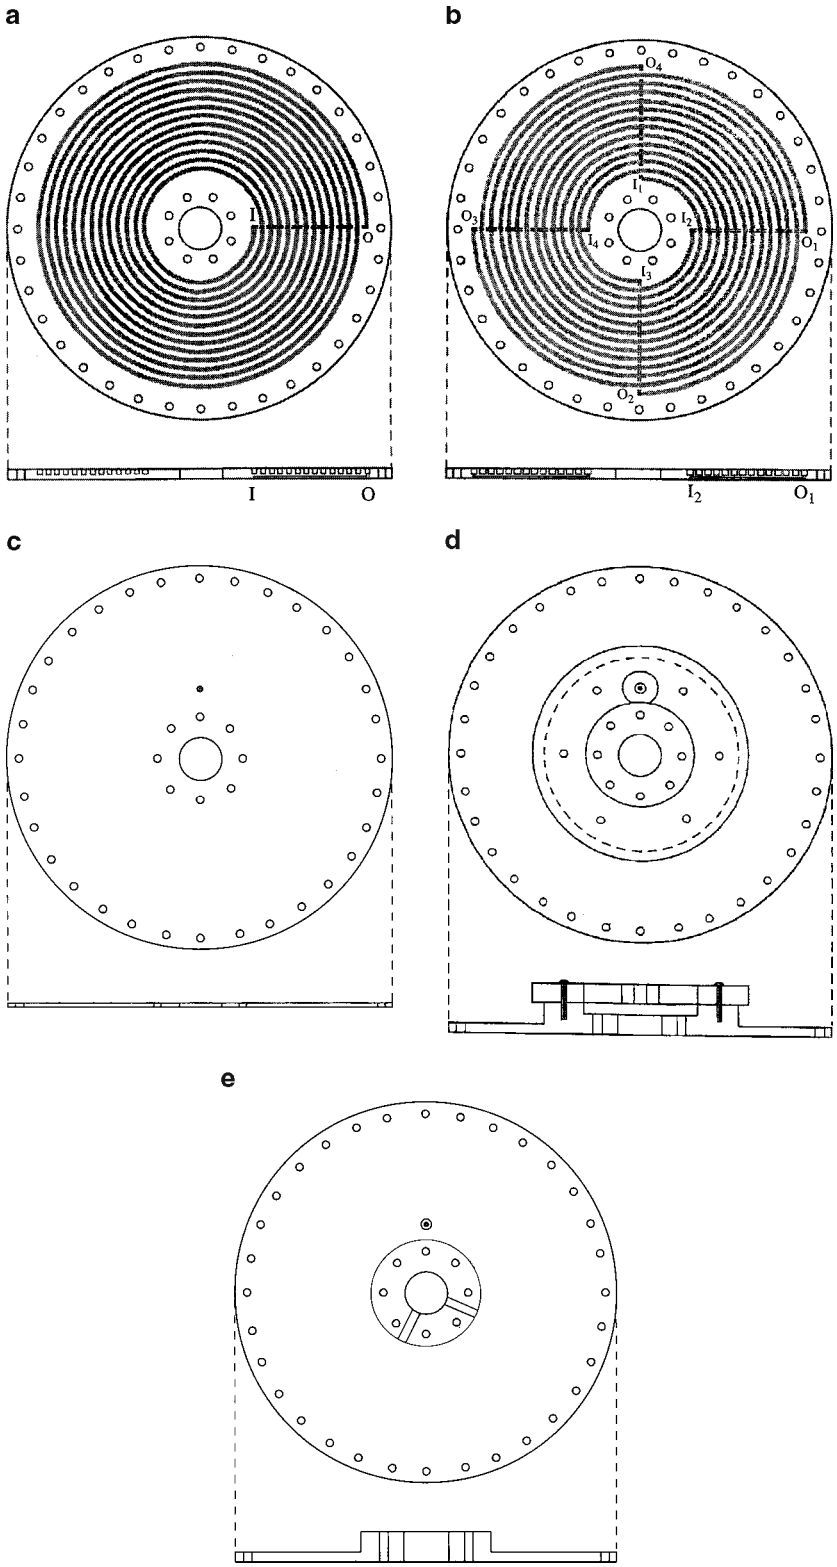

Fig. 2 Drawing of each component of the spiral disk assembly. a, Disk with a single spiral; b, Disk with four spirals; c, Teflon sheet septum; d, Upper flange equipped with a plastic gear; e, Lower flange.

the disk in terms of partition efficiency and retention of the stationary phase, by using three different types of two-phase solvent systems: 1-butanol/acetic acid/water (4 : 1 : 5, v/v/v) for separation of dipeptides; 12.5% (w/w) polyethylene glycol (PEG)-1000, 12.5% (w/w) dibasic potassium phosphate in water for protein separations; and 4% (w/w) PEG-8000, 5% (w/w) dextran T500 in water for measuring the retention of the stationary phase. The experiments were performed at various flow rates of the mobile phase, using four different elution modes, i.e., L–I–T (lower phase eluted from the inner

terminal at the tail); L–I–H (lower phase eluted from the inter terminal at the head); U–O–T (upper phase eluted from the outer terminal at the tail); U–O–H (upper phase eluted from the outer terminal at the head). Four other reversed elution modes, including L–O–T, L–O–H, U–I–T, and U–I–H, showed considerably less retention of the stationary phase, compared with their counterparts, because of the adverse effect of the radial centrifugal force gradient. The dimensions of these four spiral channels are given in Table 1.

1-Butanol/Acetic Acid/Water (4 : 1 : 5) System

Fig. 3a–d shows the separation of a standard sample mixture of trp–tyr (0.5 mg) and val–tyr (2 mg) with a

Experimental conditions: apparatus, type-J coil planet centrifuge with 10 cm revolution radius; a, Column I. b, Column II. c, Column III. d, Column IV (dimensions of channels are listed in Table 1). Sample: trp–tyr (0.5 mg) + val–tyr (2 mg) in 1 ml of upper phase; solvent system: 1-butanol-acetic acid/water (4 : 1 : 5); elution modes: L–I–T, lower phase from the inner terminal at tail, L–I–H, lower phase from the inner terminal at head, U–O–T, upper phase from the outer terminal at tail, and U–O–H, upper phase from the outer terminal at head; flow rate: 0.5–10 ml/min as indicated; rpm: 800, stationary phase retention: indicated in the figure.

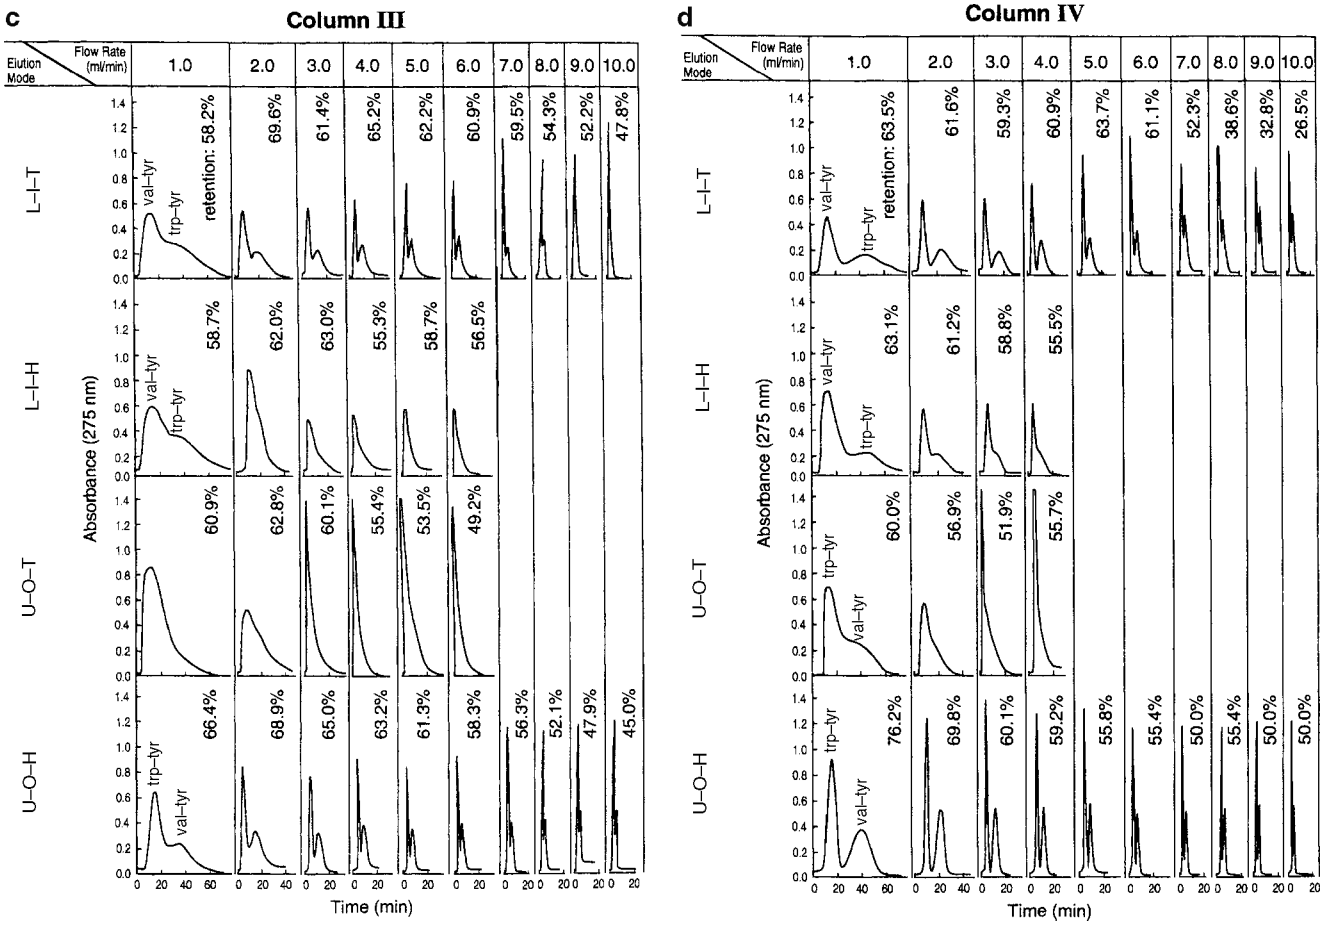

Fig. 3 (*Continued*)

two-phase solvent system composed of 1-butanol/acetic acid/water (4 : 1 : 5), by using a set of four different spiral columns (columns I–IV in Table 1).

In each chromatogram, the UV absorbance (280 nm) was plotted against the elution time, together with the % retention volume of the stationary phase relative to the total column capacity. In each group, a set of chromatograms is arranged according to the four different elution modes, i.e., L–I–T, L–I–H, U–O–T, and U–O–H, where L and U indicate the lower phase mobile and upper phase mobile; I and O denote eluting from internal terminal and external terminal of the spiral; and T and H represent "tail-to-head" and "head-to-tail" elution mode, each under various flow rates of the mobile phase.

In column I (Fig. 3a), the elution with upper phase from the head of the spiral (U–O–H) produces the best peak resolution and the highest % retention of the stationary phase. The elution with the lower phase from the head of the spiral (L–I–T) also shows a good peak resolution up to the flow rate of 6 ml/min, in spite of its low retention of the stationary phase. Elution of the lower phase from the head (L–I–H) retains a satisfactory amount of the stationary phase under the flow rate of 0.5–2 ml/min, while the peak resolution is much lower than those of its counterpart (L–I–T). The elution of the upper phase from the tail (U–O–T) shows no retention of the stationary phase, even at a low flow rate of 0.5 ml/min. These elution trends are also found in column II (Fig. 3b), except that the peak resolution is much reduced in the elution of the lower phase from the tail (L–I–T), under a similar retention level of the stationary phase.

Fig. 3c and d shows the chromatograms obtained from the four-spiral disks under otherwise identical experimental conditions. It clearly indicates that the retention of the stationary phase is much improved in all elution modes. Although the peak resolution of the two dipeptides was substantially reduced, the flow rate could be increased up to 10 ml/min to yield a moderate degree of peak resolution as emphasized by column IV (Fig. 3d).

This suggests that, if one used a multichannel spiral disk with a large pitch, the separation of peptides might be achieved in a very short elution time.

PEG 1000-Dibasic Potassium Phosphate Polymer Phase System

Fig. 4a–d similarly illustrates the peak resolution between two protein samples (lysozyme and myoglobin, 10 mg each) in the PEG–phosphate system obtained from the four

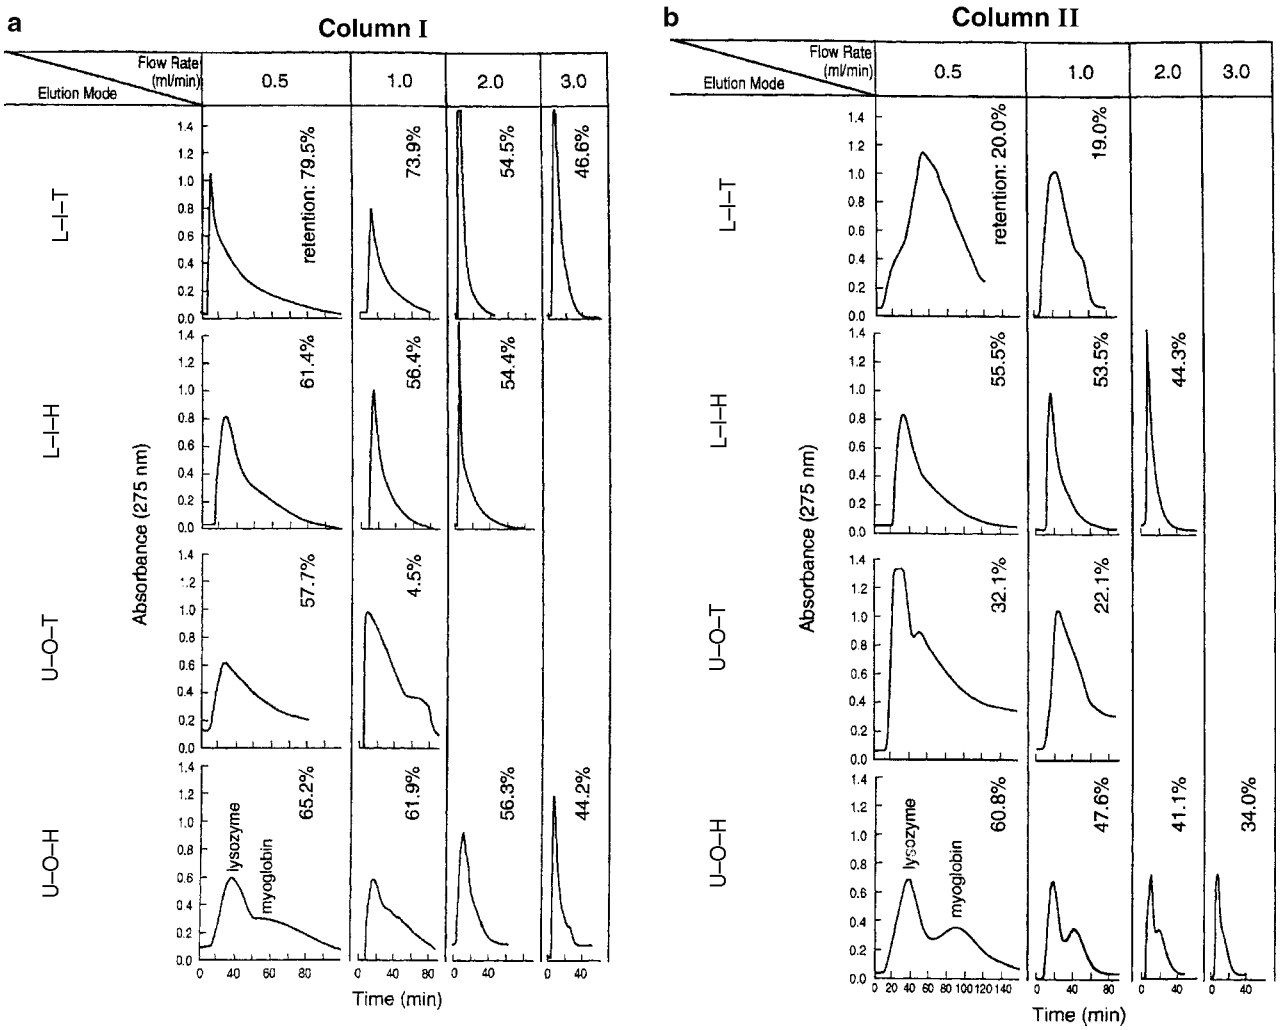

Fig. 4 Separation of proteins with a set of four single disks. Experimental conditions: apparatus, type-J coil planet centrifuge with 10-cm revolution radius; a, Column I. b, Column II. c, Column III. d, Column IV (dimensions of channels are listed in Table 1). Sample: lysozyme and myoglobin each 5 mg in 1 ml of upper phase; solvent system: 12.5% (w/w) PEG1000 and 12.5% (w/w) potassium diphosphate in water; elution modes: L–I–T, lower phase from the inner terminal at tail, L–I–H, lower phase from the inner terminal at head, U–O–T, upper phase from the outer terminal at tail, and U–O–H, upper phase from the outer terminal at head; flow rate: 0.5–5 ml/min as indicated; rpm: 800, stationary phase retention: indicated in the figure.

different spiral disks. In the single-spiral disks (Fig. 4a and b), the best results were obtained by eluting the upper PEG-rich mobile phase from the head end of the outer terminal (U–O–H); other modes resulted in low resolution. Except for L–I–T and I–O–T in column II, all groups show a satisfactory level of stationary phase retention with a flow rate of 0.5 ml/min, indicating that mixing of two phases in the spiral column is inefficient. This tendency is more pronounced in the four-spiral disks (Fig. 4c and d), which show much higher retention of the stationary phase (over 60%), but without any peak resolution. Comparing columns in Fig. 4a and b shows the latter to yield somewhat higher peak resolution, which is probably a result of the shallow channel which facilitates mass transfer between the two phases. This suggests that the separation might be further improved by reducing the width of the spiral groove.

PEG 8000–Dextran 500 Polymer Phase System

A series of experiments was performed to examine the retention of the PEG–dextran polymer phase system without samples. Results are shown in Table 2, where % retention of the stationary phase is indicated at the flow rates of 0.5–1 or 2 ml/min for each spiral column. The results indicate that, among the single-spiral disks (I and II), column I with a deep channel retained over 60% of the lower dextran-rich stationary phase (U–O–H and U–O–T), at a low flow rate of 0.5 ml/min while, under other conditions, the retention was substantially less than 50% of the total column capacity. In contrast, the four-spiral disks (columns III and IV) attained remarkably improved retention of over 50% for all elution modes, at 0.5 ml/min flow rate. Again, the results

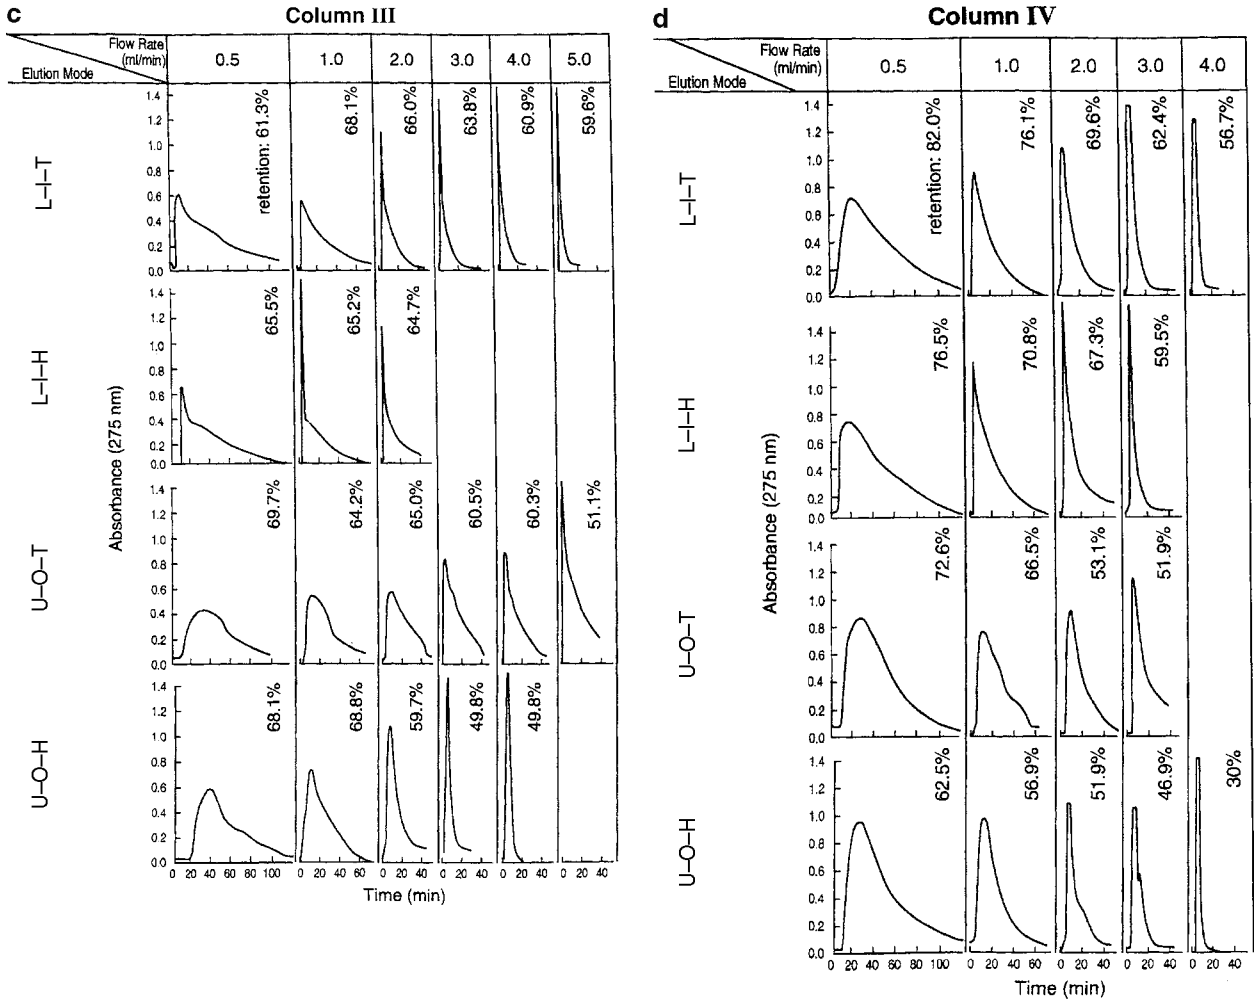

Fig. 4 (*Continued*)

indicate the effect of the greater spiral pitch, which favors the retention of the stationary phase.

PRELIMINARY SEPARATION WITH A SPIRAL DISK ASSEMBLY

The performance of the present column design was examined by using a spiral disk assembly consisting of eight units of column I, with a total capacity of 165 ml. Results are shown in Fig. 5a and b. In Fig. 5a, a mixture of five dipeptides was well resolved and was completely eluted in 2 hr. The upper organic phase of the 1-butanol solvent system was eluted at a flow rate of 4 ml/min. Similar separations were shown with the standard multilayer coils in HSCCC, but only with more stable butanol solvent systems.[1]

Fig. 5b shows the separation of two stable proteins (lysozyme and myoglobin) by using a PEG 1000/

K_2HPO_4 polymer phase system at a flow rate of 1 ml/min, where they were well resolved in slightly over 5 hr. As suggested by the basic studies, the separation may be substantially improved by using the column II disk assembly, which provides a shallower channel to facilitate mass transfer in viscous polymer phases.

CONSIDERATION OF VARIOUS PARAMETERS GOVERNING PERFORMANCE OF THE SPIRAL COLUMN

Depth and Width of the Spiral Channel

Differing from the ordinary coiled column prepared from Teflon tubing, the channel of the spiral column has a rectangular cross-section. Because the centrifugal force acts along the radius of the disk, the width of the groove on the disk becomes the depth of the channel, and the depth of the groove becomes the width of the channel. Here it is reasonable to consider that a greater depth of the channel favors the retention of the stationary phase, while it provides a less efficient mass transfer rate. In the present studies, we used two different dimensions of the spiral channel: columns I and III are 2.6 mm in depth (or width of the groove) and 2.0 mm in width (or depth of the groove), while columns II and IV are 1.5 mm in depth and 3.7 mm in width. The experimental data clearly indicate that, with few exceptions, the deeper column (columns I and III) produces a better retention of the stationary phase. This trend is most clearly observed in the viscous PEG–dextran system in the single-channel spiral disks (columns I and II).

The effects of channel geometry on partition efficiency in terms of peak resolution gives a more complex picture: in the dipeptide separation with the butanol solvent system, the deeper channel of the single spiral disk (column I) produced a substantially better peak resolution, especially in the lower phase mobile mode (L–I–T), whereas the shallower channel in the four-spiral disks (column IV) produced a somewhat better separation than its counterpart. We do not understand the reason why higher peak resolution is obtained in the deeper channel of column I in L–I–T, despite the low retention of the stationary phase. In protein separation, with the PEG–phosphate system, the shallower spiral channel of the single-spiral disk displayed the best separation in the upper PEG-rich mobile phase, whereas both four-spiral disks (columns III and IV) showed less efficient separations.

The overall results suggest that the shallower channel shows better separation of proteins by using the PEG–phosphate polymer phase system and the deeper channel favors the retention of viscous PEG–dextran solvent systems.

Spiral Pitch

The effects of the spiral pitch on the present studies are observed by comparing the chromatograms between columns I and III for the deep channel and between columns II and IV for the shallow channel. It is clearly observed that, in the dipeptide separation with the 1-butanol solvent system, the greater pitch results in lower peak resolution at a given flow rate, while it provides higher retention of the stationary phase, thereby allowing a higher flow rate of the mobile phase to reduce the separation time. Similar effects are also observed in the protein separation with the PEG–potassium phosphate solvent system. In the PEG–dextran system, a greater pitch provides a substantial increase in retention of the stationary phase, some exceeding 50% retention at a flow rate of 1 ml/min.

Flow Rate of the Mobile Phase

The flow rate of the mobile phase is an important parameter which determines the elution time. In the dipeptide separation, the optimum flow rate producing the best peak resolution is present in all spiral disks. In the four-spiral disk systems (columns III and IV), which retain a large volume of the stationary phase, the application of a high flow rate of up to 10 ml/min is possible to reduce the separation time, without substantial loss of peak resolution. In the separation of proteins with PEG–phosphate, the low

flow rate produced the best peak resolution with higher retention of the stationary phase.

EFFECTS OF VARIOUS INSERTS PLACED INTO THE CHANNEL SPACE

One of the advantages of the spiral disk over the spiral tubing is that the spiral channel can be modified in various ways to improve the partition efficiency. Early trials to place fine Teflon tubing (end closed) or small glass beads (less than 1.5 mm diameter) into the channel resulted in continuous carryover of the stationary phase, apparently a result of vigorous mixing (turbulence) caused by the rotating centrifugal force field. However, inserting short segments of Teflon tubing (~2 mm O.D., 2–3 mm in length) into the channel at regular intervals (1 cm) produced substantial improvement of the peak resolution, especially in column IV with high-pitch four spiral channels (Table 1). These findings suggest that the shape of the spiral groove can be modified into a locular configuration to improve the partition efficiency (Fig. 6).

CONCLUSIONS

The rectangular spiral channel embedded in a solid plastic disk, applied to the J-type HSCCC centrifuge, enhances the retention of stationary phase for viscous, low interfacial tension, two-phase solvent systems. Its main advantages are as follows:

1. Use of polymer phase systems for separation of biopolymers [proteins, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), and polysaccharides].
2. Reliable retention of the stationary phase for polar or low interfacial tension solvent systems (e.g., 1-butanol/water), which are useful for separation of bioactive compounds such as peptides.
3. Improved stationary phase retention against emulsification.
4. Application of the large column for industrial-scale separations by mounting the column assembly on the slowly rotating horizontal shaft.
5. The system allows further modification of the shape of spiral channels to improve the partition efficiency.

Split/Splitless Injector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The split/splitless detector has been designed for use with open-tubular columns or solid-coated open-tubular (SCOT) columns. Due to the small dimensions of such columns, they have very limited sample load capacity and, thus, for their effective use, require sample sizes that are practically impossible to inject directly. The split injector allows a relatively large sample (a sample size that is practical to inject with modern injection syringes) to be volatilized, and by means of a split-flow arrangement, a proportion of the sample is passed to the column while the remainder is passed to waste. A diagram of a split/splitless injector is shown in Fig. 1.

DISCUSSION

The body of the injector is heated to ensure the sample is volatilized and inside is an inert glass liner. This glass liner helps minimize any sample decomposition that might occur when thermally labile materials come in contact with hot-metal surfaces. The carrier gas enters behind the glass liner and is thus preheated. The sample is injected into the stream of carrier gas that passes down the center of the tube, a portion passes down the capillary column, and the remainder passes out of the system through a needle valve. The needle valve is used to adjust the relative flow rates to the column and to waste and, thus, controls the amount of sample that is placed on the column.

This process of sample injection has certain disadvantages. Due to the range of solute types present in most mixtures for analysis, the components will have different volatilities and their vapors will have different diffusivities in the carrier gas. Differential volatilization and diffusion rates will result in the sample that enters the capillary tube, being unrepresentative of the original mixture. For example, the more rapidly diffusing solutes will be more dispersed and, consequently, more diluted in the carrier gas than those of lesser diffusivity. This results in the slower-diffusing substances having a higher concentration in the sample entering the column than those of higher diffusivity. As a consequence, the sample will be proportionally unrepresentative of the original mixture. The differential sampling that results from split injection systems can become a serious problem in quantitative analysis with capillary columns.

An alternative approach is to use a splitless injection system. If the valve in Fig. 1 is closed, then all the sample passes into the column and there is no split; *ipso facto*, the device is a *splitless* injector. When used in the splitless mode, however, it is usual to employ a somewhat wider capillary column, which will allow the penetration of a small-diameter injection syringe and thus permit *on-column* injection. Under these circumstances, there can be no differential sampling of the form described. This procedure, however, introduces other injection problems that can affect both resolution and quantitative accuracy that need to be addressed (see *Retention Gap Injection Method*, p. 2035 and *Solute Focusing Injection Method*, p. 2187).

Stationary Phase Retention in CCC

Jean-Michel Menet
Aventis Pharma, Vitry-sur-Seine, France

INTRODUCTION

The retention of the stationary phase is a key parameter for countercurrent chromatography (CCC), as it influences all the chromatographic parameters describing a separation. First, it is important to closely monitor its value, commonly named SF; we give the reader three methods to determine this value. Then, the best conditions for obtaining the highest SF value are described for the three main CCC devices, which include: (a) a Sanki centrifugal partition chromatography, (b) a type J high-speed countercurrent chromatography, and (c) a cross-axis countercurrent chromatography. Finally, some theoretical approaches are introduced in order to estimate the value before any experimental work is performed.

HOW TO MEASURE SF

Fig. 1 indicates the principle of use of any CCC device for the equilibrium of two liquid, non-miscible phases. In this case, the stationary phase which is chosen is the lighter phase of the solvent system (dark gray in Fig. 1), whereas the mobile phase is indicated in white. For simplification, the coil is considered as an empty cylinder and the phenomena which occur inside the column are highly schematized as a stack of disks of mobile and stationary phases. This allows us to visualize the progression of the mobile phase inside the column. After the solvent system has reached equilibrium (complete settling of the two phases), the phase chosen as the stationary phase is pumped into the apparatus. The latter is considered as filled as soon as droplets of this stationary phase are expelled out of the column; this is Step 1 of Fig. 1.

The apparatus is then started, and when the desired rotational speed is reached, the mobile phase is pumped into the apparatus. A graduated cylinder is then put at the outlet of the apparatus. The two phases undergo a hydrodynamic or hydrostatic equilibrium inside the column while the mobile phase progresses toward the outlet of the column; this is Step 2. After a certain time, the mobile phase has reached the end of the column and then the first droplet of the mobile phase falls into the graduated cylinder; this Step 3. The experimenter then reads the volume, V_1, of the stationary phase which has been expelled from the column. The experiment is continued until the desired total volume is reached in the graduated cylinder. The experimenter can read the respective volumes of the stationary phase, named V_2, and the mobile one; this is, Step 4. Finally, the apparatus can be emptied (for instance, by pushing with nitrogen gas) and the liquids collected in another graduated cylinder; the volume of the stationary phase is V_3. For simplification purposes, the extracolumn volumes are neglected. Three measurements of the stationary phase retention are available:

- One just after the equilibrium inside the column: $SF_1 = (V_{column} - V_1)/V_{column}$
- One after a certain amount of time: $SF_2 = (V_{column} - V_2)/V_{column}$
- One by emptying the apparatus: $SF_3 = V_3/V_{column}$

If the equilibrium of the two phases was stable and not disturbed by any external event (change in rotational speed, flow rate, etc.), the three values of SF should be similar by a few percent of precision.

BEST CONDITIONS FOR SF FOR THE THREE MAIN CCC DEVICES

The best combinations of experimental parameters (e.g., choice of lighter or heavier phase, choice of the inlet to pump the mobile phase into, etc.) in order to retain the maximum amount of stationary phase inside the column are related to complex hydrodynamic phenomena which are based on the behavior of the solvent system inside the column of a given CCC apparatus. Many experiments have been carried out on the three main types of CCC devices by varying the experimental parameters and the solvent systems, in order to gather solvent systems by groups characterized by a combination of experimental parameters.

Sanki-Type Apparatus

The principle of this instrument has been precisely described in the entry (see *Centrifugal Precipitation Chromatography*, p. 378) devoted to this topic in this encyclopedia. The apparatus is a centrifuge, in which cartridges or plates are installed. Two rotating seals are required to allow the flow of the liquid phase: One stays at the top of the centrifuge, the other one at the bottom (solvent inlet and outlet).

Whatever the solvent system may be, the optimization for the best retention of the stationary phase is quite simple. Among the four possibilities, only two of them lead to a good retention of the stationary phase inside the cartridges

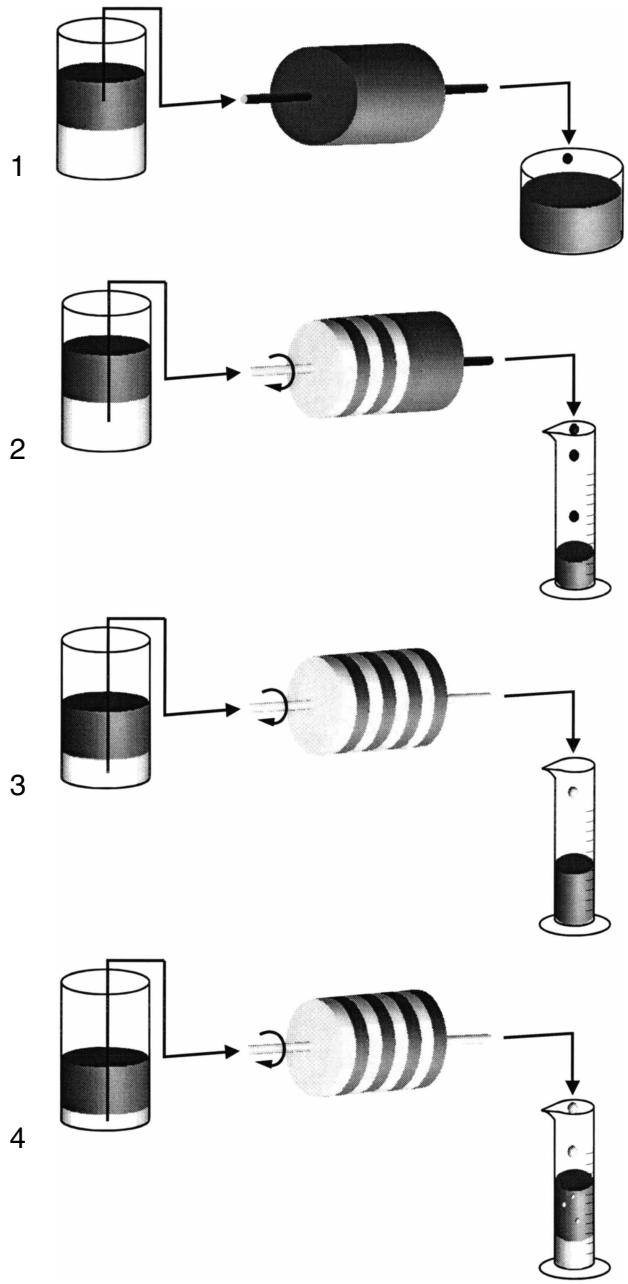

Fig. 1 Principle of the two-phase equilibrium inside a CCC column.

or the plates; they are based on the combination of the lighter mobile phase pumped from the bottom to the top seal, also called the "ascending" mode, and the heavier mobile phase pumped from the top to the bottom seal, also called the "descending" mode.

Type J Apparatus

The principle of this apparatus has been precisely described in an entry (see *Dual CCC*, p. 679) devoted to this topic in this encyclopedia. Two main parameters for using a two-phase solvent system with this apparatus are the choice of the heavier or the lighter mobile phase and the pumping mode [i.e., from the tail to the head or the head to the tail of the column (as a rotating coil defines a tail and a head, carrying, for instance, a small solid from the tail to the head)].

The designer of this type of device [Dr. Yoichiro Ito (National Institutes of Health, Washington, DC)], has tried various solvent systems in order to ascertain the best combinations of the two main parameters.[1] He observed that, among the four possibilities, only two led to the best retention of the stationary phase. However, the two optimal conditions were dependent on the nature of the solvent system and, for some solvent systems, on the geometrical dimension of the apparatus.

Ito has, consequently, decided to carry out a systematic study with 15 solvents.[1] His first conclusion was that only one condition was optimal among the two pumping modes for a given phase (i.e., lighter or heavier phase). The second conclusion was that the pumping modes to be used are reversed if the liquid phase is chosen as lighter instead of heavier, or vice versa.

Two groups of solvent systems have, consequently, been defined. One gathers solvent systems for which the two best combinations are the pumping of the lighter phase from the tail to the head of the column and the pumping of the heavier phase from the head to the tail of the column. The organic phases of such solvent systems are hydrophobic; thus, this group is called "hydrophobic" (e.g., hexane–water). The other group gathers solvent systems for which the two best combinations are the pumping of the lighter phase from the head to the tail of the column and of the heavier phase from the tail to the head of the column. The organic phases of such solvent systems are quite hydrophilic; thus, this group is called "hydrophilic" (e.g., butanol-2–water). The best combinations are reversed between the two groups.

However, there was a need to define a third group to take into account the behaviors of some solvent systems for which optimal combinations depend on the geometric dimensions of the apparatus. The discriminating parameter was found to be the β ratio of the coil radius on the distance between the two axis of rotation. For β values smaller than 0.3, solvent systems belonging to this third group behave like the solvent systems of the "hydrophilic" group. Conversely, for β values greater than 0.3, they behave like solvent systems of the "hydrophobic" group. The group was named "intermediate," which was also consistent with the mild hydrophobic (or hydrophilic) character of the organic phase (e.g., chloroform–methanol–water).

The main drawback of this classification comes from the experimental determination of the three groups. For a solvent system not previously studied, either by Ito or cited in the literature, the experimenter has to carry out four experiments in order to determine the two best combinations and, consequently, the group to which it belongs.

CROSS-AXIS-TYPE APPARATUS

The general principle of this type of apparatus is described in the corresponding entry (see *Proteins: Cross-Axis Coil Planet Centrifuge Separation*, p. 1935) of this encyclopedia. Contrary to the two previous CCC devices, four main parameters have to be considered here. Two of them are common to the other types of CCC units (i.e., choice of a lighter or a heavier phase and pumping mode from tail to head or from head to tail). Two additional parameters intervene: the pumping direction, from the inside to the outside of the core or reverse, and the rotation direction, clockwise or counterclockwise.

The same designer of this type of apparatus as for type J device, Ito, has applied the same procedure to classify various solvent systems by varying the main running parameters.[2,3] However, it has proven difficult to draw clear and precise conclusions from the results, because of the number of operating parameters. The methodology of experimental design has, consequently, emerged as the rational method to use for this purpose; it is easy to use and it elucidates the effects of the parameters and their interactions. A thorough, but global, analysis based on the experimental design methodology applied to the cross-axis-type device, was reported by Goupy et al.[4] The overall analysis carried out by the use of experimental design with a coil mounted in the L position simplifies the operation of the cross-axis apparatus, as the best combination does not depend on the solvent system. Indeed, the retention of the stationary phase is mainly related to the choice of the mobile phase and of the elution direction. A heavier mobile phase requires the outward elution direction, whereas a lighter mobile phase requires an inward elution direction.

Consequently, no classification among solvent systems may be built from their behaviors inside a cross-axis device.

THEORETICAL APPROACHES TO CORRELATE PHYSICAL PARAMETERS AND OBSERVED BEHAVIOR INSIDE A CCC COLUMN

The capillary wavelength and settling velocities have been retained as interesting parameters to step forward the description of the behavior of solvent system inside a CCC column. Moreover, they have also enabled a simple prediction of the effect of the temperature on the behavior of solvent systems, thus, on "Ito's classification."

The "theoretical" parameter capillary wavelength, λ_{cap}, has been precisely described by Menet et al.[4,5] The capillary wavelength is a means of describing the microscopic behavior at the interface between two immiscible liquids. It stands for the wavelength of the deformations which may occur at the interface of the two liquids or represents the mean diameter of drops of a liquid in another one. For common liquids, its average value is 1 cm in the Earth's gravitational field. For CCC devices, it is in the order of 1 mm, because of the generated centrifugal force field.

As the capillary wavelength only enables the description of the formation of droplets of one liquid in another one, it seemed interesting to introduce other "theoretical" parameters to better describe the dynamic phenomena occurring inside a CCC column. Two of these are presented here, namely V_{low} for the fall of a droplet of the heavier liquid phase (lower) in the continuous lighter one (upper) and V_{up} for the rise of a droplet of the lighter liquid phase in the continuous heavier one.

In order to determine if a correlation exists between "Ito's classification" and the values of the previous "theoretical" parameters, the 15 solvent systems used for the design of the classification have been studied. The values of interfacial tension, of densities, and of dynamic viscosities of the solvent systems were used to compute the values of the capillary wavelength and the settling velocities. The values of the three theoretical parameters have allowed to set ranges within which a solvent system is named "hydrophobic," "intermediate," or "hydrophilic." The main interest is that the knowledge of some physical parameters of the solvent systems allows one to know, before any experiments, the best combinations for the greatest stationary-phase retenion.

The values of the capillary wavelengths are smaller for "hydrophilic" solvent systems than those for "hydrophobic" ones: The first family of solvent systems tends to form small droplets of one phase in the other one, hence leading to a more stable emulsion. Their stationary phase is consequently less retained in the CCC column than the one of "hydrophobic" solvent systems; this phenomenon is well known in CCC.[1]

From additional studies of six new solvent systems and by studying the influence of the temperature, Menet et al. have shown the best classification is that based on V_{up}.[4]

Stationary Phase Retention versus Peak Elution in CCC

Philip Wood
Brunel Institute for Bioengineering, Brunel University, Uxbridge, Middlesex, U.K.

INTRODUCTION

Walter Conway[1] adapted the countercurrent distribution (CCD) formula for predicting peak elution times for countercurrent chromatography (CCC). The equation for peak elution time is

$$t_D = \frac{V_C}{F}[S_f(D-1)+1] \quad (1)$$

where V_C is the column (coil) volume, F the mobile phase flow rate, S_f the stationary phase retention (expressed as a fraction), and D the distribution ratio. D is defined as the ratio of the total analytical concentration of a solute in the liquid stationary phase, regardless of its chemical form, to its total analytical concentration in the mobile phase.[2] This basic equation is the same regardless of the type of CCC equipment used. However, this equation does not take into account the extra-coil volumes or the sample volume. Originally, the influence of these volumes was not noticed because the extra-coil volumes were a small fraction of the column volume, sample volumes were small, less than 1% of the column volume, and elution times were measured in hours. However elution times can now be measured in minutes, sample volumes have increased to as much as 33% of coil volume[3] and extra-coil volumes are a much larger proportion of the column volume. These factors combined with the mobile phase flow rates now possible, 850 ml/min,[3] indicate that the accuracy of retention measurements should be improved to allow accurate predictions of the times between sample injection and peak detection to be made.

Shorter elution times mean that the time interval between peaks is also reducing. This interval is now measured in minutes, hence to collect the peak of interest requires precise knowledge of when it will elute.

To date, CCC has mainly been conducted with the aim of achieving baseline separations. However, CCC devices, both J-type high-speed countercurrent chromatography (HSCCC) centrifuges and centrifugal partition chromatography (CPC) machines, are now beginning to be used to manufacture pharmaceutical products where the sample loading is increased to the point where peaks are not fully resolved.[3–5] The higher the sample loading, the more asymmetric the peaks of a separation become, causing a loss of resolution and the merging of peaks. In case of the peaks that are not fully resolved peak shaving (precise fraction collection) is used to obtain the desired purity of a target solute. Peak shaving works efficiently if the asymmetric nature of peak elution is acknowledged.

PEAK ELUTION TIME

Put simply, peak elution time is the period between a sample entering the column and a peak eluting from the downstream end of the column. However, this definition is a little imprecise because the sample will take time to load into the coil and the peak will also take time to leave the column and reach the detector. In the past, injection times have been short compared with elution times; however, as separation times have become much shorter and injection volumes have increased, the injection time must be considered to accurately predict elution times. In Fig. 1,[6] it is demonstrated how peaks elute later as the sample volume was increased from 0.005 to 2 ml at a flow rate of 1 ml/min. The 0.005 ml sample took 0.3 sec while the 2 ml sample took 2 min to inject. Compared with the 25 min separation time, 0.3 sec is insignificant whilst 2 min represent 8% of the separation time.

The results presented in Fig. 1 were produced using the heptane : ethyle acetate : methanol : water (1.4 : 0.2 : 1 : 1 v/v) phase system in two 12.5 ml, 0.8 mm bore helical coils connected in series. These coils had a β-value of 0.88 at a rotor radius of 110 mm and were rotated at 1400 rpm in a J-type centrifuge. The concentration of each component was 10.5 mg/ml.

In Fig. 2,[6] the same separation modeled on the eluting CCD software developed by Sutherland, De Folter and Wood[7] is shown. In this model, each 5 μl of sample volume is represented by one injection step. This modeling reinforces the experimental observation that sample size needs to be taken into account.

A more precise definition is that the peak elution time is measured from the point when half the sample has entered the column[8] to the time of maximum peak height (the highest concentration of the sample component) elutes from the column. The time taken for half of the sample volume to enter the coil is ($t_{S/2}$),

$$t_{S/2} = \frac{V_{Sa}}{2F} \quad (2)$$

where V_{Sa} is the sample volume.

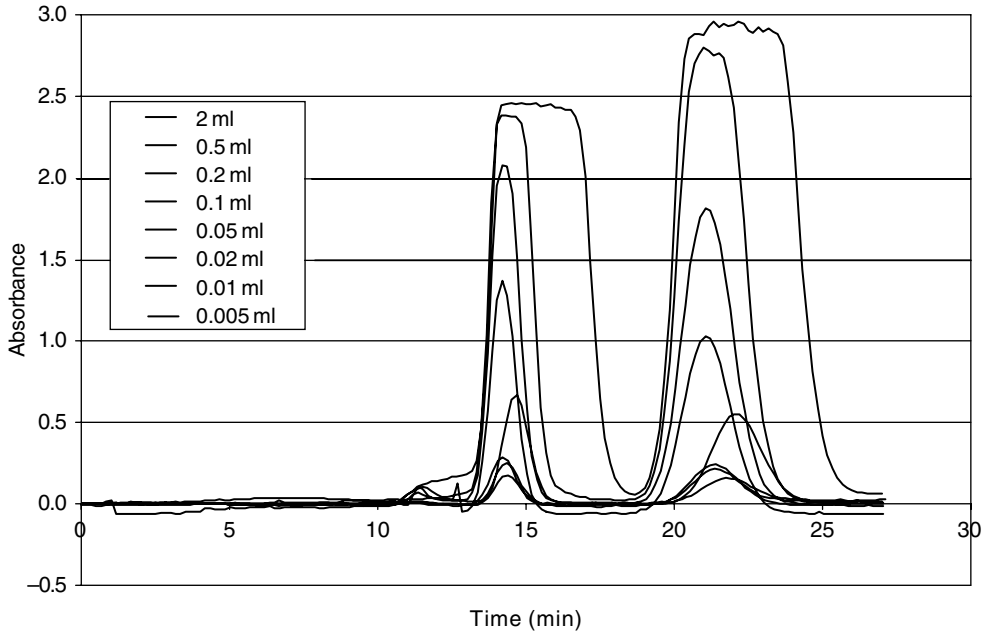

Fig. 1 The influence of sample volume on peak elution times for a benzyl alcohol and *p*-cresol separation.
Source: From Sample volume and resolution in analytical countercurrent chromatography, in Proceedings of the Pittsburgh Conference.[6]

Usually, when a separation is performed, the recording of the trace is started when the injector valve is triggered to insert the sample into the flow of mobile phase. However, the sample will not start to separate until it reaches the column after passing through tubing linking the injector valve to the column, see V_3 in Fig. 3. There is also a second period of time between the peak eluting from the column and arriving at the detector's cell, see V_4 in Fig. 3. The sum

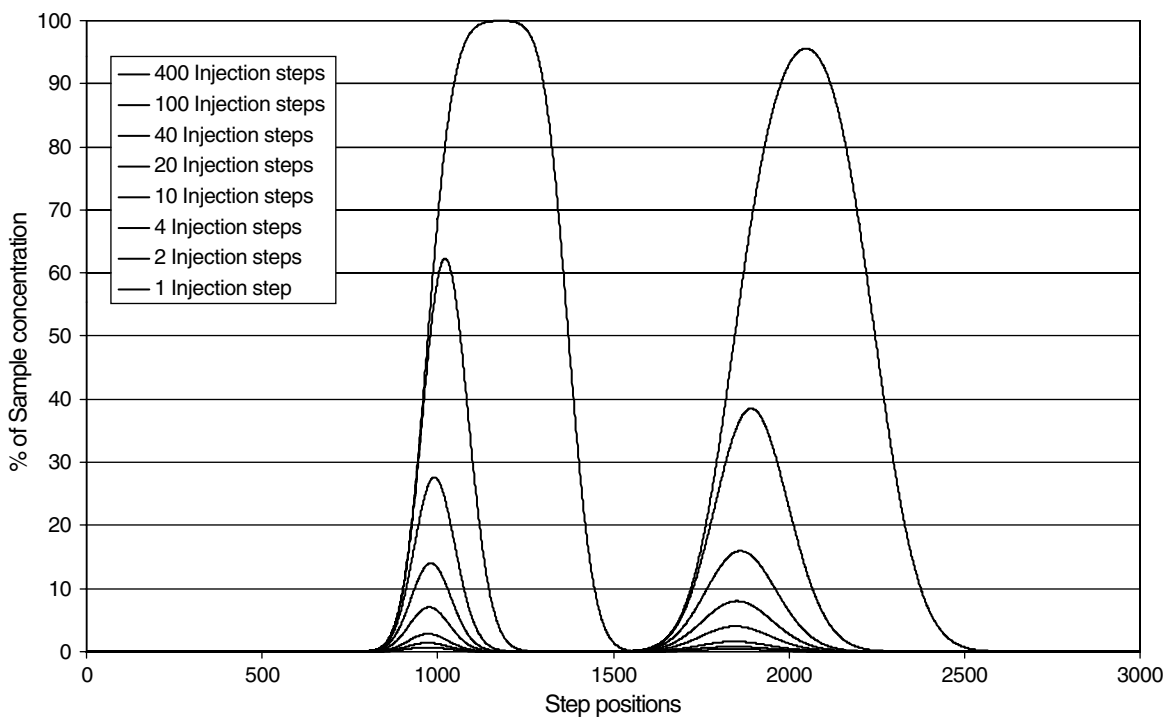

Fig. 2 A mathematical prediction of the benzyl alcohol and *p*-cresol separation shown in Fig. 1.
Source: From Modelling CCC using an eluting countercurrent distribution model, in J. Liq. Chromatogr. Relat. Technol.[7]

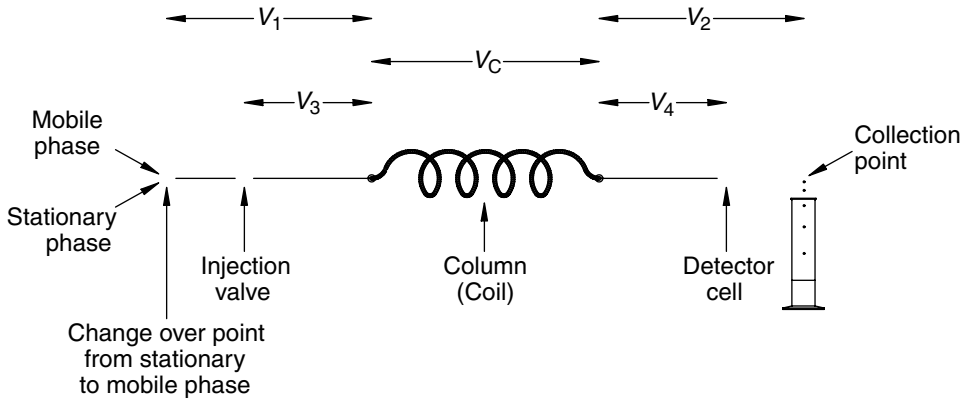

Fig. 3 Schematic diagram of a CCC system.

of these two extra volumes ($V_3 + V_4$) provides the chromatographic extra-coil volume (V_{Cext}). The time for the peak to pass through this volume is

$$t_{Cext} = \frac{V_{Cext}}{F} \tag{3}$$

Fig. 4 is a typical chromatogram for the separation of two components from a binary sample. It shows that the peak elution time (t_D) is determined by subtracting both the time (t_{Cext}) spent in the chromatographic extra-coil volume (V_{Cext}) and half the sample injection time ($t_{S/2}$) from the trace time (t_{tD}):

$$t_D = t_{tD} - t_{Cext} - t_{S/2} \tag{4}$$

Hence,

$$t_D = t_{tD} - \frac{V_{Cext}}{F} - \frac{V_{Sa}}{2F} \tag{5}$$

For peak b in Fig. 4, Eq. 5 can be rewritten as

$$t_b = t_{tb} - \frac{V_{Cext}}{F} - \frac{V_{Sa}}{2F} \tag{6}$$

A similar equation for peak a, from Fig. 4, can also be written. Therefore, it is necessary to know the chromatographic extra-coil volume (V_{Cext}) of a CCC system to accurately determine the elution time of a peak.

EXTRA-COIL VOLUMES

The extra-coil volumes are usually determined by calculation from the various volumes of the associated plumbing.

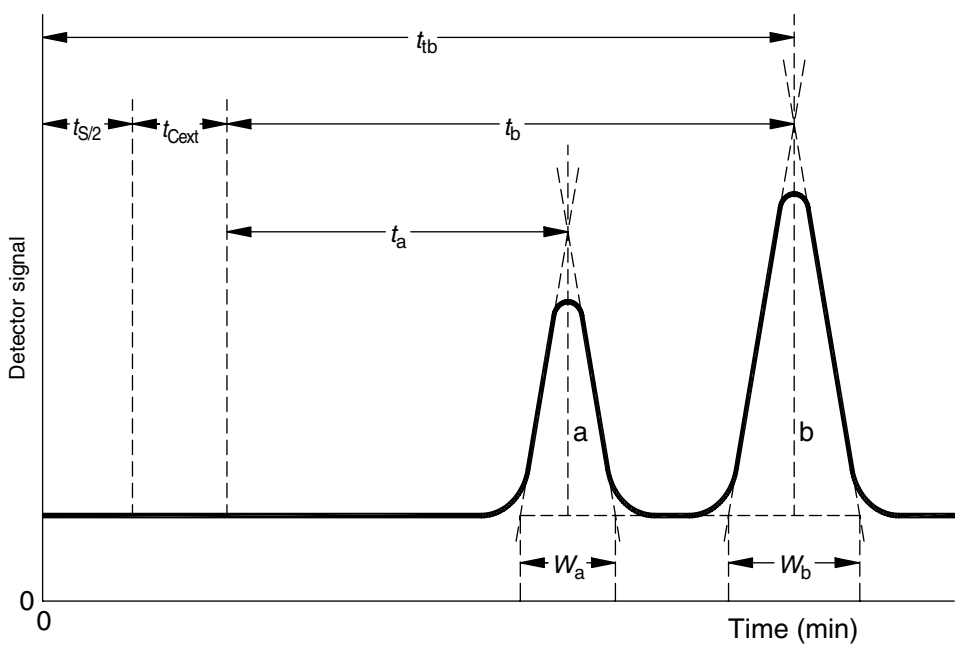

Fig. 4 Simplified chromatogram of a two-peak separation.

The components of the associated plumbing include flying leads, switching valves, injectors, detectors, and fraction collectors. There are two extra-coil volumes for any CCC device. The first is the chromatographic extra-coil volume (V_{Cext}) described earlier. The second one, the retention extra-coil volume (V_{ext}), is the volume between the point where the flow is switched from stationary to mobile phase and the column, V_1 in Fig. 3, plus the volume between the column and the collection point of the stationary and mobile phases, V_2 in Fig. 3. V_{ext} is usually larger than V_{Cext} because the switching point between the stationary and mobile phases is upstream of the injector valve and the collection point (fraction collector) is downstream of the detector's cell, where

$$V_{ext} = V_1 + V_2 \tag{7}$$

and

$$V_{Cext} = V_3 + V_4 \tag{8}$$

Using the wrong extra column volume can lead to common errors in determining stationary phase retention or calculating elution times. V_{ext} is used to determine the stationary phase retention and V_{Cext} is used to calculate elution times.

ACCURATE MEASUREMENT OF STATIONARY PHASE RETENTION

Precise prediction of the elution times relies upon knowing the accurate stationary phase retention (S_f). This can be measured in three different ways:

1. To determine how retention varies with the mobile phase flow rate for a given rotational speed. This method also confirms the retention extra-coil volume (V_{ext}), and will be discussed next.
2. To determine how retention varies with rotational speed for a given mobile phase flow rate.
3. Measuring the retention while performing an isocratic separation when the rotational speed and flow rate are constant.

The first two methods give information as to how a stationary phase will retain in a CCC system. It is recommended that the rotational speed and one flow rate from the first method forms one of the data points in the second method. The third method is used to ensure that the sample concentration and volume is not reducing the retention. Du, Ke and Ito[9] demonstrated how high-sample concentrations and large injection volumes could reduce retention.

The Theory of Measuring Retention

Stationary phase retention cannot be measured directly and, hence, its determination relies upon the measurement of displaced volumes of stationary phase (V_E) from a CCC system and a number of assumptions. The basic equations for the measurement of retention are:

By definition:

$$S_f = \frac{V_S}{V_C}$$

and because $V_S = V_C - V_m$ giving

$$S_f = \frac{V_C - V_m}{V_C}$$

Therefore

$$S_f = 1 - \frac{V_m}{V_C} \tag{9}$$

The volume of stationary phase (V_E) displaced from a CCC system by the mobile phase is equal to the sum of entire retention extra-coil volume V_{ext} and a proportion of the column volume. The latter is equal to the volume of mobile phase in the column (V_m), hence

$$V_E = V_m + V_{ext} \tag{10}$$

Rearranging Eq. 10 gives:

$$V_m = V_E - V_{ext} \tag{11}$$

Substituting for V_m from Eq. 11 into Eq. 9 gives:

$$S_f = 1 - \frac{V_E - V_{ext}}{V_C} \tag{12}$$

These equations are underpinned by the following list of assumptions, and errors are inevitable if any of these are not met. These are

1. The coil volume (V_C) is accurately known.
2. The volume of the retention extra-coil volume (V_{ext}) is accurately known.
3. The system was initially completely filled with only stationary phase, i.e., no mobile phase and no air bubbles.
4. No air is introduced while retention of stationary phase is being measured.
5. The amount of stationary phase displaced from a column by the mobile phase is equal to the volume of mobile phase in the column (V_m).

6. The mobile phase displaces all of the stationary phase from the retention extra-coil volume (V_{ext}), i.e., V_1 and V_2 (Fig. 3), only contain mobile phase.
7. The set flow rates are accurate and consistent throughout an experiment.
8. The flow of the mobile phase is steady, i.e., free from flow pulses and pressure irregularities.

Measuring the retention a number of times under the same conditions does not guarantee accuracy, as systematic errors may be present. Systematic errors may be caused if a number of the above assumptions are not met. However, measurement techniques that reduce these errors are now available and are explained in the following sections.

Measuring Retention at Constant Rotational Speed

First of all, the CCC system is completely filled with stationary phase. The column is rotated at a set speed and the mobile phase is pumped through the system at the lowest intended flow rate. This causes stationary phase to be displaced from the entire extra-coil volume (V_{ext}) and a proportion of the column volume. Once stationary phase stops being displaced, dynamic equilibrium is reached, and the minimum value of V_E is obtained. The mobile-phase flow rate is then increased, causing more stationary phase to be displaced from only the column. When dynamic equilibrium has been reached again, the next value of V_E is acquired. This process is repeated until five or six sets of readings have been taken. Eq. 12 is then used to calculate the retention S_f, and the value of V_{ext} can be determined as described below in the section titled "Measuring the Retention Extra-Coil Volume." In the case of a J-type centrifuge, retention (S_f) is plotted against the square root of the mobile phase flow rate. Once this test is complete, the CCC system can be emptied and the accuracy of the retention measurements can then be checked, see section titled "Checking the Accuracy of Retention Measurements."

Measuring Retention at Constant Mobile Phase Flow Rate

The procedure is the same as the one given in the previous section, except that the flow rate is constant and the centrifuge is first rotated at its highest speed. After reaching dynamic equilibrium, a value of V_E is obtained. The rotational speed is then decreased, causing a larger value of V_E to be acquired when dynamic equilibrium is achieved. Retention S_f is plotted against rotational speed, see Fig. 4 of Ref.[10]

Measuring Retention During an Isocratic Separation

After filling with stationary phase, the column is rotated at the desired speed and the mobile phase is pumped through the system at the required flow rate. When dynamic equilibrium has been achieved, V_E can be measured as described above. The nature of some samples can reduce the retention and therefore increase the value of V_E after sample injection. If this occurs, the followings approaches can be applied:

1. Simply reject the sample and look for any further reductions in retention.
2. Reduce the sample volume and/or concentration.
3. Increase rotational speed and/or reduce the mobile phase flow rate.

Measuring the Retention Extra-Coil Volume

There are two approaches to determine the retention extra-coil volume. The first is to calculate the volumes V_1 and V_2 from Fig. 3, as previously discussed. The second approach is to use data from measuring retention at a constant rotational speed and different flow rates. For a J-type centrifuge, V_E is plotted against the square root of the mobile phase flow rate. V_{ext} is the intercept on the vertical axis[11] (Fig. 5). The values determined by both methods are compared to ensure that an accurate volume of V_{ext} has been determined. This volume can then be used for the accurate prediction of retention. This value of V_{ext} will be constant until the set up is modified. This technique can be adapted for other CCC devices provided that the mathematical relationship between retention and mobile phase flow rate is known.

Checking the Accuracy of Retention Measurements

After measuring the retention, or performing a separation, the CCC system is emptied. The sum of the volume of the stationary phase (V_S) and mobile phase (V_{mp} not V_m) should be compared with the total volume of the system (V_{SYS}). The latter is the sum of the column volume (V_C) and the retention extra-coil volume (V_{ext}). If the sum of V_S and V_{mp} is less than V_{SYS}, then the system has not been completely emptied. If the sum of V_S and V_{mp} is greater than V_{SYS}, then the volumes V_C and V_{ext} should be checked. Alternatively, additional volumes of mobile and/or stationary phase have been collected for some reason. If the sum of V_S and V_{mp} is approximately equal to V_{SYS}, then the following check should be conducted.

The volume of mobile phase emptied from a CCC system (V_{mp}) should be equal to the volume of mobile

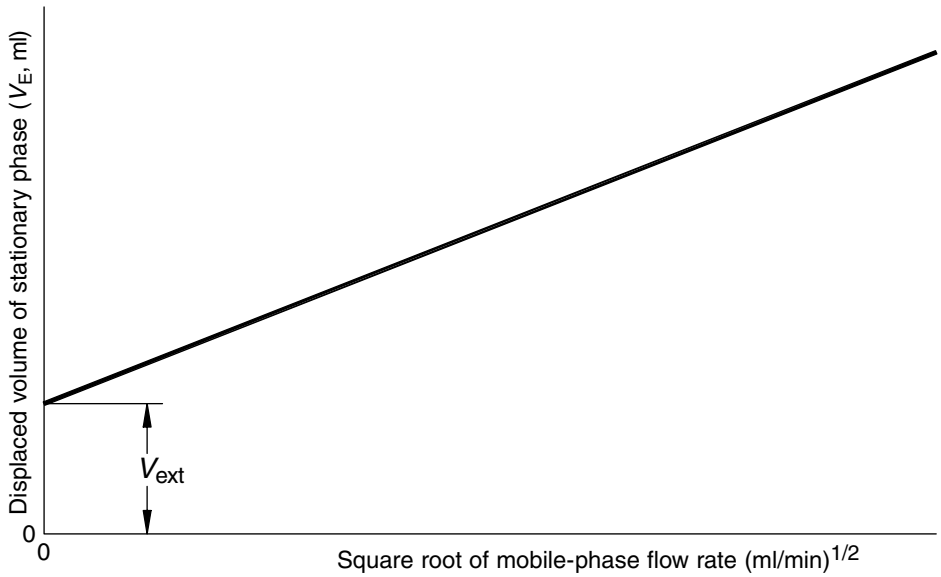

Fig. 5 The method of determining V_{ext} for a J-type centrifuge.
Source: From Determination of J-type centrifuge extra-coil volume using stationary phase retentions at differing flow rates, in J. Liq. Chromatogr. Relat. Technol.[11]

phase in the column (V_m) and the volume of mobile phase retained in the extra-coil volume (V_{ext}):

$$V_{mp} = V_m + V_{ext} \quad (13)$$

This can be rearranged to give

$$V_m = V_{mp} - V_{ext} \quad (14)$$

Substituting Eq. 14 for V_m into Eq. 10 gives:

$$V_E = V_{mp} - V_{ext} + V_{ext}$$

$$V_E = V_{mp} \quad (15)$$

The difference between these volumes determines the accuracy of the retention measurements.

COMMON ERRORS WHEN MEASURING RETENTION

The following is a list of possible errors in measuring retention and the effect on the measurement is explained:

1. Incorrect column volume (V_C). This error is because of the supplier or manufacturer not measuring this volume accurately. The process of winding a column can make the inner bore slightly oval, reducing the volume below that calculated using the original internal diameter.
2. Incorrect estimation of extra-coil volumes. In the section "Measuring the Retention Extra-coil Volume," it is shown how the calculations to estimate V_{ext} can be checked. Once this check has been conducted, it is quite simple to correct the calculated volume of V_{Cext}, if necessary.
3. If the errors in V_C and V_{ext} do not cancel out, the system volume will be incorrect. If this figure is too low, the system may not be completely emptied after a test, possibly leaving mobile phase in the column, see the next point.
4. If, at the start of a test, the column is not completely empty of mobile phase and this phase is not then completely displaced by filling with stationary phase, the readings of V_E will be too low, causing the value of S_f to be higher than it should be. This error is detected when the measured volume of V_{ext} is lower than previous measurements; see the section titled "Measuring the Retention Extra-coil Volume."
5. When a number of measuring cylinders are used to collect the displaced stationary phase. The error in determining the value of V_E will be the sum of reading errors from each measuring cylinder. Collecting the stationary phase in one large measuring cylinder with a suitably fine scale can reduce this error. Alternatively, when the lighter phase is used as the mobile phase, a measuring cylinder or burette can be fitted with a spout, see Fig. 1 of Ref.[12] This enables the lighter mobile phase to flow out of the spout and the denser stationary phase (V_E) is collected at the bottom.

6. Fluctuations in rotational speed of a CCC centrifuge will cause the retention to change, thereby causing errors. To reduce, and perhaps remove, this source of error, the manufacturers of CCC equipment should provide a better control of the set rotational speed.
7. Single head HPLC pumps create an unsteady flow with regular pulses, which, at best, reduces the retention achievable but, at worst, is a source of errors. Twin headed pumps that create a pulse free steady flow should be used.
8. The mobile phase flow rate should be checked to ensure that the set flow is being accurately delivered. Errors in the flow can be attributed to siphoning, incorrect operation of the one-way check valves in the pump heads or worn seals. Fitting a backpressure regulator downstream of the column stops siphoning and will force the one-way check valves to operate correctly.
9. At the higher mobile phase flow rates now being used to perform retention tests[12] and separations,[13] the mobile phase appears cloudy because of the stationary phase still being suspended in the mobile phase. There is often enough suspended stationary phase to cause errors in determining the retention.
10. The formation of small gas bubbles within the CCC system causes errors, even when a backpressure regulator is applied. Using degassed solvents reduces this error.

INCREASING RETENTION TO INCREASE RESOLUTION

Resolution is a measure of how well two adjacent peaks are separated from each other. For symmetrical peaks, the resolution is the difference in the elution times between the peaks divided by half of the sum of the peak widths. For the example shown in Fig. 4, the resolution is

$$R_S = \frac{2(t_b - t_a)}{W_a + W_b} \tag{16}$$

Either reducing the mobile phase flow rate or increasing rotational speed will provide a higher retention. The higher the retention, the longer the periods of time between the elution of successive peaks. This increases the value of the numerator of Eq. 16, thereby increasing the resolution. This can be further demonstrated by adapting Eq. 1 for three components with distribution ratios of 0, 1, and 2 to give:

Table 1 The elution times for all three peaks in all three separations.

	Elution times (min)		
Distribution ratio	$F = 1$ ml/min, $S_f = 0.5$	$F = 1$ ml/min, $S_f = 0.64$	$F = 0.5$ ml/min, $S_f = 0.64$
$D = 0$	5	3.5	7.1
$D = 1$	10	10	20
$D = 2$	15	16.5	32.9

when $D = 0$, then

$$t_0 = \frac{V_C(1 - S_f)}{F} \tag{17}$$

when $D = 1$, then

$$t_1 = \frac{V_C}{F} \tag{18}$$

when $D = 2$, then

$$t_2 = \frac{V_C(S_f + 1)}{F} \tag{19}$$

Consider a CCC device with a 10 ml column volume (V_C) used to separate these three components. This separation is repeated three times: the first with the rotational speed set to give a retention (S_f) of 0.5 and a mobile flow rate (F) of 1 ml/min, the second at a higher rotational speed where the retention has increased to 0.64 and a 1 ml/min flow rate and, finally, at the original rotational speed, but with a 0.5 ml/min flow rate to give a retention of 0.64.

As can be seen from Table 1, the elution times and the interval between peak elution have changed, in turn varying the resolution. However, the resolution cannot yet be predicted owing to the effects of flow rate and rotational speed on peak widths, which are not fully understood. Currently, an empirical approach is required when aiming to improve resolution using the approaches described above.

PEAK BROADENING WHEN ELUTING

Asymmetric peaks, similar to those in Fig. 6, are often observed in separations performed using CCC devices. The main reason for this is the higher retention of stationary phase in comparison to HPLC columns. The

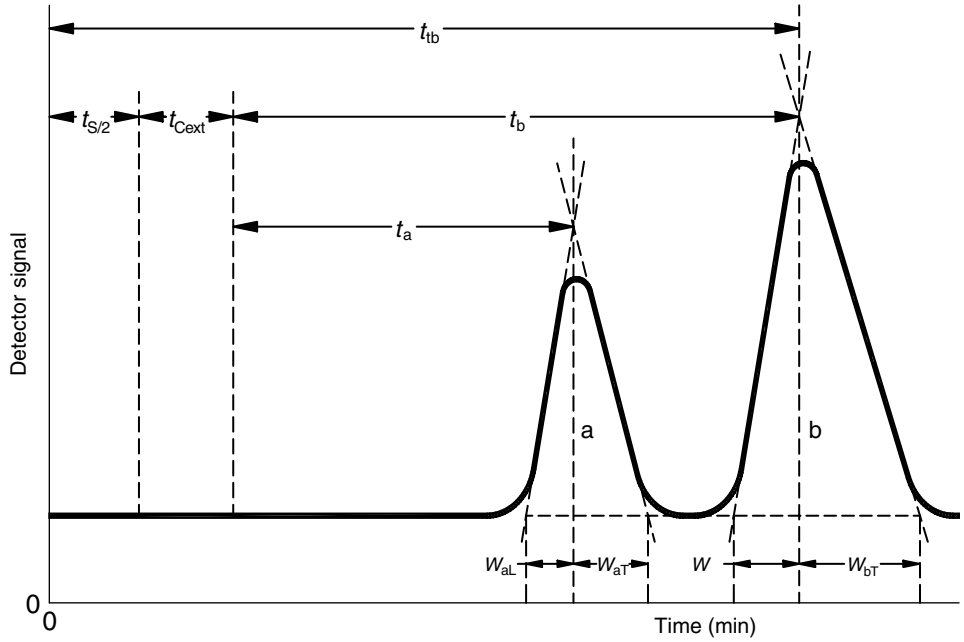

Fig. 6 Asymmetric peaks caused by a combination of high retention, sample volume, and sample concentration.

software developed by Sutherland, De Folter, and Wood[7] demonstrates the formation of asymmetric peaks. High concentration of samples, larger sample volumes, and higher distribution ratio (D) also increase the asymmetry of peaks. The leading edge of a peak elutes from the column, as a symmetrical peak would do. However, the tailing edge takes much longer to elute because most of the material is still dissolved in the stationary phase.[14] In Figs. 1 and 2, only a limited amount of asymmetry is shown, even though the S_f was 86%,[6] because the D values of benzyl alcohol and *p*-cresol were 0.4 and 0.7, respectively, in the phase system used and the sample concentration was too low.

Taking into account the asymmetry of peaks the formula for resolution (Eq. 16) needs to be modified. Let an L denote leading edges and a T denote tailing edges in Fig. 6. Therefore, the modified equation for resolution is

$$R_S = \frac{t_b - t_b}{W_{aT} + W_{bL}} \tag{20}$$

CONCLUSIONS

The theory and results presented herein have shown how the knowledge of both stationary phase retention and peak elution has been recently developed. The challenge still facing CCC is to understand the controlling influences on mass transfer and peak width. Such knowledge will allow the user to predict resolution and control a separation to match requirements.

Stationary Phases for Packed Column SFC

Stephen L. Secreast
Pharmaceutical Sciences, Pharmacia Corporation, Kalamazoo, Michigan, U.S.A.

INTRODUCTION

The name, packed column supercritical fluid chromatography (pSFC), has been applied to separations performed on particulate stationary phases, using mobile phases pressurized to supercritical, near-critical, or subcritical conditions.[1,2] Typically, the stationary phases used for pSFC are commercially available high-performance liquid chromatography (HPLC) columns, consisting of a porous solid support, usually with a covalently linked bonded phase to provide desired chromatographic interactions. Various column configurations have been used. Separate consideration of supercritical, near-critical, and subcritical pSFC applications provides a convenient, although arbitrary, means of subgrouping a discussion of the types of stationary phase used. More specific information on the stationary phases discussed in this overview can be found in Refs.[1–4]

SUPERCRITICAL APPLICATIONS

Supercritical pSFC applications can be defined as those in which the mobile phase is a single substance heated and pressurized above its critical point. Carbon dioxide has overwhelmingly been the compound of choice for these mobile phases. Stationary phases typically used for these applications have been polymeric materials or polymer-coated porous silica. Chromatography on uncoated silica-based stationary phases with CO_2 has, in general, been unsuccessful.

Polystyrene–divinyl benzene beads are the most common polymer material phases reported. The successful use of these phases has been mainly limited, however, to relatively hydrophobic compounds. Also, problems associated with bead physical instability, such as shrinking and swelling, affecting chromatographic reproducibility, have also been encountered. Stationary phases consisting of porous silica coated with a covalently bonded polysiloxane layer, containing cyano, phenyl, or alkyl functional groups, have been used with more success. The polymer coating is applied to the silica to mask excessive analyte–stationary phase polar interactions that generate poor peak shapes and yield incomplete analyte recovery with the neat CO_2 mobile phase. As with the polymer materials, these phases work best for hydrophobic compounds such as petroleum-based compounds, lipids, and plastics additives. The apparent degree of silica deactivation obtained with the polymer coating is insufficient to provide quality CO_2 chromatography for polar compounds. An example of plastic additives chromatography obtained with CO_2 on a polymer-coated stationary phase is shown in Fig. 1.[5]

Recently, interest in polymer-coated silica phases has been renewed, with investigators (Chen and Lee[2]) exploring the use of more efficient deactivation techniques and more polar polymers to coat silica particles for neat CO_2 chromatography. Polyethyleneimine-coated silica and amino-terminated polyethylene oxide-coated silica appear promising for pSFC of moderately polar basic compounds. Similarly, hydroxy-terminated polyethylene-oxide-coated silica has been used successfully for pSFC of alcohols and acids. Optimization and commercial production of these stationary phases could significantly extend the polarity range of compounds that can be chromatographed with neat supercritical CO_2.

NEAR-CRITICAL APPLICATIONS

Near-critical pSFC applications can be described as those where the mobile phase is solvent-modified CO_2, pressurized only enough to maintain a single phase, with temperatures near (typically less than) the critical temperature. Many commercially available HPLC bonded silica phases have been used with modified-CO_2 mobile phases to achieve normal-phase separations, the choice of stationary phase being dictated by sample polarity. The modifiers added to CO_2 acceptably overcome the unwanted analyte–silica interactions observed with neat CO_2 mobile phases. For structural separation of polar compounds such as pharmaceuticals [typically weak acids or bases of molecular weight (MW) < 1000], polar phases such as diol-, amino-, and cyano-bonded silica (or bare silica) are used. Numerous applications for pharmaceutical, natural product, environmental and other compound classes have been reported in the recent literature (reviewed in Refs.[1,2]). For structural separation of higher-molecular-weight, less polar compounds, octyl- or octadecyl silane (ODS)-bonded phases are used (Berger[1] and Lesellier and Tchapla[2]). The reported applications include stationary-phase columns obtained from many different commercial manufacturers, covering almost the complete range of packing particle size and pore size.

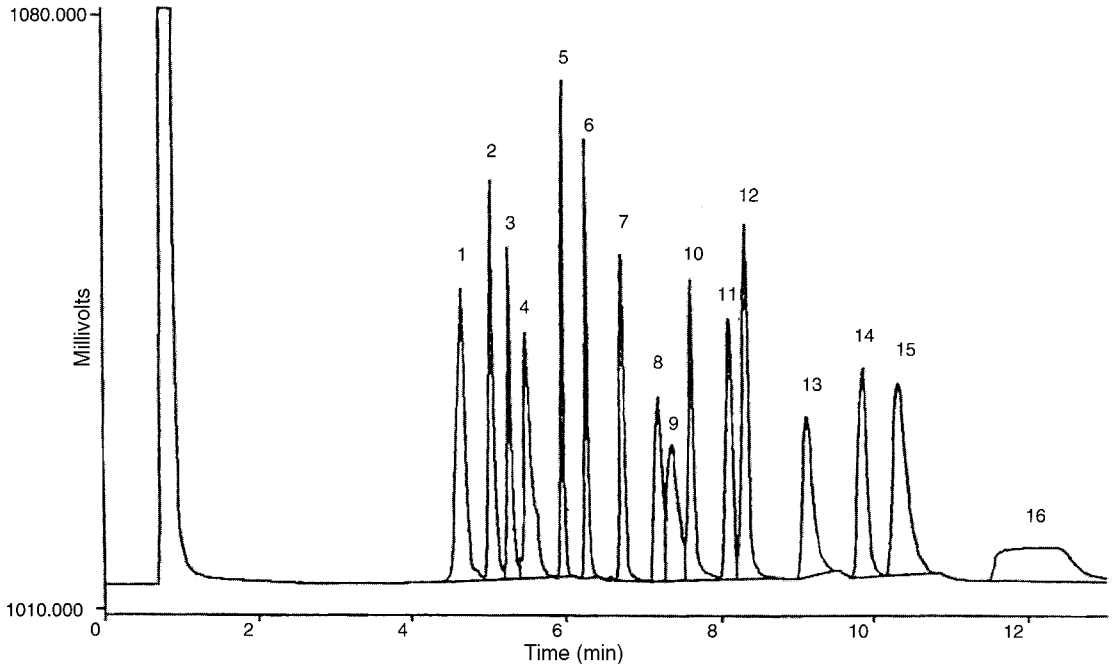

Fig. 1 Use of polymer-coated silica stationary phase with a neat carbon dioxide mobile phase. Column: Deltabond SFC Methyl (150 × 2.0 mm); mobile phase: CO_2; pressure gradient: 75 bar initial for 2 min, then 50 bar/min ramp to 180 bar, then 15 bar/min ramp to 300 bar; flow: 0.5 ml/min; temperature: 100°C; injection: 5 μl; detection: flame ionization detector; sample solvent: methylene chloride. Peak key: 1, BHT; 2, dimethyl azelate; 3, triethyl citrate; 4, tributyl phosphate; 5, methyl palmitate; 6, methyl stearate; 7, diethylhexyl phthalate; 8, Tinuvin 327; 9, Spectra-Sorb UV531; 10, tri(2-ethylhexyl) trimellitate; 11, dilauryl thiodipropionate; 12, Irganox 1076; 13, 1,3-diolein; 14, distearyl thiodipropionate; 15, Ionox 330; 16, Irganox 1010.

Modified-CO_2 mobile phases excel at stereochemical separations, more often than not outperforming traditional HPLC mobile phases. For the separation of diastereomers, silica, diol-bonded silica, graphitic carbon, and chiral stationary phases have all been successfully employed. For enantiomer separations, the derivatized polysaccharide, silica-based Chiralcel and Chiralpak chiral stationary phases (CSPs) have been most used, with many applications, particularly in pharmaceutical analysis, readily found in the recent literature (reviewed in Refs.[1,2]). To a lesser extent, applications employing Pirkle brush-type, cyclodextrin and antibiotic CSPs have also been described. In addition, the use of silica and graphitic carbon stationary phases with chiral modifiers added to the CO_2 mobile phase has been reported.

A major advantage of modified-CO_2 pSFC is that due to the low pressure and similarity of the mobile phases used for structural and stereochemical separations, multiple stationary-phase columns can be connected in series, generating separations not achievable by other chromatographic methods. Multiple columns of the same phase have been serially connected to provide significantly amplified chromatographic efficiencies.[1] A recent example chromatogram obtained by connecting four 250 × 4.6 mm Chiralpak AD columns in series is shown in Fig. 2.[6] With the four columns in series, concurrent separation of the four stereoisomers of each of two structurally different compounds was achieved.

Serial connection of different stationary phases provides some very interesting separations. The combination of different CSPs provides systems capable of resolving a wide range of enantiomers (Sandra et al.,[2] Gyllenhaal[2]). Recent applications combining normal-phase bonded-silica (diol, cyano, amino) columns with CSPs in series, to provide concurrent structural and stereochemical separations, have been described (Phinney,[4] Kline and Matuszewski,[4] and Williams et al.[4]). An example of chromatography obtained for a pharmaceutical compound and its degradants by connecting a Zorbax SB cyano column and three Chiralpak AD columns in series is shown in Fig. 3.[7] The cyano column provides the structural separation of the parent compound and the two degradants, and the Chiralpak columns provide concurrent enantiomer separations for the two degradants. The ability to combine different or multiple traditional HPLC stationary phases to generate unique separations is a hallmark of modified-CO_2 pSFC.

SUBCRITICAL APPLICATIONS

Recent work describing the use of subcritical water as a chromatographic mobile phase has been reported. Water heated to 100–200°C, pressurized to 20–50 bar, can be used as a reversed-phase chromatography eluant. This application exists somewhere in the boundary region

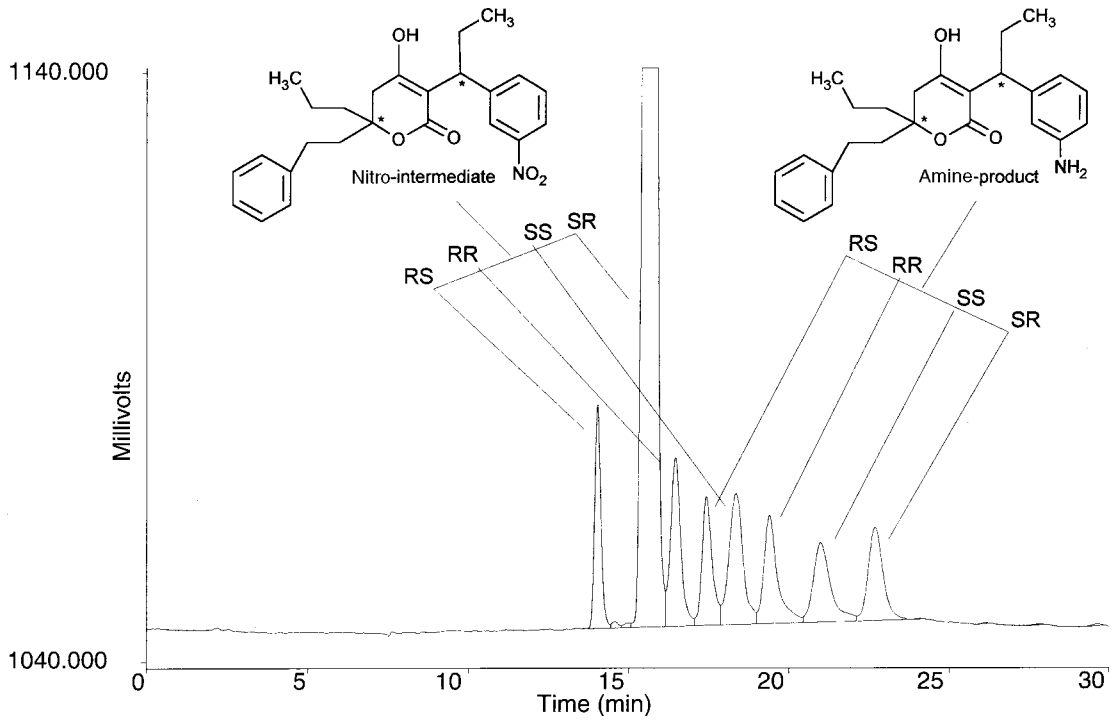

Fig. 2 Use of multiple columns (same stationary phase) in series to improve chromatographic efficiency. Columns: four Chiralpak AD (5 μm, 250 × 4.6 mm) in series; mobile phase: CO_2 with modifier gradient; modifier: ethanol–methanol–isopropylamine (50:50:0.5); gradient: 20% modifier for 2 min, then 1%/min ramp to 35%; flow: 2.0 ml/min; pressure: 150 bar; temperature: 35°C; injection: 5 μl; detection: UV 210 nm; sample solvent: methanol.

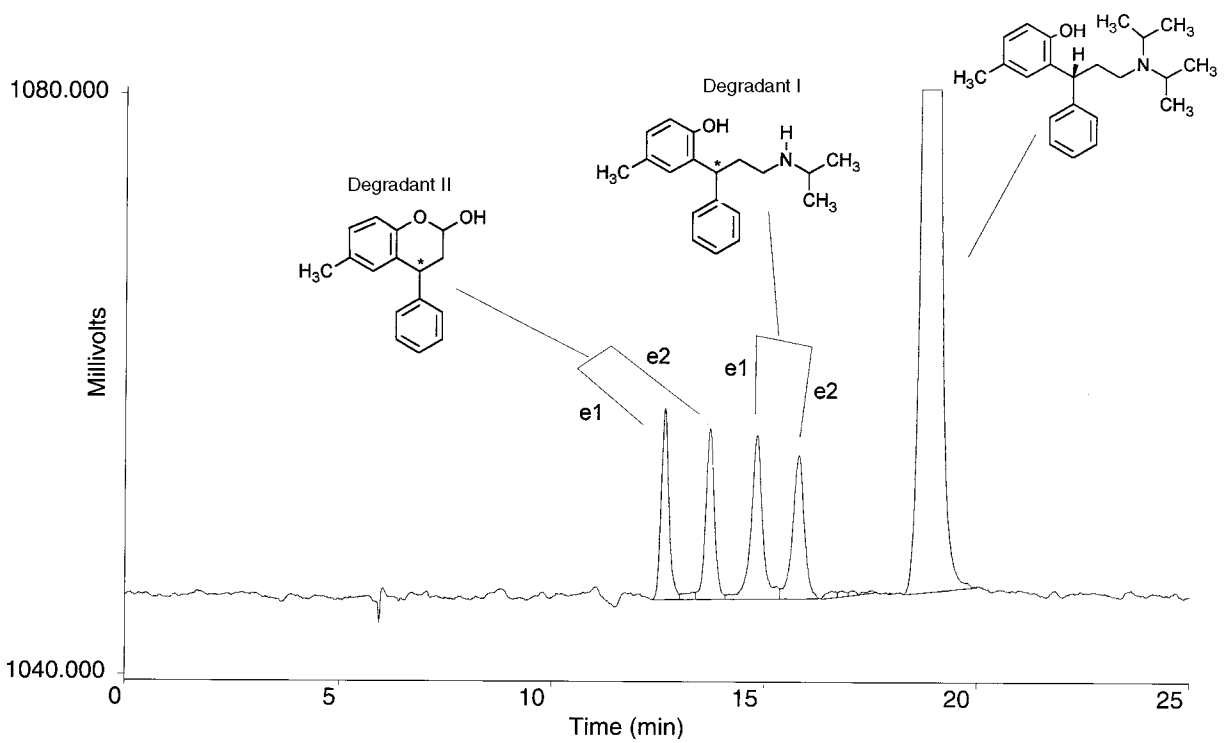

Fig. 3 Use of multiple columns in series (achiral and chiral stationary phases) to provide mixed-mode selectivity. Columns: Zorbax SB CN (5 μm, 250 × 4.6 mm) plus three Chiralpak AD (5 μm, 250 × 4.6 mm) in series; mobile phase: CO_2–methanol (containing 0.5% isopropylamine) (85:15); flow: 2.0 ml/min; pressure: 150 bar; temperature: 35°C; injection: 5 μl; detection: UV 220 nm; sample solvent: methanol.

between pSFC and HPLC. Stationary phases that have been used successfully for subcritical (or superheated) water chromatography include polystyrene–divinyl benzene beads,[8,9] ODS silica,[8,10] porous graphitic carbon,[11] and polybutadienecoated zirconia.[11] Of these phases, relatively rapid performance deterioration was reported for the ODS silica materials,[11] presumably due to silica solubility. As research in this area increases, undoubtedly so will the number of identified suitable stationary phases.

CONCLUSIONS

Packed column SFC stationary phases are very similar or identical to those used for HPLC. With neat CO_2 mobile phases, polymer or polymer-coated silica stationary phases have typically been used. With modified-CO_2 mobile phases, bonded-phase silica columns are typically used. For structural separations, diol, amino, or cyano stationary phases are most often used. For stereochemical separations, derivatized polysaccharide-bonded silica columns are most often the stationary phases of choice. A powerful feature of modified-CO_2 pSFC is the ability to serially connect different stationary phases to obtain enhanced or multiple mechanism separations. With subcritical (super heated) water mobile phases, the use of polymer, porous graphitic carbon, and polymer-coated zirconia stationary phases has been described.

Stationary Phases: Reverse-Phase

Joseph J. Pesek
Maria T. Matyska
Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

The primary purpose for the developement of chemically modified stationary phases was to provide a separation medium that was suited to the type(s) of solute present in the mixture to be analyzed. Historically, silica gel was the most common material used in the early development of column liquid chromatography (LC). However, silica is a polar material that contains hydroxyl groups (silanols) that are both acidic and strongly hydrogen-bonding in character. These properties make it unsuitable as a stationary phase for many typical organic molecules that are predominantly hydrophobic compounds. In addition, the silanols interact strongly with basic compounds leading to poor chromatographic results.

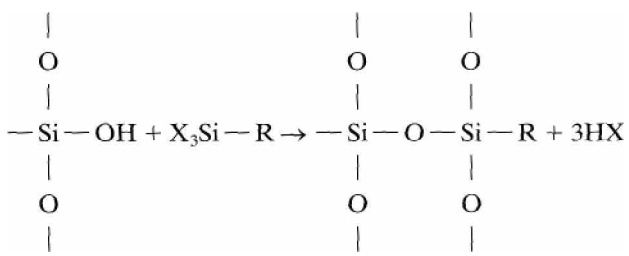
DISCUSSION

In order to overcome these undesirable effects of silica and to have a medium more suitable for the separation of a large variety of organic compounds, modification of the surface is necessary to provide a more non-polar (hydrophobic) material. It is advantageous to retain silica as the primary material in the column because it possess physical and mechanical properties that make it particularly useful for modern liquid chromatography [i.e., the use of high-pressure liquid chromatography (HPLC) to force the mobile phase and sample through the system at a reasonable flow rate].

The desirable characteristics of silica are as follows: high mechanical strength, a narrow range of particle diameters, a variety of pore sizes, a broad range of surface areas, and the ability to be modified either chemically or physically by adsorption. It is the latter property (i.e., the ability for modification) that makes silica particularly useful as a separation medium in chromatography. Although physical adsorption has been used occasionally to modify silica surfaces for chromatographic purposes, its usefulness is limited because of the nature of modern HPLC. The use of high pressure creates shear forces at the stationary phase–mobile phase interface so that the absorbed moiety is removed from the silica surface even though the coating may be insoluble in the liquid being pumped through the column. Therefore, chemical modification is the only practical approach to modifying the silica surface in order to create a stationary phase that is compatible with the types of solutes to be separated. The most common method for modifying silica in order to produce a hydrophobic surface is organosilanization. Two types of reaction are available by this method. The first alternative is referred to as a monomeric approach:

$$\equiv Si - OH + X - SiR'_2R \rightarrow \equiv Si - O - SiR'_2 + HX$$

Here, the organosilane reagent is composed of a reactive group, X, which can be a halide, usually chloride, methoxy, or ethoxy; R′ is one of two small organic groüps usually methyl, and R is the main group that gives the surface its hydrophobic properties. The end result is a single point of attachment between the organosilane reagent and the surface. The second alternative shown in the following reaction is referred to as the polymeric approach for bonding



In this case, the organosilane reagent is composed of three reactive groups; X is as described earlier and R is the main organic group that provides the hydrophobic properties to the surface. Here, the end result is that the bonded phase is attached to the surface at one point and cross-linked to neighboring bonded organosilanes through a siloxane linkage. Both of these synthetic routes are used in the production of commercially available stationary phases for HPLC. The monomeric approach generally is more reproducible from batch to batch, whereas the polymeric approach leads to higher bonding densities (more R groups per unit surface area) and some additional stability due to the multiple sites of attachment.

In both types of reactions, it is the R group that determines the overall characteristics of the surface if there is a resonable bonding denisity as measured in terms of micromoles per square meter. There must be a significant number of organic moieties per unit surface area so that most of the silica is covered by the R groups and relatively few of

the siloxane and silanols are accessible. Under these conditions, when the organic moiety is hydrophobic, non-polar solutes will be selectively retained by the stationary phase. Even in the case where the bonding density is reasonably high, there is still the possibility that some silanols may be accessible to solutes. This is mainly a problem when the analytes are strongly basic compounds. In order to diminish the effect of unreacted silanols on the surface or those that can be created in the polymeric reaction process when complete cross-linking does not take place, a secondary reaction involving a small reactive organosilane can be used. Typically, this reagent is trimethylchlorosilane, a compound with one reactive group and three small organic moieties. This compound is small enough to fit into the larger spaces between bonded hydrophobic groups so that access to the surface will be even more limited for typical solutes. The process of bonding a small moiety to diminish the number of accessible silanols is referred to as "endcapping." Many commercial sources will often designate whether or not a particular bonded phase has been endcapped. The presence or absence of endcapping will determine the nature of the stationary phase surface and, hence, its retention characteristics.

However, it is still the main R group that controls the overall degree of hydrophobicity of the surface. Within this context, the predominant factors in determining the hydophobicity are the length of the alkyl chain or the total number of carbon atoms as well as the bonding density. Some examples of various alkyl groups that have been used as reversed-phase (RP) materials are shown in Table 1. The most common types of these phases are designated by where n is the number of carbon atoms for bonded linear alkyl hydrocarbon moieties. The simplest case is where $n = 1$ for the methylbonded phase (C_1). This material has the lowest degree of hydrophobicity and provides limited retention for most small organic molecules. However, for large biomolecules such as proteins and peptides that can have extensive hydrophobic regions as part of their three-dimensional structure, these phases can prove useful in limiting the strong interactions, leading to excessively long retention times for these compounds. As the degree of hydrophobicity decreases for these large species (i.e., the macromolecule has larger hydrophilic regions or the hydrophobic areas are buried within the three-dimensional structure), the stationary phase will have to become more non-polar. This is accomplished by extending the chain length of the bonded alkyl group. Hence, the C_2 and C_4 phases have been developed to accomplish this purpose. In general, the bonded phases C_1, C_2, and have been used for separations of large molecules. In order to develop more hydrophobic interactions, the next most common phase utilizes the octyl-bonded moiety (C_8). At relatively high bonding densities (3–4 $\mu mol/m^2$), a wide range of compounds can be separated in the reversed-phase mode with this bonded moiety. Although applications involving large molecules are readily found in the literature, the predominant use involves the separation of typical small [molecular weight (MW) < 500] organic compounds. The most common reversed-phased material contains the octadecyl moiety ($n = 18$) as the bonded group. Although there are reports of phases in the literature with n values between 8 and 18, these are relatively uncommon and have not found widespread use or commercial development. The C_{18}-bonded phase was the separation material used in most of the early development of HPLC; therefore, there are several decades of applications documented in the literature. It is still by far the most often used bonded material in reversed-phase HPLC and is available in a wide variety of forms (type of silica, pore size, surface area, monomeric, polymeric, endcapped, non-endcapped, etc.) from more than 100 commercial sources. Although small organic molecules account for the majority of applications, its early commercial availability and its role in the development of HPLC has lead to examples of separations involving a broad range of compounds, including ionic species, polar compounds, biomolecules, fatty acids, and diastereomers. Because most laboratories with HPLC equipment will have a C_{18} column available, and sometimes the only one on hand, it is the first choice for initial experiments. In addition, with the broad range of applications accessilble in the literature or from commercial sources, it is often easy to find a separation that is similar, allowing for selection of mobile-phase conditions that are likely to be suitable for solving a particular analytical problem.

As shown in Table 1, a number of other bonded groups have also found use in reversed-phase HPLC. Theoretically, there is no limit to the value of n for bonded alkyl groups. However, until recently, there has been little interest in phases longer than 18 carbons. Some recent studies have demonstrated interesting applications for the C_{30} phase so that its use as well as materials with alkyl chain lengths between 18 and 30 might become more common. phenyl-bonded group (with alkyl chains attaching it to the surface of various lengths) can also function in the reversed-phase mode. The possibility of utilizing $\pi - \pi$ interactions or charge-transfer effects with the phenyl phase leads to a different selectivity than the solely hydrophobic intereactions that are available from the common alkyl-bonded materials. A similar reasoning can be applied

Table 1 Bonded hydrophobic groups.

Methyl	$-CH_3$
Ethyl	$-CH_2CH_3$
Butyl	$-CH_2-(CH_2)_2-CH_3$
Octyl	$CH_2-(CH_2)_6-CH_3$
Octadecyl	$-CH_2-(CH_2)_{16}-CH_3$
Triacontyl	$-CH_2-(CH_2)_{28}-CH_3$
Phenyl	Perfluoro	$-CH_2-(CF_2)_x-CF_3$

for the phases where F is substituted for H in the bonded organic group.

Although the vast majority of stationary phases for RP/HPLC are based on chemically modified silica, there are a few other supports that have been investigated and some which are available commercially. Although silica has many advantages, its main limitation is the pH range over which it is stable. Depending on the type of silica, bonding method, and surface coverage, most chemically modified silicas are useful from pH 2 to 8. Outside of this range, most materials will experience some type of accelerated degradation. One solution to this problem is to substitute an oxide with a greater pH stability than silica. Some possibilities include alumina, zirconia, and titania, which can all be fabricated in particles with properties similar to those of silica (size, porosity, and surface area) as well as having hydroxide groups on the surface that can be used for chemical modification. Another approach is to use polymeric materials as supports in RP/HPLC. Polymers can be formed into beads similar to oxide particles, can be chemically modified to contain various organic functional groups to control their chromatographic properties, and can possess pH stability in strong acids and bases. If such modification or the basic structure of the polymer is hydrophobic, then these materials can be used in the reversed-phase mode. The main disadvantage to many polymeric materials is that they often expand or contract in various mobile-phase compositions, leading to non-reproducible chromatographic performance. Despite the potential pH advantages of these alternative supports, they have not been extensively exploited because of the long-term use of silica in the development of chemically bonded stationary phases and the limited number of applications where either very acidic or basic eluents are an absolute necessity.

The structure of the alkyl-bonded moiety on the support surface has been the subject of many investigations. A variety of spectroscopic and chromatographic methods have been employed to determine the configuration of various bonded organic groups (although the vast majority of studies have been on) in order to understand the mechanism of separation for typical solutes. There are many variables to be considered in these investigations, which include type of bonded group, bonding density, and the nature of the support surface. Some studies involve the presence of solvents to mimic the mobile phase, whereas others utilize the bonded material in the absence of any liquids. Despite these differences, some generalizations can be made about the structure of typical bonded phases in the presence of water–organic solvents, as illustrated in Fig. 1. At low concentrations of an organic constituent (A), the environment around the bonded moiety is polar and the hydrophobic chains tend to collapse on each other in order to minimize their exposure to the surronding solvent. As the percent of organic in the liquid around the bonded group increases (B → C), the medium is less polar and the groups are no longer strongly associated with each other. Although reversed-phase bonded materials have been availabe for many years, there is continued development to improve their chromatographic performance and to develop new phases for specialized applications.

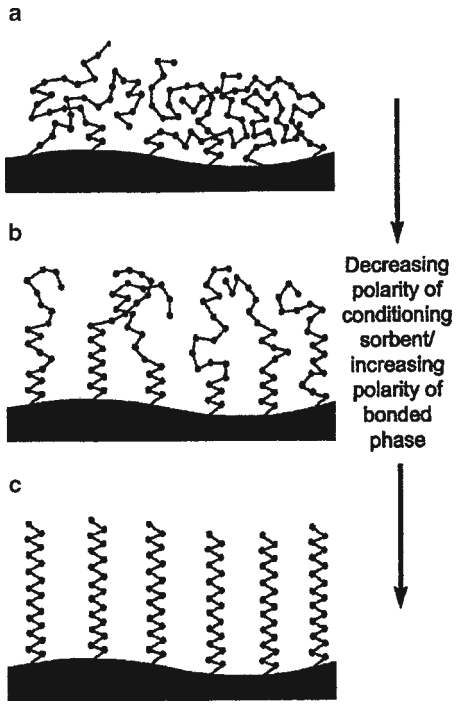

Fig. 1 Structure of a bonded phase as a function of polarity of a mobile phase: (a) highly polar mobile phase; (b) intermediate polarity mobile phase; (c) low-polarity mobile phase.

Steroidal Alkaloid Glycosides: TLC Immunostaining

Waraporn Putalun
Hiroyuki Tanaka
Yukihiro Shoyama
Graduate School of Pharmaceutical Sciences, Kyushu University, Fukuoka, Japan

INTRODUCTION

The immunoassay system using monoclonal antibodies (MAbs) is indispensable to biological investigations. However, because this was rare for naturally occurring bioactive compounds having small molecular weights, we have prepared the MAbs and established assay systems using enzyme-linked immunosorbent assay (ELISA) for forskolin,[1] marijuana compound,[2] opium alkaloids,[3] solamargine,[4] ginsenoside Rbl,[5] crocin,[6] and glycyrrhizin.[7] Furthermore, the Western blotting method against ginseng saponins[8] and glycyrrhizin[9] have been established for the search of natural resources and for the breeding project of medicinal plants.

The natural resources of adrenocortical and sex hormones, which have been mainly supplied by diosgenin, are becoming rare in the world. The most important feature of solasodine is that it can be converted to dehydropregnenolone. Therefore, the steroidal alkaloid glycosides of solasodine type, such as solamargine, have become important as a starting material for the production of steroidal hormones. Rapid, simple, highly sensitive and reproducible assay systems are required for a large number of plants and a limited, small amount of samples, in order to select the strain of higher yielding steroidal alkaloid glycosides.

We present, here, a simple determination method for solasodine glycosides by using thin-layer chromatography (TLC)–immunostaining.

MATERIALS AND METHODS

Chemicals and Immunochemicals

Bovine serum albumin (BSA) and human serum albumin (HSA) were provided by Pierce (Rockford, Illinois, U.S.A.). Peroxidase-labeled anti-mouse IgG was provided from Organon Teknika Cappel Pruducts (West Chester, Pennsylvania, U.S.A.). Polyvinylidene difluoride (PVDF) membranes (Immobilon-N) were purchased from Millipore Corporation (Bedford, Massachusetts, U.S.A.). A glass microfiber filter sheet (GF/A) was purchased from Whatman International Ltd. (Maidstone, U.K.). All other chemicals were standard commercial products of analytical grade.

Solamargine and solasonine were isolated from fresh fruits of *S. khasianum* as previously described.[10] Solasodine was obtained from solamargine by acid hydrolysis as previously described.[10] Solamargine (1 mg) was dissolved in MeOH containing 1*M* HCl (1 ml). The mixture was heated at 70°C for 10, 20, 30, 60, and 90 min, respectively. Individual hydrolysates were evaporated *in vacuo* and applied to TLC. Spots developed on TLC were determined by and Dragendorff reagent.

TLC

Solasodine glycosides were applied to TLC plates and developed with chloroform–methanol–ammonia solution (7 : 2.5 : 1). A developed TLC plate was dried and then sprayed with blotting solution mixture of isopropanol–methanol–water (5 : 20 : 40, by volume). It was placed on a stainless-steel plate, then covered with a PVDF membrane sheet. After covering with a glass microfiber filter sheet, the whole plate was pressed evenly for 45 sec with a 130°C iron, as previously described,[11] but with a modification. The PVDF membrane was separated from the plate and dried.

Immunostaining of Solasodine Glycosides on PVDF Membrane

The blotted PVDF membrane was dipped in water containing $NaIO_4$ (10 mg/ml) under stirring at room temperature for 1 h. After washing with water, 50 m*M* carbonate buffer solution (pH 9.6) containing BSA (1%) was added and stirred at room temperature for 3 hr. The PVDF membrane was washed twice with phosphate buffer solution containing 0.05% of Tween 20 for 5 min, and then washed with water. The PVDF membrane was immersed in anti-solamargine MAb and stirred at room temperature for 1 hr. After washing the PVDF membrane twice with TPBS and water, a 1000 times dilution of peroxidase-labeled goat antimouse IgG in phosphate buffer solution containing 0.2% gelatin (GPBS) was added and stirred at room temperature for 1 hr. The PVDF membrane was washed twice with TPBS and water, then exposed to 1 mg/ml 4-chloro-l-naphthol–0.03% H_2O_2 in PBS solution which was freshly prepared before use for 10 min at room

temperature, and the reaction was stopped by washing with water. The immunostained PVDF membrane was allowed to dry.

RESULTS AND DISCUSSION

After solasodine glycosides were transfered to the PVDF membrane sheet from the TLC plate by heating as previously reported,[11] the PVDF membrane was treated with $NaIO_4$ solution, followed by conjugation with BSA, because solasodine glycosides on PVDF membrane are washed out by buffer solution or water without the formation of conjugate with carrier protein. The PVDF membrane was immersed in antisolamargine MAb and then peroxidase-labeled secondary MAb. When the substrate and were added, clear blue spots appeared.

Fig. 1 shows the immunostaining of acid hydrolysis products of solamargine hydrolyzed by 1*M* HCI for 10, 20, 30, and 60 min, respectively. Individual hydrolysates were applied to three TLC plates, then developed with a $CHCl_3$–MeOH–NH_4OH solvent system. Two plates were sprayed and colored with H_2SO_4. Fig. 1 shows the immunostaining (a) and stainings by H_2SO_4 (b) and Dragendorff reagent (c). When the staining sensitivities of the three methods were compared, the immunostaining was the highest, followed by the H_2SO_4, then Dragendorff reagent. It is easily suggested that product 1 may be aglycone of solamargine, solasodine and products 2–4 might be solasodine monoglycosides and diglycosides. Therefore, products 1–4 were identified as solasodine, 3-*O*-β-D-glucopyranosyl-solasodine, *O*-α-L-rhamnosyl-(1 → 4)-3-*O*-β-D-glucopyranosyl-solasodine and *O*-α-L-rhamnosyl-(1 → 2)-3-*O*-β-D-glucopyranosyl-solasodine,respectively, by direct comparison with authentic samples. Compared with two stainings between immunostaining (Fig. 1a) and staining (Fig. 1b), solasodine was not detected by immunostaining despite 44% of cross-reactivity;[4] the sugar moiety was necessary in this staining process. Thus, we separated two functions, the sugar moiety of solasodine glycosides conjugates to the membrane via Schiff base and an aglycone part which is stained by MAb.

Fig. 2 shows the immunostaining and H_2SO_4 staining of the crude extracts of *Solanum* species fruits which contain the higher solasodine glycosides.[10] Although the H_2SO_4 staining (Fig. 2b) detected many spots, including, probably, sugars and different types of saponins in various *Solanum* species, the immunostaining (Fig. 2a) detected only limited solasodine glycosides. Bands 1, 2, and 3 were identified to be khasianine, solamargine, and solasonine, respectively, by comparison with authentic samples. Different sensitivities between solamargine and solasonine were observed, and the sensitivity of solasonine was somewhat higher compared to that of solamargine. The detectable limit was 1.6 ng of solasonine, as previously reported.

This is the first report in which the TLC–immunostaining for solasodine glycosides is described. This assay method can be routinely used for survey of natural resources of solasodine glycosides as a simple and rapid analysis. Moreover, this methodology may be available for the assay in vitro *Solanum* plantlets; therefore, it makes it possible to study a large number of cultured plantlets, and a limited small amount of sample in vitro for the breeding of *Solanum* species containing a higher amounts of steroidal alkaloids. Furthermore, this system may be useful for the analysis of animal plasma samples of glycoside or glucronide not limited to solasodine glycosides and/or distributions in organs or tissues, because very low concentrations are expected. Although it is difficult to detect a low-molecular-weight compound by the Western blotting method, the approach described here will be particularly attractive in a wide variety of comparable situations as indicated in the distribution of solasodine glycosides in the fruit of *S. khasianum*. In the expanding studies of this result, naturally occurring pharmacologically active glycosides such as ginsenosides Rb_1,[8] and glycyrrhizin[9] have been investigated.

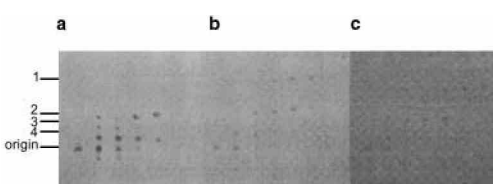

Fig. 1 Hydrolyzed products of solamargine by HCl. a, b, and c, show TLC–immunostaining and the stainings with sulfuric acid and with Dragendorff reagent, respectively. Solamargine was hydrolyzed by 1*M* HCl for 10, 20, 30, 60, and 90 min, respectively. Spots 1–4 were identified with solasodine, 3-*O*-β-D-glucopyranosyl solasodine, L-rhamnosyl-(1 → 4)-*O*-3-β-D-glucopyranosyl solasodine, L-rhamnosyl-(1 → 2)-3-β-*O*-D-glucopyranosyl solasodine, respectively.

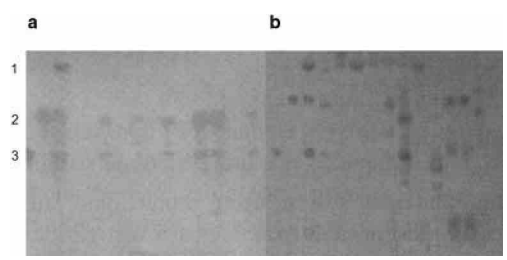

Fig. 2 TLC–immunostainings of steroidal alkaloid glycosides in the crude extracts of *Solanum* species fruits. Crude extracts were developed by a $CHCl_3$–MeOH–NH_4OH solvent system on silica gel TLC plate. After being transferred to a PVDF membrane, the membrane was treated with $NaIO_4$ and stained by MAb. Spots 1–3 were identified with khasianine, solamargine, and solasonine, respectively.

Steroids: Derivatization for GC Analysis

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Steroids, bile acids, and similar compounds pose certain problems when they require to be derivatized for separation by gas chromatography (GC). The hydroxyl groups in the respective structures differ greatly in their reaction rate, which will depend on their nature (whether they are primary, secondary, or tertiary) and also, to a certain extent, on their steric environment.

DISCUSSION

After considerable research, which examined a wide variety of different derivatives, trimethylsilylation has emerged as the procedure of popular choice for steroid and steroidlike compounds. Pure compounds or biological extracts containing 3β-hydroxyl groups can be readily silylated by treatment with *N*,*O*-bis-trimethylsilyltrifluoroacetamide containing 1% trimethylchlorosilane at 60°C for 30 min, with or without added pyridine. *N*,*O*-bis-trimethylsilyltrifluoroacetamide, under some circumstances, can also be used alone or with a mixture of hexamethyldisilazane and trimethylchlorosilane (10:10:5 v/v/v) at 60°C for 30–60 min. The trimethylsilyl derivatives separate well on capillary columns carrying apolar stationary phases. The derivatives also provide excellent electron-impact mass spectra.

In addition, *N*,*O*-bis-trimethylsilyltrifluoroacetamide has been used very effectively for the silylation of estradiol and catechol estrogens. Employing *N*,*O*-bis-trimethylsilyltrifluoroacetamide : pyridine : trimethylchlorosilane (5:5:1 v/v/v) at 40°C for 8–10 hr, tetrahydroaldosterone (11β,18-epoxy-3α,16,21-trihydroxy-5β-pregnene-20-one) and aldosterone (11β,21-dihydroxy3,20-dio-exopregn4-en-18-al) have been derivatized. Employing stable isotope dilution, cortisol has been determined in human plasma by GC/MS after reacting the dimethoxime cortisol derivative with 50 μl of *N*,*O*-bis-trimethylsilyltrifluoroacetamide at 100°C for 2 hr.

More sterically hindered steroids and, in particular, the polyhydroxylated compounds were more efficiently derivatized with trimethylsilylimidazole. The ease of silylation of the ecdysteroids (polyhydroxylated anthrapod moulting hormones) tracked the following order: 2, 3, 22, 25 > 20 ≫ 14. Those substances containing a 14α-hydroxyl group require very strong reaction conditions. For example, 20-hydroxyecdysone could only be silylated using neat trimethylsilylimidazole at 100°C over a reaction period of 15 hr. It has also been established that the addition of 1% trimethylchlorosilane to the trimethylsilylimidazole catalyzed the reaction of the reagent with the 14α-hydroxyl group, reducing the reaction time to 4 hr at 100°C. The use of larger quantities of trimethylchlorosilane caused confusing side reactions to occur and should be avoided. However, the addition of potassium acetate also appeared to increase the reaction rate, allowing the reaction time to be reduced to 2–3 hr.

The conversion of the enol form of keto steroids to a silyl derivative is somewhat fraught with difficulties, as mixtures of silylated substances can be easily formed. Nevertheless, the quantitative conversion of keto steroids to their trimethylsilyl-enol ethers has been optimized. Silylation of dexamethasone (9α-fluor-11β, 17α,21-trihydroxy-16α-methyl-pregna-1,4-diene-3,20-dione) using *N*,*O*-bis-trimethylsilyltrifluoroacetamide in the presence of sodium acetate yielded the pure tetra-trimethylsilyl derivative. In this case, the trimethylsilyl-enol ether of the 20-one moiety was produced, leaving the 3-one group unreacted. An unusual reaction associated with the enolization of keto steroids is the aromatization of the (A) ring of norethynodrel (a 3-keto-5,10-ene-nor-19-methyl steroid) during trimethylsilylation. It has been suggested that, under routine silylation conditions, aromatic derivatives are very likely to form from 3-keto-4,5-epoxides of nor-19-methyl steroids. The yield of aromatic silylated products were greater when the more basic reagents were employed and at higher temperatures.

Formyl derivatives are also popular in situations where several groups have to be blocked, as in steroid analysis, because the formyl group adds little to the molecular weight. To prevent the formation of artifacts, the strength of the formic acid should be kept at 95% and reaction allowed to take place for 30 min at 40°C. Alternatively, sodium formate can be used, an example of which is in the preparation of the enol *tert*-butyldimethylsilyl derivatives of steroids and bile acids. Sodium formate solution (1 mg in 100 μl) is dried under a stream of nitrogen in a 1 ml reaction tube fitted with a Teflon-lined screw cap. The tube is then heated to 270°C for 30 min, cooled, and 10 μg of the steroid in 100 μl of methanol added. The solvent is evaporated under a stream

of nitrogen and 20 μl of *t*-butyldimethylsilylimidazole added. The tube is then filled with nitrogen, sealed, and heated at 100°C for 4 hr. Twenty microliters of 2-propanol are then added to remove excess reagent, the tube sealed, and then heated again to 100°C for 10 min. One-half milliliter of water is then added to the reaction mixture and then extracted three times with 0.5 ml of hexane. The hexane solution is concentrated under a stream of nitrogen and the concentrated solution is used for analysis.

The literature indicates that *t*-butyldimethylsilylimidazole is probably the most popular reagent for derivatizing steroids, and it is often used in conjunction with *t*-butyldimethylchlorosilane. These reagents form derivatives under relatively mild conditions (room temperature, reaction time, 1 hr), reaction goes close to completion, and relatively few side products are generated.

Steroids: GC Analysis

Gunawan Indrayanto
Mochammad Yuwono
Suciati
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

Abstract
Insufficient volatility and thermal stability are the biggest challenges in the application of gas chromatography for the analysis of steroids. The development of gas chromatography (GC) methods for steroids analysis should take in consideration thermal stability, the derivatization step to increase volatility, the stationary phase, and the detector. Several GC methods have been summarized for the analysis of various steroids including anabolic steroids, brassinosteroids, corticoids, estrogen, endocrine-disrupting chemicals, neurosteroids, sterols, steroid saponins, and steroid alkaloids.

INTRODUCTION

Steroids are a class of compounds that have a cyclopentanoperhydrophenanthrene skeleton, which occur in nature and in synthetic products, and which can be classified into six groups according to the number of C atoms: gonane (C-17), estrane (C-18), androstane (C-19), pregnane (C-21), cholane (C-24), and cholestane (C-27). These compounds, except for cholane, are natural hormones or hormone precursors. In the naturally occurring steroids, the fusion of rings B and C is always *trans* and of the rings C and D usually *trans* (*cis* in cardenolides and bufadienolides). Rings A and B are fused in *cis* and *trans* configurations with about equal frequency. Natural steroids possess either one or, more usually, two methyl groups at angular positions at which two rings meet. According to their function, steroid hormones can be divided into estrogens, androgens, gestagens, and corticoids.

The other steroids such as bile acids (cholane), vitamin D, saponin steroids, steroid alkaloids, cardiac glycosides, and brassinosteroids also have biologically important activities. Owing to the metabolic versatility of steroid molecules, extremely complex mixtures are often encountered, necessitating the use of chromatographic methods like high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), and gas chromatography (GC) for their analyses.

The application of GC to steroid analysis seems to face many difficulties owing to the insufficient volatility and thermolability of the steroids. The development of high-resolution gas chromatography (HRGC) and various derivatization procedures enables the efficient separation of complex steroid mixtures for application in clinical- and forensic toxicology and natural product analysis. The development of low-cost mass spectrometry (MS) detectors in recent years has also promoted the application of GC/MS systems for the analysis of complex mixtures.

THERMAL STABILITY OF STEROIDS

According to their thermal stability, steroids can be divided into three groups.[1] The first group of steroids can be analyzed by GC without any difficulties. This includes steroids that possess Δ^5-3-hydroxy, Δ^4-3-keto, $\Delta^{1,4}$-3-keto, 11-hydroxy, 17-hydroxy groups, and the phenolic ring A in free, ether, or ester form. The steroids of the second group possess tertiary hydroxyl groups (e.g., 17α-methyl-17-hydroxy steriods) and involve de-ethynlation of 17α-ethynyl-17-hydroxy steroids to 17-ketone. These steroids undergo a certain decomposition at high temperatures, but this decomposition could be suppressed by a careful selection of te GC experimental procedures. The third group of steroids decomposes during analysis by GC; hence, their direct chromatographic determination by GC cannot be carried out. The steroids belonging to this group are corticosteroids and Δ^4-3-hydroxy or acyloxy derivatives. Another source of instability is the possible decomposition of steroids and their derivatives by metals; so, using all-glass systems, including glass-line vaporizer of the GC equipment, is essential.[2]

DERIVATIZATION OF STEROIDS FOR GC ANALYSIS

The main objectives for the derivatization of steroids are to decrease heat sensitivity; avoid irreversible adsorption onto the stationary phase; increase volatility; increase the separation efficiency; achieve enhanced selectivity of separations,

and improve the sensitivity of the detectors.[2] Segura, Ventura, and Jurado[3] described some important general requirements for derivatization reactions: a single derivative should be formed for each analyte; the reaction should be simple and rapid, and they should occur under mild conditions; the derivate should be stable, reproducible, and produced with high yield; in quantitative analyses, the calibration curve should be linear. Different derivatization reagents in combination with catalyzers or antioxidants have been reported in literature.[4,5] In most cases, trimethylsilylation (TMS) derivatization is preferred using *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA) as the derivatization reagent.[4,5] A mixture of MSTFA and trimethyliodosilane (TMIS), which is usually called MSTFA^{++}, can also be used as the derivatization reagent before GC–MS/MS analysis.[4] Other derivatization reagents, e.g., acetic acid anhydride, trifluoroacetic anhydride (TFA), pentafluoropropionic acid (PFPA), or heptafluorobutyric acid (HFBA) anhydride, can also be used.[3,6] For anabolic steroids and metabolites containing nitrogen, the use of acyl derivatives is also interesting.[3] The primary factor upon which the choice of a suitable derivative will be dependent is the type of detector used. For the application of the highly sensitive electron capture detector (ECD), it is quite favorable to prepare derivatives that show a high affinity for electrons; so, in such cases, chloroacetate and heptafluorobutirate derivatives are mostly used. For analysis of steroids using isotope dilution GC/MS (GC–ID/MS), silylation is not recommended on account of the fairly high abundance of ^{29}Si and ^{30}Si in natural silicon,[6] so derivatization using TFA, PFPA, or HFBA is preferred. Enzymatic hydrolysis is required before performing derivatization of glucono- or sulfoconjugated steroids in urine.[7,8] Derivatization of steroids using solid-phase microextraction (SPME) and head space methods was also described previously.[9] Conventional derivatization procedures used conventional heating process in an oven, sand bath or water bath, which is very time-consuming. Recently Zuo, Zhang, and Lin[10] reported the use of microwave in the formation of trimethylsilyl derivatives of estrogen steroids for GC–MS analysis. The advantage of this method is the minimization of the time needed for the derivatization process of estrogenic steroids. Also, the derivatives produced using microwave acceleration were identical and comparable to those produced by the conventional heating method. Detailed discussions of the derivatization methods for steroids are provided in an earlier entry in this encyclopedia[11] and in Refs. 3, 10.

STATIONARY PHASES

In the analysis of steroids by GC, silicone oils (SE-30, OV-1, OV-101) are most often used. These phases are suitable for the analysis of steroids on the basis of their molecular weight or the shape of the molecules. These silicone phases are considered as non-selective stationary phases. For separating stereoisomers or structural isomers, saturated or unsaturated derivatives, selective stationary phases such as methyltrifluoropropyl (QF-1, OV-210), methylphenylcyanopropyl (OV-225), and methyl-β-cyanoethyl (XE-60, AN-600) can be used.[2] For packed-column applications, solid supports such as Gas-Chrom Q, Gas-Chrom S, Chromosorb AW or DMCS, and Chromosorb W HP DMCS, with 3% concentration of the stationary phase, have been generally used.[1,12] For separating complex steroid mixtures, application of a glass or a fused-silica column is recommended. The length of the column is in the range between 17 and 30 m, diameter of 0.2–32 mm, and film thickness of 0.1–0.33 μm. The stationary phase consists mostly of polydimethylsiloxane, with 0–50% diphenyl groups.[6]

DETECTORS

The flame ionization detector (FID) is the detector most often used in steroid analyses. For very low concentrations of steroids, the application of ECD is needed. Thermal conductivity detectors (TCDs) cannot be used in the analysis of steroids because of their very low sensitivity.[1,2] For steroidal alkaloids, a nitrogen-specific detector (NPD) has also been used. By the use of dual detector systems (e.g., FID and NPD), closely related nitrogen-containing and non-nitrogen-containing steroids can be easily differentiated. The application of MS as detector was already discussed in a previous entry in this encyclopedia.[13] By using a GC/MS system, the identity of the peak(s) can be determined in an undisputed manner.[3]

GC PARAMETERS FOR STEROID IDENTIFICATION

The identification of steroids in an unknown sample can be based on GC or GC/MS parameters, such as relative retention times, retention indices, steroid number, mass spectra, and/or important ion fragments.

Relative retention time (RR_t) is defined as the ratio of the analyte's and the reference compound's retentions. The RR_t of sterols relative to cholesterol and cholestane, stearyl acetates to cholesteryl acetate, estrogen derivatives to cholestane, and estrogen TMS ether to cholestane, on various packed columns, was reported by Heftmann.[12] The RR_t of some estrane, androstane, and pregnane derivatives was also reported.[2]

The concept of retention index (RI) was first published by E. Kovats in 1961. Detailed discussion on RI is included in a previous entry in this encyclopedia.[14] Van Gelder[15] described the RI of various steroid alkaloids and saponins.

Steroid number (SN) is the sum of quantities characteristic of the skeleton and the functional groups in a molecule.[1,9]

$$SN = S + F_1 + F_2 + \ldots + F_N$$

where S is the number of C atoms, and $F_1, F_2, \ldots, F_N$ are values that are characteristic of the functional groups. The values of SN and F of some steroids, determined in packed columns, were already described in previous works.[1,12]

GC/MS parameters for anabolic steroid metabolites,[7,16,17] steroid alkaloids, and saponins,[15] and their MS data have been published previously.

SELECTED APPLICATIONS

Anabolic Steroids

Anabolic steroids, which are related in structure and activity to testosterone, are used to improve muscle mass and to accelerate recovery times from exercises. The use of anabolic steroids by athletes during competition and training was forbidden by the International Olympic Committee (IOC). Anabolic steroids have been abused not only by humans, but also for sporting purposes such as horse racing.[18,19,20] For doping control in sports, urine samples are mostly tested. The most often used anabolic steroids are androgens, such as testosterone.[4] It is not easy to detect parent compounds except for oxandrolone and testosterone, because the steroids are extensively metabolized.[21] Before derivatization, urine samples are passed through a Pasteur pipette containing Serdolit AD-2 slurry[21,22] or extracted using solid-phase extraction (SPE).[7,8] For conjugated steroids, hydrolysis is performed (at pH 8.5) before derivatization.[8] For analysis of anabolic steroids, Choi et al.[21] used an Ultra-2 cross-linked capillary column of 5% phenylmethylpolysiloxane (30 m × 0.2 mm, film thickness 0.33 μm) with an oven temperature of 150°C (2 min) to 300°C (2 min) with a step rate of 20°C/min; injection temperature of 300°C; and detection using MS (negative chemical ionization using methane) and tandem MS (MS/MS with collision energy for a collision-induced dissociation of 1.0). Yoon and Lee[8] used a glass capillary column (17 m × 2 mm) with an oven temperature of 180°C (6 min), then increased to 224°C (4°C/min), and finally to 300°C (15°C/min), and detection using MS (negative chemical ionization using methane). Ho et al.[19,20] reported the analysis of turinabol and mesterolone in horse urine using an HP1-MS column (~30 m × 0.25 mm, 0.25 μm film thickness) with constant helium flow at 1.2 ml/min. For the analysis of turinabol the oven temperature was set at 60°C (1 min), then increased to 220°C (60°C/min) and, finally, to 300°C (3°C/min), which was held for 5 min, while for mesterolone the column was initially set at a higher temperature of 120°C (0.5 min), then increased to 180°C (30°C/min), followed by an increase to 230°C (4°C/min), and finally to 300°C (30°C/min), which was held for 5 min. The MS analysis was performed on electron impact (EI) mode. The analysis of residual anabolic steroids in meat was reported by Fuh, Huang, and Lin.[23] The isolation was conducted by SPE. To derivatize the isolated steroids, $MSTFA^{++}$ was used. The enzymatic hydrolysis was not conducted, as previous studies have discovered that there was no significant hormone liberation involved in muscle, fatty tissue, and meat. The derivatization products were then subjected to GC–MS/MS analysis. For this purpose, a DB-5 GC column (30 m × 0.25 mm, with 0.25 μm film thickness) was used, with a flow rate of 1.0 ml/min. The oven temperature was initially set at 180°C (1 min), increased to 240°C (6°C/min, for 2 min), and finally increased to 290°C (6°C/min, held for 10 min). The MS analysis was performed on EI mode. Impens et al.[24] used a non-polar 5% phenyl-polysilphenylene-siloxane BPX-5 GC column to analyze anabolic steroids in bovine urine. The sample was derivatized with $MSTFA^{++}$ before being injected for the GC–MS/MS and GC–MS/MS/MS analyses. The oven temperature was initially set to 100°C (1 min), then increased to 250°C (30°C/min), followed by an increase to 290°C (2.5°C/min), and finally to 300°C (10°C/min), which was held for 1.5 min. Interested readers can consult Refs. 3, 8, and 18–25 for details.

Brassinosteroids

Brassinosteroids are steroidal plant hormones that are required for normal growth and development. Brassinosteroids are distributed in both aerial and underground parts of plants; however, the concentration is higher in the aerial parts.[26] About 40 brassinosteroids have been identified from the plant kingdom.[27] The use of brassinosteroids as an anticancer agent has been investigated by Malíková et al.[28] For the analysis of brassinosteroids, Park, Kim, and Kim,[27] Kim et al.,[29] and Kim, Kim, and Kim[26] used an HP-5 fused-silica column (30 m × 0.25 mm, film thickness 0.25 μm) with an oven temperature of 175°C (2 min), then elevated to 280°C (40°C/min). Prior to injection, the samples were treated with methaneboronic acid in pyridine (70°C for 30 min) to produce bismethaneboronate. For analyzing typhasterol, testosterone, 6-deoxytyphasterol, and 6-deoxoteasterone, Nomura et al.[30] silylated the methaneboronate to MB-TMS derivatives before injecting into the GC (capillary DB-1 column 25 m × 0.25 mm, 0.25 μm film thickness; oven temperature 170°C for 1.5 min, then increased to 280°C in steps of 37°C/min).

Corticoids

Corticoids or corticosteroids are divided into mineralocorticoids that act in the regulation of blood volume and metabolism of electrolytes, and glucocorticoids that act in saccharometabolism.[4,25] On account of the instability of

their dihydroxy acetone side chain at C-17, direct analysis using GC is impossible. Methoximation followed by TMS derivatization is the most widely used approach.[3] For the analysis of glucocorticoids, Mozzarino et al.[31] used an HP-1 fused-silica cross-linked methyl silicone capillary column (17 m × 0.20 mm, film thickness 0.11 μm) at a flow rate of 1 ml/min. The temperature was set at 180°C (4.5 min), increased to 230°C (3°C/min), followed by an increase to 290°C (20°C/min), and finally to 320°C (30°C/min). The derivatization with MSTFA/NH_4I/dithioerythrytol (1000:2:4, v/w/w) at 70°C for 20 min was conducted before GC–MS analysis. Shakerdi et al.[32] investigated a GC–MS method to analyze the excretion rate of 18-hydroxytetrahydro-11-dehydrocorticosterone using the non-homologous reference standard β-cortol. After derivatization the sample was injected to a DB-1 column (30 m × 0.322 mm, film thickness 0.25 μm). The oven temperature program was as follows: starting from 100°C (3 min) increased to 190°C at a rate of 20°C/min, then to 285°C at a rate of 2°C/min, which was held for 10 min. The analysis was performed on positive EI ionization mode. Interested readers should consult previous publications.[6,25,31,32]

Estrogens

Estrogens (C18) are regarded as typical female hormones owing to their importance in the estrous cycle. These hormones have been used in animal fattening because of their anabolic effects. These C18 steroids differ from all other steroids in a way characterized by the presence of an aromatic A ring and the lack of a methyl group at C-10. Fritsche[33] analyzed 17β-estradiol and estrone and the estrogenic metabolites estriol and 17β-estradiol in foodstuffs using a DB-5 fused-silica column (30 m × 0.25 mm, film thickness 0.25 μm) and detection using MS (EI, electron energy: 60 eV, ion source temperature: 180°C). The steroids were previously derivatized with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide/TMIS/dithioerythrytol (1000:2:2) at 60°C for 15 min. Roy, Hachey, and Liehr[34] developed a GC method with a ^{53}Ni-pulsed ECD for measuring the rate of formation of 2-hydroxyestradiol and 4-hydroxyestradiol from estradiol in microsomal preparations. The steroids were converted to heptafluorobutyryl esters and separated with a DB-5 fused-silica capillary column (30 m × 0.25 mm). The GC conditions were splitless injection, 280°C injection temperature, and a temperature gradient of 30°C/min from 100°C to 245°C followed by a 5 min isothermal period at 245°C and a second temperature gradient of 1°C/min from 245°C to 265°C. GC analysis of the pentafluorobenzyl derivatives of estrogen in river water and effluents was also developed by Xiao, McCalley, and McEvoy.[35] Impens et al.[36] have undertaken a study on the residues of estrogens in kidney fat and meat. For this purpose the sample was derivatized with MSTFA, which was then subjected to GC–MS analysis. For this purpose, a non-polar 5% phenyl-polysilphenylene-siloxane SGE BPX-5 column (25 m × 0.22 mm, film thickness 0.25 μm) was used. The initial oven temperature was keep at 100°C for 1 min, then increased to 250°C at a rate of 30°C/min, then to 290°C (2.5°C/min), and finally to 300°C (10°C/min), which was held for 1.5 min. For further confirmation of the steroids a GC–MS/MS analysis was performed.

ENDOCRINE-DISRUPTING CHEMICALS

Endocrine-disrupting chemicals (EDCs) are exogenous substances that cause alterations of normal hormone function and physiological status in wildlife and in humans.[37,38] There are two major types of compounds classified as EDCs: phenolic and estrogenic. These dangerous chemicals can be released directly or indirectly from domestic or industrial waste as pollutants in aquatic environment. Analysis of EDCs in sludge and waste water samples have been described by Jeannot et al.[38] The samples were extracted by SPE with C18 cartridges and SPE with polymeric cartridges. Before GC–MS and GC–MS/MS analyses, the sample was derivatized with bis(trimethylsilyl)trifluoroacetamide (BSTFA). A CP-Sil 8 CB column (95% dimethyl-5% phenyl polysiloxane, 30 m × 0.25 mm, film thickness 0.25 μm) was used. The oven temperature was programmed at 85°C (3 min), then increased to 130°C (10°C/min), and then slowly to 300°C (3°C/min). Liu, Zhou, and Wilding[37] have developed a simultaneous analysis of EDCs in water samples using SPE–GC–MS method. For this purpose nine types of SPE cartridges were employed. The sample derivatization was carried out with BSTFA at 60–70°C for 30 min same as Jeannot et al.[38] The GC–MS analysis was conducted on a ZB5 (5% diphenyl-95% dimethyl polysiloxane) capillary column (30 m × 0.25 mm, film thickness 0.25 μm). The column temperature was initially set at 100°C (1 min), which was then increased to 200°C (10°C/min), followed at a rate of 15°C/min until it reached 260°C, and finally slowly increased at a rate of 3°C/min to 300°C, which was held for 2 min. Interested readers should consult Refs. 37 and 38.

Neurosteroids

Neurosteroids are steroids that are synthesized de novo in the central nervous system (androsterone, dihydrotestosterone, testosterone, allopregnanolone, isopregnanolone, and pregnanole). These steroids are synthesized from cholesterol or from a blood-borne precursor.[39] After the extraction of plasma and cerebrospinal fluids using SPE and derivatization with carboxymethoxime, pentafluorobenzyl, and trimethylsilyl, the derivatized samples were injected into a GC/MS system for quantitative evaluation with a selected-ion monitoring (SIM) method, which was used to maximize sensitivity as only a selected *m/z* is monitored. Details of the method have been described in Refs. 40 and 41. To analyze neurosteroids in the rat brain, Liere et al.[42,43] used a BPX5 column (5% phenyl-95% dimethyl polysiloxane, 25 m × 0.22 mm, film thickness

0.25 μm) and a BPX35 column (35% phenyl-65% dimethyl polysiloxane, 30 m × 0.25 mm, film thickness 0.25 μm). The oven temperature was set as follows: starting at 50°C (1 min), increased to 140°C (30°C/min), followed by an increase to 300°C (10°C/min) for the first column; and starting at 50°C (1 min), increased to 175°C at the rate of 30°C/min, and finally to 320°C at the rate of 10°C/min for the second column. The MS was performed in the EI mode. Before being injected to GC–MS, samples were derivatized with HFBA anhydride or triethylamine (TEA)/HFBA. A review article on the analysis of neurosterols and neurosteroids by MS has been published by Wang, Karu, and Griffiths.[41]

Sterols

Various TMS derivatives of sterols in tuna olive oil could be separated using CP-Sil 8 CB fused-silica column (15 m × 0.22 mm; 240°C isothermal; FID). Plant sterols (brassicasterol, campesterol, stigmasterol, and sitosterol) were analyzed using a fused-silica column (15 m × 0.25 mm, 260°C isothermal; FID).[44] The analysis of campesterol, sitosterol, and diosgenin using a glass-packed column (6 ft × 0.125 in.; 3% SE-30 on Gas Chrom Q, 220–270°C, 4°C/min; FID) was described.[45] The separation of plant sterols (cholesterol, campesterol, stigmasterol, and sitosterol), squalene, and some lupane triterpenes using a glass-packed column (2 m × 2 mm; 3% OV-1 on Gas Chrom Q; 200–280°C, 4°C/min; FID) was reported.[46] The analysis of sterols (β-sitosterol, stigmasterol, campesterol, and cholesterol) in sugarcane waxes was undertaken in a fused-silica capillary column, CP Sil 5 (25 m × 0.25 mm, film thickness 0.25 μm). The temperature was programmed from 150°C to 320°C at the rate of 6°C/min. The MS was recorded in EI mode. TMSi derivatives of sterols were prepared using HMDS/TMSiCl (NF ISO 6799).[47] Seo et al.[48] reported the analysis of squalene and phytosterol (β-sitosterol and stigmasterol) in *Eleutherococcus senticosus* using an HP-1 (25 m × 0.25 mm, film thickness 0.33 μm) methyl polysiloxane cross-linked capillary column. The temperature was programmed from 100°C to 250°C at the rate of 20°C/min. The amount of squalene and phytosterol was calculated from the ratio of the peak area of the relevant compound to that of the standard. To analyze the constituents (alkanes, esters, aldehydes, ketones, fatty acids, and sterols) of cuticular waxes from potato, GC–MS analysis was performed in a RTX-1 WCOT capillary column (30 m × 0.25 mm, film thickness 0.25 μm). The oven temperature was initially set to 200°C and then increased to 320°C (4°C/min), which was held for 15 min.[49] The analysis of phytosterol in fungus *Mortierella alpine* was conducted in a DB-5 column (30 m × 25 mm, film thickness 0.25 μm).[50] Analysis of plant sterols in food and vegetable oils has been reviewed by Abidi.[51] Kalo and Kuranne[52] described the GC analysis and electrospray tandem MS of free sterols in fats and oils.

Steroid Saponins and Steroid Alkaloids

Steroidal saponins are steroids coupled to sugar units. Before GC analysis, steroid saponins need to be derivatized to their acetyl, methyl, or trimethylsilyl ether derivatives. There are two methods that can be used to analyze steroidal saponins using GC. First, GC analysis was conducted on the steroidal saponins after the separation of aglycone and sugar moiety through hydrolysis. Second, the analysis was undertaken in steroidal saponins without hydrolysis of the sugar units. The latter method can be used if the sugar units are not attached to the steroids through ester linkage; otherwise, the deglycosylation of the steroidal saponins can occur in the injection port of the GC.[53]

The separation of diosgenin and solasodine was reported using a glass-packed column (6 ft × 0.125 in.; 3% SE-30 on Gas Chrom Q, 220–270°C, 4°C/min; FID). Diosgenin and its 5-α-derivative (tigogenin) can be separated well after derivatization using TFA, and analyzed using a glass-packed column (10 ft × 0.125 in.; 3% QF-1 on Gas Chrom Q; 220°C isothermal; FID).[45] Solanidine, demissidine (5-α-derivative of solanidine), and solasodiene, which could not be separated using a glass-packed column (1 m × 2 mm; 10% SE-30 on Chromosorb W-HP, 260–300°C, 5°C/min, FID), were separated well using a fused-silica column (50 m × 0.22 mm; CP-Sil 5, film thickness 0.12 μm; 290°C isothermal; FID).[13] Using a fused-silica column (50 m × 0.22 mm; CP-Sil 5 CB, film thickness 0.12 μm; 270°C isothermal; FID), various steroids, 5-α-cholestane, solanthrene, cholesterol, solanidine, demissidine, solasodiene, stigmasterol, diosgenin, tigogenin, solasodine, and tomatidine, could be separated without derivatization.[15] Some methods of analysis of solasodine using GC were described in a previous publication.[54]

Li et al.[55] has developed a method to analyze isosteroidal alkaloids (ebeiedine, ebeiedinone, ebeienine, hupehenine, isoverticine, verticine, verticinone, and imperialine) in *Fritillaria* species through direct injection of these alkaloids without precolumn derivatization. Two GC columns, namely Supelco SAC-5 (30 m × 0.25 mm, film thickness 0.25 μm) and HP-1 (12.5 m × 0.22 mm, film thickness 0.33 μm) were compared. The result has shown that in Supelco SAC-5 six out of the eight alkaloids tested were resolved better.

Steroids: TLC Analysis

Muhammad Mulja
GunawanIndrayanto
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

INTRODUCTION

Steroids, which are a class of compounds that occur in nature and in synthetic products, have a cyclopentanoperhydrophenanthrene skeleton. The carbon atoms and rings are labeled according to the schemes shown in Fig. 1. The following classes of compounds belongs to sterioids: sterols, bile acids, cardenolides, androgens, estrogens, corticosteroids, steroid sapogenins, steroid alkaloids, ecdysteroids, and vitamin D.

In the naturally occuring steroids, the fusion of ring B and C is always trans and that of the ring C and D is usually *trans* (*cis* in the cardenolides and bufadienolides). Rings A and B are fused in cis and trans configurations with about equal frequency. The configuration of the substituents is referred to that of the 19-methyl group on C_{10}. Every substituent that is in a configuration identical to the methyl group i indicated by the β-position; substituents of opposite configuration are termed α-substituents (dotted lines). If the substituents lie in the planes of the rings, they are termed equatorial (e), and if perpendicular to the rings, they are called axial (a). Thus, for example, in an A/B *cis*-steroid, a 3β-hydroxy group is axial and equatorial in an A/B *trans*-steroid (see Fig. 1). In general, equatorial substituents are more stable than axial substituents. In various reactions, the formation of the former is favored.

In the field of steroid analysis, thin-layer chromatography (TLC) is still the method of choice, especially when many simultaneous analyses have to be carried out; hundreds of analyses can be performed in a short time and with small demands on equipment and space. Samples can be analyzed with minimal cleanup, and analyzing a sample by the use of multiple separation steps and static postchromatographic detection procedure is also possible because all sample components are stored on the layer without the chance of loss. The time required in TLC analysis is about 10–60 min. As little as 0.001 μg of steroids/spot can be can be detected by TLC. Using a TLC plate with thicker adsorbent layers (0.5–2 min), several grams of substance can be isolated (preparative TLC).

SORBENTS

The TLC of steroids has been tried on a great variety of sorbents, but various forms of silica gels are most frequently used. In order to achieve adequate stability, adhesion, and resistance to abrasion of the (pre-coated) layers, the sorbents usually contain a binder. Either they do not contain any additive at all, designated by "H" in the article designation, or gypsum ("G") as binder. The sorbents designated by "P" designates the addition of flourescent indicators and, if applicable, the number that follows gives the excitation wavelength and an "s" following this indicates the acid stability of the indicators. A number placed immediately after the name of the sorbent indicates the pore diameter of the sorbents (in Å). In high-performance thin-layer chromatography (HPTLC), the particle diameter is about 3–10 μg, whereas in TLC, it is about 4–25 μm. The plates can be easily prepared in the laboratory or readily purchased from commercial sources as precoated plates or sheets, but it is recommended to use ready-made (pre-coated) plates or sheets because they are more convenient and more uniform than those manually prepared in the laboratory.

An addition of 3–10% of silver nitrate to silica gel or kieselguhr is considerable helpful in the separation of sterols and steroids that differ only through an unconjugated double bond. For C_{27} steroid sapogenins and alkaloids, it was recommended to use a higher concentration of silver nitrate (15%). Precoated TLC/HPLTC plates can be dipped in a 20% silver nitrate solution for 15–20 min, then in the absence of light, drying the plate in air. Finally, it is activated in a drying oven. Impregnating silica gel with 10–25% formamide in acetone can be used for separating digitals glycosides, estrogens, and equilin. Impregnation with boric acid could be used, also, for the delicate separation of cardiac glycosides on silica gel layers. The silica gel can also be modified into non-polar reversed phases (RP) such as C_{18} (octadecyl function), C_8 (octyl function), CN (cyanopropyl function), NH_2 (aminopropyl function), and diol (vicnal hydroxyl function on C chains). Progesterone sterioids can be well separated using CN F_{254} and RP plates. Reversed phases C_{18}, C_8, and C_2 could be used for analyzing the ecdysone steroids and RP C_{18} for estrogen conjugates.

Other sorbents that have also been used for separating steroids in TLC are cellulose, kieselguhr, alumina, polyamide, magnesium oxide, and celite. Androstanes can be analyzed using cellulose layers impregnated with 1,2, propanediol. Layers consisting of alumina and magnesium oxide can be used to separate some sterols and sterol acetates.

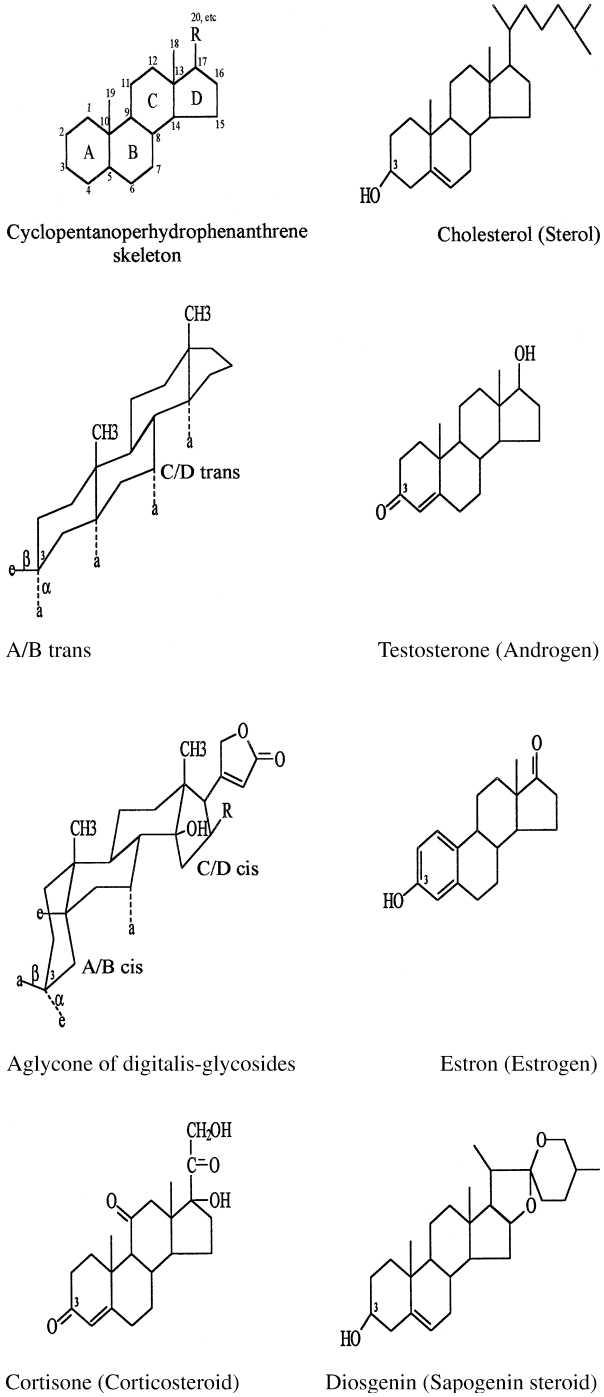

Fig. 1 The structure of some important steroids.

Layers of alumina that are deactivated with 2.5% acetic acid could be employed for separating some corticosteroids. An advantage of using alumina rather than silica gel in TLC of Δ^4-3-ketosteroids is that they form fluorescent oxidation products when the plate is heated to 150–180°C. As little as a nanogram of steroids can be detected by this method. By using a layer that consist of a mixture of $MgO\text{-}Al_2O_3\text{-}CaSo_4$ (15 : 5 : 1), complex mixtures of sterols their 3, 5 dinitrobenzoate derivatives can be resolved using hexane-ethyl acetate (9 : 1, v/v) as the mobile phase.

Although most steroids are stable on the silica gel layers, some steroids (e.g., estrogens and vitamin D) can be decomposed readily. To avoid the decomposition, a preliminary treatment of the sorbent with a solution of ascorbic acid (antioxidants) in ethanol is recommended.

DEVELOPMENT

Simple development will usually be enough for the TLC of steroids. In some cases, multidevelopment in the same or different solvent system or a two-dimensional technique is required to achieve better separation. For ensuring reproducibility of the R_f value, Neher[1] recommended the use of the same number of plates and always using fresh solvent for each run. A system containing a similar volatility maintains a more stable composition and, thus, has more reproducible R_f values during several runs. Our experiences shown that, by weighing the solvent components, the R_f values of testosterone (0.37) and estradiol (0.52) on silica gel plates were unchanged after four runs by using cyclohexane-ethyl acetate (1 : 1, w/w) as the mobile phase.

DETECTION

Destructive Detection Methods

Most of the reagents used for detecting steroid spots by *in situ* reactions (destructive reagents) contain sulfuric acid. Sulfuric acid, without any additive, can also produce characteristic colors and fluorescence response, as well as permanent black zones after heating. The initial color, the color after heating for 10 min, and the color in ultraviolet (UV) (366 nm) of various classes of steroids (141 compounds) were presented by Heftmann.[2] Other destructive reagents that are most generally applicable are antimony trichloride (Carr-Price's reaction; for vitamin D, cardenolides, bufadienolides, triterpenoids), aromatic aldehyde–acids (for sapogenin steroids, steroid alkaloids, ketosteroids), molybdophosphoric acid (reducing and unsaturated steroids, cholestrol ester, bile acids; blue on yellow background), chlorosulphonic acid–acetic acid (cardenolides, green, blue violet fluorescence), and phosphoric acid (color similar to sulfuric acid).

For the detection of ketosteroids, an *m*-dinitrobenzene solution can be used (17-keto-steroids, violet; 3-keto-Δ^4 groups, blue). Δ^4-3-Oxo steroids and $\Delta^{4,6}$-3-oxo steroids can be distinguished using a phthalic acid-*p*-phenylenediamine reagent, which gives yellow and orange-brown colors, respectively. Detailed discussion of the

destructive detection methods of steroid spots is described in the books of Mecek[3] and Touchstone.[4] Thus, by spraying and heating the plates, various class compounds of steroids can be deduced; to confirm this, cochromatography with authentic standards is needed. If the standard is unavailable, isolating the substance and then identification by spectroscopic analysis is recommended.

Non-destructive Detection Methods

Steroids containing an α,β-unsaturated structure, such as Δ^4-3-oxo, Δ^7-6-oxo, Δ^5-7-oxo and Δ^{16}-20-oxo groups, can be visualized under UV light (254 nm). For this purpose, the samples should be spotted on plates that contain a fluorescent indicator (GF_{254} or F_{254}). The steroids spots will appear as dark zones on the layer. Sorbent layers with out the indicator must be sprayed with a dilute solution of fluorescein or morin before exposure to UV light. This method has a great advantage over the destructive methods because the unchanged steroids can be eluted or isolated from the sorbents for further analysis.

Other non-destructive detection methods use iodine vapors or iodine–potassium iodide reagents (Mylius's reaction). Yellow, orange, or brown zones will appear on the layer. The zones will have to be marked, because the iodine will eventually evaporate. The sensitivity of the iodine test can be greatly increased by the use of layers containing rhodamine 6G. Most of the steroids are recovered unchanged after exposure for 30 min with iodine vapor, except for estrogen and Vitamin D.

FORMATION OF DERIVATIVES (MICROREACTION)

It is well known that steroid derivatives such as acetates, benzoates, propionates, and trifluoracetates can be better separated in TLC/HPTLC than the free substances themselves. These derivatization reactions can be performed directly on the TLC layers. Acetylation can be accomplished by treating 10–100 μg of steroids with 0.1 ml acetic anhydride and 0.1 ml pyridine for 8–16 hr at room temperature. Following the reaction, blowing with nitrogen at 60°C can remove the reagent. Benzoylation is carried out in the same way, but by using 0.1 ml benzoyl chloride. Propionylation is performed by dissolving the steroids in 0.3 ml of warm propionyl chloride and allowing the mixture to stand 10 min at 20°C. Extraction with hexane and washing with water and sodium carbonate solution can purify the ester. Trifluoroacetylation is performed by mixing the steroids with a small excess of trifluoroacetic anhydride in hexane.

QUANTITATIVE ANALYSIS

Spot Elution Technique

After elution from the chromatoplates, the separated steroids can be analyzed by using various methods such as UV–Vis spectroscopy or fluorometry. Although this method is very simple, at the present time its application is significantly diminished due to some disadvantages (e.g., it is difficult to locate the spot position accurately, nearly quantitative elution of the spots is required, the loss originating from irreversible adsorption during chromatography must be minimized, etc.). When the UV method is used, special care should be taken because the eluate of silica gel with some semipolar solvents (e.g., ethanol, methanol) exhibit absorption in the UV region. It is recommended to use a blank containing the same amount of adsorbents from an empty part of the plate.

In Situ TLC Technique (Densitometry)

In situ quantification of steroids on the chromatoplate can be performed by using UV (for UV-active steroids), Vis (usually using destructive reagents), and fluorometric methods. Fro UV-active steroids, such as corticosteroids, it is common to scan the steroid spots on the basis of fluorescence quenching at 254 nm using F_{254} precoated layers. Fro steroids that use destructive reagents for their visualization, a reflectance-absorbance method in the Vis range (370–700 nm) is used. The steroid sapogenins (diosgenin, hecogenin, manogenin, etc.), steroid alkaloids (solasodine, tomatidine), and total sterols may be assayed using an absorbance-reflectance densitometry method (in the Vis region) after treatment of the steroid spots with anisaldhyde-sulfuric acid reagent. It was found that this densitometric method was faster, simpler, and less expensive when compared to HPLC or gas liquid chromatography (GLC). Three methods are available for *in situ* fluorometric measurement. The first is to produce active derivatives on the layer by spraying with a suitable reagent. The second is to induce fluorescent derivatives prior to the analysis. The DL (detection limit) of the fluorometric method is much lower compared to the UV and Vis evaluation methods.

Validation of the Method

Before the assay methods can be used for routine application (e.g., in a quality control laboratory), it must first be validated. The parameters for the validation methods are specificity, linearity, accuracy, precision (repeatability and intermediate precision), DL, quantitation limit (QL), and applicable range. A detailed discussion is provided in Ref.[5]

APPLICATIONS

Many publications dealing with TLC/HPTLC steroid analysis have appeared every year. The publications can be summarized into categories as follows: analytical control of steroid formulations (drug preparations), determination of steroids in biological media and natural resources, and analytical control of the production of steroids (including raw material, synthesis, and biotransformation). A cumulative database of thousands of TLC methods (including steroids) is provided in compact-disk (CD) format by Camag.[6]

Supercritical Fluid Extraction

Christopher E. Bunker
Propulsion Directorate, Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio, U.S.A.

INTRODUCTION

Supercritical fluid extraction (SFE) was originally proposed as a process for compound separation or purification as early as 1879 by Hannay and Hogarth.[1,2] A rebirth of the field in the 1940s, and again in the 1970s, was brought about by significant advances in technology and a drive toward more energy-efficient and environmentally friendly processes.[1,2] Today, SFE is widely applied in various industries for purification of high-value chemicals or materials, for environmental remediation, and for incorporation into larger green processes that employ supercritical fluids as reaction solvents. Currently, its most widely known application is associated with the decaffeination process used in the treatment of coffee beans. Within the petroleum field, the application of SFE technology varies widely from cleanup procedures to high-value materials production.[3–5] In this entry, first we will discuss the properties of a supercritical fluid that make SFE an attractive alternative to normal liquid–solvent processes; next, we will describe the equipment and function of a typical SFE process; and, finally, current areas of interest in petroleum research will be reviewed briefly.

SUPERCRITICAL FLUID PROPERTIES

To understand the properties of a supercritical fluid, one must first understand what is meant by the term "supercritical." In this case, "supercritical" refers to that region of the phase diagram (Fig. 1) defined by temperatures greater than the critical temperature ($T > T_c$) and pressures greater than the critical pressure ($P > P_c$). In this region, the substance exists as a single phase, regardless of temperature or pressure. In most industrial applications, supercritical fluids are used in this region; however, it is important to note that a single phase exists for a substance at any pressure when the system is above T_c. Researchers investigating the properties of supercritical fluids have found it necessary to include the pressure region below P_c to obtain a full understanding of the nature of a supercritical fluid.[6–8] For this reason, the loose definition of a supercritical fluid is: any substance at a temperature greater than its critical temperature.

The most important properties of a supercritical fluid are the low densities between those of a gas and those of a liquid, which are easily tunable with a change in pressure at constant temperature, and the local density effects. The latter are termed solute–solvent and solute–solute clustering and are best understood as local concentrations of a solvent or solute, respectively, that are greater than the bulk concentration. These phenomena are attributed to the unique nature of a supercritical fluid (i.e., a supercritical fluid is macroscopically homogeneous but microscopically inhomogeneous, consisting of solvent clusters and free volumes). An experimentally observable effect related to this unique structure is critical opalescence, where a fluid viewed through an optical port is observed to become opaque as it transitions through the critical region. This phenomenon is attributed to the efficient scattering of light by the unique structure of a supercritical fluid in the near-critical region.

In SFE processing, the low and tunable fluid densities are of the greatest importance. For a constant temperature greater than T_c, low pressures yield gaslike densities, and high pressures yield liquidlike densities (Fig. 1). Increasing the pressure from low to high moves the fluid density through the near-critical region, where small changes in pressure result in large changes in fluid density (see Fig. 4 of Ref.[2] for an idealized density-vs.-pressure diagram). Because solubility is, to a first approximation, proportional to fluid density, the solubility of an analyte can be dramatically affected by small changes in pressure in the near-critical density region.

For many supercritical fluids, the solubilities of the compounds of interest, even in the high-density region, may be too low for practical application. This limitation can be overcome through the use of a cosolvent. Early on, researchers discovered that the addition of small amounts of a cosolvent could dramatically enhance the solubility of various analytes.[6–8] In many cases, the enhancement exceeded that predicted based on the bulk concentration of the cosolvent in the supercritical fluid. The results suggested an enhancement of solvent strength under supercritical conditions. The phenomenon, termed the entrainer effect, is related to solute–solute clustering; the entrainer effect served as preliminary evidence of unusual behaviors and pointed researchers toward solute–solute clustering.

Thus, taken as a whole, the tunable densities and tunable solubilities, the availability of cosolvents as property modifiers, the ability to utilize fluids that are gases under ambient conditions, and the possibility of employing fluids

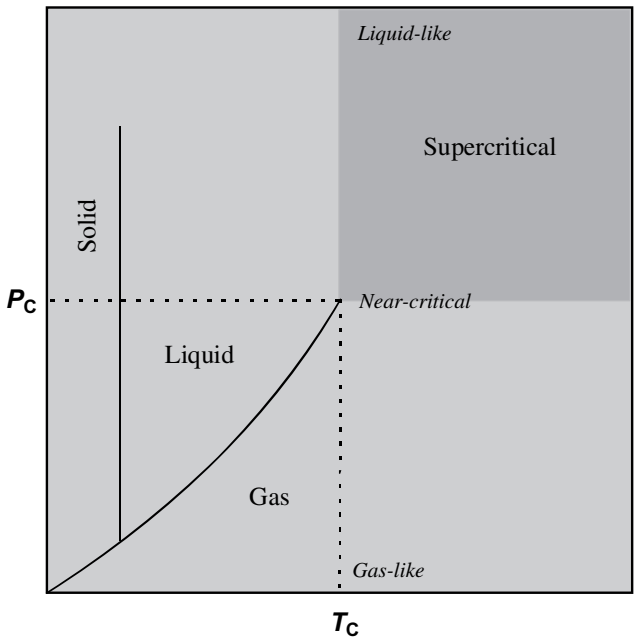

Fig. 1 Idealized phase diagram depicting the supercritical region. T_c and P_c are the critical temperature and pressure, respectively.

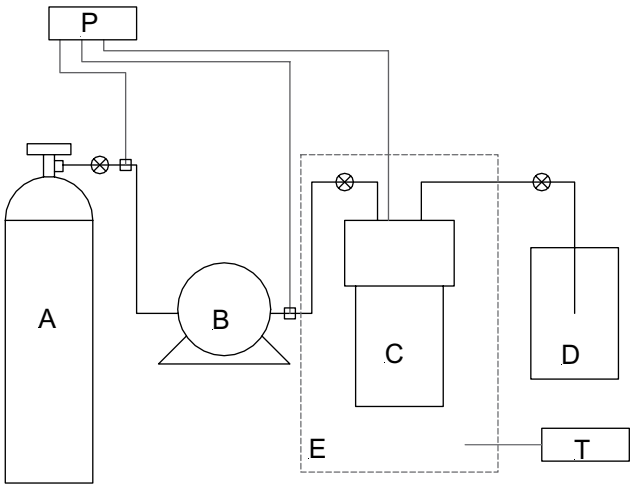

Fig. 2 Schematic for a typical laboratory-scale supercritical fluid extraction system: (A) fluid supply; (B) pump/delivery device; (C) extraction vessel; (D) collection vessel; (E) heated zone; (P) pressure measurement device; (T) temperature controller.

that are environmentally friendly (e.g., CO_2 or water) (the unique properties of supercritical fluids) make SFE a valuable alternative to normal liquid extraction processes.

SFE SYSTEM

The design of any SFE system will be a function of the application, and the details will vary depending on the size and the mode of the process (batch or continuous), the nature of the extracted material and the substrate (corrosive, toxic, and benign), and the fluid employed. The only guaranteed commonality with all such systems is the necessity to ensure safe operation. Proper safety precautions must be observed in the handling and maintenance of the required high-pressure equipment; the consequences of a failure can be severe.

A simple laboratory-scale SFE system is shown in Fig. 2. The system consists of a fluid supply, a pump/delivery device, an extraction vessel, a temperature-controlled zone, a collection vessel (including restrictor), and numerous valves, pressure gauges, and temperature sensors (although not shown, pressure-relief valves are highly recommended). Such systems embodying these components and offering many variations in operation (e.g., programmable control, recirculation, and multistage extraction) are readily available. In a typical extraction, the extraction vessel is loaded with the substrate to be extracted. In the configuration shown in Fig. 2, this would involve disassembly of the extraction vessel and manual loading of the material. In many industrial processes, this step is automated. Once loaded, the extraction vessel is equilibrated at the desired temperature ($T > T_c$), and fluid is introduced. For a static process, the system is brought to the desired pressure and sealed; for a continuous process, backpressure regulators or restrictors are used to maintain the pressure while the fluid is continuously flowed. In the recovery of the extracted material, it is important to recall that small changes in pressure in the vicinity of the critical region result in large changes in density and solubility. To avoid precipitation of the extracted material within the extraction system, additional fluid must flow to maintain the system pressure. Several collection vessel designs facilitate collection of the extracted material. The simplest ones involve expansion of the fluid into a low-pressure region, thus inducing nucleation and precipitation of the extracted material [rapid expansion of a supercritical solution (RESS)], expansion of the fluid into a collection liquid where the extracted material has good solubility (applicable to somewhat volatile species), or expansion of the fluid onto a solid absorbent. Other possibilities include recovery and recirculation of the supercritical fluid, secondary extraction with modification of the fluid, and reaction of the extracted material using the fluid as an alternative reaction solvent. The reader is referred to Refs.[1,2] for additional information.

CURRENT AREAS OF INTEREST IN PETROLEUM RESEARCH

With respect to the petroleum industry, research into supercritical fluids and SFE can be roughly divided into product-oriented research, property investigations, and environmental remediation efforts.[3–5] In a recent review, Rudzinski and Aminabhavi[3] noted that researchers have

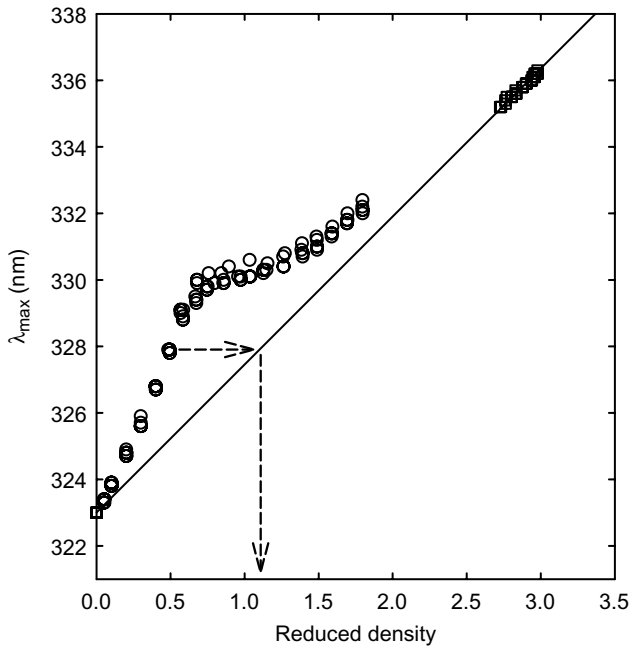

Fig. 3 Experimental data obtained for the spectral maximum of the pyrene excitation spectrum in supercritical toluene at 335°C as a function of reduced density: (—) normal liquid behavior; (ö) supercritical fluid data; (θ) liquid data.
Source: From Fundamental properties of supercritical fluids, in *Supercritical Fluid Technology in Materials Science and Engineering*.[7]

been investigating the application of SFE technology to the processing of coal, bitumen, oil shale, crude oil, and coal tar pitch. The fluids utilized included pure CO_2, modified CO_2, organic fluids such as propane and toluene, and water. Concerning property investigations, research is ongoing to understand the fundamental properties of high-temperature supercritical fluids because these fluids can serve as models for supercritical aviation fuel.[7] Fig. 3 demonstrates the unusual nature of supercritical toluene. Reduced density (density divided by the critical density) is plotted as a function of the solvation strength of toluene (λ_{max} is the solvatochromic shift of the excitation spectrum of the molecular probe, pyrene). The solid line represents the normal liquid behavior of toluene—a trend that is proportional to fluid density. The data obtained in supercritical toluene (circles) clearly deviate from that line. The dashed arrows demonstrate that, at any given point, the observed density is greater than the measured bulk density—a direct result of solute–solvent clustering—the implication being possible discrepancies between predicted properties based on bulk densities and observed properties influenced by local densities (the properties being solubility, viscosity, polarity, heat transfer characteristics, etc.). The goal of such research is to develop quantitative models capable of determining the local (as opposed the bulk) properties of a supercritical fluid. The significance of the discrepancies shown in Fig. 3 will be determined in future efforts to design and operate supercritical fluid fuel systems.

Synthetic Dyes: HSCCC Separation

Adrian Weisz
Office of Cosmetics and Colors, Center for Food Safety and Applied Nutrition, U.S. Food and Drug Administration (USFDA), Washington, District of Columbia, U.S.A.

Abstract
This entry succinctly presents the application of high-speed countercurrent chromatography (HSCCC) in its various forms to the separation and purification of synthetic dyes used in food, drugs, and cosmetics.

INTRODUCTION

Countercurrent chromatography (CCC) is a liquid–liquid partition technique that does not involve use of a solid support. In high-speed countercurrent chromatography (HSCCC), one of the two immiscible liquid phases (the stationary phase) is retained in an Ito multilayered coil column by centrifugal force while the other liquid phase (the mobile phase) is pumped through the rotating column. A variation of HSCCC, known as pH-zone-refining CCC, was developed in the early 1990s. Both conventional HSCCC and pH-zone-refining CCC have been applied to the separation of synthetic dyes. The principles of these techniques, the instrumentation involved, the basis for selecting the two-phase solvent systems, and the separation procedure itself have all been discussed by Ito in the earlier literature[1–4] and in the countercurrent chromatography entries of the present volume. A general approach to the separation of synthetic dyes using HSCCC is shown in Fig. 1.

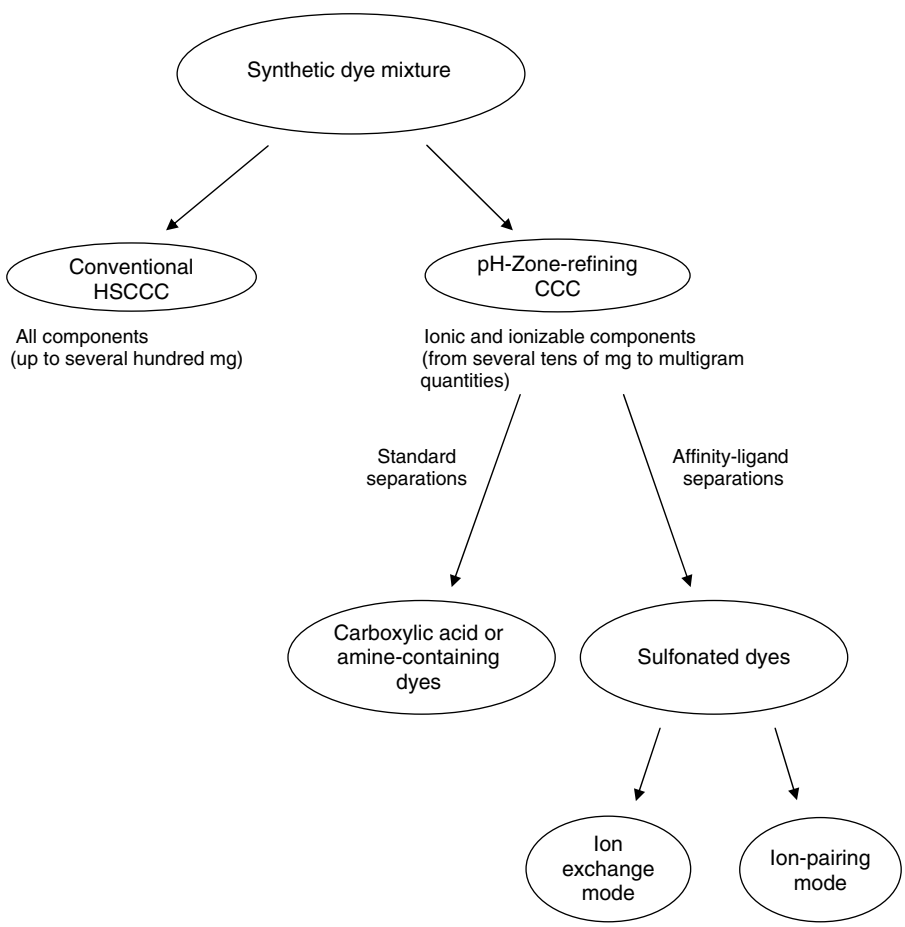

Fig. 1 General approach to the preparative separation of synthetic dyes using HSCCC.

CONVENTIONAL HSCCC

Conventional HSCCC has been used for synthetic dye separations since the mid-1980s. At that time, Fales et al.[5] separated various methylated homologues and contaminants from a 6 mg portion of the triphenylmethane dye Methyl Violet 2B (CI 42535), and Freeman and Willard[6] purified up to 520 mg of azo textile and ink dyes. Later applications have been documented for Sulforhodamine B (CI 45100)[7] and Phloxine B (CI 45410).[8]

There are two notable advantages of using this technique for the separation of synthetic dyes. First, it is applicable to the separation of both ionic and non-ionic components of a dye mixture. Second, it has been shown to be one of the best methods for successfully separating small quantities (20 mg or less) of dye mixtures. On the contrary, several hundred milligrams is the upper limit beyond which conventional HSCCC cannot be used for separating dye mixtures. Two examples of the application of this technique are shown in Figs. 2 and 3. Fig. 2 shows

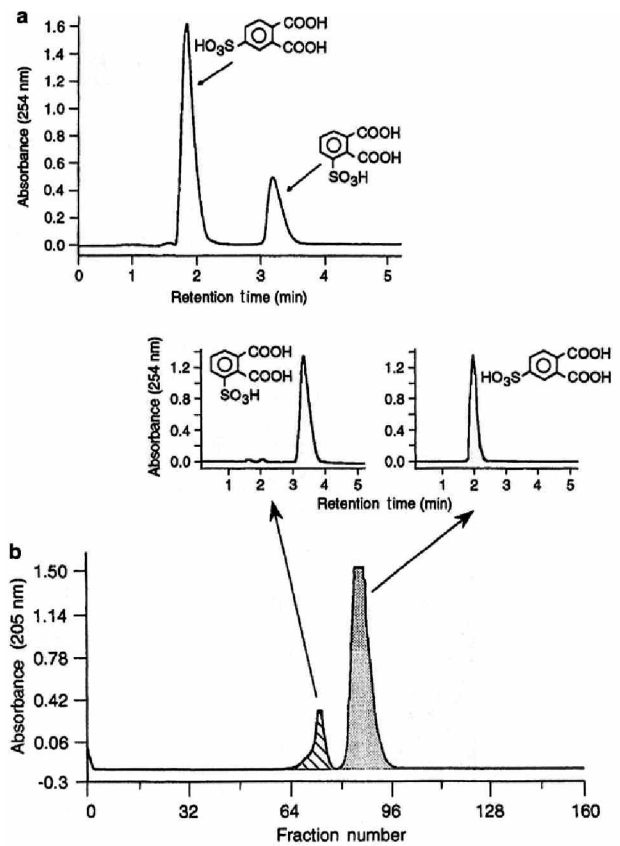

Fig. 2 Separation of 230 mg of a commercial mixture of two isomeric sulfophthalic acids by conventional HSCCC. a) HPLC analysis of the original mixture; b) HSCCC elution profile of the separation and HPLC analyses of the separated components.
Source: From Preparative separation of isomeric sulfophthalic acids by conventional and pH-zone-refining counter-current chromatography, in J. Chromatogr. A.[9]

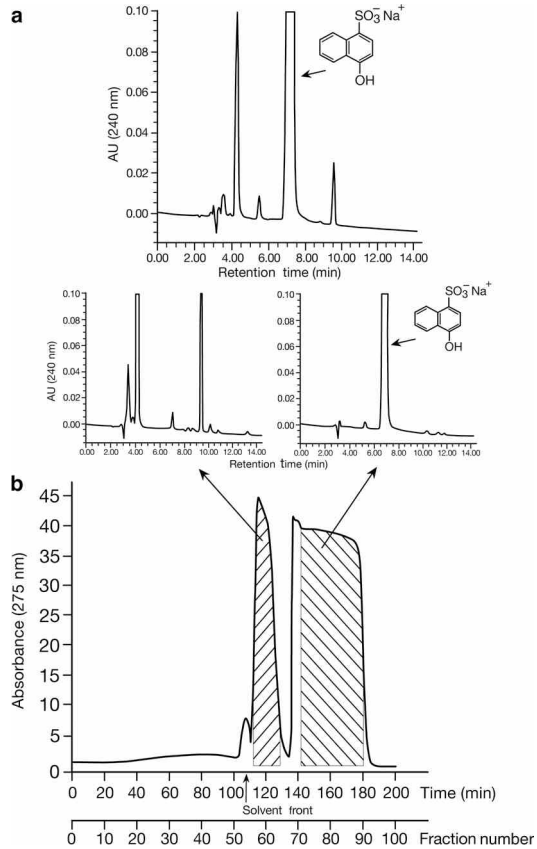

Fig. 3 Purification of 550 mg of "practical" grade 4-hydroxy-1-naphthalenesulfonic acid by conventional HSCCC. a) HPLC analysis of the original material; b) HSCCC elution profile of the separation and HPLC analyses of the separated components.
Source: From Preparative purification of 4-hydroxy-1-naphthalenesulfonic acid sodium salt by high-speed counter-current chromatography, in J. Chromatogr. A.[10]

the separation of 230 mg of a commercial mixture of two isomeric sulfophthalic acids,[9] and Fig. 3 shows the purification of 550 mg of commercially obtained "practical" grade 4-hydroxy-1-naphthalenesulfonic acid.[10] In both cases, the U.S. Food and Drug Administration (FDA) used the separated materials as standards in the development of analytical methods for batch certification of color additives.

pH-ZONE-REFINING CCC

pH-Zone-refining CCC is a relatively new preparative method of separation[3,4,11] that allows the separation of organic acids and bases according to their pK_a values and hydrophobicities. In contrast to conventional HSCCC, it permits the separation or purification of multigram quantities of dye mixtures, as long as those mixtures contain

ionic or ionizable components. The technique has been applied to the separation of synthetic dyes containing various functional groups, such as –COOH, –OH, $–NH_2$, and $– SO_3H$. Details on its application to dye separation were described.[12] Briefly, pH-zone-refining CCC of dyes can be divided into two categories:

1. Standard separations, for carboxylic acid- or amine-containing dyes
2. Affinity-ligand separations, for sulfonated dyes

STANDARD pH-ZONE-REFINING CCC

For separation by standard pH-zone-refining CCC, the sample components should be stable over a pH range of 1–10 during the separation period, and the minimum quantity of each targeted component should be no less than 0.1 mmol and preferably over 1 mmol. The requirements for the selection of a solvent system are different from those for conventional HSCCC separations. Carboxylic acid-containing dyes (e.g., xanthene dyes or their lactone analogues, fluoran dyes) may be separated by using an organic acid (e.g., trifluoroacetic acid) as a retainer in the organic stationary phase and a base (e.g., ammonia) as an eluter in the aqueous mobile phase. Dyes containing amino groups may be separated by using an organic base as a retainer (e.g., triethylamine) and an inorganic acid (e.g., HCl) as an eluter. The recommended steps in selecting an appropriate solvent system for the separation of dyes and the separation procedure have been described in detail elsewhere.[12]

Standard pH-zone-refining CCC was applied to the separation of pure components, sometimes multigram quantities, from the various types of halogenated fluoran and xanthene dyes shown in Table 1.

These dyes are used as biological stains and, except for Rose Bengal, as color additives permitted for coloring food (FD&C Red No. 3), drugs, and cosmetics in the United States. Standard pH-zone-refining CCC was also applied to the separation of contaminants from these colors and their intermediates. The purified contaminants were then used as reference materials in the development of analytical methods [high-performance liquid chromatography

Table 1 Fluoran and xanthene synthetic dyes separated by standard pH-zone-refining CCC.

U.S. listed name[a]	Common names[b]	CI no.[c]	CAS no.[d]	R_1	R_2	R_3

(HPLC), thin-layer chromatography (TLC), etc.] for batch certification of the color additives. Fig. 4 shows the separation of components from a 3 g test portion of FD&C Red No. 3 (Erythrosine, CI 45430) using standard pH-zone-refining CCC.[13] More details of the separation of the dyes shown in Table 1 by standard pH-zone-refining CCC have been described.[14]

AFFINITY-LIGAND pH-ZONE-REFINING CCC

Sulfonated dyes have not been amenable to separation by standard pH-zone-refining CCC because of their very low pK_a values, which prevent their partitioning into the organic phase of a conventional two-phase solvent system. The addition of a ligand, either an ion-exchange reagent (e.g., dodecylamine) or an ion-pairing reagent (tetrabutylammonium hydroxide), and a retainer acid (e.g., HCl, H_2SO_4) facilitate the partitioning of the sulfonated dye components into the organic stationary phase, thus enabling their separation by pH-zone-refining CCC. The more stringent conditions require that the components of a sulfonated dye mixture be stable over a pH range of 0.5–13.5 during the time of the experiment. The details and conditions required for the separation of sulfonated dyes by affinity-ligand pH-zone-refining CCC in the ion-exchange mode and in the ion-pairing mode can be found elsewhere.[12] Fig. 5 shows the separation by affinity-ligand pH-zone-refining CCC in the ion-exchange mode of the main components from a 1.8 g portion of the color additive D&C Yellow No. 10 (Quinoline Yellow, CI 47005).[15] The two-phase solvent system used consisted of iso-amyl alcohol:methyl *tert*-butyl ether:acetonitrile:water (3:1:1:5). The ligand (dodecylamine), at a concentration of 5% (w/v), and sulfuric acid used as the retainer were added to the organic stationary phase. The separation obtained for the two monosulfonated positional isomers, 6SA (0.6 g) and 8SA (0.18 g),

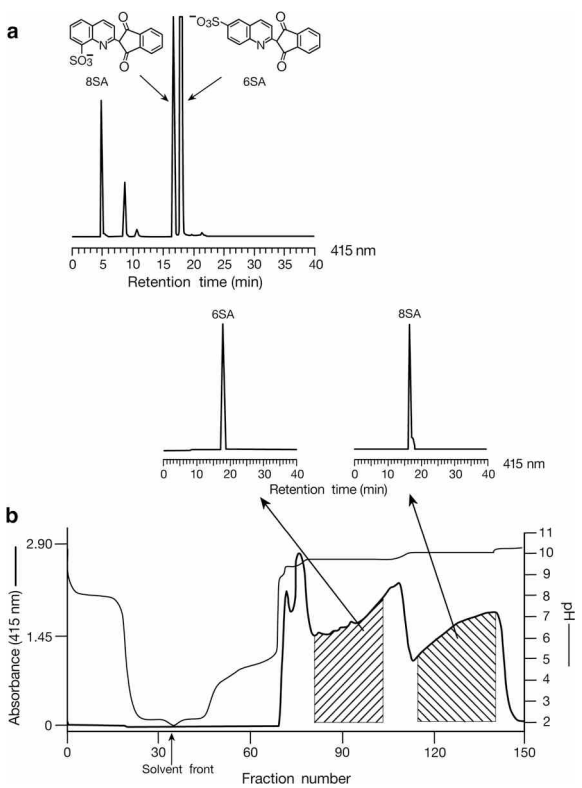

Fig. 5 Separation of a 1.8 g test portion of color additive D&C Yellow No. 10 (Quinoline Yellow, CI 47005) by affinity-ligand pH-zone-refining CCC in the ion-exchange mode. a) HPLC analysis of the original dye; b) pH-zone-refining CCC elution profile of the separation and HPLC analyses of the separated components.

both at over 99% purity, is shown by the associated HPLC chromatograms in Fig. 5.

Using a modified procedure, the applications of this technique have been extended to the separation of the highly polar disulfonated and trisulfonated components of D&C Yellow No. 10 and Yellow No. 203 (the Japanese Quinoline Yellow, CI 47005).[16] Other sulfonated dyes such as the azo dyes FD&C Yellow No. 6 (Sunset Yellow, CI 15985)[4] and FD&C Red No. 40 (Allura Red, CI 16035) have also been separated by this method.

CONCLUSION

HSCCC in its conventional and pH-zone-refining modes is an effective method for the separation and/or purification of synthetic dyes. Conventional HSCCC is useful for separating both the ionic and non-ionic components of a dye mixture in quantities of up to several hundred milligrams. On the contrary, pH-zone-refining CCC is the method of choice if ionic or ionizable dye components are to be separated at the multigram level. The latter application is particularly noteworthy since there is no evidence in the literature of preparative-scale separation of multigram quantities of these dyes by any other chromatographic method. Furthermore, it is likely that with modifications of current HSCCC instrumentation, the technique could be scaled up for successful separation of kilogram quantities of dyes. Among the benefits of obtaining large quantities of highly purified dyes is the potential for standardization of biological stains, which in turn would enable reliable comparisons of data across medical laboratories.

Synthetic Dyes: TLC

Tibor Cserháti
Esther Forgács
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

INTRODUCTION

Synthetic dyes are extensively used in many up-to-date industrial processes and research, mainly in the preparation of textile, food, and leather products, as well as in cosmetics and medicine. The widespread application of synthetic dyes has resulted in serious environmental pollution: Their occurrence in ground water and wastewater and the accumulation in sediment, soil, and various biological tissues has often been observed and reported. Dyes and intermediates can cause abnormal reproductive function in males and show marked toxic effects toward bacteria. The rate of biodegradation of the majority of synthetic dyes is very low, enhancing the toxicological hazard and environmental impact.

DISCUSSION

Commercial synthetic dyes generally contain more than one color product. As the knowledge of the exact composition of dye mixtures is prerequisite for their successful application in many fields of industry and research, many efforts have been devoted for the development of various chromatographic techniques suitable for their separation and quantitative determination. Moreover, the exact determination of the composition and quantity of synthetic dye is required in the control of industrial processes, in the following of efficacy of wastewater treatment, in environmental protection studies, and in forensic science.

The chemical structures of synthetic dyes show considerable variety. They generally contain more than one aromatic group, condensed aromatic substructures or heterocyclic rings (pyrazolone, thiazole, acridine, thiazine, oxazine) which are mainly hydrophobic, and, frequently, a polar basic or cationic group which is strongly hydrophilic. Due to these structural characteristics, they readily bind both to polar adsorptive and apolar reversed-phase (RP) chromatographic supports, making their successful separation difficult. As the synthetic dyes are not volatile and volatile derivatives are not known, gas chromatography (GC) methods cannot be employed for their analysis. Thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC) and, to a lesser extent, capillary zone electrophoresis (CZE) have been equally applied for this purpose. Due to its inherent advantages (simplicity, low cost, rapidity, etc.), a large number of TLC methods have been developed and successfully applied for the analysis of synthetic dyes. Previous results obtained in the application of TLC for the separation of synthetic dyes were reviewed earlier.[1] The planar chromatography of dyes used in the leather[2] and cosmetic industries[3] was reviewed separately. The majority of TLC separations have been performed on the traditional silica layers using many solvents and solvent mixtures (chloroform, various alcohols, pyridine, *n*-hexane, toluene, ethyl acetate, etc.). The polar character of some substructures in the dyes frequently made necessary the addition of acidic (formic and acetic acid) or basic additives (ammonia, diethylamine) to the mobile phase to suppress the dissociation of these hydrophilic groups in order to increase, in this manner, the efficiency of separation and to improve spot shape. However, other than silica layers, various eluent additives have also been employed for the enhancement of the efficacy of TLC. Thus, microcrystalline cellulose thin layers were employed for the study of the retention behavior of some synthetic dyes such as methyl orange (4-[4-(dimethylamino)phenyl]azo]benzene acid sodium salt), methyl red (2-[4-(dimethylamino)phenyl]azo]benzoicacid), methyl yellow (*N*,*N*-dimethyl-4-(phenylazo)benzeneamine), ethyl orange (4-[4-(diethylamino) phenyl]azo]benzene acid sodium salt), ethyl red (2-[4-(diethylamino)phenyl]azo]benzoic acid), alizarin yellow R (2-hydroxy-5-[(4-nitrophenyl)azo]benzoic acid) and alizarin yellow 2G (2-hydroxy-5-[(3-nitrophenyl)azo]benzoic acid monosodium salt).[4] The R_f values of dyes obtained in the presence of various eluent additives are compiled in Table 1. The data clearly show that eluent additives can be successfully used for the modification of the retention behavior of azo dyes, improving the separation capacity of TLC.

Table 1 Values of azo dyes on microcrystalline cellulose thin layers (merck 557) with various eluent additives at room temperature (CD = cyclodextrin).

	0.5 *M* HCl		1 *M* Na_2CO_3			1 *M* NaCl		
Azo dye	α-CD polymer 1%	α-CD 1%	α-CD polymer 1%	α-CD 1%	Control	α-CD polymer 0.5%	β-CD polymer 0.5%	τ-CD polymer 0.5%

The separation characteristics of a considerable variety of other TLC supports were also tested using different dye mixtures (magnesia, polyamide, silylated silica, octadecyl-bonded silica, carboxymethyl cellulose, zeolite, etc.); however, these supports have not been frequently applied in practical TLC of this class of compounds. Optimization procedures such as the prisma and the simplex methods have also found application in the TLC analysis of synthetic dyes.[5] It was established that six red synthetic dyes (C.I. 15580; C.I. 15585; C.I. 15630; C.I. 15800; C.I. 15880; C.I. 15865) can be fully separated on silica high-performance TLC (HPTLC) layers in a three-solvent system calculated by the optimization models. The theoretical plate number and the consequent separation capacity of traditional TLC can be considerably enhanced by using supports of lower particle size (about 5 μm) and a narrower particle size distribution. The application of these HPTLC layers for the analysis of basic and cationic synthetic dyes has also been reviewed.[6] The advantages of overpressured (or forced flow) TLC include improved separation efficiency, lower detection limit, and lower solvent consumption, and they have also been exploited in the analysis of synthetic dyes.

The detection of synthetic dyes on any type of TLC or HPTLC support is very easy; they contain chromophore groups and can be seen without using an ultraviolet (UV) lamp or detection reagents.

The quantitative evaluation of the amount of dyes in a spot can be carried by the traditional method of scrapping the spot from the plate, dissolving the dyes in a solvent and measure the extinction of the solution. This method is time-consuming and the reproducibility is fairly poor. To date, quantitative evaluation methods such as videodensitometry and scanning densitometry have also found application in the TLC analysis of dyes. The reproducibility of these evaluation methods is higher and commensurate with those obtained by HPLC; the time consumption is signifacantly lower than that of the traditional "scraping-dissolving" method. The separation and quantitative determination of the impurities of the dye Phloxim B (2′,4′,5′,7′-tetrabromo-4,5,6,7-tetrachloro-3′,6′-dihydroxyspiro[isobenzofuran-1(3*H*),9′-[9*H*]xanthen-3-one-sodium salt) was performed on silica HPTLC layers.[7] A lower-halogenated impurity (2′,4′,5′-tribromo derivative) was separated by the mobile-phase acetone-chloroform-*n*-butylamine (66 : 24 : 4.5 v/v). Ethyl ester impurity was separated from the main fraction of Phloxim B with chloroform–glacial acetic acid (4 : 1 v/v). The concentration of impurities was determined *in situ* by videodensitometry. It was established that HPTLC–videodensitometry is rapid and reliable and can be successfully used for the measurement of impurities in Phloxim B. Although the TLC analysis of synthetic dyes is well established, the number of theoretical articles dealing with the quantitative relationship between retention characterisitcs, molecular structure, and physicochemical parameters of solutes is surprisingly low. The retention behavior of seven monotetrazolium and nine ditetrazolium salts on alumina and RP alumina was recently studied and the relationship between retention and physicochemical parameters of this class of synthetic dyes was elucidated by canonical correlation analysis.[8]

Calculations indicated that the retention on both TLC supports is of mixed character, including hydrophobic, electronic and steric parameters.

It can be concluded from the present state of the art of TLC analysis of synthetic dyes that the methods are mainly limited to the application of traditional TLC technique. Due to the rapidly developing instrumentation and

automation of the various steps of TLC analysis and the introduction of coupled methods (TLC/MS, TLC–Fourier transfer infrared spectrometry, etc.), their acceptance and successful application in the analysis of synthetic dyes can be expected in the near future. The use of new TLC techniques not only increases the separation capacity of the method but also considerably decreases the detection limit of solutes and may contribute to their identification.

Taxanes: HPLC Analysis

Georgios A. Theodoridis
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Taxanes have gained wide interest due to the pharmacological properties of paclitaxel (Taxol™), the most well-known member of this large family of natural products. Paclitaxel is a complex diterpene amide originally derived from the pacific yew tree. The drug has been characterized by the National Cancer Institute (NCI) as "the most important anticancer agent for the past 15 years." The interest in paclitaxel dates back to 1962, when crude extracts of *Taxus brevifolia* bark were tested in a large-scale exploratory plant-screening program of the NCI. Paclitaxel was identified as the active constituent of the bark extracts by Wani et al.[1] However, the clinical development of paclitaxel was delayed due to high toxicity, difficulties in formulation, and mainly its scarcity, which hampered a reliable supply for clinical use.

PACLITAXEL AND TAXANES

Awareness about paclitaxel increased dramatically in the late 1970s, when scientists at Albert Einstein Medical College (New York) described the unique mechanism of its cytotoxic action as a promoter of microtubule assembly. In contrast to most of the conventional anticancer drugs, paclitaxel inhibits mitosis through the enhancement of tubulin's polymerization and the consequent stabilization of microtubules. In 1983, the NCI commenced Phase I clinical trials. Six years later, the John Hopkins Oncology Center (Baltimore) reported exceptional clinical results for the treatment of ovarian cancer. The same year, Bristol-Myers Squibb was selected by the NCI as its partner to commercialize the drug under the trademark Taxol™. Since then, numerous other pharmaceutical companies focused on the development of novel anticancer agents of *Taxus* origin. Hence, a number of taxane pharmaceuticals were launched: Yewtaxan® (paclitaxel from Yew Tree Pharmaceuticals), paclitaxel (Napro; Australia). Researchers at the French CNRS, in cooperation with Rhone Poulenc (now Aventis), developed a semisynthetic derivative, starting from 10-deacetylbaccatin III (Fig. 1). The drug was called Taxotere and it exhibited attractive features compared to paclitaxel itself: better water solubility, potency, and the particular way of its production from a renewable source. Taxotere has received Food and Drug Administration (FDA) approval for the treatment of locally advanced or metastatic breast cancer and non-small cell lung cancer (NSCLC). Taxanes, in general, are used as a second-line cytostatic agent, meaning that they are often administered in cases where cancer recurs after chemotherapy with platinum drugs.

Paclitaxel is one of the best performers in the pharmaceutical market, with sales increasing by 62% in 1995 and reaching $941 million in 1997. Paclitaxel and taxotere have shown promising results in patients with advanced squamous cell carcinoma of the head and the neck, malignant melanoma, advanced NSCLC, small cell lung cancer (SCLC), germ cell cancer, urothelial cancer, esophageal cancer, non-Hodgkins lymphoma, and multiple myeloma. Furthermore, they have been tested in HIV and multiple sclerosis patients. Taxanes were also successfully combined with cisplatin, carboplatin, and/or etoposide in the treatment of patients with NSCLC, SCLC, or advanced squamous cell carcinoma of the head and neck.

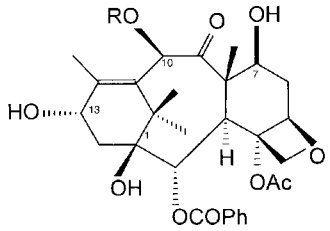
The drugs are now considered a prototype for a new class of chemotherapeutic agents and research has been proceeding at record pace for years. The publication of five books on the chemistry, pharmacology, and medical therapy stands as a witness of the excitement that the compound has raised.[2–6]

Despite its low content (100 mg/kg of dry bark) and its notoriously slow growth, *T. brevifolia* was, until recently, the sole source of paclitaxel. Supply shortage and increasing demands for clinical use necessitated the investigation for alternative sources. Hence, plant species, tree parts, cell culture, fungi, and (semi)synthesis have been sought to solve the tremendous supply crisis in the mid-1990s. Nowadays, remaining problems include the compound's inherent toxicity, poor solubility in water, and difficulty encountered during formulation. Hence, optimization of the drug delivery, improvement of its molecular properties, and production of paclitaxel analogues (more potent, less toxic, and easier to formulate) are still a matter of considerable research and development efforts.

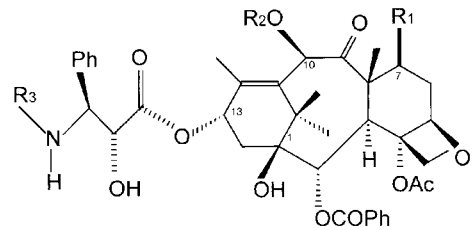
ANALYTICAL CHALLENGES AND METHODS

In general, the analysis of taxanes is driven by the following:

1. The need for the determination of paclitaxel (or docetaxel to a lesser extent) and their metabolites in biological samples.



(1) 10-DAB III: R=H
(2) Baccatin III: R=Ac



(3)	7-xylosyl-10-deacetylpaclitaxel B:	R1=xylose (β);	R2=H;	R3=tigloyl =
(5)	7-xylosyl-10-deacetylpaclitaxel:	R1=xylose (β);	R2=H;	R3 =Benzoyl

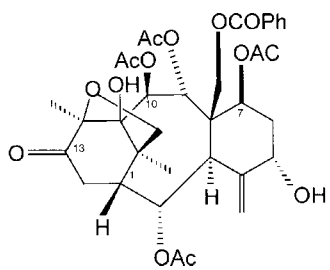
(14)	Docetaxel	R1=OH (α);	R2=Ac;	R3=butoxy carbonyl



(4) Taxinine M

Fig. 1 Molecular structures of the most common taxanes.

2. The need for the purification or/and determination of taxanes in plant material, cell culture, or synthetic mixtures.

The starting point presides over the choice of the final analytical protocol. Analysis in biological samples for pharmacokinetic purposes poses limited difficulties because the determination of paclitaxel in human blood is rather straightforward. In contrast, analysis of plant samples deals with samples containing lesser quantities of a complex mixture of several taxanes. Separation and identification is thus a real challenge for the chromatographer.

Analysis of taxanes is performed almost exclusively by high-performance liquid chromatography (HPLC). Immunological techniques [enzyme-linked immunosorbent assay (ELISA), radioimmunoassay (RIA)] have found minimal use in screening human plasma and plant extracts. Such biological methods suffer from cross reactivity of several taxanes with paclitaxel and their use is thus limited in semiquantitative aspects.

MS, employing most of the ionization techniques, has been used either independently, or in combination with HPLC, for the determination of the dissociation scheme of paclitaxel or for the identification of taxanes and paclitaxel metabolites. Tandem MS has enhanced identification and structure elucidation capabilities in the analysis of either biological or plant samples.

A few research groups utilized other chromatographic techniques for the purification of taxanes from natural

sources or synthetic organic mixtures. Techniques such as TLC, flash chromatography, high-speed countercurrent chromatography (HSCCC), micellar electrokinetic chromatography (MEKC), and supercritical fluid chromatography (SFC) and extraction (SFE) have been used for either sample purification and/or analysis. TLC on silica gel has been used for the isolation and, together with NMR and MS, for the identification of new taxanes from several *Taxus* species. Visualization was accomplished by spraying the plates with anisaldehyde solution and heating. HSCCC provides an elegant method for fast and efficient processing of large sample quantities, a parameter of great importance for scale-up purposes. HSCCC is not based in adsorption chromatographic mechanisms, in contrast to the established taxane purification methods (including the FDA-approved official method), which employ column chromatography. A two-phase system of light petroleum–ethyl acetate–methanol–water purified plant samples of up to 400 mg, achieving purity of up to 97% for paclitaxel. MEKC performed on uncoated fused silica capillaries proved suitable for the analysis of paclitaxel, cephalomannine, and baccatin III in needle extracts. Finally, SFC has been carried out in both capillary and packed C_{18} or cyano columns. The packed cyano column gave the best performance for the analysis of taxanes after SFE of *Taxus baccata* clippings.

HPLC OF TAXANES

HPLC analysis of taxanes is achieved almost exclusively in reversed-phase (RP) mode on various stationary phases. The normal-phase HPLC mode has been applied in very limited cases and resulted in broad peaks and long analysis times (retention times of 45 min for paclitaxel and 38 min for cephalomannine). The nature of the sample is the main criterion for the choice of the stationary phase. Analysis of plant material is performed mostly on phenyl, biphenyl, and pentafluorophenyl materials, but silica-based cyano, C_{18}, and C_8 materials have been used as well. C_{18} phases are the most common material utilized in pharmacokinetic studies. Mobile phases typically consist of mixtures of methanol, acetonitrile, and water or buffer (mostly ammonium acetate). Detection is performed by UV, mostly in the low region of 225–230 nm. Taxanes give similar UV spectra with a minimum at 210–215 nm and a maximum at 225–232 nm. Therefore, detection is performed, preferably at 227–228 nm. Dual/multiple UV detection is performed in both low and upper regions, e.g., 227 and 273 nm; 230 and 280 nm; 227, 254, and 270 nm, etc. (Fig. 2).

In the reported LC-MS schemes, both positive and negative ionization modes have been used; however, positive ionization is the dominant mode. Thermospray and

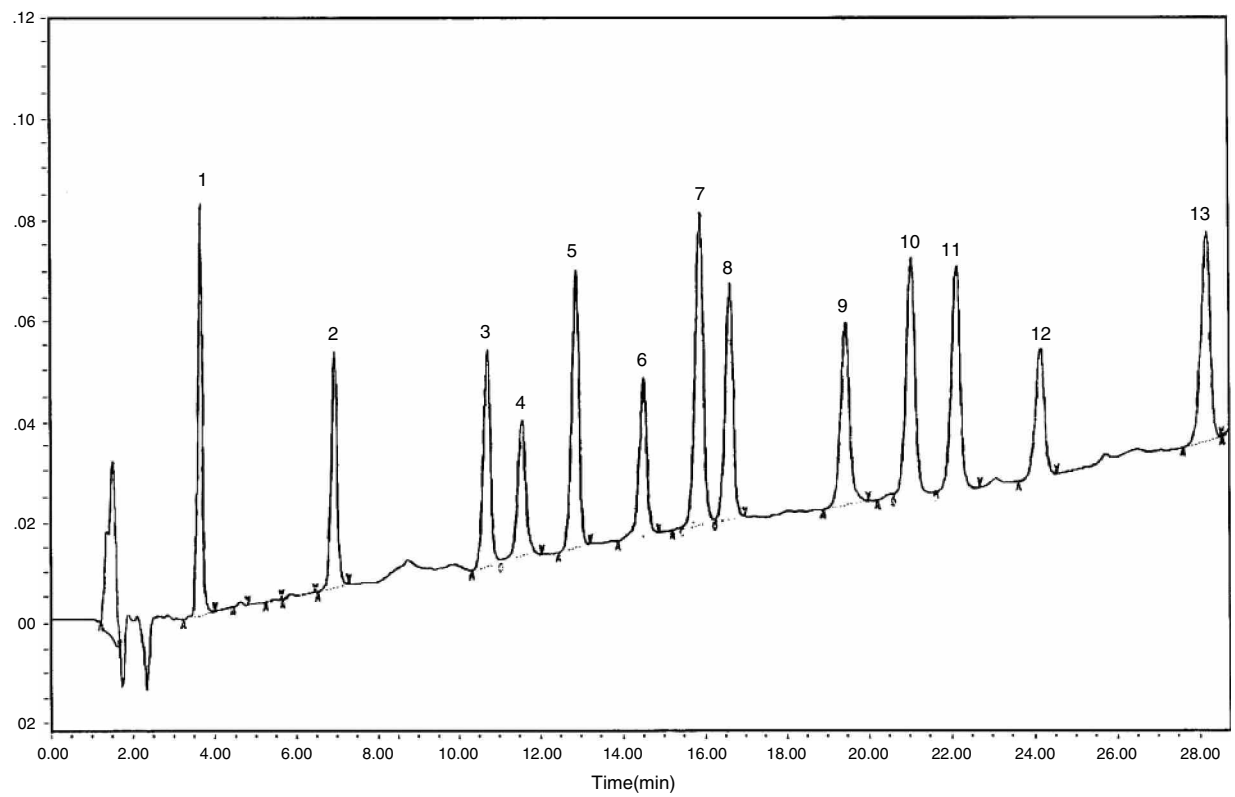


Fig. 2 UV spectra obtained by HPLC analysis of a *Taxus* cell culture extract. Detection with a photodiode array detector. **1** = Paclitaxel, **2** = cephalomannine, **3**, **4**, and **5** correspond to unknown interferences from the sample.

electrospray interfaces have been utilized for the coupling of RP mobile phases to the MS. In tandem MS, fragments are obtained from the taxane ring (ions with *m/z* 268 and 286) and the C-13 side ester chain (ions with *m/z* 569, 551, and 509).

Detailed description of the analytical separation systems for the analysis of paclitaxel by HPLC (stationary and mobile phases, sample type, sample pretreatment) can be found in a review that appeared recently.[7]

HPLC Analysis of Plant Material and Cell Culture

Analysis of paclitaxel in plant material bids a challenge for the separation scientist for many reasons:

1. The taxanes are present in low quantities in the original samples (either plant or cell culture).
2. The differences between the molecular structure of different taxanes are small (Fig. 1).
3. Plant extracts encompass a diversifying range of endogenous compounds.

These problems can be easily perceived in the reported chromatograms: broad peaks, long analysis times, and poor resolution from endogenous interferences.

Initially, researchers focused on the separation of paclitaxel from cephalomannine, a paclitaxel analogue that shares the C-13 ester side-chain and, therefore, exhibits cytotoxic activity. Cephalomannine was found to elute close to paclitaxel and caused interferences for determination and purification purposes. Lately, the main taxane targets are baccatin III and 10-deacetylbaccatin III (10-DAB III). Both compounds lack the C-13 side-chain (Fig. 1); thus, they do not show antitumour activity. Both baccatins, especially 10-DAB III, serve as synthons for the synthesis of paclitaxel or analogues. 7-Epi-paclitaxel differs from paclitaxel only in the stereochemistry of the hydroxy group in the C-7 position. 7-Epi-paclitaxel, a product of paclitaxel epimerization, shows cytotoxic activity and difficulty in separation from paclitaxel. The deacetyl derivatives of paclitaxel, 7-epi-paclitaxel, baccatin III, and cephalomannine, are also quite often the subject of analysis. The problems mentioned above designated a market for HPLC column manufacturers, which did not take long to fill with "tailor made" or "specialty" columns. Taxanes are probably the sole group of compounds that labeled so many HPLC columns: Phenomenex has produced three Curosil™ columns (silica-based RP packing material), Metachem Technologies also manufactured three Taxil™ columns, Zorbax made the SW-Taxane column (bonded silica), and Whatman the TAC 1 column. It should be pointed out that such columns are usually developed in order to solve special problems. According to their manufacturers, the chemical and physical properties of the packing material (which are often proprietary) are designed with appropriate characteristics for a specific analyte or group of analytes. However, it is often observed by many researchers (the author included) that the best results are actually obtained by utilizing a low-cost conventional material.[9] An example is illustrated in Fig. 3, which shows a UV chromatogram of a reference taxane mixture obtained by gradient elution on a generic phenyl column. The same chromatographic analysis performed on electrospray MS provided mass spectral data that were used for the identification of unknown peaks in *Taxus* bark extracts. Results are depicted in Table 1.

Sample Pretreatment of Plant Material and Cell Culture

Optimization of the extraction and purification of taxanes from plant material, tissue culture, or biological fluids has been the subject of extensive research. As mentioned already, taxanes are present in small quantities in a very complex matrix, thus making extraction and purification complicated. Simple extraction schemes do not cope with straightforward HPLC analysis because they are subject to column plugging and deterioration, low recovery, and poor chromatographic resolution. On the other hand, tedious and complex procedures that have been developed to overcome such problems require large amounts of solvent and long extraction times (surpassing even 48 hr).

A typical strategy takes advantage of the limited water solubility of taxanes to partition the compounds between water, and an apolar organic solvent (often a chloromethane). Hence, a plant material in the form of a crude methanolic plant extract is partitioned between water and dichloromethane; the dichloromethane fraction is evaporated to dryness, reconstituted in methanol, and analyzed by HPLC. Initially, such simple extraction procedures were used for the determination of taxanes in plant extracts, but they resulted in high back pressure and the need for frequent column flushing. Furthermore, as *Taxus* phytochemistry consolidated, analytical methods of higher resolving power became necessary. Additional extraction steps for the removal of non-polar components (especially from samples such as needles) utilized hexane or similar apolar solvents. The plant material is first extracted with hexane for the removal of waxes and other lipophilic substances. Alternative protocols employed techniques such as column chromatography, HSCCC, SFE, and semipreparative HPLC.

Recently, solid phase extraction (SPE) on several stationary phases has been extensively used in the pretreatment of both plant and biological samples. Typically, crude extracts are mixed with appropriate solvents (methanol or ethanol) and the resulting solutions are applied onto the SPE cartridges. The cartridges are next washed with appropriate solvents to take out impurities and, finally, the taxanes are eluted in an optimized "recovery solvent." The obtained taxane fraction is evaporated to dryness and, after reconstitution to solution, an aliquot is analyzed by HPLC.

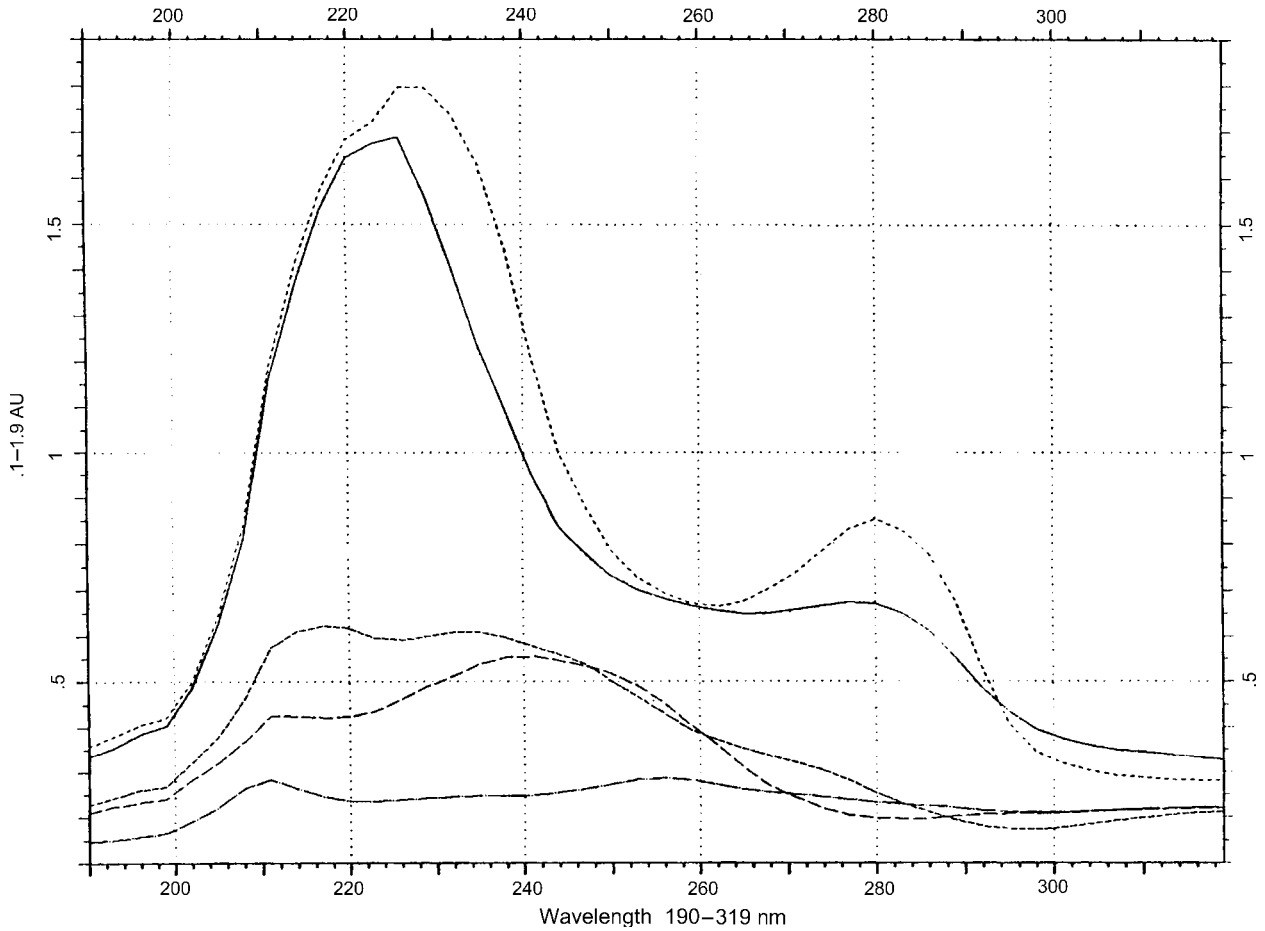

Fig. 3 Analysis of a taxane standard mixture. Chromatographic conditions: Column Novapak Phenyl column (Waters); eluted with the gradient program: Initially 100% A–0% B, linearly 56% A–34% B at 30 min and then back to 100% A–0% B at 32 min. A = 0.05 *M* CH_3COONH_4:CH_3CN 7:3 v/v, B = 0.05 *M* CH_3COONH_4:CH_3CN 1:9 v/v. Flow rate 0.8 ml/min and detection at 227 nm. Peak identities as in Fig. 1.

The author has studied the SPE of taxanes at length.[10] SPE offers an attractive alternative to the long and tedious liquid–liquid extraction schemes. The author's work on HPLC determination of taxanes[9] and SPE for the pretreatment of *Taxus* plant and cell culture samples[10] resulted in fast and robust schemes for either screening or accurate determination of taxanes in plant and cell cultures. In this work, problems were observed in liquid–liquid extraction of the cell suspension medium as a result of the formation of emulsions. Such formations are difficult to break and require time-consuming and laborious centrifugation. Therefore, the major goal of the developed SPE protocols was the straightforward application of aqueous medium on the SPE column. As a result, consumption of time and organic solvents was lowered significantly. Washing the cartridge with water and aqueous MeOH (up to 50% in water) facilitated the removal of many interfering matrix constituents. Taxanes were recovered from the SPE cartridge with the elution fraction of 80% MeOH.[10]

HPLC Analysis of Biological Material

Interest for the analysis of taxanes in biological fluids deals, in most cases, with the determination of the two pharmaceuticals, paclitaxel, and docetaxel, and their metabolites in blood plasma. The complexity of this matrix and the interference of endogenous compounds are, in principle, decreased, compared to plant material; therefore, extensive sample pretreatment and high chromatographic resolution are not essential. Thus, fast and simple separation systems with the use of a C_8 or a C_{18} column are often preferred. SPE is extensively used for sample pretreatment (especially in recent reports) because of its advantages over liquid extraction: limited organic solvent consumption, higher reproducibility and extraction efficiency, and cleaner extracts. Furthermore, sophisticated online SPE schemes that employ column switching or automated SPE increase sample throughput.

Paclitaxel and docetaxel are very lipophilic pharmaceuticals; thus, they bind to plasma proteins rapidly and to a

great extent (>95%). Small quantities are excreted in urine because most of the drug is removed from the plasma metabolized in the liver and subsequently excreted into the bile.[2] Paclitaxel pharmacokinetics follow a bimodal distribution. Usually, such studies are modeled with a two-compartment system: a central administration compartment (plasma-liver) and a second peripheral compartment (tissue where the drug is transported by secondary mechanisms). It should be pointed out that the lipophilicity of taxane pharmaceuticals causes tremendous problems in formulation and clinical administration. Paclitaxel's vesicle is a mixture of 50% polyethoxylated castor oil (a surfactant labeled Cremophor EL), and 50% ethanol. This mixture causes serious adverse effects to patients. Cremophor is also subject to interferences in chemical analysis of pharmaceutical preparations of the drug. The drug is infused intravenously for varying time periods. Depending on the length of infusion, the concentration maximum in plasma varies from 3–4 μM (short infusion of 6 hr) to 0.7–0.9 μM (long infusion of 24 hr). Following HPLC, detection of paclitaxel by UV (227 nm) is sufficient; however, MS offers much higher sensitivity and identification capabilities.

Separation systems are rather simple and they employ solvents such as methanol or acetonitrile and buffers such as sodium acetate, ammonium acetate, or phosphate buffers. Isocratic elution suffices in most cases because the polarity of the drug is far different than most endogenous compounds, thereby enabling an easy chromatographic separation.

The sample that draws the greatest interest is human plasma, but other physiological human fluids, such as urine and bile, have also been the subject of analysis. To cover the needs of in vivo preclinical studies, many researchers developed methods for the determination of paclitaxel/docetaxel and their metabolites in samples from animal models such as rat and mouse.

Coupling of HPLC analysis to MS (either online or off-line) provided the means for structure elucidation and identification of taxane metabolites. Utilizing tandem MS (MS/MS), both aspects were significantly enhanced. Hydroxylation, epimerization, and hydrolysis are considered to be the main routes of metabolism of taxane pharmaceuticals.[3] The principal metabolites of both paclitaxel and docetaxel result from hydroxylation. Hydroxylation of paclitaxel was initially observed in rat and mouse, but the finding was later extended to human subjects. Nine metabolites of paclitaxel (mono or dihydro derivatives) have been identified in rat by HPLC, NMR, and LC/MS. With regard to docetaxel, 18 derivatives have been identified in the rat bile. Hydrolytic derivatives result from cleavage of the side C-13 chain, and include baccatin III and 10-DAB III. Epimerization of taxanes is mainly focused on the C-7 and C-10 atoms, and occurs in solution. Epimerization has also been detected in cell culture in both the medium and inside the cell. It should be stressed that epimers are not naturally occurring taxanes; thus, they are not found in plants.[2–3,8–9]

A detailed tabulated list of HPLC methods (columns, mobile phases, applications, and detection modes) can be found in Ref.[8]

CONCLUSIONS

Analysis of taxanes in biological samples and plant extracts is performed, mainly by RP-HPLC. Separation of paclitaxel from cephalomannine, baccatin III, and other taxanes is often performed with phenyl columns (especially for plant material analysis). For less complex biological samples, C_{18} columns are preferred because they give shorter analysis times. Extraction of plant material or cell cultures is often performed by water–

dichloromethane partitioning, but lately, the application of SPE has become a basic step in order to obtain cleaner samples, higher extraction recovery, better chromatographic resolution, and longer column lifetime. Detection of taxanes is performed, in most cases, at 227–228 nm.

Taxines: HPLC Analysis

Georgios A. Theodoridis
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

The toxicity of *Taxus* plants has been known for a long time (reports date as far back as the time of Julius Caesar).[1] In the 19th century, phytochemical work attributed *Taxus* toxicity to an alkaloid that was called taxine. This alkaloid was a complex mixture, isolated from leaves. Taxine was later shown to be a mixture of more than seven alkaloids, with taxine A and taxine B as main constituents. Taxines are very strong cardiotoxic agents; they cause convulsions, fall in blood pressure, and stopping of the heart in diastole. Phytochemical work on *Taxus* during the 1940s and 1950s was focused on taxines and their cinnamate analogues, taxinines. The discovery of the potent cytostatic agent paclitaxel in *Taxus* bark in the late 1960s overshadowed any interest in taxines. Paclitaxel and the semisynthetic derivative docetaxel attracted unprecedented interest and remained the major research topic for scientists on diverse areas as follows: phytochemistry, pharmacognosy, molecular pharmacology, synthetic chemistry, analytical chemistry, and, most of all, clinical medicine.

TAXINES

A chief problem in the early development of taxane pharmaceuticals was the establishment of a steady and dependable supply. Taxanes are present in low quantities in plants. In contrast, taxines are relatively abundant in plants (especially in *Taxus baccata* and *Taxus cuspidate*); they can serve as an alternative starting material for semisynthetic production of paclitaxel derivatives. The major taxines are taxine A and taxine B.[2,3] There is a significant structural resemblance between taxine B and taxanes (Fig. 1). Both groups share the main taxane ring; moreover, the C-5 side chain of the taxines has a close spatial position to the C-13 side chain of the taxanes (the latter is essential for antitumor activity). A biosynthetic hypothesis involved the intermediacy of a C-5 to a C-13 ester transfer; it was also demonstrated that taxine B can be converted into a baccatin V derivative. Taxines do not show antitumor activity, whereas the cardiotoxicity of taxol is lower compared to taxines but is undesirable for clinical administration. Hence, it was assumed that the structural features necessary for cardiotoxicity are different from the features necessary for antitumor activity. Understanding the factors responsible for the toxicity of taxines could lead to the design of taxol analogues with diminished cardiotoxicity. However, taxines do not show intrinsic antitumor activity, whereas the cardiotoxicity of paclitaxel is lower compared to taxines but is undesirable for clinical administration. Hence, it was assumed that the structural features necessary for cardiotoxicity are different from the features necessary for antitumor activity. Understanding the factors responsible for the toxicity of taxines could lead to the design of paclitaxel analogues with diminished cardiotoxicity. Sophisticated analytical methods are therefore necessary for their analysis and determination in plant or biological samples.

Unfortunately, research work on taxines was hampered by their instability and the loss of activity upon storage because of the loss of dimethylamino moiety from the C-3′ atom (Fig. 1) and the formation of corresponding cinnamates. Isolation of taxines is accomplished by alkaline/base extraction but it is difficult to obtain them in a purified form because of rapid acetate isomerization and/or decomposition to taxinines. To the author's knowledge, there are no taxine/taxinine reference compounds commercially available. It is no surprise therefore that there are limited works that report on the high-performance liquid chromatography (HPLC) of taxines. Taxines were found in plant extracts interfering in extraction, isolation, and analysis of paclitaxel from plant material.[2–6]

HPLC ANALYSIS OF TAXINES

Workers of the phytochemical group at the University of Wageningen identified and isolated six taxine alkaloids from the needles of *T. baccata*. Acidic extraction with 0.5% (v/v) H_2SO_4 was followed by an extraction with Et_2O and basic extraction with 25% aq. NH_3. Taxines were recovered with $CHCl_3$ with a yield of 0.5–1% for the total crude taxine fraction. This report comprises the first analytical methodology for the determination of taxines. HPLC analysis employed a C_{18} column, eluted by a linear gradient of acetonitrile over methanol and 0.05 *M* sodium dihydrogen phosphate buffer.[7]

The research group of P. Potier, a group that has long been engaged in research activity on *Taxus*, studied the analysis of four taxines and 10-DAB III in *Taxus* needles in investigations for highly productive plants. The authors developed a normal phase separation system (silica eluted with chlorofom/methanol/triethylamine, 99.4 : 0.5 : 0.1)

for the evaluation of the total taxine content in *Taxus* needles. To separate the taxines, they used reversed phase (C_{18} eluted with acetonitrile/water/tetrahydrofuran, 23 : 77 : 0.5). The method, although it suffered from peak asymmetry and tailing, was useful for preparative objectives because it avoids the use of buffers.[8] Taxines have also been determined by gas chromatography/mass spectrometry (GC/MS) in a search of *Taxus* poisoning in cattle and horses. Even though taxines are molecules that are too large to be analyzed by GC, the authors actually measured an ion at 134 m/z^+, which was attributed to a specific fragment at the 2′ atom of the taxine side chain (Fig. 1).

The author's work on the HPLC analysis of taxines was a follow-up of previous research work on the HPLC of taxanes.[9,10] Unknown peaks present in the analysis of plant and cell culture extracts were suspected to be taxines. In previous works, several other researchers have reported the detection of impurity peaks in the extracts of *Taxus* × *media* (Hicksii) needles during the determination of taxanes. These uncharacterized impurities showed a UV maximum at 280 nm, with a A_{280}/A_{228} ratio of approximately 3.5. Using absorbance ratio with these two or similar wavelengths, the researchers managed to overcome quantitation problems.[11] Taxines and taxinines were also reported to cause problems in the HPLC analysis of taxanes, coeluting with the peak of paclitaxel.

In our work at Leiden University, apart from HPLC-photodiode array (PDA) detection, HPLC-electrospray mass spectrometry was used as characterization and identification tools. A semipurified taxine extract obtained with acid/base extraction of *T. baccata* needles was analyzed in reversed phase; nine taxines, one taxinine, and six taxanes were found present in the sample. Furthermore, 10-deacetylbaccatin III (paclitaxel's main precursor) and other taxanes were also found in the extract. Identification of the peaks was made with online liquid chromatography/mass spectrometry (LC/MS) and off-line nuclear magnetic resonance (NMR) following fraction collection at the end of the HPLC. Retention and spectral data of the identified peaks were used as tool to screen for taxines and taxinines in plant and cell culture extracts. Several

Source: From Analysis of taxines in *Taxus* seeds, needles and cell culture by HPLC-PDA and HPLC-ESI-MS, in J. Liq. Chromatogr.[12]

members of both groups of compounds were found in samples of various origin. LC/MS verified the presence of some of the known taxines and taxinines in extracts of *Taxus* needles, pollen, and seeds.[9,10]

HPLC-PDA detection offers an alternative for the cost-effective separation of taxanes and taxines in complex plant extracts. The spectrum index plots in Fig. 2 depict the chromatographic analysis of the taxine-purified extract on a C_{18} column with gradient elution. The UV spectra of the detected peaks are illustrated in the upper part of the chromatogram. A clearer prospect of the corresponding spectra is given in Fig. 3. It can be seen that 227 nm represents the maximum for the UV spectrum of taxanes, whereas 280 nm is the λ_{max} of taxinines and taxines. Hence, 280 nm can be used as a "selective" wavelength for the detection of taxines and taxinines. Use of absorbance ratios between three (or more) wavelengths can also provide a means of identification.[13] The absorbance ratios obtained after the analysis of reference mixtures were as follows:

- For 10-DAB III: $A_{227}/A_{215} = 1.67$, $A_{227}/A_{249} = 2.99$, $A_{215}/A_{249} = 1.78$.
- For taxol: $A_{227}/A_{215} = 1.35$, $A_{227}/A_{249} = 3.51$, $A_{215}/A_{249} = 2.55$.

Comparison of these values with the ones calculated from peaks eluting at similar retention times in the analysis of extracts could be a fast way to verify the identity and to check the peak purity. Analysis of the semipurified taxine mixture by gradient HPLC-DAD revealed the presence of seven taxanes with 10-deacetylbaccatin III (10-DAB III) among them. All the nine expected taxines were positively identified (Table 1).

CONCLUSIONS

Taxines were the subject of very few reported works over the last two decades although, until the 1960s, they were in the heart of phytochemical work on *Taxus*. The major reason for this is the instability of taxines and the unavailability of reference compounds. It can be concluded that HPLC seems to be the best method for the analysis of taxines because all the publications reporting on the analysis of taxines employ HPLC. Since taxines are abundant in plants, they could offer an attractive alternative for the supply of high-value taxanes by semisynthesis.

Taxoids: TLC Analysis

Tomasz Mroczek
Kazimierz Glowniak
Department of Pharmacognosy, Medical University of Lublin, Lublin, Poland

INTRODUCTION

Taxoids (Fig. 1) are diterpenoid compounds isolated from different yew species and possessing strong anticancer activity. They are applied usually in the treatment of cancers resistant to other antineoplastic drugs such as cisplatin or in conjunction with them. There are different chemical groups of natural taxoids, but among the most important is a group derived from 10-deacetylbaccatin III (10-DAB III), a diterpenoid compound occurring in high concentration in European yew, *Taxus baccata* L. It possesses a skeleton of four rings (6/8/6/4-membered), named taxan, and is a derivative of hexahydroxy-11-taxen-9-one. Baccatin III, which is another compound in this group, has in addition an acetyl group esterified with a β-OH group at position C-10. Paclitaxel and cephalomannine are less polar taxoids because they possess amide-acid side chains at position C-13. In case of paclitaxel, this is (2*R*,3*S*)-*N*-benzoyl-3-phenylisoserine, and in cephalomannine, (2*R*,3*S*)-*N*-tigloyl-3-phenylisoserine. There are also compounds in this group that have an epimer OH group at position C-7, and other substituents are also met. Thus, there are many compounds, usually with similar polarity and small differences in structure, that are difficult to separate.[1]

DESCRIPTION OF METHOD

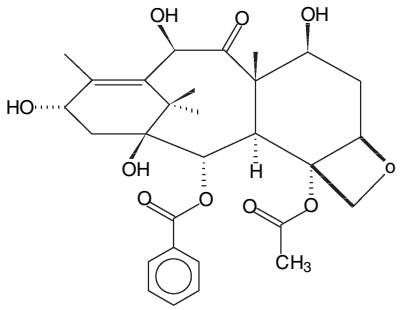
Thin-layer chromatography (TLC) is mainly applied in micropreparative taxoid separation.[2–4] Silica gel $60F_{254}$ preparative plates are usually employed for this purpose. The problem of taxoid separation involves not only their similar chemical structure (e.g., paclitaxel vs. cephalomannine) but also the different coextracted compounds usually encountered in crude yew extracts (polar compounds such as phenolics and non-polar ones such as chlorophylls and biflavones); the separation is therefore very difficult. The common band of paclitaxel and cephalomannine was satisfactorily resolved from the extraneous fraction in isocratic elution with ethylacetate as polar modifier[4] and *n*-heptane–dichloromethane as solvent mixture, and was of suitable purity for high-performance liquid chromatography (HPLC) quantitative determination. The combination of micropreparative TLC separation of callus extract of *T. baccata* with *n*-hexane–ethylacetate (2:3) mobile phase and preparative HPLC on Lichrosorb RP-18 column enabled 10-DAB III isolation.[3]

Systematic studies on selection of the best mobile phases to ensure the best micropreparative separation of analyzed taxoids—especially of 10-DAB III as well as its less polar derivatives, baccatin III, paclitaxel, and cephalomannine, obtained from the extracts of fresh and dried needles and stems of *T. baccata*—have been undertaken by Mroczek and Głowniak.[2] The TLC investigation on silica gel included solvent systems with one and two polar modifiers and multicomponent mobile phases, as well as some multiple development techniques and gradient elutions. As polar modifiers, methanol, acetone, dioxane, ethylacetate and ethylmethylketone as well as their mixtures were reinvestigated; dichloromethane, chloroform, benzene, toluene, heptane, and their mixtures were used as solvents.

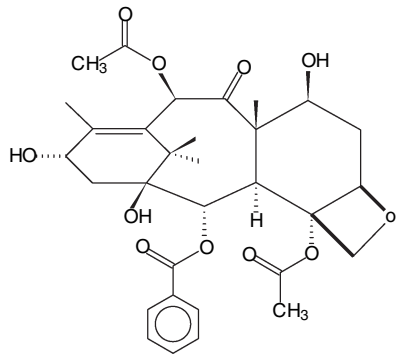
Using binary mobile phases containing 25–30% of one polar electron-donor modifier (acetone, dioxane) in dichloromethane or chloroform, high values of separation factor α (10-DAB III/paclitaxel) are observed as well as low elution of polar ballast compounds. Such chromatographic systems can be applied in separation by column chromatography (CC) of polar from less polar taxoids and their polar coextracted compounds in preliminary CC investigations on taxoids before further detailed studies. The addition (even just 15%) of a small amount of π-electron solvents such as benzene improves the separation of the band of less polar taxoids (paclitaxel, cephalomannine) and closely eluted chlorophylls. Mobile phases with two polar modifiers (acetone–methanol, ethylmethylketone–methanol) ensure relatively high values of α factor and the separation in the area of less polar taxoids is better in comparison with the separation obtained by single electron-donor mobile phases.

Because of the complexity of composition of yew extracts, different gradient elutions can be considered as further steps of detailed CC or TLC separations of different taxoids on silica gel.

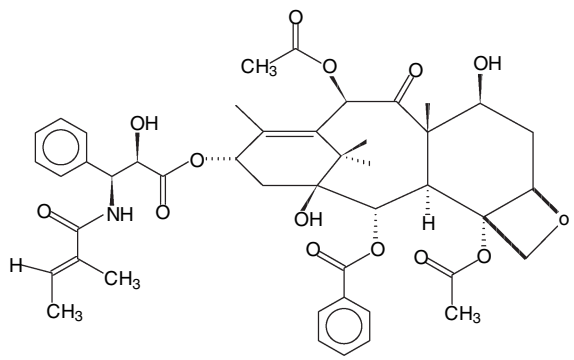
The multicomponent solvent system consisted of benzene–chloroform–acetone–methanol (20:92.5:15:7.5) developed over a distance of 15 cm (2×; in some cases, a third development was necessary), which enabled very good separation of coextracted compounds with both 10-DAB III



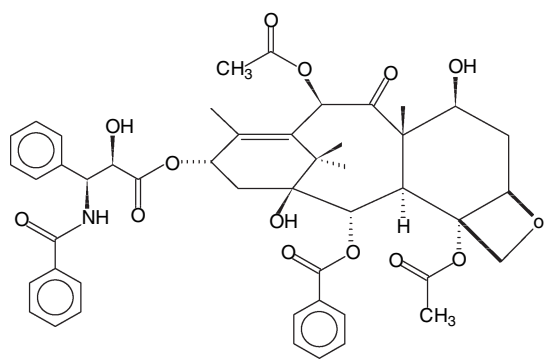
10-Deacetylbaccatin III (10-DAB III)



Baccatin III



Cephalomannine



Paclitaxel

Fig. 1 Chemical structures of taxoids.

and paclitaxel; the separation of whole yew extracts (*T. baccata*) was also very good. The separation of taxoids was better in extracts obtained from fresh needles and stems than from dried plant material. The extracts from the dried needles contained the highest concentrations of ballast compounds interfering with the bands of analyzed taxoids. The common band of paclitaxel, cephalomannine, and baccatin III was satisfactory purified from coextractives; the 10-DAB III band could be easily isolated and further HPLC determination in two isocratic mobile phases was applied. The investigated taxoids eluted in the following order: paclitaxel + cephalomannine, baccatin III, and 10-DAB III. An interesting observation was the considerable slope of baccatin III retention on silica gel in comparison with that of its 10-deacetyl derivative (10-DAB III) (α 10-DAB III/baccatin III amounted to 2.8).[2] This indicates the more hydrophobic properties of baccatin III. This chromatographic behavior of baccatin III can be explained first by lack of a free OH group at position C-10 capable of competing with free OH groups on the surface of silica gel (hydrogen-bonding interactions). On the other hand, the presence of an acetyl (ester) group at position C-10 can impede adsorption of baccatin III on silica gel due to hydrogen-bonding interactions between the carbonyl group at position C-9 and OH groups on the surface of silica gel (a

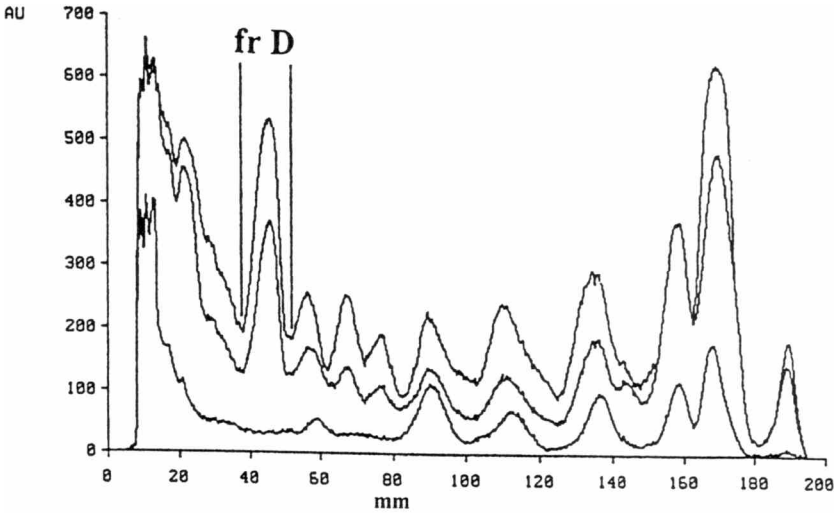


Fig. 2 Densitogram obtained from a preparative thin-layer chromatogram of the 10-DAB III fraction from the preparative column. TLC was performed on a 200 mm × 200 mm plate coated with a 0.5 mm layer of silica (E. Merck); the mobile phase was dichloromethane–dioxane–acetone–methanol, 84:10:5:1 (v/v). The chromatogram was scanned at three wavelengths—366, 254, and 230 nm (down to up) —by means of a Camag 3 scanner. The fraction isolated is indicated as "fr D".

kind of spherical hindrance, observed in computer modeling of spatial structure of taxoids by HYPERCHEM). The role of this carbonyl group in the polar properties of taxoids was confirmed by analysis of ^{1}H-NMR spectra. This can be responsible for the decrease of baccatin III retention on silica gel, which is similar to the retention of paclitaxel and cephalomannine, both of which possess an acetyl group at position C-10 and a low-polar side chain at position C-13. Because of the very slight difference in the structure of the amide substituent of the acyl side chain at position C-13 (*N*-benzoyl vs. *N*-tigloyl) and low polarities, these two compounds have the same retention on silica gel.

Similar solvent systems can be applied for analytical TLC of taxoids in screening of, for example, callus cultures for taxoid presence.[5]

Another approach in taxoid preparative separation included solid-phase extraction (alumina, silica, or RP-8 cartridges) followed by preparative TLC on silica gel plates with quaternary mobile phase consisting of dichloromethane–dioxane–acetone–methanol (83:5:10:2, v/v).[6,7] In this way, 10-DAB III, paclitaxel, and cephalomannine as well as two further taxoids could be easily isolated with relatively high efficiencies from yew materials (Fig. 2). Multiple development technique or further separation of the isolated taxoid fractions (especially less polar ones) on RP-2 silica bond stationary phase with methanol–water mixtures as mobile phases was applied for purification of the compounds isolated. 10-DAB III isolated in this way was relatively pure, as was shown in reversed-phase (RP)-HPLC analysis (Fig. 3).

An RP-TLC system with tertiary mobile phase [stationary phase: RP-18 F254s; mobile phase: water–methanol–tetrahydrofuran (5:2:3, v/v/v) applied twice] was used in the analysis of taxoid fractions obtained after high-speed countercurrent chromatography (HSCCC) isolation and was suitable for paclitaxel and cephalomannine qualitative determination.[8]

High-performance TLC/densitometric paclitaxel quantitative determination in different yew samples with two-stage gradient development has also been attempted[9] but, due to the high concentration of coextractives, it is difficult to estimate the precision of this method.

Stasko et al.[10] elaborated two interesting procedures of multimodal TLC for the separation of paclitaxel and related compounds from *T. brevifolia*. In the first procedure, a cyano-modified silica gel plate was developed, in the first dimension, in dichloromethane–hexane–acetic acid (9:10:1) and, in the second dimension, in water–acetonitrile–methanol–tetrahydrofuran (8:5:7:0.1). In the second procedure, a diphenyl-modified silica gel plate was developed, in the first dimension, in hexane–isopropanol–acetone (15:2:3) and, in the second dimension, in methanol–water (7:3). These two methods enabled paclitaxel resolution from both cephalomannine, which is impossible on silica gel plates, and at least 20 other compounds.

Fujino et al.[11] described an interesting radio-TLC method for the analysis of paclitaxel and its 3-OH and 6-OH metabolites. After incubation of ^{14}C-paclitaxel with human liver microsomes, the supernatants were developed using a solvent system consisting of toluene–acetone–formic acid (60:39:1, v/v) and quantified with a bioimaging analyzer. The results obtained correlated well with those from RP-HPLC.

Besides typical UV detection on plates with a fluorescent agent (F_{254}), different visualization methods can be applied:

1. Anisaldehyde spray reagent[10] (76% methanol, 19% *O*-phosphoric acid, and 5% *p*-anisaldehyde) followed by heating at 110°C for 5 min. Paclitaxel appears as a gray-brown spot.
2. A 3% sulfuric acid methanolic solution followed by heating at 115°C for 5 min (visualization: UV at 366 nm and VIS).[8]

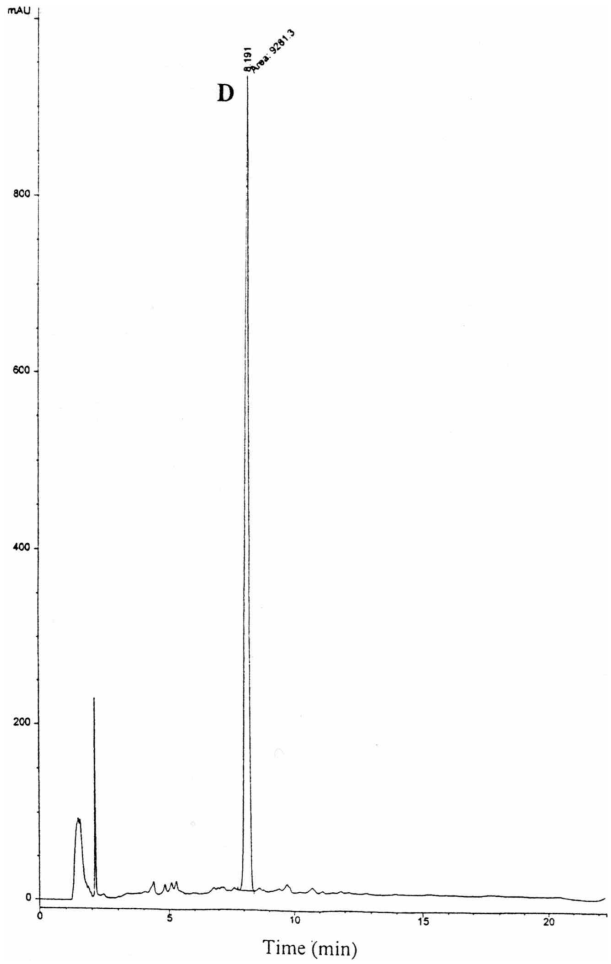

Fig. 3 HPLC chromatogram obtained from the TLC fraction containing 10-DAB III (D) as shown in Fig. 1. A 5 μm Waters Symmetry Shield C_{18} column, 150 mm × 4.6 mm I.D. was used and eluted with the gradient of acetonitrile in double distilled water.

Source: From Application of pseudo-reversed-phase systems to the purification and isolation of biologically active taxoids from plant materials, in Chromatographia.[7] © Vieweg Verlag/ *Chromatographia*, 2002.

3. A 3% sulfuric acid ethanolic solution, then a 1.5% solution of vanillin in ethanol, followed by heating at 105°C for 10 min.[5] DAB III appears as a gray spot.

CONCLUSIONS

Summing up this review, it should be emphasized that because of differences in composition of taxoids and other compounds in different yew and yew-derived materials, a suitable approach for TLC taxoid separation ought to include problems involving both taxoid separation and appropriate separation of coextracted compounds from taxoids, which usually are in higher concentration. The separation method should also be elaborated precisely for each type of extract. A combination of various solid-phase extraction and chromatographic techniques seems to be the most relevant approach to efficient preparative separation of taxoids.

Temperature Program: Anatomy

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The principle of temperature programing in gas chromatography (GC) is based on the thermodynamic explanation of retention and is employed for samples that have components that cover a wide range of polarities and/or molecular weights. Its purpose is to accelerate the late eluting peaks through the column to reduce the analysis time and, at the same time, to maintain symmetrical elution profiles that are amenable to accurate quantitative assessment. As the temperature is increased, the magnitude of the distribution coefficient with respect to the stationary phase is reduced and, as a consequence, the retention volume and retention time is reduced. The programing rate must be chosen such that the integrity of the separation is maintained and the peak shapes are not distorted.

DISCUSSION

The programing procedure usually involves three stages. An initial isocratic period is introduced to efficiently separate the early eluting peaks with adequate resolution. The isocratic period is followed by a linear increase in column temperature with time, which accelerates the well-retained peaks so that they also elute in a reasonable time and are adequately resolved. The effect of linear programing can be calculated employing appropriate equations and the retention times of each solute predicted for different flow rates (see *Programmed Temperature GC*, p. 1918). To do this, some basic retention data must be measured at two temperatures and the results are then employed in the retention calculations. The temperature program often ends with a final isothermal period. This is usually introduced either because the upper temperature limit of the stationary phase has been reached and so a higher temperature will damage the column, or to purge any remaining, strongly retained solutes from the column. The upper temperature limit of the stationary phase should not be exceeded, as not only will the column be spoiled but the performance of the detector is often impaired and deposits are formed that can permanently increase the detector noise. Temperature programing is employed in most GC separations and the optimum programing conditions are usually easy to identify from a few preliminary separations using different gradients. If, however, there is a pair of solutes that elute close together (e.g., a pair of enantiomers) and there is a temperature of coelution, then some considerable effort may be necessary to identify the optimum temperature program[1] to achieve a satisfactory separation in a reasonable time.

Such situations, however, are not common, unless the applications involves complex samples such as multicomponent chiral mixtures.

Temperature: Effect on MEKC Separation

Koji Otsuka
Shigeru Terabe
Department of Material Science, Himeji Institute of Technology, Hyogo, Japan

INTRODUCTION

The distribution coefficient, K, of a solute for an equilibrium between the aqueous phase and micelle, or the micellar solubilization, depends on temperature; generally, the distribution coefficient decreases with an increase in temperature. This means that the migration time of a solute, t_R, will be reduced when the temperature is elevated under typical micellar electrokinetic chromatogaphy (MEKC) conditions, where, for example, sodium dodecyl sulfate (SDS) is employed as a pseudo-stationary phase at a neutral condition (i.e., pH 7). Also, the velocity of the electro-osmotic flow (EOF), u_{EOF} and the electrophoretic velocity of the micelle, u_{cp} (mc), will be increased by an increase in temperature because of a reduced viscosity of the micellar solution employed in a MEKC system.

DISCUSSION

The increase in temperature during a separation is observed to be due to Joule heating: Ideally, the retention factor, k, should be independent of the applied voltage or current, but, actually, k does depend on the applied voltage. Although the temperature of the separation capillary is controlled with a liquid coolant or a circulating airstream in most commercially available capillary electrophoresis (CE) instruments, the retention factor usually decreases, almost linearly, with an increase in the velocity of the EOF or an increase in the current. However, the dependence is much less than that observed in a CE system without forced-cooling apparatus.

The critical micelle concentration (CMC) and the partial specific volume, $\bar{v}$ depend on the temperature. The relationship between k and K is represented as

$$k = K\left(\frac{V_{mc}}{V_{aq}}\right) \tag{1}$$

where V_{mc} and V_{aq} are the volumes of the micelle and the remaining aqueous phase, respectively. The phase ratio, V_{mc}/V_{aq} is described as

$$\frac{V_{mc}}{V_{aq}} = \frac{\bar{v}(C_{sf} - \mathrm{CMC})}{1 - \bar{v}(C_{sf} - \mathrm{CMC})} \tag{2}$$

where C_{sf} is the surfactant concentration. Approximately, the volume of the micelle is negligible and, hence, Eq. 1 can be rewritten as

$$k = K\bar{v}(C_{sf} - \mathrm{CMC}) \tag{3}$$

For example, the CMC of SDS and $\bar{v}$ of the SDS micelle depend on temperature as presented in Table 1, where a 100 m*M* borate–50 m*M* phosphate buffer (pH 7.0) was used to prepare SDS solutions. It should be noted that the CMC value observed in a buffer solution or electrolyte solution is smaller than that in pure water (e.g., 8.1 m*M* at 20°C).

In MEKC, an ionic surfactant is used as a pseudo-stationary phase, and the Krafft point is also an important temperature. At a temperatures lower than the Krafft point, C_{sf} does not exceed the CMC, due to reduced solubility and, therefore, no micelle is formed. At the Krafft point, C_{sf} reaches the CMC and then the formation of the micelle is begun. The Krafft point of SDS is ~16°C in a pure water, whereas it is ~31°C for potassium dodecyl sulfate in pure water. Thus, a

potassium salt is not an adequate buffer component for the SDS/MEKC system.

Fig. 1 shows the dependence of the distribution coefficients on temperature for several solutes in MEKC, where SDS is employed as a pseudo-stationary phase. Different dependencies are observed among the solutes; that is, temperature affects the selectivity.

As mentioned, temperature seriously affects the migration time, whereas its effect on selectivity is not remarkable. It is important to maintain temperature precisely to obtain reproducible results.

Temperature: Mobility, Selectivity, and Resolution in CE

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

Although not a major separation parameter, as in gas chromatography, the operating temperature clearly affects migration behavior in capillary electrophoresis (CE). This alone should be reason to work under uniform, well-thermostated conditions. The temperature affects bulk viscosity, electro-osmotic flow (EOF), ionic mobilities, even pK values and buffer pH.

BUFFER BEHAVIOR

A buffer for electrophoresis is usually prepared at room temperature by adding ingredients and measuring the final pH. When this buffer is used for CE at a different temperature, a different pH might result. For example, when a buffer consists of Tris-acetate at pH 5, Tris is fully charged and the temperature dependence of pK of acetic acid is the one involved. This value is small so that the pH of the buffer is virtually independent of temperature. This is not the case if the same buffer ingredients are used to prepare a buffer around pH 8; in that case, acetate is fully ionized and the pK of Tris is involved. This pK has a temperature coefficient of − 0.031 per degree; a 10°C increase leads to a 0.31 decrease in buffer pH (Table 1).

Table 1 pK Values and their temperature dependence of some buffer components.

Name	pK (20°C)	dpK/dT
Phosphoric acid, pK_1	2.12	*M*
Citric acid, pK_1	3.13	*M*
Formic acid	3.75	–0.000
Glycine, pK_1	3.75	–0.000
Acetic acid	4.76	–0.000
Histidine	6.12	–0.045
MES	6.15	–0.011
ACES	6.90	–0.020
Imidazole	6.95	–0.018
MOPS	7.20	–0.006
HEPES	7.55	–0.014
Tris	8.30	–0.031
Boric acid	9.24	–0.007
CHES	9.50	–0.009
Glycine, pK_2	9.77	*M*
CAPS	10.40	–0.009

In case of single-buffering background electrolyte solutions, the temperature coefficient of the buffer pH equals the temperature coefficient of the pK of the buffering ion. In case of a double-buffering system, pK's of both buffer anion and buffer cation are involved, which obviously makes the situation potentially more complicated.

In some situations, the pH of the buffer can be very critical. An example of such a critical pair of components is given in Fig. 1; a mixture of benzoic and 2,3-dimethoxy benzoic acid, analyzed around pH 4.67. A pH change of as little as 0.04 pH units will change the migration order.

Another aspect involved is buffer conductivity; on average, ionic conductivities have a temperature coefficient of around 2.5%/degree. A higher temperature, therefore (at constant voltage), leads to a higher current. This can have a significant effect on power dissipation and, through the corresponding plate-height terms, on separation efficiency (see *Band Broadening in CE*, p. 144).

SAMPLE ION BEHAVIOR

Ionic mobilities generally have a temperature coefficient of around +2.5%/degree, but it is not exactly the same for all ions. Incidentally, water viscosity has a temperature coefficient of approximately –2.5%/degree. This sometimes leads to the erroneous conclusion that ionic mobility is, by definition, inversely proportional to liquid viscosity, which is an oversimplification, originating also from the following relationship:

$$\mu = \frac{q}{6\pi\eta r}$$

in which q is the effective charge, η is the liquid viscosity, and r is the radius. The misunderstanding is that, in reality, the above relationship is valid only for rigid spherical particles, not necessarily for individual solvated ions.

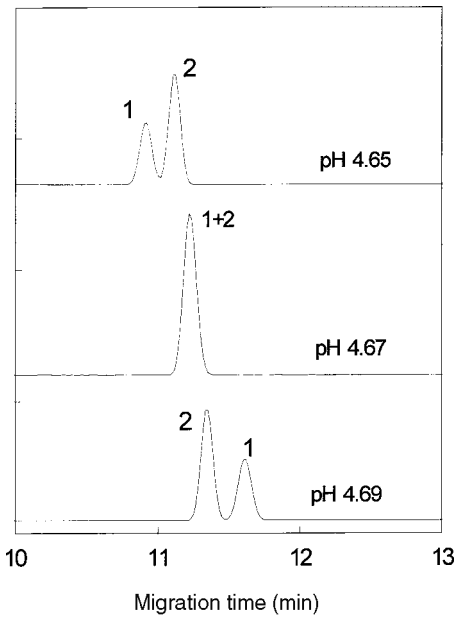

Fig. 1 Separation of benzoic acid (1) and 2,3-methoxy benzoic acid in 10 m*M* Tris-acetic acid buffer of three different pH values.

For the electro-osmotic flow, temperature-induced viscosity change at the plane of shear for the electric double layer is more straightforward. Analysis times will generally shorten with increasing temperature.

Terpenoids: HPLC Separation

Gabriela Cimpan
Sirius Analytical Instruments Ltd., East Sussex, U.K.

INTRODUCTION

Terpenoids are C_{10} and C_{15}, usually volatile, organic compounds derived from plants; they are generally associated with characteristic fragrances. Some terpenes are alcohols (e.g., menthol from peppermint oil), and some terpenes are aldehydes (e.g., citronellal). Terpenes are made up of isoprene (C_5) units. Because terpenoids occur in complex mixtures in natural products or in plants, chromatography is a powerful method for their separation and further analysis. Gas chromatography (GC) provides good separations and low detection limits for the volatile compounds. This was the reason for the delay in the development of high-performance liquid chromatography (HPLC) methods for terpenoids and has become the method of choice for the non-volatile, thermolabile, or polar compounds.

OVERVIEW

High-performance liquid chromatography can be used as a separation method of volatile compounds, followed by GC or GC/MS for further separation and analysis. The most common assay is performed by reversed-phase HPLC, usually on C_{18}, when the separation of the compounds is according to their hydrophobicity, i.e., according to chain length and polar groups.

Sonication and liquid chromatography are a rapid pair of techniques for extraction and fractionation of plant material. The method combines extraction by sonication with a mixture of non-miscible solvents, rapid preseparation of the crude extract by vacuum-liquid chromatography (silica gel 60H), and separation by preparative, reversed-phase HPLC or classical liquid chromatography with polyvinylpyrrolidone.

HPLC can be also used as an analytical method for the separation, identification, and quantification of terpenoids.

TERPENOID ANALYSIS

The use of diode-array detection is limited because many of the terpenoids do not have chromophores for the UV region. Refractive index, evaporative light scattering detectors (ELSD), or low-UV detectors can overcome, to a certain extent, this problem. However, the refractive index detector has a lower sensitivity compared with the spectrophotometric detectors, and it will not be useful for trace analysis. The organic solvents used for the mobile-phase composition absorb the low-UV radiation, and this is another problem for the terpenoids analysis by HPLC.

Temperature influences dramatically the separations; in the literature, assays can be found performed at −15°C, with pentane as mobile phase on LiChrosorb Si60.

The stationary phase is usually C_8 or C_{18}, but the use of Spherisorb CN or Nucleosil columns was also reported. The mobile phase for reversed-phase chromatography is aqueous, while, for normal-phase chromatography, it generally contains pentane or hexane. The elution can be isocratic or with a gradient. The detection is usually UV in the range 116–254 nm.

One of the most studied plants is *Ginkgo biloba* because of its medical applications. *Ginkolides* are a group of unique terpene lactones with properties of improving cardiovascular and cerebrovascular activities. Ginko terpene lactones have very weak absorption below 220 nm; therefore HPLC cannot be coupled with UV detection methods. Infrared was proposed as an alternative, but HPLC/MS and HPLC/NMR have produced the best results in terms of simplicity, sensitivity, and selectivity. High-performance liquid chromatography-evaporative light-scattering detection (HPLC/ELSD) is an economic option for this type of measurements.

Ginkgolide A, B, C, and bilobalide in *G. biloba* leaves were determined simultaneously by RP/HPLC/ELSD. Methanolic extracts (10%) of the leaves were cleaned up by solid-phase extraction (SPE) via polyamide cartridge and silica gel cartridge, successively. RP/HPLC was carried out on a C_{18} column with MeOH–H_2O as mobile phase, eluted in gradient mode, and detected by ELSD. The poor linear response of ELSD could be compensated by multilevel calibration and logarithmic calculation. Methanol–water–orthophosphoric acid mobile phase was used in conjunction with refractive index (RI) detection.

Terpenes in *G. biloba* L. extracts were analyzed on a column packed with C_8 Nucleosil 300, and PrOH–THF–H_2O was used as the mobile phase with detection at 220 nm.

High-performance liquid chromatography was the first method of choice for the non-volatile terpenes as terpene trilactones. The analysis is performed by RP/HPLC on C_{18} with isocratic development either in methanol–water or methanol–water–THF. Detection can be carried out by

UV (taking into consideration poor UV absorption of the compounds), RI, ELSD, or MS.

Sesquiterpenes

Sesquiterpenes are C-15 terpenoids which can be found in natural products as hydrocarbons, oxygenated forms (aldehydes, ketones, etc.), or lactones. Sesquiterpene lactones can be found in a limited number of plant species and often have therapeutic properties.

The major constituents of the plant *Ambrosia maritima* L. were isolated using thin-layer chromatography (TLC) and identified by IR and GC/MS. From HPLC screening, ambrosin and damsin were detected at high levels in the leaves and flowers, while stems and seeds contained only traces. Sesquiterpenes from *Aucklandia lappa* (Decne.) were determined by HPLC. A Shim-pack CLC-ODS column (6.0×150 mm) was used as separation column, MeOH–H_2O (65:35) as mobile phase, and the detection wavelength was 225 nm.

The GC/MS and HPLC analyses of oils from *Salvia sclarea* provided a comparative analysis profile of different plant materials. Sesquiterpene hydrocarbons (e.g., germacrene D and β-caryophyllene), monoterpene alcohols (e.g., α-terpineol), diterpenoids (mainly sclareol), monoterpene hydrocarbons (e.g., myrcene, limonene, and the two ocimene isomers), and the principal components (linalyl acetate and linalool) were analyzed.

Two comparable procedures of reverse-phase HPLC with spectrophotometric detection at 254 nm, with mobile phases of MeOH–0.05 *M* acetate buffer (70 : 30) or THF–0.01 *M* phosphate buffer (55 : 45), were used to resolve leukomisin, matricarin, austricin, anhydroaustricin, and potential antiarteriosclerotic sesquiterpene lactones from aerial parts of *Artemisia leucodes*.

A new HPLC technique has been developed for the rapid analysis of sesquiterpene phytoalexins such as capsidiol, rishitin, luminin, and phytuberol. This method employs a cyanopropyl-bonded-phase column with an isocratic mixture of hexane and isopropanol. Flame ionization and UV detection were used for the analysis of capsidiol, rishitin, lubimin, phytuberol, and debneyol. Although both detectors proved to be useful, the signal response with the flame ionization detector was proportional to the mass of each of the phytoalexins, while the signal with the UV detector was proportional to the number of carbon–carbon bonds in each of the compounds.

The antifungal sesquiterpene dialdehydes polygodial and warburganal, from *Polygonum hydropiper*, were determined by HPLC on an ODS column using methanol–H_2O as a mobile phase. These sesquiterpene dialdehydes were accumulated in young leaves and shoots and possessed antifungal activity.

Fourteen sesquiterpenes of *Petasites hybridus* (L.) G.M. et Sch. were separated on a normal-phase Nucleosil 100-3 column with hexane-diisopropyl ether-acetonitrile mixtures as eluents and photodiode array detection.

Sesquiterpenes were also separated by chiral chromatography on a Chiracel OD column.

Sometimes, the analyzed compounds absorb significantly only below 220 nm. In this case, postcolumn derivatization was used for a better UV detection.

Terpenes

A liquid chromatography-tandem mass spectrometry (LC/MS/MS) method was developed to detect tumor-promoting diterpene esters of the tigliane and ingenane types within plant extracts. Fractionation on a C_{18} HPLC column was followed by MS/MS-multiple reaction monitoring (MRM).

Liquid chromatographic-thermospray mass spectrometry (LC/TSP/MS) was used for the analysis of crude plant extracts containing phenolic and terpene glycosides. In crude plant extracts, constituents of biological or pharmaceutical interest often exist in the form of glycosides. Mass spectral investigations of these metabolites require soft ionization techniques such as desorption chemical ionization (D/CI) or fast atom bombardment if information on molecular mass or sugar sequence is desired. Thermospray provides mass spectra similar to those obtained with positive-ion D/CI/MS using NH_3 and thus is potentially applicable to online analyses for these compounds and can be applied to plant extract analysis. Extracts of Gentianaceae, Polygalaceae, and Leguminosae species have been screened by LC/TSP/MS. High-performance liquid chromatography was performed on reversed-phase columns using methanol–water or acetonitrile–water gradients. Good optimization of the temperature of the source and the vaporizer was crucial for the observation of pseudomolecular ions of glycosides.

Triterpenes

Bisdesmosidic triterpene saponins were isolated from the aquatic plant *Ranunculus fluitans* L. (Ranunculaceae) in the Rhine river. The saponin structures were established by the identification of the aglycon and sugar moieties by HPLC and chiral capillary zone electrophoresis (CZE), ion-spray LC/MS, and extensive 1-D and 2-D homonuclear and heteronuclear NMR spectroscopy.

Many triterpene derivatives (some of them being new compounds) were isolated from the AcOEt fraction of Brazilian medicinal plant Carucaa, *Cordia multispicata* (Boraginaceae). The separation was performed on silica gel and reversed-phase HPLC columns, and the structures were elucidated by means of spectral methods, especially with 2-D NMR.

Several ginsenosides, previously obtained from *Panax ginseng* and *Panax notoginseng*, were analyzed by HPLC.

A new HPLC method permitted the separation of 13 triterpene glycosides isolated from different Astragalus species within 40 min. A water/acetonitrile gradient was used as eluent, RP-18 was used as stationary phase, and evaporative light scattering detection was used. The method facilitated differentiation of different Astragalus species.

Preparative HPLC

Successful preparative separations were obtained for pure compounds by RP/HPLC. When normal-phase chromatography was used, better results were obtained if the silica-based stationary phase was treated with silver ions.

Preparative HPLC was used to separate sterols and triterpene alcohols from the unsaponifiable matter in plant oils from *Camellia weiningensis* L., *Brassica juncea* L., and *Microula sikkimensis*. The isolated compounds were acetylated and further purified by $AgNO_3$-impregnated silica gel preparative TLC. The identification was done by IR and MS.

Oryzanols are mixtures of ferulic acid esters of triterpene alcohols and plant sterols. Oryzanols were extracted from crude rice by column chromatography on a silica gel column using different volumes and ratios of hexane and di-Et ether. The fraction containing 18% oryzanol was further enriched by rechromatography, then 98% pure oryzanol was crystallized.

Coupled Methods with HPLC

High-performance liquid chromatography can be coupled, online, with high-resolution gas chromatography (HRGC) and MS. Gas chromatography allows the separation of chemically similar compounds from the previous separation provided by HPLC between the compounds with different polarities.

When thermolabile compounds are present, GC cannot be used, so MS can be coupled directly with HPLC. Care should be taken when using ionization methods, as MS does not provide a characteristic fragment pattern and the molecule cannot be identified precisely.

Natural products are often sources for drugs. When screening a natural compound extract, many of the analyzed compounds have been analyzed previously; therefore a method capable of selecting the new compounds such as HPLC/NMR/MS is very useful. Many plant extracts were analyzed by this method. Alternatively, HPLC/UV/MS can be used to obtain rich spectral information [application on *Tanacetum parthenium* (L.) Schultz Bip., Asteraceae].

Terpenoids: TLC Analysis

Simion Gocan
Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania

INTRODUCTION

Terpenes are among the most widespread and chemically diverse groups of natural products. Fortunately, despite their structural diversity, they have a simple unifying feature by which they are defined and by which they may be easily classified. Terpenes are a unique group of hydrocarbons, based on isoprene or an isopentane structure.

Terpenes can be classified by the number of five-carbon units they contain: hemiterpene (C_5), monoterpene (C_{10}), sesquiterpene (C_{15}), diterpene (C_{20}), triterpene (C_{30}), and tetraterpene (C_{40}). Like the monoterpenes, most of the sesquiterpenes are considered to be essential oils because they belong to the steam distillable fraction. Diterpenes have higher boiling points; they are considered to be resins. Triterpenes include common triterpenes, steroids, saponins, sterolins, and cardiac glycosides. The most common tetraterpenoids are the carotenoids. Sesquiterpenes exist in a variety of forms, including linear, bicyclic, and tricyclic frameworks. The type of cyclization can be with open chain, mono-, bi-cyclic, etc. Also, the number and positions of the double bonds, the asymmetric centers, and the type and number of functional groups distinguish numerous components of each group.

Terpenoids can be classified also into hydrocarbons, alcohols, carbonyl compounds, phenols, acids, esters, oxides, and peroxides.

CHROMATOGRAPHIC SEPARATION

Hydrocarbons

Generally speaking, thin-layer chromatography (TLC) has a large number of applications. The first problem with which the analyst is confronted concerns gathering information regarding the mixture to be separated, in terms of mixture polarity and the range of molecular masses. In the case of hydrocarbons that have one no-polar character, an adsorption separation technique is recommended. Terpene hydrocarbons (mono- and sesquiterpene) can be conveniently separated on layers of silica gel or alumina. Moreover, highly active layers are necessary. After the usual drying, they have to be stored in a vacuum desiccator at 30 mm Hg, containing potassium hydroxide as a desiccant. Because of the weak polar nature of the compounds, solvents of low polarity must be used as mobile phases for the separation. The most frequently used solvents as the mobile phase are as follows: petroleum ether, hexane, isopentane, dimethylbutane, cyclohexane, methylcyclohexane, benzene, chloroform, benzene-acetone (95:5, v/v), benzene-ethyl acetate (2:1, v/v), and toluene. The choice of solvent depends upon the polarities of the components of the terpene hydrocarbon mixtures on the desired separation. For the detection (visualization) of the compounds after separation, the solvent will be evaporated from the plate and various zones will be indicated by spraying with suitable reagents. On spraying with a fluorescein solution and exposing to bromine vapor, compounds that absorb bromine faster than the fluorescein show up as yellow spots on a pink background. Other reagents can be used for detection with good results; they include iodine vapor, vanilin/H_2SO_4, or $KMnO_4/H_2SO_4$, and a chloroform solution of antimony pentachloride. Very unreactive compounds can be located by spraying with a concentrated sulfuric–nitric acid mixture and heating to cause charring of the compounds.[1,2] Table 1 gives the R_f values of some terpenes on silica gel and alumina in various solvents used as mobile phases.

A good separation of sesquiterpene hydrocarbons has been performed on alumina in combination with a perfloroalkane (70°C to 80°C) mobile phase.[3]

To increase the resolution in TLC separation of some monoterpenes, silver nitrate-impregnated silica gel, with benzene as the mobile phase, was used. Three conclusions were drawn from these studies:[7] 1) cyclic terpenes with a single internal double bond did not readily form a π-complex; 2) cyclic or acyclic terpenes with two non-terminal double bonds do not readily form π-complexes unless the double bonds are *cis* conjugated; and 3) cyclic or acyclic terpenes with exocyclic or terminal double bonds do form π-complexes.

The silver nitrate-impregnated silica gel (25%) was applied to the separation of some sesquiterpenes. It was found that a mixture of β-selinene and caryophyllene could be separated satisfactorily by development with *n*-hexane and benzene–acetone (95:5, v/v) as mobile phases.[8] After the development, the plates are dried in air and then sprayed with a solution of chlorosulfonic acid in acetic acid (1:2) and heated at 130°C. Usually, different colored spots are observed, e.g., humulene, brown; caryophyllene, blue; longifolene, pink.

Oxygenated Terpenes

The problem of identifying individual compounds from essential oils is often complicated by the similarities in

Table 1 hR_f values of terpenes and color reaction with vanillin/H_2SO_4 reagent.

	Silica gel					Alumina			Silica gel impregnated $AgNO_3$

S_1 = Skellysolve B (hexanes);[3] S_2 = hexane;[4] S_3 = cyclohexane;[4] S_4 = benzene;[5] S_5 = 15% ethyl acetate in hexane;[5] S_6 = perfluoroalkene, b.p. 70–80°C;[3] S_7 = low boiling perfluokerosene;[3] S_8 = benzene, 25% $AgNO_3$,[6] and 3.125% $AgNO_3$.[7] Vanillin/H_2SO_4.[3]

molecular structures and physical properties. In a very important instance, the R_f values serve as a means of distinguishing two classes of material-hydrocarbons from non-hydrocarbons. Hydrocarbons have an appreciable R_f value with hexane as the mobile phase, whereas non-hydrocarbons have an R_f equal to zero (Table 2). By use of this property, it is possible to separate hydrocarbons from oxygenated compounds for the preparation of terpene oils. Table 2 contains the hR_f values of oxygenated terpenes on a silica gel thin-layer plate in different solvents that have been found useful for characterizing these types of materials.

Terpene Alcohols

The alcohols were chromatographed on silica gel using various eluent systems. The compounds were detected with the fluorescein–bromine reagent. The phosphomolybdenic acid reagent is very sensitive but non-specific. The anisaldehyde-sulfuric acid reagent is of higher sensitivity and specificity.

It is possible to achieve a separation of the stereoisomeric menthols on silica gel G layers using chloroform and a series of solvents that are nearly isoeluotropic with chloroform.[2] The following hR_f values were obtained: menthol, 32; isomenthol, 29; neomenthol, 40; and neoisomenthol, 36. With anisaldehide-sulfuric acid, a blue violet color is obtained. Another example is the stereoisomeric separation of *trans*, *trans*-farnesol, and *cis*, *trans*-farnesol on silica gel using ethyl acetate–benzene (5:95, v/v) as the mobile phase, giving hR_f values of 27 and 36, respectively. For the detection of these substances, the vanillin/H_2SO_4 reagent proved suitable.[10] This system, slightly modified, which used benzene-ethyl acetate (80:20, v/v), gives a good separation of all the

Table 2 hR_f values of some oxygenated terpenes and other essential oil constituents on silica gel in various eluent systems.

stereoisomers of farnesol present in a commercial mixture, as well as other terpene alcohols.[11]

The silver nitrate-impregnated silica gel G was used to obtain a separation with a group of tetracyclic triterpene alcohols, which could not be separated on untreated silica gel. However, on silica gel G (Ag impregnated), the R_f values were sufficiently different so as to enable the substances to be identified separately. Chloroform was used as the mobile phase. The tetracyclic triterpenes were detected by spraying with one of the three reagents: 50% sulfuric acid in water or 10% phosphomolibdic acid in ethanol or chlorosulfonic and acetic acids (1:2) followed by heating in an oven at 150°C.[12]

Besides normal-phase TLC, reversed-phase TLC was used by impregnating the silica gel layer with paraffin or silicone oil and using hydrophilic solvents as mobile phases. By this method, it is possible to achieve a good separation of alcohols belonging to groups with the same number of carbon atoms.

Acids and Esters

Essential oils often contain esters of terpene alcohols; the most common are the acetates, formates, propionates, etc. The separation of different esters was performed on silica gel layers, using benzene, chloroform, and other similar solvents as mobile phases. All of the color reactions for terpene alcohols can be used for the detection of their esters. No differences have been observed in the color esters function as a result of their acid nature.

A group of triterpenic acids were found in *Bredemeyera floribunda*, *Alphitonia excelsa*, and *Crataegus oxyacantha*.[13] The separation was carried out on silica gel layers using diisopropyl ether–acetone (5:2, v/v). In this case, oleanic, oleanonic, ursolic, and betulinic acids showed the same hR_f value, i.e., 68. As cochalic, bredemolic, and machaerinic acids gave tailings in this eluent, addition of 5% pyridine to the same solvent gave the following R_f values: 15, 62, and 27, respectively. The compounds were detected with chlorosulfonic acid.

Another example of applications concerning separation of piperonylic, 5-, 2-, and 6-methoxypiperonylic acids was performed on silica gel layers using ethyl acetate–hexane–acetic acid (50:50:0.5, v/v) as the mobile phase. Detection was performed by spraying with a chromotropic–sulfuric acid reagent. With these conditions the following hR_f values of 64, 54, 47, and 37 were obtained, respectively.[14]

Aldehydes and Ketones

These compounds appear in various essential oils and are distinguished by characteristic odors. Some of them are easily produced by synthesis and are frequently used in the perfume industry. Aldehydes and ketones can be separated on silica gel thin-layer plates with solvents such as hexane, chloroform, and benzene in different proportions with ethyl acetate, or only in chloroform or benzene. The detection of the aldehydes can be performed by spraying with a solution of *o*-dianisidine in glacial acetic acid. Some ketones can be detected with the fluorescein–bromine spray, but compounds such as camphor, which are very unreactive, could be detected only by spraying with concentrated sulfuric acid containing nitric acid, followed by heat. A 5% solution of $AlCl_3$ in ethanol is specific for sesquiterpene lactones. Other terpenes, steroids, antrachinones, glycosides, and alkaloids do not interfere, nor do other types of lactones such as coumarins, cardenolides, and saturated or unsaturated γ-lactones. The reaction gives a violet or brown color on the layer, or yellow, brown, or green fluorescence under UV radiation at 366 nm, after spraying a plate with reagent solution and heating at 120°C for 10 to 15 min.[15]

The 2,4-dinitrophenylhydrazones have also been used as a means of separating terpene carbonyl compounds. The oxo-terpene was separated by means of these derivatives using silica gel with chloroform-carbon tetrachloride in various proportions (1:19, 1:9, 1:5.6 v/v) as well as petroleum ether-benzene (3:7, v/v). No spraying agent was used, as the spots themselves were distinctly colored.[16]

The ionone derivatives and pseudoionones were separated on silica gel layers with benzene as the mobile phase. The compounds, after development, were detected by spraying with either 2,4-dinitrophenylhydrazine or a vanillin-sulfuric acid mixture. The following mean R_f values were obtained: pseudoionone, 0.384; α-ionone, 0.580; β-ionone, 0.505; α-methylionone, 0.756; and β-methylionone, 0.699.[17] For improved separation, 14 terpenoids, e.g., α- and β-ionone, were subjected to TLC on silica gel impregnated with 15% $AgIO_3$, with benzene-ethyl acetate (4:1, v/v) as the mobile phase. The spots were detected by spraying the dried plate with methanol-sulfuric acid and heated at 110°C. The R_f values obtained were approximately equal to or considerably higher than those obtained on $AgNO_3$-impregnated plates.[18]

Oxides and Peroxides

Oxides and peroxides can occur in many essential oils by a photochemical reaction. 1,8-Cineol and linalool monoxide can be readily separated on silica gel thin layers with 1-nitropropane-hexane (1:1, v/v), as the mobile phase.[4] In this case, they have exhibited R_f values of 73 and 8, respectively.[4] Another pair of compounds, ascaridole and 1,8-cineol, can be easily separated on a silica gel layer, obtaining a value for chloroform as the mobile phase of 63 and 54, respectively.[2] The antimony chloride reagent gives a gray color. The potassium iodide-acetic acid-starch test is usually better than ferrous thiocyanate.

Phenylpropane and Phenol Derivatives

The separation of the hydroxyphenylpropane derivatives used in medicine and the perfume industry is of particular interest. Today, many useful drugs can be obtained from plants. TLC is one of the most rapid methods for the identification of the active substances in medicinal plant extracts containing hydroxyphenyl propane derivatives. Using silica gel plates with benzene solvent as the mobile phase could separate a series of these compounds. Besides silica gel thin layers, alumina and polyamide layers were used in combination with different solvents as mobile phases, for instance, chloroform, petroleum ether–acetic acid (95:5, v/v), or petroleum ether–pyridine (95:5, v/v). There are many different color reagents that can be used for the detection of the spots. A blue coloration is obtained after spraying with the phosphomolybdic acid reagent. The clearest color distinction is obtained by spraying a mixture of antimony tri- and penta-chloride (1:1), or anisaldehyde-sulfuric acid. Antimony trichloride solution makes the colors intense, but the spots do not show fluorescence immediately in long-wave UV light; but it does appear in about 1 day. Besides the R_f values, the colors of fluorescence can contribute to the identification of some compounds. For instance, eugenol methyl ether gives a greenish-yellow

fluorescence, and isoeugenol methyl ether (*cis–trans* mixture) shows up reddish brown.[1,2]

The following rules were obtained from the R_f values of a large group of phenylpropane and phenol derivatives under the conditions described above: 1) The polarity of the compound increases with increasing number of free phenol groups (OH). 2) Methylation of the hydroxyl group (OCH_3) decreases the polarity. The R_f values decrease with increasing of the methoxy number. For silica gel with benzene as the mobile phase in a saturation chamber: anethol, 1 OCH_3, h$R_f = 56$; eugenolmethyl ether, 2 OCH_3, h$R_f = 15$; and asarone, 3 OCH_3, h$R_f = 10$. 3) The effect of hydrogen bond formation between two adjacent phenolic groups and the consequent decrease in the polarity: *ortho*-compound < *p*-compound (safrol, h$R_f = 57$, and catechol, h$R_f = 0$). 4) Increase in the size of the alkylating group decreases the polarity: propenyl guaetol < benzyleugenol < methyleugenol. 5) When functional groups are situated closely together, the adsorption affinity of each is decreased and the R_f value of the compound increases. 6) The introduction of an aliphatic side chain on the nucleus has a negligible effect on the R_f values.[1,2]

Phenylpropane derivatives (feluric, caffeic, and chlorogenic acids) and flavonoids were identified in a methanolic extract from flowers of *Sambuci nigra* by using TLC on silica gel 60 F_{254}. The efficiency of 10 TLC eluent systems was investigated by three mathematical techniques. It has been established that the favorable mobile phases for TLC of compounds investigated are ethyl acetate–methanol–water (100:13.5:2.5:10, v/v) and ethyl acetate–formic acid–water (8:1:1, v/v).[19] In the same manner, there were selected optional solvent systems for the separation of caffeic acid, chlorogenic acid, and some flavonoids from methanolic extracts from *Lavandula flos*. It has been shown that the best eluent systems are ethyl acetate–formic acid acetic acid–water (100:11:11:27, v/v) and ethyl acetate formic acid–water (8:1:1, v/v).[20] Also, for TLC separation of the methanolic extract from *Rosmarinus officinalis* L. the system ethyl acetate–formic acid–acetic acid–water (100:11:11:27, v/v) has been found.[21] Detection of the phenolic acids and flavonoids was achieved by spraying the plates with 1% methanolic diphenylboryloxyethylamine, then 5% ethanolic polyethylene glycol 4000. The chromatograms were evaluated in UV light at 366 nm (phenolic acids appeared as blue spots and flavonoids as orange-yellow fluorescent spots).[22]

Thermodynamics of GPC/SEC Separation

Iwao Teraoka
Department of Chemistry, Polytechnic University, Brooklyn, New York, U.S.A.

INTRODUCTION

As with most other chromatographic separation methods, gel permeation chromatography–size-exclusion chromatography (GPC–SEC) is based on partitioning of analyte polymer molecules between the stationary phase (which, in the case of GPC–SEC, is contained within the pores of a porous stationary-phase support) and the mobile phase. Ideally, the mobile phase establishes a concentration equilibrium with the stationary phase at each plate in the column before being transferred to the next plate. The concentration equilibrium is dictated by an equal chemical potential of the polymer chain between the two phases.[1,2] In normal conditions of GPC–SEC, the polymer concentration c_M in the mobile phase is sufficiently low, and the solution behaves ideally dilute. Its chemical potential μ_M per molecule in the mobile phase is then given as

$$\mu_M = \mu^0 + k_B T \ln\left(\frac{c_M}{c^0}\right) \tag{1}$$

where μ^0 and c^0 are the chemical potential and the concentration, respectively, at an appropriate reference state, k_B is the Boltzmann constant, and T is the temperature. In the stationary phase, the chemical potential μ_S has additional terms due to changes in the entropy and the enthalpy upon bringing the polymer chain into the stationary phase:

$$\mu_S = \mu_0 + k_B T \ln\left(\frac{c_S}{c^0}\right) - T\Delta S + \Delta H \tag{2}$$

where c_S is the polymer concentration in the stationary phase, and ΔS and ΔH refer to the changes per chain. The partition coefficient K, defined as the ratio of the two concentrations, is then given as

$$K \equiv \frac{c_S}{c_M} = \exp\left(\frac{\Delta S}{k_B} - \frac{\Delta H}{k_B T}\right) \tag{3}$$

The primary purpose of GPC–SEC is to obtain a retention curve that represents the molecular weight (MW) distribution of the analyte. Because the retention volume is a linear function of the partition coefficient, the coefficient must be a monotonically decreasing or increasing function of MW.

In GPC–SEC, porous beads of various pore sizes are used as separating media. The solution in the pore channels is the stationary phase, and the volume of liquid between the beads constitutes the mobile phase. A linear polymer chain can take different conformations in the unrestricted mobile phase. The number of conformations, W, increases in a power law of N, with N being the degree of polymerization. In the stationary phase, however, all of the monomers on a single chain have to reside within the pore space. Thus, W does not increase as rapidly with N as in the mobile phase. Because the conformational entropy of the polymer chain is calculated as $k_B \ln W$, the geometrical confinement of the pore makes $\Delta S < 0$. The way $|\Delta S|$ increases with N is determined by the geometry of the polymer chain (whether the chain is linear or branched, whether the chain is swollen or not, whether the chain is stiff or not, etc.) and the pore geometry, but $|\Delta S|$ is roughly a function of the chain dimension to the pore size, as shown below. The detailed atomic sequence in each polymer is rather of second importance. This feature is responsible for the universality of GPC–SEC.

Columns used in GPC–SEC are supposed to provide negligible ΔH regardless of MW for a given polymer. Otherwise, the dependence of ΔH on MW, different from that of ΔS, will complicate the analysis of the retention curve. Furthermore, ΔH would exhibit widely different characteristics determined by the interactions among the polymer, the pore surface, and the solvent, and thus negate the universality of GPC–SEC. With negligible ΔH, the partition coefficient is determined solely by the decrease in the conformational entropy:

$$K = \exp\left(\frac{\Delta S}{k_B}\right) \tag{4}$$

Equivalently, K is the ratio of the probability to place the polymer chain in the pore without touching the pore walls, averaged over different conformations.

As MW increases, K decreases from 1 to 0. To have a high resolution in GPC–SEC, the dependence of K on MW needs to be sharp. Users of GPC–SEC also want the range of MW analysis in a single run to be as broad as possible, typically three to five decades. The finite range of K, however, makes the two requirements mutually exclusive, a severe restriction on the resolution. The resolution can be improved by increasing the number of theoretical plates, typically employing smaller porous beads and connecting a multiple columns in series. In normal-phase and reversed-phase high-performance liquid chromatography (RPHPLC), by contrast, a stationary phase that gives a large value of K,

in excess of unity, offers high resolution and a broad range of analyte composition in a relatively short column.

PARTITION COEFFICIENT

Examples for the plots of the partition coefficient as a function of the chain dimension are shown for some of the geometries of polymer molecules in a cylindrical pore of radius R_P. The simplest geometry is a sphere. The center of a spherical molecule of radius R_S is not allowed to get closer to the pore wall beyond the distance equal to the sphere radius. The ratio of the volume accessible to the sphere center to the total pore volume gives the partition coefficient. In Fig. 1, the two volumes are indicated by the interior and the exterior cylinders, respectively. Then,

$$K = \left(1 - \frac{R_S}{R_P}\right)^2 \tag{5}$$

The partition coefficient of a Gaussian chain of radius of gyration R_g was calculated by Casassa[3] and the partition coefficient of a rodlike molecule was obtained by Giddings et al.[4] The results are compared in Fig. 2. When plotted as a function of R_g/R_P, the three polymer geometries show only a small difference, except that, at large R_g/R_P, the rodlike molecule has a larger K than the other two geometries of the molecule. The plots were converted to functions of N, in Fig. 3, for the monomer size a equal to $R_P/100$. The partition coefficient of a star-branched polymer, in which each arm takes a Gaussian conformation, was calculated by Casassa and Tagami.[5]

The partition coefficient for a real chain (excluded volume chain) has not been obtained except by the scaling theory.[6] The theory gives only a qualitative relationship between K and N for chains sufficiently longer than the pore size ($R_g \gg R_P$):

$$\frac{\Delta S}{k_B} \equiv -N\left(\frac{a}{R_P}\right)^{1/\nu} \approx -\left(\frac{R_g}{R_P}\right)^{1/\nu} \tag{6}$$

where $\nu \approx 0.588$. A computer simulation result shows that, compared at the same R_g, the real chain has a slightly larger K than the ideal chain that allows monomer overlap.[7] It is

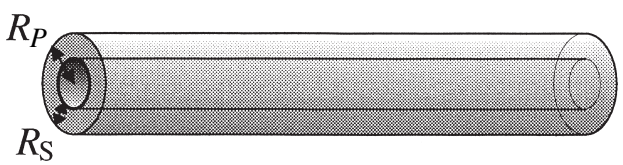

Fig. 1 The volume accessible to the center of a spherical molecule of radius R_S within a cylindrical pore of radius R_P is the interior cylinder of radius $R_S - R_P$.

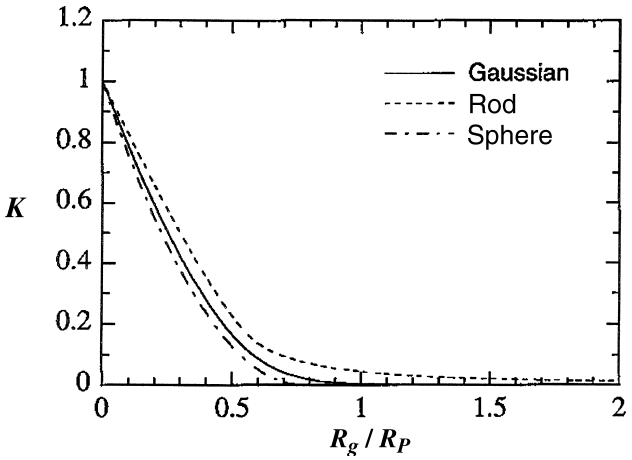

Fig. 2 Partition coefficient K plotted as a function of the radius of gyration R_g relative to the pore radius R_P for a spherical molecule, Gaussian chain, and a rodlike molecule.

common to both models for sufficiently long chains that $K \sim \exp(-\beta M)$, where β is a numerical coefficient and M is the molecular weight.

All of the currently used porous packing materials have a three-dimensional network structure, effectively giving rise to a pore size distribution. In these separating media, the dependence of K on N will be less sharp compared with the one in Fig. 3. It is desired by chromatographers that the retention time is a linear function of log M. Because the retention time is a linear function of K, the plot of K needs to be a linear function of log M in as broad a range of MWs as possible. A naturally occurring pore size distribution is not sufficient to cause the desired linearity. Therefore, mixed-bed columns, packed with porous materials of different pore-size-distribution ranges, have been developed and used broadly as "linear" columns.

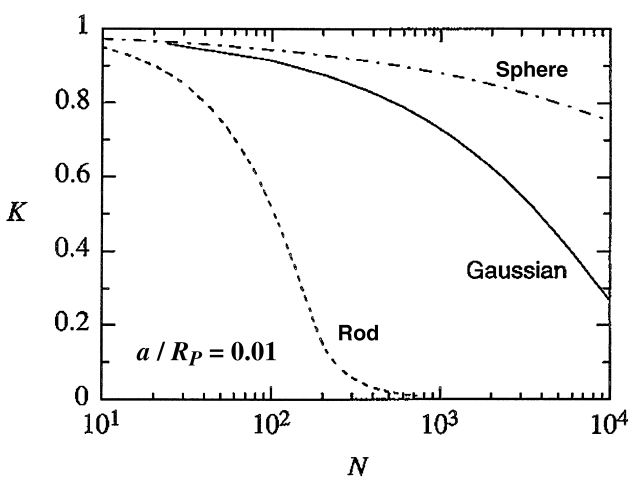

Fig. 3 Partition coefficient K plotted as a function of degree of polymerization, N, for a spherical molecule, Gaussian chain, and a rodlike molecule. The monomer size a is set to be $R_P/100$.

EFFECT OF INTERMOLECULAR INTERACTIONS

It is often observed that, as the concentration of the polymer solution injected increases at a constant injection volume, the retention curve shifts toward a longer time.[8] This effect, called "overloading," is manifested universally when the mobile phase is a good solvent for the polymer being analyzed and is more significant for a polymer of a higher MW. Simple thermodynamics explains this effect[2]: As c_M increases, the solution starts to deviate from the ideally dilute solution, and it becomes difficult to neglect the second virial coefficient A_2. For a solution in a good solvent, a positive A_2 makes μ_M larger than the one in the ideally dilute solution of the same concentration, as given by Eq. 1. The same change applies to μ_S. Since $c_S < c_M$, the increase in μ_M is greater than the increase in μ_S, resulting in an increase in K. At higher concentrations, the analyte polymer is retained longer, thereby delaying the retention curve. The concentration at which the effect of A_2 becomes not negligible is around the overlap concentration c^* which can be defined as $c^*[\eta] = 1$, where $[\eta]$ is the intrinsic viscosity. The actual concentration of c^* is low, especially for high-MW polymer. This is why a concentration as low as 0.1 wt% sometimes exhibits a concentration-dependent chromatogram.

Another mechanism that causes a change in the retention curve with concentration is intermolecular association. In a solution in which is negative, such as a solution in a poor solvent, a polymer chain tends to associate with other chains at higher concentrations. In effect, the pore in the GPC–SEC column senses the presence of suspensions of a larger dimension, causing the retention curve to shift to a shorter time.

Thermodynamics of Retention in GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The Plate theory shows that retention volume of a solute is directly proportional to its distribution coefficient between the two phases. Classical thermodynamics provides an expression that relates the *equilibrium constant* which, in the case of chromatographic retention, will be the distribution coefficient to the change in *standard free energy* of the solute, when transferring from one phase to the other.

APPLICATION

The expression is

$$RT \ln K = -\Delta G_0$$

where R is the gas constant, T is the absolute temperature, and ΔG_0 is the standard free-energy change.

Now,

$$\Delta G_0 = \Delta H_0 - T\Delta S_0$$

where (ΔH_0) is the standard enthalpy change and ΔS_0 is the standard entropy change.

Thus,

$$\ln K = -\left(\frac{\Delta H_0}{RT} - \frac{\Delta S_0}{R}\right)$$

or

$$K = \exp\left[-\left(\frac{\Delta H_0}{RT} - \frac{\Delta S_0}{R}\right)\right] \quad (1)$$

Eq. 1 can also be used to identify the type of retention mechanism that is taking place in a particular separation by measuring the retention volume of the solute over a range of temperatures. Rearranging Eq. 1,

$$\log K = -\frac{\Delta H_0}{RT} + \frac{\Delta S_0}{R}$$

Bearing in mind that

$$V' = KV_S$$

$$\log V' = -\frac{\Delta H_0}{RT} + \frac{\Delta S_0}{R} - \log V_S$$

It is seen that a curve relating $\log(V')$ to $1/T$ should give a straight line, the slope of which will be proportional to the *enthalpy* change during solute transfer. In a similar way, the intercept will be related to the *entropy* change and, thus, the dominant effects in any distribution system can be identified from such curves. Curves relating to $1/T$ are called van't Hoff curves, which can be used to identify the mechanism of retention and elucidate the role played by temperature in a separation (see *van't Hoff Curves*, p. 2406 and *Chiral Separations by GC*, p. 425).

In the majority of distribution systems encountered in gas chromatography (GC), the slopes of the van't Hoff curves are positive and the intercept negative. The negative value of the intercept means that the standard entropy change of the solute has resulted from the production of a less random and more orderly system during the process of distribution. More important, this entropy change *reduces* the magnitude of the distribution coefficient. This means that the greater the forces between the molecules, the greater the energy (enthalpy) contribution, the larger the distribution coefficient, and the greater the retention. In contrast, any reduction in the random nature of the molecules or an increased amount of order in the system reduces the distribution coefficient and *attenuates* the retention. Thus, in the majority of distribution systems in chromatography, the enthalpy and entropy changes oppose one another in their effect on solute retention, although one will generally dominate over the other.

ThFFF

Martin E. Schimpf
Chemistry Department, Boise State University, Boise, Idaho, U.S.A.

Abstract
This entry provides an overview of thermal field-flow fractionation (ThFFF) and its application to polymer and particle analysis. The separation mechanism is described and contrasted with that in size exclusion chromatography (SEC). The two techniques are somewhat complementary. Thus, SEC typically provides superior resolution of low molecular weight (M) polymers (M <100,000 Da), while ThFFF excels in the separation of high-molecular weight polymers (M >100,000 Da), gels, and particles.

INTRODUCTION

Thermal field-flow fractionation (ThFFF) is a subtechnique of the FFF family that employs a temperature gradient as the applied field. This subtechnique is applied primarily to the analysis of industrial polymers that are soluble in organic liquids where the molecular weight range complements that of size exclusion chromatography (SEC). Thus, oligomers and polymers with molecular weights below about 10^4 g/mol are not generally separated well by ThFFF unless extraordinary measures are taken. On the other hand, the resolving power of ThFFF for polymers with molecular weights above 10^5 g/mol is generally several times that of SEC. For molecular weights above 10^6 g/mol, SEC is limited by shear-induced fragmentation of the chains as they travel through the packed bed under high pressure. In contrast, shear forces in the FFF channel are extremely low; therefore, ultra-high molecular-weight polymers, gels, and particles can be separated without degradation and without sample pretreatment.

ThFFF RETENTION

Like in other FFF subtechniques, materials are retained in ThFFF as a result of their field-induced concentration at one wall of the channel.[1] In ThFFF, this field is a temperature gradient. Several terms, including thermal diffusion, thermophoresis, and the Soret effect, are used to express the movement of materials in response to a temperature gradient.

Like other transport processes, thermal diffusion is typically quantified by a phenomenological coefficient that defines the dependence of a mass or energy movement on a potential-energy gradient. Thus, the thermal diffusion coefficient (D_T) relates the velocity (U_x) induced in a material by a temperature gradient: $U_x = D_T\,(dT/dx)$, where T is temperature and x represents the dimension in which the gradient is applied. This definition of thermal diffusion coefficient can be substituted into the general model of FFF retention to yield the following equation, which approximates the retention volume (V_r) of an analyte component in a ThFFF channel under the "normal" mode of operation:

$$\frac{V_r}{V^o} \cong \frac{\Delta T}{6}\frac{D_T}{D} \tag{1}$$

Here, ΔT is the temperature drop across the channel, which is set by the user, D is the ordinary (mass) diffusion coefficient, and the ratio D_T/D is the Soret coefficient. Parameter V^o is the geometric volume of the channel, which is constant for a given instrument. Note that V_r is the same parameter used to define retention in SEC, and that the ratio on the left side of Eq. 1 is the number of channel volumes required to flush a sample component through the ThFFF channel. Although Eq. 1 is an approximation, it becomes accurate to within 3% when $V_r/V^o > 10$. More important for this discussion, Eq. 1 characterizes the influence of analyte parameters D and D_T on retention in the normal mode of ThFFF.

The "normal" mode of ThFFF, as in all FFF subtechniques, refers to the situation in which analyte is freely diffusing away from the accumulation wall. However, if the field (ΔT) is high enough or the analyte is large enough, then the field-induced compression of sample is so great that the sample does not freely diffuse away from the wall, but is rather lifted away by hydrodynamic forces which increase with the analyte size. In this so-called hyperlayer mode, the elution order is reversed, with larger-molecular-weight components eluting ahead of their lower-molecular-weight counterparts of the same chemical composition. The particle size at which the elution order reverses is dependent on the channel thickness and the flow rate of the carrier liquid; under typical operating conditions the reversal occurs at a particle diameter of 1–2 μm. Thus, the hyperlayer mode is typically in operation for micron sized particles.[2] However, high-molecular-weight

polymers can also be separated efficiently in the hyperlayer mode by the use of elevated flow rates.[3]

According to Eq. 1, the retention of an analyte component in the normal mode is governed by the two transport coefficients D and D_T. Coefficient D scales directly with hydrodynamic volume and is the same parameter that differentiates retention in SEC. Thus, ThFFF, like SEC, separates materials according to differences in their hydrodynamic volume, which is related to molecular weight (M). However, V_r increases with D in SEC and decreases with D in ThFFF, so the elution orders are opposite in the two techniques; low-molecular-weight components elute ahead of higher-molecular-weight components in ThFFF.

While V_r scales with log D in SEC, it scales directly with D in ThFFF. As a result, the molecular weights of components are distributed across a wider range of retention volumes in ThFFF, as compared to SEC. Although resolving power benefits from this spread in molecular weight over V_r, ThFFF has fewer theoretical plates than SEC. As a result, the resolving power of ThFFF exceeds that of SEC only for molecular weights above about 10^5 g/mol, where the increasing compression of a greater range of M within a given range of V_r leads to a rapid decline in the resolving power of SEC.[4]

The dependence of retention on thermal diffusion imparts an additional dimension to the ThFFF separation that is not present in SEC. Although our understanding of thermal diffusion in solids and liquids is incomplete, certain aspects are clear. For example, thermal diffusion is very sensitive to the chemical composition of the polymer. As a result, ThFFF is capable of separating components that differ in composition, even when they have the same molecular weight or diffusion coefficient. An example[5] is the separation of polystyrene and poly(methyl methacrylate) standards by ThFFF as illustrated in Fig. 1. This separation cannot be accomplished with SEC because the diffusion coefficients (or hydrodynamic volumes) of the two materials are virtually identical. The ability of ThFFF to separate materials by chemical composition has spurred additional research designed to increase our understanding of thermal diffusion,[6] which in turn has led to the application of ThFFF to polymer blends and copolymers.[7]

Although D_T varies with the polymer–solvent system, it is independent of molecular weight in a given system, at least for random-coil homopolymers. The separation of differing-molecular-weight components is therefore based solely on differences in D, which means that the principles of universal calibration that are relevant to SEC are also applicable to ThFFF. Thus, a calibration curve made with one polymer–solvent system can be applied to other systems, provided the values of the thermal diffusion coefficient associated with each polymer–solvent system are available. Fortunately, accurate values of D_T can be obtained from the combination of ThFFF with any technique that measures D, such as dynamic light scattering[8]

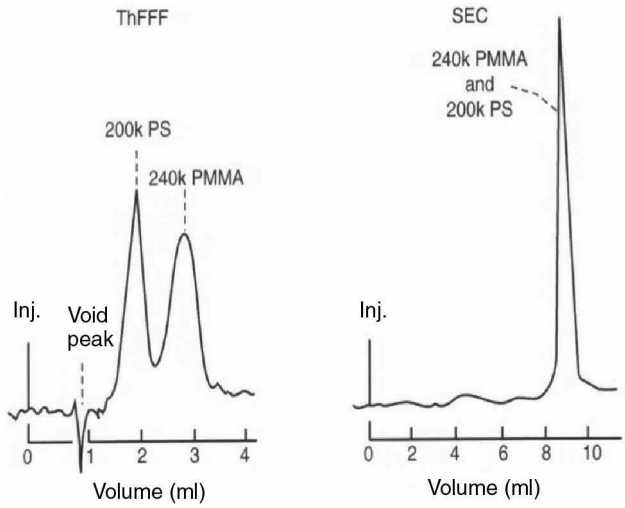

Fig. 1 Elution of similarly sized polystyrene (PS) and poly(methyl methacrylate) (PMMA) polymers by ThFFF and SEC, illustrating the dependence of ThFFF retention on polymer composition.
Source: From Field-flow fractionation, in *Comprehensive Polymer Science, Vol. I, Polymer Characterizations.*[5]

or even SEC; the latter is a secondary method that relies on calibration curves.[9] Values of D_T for many polymer–solvent systems are available in the ThFFF literature.

Compared to SEC, a broader concept of universal calibration is possible with ThFFF because ThFFF channels do not contain the inherent variability associated with SEC packing materials. As a result, relatively simple calibration curves can be employed, which are universal to all ThFFF channels that use the same cold-wall temperature. A common cold-wall temperature is important because both D and D_T vary with temperature. More complex calibration curves incorporate variations in cold-wall temperature.[10]

Retention in ThFFF is directly proportional to the temperature drop (ΔT) across the channel (see Eq. 1). The linear relationship between V_r and ΔT holds even for moderate levels of retention ($V_r/V^o > 3$). Having a predictable dependence of retention on ΔT means that ΔT can be efficiently tuned to optimize the trade-off between resolution and analysis time for each application. ΔT can also be varied over the course of a separation to resolve samples of extreme polydispersity in the most efficient manner. Decreasing ΔT over the course of a separation is analogous to temperature programing in gas chromatography or solvent programing in reversed-phase HPLC.

APPLICATIONS OF ThFFF

Historically, ThFFF has been applied primarily to the analysis of lipophilic polymers. The technique has not found

wide applicability to hydrophilic polymers because thermal diffusion, and therefore retention, is very weak in water.[11] Although a few hydrophilic polymers have been separated by ThFFF, they generally must have a high-molecular weight ($>10^5$ g/mol) to be adequately retained for characterization by ThFFF. Alternatively, an aprotic solvent such as dimethyl sulfoxide can be used to separate hydrophilic polymers with lower-molecular weights. However, flow FFF is more suited to the characterization of hydrophilic polymers.

The open FFF channel is especially suited to fragile materials, and ThFFF has found a definite niche in its application to ultra-high-molecular-weight polymers. Furthermore, as samples need not be filtered, ThFFF is the technique of choice for analyzing gels, rubbers, and other materials that tend to plug SEC columns.[12] Although other FFF subtechniques are more commonly used to separate particles, namely flow FFF and sedimentation FFF, ThFFF has the unique ability to separate particles by composition,[13,14] as well as by size.

Advances in our understanding of thermal diffusion in polymer solutions have led to increased application of ThFFF to copolymers. With random copolymers, for example, the dependence of D_T on chemical composition is now predictable,[7] so that compositional information can be obtained from retention measurements. With block copolymers, ThFFF can still be used to separate components according to molecular weight, branching, and composition, but independent measurements on the separated fractions must be made to get quantitative information, except when "special" solvents are used. Special solvents yield a predictable dependence of D_T on composition even for block copolymers.[7] Different solvents are "special" for different copolymer systems.

Like SEC, ThFFF with information-rich detectors makes a powerful combination. Detectors that yield information on the intrinsic viscosity, molecular weight, or chemical composition of eluting fractions provide detailed information on the distribution of such parameters in a complex sample. ThFFF can also be combined with SEC or hydrodynamic chromatography to achieve 2-D separations. The combination of SEC and ThFFF is a particularly powerful one and has been used to characterize variations in chemical composition of copolymers with molecular weight.[15]

MINIATURIZATION

Although not yet commercially viable, two groups are working on the miniaturization of ThFFF channels. When Giddings first addressed scaling effect in FFF,[16] he concluded that miniaturization has limited potential. However, Gale, Caldwell, and Frazer[17] showed that ThFFF can, in principle, benefit from it in certain ways. Early attempts at miniaturization have yielded mixed results,[18–20] owing in large part to difficulties with microscale injection and detection of the analyte, and it remains to be seen whether such channels will enjoy any significant market share in the future.

THE PRICE OF VERSATILITY

The ability of a single ThFFF channel to be used for the separation of lipophilic polymers, gels, rubbers, and particles makes it a very useful tool for polymer and colloid analysis. The versatility, however, comes at a price. As all of the various applications cannot be implemented with a single field strength or carrier liquid, the user must have more than just a basic familiarity with the technique. To use ThFFF efficiently, while taking advantage of its versatility, the user must understand the fundamentals behind the separation mechanism, and assimilate a certain amount of experience.

Perhaps the most common difficulty encountered by new users arises from their tendency to use high field strengths and high sample concentrations. Unlike in SEC, the elution volume is, in principle, without limit, and the application of a high field can easily lead to an elution time of hours. Thus, in the development of a new application, it is best to begin with a small temperature gradient (ΔT = 10–20 K), and then increase it as necessary to achieve the desired resolution.

For a detailed discussion of appropriate sample concentrations, see *Polymers and Particles: ThFFF*, p. 1869. In general, much lower sample concentrations are used in ThFFF as compared to SEC because the sample is initially concentrated at one wall by the field. Owing to the viscous nature of flow in the thin FFF channel, sample concentrations that are too high lead to poor resolution and reproducibility. On the other hand, although samples are initially concentrated by the field, extremely polydisperse samples eventually get diluted over a wide range of retention volumes owing to the high resolving power of the technique. As a result, such samples require highly sensitive detectors. Although this requirement once posed a significant problem, the availability of highly sensitive and universal detectors, such as the evaporative mass detector, has virtually eliminated the issue of sensitivity in ThFFF.

CONCLUSIONS

ThFFF is a technique that relies on an open channel and an applied temperature gradient to separate materials that respond to a temperature gradient. When employed in the "normal" mode of operation, the elution order of materials is generally opposite to that in SEC, with smaller molecules and particles eluting ahead of larger ones. The technique is applied primarily to lipophilic polymers, copolymers, and gels. Some hydrophilic polymers can also be separated; however, they must not

be charged and generally their molecular weight must be above 10^5 g/mol, and often higher. For hydrophilic polymers, an alternate FFF subtechnique, namely flow FFF is a much more powerful technique (see *FFF Fundamentals*, p. 849). ThFFF separates materials according to their chemical composition, making it applicable to polymer blends and copolymers. For a more detailed discussion of the application of ThFFF to polymers and particles, see *Polymers and Particles: ThFFF*, p. 1869 and the *Field-Flow Fractionation Handbook*.[1]

ThFFF: Cold Wall Effects

Martin E. Schimpf
Chemistry Department, Boise State University, Boise, Idaho, U.S.A.

Abstract
Controlling the temperature of the cold wall is important for obtaining the greatest possible precision in thermal field-flow fractionation (ThFFF). This entry describes the effect of temperature on the transport process, which underlies separation by ThFFF, as well as the practical implications of temperature when ThFFF is applied to polymer analysis.

INTRODUCTION

In field-flow fractionation (FFF), like chromatography, retention and resolution are affected by temperature. For calibration curves to be as precise as possible, or in the case of ThFFF, to universally apply a calibration curve to channels in different laboratories, it is important to closely control the temperature. In ThFFF, the analyte is typically compressed into a layer very close to the cold wall. Therefore, the temperature of the analyte is usually within a few degrees of the cold wall temperature. Consequently, the retention of a given component from one run to the next, or from one instrument to another, will be identical only if the cold wall temperatures are identical.

Fluctuations in the cold wall temperature (T_c) of a couple degrees are generally not a problem. For example, the retention of polystyrene in ethylbenzene decreases 1% for each 2°C increase in T_c when the temperature gradient (ΔT) is held constant.[1] This variation is typical of most polymer–solvent systems. Fluctuations in T_c greater than a couple of degrees, however, will affect both the accuracy and precision of molecular weight distributions that rely on calibration. Such fluctuations can be critical, for example, when retention is used to monitor small batch-to-batch variations in a quality control situation.

TEMPERATURE CONTROL AND ThFFF

The temperature of the cold wall depends on several factors. Heat transferred from the hot wall to the cold wall is typically removed by heat exchange with water. The cooling efficiency is affected by the temperature of the incoming water, which can vary by several degrees among different laboratories. The temperature of the incoming water may also vary by several degrees over time in a given laboratory. The effect of variations in the incoming water temperature can be attenuated with the use of a flow-control valve, since T_c also varies with the flow rate of the water. For example, a lower coolant flow rate can be used in the winter to offset the effect on T_c of the lower water temperature. An alternative to varying the flow rate is to maintain a constant water temperature by running it through a thermostated heater/chiller.

For a given polymer–solvent system, variations in T_c can be incorporated into the calibration equation.[2–4] However, applying T_c into the calibration requires the systematic accumulation of large amounts of data. Furthermore, the temperature dependence of the transport coefficients that govern retention vary with the polymer–solvent system. Consequently, calibration curves that incorporate temperature variations are not necessarily transferable from one polymer–solvent system to another.

Because there are well-defined equations that relate retention to the underlying transport coefficients, ThFFF retention can be used to measure those transport coefficients. In fact, the measurement of thermal diffusion coefficients by ThFFF can be used to obtain compositional information on polymer blends and copolymers (see *Polymers and Particles: ThFFF*, p. 1869). ThFFF is also used in fundamental studies of thermal diffusion because it is a relatively fast and accurate method for obtaining the transport coefficient that quantifies the concentration of material in a temperature gradient, namely the Soret coefficient. However, the accuracy of Soret coefficients obtained from ThFFF experiments depends on appropriate accounting for several factors that involve temperature. To understand the effect of temperature on transport coefficients, as well as the effect on ThFFF calibration equations, a brief outline of retention theory is provided in the following section.

THEORY OF ThFFF RETENTION

In all FFF subtechniques, retention depends on a balance of two opposing motions. The first motion is induced by the applied field and results in the concentration of material at

the accumulation wall (typically the cold wall in ThFFF). The buildup in concentration induces the opposing motion of diffusion. Both motions are accounted for in the retention parameter λ, which is defined for all FFF subtechniques as:

$$\lambda = \frac{D}{Uw} \tag{1}$$

where D is the (mass) diffusion coefficient, U is the field-induced velocity of the sample, and w is the channel thickness. In ThFFF, U is governed by the thermal diffusion coefficient (D_T) and the temperature gradient (dT/dx), which is applied in the same dimension (x) as the channel thickness (x varies in value from 0 at the cold wall to w at the hot wall). Using the dependence of U on D_T and dT/dx, the retention parameter in ThFFF can be expressed as:

$$\lambda = \frac{D}{D_T(dT/dx)w} \cong \frac{D}{D_T \Delta T} \tag{2}$$

where ΔT is the difference in temperature between the hot and the cold walls. Since x and w are in the same dimension, dT/dx can be approximated by $\Delta T/w$, therefore $w(dT/dx)$ is approximated by ΔT on the right-hand side of Eq. 2.

When the parameters in Eq. 1 are constant throughout the channel, the volume V_r of the fluid required to flush a sample component through the channel is related to λ by the following equation:

$$V_r = \frac{V^o}{6\lambda}\left[\coth\left(\frac{1}{2\lambda} - 2\lambda\right)\right]^{-1} \tag{3}$$

Here V^o is the volume of the fluid required to flush a sample that is not affected by the field ($U = 0$). In most FFF subtechniques, the parameters in Eq. 1 are in fact constant throughout the channel. In ThFFF, however, these parameters vary across the channel because they depend on temperature, which varies between the hot and the cold walls. As a result, Eq. 3 is only an approximation in ThFFF. Fortunately, the approximations associated with Eq. 3 are inconsequential for the determination of molecular weight distributions, so that the only concern is variations in T_c, as discussed above. For measuring transport coefficients, on the contrary, the approximations can lead to significant errors.

When calculating transport coefficients from the measured values of V_r, the retention parameter λ is first calculated using Eq. 3. Then, the Soret coefficient D_T/D is calculated from λ using Eq. 2. From the Soret coefficient, the value of D_T can be calculated if an independent measure of D is available. The accuracy of the resulting value is adjusted by the approximations involved in deriving Eq. 3. First, a parabolic velocity profile is assumed. In reality, the velocity profile is skewed toward the hot wall by a carrier-liquid viscosity (η) that varies across the channel as a result of the temperature gradient.[5] Variations in thermal conductivity (κ) with temperature across the channel must also be considered. Finally, the accuracy of Eq. 3 is compromised by an assumption that the analyte forms an exponential concentration profile, whereas in reality the profile is more complicated due to the temperature dependence of the transport coefficients.

The consequences of the temperature dependence of η, κ, D, and D_T have been discussed in several papers.[6–9] Ko, Richards, and Schimpf[6] demonstrated that the temperature dependence of the Soret coefficient actually increases the resolution of different molecular weight components. In a theoretical study by van Asten et al.,[7] it was shown that the consequence of ignoring the temperature dependence of κ has a nearly negligible effect on the accuracy of D/D_T values calculated using Eqs. 2 and 3. Ignoring the temperature dependence of η and D/D_T, on the contrary, can lead to significant errors when D/D_T values are calculated from the retention data. Several refinements to Eq. 3 have been made over the years. When these refinements are used, they yield accurate values for the transport coefficients. Although the resulting equations are quite complex, they are not required for the routine analysis of polymers by ThFFF.

CONCLUSION

Like most analytical techniques, the measurements employed in ThFFF are sensitive to temperature. The most critical temperature to control in ThFFF is the cold wall temperature. By controlling that temperature, the preparation of universal calibration plots is simple and straightforward. Once such plots are obtained, they can be applied to all ThFFF instruments with adequate control of the cold wall temperature. Without precise temperature control, universal calibration plots can still be obtained, but this involves a tedious procedure for each polymer–solvent system under consideration. The incorporation of cold wall temperature in ThFFF calibrations for polymer analysis is well described in the entry *ThFFF: Molecular Weight and Molecular Weight Distributions*.

ThFFF: Molecular Weight and Molecular Weight Distributions

Martin E. Schimpf
Chemistry Department, Boise State University, Boise, Idaho, U.S.A.

Abstract
In field flow fractionation (FFF), retention can be related to the applied field through a well-defined equation governing physicochemical parameters of the analyte. Therefore, in principle, FFF is a primary measurement technique that does not require calibration, but only if the governing physiochemical parameters are the analyte parameters of interest, or their relationship to the parameter of interest (such a molecular weight) is well defined. This entry outlines the procedures for obtaining molecular weights and molecular weight distributions (MWDs) from ThFFF elution profiles in various experimental situations.

METHODOLOGY

In thermal field-flow fractionation (ThFFF), the applied field is a temperature drop (ΔT) across the channel, and the physicochemical parameter that governs retention is the Soret coefficient, which is the ratio of the thermal diffusion coefficient (D_T) to the ordinary (mass) diffusion coefficient (D). Because ΔT is set by the user, retention in a ThFFF channel can be used to calculate the Soret coefficient of a polymer–solvent system. However, to calculate the molecular weight (M) or molecular weight distribution (MWD) of the polymer, the dependence of the Soret coefficient on M must be known. Because D_T is virtually independent of M, at least for solvated homopolymers, the dependence of retention on M reduces to the dependence of D on M. The separation of molecular weight components by D (or hydrodynamic volume, which scales directly with D) is a feature that ThFFF shares with size exclusion chromatograpy (SEC). In the latter technique, the dependence of retention on D forms the basis for universal calibration, as D scales directly with the product $[\eta]M$, where $[\eta]$ is the intrinsic viscosity. Thus, a single calibration plot prepared in terms of log ($[\eta]M$) vs. retention volume (V_r) can be used to measure M for different polymer compositions, provided an independent measure of $[\eta]$ is available. In ThFFF, a single calibration plot can be used for multiple polymers only when the values of D_T for each polymer–solvent system of interest are known. However, a single calibration plot, once established for a given polymer–solvent system, can be used with any ThFFF channel. In summary, calibration plots in SEC are specific to each column but can be made universal with respect to their application to a variety of different polymer compositions. Calibration plots in ThFFF are specific to each polymer–solvent system but universal with respect to different ThFFF channels. The following discussion outlines the various forms that can be used to calibrate a ThFFF channel and how they are used to obtain average values of M and MWDs.

The simplest calibration plot takes the following form:

$$\log V_r = a + S_m \log M \tag{1}$$

where a and S_m are calibration constants. The parameter S_m is referred to as the mass-based selectivity in the FFF literature and is very close but not identical in value to the exponent (b) which defines the dependence of D on M:

$$D = AM^b \tag{2}$$

The difference between S_m and b can be explained by the fact that components of different M experience different temperatures as they separate in the ThFFF channel (see *ThFFF: Cold Wall Effects*, p. 2312).[1]

Eq. 1 fails for very low levels of retention, which can occur with components of low-molecular weight. For such components, where V_r approaches the geometric (void) volume of the channel V^o, calibration plots in the form of Eq. 1 exhibit curvature. An alternate form of Eq. 1, which works over a wider range of retention levels, including low levels of retention, is:[2]

$$\log(V_r - V^o) = a + S_m \log M \tag{3}$$

Because ΔT can be varied to optimize the separation of different samples, it is convenient to incorporate the dependence of retention on ΔT into the calibration plot:

$$\log(\lambda \Delta T) = \phi + n \log M \tag{4}$$

Here, n and ϕ are calibration constants, and λ is the FFF retention parameter, which is calculated from V_r using the following equation:

$$V_r = \frac{V^o}{6\lambda[\coth(2\lambda)^{-1} - 2\lambda]} \quad (5)$$

When ΔT is incorporated into the calibration plot, retention parameter λ is used in place of $(V_r - V^o)$ in order to maintain linearity in the plot over a wide range of applied fields and retention levels.

Once the calibration constants ϕ and n have been determined for a given polymer–solvent system, Eq. 4 can be used for all ThFFF channels, provided the temperature of the cold wall (T_c) is held constant. The cold wall temperature affects the calibration plot because the Soret coefficient (D_T/D) and therefore ϕ varies with T_c. For a detailed discussion of temperature effects (see *ThFFF: Cold Wall Effects*, p. 2312). In a thorough study of temperature effects, Myers and coworkers[3] demonstrated that the dependence of the Soret coefficient on T_c can be accurately modeled by the following equation:

$$\frac{D}{D_T} = \lambda\Delta T = a' T_c^m \quad (6)$$

The validity of this model is illustrated in Fig. 1 by the linearity in plots of log $(\lambda\Delta T)$ vs. log $(T_c/298)$. Based on Eq. 6, the following universal calibration equation has been proposed:

$$\log(\lambda\Delta T) = \phi + m\log\left(\frac{T_c}{298}\right) - n\log\left(\frac{M}{10^6}\right) \quad (7)$$

In order to utilize Eq. 7, a set of linear plots of log $(\lambda\Delta T)$ vs. log $(M/10^6)$ is established for a given polymer–solvent system, with one plot being generated for each of several cold wall temperatures. Such plots run parallel to one another with slopes equal to n and with intercepts that equal $[\phi + m \log (T_c/298)]$. To obtain the values of ϕ and m, linear regression is performed on the intercept values as a function of $T_c/298$. In Eq. 7, the values of T_c and M are divided by 298 and 10^6, respectively, to avoid large extrapolations in obtaining the various intercept values by regression.

Although Eqs. 4 and 7 are applicable over a range of field strengths (ΔT values), the field must be held constant during any given analysis. A more complex calibration method is required when the field is programed, in order to more efficiently separate very broad polymer distributions.[4]

When a mass-sensitive detector such as a refractometer or photometer is used, the weight-average molecular weight (M_w) of a polymer sample is calculated from the calibration equation using the value of V_r that corresponds to the center of gravity of the elution profile. The center of gravity is defined by placing a vertical line through the

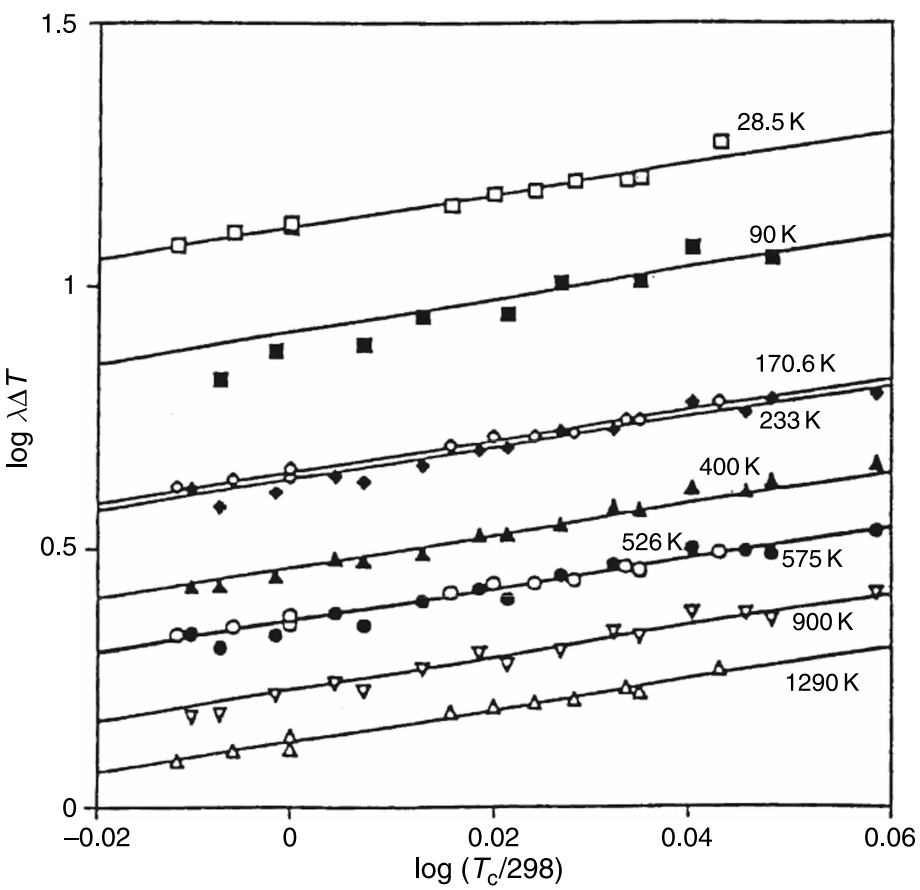

Fig. 1 Plots of log $\lambda\Delta T$ vs. log $T_c/298$ for polystyrene in tetrahydrofuran. The data were gathered using a variety of different ThFFF channels. Values of ΔT ranged from 30 to 70 K. **Source:** Reproduced with permission from Thermal field-flow fractionation universal calibration: Extension for consideration of variation of cold wall temperature, in Anal. Chem.[3]

elution profile such that the line bisects the profile into two halves of equal area. The intersection of this line with the elution–volume axis defines the weight-average V_r, which is converted to M_w through the calibration equation. If the elution profile has a Gaussian shape, then the weight-average V_r is the value of V_r that corresponds to the peak of the elution profile.

In ThFFF, the shape of the elution profile is not significantly affected by band broadening for polydisperse ($\mu > 1.2$) polymers, provided that low flow rates (<0.2 ml/min) are used. In that case, accurate information on the MWD can be obtained directly from the elution profile. For example, if a mass-sensitive detector is used, the signal (s) is linearly related to the mass of polymer in the eluting stream, and the number-average molecular weight (M_n) of the sample is calculated as:[2,5]

$$M_n = \frac{\sum s_i}{\sum \frac{s_i}{M_i}} \tag{8}$$

Here, the summation extends over small equal elements of elution volume from the beginning to the end of the elution profile. Thus, s_i is the detector signal of the ith digitized increment, and M_i is calculated from the associated value of V_r using the calibration equation. The weight-average molecular weight (M_w) is calculated as:

$$M_w = \frac{\sum s_i M_i}{\sum s_i} \tag{9}$$

Polydispersity μ, defined as the ratio M_w/M_n, thus becomes

$$\mu = \frac{\left(\sum s_i M_i\right)\left(\sum \frac{s_i}{M_i}\right)}{\left(\sum s_i\right)^2} \tag{10}$$

ThFFF elution profiles can also be converted into a detailed MWD. With a mass-sensitive detector, the elution profile is essentially a plot of the polymer concentration c (with units of mass/volume) in the eluting stream vs. V_r. In order to obtain the mass-based MWD, $m(M)$, we need to transform this profile using the following equation:

$$m(M) = c(V_r)\frac{dV_r}{dM} \tag{11}$$

The normalized and digitized form of this equation is

$$m_i = \frac{s_i}{\sum s_i}\frac{\Delta V_r}{\Delta M_i} \tag{12}$$

where ΔV_r is the fixed elution volume element corresponding to one digitized interval. In the case of linear calibrations, as defined by Eqs. 1 and 3, $d(\log V_r)/d(\log M)$ is a constant equal to S_m, and Eq. 12 is more conveniently expressed in the following form:

$$m_i = \frac{s_i}{\sum s_i}\frac{M_i}{V_{r,i}}S_m \tag{13}$$

If needed, the differential number MWD can be obtained by dividing $m(M)$ by M:

$$n(M) = \frac{m(M)}{M} \tag{14}$$

For polymers with low polydispersity ($\mu < 1.2$), a detailed MWD is not generally required, and simply calculating M_n and M_w from Eqs. 8 and 9 is generally adequate. However, the elution profile of such a narrow MWD is affected significantly by band broadening, which must be accounted for in order to obtain the most accurate possible values of M_n and μ.[6] Even the elution profile of more polydisperse samples ($\mu > 1.2$) can be affected by band broadening if high flow rates (>0.2 ml/min) are used. Fortunately, band broadening is well defined in ThFFF and can be removed by one of two methods. For samples of low polydispersity, μ is well approximated by[6]

$$\mu = 1 + \frac{H_P}{LS_m{}^2} \tag{15}$$

where L is the channel length and H_P is the polydispersity contribution to plate height (H). H_P is obtained by plotting the experimental H as a function of flow rate. With the appropriate technique,[6,7] such plots are linear and the y-intercept is equivalent to H_P. Alternatively, H_P can be obtained by subtracting the non-equilibrium band-broadening contribution to H (H-sub-N) from the experimentally measured value. Methods for calculating H_N from well-established models of band broadening in ThFFF can be found in the literature.[2] Since the elution profile of samples with low polydispersity are generally symmetrical, M_w is calculated using the peak value of V_r in the calibration equation, and then Eq. 15 is used to calculate μ. Finally, M_n is calculated from $\mu = M_w/M_n$.

Samples with higher polydispersity do not generally yield symmetrical elution profiles. Moreover, a detailed MWD [either $m(M)$ or $n(M)$] is often desired. As mentioned above, band broadening does not significantly affect the elution profile when low flow rates are used. Therefore, the elution profile can be directly converted into a MWD by the procedures outlined above. If, on the contrary, fast flow rates are used to shorten analysis time, the observed elution profile must be adjusted to account for the effects of band broadening. A deconvolution algorithm that filters out the band-broadening contribution to the elution profile is described in the literature.[2] Fig. 2 illustrates that the elution profiles

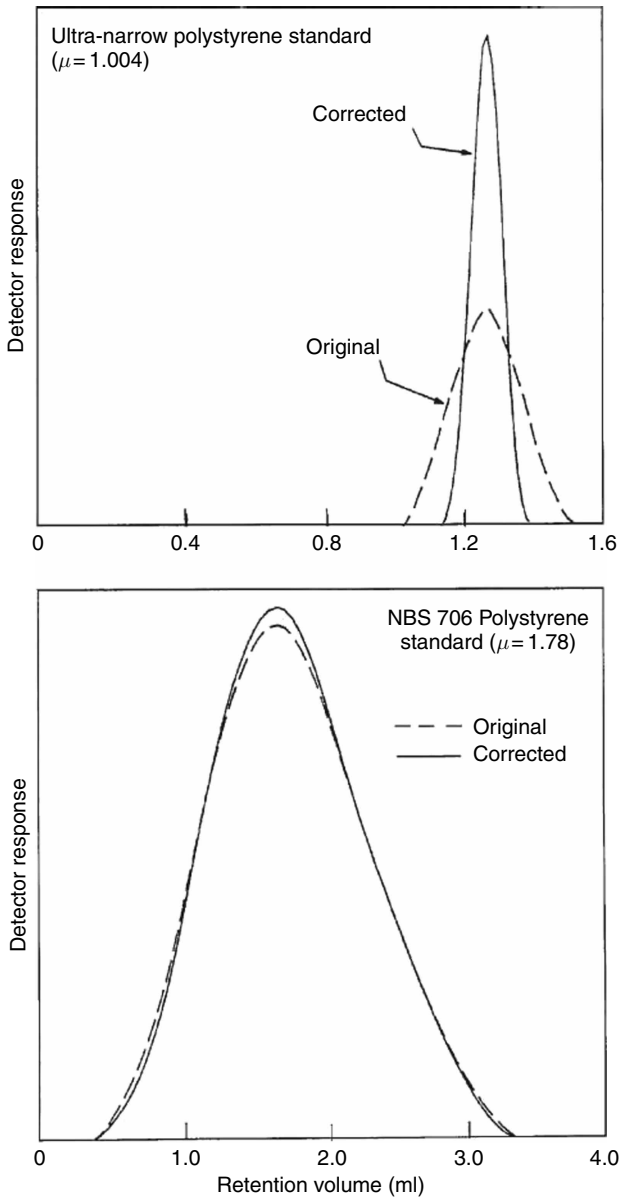

Fig. 2 ThFFF elution profiles before (original) and after (corrected) removing the effects of band broadening. With the polydisperse sample (NBS 706), which was analyzed at a flow rate of 0.4 ml/min, the effect of band broadening on the elution profile is minimal. The polydispersity values listed were determined using ThFFF.

before and after the effects of band broadening are removed for samples of both low and high polydispersity.

CONCLUSION

A variety of calibration procedures have been developed for characterizing the molecular weight and MWD of polymers by ThFFF. The procedures range in complexity depending on the desired flexibility. One of the unique features of ThFFF compared to SEC is the ability to tune the external field, in order to optimize the method for a given sample and/or molecular weight range. It is a simple matter to incorporate the field strength into the calibration plots, so that a single plot can be applied for a given polymer–solvent system under a range of applied temperature gradients. When the thermal diffusion coefficient is known for each polymer–solvent system under consideration, such coefficients can also be incorporated so that a single calibration plot can be applied to multiple polymer types.

For determining MWDs, the resolving power of ThFFF is high enough that band-broadening effects are generally negligible, except for nearly monodisperse materials or when high flow rates are used for rapid analysis. For cases in which band broadening is not negligible, the open ThFFF channel has a distinct advantage over SEC because band broadening is well understood and can be accurately modeled and precisely removed from the elution profile. As a result, techniques have been established that accurately account for the effect of band broadening on MWDs derived from ThFFF elution profiles. For more detailed information on the determination of molecular weight and MWDs by ThFFF, see *the Field-Flow Fractionation Handbook*.[7]

Thin Layer Radiochromatography

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

Abstract
The techniques and instruments for the detection and quantification of radiolabeled zones in thin layer chromatograms are described. Included are film autoradiography, liquid scintillation counting (LSC), storage phosphor imaging, and in situ radioactivity scanning. These methods are widely applied in radiopharmaceutical purity determination, metabolism studies, and many other chemical, biochemical, and biological investigations.

INTRODUCTION

Thin layer chromatography (TLC) is often used for the separation, detection, and qualitative and quantitative determination of radiolabeled substances. The method is termed thin layer radiochromatography (TLRC) or radio-TLC. Applications include following the course of chemical and biochemical reactions and determining the distribution of radiolabeled substances in a reaction mixture; metabolism studies of drugs, pesticides, pollutants, and natural substances in human, animal, and plant tissues or soil; assessing the purity of radiopharmaceuticals and isotopes; and for biochemical studies such as elucidation of biochemical pathways, radiotracer binding, and assessment of enzyme activity. TLRC is often the best method for carrying out such studies because of its low detection limits (often better sensitivity than radio high-performance liquid chromatography, HPLC); variety of methods for detecting and quantifying tagged compounds; capability for fast method development and serial analysis; and no sample loss due to sorption on a column (the entire sample is detected), and it can provide information complementary to that from radio-HPLC.

It is important to use proper safety precautions in TLRC experiments, such as working in a well-ventilated area (preferably a fume hood) and frequent monitoring of analysts for exposure. Both the half lives and energies of the isotopes used should be considered in designing safety protocols for sample handling and analytical procedures.

TLC PROCEDURES

The chromatographic analyses are normally carried out using precoated commercial TLC and high performance TLC (HPTLC) plates with one-dimensional (1-D) isocratic ascending development. Glass-backed plates are flat and uniform and best to use for direct scanning detection in TLRC. Plates with plastic or aluminum backing can be cut into sections, thereby facilitating liquid scintillation counting (LSC) or preparative isolation of separated compounds.[1] Normal-phase silica gel is the most widely used layer by far, but reversed-phase and ion-exchange layers have been reported in TLRC analyses. In many cases layers with a preadsorbent or concentrating zone are used because smaller, better-resolved zones can be obtained when large volumes of dilute solutions are applied.

Samples should be applied manually or with an automated instrument[2] as small spots or narrow bands sufficiently far apart to avoid measurement of radioactivity from adjacent lanes. Highest-resolution separations are obtained on HPTLC plates with optimized mobile phases and small-volume samples, if the level of activity allows. The layer should be dried after development under conditions that completely remove the mobile-phase constituents but do not volatilize sample components. Compound degradation on the plate can be checked by two-dimensional (2-D) development of a mixture with the same mobile phase; all of the zones will lie on a diagonal straight line if no decomposition occurs during development. Higher resolution for complex samples can be obtained by 1-D automated gradient elution multiple development (AMD) or forced flow development overpressured layer chromatography (OPLC), or by 2-D development at right angles with complementary mobile phases having different separation mechanisms.

Earlier sources[3–5] described methods and instruments (many now outdated and not commercially available) for detection and quantification of radioactivity in TLC and HPTLC. However, no book or journal article published since 2003 has included an updated description of the field, which is provided in this entry.

FILM AUTORADIOGRAPHY

In the classical autoradiography method, the thoroughly dried layer containing the separated radioactive zones (spots or bands) is put in direct contact with a photographic (X-ray) film or emulsion, which shows the image of the chromatogram as darkened zones after film development. The process involves detection of beta-particles based on reduction of silver ions to silver atoms within the film. Film development is carried out by standard photography processing methods in a darkroom.

When properly exposed, the resolution of the zones in autoradiography can be comparable to that on the original chromatogram and as high as any other radioactivity detection method. The major disadvantage is that exposure times can vary from a few hours to several weeks, depending on the amount of radioactivity in the TLC zones. Various commercial films are used, one of the newest and most sensitive being Biomax MR from Kodak (Rochester, New York, U.S.A.).

Enhancement of detection sensitivity in the range of 1–16 fold has been obtained by using an inorganic phosphor-coated intensifying screen placed behind the film. The phosphor emits light when beta-particles pass through the film, increasing film exposure.[4]

Fluorography is another sensitivity enhancement method in which a scintillator such as 2,5-diphenyloxazole (PPO) is added to the layer postchromatography using a commercial spray reagent. The energy of the disintegrating radionuclides is converted to light, which is detected by the film to produce a "fluorogam." In one study, Kodak X-OMAT R film treated with EN^{3}HANCE spray (New England Nuclear; PerkinElmer Life and Analytical Sciences, Shelton, Connecticut, U.S.A.) and exposed at dry ice temperature for 24 hr produced a 100–200 fold enhancement of the sensitivity of ^{3}H and ^{14}C detection compared to autoradiography.[4]

Qualitative assessment of chromatograms is made by visual inspection of the film and quantitative analysis by optical density measurement of the zones with a slit-scanning, video, digital camera, or flatbed scanner densitometer; these types of light-based densitometers, which are also used for quantification of colored, ultraviolet (UV) absorbing, and fluorescent TLC zones, have been described in previous articles.[6–9] Optical density is related to the amount of radioactivity through a calibration curve prepared using a set of radioactive standards during each exposure. The curve corrects for the variables related to the film type, exposure period, and film development procedure. Further details on film autoradiography are presented in Refs. 3 and 4.

LIQUID SCINTILLATION COUNTING

For LSC, radioactive zones are scraped from a glass-backed layer or cut from a layer with flexible backing (plastic or aluminum) and transferred into a vial, mixed with a scintillation solution (commercial "cocktails" are available), and indirectly quantified based on measurement of the light energy produced in a scintillator counter with a photomultiplier tube (PMT). As an alternative, scraped or cut zones can be eluted with solvent into a vial to isolate the radiolabeled sample and then counted. The number of counts for each zone can be plotted as a histogram profile of the radioactivity in the chromatogram along the lane of a TLC plate.

Because high resolution depends on small widths of adsorbent zones being scraped, LSC can be very labor intensive and time consuming. Scraping must be done manually with a commercial device such as a sharp, flat spatula because there are no commercial automatic scrapers available. Great care is needed to minimize loss of sorbent during scraping and transfer to vials.

Quenching effects of solvents, layer sorbents, and sample constituents are taken into account by modern LSC instruments. Samples with low levels of radioactivity are counted for a longer period and background correction is performed using a blank layer section taken from an area adjacent to the zone of radiolabeled compound.

In general, LSC is among the most sensitive and quantitative TLRC methods, but resolution is limited and great care is needed to obtain accurate and precise quantitative results. LSC is described further in Refs. 3 and 4.

PHOSPHOR IMAGING

Storage phosphor screen imaging is often termed filmless autoradiography. The phosphor screens are sensitive to any source of ionizing radiation, e.g., ^{14}C, ^{3}H, ^{35}S, ^{125}I, ^{32}P, ^{33}P, ^{18}F, and ^{99m}Tc. They contain small crystals of a

photostimulable phosphor coated on a support in which luminescence is produced and stored when exposed to radioactive TLC zones. The luminescence is evaluated by scanning with a laser in a reading device, and quantification is carried out by use of a calibration curve to exclude the effects of the phosphor screen type and exposure period. The screens can be reused after being erased by exposure to visible light.

The BAS-5000 bioimaging analyzer from Fujifilm Life Science USA (Stamford, Connecticut, U.S.A.) is an example of a phosphor screen imaging system. The imaging plate (IP) consists of 5 μm crystals of barium fluorobromide containing a trace amount of bivalent europium ($BaFBr:Eu^{+2}$) as a bioluminescence center coated on a polyester support film. When the crystal is exposed to a radiolabeled zone, the energy of the radioisotope ionizes the Eu^{+2} to Eu^{+3}, liberating electrons to the conduction band of the phosphor crystals. The electrons are trapped in the bromine vacancies introduced during the manufacturing process. The exposed IP is scanned with a laser beam of red light (633 nm) focused by a mirror while being moved in the reader; the photostimulated phosphorescence (PSL) released by the laser as photons of blue light (390 nm) is collected onto a PMT through a light collection guide and is converted to electrical signals. A 20 × 25 cm IP with the images of chromatograms from a 20 × 20 cm TLC plate can be scanned at 50 μm in as little as 5 min. Compared to X-ray film, sensitivity is about 100 times higher, processing is 10–100 times faster, and quantitative accuracy is greater.

The benchtop Cyclone Plus quantitative radiometric phosphor imager (PerkinElmer Life and Analytical Sciences) operates with the same storage phosphor and scanning process except that a helical scanning mechanism is used with the flexible phosphor screen loaded into a cylindrical carousel that spins at 360 rpm. This allows the instrument to be more compact and lower in cost than the BAS-5000, in which the phosphor screen is kept on a flat plane during scanning.

The following TLC applications cited by PerkinElmer for the Cyclone Plus are typical of other phosphor imaging systems: imaging of ^{3}H, ^{125}I, ^{14}C, ^{32}P, ^{33}P, ^{18}F, ^{90}Y, ^{99m}Tc, ^{111}In, and ^{177}Lu; nucleotide metabolism studies with ^{32}P- and ^{33}P-labeled adenosine triphosphate (ATP) or guanosine triphosphate (GTP); ^{14}C-UDPGA glucuronidation assay; quality control (QC) of ^{177}Lu- and ^{90}Y-DOTA-TOC; ^{18}F silica gel TLC for analysis of position emission tomography (PET) radiochemicals; QC of ^{99m}Tc; and radiochemical purity of ^{90}Y Zevalin.

RADIOSCANNERS FOR DIRECT MEASUREMENT ON TLC PLATES

Scanners with a position-sensitive proportional gas flow counter detector are used primarily for detection of beta radiation. The process involves ionization of the counting gas by interaction with radioactive TLC zones, producing a pulse of electrons that is proportional to the amount of radioactivity.

An example of this type of detector is the MARITA Star from Raytest USA (Wilmington, North Carolina U.S.A.; Fig. 1), an automatic single trace instrument for measurement of one 5 × 20 cm TLC plate. The Raytest RITA Star beta radiation layer analyzer can measure two 20 × 20 cm plates at once. The detector for each has an active length of 200 mm and active width of 20, 15, 10, 3, or 1 mm controllable by exchange of the diaphragm. The sensing element is gold plated for easy cleaning and long life. For measurement of low energy betas from ^{3}H, the counting tube is used without any window and is placed as close as possible to the radioactive TLC zone. Therefore, the detector rests on the surface of the layer in order to close the counting chamber and reduce gas leakage, and the gold-plated tungsten counting wire can be accurately aligned for optimum results. In the RITA Star, the counting tube is automatically moved to measure traces of multiple chromatograms on a layer. 2-D thin layer chromatograms are measured by assembling individual 1-D traces. Data collection, analysis, and documentation meet good laboratory practice (GLP) requirements. Both instruments are designed for maximum sensitivity for low-energy beta- emitting nuclides such as ^{3}H, ^{14}C, ^{35}S, ^{33}P, and ^{32}P; gamma- and positron-emitting nuclides such as ^{125}I, ^{99m}Tc, and ^{18}F can be detected more sensitively with the Raytest GITA or miniGITA Star (below).

The AR-2000 imaging scanner (Bioscan Inc., Washington, District of Columbia, U.S.A.) is another instrument that has a windowless gas-filled proportional detector and can detect gamma, beta, and positron emitters. Sensitivity for a 10 min analysis is 1000 dpm for ^{3}H and ^{125}I and 100 dpm for ^{14}C, ^{32}P, and most other isotopes, and resolution is 0.5–1 mm for ^{3}H, 1–2 mm for ^{14}C, and 3 mm for ^{32}P and most gamma emitters. An entire TLC lane can be imaged in under 1 min, and multiple lanes can be measured in a single automated run without operator intervention. Models are available that hold one, two, or three 20 × 20 cm TLC plates. Single-lane or 2-D color imaging and automated quantification can be performed with WinScan software, or with Bio-Chrom software for compliance with 21 CFR Part 11 U.S. Food and Drug Administration and GLP standards. Applications for which the AR-2000 have been used include PET or single photon emission computed tomography (SPECT) radiopharmaceutical QC and synthesis process control (compounds labeled with ^{18}F, ^{11}C, ^{99m}Tc, ^{111}In, etc.); pharmaceutical metabolite analysis for beta-, gamma-, or positron-labeled products; radiotracer toxicology studies with ^{14}C labeled organic compounds and agrochemicals; biosynthesis studies involving complex lipids, phospholipids, and glycolipids; radiochemical purity quality

assurance (QA) analyses for tracer or metabolism studies; radiolabeled reporter gene or enzyme assays; and quantitative radiolabeled biochemical separations (programmable scanning and quick-change magnetic collimators can be used for optimization of resolution and sensitivity).

The GITA gamma isotope TLC analyzer is an X–Y scanner controlled by a personal computer (PC) for automatic measurement, data evaluation, and report printing. It has a V-shaped bismuth germanate (BGO-V) crystal scintillation probe detector mounted in tungsten shielding, can be automatically energy-calibrated using a ^{137}Cs standard, and many energy windows can be preprogrammed for various nuclides. Up to 80 sample traces can be programmed in terms of location, scan speed, etc. in both directions on two 20 × 20 cm plates. Beta/positron detection can be made using an optional Geiger-Mueller (GM) detector (^{3}H is not detected). Collimators of 3 mm (stainless steel) and 5–20 mm (tungsten) size are available to optimize resolution and sensitivity for gamma detection of different nuclides. The miniGITA Star from Raytest is a scanner for gamma and beta/positron radiation from TLC zones that is similar to the GITA Star. The major differences are that the scan area is 5 × 20 cm and only one trace can be made at a time in the X direction.

CONCLUSION

TLRC can be used for animal, human, and plant metabolism analysis; radiochemical purity and stability assessment; toxicology and biochemical studies; and separation, detection, and quantification of separated radioactive zones of all compound classes. Traditional film autoradiography and LSC continue to be widely used, but phosphor imaging and layer scanners are being increasingly applied. The instruments for these methods are highly automated and can have significant advantages in terms of simplicity, speed, accuracy, precision, and sensitivity. The in situ scanner methods are direct analyses that minimize technician radiation exposure and do not require disposal of contaminated screens or liquid waste.

Three-Dimensional Effects in FFF: Theory

Victor P. Andreev
Institute for Analytical Instrumentation, Russian Academy of Sciences, St. Petersburg, Russia

INTRODUCTION

A field-flow fractionation (FFF) channel is normally ribbonlike. The ratio of its breadth b to width w is usually larger than 40. This was the reason to consider the two-dimensional (2D) models adequate for the description of hydrodynamic and mass-transfer processes in FFF channels. The longitudinal flow was approximated by the equation for the flow between infinite parallel plates, and the influence of the side walls on mass-transfer of solute was neglected in the most of FFF models, starting with standard theory of Giddings and more complicated models based on the generalized dispersion theory.[1] The authors of Ref.[1] were probably the first to assume that the difference in the experimental peak widths and predictions of the theory may be due to the influence of the side walls.

DISCUSSION

The essence of the side walls effect follows. The flow velocity turns to zero at the side walls as well as at the main (accumulation and depletion) walls of the FFF channel. Therefore, the flow profile is non-uniform, not only along the width of the channel but also along its breadth. The size of the regions near the side walls where the flow is substantially non-uniform is of the same order as w. The non-uniformity of the flow in both directions, combined with diffusion of solute particles, leads to Taylor dispersion and peak broadening that could be different from the one predicted by the 2D models.

The first 3D model of FFF was developed in Ref.[2] The 3D diffusion–convection equation was solved with the help of generalized dispersion theory, resulting in the equations for the cross-sectional average concentration of the solute and dispersion coefficients K_1 and K_2, representing the normalized solute zone velocity and the velocity of the corresponding peak width growth, respectively. Unfortunately, only the steadystate asymptotic values of dispersion coefficients $K_1(\infty)$ and $K_2(\infty)$ were determined in Ref.,[2] leading to the prediction of the solute peaks much wider than the experimental ones.

The incorrectness of the steady-state approach was noted by the authors of Ref.[3] and can be explained as follows. There are two characteristic diffusion times in an FFF channel: $t_{D1} = w^2/4\mathrm{D}$ and $t_{D2} = b^2/4\mathrm{D}$, where D is the diffusion coefficient of solute molecules. As the ratio b/w 40, then $t_{D1}/t_{D2} > 1600$. Experimental values of retention time are usually equal to several t_{D1}, but are never as large as $1600t_{D1}$. Thus, the steady-state values of K_1 and K_2 corresponding to $t > t_{D2}$ are never reached during the experiment. (For the channel with $w = 200$ μm, $b = 1$ cm, and solute with $D = 10^{-6}$ cm^2/sec, $t_{D1} = 100$ sec and $t_{D2} = 2.5 \times 10^5$ sec.)

In Ref.[3] the non-stationary solution was produced for $K_1(\tau)$ and $K_2(\tau)$ where $\tau = t/t_{D1}$, leading to much better correspondence with experimental peak widths. Similar to Ref.[2] not the exact equation for the flow profile in the rectangular channel but its approximation was used:

$$V_x(y,z) = V_{\max}\left(1 - \frac{4y^2}{w^2}\right)\left(1 - \frac{\cos h\left(2\sqrt{3}z/w\right)}{\cos h\left(\sqrt{3}b/w\right)}\right) \quad (1)$$

Only the case of uniform initial distribution of solute in the channel cross section was studied in Ref.[3]

A more general case was studied in Refs.[4,5] where different initial solute distributions were examined, including the distributions describing the syringe inlet with and without the stop-flow relaxation. The 3D generalized dispersion theory was used to solve the 3D diffusion–convection equation. Unlike Refs.[2,3] the exact equation for flow profile in the rectangular channel was used:

$$V_x(y,z) = 4V_{\max}\sum_{n=0}^{\infty}(-1)^n\left(1 - \frac{\cosh(2\varphi_n z/w)}{\cosh(\varphi_n b/w)}\right) \times \frac{\cos(2\varphi_n y/w)}{\varphi_n^3} \quad (2)$$

where $\varphi_n = (2n + 1)\pi/2$, $|z| \le b/2$, and $|y| \le w/2$, transversal coordinates (the zero of coordinates being at the axis of FFF channel).

The exact equation for the flow profile was chosen because, although approximation (1) gives very similar results for $K_1(\tau)$, the deviation for $K_2(\tau)$ could be very significant. Fig. 1 presents dependences of $K_2(\tau)$ for different values of the FFF parameter λ, calculated with the help of 3D[4] and 2D[1] models. It can be seen that the difference between 2D and 3D results is growing with time τ and is larger for smaller values of λ. The growth of $K_2(\tau)$ with time leads to the non-linear growth of the peak variance with time:

$$\sigma^2(t) = 2Dt + \frac{V_{\max}^2 w^4}{8D^2} \int_0^{4Dt/w^2} K_2(\gamma) d\gamma \quad (3)$$

If K_2 is constant for the typical experimental values of retention time, as predicted by the 2D theory, then $\sigma^2 \sim t$ and resolution $R_s \sim \sqrt{t}$, where $R_s = \Delta X/4\sigma$ and ΔX is the distance between peak maximums for two types of solute molecule. According to the 3D model, $K_2(\tau)$ grows with time, so $\sigma^2 \sim \alpha t + \beta t^2 + \ldots$, and there exists some value of retention time for each λ, when resolution stops growing with time.

This effect is even more pronounced for the case of a syringe inlet. At the beginning of the process, the solute is distributed in the region close to $z = 0$, so it does not feel the influence of the side walls and, only after the period of time commensurate with the second diffusion time t_{D2}, the solute particles diffuse to the side walls. That is why, at the beginning of the process, the value of K_2 is close to the 2D value of K_2 and is growing toward its asymptotic 3D value slower than for the case of the solute initially distributed uniformly in the channel's cross section (presented in Fig. 1).

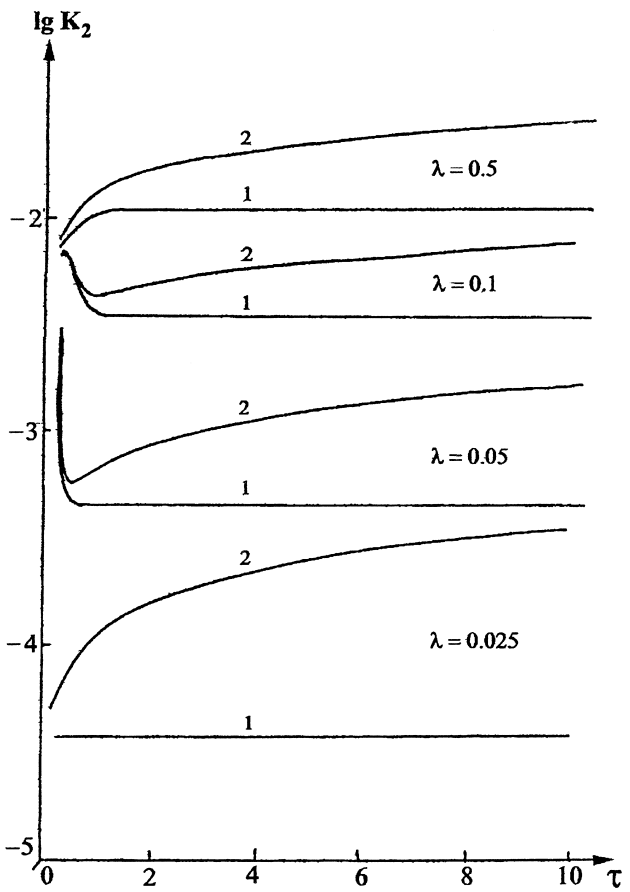

Fig. 1 Time dependences of the dispersion coefficient $K_2(\tau)$. Curve 1 : 2D model; curve 2 : 3D model. The solute was initially uniformly distributed in the channel cross section.

In Ref.[5] the time needed to separate two types of solute molecule with resolution $R_s = 1$ was studied for the cases of different initial solute distributions. It was shown, for example, that for solute molecules with $\lambda = 0.1$ and $\lambda = 0.125$, the time needed to separate them, predicted by the 3D model for uniform initial solute distribution, is 5% larger than predicted by the 2D theory, whereas, for the case of the syringe inlet, the value predicted by the 3D model is much closer to the 2D value (only 0.5% difference). The difference in 2D and 3D predictions can be more significant for closer values of λ, when the retention time needed to fractionate the solute is larger.

More complicated 3D effects were studied in Refs.[6,7] with the help of 3D Monte Carlo digital simulation performed with a rather powerful computer (RISK System/6000). Sedimentation FFF with different breadth-to-width channel ratios and both codirected and counterdirected rotation and flow were studied. Secondary flow forming vortexes in the y–z plane is generated in the sedimentation FFF channel, both due to its curvature, and the Coriolis force caused by the centrifuge rotation. The exact structure of the secondary flow was calculated by the numerical solution of the Navier–Stokes equations and was used in the Monte Carlo simulation of the movement of solute molecules.

It was shown that when rotation and flow are codirected, there is a considerable amount of molecules eluted prematurely before the main peak, because they are caught by the vortex of the secondary flow. This effect is practically negligible when the flow and rotation are counterdirected. So, the counterdirected mode is always preferable in sedimentation FFF. Note that this important practical finding of Ref.[7] is of pure 3D nature and cannot be done with the 2D theory.

The contribution of the channel endpieces to the peak broadening is certainly a 3D effect and should be mentioned here, although the theory used in Ref.[8] to analyze this effect was a 2D, not a 3D, one. In FFF instruments, the inlet and outlet tubes are connected with the rectangular FFF channel by triangular end-pieces. So, if the solute is introduced to the channel with the flow, then "the fanning out process between the inlet and the main rectangular section of the FFF channel leads to crescent-shaped bands, a type of distortion that persists down the channel and is responsible for some incremental band broadening".[8] The 2D (in the x–z plane) model was developed. The flow was considered to be ideal and described by the stream function, satisfying the Laplace equation. The streamlines calculated were used to simulate the solute band profile and to estimate the contribution of the endpieces effect to the theoretical plate height:

$$H_e = \frac{b^2 \beta^2 \tan^2(\theta/2)}{4L} \quad (4)$$

where L is the total FFF channel length, θ is the angle of the triangular endpiece, and β is a function of θ, determined from the calculated band profiles. It was shown that $\beta^2\tan^2(\theta/2)$ grows dramatically with θ, and is equal to 0.0226 for $\theta = 30^\circ$ and to 0.389 for $\theta = 120^\circ$. The role of the end effects must not be overestimated, as even for the channel with unusually large breadth $b = 6$ cm ($\theta = 75^\circ$), the absolute value of H_e was 0.0586 cm, much smaller than the typical FFF HETP values ($\sim$1 cm). Naturally, this type of contribution to peak width is absent if the solute is introduced by the syringe into the main rectangular section of the channel.

Finally, it must be said that in most of the practical cases, retention ratio and peak width are satisfactorily predicted by the 2D models. The role of the 3D models was to estimate the contributions of the 3D effects and to determine the optimal conditions when these contributions are negligible. As it was shown, to minimize the 3D effects, one must use FFF channels with a larger breadth-to-width ratio, use the syringe inlet, and/or use the longer endpieces with the sharper angle; in the case of sedimentation FFF, one is to avoid codirected flow and rotation mode.

TLC/MS

Jan K. Rozylo
Department of Adsorption Chromatography and Planar Chromatography, Marie Curie-Sklodowska University, Lublin, Poland

INTRODUCTION

There are many methods of detection of substances following separation of mixtures by thin-layer chromatography (TLC) or, in wider aspect, planar chromatography (PC). Some of the methods have been used continuously since the beginnings of TLC. These are described in other sections of this volume. The newest method in this field is mass spectrometry (MS) coupled with planar chromatography. The concept of using MS as a detection method for samples separated by TLC is not new; it dates almost to the beginning of organic MS itself. It was Kaiser who suggested the possibility of using a coupled TLC/MS method in his review 30 years ago. Despite a long and successful history of application as a detector in gas chromatography (GC) and liquid–liquid chromatography (LLC), MS has been under-utilized as a detector for TLC. The need for application of this combined analytical method (i.e., mass spectrometric detection with separation by TLC) was evident by the late 1980s. The success of the method depended, above all, on the elaboration of suitable experimental means, devices, and solutions to the challenge of transfer of substances from TLC plates to the mass spectrometer.

BASIC PRINCIPLE OF MS AND ITS APPLICATION TO TLC

In a mass spectrometer, instead of an optical spectrum we have a mass spectrum of matter radiation. The necessary condition for using MS detection is ionization of components of the analyzed sample. Thus, we can say that MS is a destructive method of analysis. There are many techniques and systems for MS, but they all have the same three elements: source of ions, ion analyzer, and ion detector (Fig. 1).

SOURCE OF IONS

Positive ions can appear by simple removal of one electron. This process can be demonstrated by means of the equation

$$M \rightarrow M^+ + e$$

The M^+ ion is called a *molecular ion*. It is characterized by means of mass (m) and charge (z). In order to produce a molecular ion, there must be supplied energy at least equal to the energetic potential of the molecule. The first ionization potential for most organic molecules is between 8 and 15 eV. The studied sample is transferred to a vessel under vacuum in which there is an anode and a cathode. The potential difference between the anode and cathode is over 20 kV. With such a large potential difference and small distance between anode and cathode, there appear electrical discharges which cause the ionization of sample molecules. The positive ions are pushed away by repellent electrodes and directed toward an *acceleration gap*. Of course, it is possible that the electron would be captured by the analyzed molecule and produce a negative ion, but the probability of such a process is small. However, fragmentation of a negatively charged molecule is much easier than fragmentation of a positively charged molecule. The higher the ionization energy used, the greater will be the probability of fragmentation of a molecule.

ANALYSIS OF IONS

Magnetic fields affect charged molecules if these molecules are in motion. The direction of this action is perpendicular to the direction of the field and perpendicular to the direction of movement of the investigated ion. The strength of the force acting on an ion in a magnetic field depends on the ion charge and its velocity. The effects of the action of this force depend on mass and velocity. Finally, the ions move along arcs of circles and the deviation from their original direction of movement depends on their m/z ratio.

The most popular mass spectrometers used in chromatography are sector magnetic spectrometers. They are large, expensive, and relatively slow spectrometers. Their primary advantage is their high resolution. A constant, strong electrical field within the acceleration gap speeds the ions up to their terminal velocities. The ion beam goes into the analyzer, *in vacuum* (10^{-7} – 10^{-8} Tr), and is placed in the magnetic field. In order to obtain a spectrum, either the magnetic field in which the analyzer is located or the accelerating voltage between the electrodes in the acceleration gap is changed. The ion beam leads into a collector, where the signal is amplified by means of an electron multiplier.

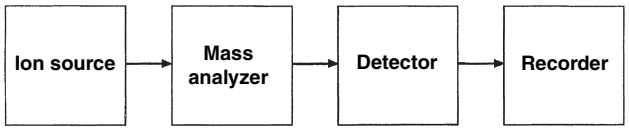

Fig. 1 Scheme of the mass spectrometry procedure.

QUADRUPOLE SPECTROMETER

The resolution of this spectrometer is not high, but the spectrometer is of relatively low cost and fast; it collects a full spectrum of the investigated substance in about 0.3 sec. In the spectrometer (also called *quadrupole filter*), there appears an electromagnetic field that causes the oscillation of ions. At given voltages, the oscillation amplitude of ions under a certain mass is larger than the distance between one of the pairs of electrodes; such ions are thrown out of the filter. Only the ions of a determined mass pass through the filter to the detector.

ION TRAP

In an ion trap, in contrast to other mass spectrometers, ionization and analysis occur in the same location but at different times. A chromatographic sample is introduced directly into the space between the electrodes where ionization takes place. An appropriate voltage across the electrodes causes the appearance of an electrical field within the trap. This field keeps the ions produced during ionization inside the trap and does not allow them to leave. When ionization is completed, the voltage of the electrodes is constantly changed so that the ions leave the trap in the order of increasing m/z ratio.

Soon after the advent of fast-atom bombardment (FAB) ionization, it was realized that there is an ionization technique ideally suited for analyzing compounds resolved on a TLC plate. There are several early examples of the direct analysis of spots from TLC plates (without prior extraction of the adsorbed material). Detection limits of these TLC-FAB-MS measurements depend on the sample, but they are typically in the 0.1–10-μg range.

The coupled TLC-FAB-MS, without the prior recovery of analyte from the TLC plate, provides a powerful tool for the unambiguous identification of sample components. The use of tandem MS/MS represents a further refinement of this approach, enabling identification to be performed even when the separated components are incompletely resolved from each other or are subject to background interference.

GENERAL APPROACHES TO SAMPLE PREPARATION FOR THE COUPLED TLC/MS

The following are combinations to these approaches:

1. The compound is eluted from the chromatographic plate, collected, and introduced into the MS as a discrete sample. In this method, samples collected from a TLC spot, identified with an independent method of visualization, must be sufficiently volatile to evaporate into the source of the MS.
2. The sample and support are not separated, but both are introduced simultaneously into the source of the MS. The spot is scraped from the support and placed on the direct insertion probe of the MS. As the probe is heated, the more volatile sample is evaporated into the source, whereas the fairly non-volatile chromatographic matrix remains in the probe.
3. The entire intact chromatogram is placed within the source of the mass spectrometer and analyzed.

For the last two methods, there is the assumption that extraneous material from the chromatogram does not unduly and adversely affect the quality of the mass spectrum recorded. The chromatogram is placed, intact, within a source housing and a spatially resolved map of organic or bio-organic compounds distributed across the surface is measured.

At the present time, the most up-to-date methods of ionization in TLC/MS are FAB and secondary ionization mass spectrometry (SIMS) in which organic molecules are sputtered from the surface by impact of a stream of high-energy molecules, and laser desorption (LD) in which sputtering of organic molecules from the surface of a support is due to the influence of high thermal energy produced by a laser beam onto a plate surface. The ions produced this way are usually even-electron $(M^+ + H)^+$ and appear by means of chemical ionization. The interpretation of the spectrum follows the same lines.

Bush designed an excellent instrument that can be used for analyses of TLC chromatograms by FAB-MS; it provides spatially discrete mass spectra directly from the surface layer.

SOME PRACTICAL PROBLEMS

The use of MS as a detector for TLC involves identification of substances in a mixture, as well their separation. A necessary condition in this approach is the purity of a sample within a spot on the chromatogram. A special problem is the large quantity of support and, sometimes, a binding material and mobile-phase residues. Some other factors that might potentially hinder TLC/MS are water, which is physically bound to the support, as well as, in some cases, the organic modifier of the support. A factor which complicates the detection process in TLC/MS may also be the presence of derivatives in a sample peak displayed on a chromatogram. That is why the analyzed sample should be as free of contamination with other additives as possible and the support matrix should be carefully removed before MS analysis. These indications refer, to a lesser degree, to other methods of detection that are performed after total extraction of sample molecules from a sample matrix. It is a widely known fact that most of the

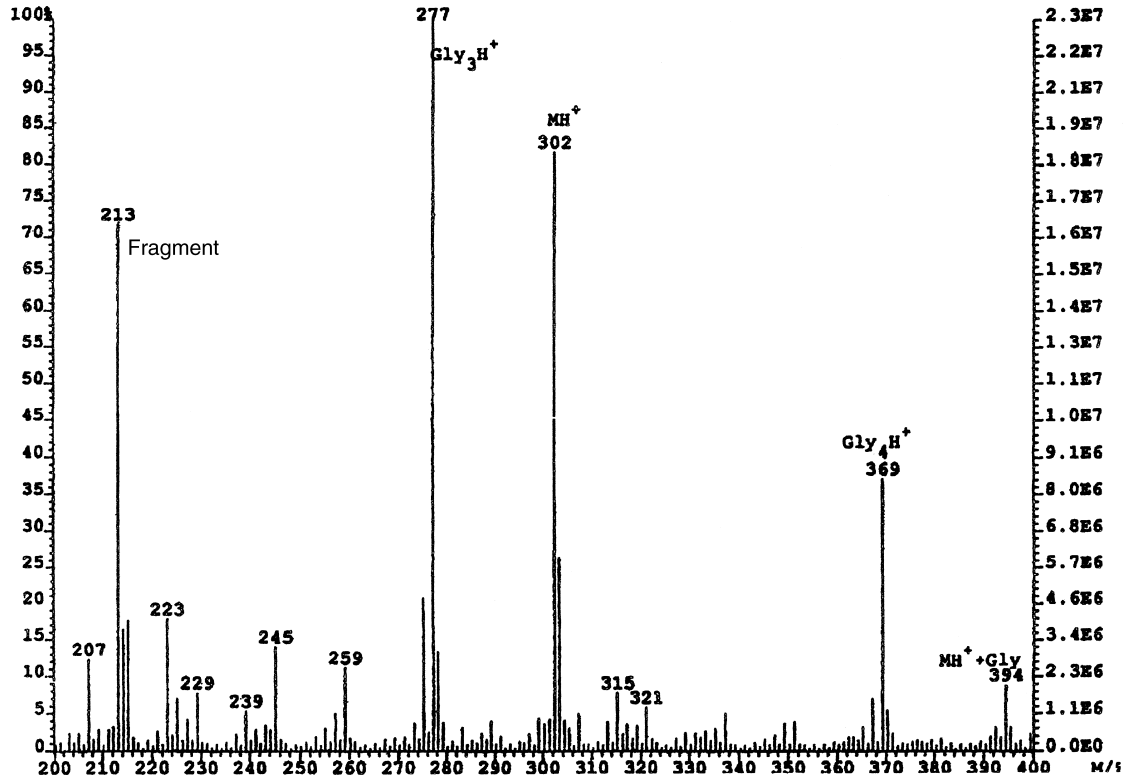

Fig. 2 TLC-FAB-MS spectrum obtained after of 1 μg deramciclane standard with an acidic mobile phase. Gly indicates glycerol clusters. **Source:** From J. Planar Chromatogr.-Mod. TLC **1997**, *10*, 90–96.

analyses using a TLC/MS method are performed after exhaustive extraction of the sample from the matrix.

There are also some practical problems connected with the instrumental issues of MS. Most of the sources used in mass spectrometers are so small that it is possible to also have, for example, a very small inlet for the gas or liquid. In this case, such TLC/MS methods may only be used if they are based on the introduction of samples via a stream of gas. The matrix, together with sample material, may be introduced directly into the MS source. Some types of instruments even allow for the insertion of a whole chromatographic plate into the MS source.

APPLICATIONS

Expansion in the field of analytical mass spectrometry has taken place in recent years; in particular, the applicability of TLC/MS in the field of chemical and biochemical science has been significantly broadened. This technique can now be used for the analysis of macromolecules such as peptides, proteins, oligosaccharides, and oligonucleotides, etc. (Fig. 2).

The combination of TLC and MS is well established and may be used for on- and off-line analyses. The increase in popularity of this combined technology also resulted from the improvements in the separating power of TLC and the widespread availability of suitable MS techniques for difficult-to-analyze molecules. The TLC/MS is, at present, a simple and readily implemented means of combining a separation with mass spectrometric identification of substances. With the development of MS suited to direct TLC analysis, it seems clear that the application of TLC/MS will grow in the next decade.

TLC: Sandwich Chambers

Simion Gocan
Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania

INTRODUCTION

In column chromatography, the stationary phase exists in a closed column that is adequately packed with a suitable sorbent. The stationary phase is preequilibrated with the mobile phase before the first sample is introduced. In this case, the stationary phase cannot be in contact with vapors of the mobile phase during the chromatographic process.

Column chromatography is different from thin-layer chromatography (TLC) because, in planar chromatography, and, therefore, in TLC, development generally starts with a dry stationary phase. Therefore, the mobile-phase front moves forward in the dry stationary phase. This process takes place in the limited, confined volume of the chromatographic chamber.

The kinetics of eluent migration will depend on the degree of saturation of the chamber. The eluent front runs faster in a saturated chamber than in an unsaturated one. The problem of the reproducibility R_f of values can be seriously affected by an unsaturated chamber.

The chromatographic chamber commonly used in TLC can be divided into two categories. A normal chamber (N chamber) is a chromatographic chamber of a large volume with a distance of gas phase in front of a thin-layer greater than about 3 mm. Conversely, a sandwich chamber (S chamber) is a small chromatographic chamber having a small volume and a distance of gas space in front of the thin layer plate less than 3 mm.

The equilibration of the sorbent thin layer with the vapor phase is easily achieved in the compact S chamber. A threefold larger variation of the R_f values for experiments in unsaturated atmosphere has been observed. Also, it has been proved that, in an unsaturated chamber, the so-called "edge effect" appears, owing to the more intense evaporation at the edge of the plate. This effect may be avoided by complete saturation of an N chamber with eluent vapor or by using an S chamber.

There are two methods for development, taking into account the position of the thin-layer plate (i.e., ascending, or vertical, and horizontal).

S CHAMBER

The S chamber (Fig. 1a) is limited to a small volume by using a thin-layer plate as a near wall (1) to the tank. The opposite wall is a cover plate (2) of small size. This is a frame plate, which has glass strips (5 mm wide and 3 mm thick) sintered along three edges. The two plates are held together by two clamps fixed at the vertical edges of the S chamber (3). This S chamber is placed in a trough which consists of a double jacket (4) of stainless steel filled with solvent (5). The other jacket can be turned to obtain slits at varying distances, which enables plates of different widths to be introduced and ensures a tight seal for the S chamber. The S chamber has a support (6) which permits a vertical position. Only 15 ml of mobile phase are needed for the thinlayer plate (20 × 20 cm). Before application, a 10 mm strip of adsorbent should be removed from three sides of the TLC plate.

There is another type of S chamber which permits prior saturation of the chamber atmosphere, simultaneously with the preconditioning of the adsorbent, before starting the chromatographic process (Fig. 1b). For this purpose, the adsorbent is removed (a 1 cm width) from all the sides of the plate (1). The opposite frame plate (2) contains, on all of its surface, a thin layer of sorbent. The two plates are fixed by two clamps (3). The chamber is introduced into the trough (4) through a slit. At the beginning, the level of the eluent (5) does not touch the bottom of adsorbent on the thinlayer plate (1). When saturation of the atmosphere is achieved, a volume of eluent is added to the eluent in the trough until the adsorbent is wetted. At this moment, the separation can be started.

Method of Operation

A template is indispensable for ensuring proper spacing of the starting spots during manual sample application. The sample is applied to the layer using a glass capillary or a micropipette of appropriate size (1–10 ml). Sample may be applied as bands to the TLC plates using a band applicator such as the Camag automatic TLC sampler. The automatic TLC sampler works by mechanically moving the plate. This applies the sample automatically by a controlled nitrogen spray from the syringe, forming narrow bands or spots on the plate surface. Programming, operation, and documentation are performed under a Windows-programmed environment.

When the samples have been applied, the frame plate is placed on the top of the TLC plate and fastened by two wide clamps at the right and left edges. In this way, the S chamber is ready to be placed into the trough filled with eluent. The S chamber is kept upright by a fork-shaped holding arm fixed to the trough. Then, the trough slit is sealed by gentle rotation of the outer jacket.

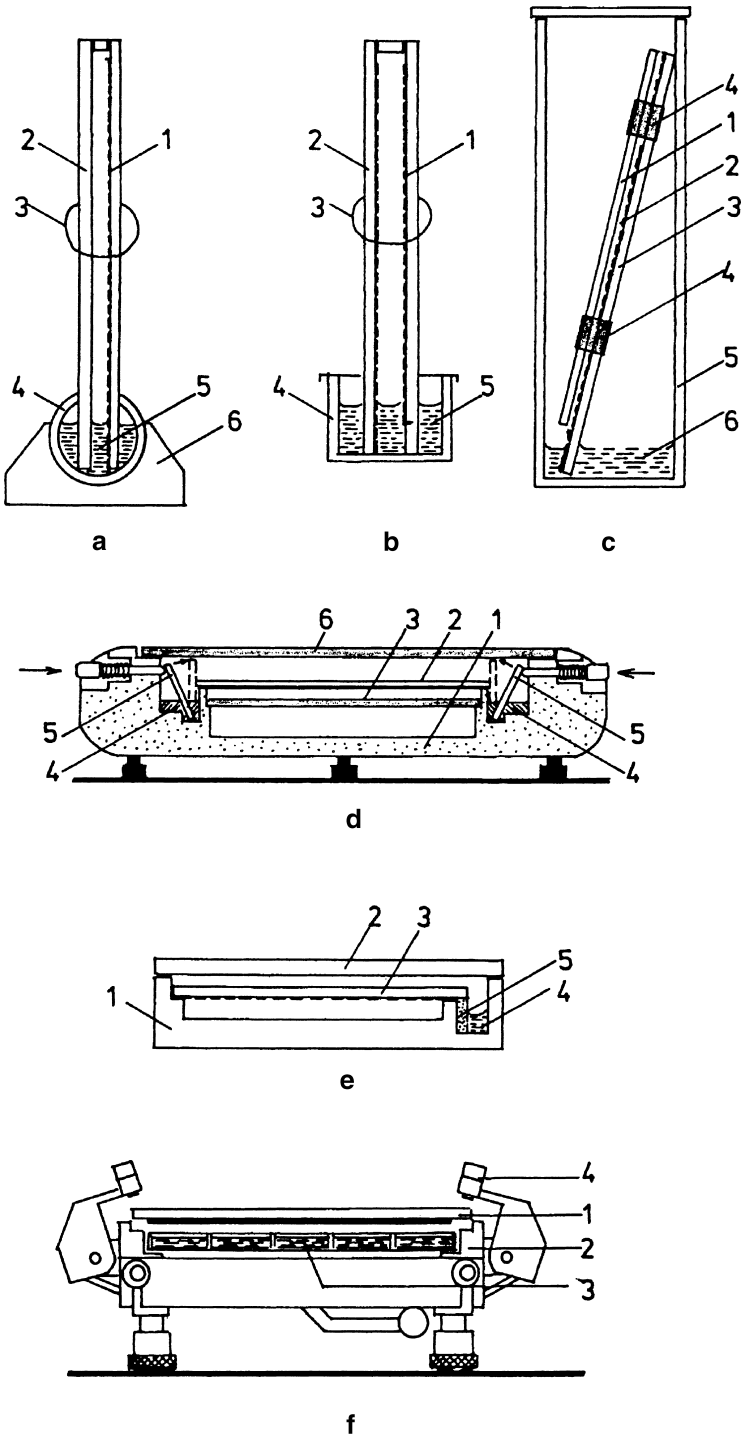

Fig. 1 Different TLC sandwich chambers: a, diagram of the S chamber; b, diagram of the saturation S chamber; c, diagram of the Camag sandwich cover plate; d, diagram of the Camag horizontal developing S chamber; e, diagram of the Desaga H-separation chamber; f, diagram of the Camag Vario-KS chamber.

The separation process can be considered finished when the eluent front touches the upper edge of the thin-layer plate.

CAMAG SANDWICH COVER PLATE

This type of S chamber has the purpose of reducing the volume of the gas phase, which is in front of the thin layer by a counterplate placed at a small distance (Fig. 1c). The cover glass (1) has two fixed glass spacers (2) located on two sides. The cover plate (1) is 2 cm shorter than the TLC plate (3) and is fixed so that it does not sit deeply into the eluent. The thin-layer plate and cover plate are held together by four stainless-steel clamps (4). The S chamber is not closed at the top edge. In this configuration, there is no need to scrape off the sorbent layer at the edges. With the Camag sandwich cover plate, the TLC plate can be developed into an N chamber (5) which contains, on the

flat bottom, the eluent (6). The N chamber is used only as eluent holder. This system permits simultaneous development of two plates.

HORIZONTAL S CHAMBER

The horizontal developing chamber is a sandwich-type chamber (Fig. 1d). The horizontal S chamber for TLC consists of a flat body of the chamber made from polytetrafluoroethylene (PTFE) (1) so that it is resistant to all liquids. The TLC or high-performance TLC (HPTLC) plate (2) lies on the supports with the thin layer facing downward. The glass plate (3) is used for development in the sandwich configuration (not presented with saturation configuration). A narrow trough (4) holds the eluent. Development is started by shifting the glass strips (5) to the chromatographic plate. In this way, a capillary slit is formed between glass strip and the trough wall, so that a vertical meniscus of the eluent is formed and rises instantaneously. It enters the layer evenly from its front. The glass strip (5) is tilted inward by pushing the rods (arrows). The chamber is kept covered with the glass plate (6) during both preequilibration and development.

Method of Operation

In the horizontal chamber, the HPTLC plate is developed from both opposing sides toward the middle. This permits the number of samples to be doubled, as compared with development in an N chamber. The horizontal S chamber is available for plate sizes 10 × 10 cm and 20 × 10 cm. The optimum separation distance for HPTLC silica gel, 45 mm, is still available.

The mobile phase is transported from the trough to the sorbent layer by surface tension and capillary forces and will continue to travel through the sorbent layer by capillary action. When a plate is developed from both edges simultaneously, the chamber must be kept in a perfectly horizontal position to allow the two solvent fronts the same rate of migration and to meet precisely in the middle. At this point, the capillary forces balance out and the chromatographic development ceases.

The chromatographic process takes less than 10 min per plate and the amount of solvent used is much smaller than in an N chamber. On a 20 × 20 cm HPTLC plate, it is possible to simultaneously develop, from both ends to the centers, up to 70 samples, or 35 samples in a single direction, from one end to the other.

The horizontal S chamber can be used in saturation configuration (N type) when the counter glass plate (3) is not inserted. In this way, the horizontal S chamber permits the conditioning of the adsorbent layer with the different solvent vapors by introducing several drops of the eluent or another solvent on the bottom of the chamber before placing the chromatographic plate face down.

H-SEPARATION CHAMBER

The H-separation chamber (DESAGA), a mini horizontal development chamber (Fig. 1e), is made of solvent resistant PTFE (1) covered with a sheet of glass (2) 4 mm thick. The HPTLC plate (5 × 5 cm) is laid down for development with the thin layer underneath (3). The mobile phase from the trough (4) is led by a glass frit rod (5) to the thin layer of sorbent. The groove in which the frit rod sits ensures even distribution. The maximum eluent consumption is 2 ml on the plates.

Method of Operation

The sample is applied to the starting line on the layer using a capillary of appropriate size. The applied spots have to be dried completely before the plate is introduced into the separation chamber. The effective migration distance on a plate of 5 × 5 cm is only 3 cm and the migration time is 3 min.

VARIO-KS CHAMBER

The Vario-KS chamber (Camag, Fig. 1f) is used for optimization of developing conditions for 10 × 10 cm plates by simultaneously testing of up to six different mobile phases and vapor equilibration conditions with N or S chamber conditions. Also, the Vario-KS chamber may be used for optimization of developing conditions for 20 × 20 cm TLC plates. The thin-layer plate (1) is laid down on the support (2). The eluent in the reservoir is connected to the thin layer of adsorbent by means of a filter paper strip. Under the thin-layer plate, there are many troughs (3) filled with solvents for preconditioning of the adsorbent layer. The chamber is tightly sealed by two clamps (4).

TLC: Theory and Mechanism

Teresa Kowalska
Institute of Chemistry, Silesian University, Katowice, Poland

Wojciech Prus
School of Technology and the Arts in Bielsko-Biała, Bielsko-Biała, Poland

INTRODUCTION

General classification of the modes of thin-layer chromatography (TLC) is based on the chemical nature of the stationary and mobile phases. Three types of TLC are widely recognized as different modes: adsorption TLC, normal-phase TLC, and reversed-phase (RP)/TLC.

ADSORPTION TLC

In this mode, active inorganic adsorbents (e.g., silica, alumina, or Florisil) are usually employed as stationary phases and, hence, the overall mechanism of retention is governed predominantly by the specific intermolecular interactions between the functionalities of the solutes, on the one hand, and active sites on the adsorbent surface, on the other. In adsorption TLC, aqueous mobile phases are never used, and stationary-phase activity prevails over the polarity of the mobile phase employed.

NORMAL-PHASE TLC

This mode of chromatography usually involves organic chemically bonded stationary phases with polar (e.g., 3-cyanopropyl) ligands. This particular mode is characterized by a mixed mechanism of solute retention: Solute molecules interact specifically with the polar functionalities of the organic ligand and with the residual active sites of the silica matrix, whereas their interactions with the hydrocarbon moiety of the organic ligands are entirely non-specific in nature. Again, aqueous mobile phases are never employed in normal-phase (NP) TLC, and stationary phase activity prevails over the polarity of the mobile phase employed.

RP TLC

This chromatographic mode usually involves aliphatic chemically bonded stationary phases with, for example, octyl, octadecyl, or phenyl ligands. The mode of chromatography also is characterized by a mixed mechanism of solute retention: Solute molecules interact specifically with the residual active sites of the silica matrix, whereas their interactions with the aliphatic ligands are non-specific (and predominantly hydrophobic) in nature. Reversed-phase (RP) TLC is usually performed with aqueous mobile phases containing organic modifiers [such as, e.g., methanol, acetonitrile (ACN), tetrahydrofuran (THF), etc.], and in this case, the activity of the stationary phase—as an exception—is less than that of the high-polarity mobile phase employed.

TLC PARAMETERS OF SOLUTE RETENTION

The parameter R_f is the quantity most commonly used to express the position of a solute in the developed chromatogram. It is calculated as a ratio:

$$R_f = \frac{\text{Distance of chromatographic spot center from origin}}{\text{Distance of solvent front from origin}} \quad (1)$$

Using symbols from Fig. 1, R_f can be given as

$$R_f = \frac{z}{l} \quad (2)$$

R_f values vary between 0 (solute remains at the origin) and 0.999 (solute migrates with the mobile-phase front). From a practical standpoint, the most reliable analytical results are achieved when the parameter R_f ranges from 0.20 to 0.80.

In the theory and practice of chromatography, another parameter of solute retention is also employed, the so-called R_M value. This quantity was defined by Bate-Smith and Westall[1] as

$$R_M = \log\left(\frac{1 - R_f}{R_f}\right) \quad (3)$$

SELECTED MODELS OF THE CHROMATOGRAPHIC PROCESS

The adsorption and partition mechanisms of solute retention are the two most universal mechanisms of

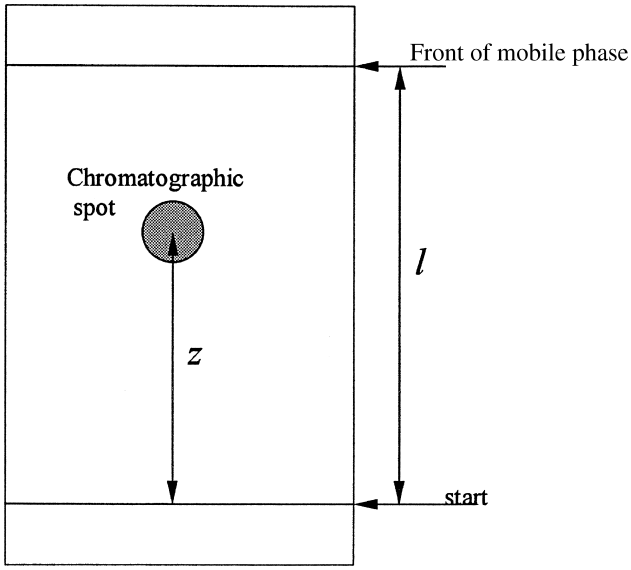

Fig. 1 The thin-layer parameters used to calculate the retention parameter R_f.

chromatographic separation, both operating on a physical principle. In fact, almost all solutes can be adsorbed on a microporous solid surface or be partitioned between two immiscible liquids. It is the main aim of semiempirical chromatographic models to couple the empirical parameters of retention with the established thermodynamic quantities generally used in physical chemistry. The validity of these models in chromatographic practice can hardly be overestimated, because when incorporated in separation selectivity-oriented optimization strategies, they often successfully help overcome the old trial-and-error approach used to optimize analyses. In the forthcoming sections, we will discuss a selection of the most popular and best-performing models and concepts of solute retention.

MARTIN AND SYNGE MODEL OF PARTITION CHROMATOGRAPHY

Partition chromatography was the first chromatographic technique to be given a thermodynamic foundation, by the pioneering work of Martin and Synge,[2] the 1952 Nobel Prize winners for chemistry. The Martin and Synge model describes the idealized parameter R_f (i.e., the parameter R_f') as

$$R_f' = \underset{\text{(I)}}{\frac{t_m}{t_m + t_s}} = \underset{\text{(II)}}{\frac{n_m}{n_m + n_s}} \underset{\text{(III)}}{\frac{m_m}{m_m + m_s}} \tag{4}$$

where t_m and t_s denote the time spent by a solute molecule in the mobile and stationary phases, respectively, n_m and n_s are numbers of solute molecules present in the mobile and stationary phases at equilibrium, and m_m and m_s are the respective numbers of moles.

Eq. 4 can be further transformed as follows:

$$R_f' = \frac{m_m}{m_m + m_s} = \frac{c_m V_m}{c_m V_m + c_s V_s} = \frac{1}{1 + c_s V_s / c_m V_m} \tag{5}$$

where c_m and c_s are the molar concentrations of the solute in the mobile and stationary phases, respectively, and V_m and V_s are volumes of these phases, respectively.

Assuming that

$$K = \frac{c_s}{c_m} \tag{6}$$

where K is the thermodynamic equilibrium constant for solute partitioning, we obtain

$$R_f = \frac{1}{1 + K\Phi} \tag{7}$$

where Φ is the so-called phase ratio (i.e., $\Phi = V_s/V_m$).

Eq. 7 unites the empirical retention parameter of the solute, R_f', with the established thermodynamic (i.e., theoretical) quantity K, expressed as

$$\ln K = \frac{\Delta {\mu_p}^0}{RT} \tag{8}$$

where $\Delta {\mu_p}^0$ is the standard chemical potential for partition. Hence, the retention model given by Eq. 8 can rightfully be called semiempirical.

SNYDER AND SOCZEWINSKI MODEL OF ADSORPTION CHROMATOGRAPHY

The semiempirical model of adsorption chromatography, analogous to that of Martin and Synge, was established only in the late 1960s by Snyder[3] and Soczewinski[4] independently, and it is often referred to as the displacement model of solute retention. The crucial assumption of this model is that the mechanism of retention consists in competition among the solute and solvent molecules for the active sites of the adsorbent and, hence, in a virtually endless process of the solvent molecules displacing those of the solute from the solid surface (and vice versa). Further, the authors assumed that some of the mobile phase remains adsorbed and stagnant on an adsorbent surface. This adsorbed mobile phase formally resembles the liquid stationary phase in partition chromatography. Thus—utilizing with imagination the main concept of the Martin and Synge model of partition chromatography—Snyder and Soczewinski

managed to define the R_f' parameter valid for adsorption chromatography as

$$R_f = \frac{t_m}{t_m + t_a} \equiv \frac{n_m}{n_m + n_a} = \frac{m_m}{m_m + m_a} = \frac{c_m(V_m - V_a W_a)}{c_m(V_m - V_a W_a) + c_a V_a W_a} \quad (9)$$

where t_m and t_a denote the time spent by a solute molecule in the mobile phase and on the adsorbent surface, respectively, n_m and n_a are numbers of solute molecules contained in the mobile phase and on the adsorbent surface at equilibrium, respectively, m_m and m_a are the numbers of moles of solute molecules contained in the non-adsorbed and adsorbed moieties of the mobile phase, respectively, c_m and c_a are molar concentrations of solute in the non-adsorbed and the adsorbed moieties of mobile phase, respectively, V_m is the total volume of mobile phase, V_a is the volume of the adsorbed mobile phase per unit mass of adsorbent, and W_a is the mass of adsorbent considered.

Transformation of Eq. 9 results in the relationship

$$R_f = \frac{1}{1 + K_{\text{th}}[V_a W_a/(V_m - V_a W_a)]} \quad (10)$$

where $K_{\text{th}} = c_a/c_m$, K_{th} being the thermodynamic equilibrium constant of adsorption, and $\Phi = V_a W_a/(V_m - V_a W_a)$.

SIMPLIFIED RELATIONSHIPS DERIVED FROM THE SNYDER AND SOCZEWINSKI MODEL

Two very simple relationships have been derived from the general framework of the Snyder and Soczewinski model of adsorption chromatography; these have proved useful for rapid prediction of solute retention in chromatographic systems employing binary mobile phases. One (known as the Soczewinski equation) proved successful for adsorption and normal-phase TLC; the other (known as the Snyder equation) proved similarly successful in RP TLC.

Soczewinski Equation

The Soczewinski equation[5] (Eq. 11) is a simple linear relationship with respect to $\log X_s$, linking the retention parameter (i.e., R_M) of a given solute with the quantitative composition of the binary mobile phase used:

$$R_M = C - n \log X_s \quad (11)$$

where C is, in the first instance, the equation constant (although with clear physicochemical significance), X_s is the molar fraction of the stronger solvent in the non-aqueous mobile phase, and n is the number of active sites on the surface of the adsorbent.

Apart from enabling rapid prediction of solute retention, the Soczewinski equation enables molecularlevel scrutiny of solute–stationary phase interactions. Thus, a numeric value of the parameter n of Eq. 11 of approximately unity ($n \approx 1$) implies one-point attachment of the solute molecule to the stationary-phase surface. Numerical values of n higher than unity indicate that in a given chromatographic system, solute molecules interact with the stationary phase at more than one point (so-called multipoint attachment).

Snyder Equation

The Snyder equation[6] (Eq. 12) is another simple linear relationship with respect to φ, which links the retention parameter (i.e., $\ln k$) of a given solute with the volume fraction of the organic modifier in the aqueous binary mobile phase (φ):

$$\ln k = \ln k_w - S_\varphi \quad (12)$$

where k is the retention coefficient of the solute [$k = (1 - R_f)/R_f$], k_w is the retention coefficient extrapolated for pure water as the mobile phase, and S is a constant characteristic of a given stationary phase.

CHROMATOGRAPHIC ACTIVITY OF ADSORBENTS AND ELUTION STRENGTH OF SOLVENTS[7–9]

Consequences of the Snyder and Soczewinski model are manifold, and they are of significant practical importance. The most spectacular conclusions of this model are: (a) the possibility of quantifying the activity of an adsorbent, and (b) the possibility of defining and quantifying the "chromatographic polarity" of solvents (known as their elution strength). These two conclusions could be drawn only upon the assumption of the displacement mechanism of solute retention. An obvious necessity in this model was to quantify the effect of displacement, which resulted in the relationship given by Eq. 13 for the thermodynamic equilibrium constant of adsorption, K_{th}, for an active chromatographic adsorbent and a monocomponent mobile phase:

$$\log K_{\text{th}} = \log V_a + \alpha(S^0 - A_{S^0}) \quad (13)$$

where α is a function of the adsorbent surface energy and is independent of the properties of the solute (it is known as the activity coefficient of the adsorbent; practical determination of its numerical values can be regarded as quantification of adsorbent activity), S^0 is the adsorption energy of a solute chromatographed on an active adsorbent with n-pentane as the monocomponent mobile phase, A_s is the surface area of the adsorbent occupied by an adsorbed

solute molecule, and ε^0 is the parameter usually referred to as the solvent elution strength, or simply solvent strength (it is the energy of adsorption of solvent per unit surface area of adsorbent).

Assuming that the adsorbent surface occupied by an adsorbed solute molecule (A_S) and that occupied by a stronger solvent (n_B) are equal, the eluent strength of a binary mobile phase, ε_{AB} has the following dependence on its quantitative composition:

$$\varepsilon_{AB} = \varepsilon_A + \frac{\log(x_B \times 10^{\alpha n_B(\varepsilon_B - \varepsilon_A)} + 1 - x_B)}{\alpha n_B} \quad (14)$$

where ε_A is the eluent strength of the weaker component (A) of a given binarymobile phase, ε_B is the eluent strength of the stronger component (B) of the same mobile phase, and x_B is the molar volume of the component B.

Combining Eqs. 13 and 14 gives the following relationship, which expresses the dependence of the retention parameter of a solute, R_M (= log k), on the quantitative composition of a given binary mobile phase:

$$\log k = \log V_a + \alpha[S^0 - A_{S^\varepsilon A}] - \frac{A_S \log(x_B \times 10^{\alpha n_B(\varepsilon_B - \varepsilon_A)} + 1 - x_B)}{n_B} \quad (15)$$

SCHOENMAKERS MODEL OF RP CHROMATOGRAPHY

In this particular model, it is assumed that Hildebrand's concept of the solubility parameter (δ), originally formulated for liquid non-ideal solutions, can also be applied to the solute and to the stationary and mobile phases of chromatographic systems.

The solubility parameter of any given substance (δ) is defined as

$$\delta = \sqrt{\frac{-E}{V}} \quad (16)$$

where E denotes its heat of vaporization at zero pressure, $-E$ is the energy of cohesion needed for transportation of one mole of an ideal gas phase to liquid phase, and V is the molar volume of the liquid.

One of the basic retention parameters (i.e., the solute's retention coefficient k) can be expressed as a function of the solubility parameters, δ:

$$\ln k_i = \frac{v_i}{RT}(\delta_m + \delta_s - 2\delta_i)(\delta_m - \delta_s) + \ln\left(\frac{n_s}{n_m}\right) \quad (17)$$

where v_i is the molar volume of the ith solute, δ_i, δ_s, and δ_m are respectively the solubility parameters of this solute and of the stationary and mobile phases employed, and n_s and n_m are respectively the numbers of moles of the stationary and mobile phases.

Finally, the principal equation of the Schoenmakers model[10] of solute retention in RP chromatography employing a binary aqueous mobile phase takes the parabolic form

$$\ln k = A\varphi^2 + B\varphi + C \quad (18)$$

where the equation constants A, B, and C have a clear physicochemical significance:

$$A = \frac{v_i}{RT}(\delta_a - \delta_w)^2 \quad (19)$$

$$B = 2\frac{v_i}{RT}(\delta_a - \delta_w)(\delta_a - \delta_i) \quad (20)$$

$$C = \frac{v_i}{RT}(\delta_w + \delta_s - 2\delta_i)(\delta_w - \delta_s) + \ln\left(\frac{n_s}{n_m}\right) \quad (21)$$

where δ_w and δ_a denote respectively the solubility parameters of water and of the organic modifier as the constituents of a given aqueous mobile phase.

TLC: Validation of Analyses

Gunawan Indrayanto

Suciati
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

Abstract
For obtaining reliable analysis results, the (high-performance) thin-layer chromatographic (TLC) method should be validated before using it as a quality control tool. The validation parameters that should be evaluated are stability of the analyte, specificity/selectivity, linearity, accuracy, precision, range, detection limit, quantification limit, and robustness/ruggedness.

INTRODUCTION

According to USP 30–NF 25,[1] validation of an analytical method is the process by which it is established, by laboratories studies, that the performance characteristics of the method meet the requirements for the intended analytical applications. Therefore, validation is an important step in determining the reliability and reproducibility of the method because it could confirm that the method is suitable to be conducted on a particular system. The performance parameters that should be determined in validation studies include specificity/selectivity, linearity, accuracy, precision, detection limit (DL), quantitation limit (QL), range, ruggedness, and robustness.[1,2] The parameters that are required to be validated depend on the type of the analyses; thus, different test methods require different validation schemes. The most common types of analyses are identification, quantitative determination of impurities, limit value determination of impurities, and quantitative determination of active ingredients.[3] Besides the general validation parameters mentioned above, the software and hardware of the thin-layer chromatographic (TLC) scanner should be validated first.[3,4] The validation of the instrument is categorized into design qualification (DQ), installation qualification (IQ), operation qualification (OQ), and performance qualification (PQ).[3]

STABILITY TESTING

A very important prevalidation method requirement is to test the stability of standards and samples. The analyte should be stable during sample preparations (at least 30 min) on the sorbent surface before development (at least 30 min) and during development (at least 1 hr).[5] The acceptance criteria are within 2%. The age mobile phase should also give the same value of R_f, T (tailing factor), and N (theoretical plate). The stability of the analyte should also be tested in biological matrices during storage. Reconstituted samples must remain stable in the solvents at the working temperature until spotted.[6] For fingerprint of herbal drugs, Reich, Schibli, and DeBatt[7] recommended to test the stability of analytes in solution and on the plate over 3 hr. Stability during chromatography should be tested using 2-dimensional development. If visualization requires a derivatization step, the stability must also be evaluated. Reich, Schibli, and DeBatt[7] suggested taking one image immediately after 5, 10, 20, 30 min, and 1 hr of derivatization, then the images are compared visually and by using video densitometry.

SPECIFICITY/SELECTIVITY

The terms specificity and selectivity are often used interchangeably. A method is said to be specific if it provides a response for only a single analyte. If the response in question is distinguished from all other responses, the method is said to be selective.[8] The International Conference on Harmonization (ICH)-2 does not differentiate both terms and defines specificity or selectivity as "the ability to unambiguously determine the analyte in the presence of other components whose presence is to be expected." This includes typical impurities, decomposition products, and matrix components.[3] The specificity of the method for TLC or high-performance TLC (HPTLC) analyses was proved by identification and purity checks of the analyte spots. This can be done by measuring in situ the ultraviolet and visible spectroscopy (UV–Vis) spectra of the analyte(s) and the authentic reference standard(s), those eluted on the same plate, and then by calculating their correlations (the r value should be ≥ 0.999). This correlation should be calculated on the upslope, the apex, and the downslope of the peaks. In a quality control laboratory, the selectivity

can be proven easily by spotting the standard, blank sample, possible impurities, or degradation products in the proposed system, analyte spot must not be interfered by other spots, which can be proven by calculating the resolution. If sources for impurities and degradation products are not available, the samples should be exposed to stress condition such as heat, UV light, acid, and base.[6] Other parameters should ideally be in the following range: R_f ($0.1 \leq R_f \leq 0.9$); tailing factor, T ($0.9 \leq T \leq 1.1$); resolution, R_s (≥ 1.0).[9] For proving the selectivity for analysis of botanical drugs, the availability of botanical reference material (BRM) is essential. It would be very nice if at least three authenticated BRM of each species from different origins can be used. This can be used to illustrate natural variability. A method is specific if during validation a sample representing target species showed identical fingerprint to that of BRM and samples representing other species give different fingerprints.[7]

LINEARITY

The linearity of a method is its ability to provide measurement results that are directly proportional to the concentration of the analyte or are directly proportional after mathematical transformation. The linearity is usually documented as the linear regression curve of the measured responses as a function of increasing analyte concentrations.[3] To perform linearity testing, it is recommended to use 5–10 concentrations with range equivalent to 80–120%,[9] 25–200%,[10] or 50–150%[11] of the expected content of the analyte. For the determination of degradant and preservative in the stability study, ranges of 0–40% and 50–110%, respectively, were recommended.[2] For dissolution testing ±20% over the specified concentration is tested, while for content uniformity a minimum of 70–130% of concentration is tested.[1] It is also essential that the basic calibration be performed by using independent samples and not by using samples that have been prepared by dilution and spotted on one TLC or HPTLC plate. For the evaluation of basic calibration line, several parameters can be used, for example, correlation coefficient (r), the relative process standard deviation value (V_{xo}), the Mandel's test, the X_p value,[12] the plot of response factor vs. concentration, the residual test, the analysis of variance (ANOVA), and so on. The lowest concentration used for the calibration curve must not be less than the value of X_p.[12] Camag (Muttents) calculated by using its CATS software the value of *sdv* [relative standard deviation (RSD) of the calibration curve] for expressing the linearity. If the reader is working with CATS software, the smallest value of *sdv* should be selected to determine the most suitable regression model that will be used for calibration. It is recommended that the correlation coefficient (r) alone not be used anymore. The correlation coefficient does not indicate the linearity or the lack thereof.[13] Readers should refer to previous works for further discussion.[12,14] The variance homogeneity over the whole range of the basic calibration line should also be proved using the F test.[9,12] If working range (WR) is defined as the ratio of the highest and lowest concentration of standards of the calibration or linear curve, it is recommended that a WR of not more than 10 be used; if WR is more than 10, a weighting regression should be used.[15] For quantitative analysis using TLC or HPTLC, the calibration curve must be performed on each plate; each plate should contain standards and unknown samples.

ACCURACY

Accuracy or trueness of an analytical method is given by the extent to which the value obtained deviates from the true value.[3] In the first approach, accuracy can be determined by analyzing a sample with known concentration and then by comparing the results between the measured and the true value. The second approach is by comparing the test results obtained from the new method to the results from the existing method that is known to be accurate. The third and fourth approaches are based on the percent recovery of known analyte spiked into blank matrices or products. The last technique is known as the standard addition method.[11] For spiking analyte into blank matrices, it is recommended to prepare the sample (laboratory-made preparation) in five different concentrations at the level of 80–120% of the target concentration. Experiences from our laboratory have shown that by using at least five levels of concentrations in duplicate (i.e., 80%, 90%, 100%, 110%, and 120% of target concentration), an accurate result can be achieved. On the contrary, for the standard addition method, the spiking concentrations are 30–60% of the label-claimed value. For dissolution studies, the accuracy should be tested at 40%, 75%, and 110% of the theoretical release.[6] To prove whether systematic errors do not occur, a linear regression of recovery curve of X_f (concentration of the analyte measured by the propose method) against X_c (nominal concentration of the analyte) should be constructed, and the confidence range of the intercept {VB(a_f)} and slope {VB(b_f)} from the recovery curves should be calculated for $p = 0.05$.[12]

PRECISION

The realistic standard deviations in TLC or HPTLC analyses are ~0.2% on multiple scanning of one spot, 0.8–1.5% on multiple spotting and analysis of the same sample solution, and 1.5–2.0% on multiple analysis of the same sample.[9] As a general rule, the standard deviation of a method should be lower than 1/6 of the specification range,[16] or the RSD value should not be more than 2%.[10] For validation purposes, precision is determined

by multiple application of the complete analytical procedure on one homogenous real sample. According to ICH, both repeatability and intermediate precision should be tested.[6] Repeatability is defined as precision under the same conditions, that is, same analyst, equipment, reagents, time, and TLC plate. Intermediate precision was performed by repeatability testing on the different combinations of analyst, equipment, reagents, and time within one laboratory. It is recommended to do 6–10 measurements on each repeatability studies.[9,10] A detailed discussion on the maximum of standard deviation for assay determination was published.[16] Other parameters that should be tested in the precision study are the David, Dixon or Grubbs, and Neumann test. Detailed discussion has been provided by Kromidas.[17] Reich, Schibli, and DeBatt[7] reported a detailed method to evaluate precision for qualitative analysis, in this case for HPTLC fingerprint of herbal drugs. They recommended to use at least three portions of the BRM and spotted onto three different plates. The fingerprint must be identical; the variability of R_f values of three markers should not exceed 0.01 across each plate, 0.02 for repeatability, 0.05 for intermediate, and 0.07 for reproducibility.

RANGE

The range of measurement is the interval for which linearity, accuracy, and precision have been tested. Analysis outside the range is not permitted.[1,3] For quality control purposes in a pharmaceutical industry, it is recommended to use a range from 80% to 120% of the target concentration, and for dissolution ±20% from upper and lower limit, respectively. For pharmacokinetic study, a wide range should be tested, the maximum value should exceed the highest expected concentration, and the minimum value is the QL.

DETECTION LIMIT AND QUANTITATION LIMIT

DL is defined as the lowest concentration of an analyte that can be detected under the analytical condition to be used. However, it cannot be quantitatively measured. QL is the lowest concentration that can be determined with acceptable accuracy and precision under the analytical conditions.[3] Generally, QL can be estimated as three times of DL.[2,14] DL and QL for instrumental (chromatographic) analytical methods can be defined in terms of the signal-to-noise ratio (2:1 to 3:1 for DL and 10:1 for QL[9] or in terms of the ratio of the standard deviation of blank response, the residual standard deviation of the calibration line, or the standard deviation of intercept (σ) and slope (S) (DL = $3.3\sigma/S$ and QL = $10\sigma/S$).[16] By constructing a linear regression of relatively low concentrations of analyte, accurate values of DL can be calculated, in this case, DL = X_p.[12] The authors recommend using 5–10 relatively low concentrations of analyte spotted on a TLC plate. DL can be increased by using pre- or postchromatographic derivatization.[3] For clinical application, QL should be at least 10% of the minimum effective concentration, and it should be within the linear WR.[6] For ensuring the safety of agricultural products, herbal medicines, and foods from the contamination of certain heavy metals, antibiotics, pesticides, and drugs by chemical analysis, DL of the method must be determined. DL should be less than the maximum permitted level of the toxic substances.

ROBUSTNESS/RUGGEDNESS

Robustness can be defined as a measure of the capability of the method to remain unaffected by small, but deliberate, variations in method parameters. It provides an indication of its reliability during normal usage.[1,18] Ruggedness of a method is the degree of reproducibility of test results obtained by the analysis of same samples under a variety of conditions such as different laboratories, analysts, and instruments; different lot of reagents; different days.[1] Some important parameters for the testing of TLC or HPTLC methods are the following: the stability of analyte in the solution being analyzed and on the plate before and after development; the influence of temperature and humidity; the method of application, scanning, and evaluation; the spot shape and size, eluent composition, and pH; the batch and sources of TLC plate; the sample volume; different chamber type; and the drying conditions of the plate.[3,18] In our laboratory, the design and analysis of effect of the robustness data were performed and calculated by using a multivariate statistical software. As an example, we studied the effect of small variation in the composition of mobile phase on R_f, T, and recovery of the active ingredient.[19] A detailed guidance for robustness/ruggedness testing has been published.[16] For robustness evaluation of botanical drugs, the R_f values of all markers should lie within the acceptance criteria of the intermediate precision.[7]

REPORTING RESULTS OF ANALYSIS

For reporting routine analytical results, it is recommended that its confidence interval[12] or uncertainty[17] or standard certainty[20] be included in the results of analysis; so the result is reported as:

$$\text{Mean} \pm \frac{t.\text{SD}}{\sqrt{N}}$$

where N is the number of replicates, SD is the standard deviation, and t is the value from the t table; if N is more than 10, the equation can be simplified as:[17]

$$\text{Mean} \pm 2 \times \text{SD} \ (\text{for } p = 0.05)$$

$$\text{Mean} \pm 3 \times \text{SD} \ (\text{for } p = 0.01)$$

Kaiser[20] suggested four replicates for analyzing samples, and in this case standard certainty can be estimated as three times the standard deviation.

CONCLUDING REMARKS

Important performance characteristics for TLC or HPTLC validation procedures have been described in brief in this entry to provide guidance to the analytical chemists. For obtaining reliable and reproducible analysis results, it is essential to validate the TLC or HPTLC method first, before using it for routine works in a quality control laboratory.

Topological Indices: TLC

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

Abstract
This entry covers the use of structural descriptors, namely, topological indices based on the adjacency, distance matrix, and information theory, as well as the electrotopological states to predict the R_F and R_M values, and the lipophilicity properties, of a variety groups of organic compounds investigated by thin-layer chromatography (TLC). This entry indicates that further investigations on the application of the topological indices in TLC are justifiable.

INTRODUCTION

Numerous activities and properties of organic compounds depend on the presence of specific atoms and/or functional groups in their structure. These features can be used for deriving QSAR (quantitative structure–activity relationship), QSPR (quantitative structure–property relationship), and QSRR (quantitative structure–retention relationship) models. Last, numerous valuable QSAR, QSPR, and QSRR models have been derived from topological indices and related descriptors, among other things the electrotopological states.[1] The range and fields of application of the topological indices are limited. The topological indices can be applied as a descriptor only when the correlated property is primarily dependent on the structure of a molecule. The compounds investigated were homologous series or mixtures of compounds from the different classes of organic compounds. The topological indices have been applied in chromatographic investigations, usually in gas chromatography (GC) and high-performance liquid chromatography (HPLC) techniques. The short distance traveled by a solute on a chromatographic plate is the reason for limited application of topological indices in thin-layer chromatography (TLC). The application of topological indices is an important field of theoretical chromatography. The topological indices open a new field of investigation in chromatographic science. Many scientists have reported the application of topological indices for prediction of the retention data for different groups of organic compounds. The extent of this application has been unexpectedly large in recent years and includes the application of the topological indices in TLC also.

In our previous entry we have summarized the applications of topological indices that were described in manuscripts published up to 2000.[2] Data presented in scientific literature up to 2000 indicate that the topological indices and electrotopological states can be used to predict and describe several properties and other phenomena: chromatographic separation, the partition coefficient in *n*-octanol–water system, and chromatographic lipophilicity, dipole moment, dissociation constant, biological activity, and water solubility for the different classes of organic compounds investigated.[2]

The objectives of this entry are the presentation and discussion of the significance of topological indices in TLC investigations that were described in the manuscripts from 2001. Scientific literature from 2001 described the applications of the structural descriptors, including the topological indices, to predict and describe: 1) the relative position of separated compounds on a chromatogram; 2) the retention parameters of the separated compounds on a thin layer; 3) the chromatographic lipophilicity and partition coefficients of investigated compounds; and 4) water solubility.

APPLICATION OF THE TOPOLOGICAL INDICES AND THE ELECTROTOPOLOGICAL STATES TO PREDICT THE RELATIVE SITUATION OF SEPARATED COMPOUNDS ON A CHROMATOGRAM

Pyka et al.[3] separated the selected essential oil components (menthol, (+)borneol, geraniol, linalool, carvone, camphor, (1R)-(−)fenchone) by adsorption thin-layer chromatography using benzene as the mobile phase. Investigated terpenes were characterized by selected topological indices based on connectivity: Randić ($^0\chi$, $^1\chi$, $^2\chi$, $^0\chi^\nu$, $^1\chi^\nu$, $^2\chi^\nu$, $^4\chi_c$, $^4\chi_c^\nu$), Gutman [(M, M^ν)], on distance matrix: Wiener (W), Rouvray (R), and Pyka (A, ^0B, ^1B) indices, and the S_i index. From among all the topological indices counted only the $S_{i(O)}$ index (the sum of the distance between the oxygen atom and all the remaining atoms in graph) and cluster Randić indices ($^4\chi_c$ and $^4\chi_c^\nu$) allow for estimation of the chromatograms obtained. The topological indices $S_{i(O)}$ are directly whereas the cluster

Randic indices $^4\chi_c$ and $^4\chi_c^v$ are inversely proportional to the R_M values of the terpenes investigated (Table 1). From the experimental data presented, it is apparent that the compounds can be ranked in accordance with increasing adsorption on silica gel in the order:

(+)borneol < menthol;
linalool < geraniol; and
(1*R*)-(−) fenchone < camphor < (*R*)(−)carvone

The S_i index is equal to the sum of a row in the distance matrix. This index measures the connection of atom i to the rest of the molecule. Low values of the S_i index indicate strongly connected positions (atom i strongly connected with the rest of the molecule), whereas high values of S_i are characteristic of weakly connected positions (atom i weakly connected with the rest of the molecule). The hydroxyl group determines the adsorption properties of terpenes investigated. For example, the $S_{i(O)}$ index for oxygen atom is greater for menthol than for (+)borneol. Similarly, the $S_{i(O)}$ for geraniol is greater than for linalool. Adsorption of menthol and geraniol is therefore greater than of (+)borneol and linalool, respectively. For the remaining terpenes investigated, the $S_{i(O)}$ index increases in the order: (1*R*)-(−)fenchone < camphor < (*R*)(−) carvone. The adsorption of these three terpenes increases in the same order. With the fact mentioned above, there exists the possibility of prediction of relative situation on the chromatogram of the terpenes investigated. For the rest of topological indices that possibility was not stated.[3]

Pyka and Bober[4] separated α- and γ-terpinene as well as α- and β-pinene on silica gel and on silica gel impregnated with various percentages of silver nitrate. It was stated that argentation thin-layer chromatography is an efficient technique for separation of isomeric α- and γ-terpinene as well as α- and β-pinene. The topological indices based on connectivity ($^0\chi$, $^1\chi$, $^2\chi$, M, χ_{012}), on distance matrix (W, I_B, A, ^0B, ^1B, ^2B, ^2B_q, C, D), S_i indices, and the electrotopological states for each atom in a molecule of the terpines investigated were calculated. The γ-terpinene has higher R_F values from α-terpinene in all chromatographic separations obtained. Likewise, α-pinene has higher R_F values as compared to β-pinene. The qualitative correlations between R_F values and topological indices $^2\chi$, D, and χ_{012} values of the investigated terpenes were stated. It was also stated that S_i index cannot explain the separation terpenes investigated in argentation thin-layer chromatography. The E-state values calculated for atoms of terpenes investigated are presented in Fig. 1. The E-state index is a structural descriptor for an atom within a covalently bonding molecule. The E-state index is formulated to encode information about the electronegativity, pi and lone-pair electron content, the topological status and the environment of an atom within a molecule. In argentation TLC the interactions between Ag^+ ions and double bonds of substances separated determine separation. For that the reason the electrotopological states of carbon atoms forming double bonds were analyzed. It was stated that the sum of electrotopological states of all carbon atoms forming double bonds is lower for γ-terpinene than for α-terpinene (Fig. 1). This sum is also lower for α-pinene than for β-pinene (Fig. 1). For that reason, γ-terpinene should form weak complexes with Ag^+ ions (higher R_F values) in relation to α-terpinene (lower R_F values). The α-pinene also should form weak complexes with Ag^+ ions (higher R_F values) in relation to β-pinene (lower R_F values). The above observations help in formulating the definite rules concerning relationships between chromatographic separation sequences and topological indices of the investigated terpenes. These rules with qualitative importance can be applied for estimation sequence during the preparative separation of isomers, which can be the subject of further physical, chemical, physicochemical, and pharmaceutical investigations.[4]

chromatography (RP-HPTLC). The selected topological indices based on connectivity (M, $^1\chi^\nu$), on distance matrix (W, ^0B, MTI), and on information theory (I_{AC}, $\overline{I}_{AC}$) were calculated for these tocopherols. As positional isomers, β- and γ-tocopherols possess the same numerical values of topological indices M, $^1\chi^\nu$, I_{AC}, and $\overline{I}_{AC}$. Only the numerical values of the topological indices ^0B and R_M values become smaller (decrease) in the following order: α-, β-, γ-, and δ-tocopherol.[5]

APPLICATION OF TOPOLOGICAL INDICES AND ELECTROTOPOLOGICAL STATES TO PREDICT THE RETENTION PARAMETERS OF SEPARATED COMPOUNDS ON THIN LAYER

The use of the structural descriptors to predict the retention parameters of the organic compounds, including drugs, is defined as QSRR.

Pyka and Dolowy[6] and Dolowy[7] applied some structural descriptors (M^ν, $^0\chi^\nu$, $^1\chi^\nu$, $^2\chi^\nu$, χ_{012}, W, A, ^0B, ^1B, C, $SdO_{(kw)}$, $SsOH_{(kw)}$, $SsOH_{(alif)}$ $SdO_{(amid)}$, and SsNH) to predict chromatographic separations of selected bile acids such as cholic acid (C), glycocholic acid (GC), glycodeoxycholic acid (GDC), chenodeoxycholic (CDC), deoxycholic acid (DC), lithocholic acid (LC), and glycolithocholic acid (GLC) on unmodified and modified silica gel plates and by using the mixture of *n*-hexane–ethyl acetate–acetic acid in various volume compositions as mobile phases. It was found that among all descriptors only the values of topological index C change inversely proportional to the R_F values and directly proportional to the R_M values of examined bile acids. Thus, only the topological index C was used for determining the correlation equations that allowed the calculation of R_F and R_M values of studied bile acids. The topological index C allowed obtaining linear equations with R_M values or quadratic equations with R_F values. Generally, they have found that the correlation equations that describe the relationships $R_F = f(C)$ have higher values of correlation coefficients than the relationship $R_M = f(C)$. The regression equations between R_F and R_M values and the topological index C for studied bile acids separated on unmodified silica gel (#1.05715, E. Merck) using the above-mentioned mobile phase in volume composition 22+22+5 are:

$$R_F = 164.577(\pm 32.978) - 11.007(\pm 2.289) \times C + 0.184(\pm 0.040) \times C^2 \quad n = 7 ; \quad (1)$$
$$R^2 = 98.47\%; \; F = 227.6; \; s = 0.058; \; p < 0.0003$$

$$R_M = -33.818(\pm 2.446) + 1.190(\pm 0.085) \times C$$
$$n = 7; \; R^2 = 97.49\%; \; F = 194.1;$$
$$s = 0.193; \; p < 0.004 \quad (2)$$

Selected *meta*- and *para*-alkoxyphenols have been separated by RP-HPTLC on cellulose impregnated with ethyl oleate, with ethanol–water, 25 + 75 and 40 + 60 (%, v/v), as mobile phases.[8] The R_M values of the alkoxyphenols have been correlated with the

structural descriptors based on the adjacency matrix ($^2\chi^\nu$, $^3\chi^\nu$, χ_{012}), on the distance matrix (W, A, ^0B, ^1B, D, C, ^2B, ^2B_q, ^3B, ^3B_q, I_B), and on electrotopological states (SssO, $ScCH_3$, SaaCH, SaasC, SsOH). Most accurate prediction of the R_M values of all the alkoxyphenols has been achieved by use of second- or third-degree polynomial correlation equations with structural descriptors from among the topological indices W, A, ^0B, ^1B, ^2B, ^2B_q, D, $^3\chi^\nu$, and I_B. The obtained regression equations can be used to calculate the R_M values of the alkoxyphenols studied. After recalculation these equations can also be used to predict the R_M values of the alkoxyphenols for which data were omitted when calculating the equations. For example, R_M data for *p*-butoxyphenol and *m*-pentoxyphenol separated using the mobile phase ethanol–water, 40 + 60 (%, v/v), were omitted and new correlation was obtained for separations:

$$\begin{aligned} R_{M(40+60)} &= 10.503(\pm 0.382) \times {}^0B - 4.670(\pm 0.168) \\ n &= 12;\ R_2 = 98.72\%;\ s = 0.080; \\ F &= 768;\ p < 0.001 \end{aligned} \quad (3)$$

The $R_{M(40+60)}$ values of *p*-butoxyphenol and *m*-pentoxyphenol were predicted by use of Eq. 3 and they are equal to 0.061 and 0.269, respectively, whereas the experimental $R_{M(40+60)}$ values for *p*-butoxyphenol and *m*-pentoxyphenol are equal to 0.035 and 0.269, respectively.

However, topological indices $^2\chi^\nu$, χ_{012}, C, SssCH, SassC, and SsOH can be used to calculate the R_M values of alkoxyphenols, but separately for the two homologous series, i.e., separately for *meta*-alkoxyphenols and *para*-alkoxyphenols.[8]

The R_M values of homologous series of higher alcohols and of methyl esters of higher fatty acids separated by RP-HPTLC can be calculated by use of monoparametric equations containing index based on the adjacency.[9] However, the R_M values of homologous series of fatty acids from pentanoic to tricosanoic separated by RP-HPTLC can be predicted on the basis of linear or quadratic equations using topological indices based on the distance matrix, the adjacency matrix, information theory, and electrotopological states.[10]

Luhua et al.[11] separated by normal-phase thin-layer chromatography (NP-TLC) (−)-ephedrine and (+)-pseudoephedrine. The topological indices based on connectivity and distance matrix A, W, and $^h\chi^\nu$ were calculated. The structures in particular of (−)-ephedrine and (+)-pseudoephedrine were described by topological indices $^h\chi^\nu$ that were applied to interpret the chromatographic separations.

Beteringe et al.[12] synthesized and separated by TLC the *Z* and *E* diasteroisomers of the *O*-methyloximes of testosterone and 17α-methyltestosterone. These compounds were characterized by the Pyka index I_{STI}, the Pogliani index $X_{cp}(p)$, the Schultz indices S and PRS, and the geometrical index J_{geom}. It was stated that R_F values were best correlated with the Schultz index S:

$$\begin{aligned} R_F &= 0.3554 \times S + 1.5309 \times 10^{-5} \\ n &= 6;\ r = 0.9895;\ s = 0.0277;\ F = 189.2 \end{aligned} \quad (4)$$

Pyka[13] separated phenol and its methyl derivatives by RP-HPTLC on RP-2 plates with three mobile phases: $R_{M(1)}$, 0.1 *M* CH_3COOH and 0.1 *M* CH_3COONa in 30% methanol (at pH = 5.00); $R_{M(2)}$, 0.1 *M* KH_2PO_4 in 30% methanol (at pH = 7.00); $R_{M(3)}$, 1 *M* ammonia in 30% methanol (at pH = 11.30)). It was affirmed that SaasC and SaaCH describe well the R_M values. For example:

$$\begin{aligned} R_{M(1)} &= 1.738(\pm 0.044) - 0.177(\pm 0.008) \times \text{SaaCH} \\ n &= 7;\ r = -0.995;\ s = 0.030,\ p < 0.0001 \end{aligned} \quad (5)$$

$$\begin{aligned} R_{M(2)} &= 1.650(\pm 0.027) - 0.168(\pm 0.005) \times \text{SaaCH} \\ n &= 7;\ r = -0.998;\ s = 0.019,\ p < 0.0001 \end{aligned} \quad (6)$$

$$\begin{aligned} R_{M(3)} &= 1.717(\pm 0.150) - 0.251(\pm 0.026) \times \text{SaaCH} \\ n &= 7;\ r = -0.974;\ s = 0.102,\ p < 0.0001 \end{aligned} \quad (7)$$

The steroids corticosterone acetate, 11-dehydrocortisone acetate, corticosterone, 11-dehydrocorticosterone, hydrocortisone, and cortisone have been separated by RP-HPTLC. The chromatographic data (R_M) and partition coefficient (log*P*) values of the compounds have been correlated with the numerical values of topological indices. The most accurate predictions of the R_M and log*P* values of the selected steroids were achieved by the use of monoparametric equations employing the topological index ^0B.[14]

Pyka and Sliwiok[15] separated six esters of nicotinic acids—methyl nicotinate, ethyl nicotinate, isopropyl nicotinate, butyl nicotinate, hexyl nicotinate, and benzyl nicotinate—by adsorption TLC on silica gel and a mixture of silica gel and kieselguhr. The mixtures containing *n*-hexane and acetone in the volume proportions (2 + 8, 3 + 7, 4 + 6, 5 + 5, 6:4, 7 + 3, 8 + 2) were used as the mobile phases. The R_M values of esters investigated have been correlated with the dipole moments (μ_{mph}) of the mobile phases applied, with numerical values of one topological index from among those based on the distance matrix (A, W, ^0B, ^1B, ^2B) or on the adjacency matrix ($^0\chi^\nu$, $^1\chi^\nu$, $^2\chi^\nu$), with electrotopological states: SaaCH, aaN, aasC, do, ssO, and dssC, and structural descriptors based on information theory (I_{SA} and $\overline{I}_{SA}$). Dipole moments were used to characterize mobile phases. All the equations obtained, which enable calculation of R_M on silica gel ($R_{M(1)}$) and on mixture of silica gel and kieselguhr ($R_{M(2)}$), had determination coefficients $R^2 > 92\%$. The best equations, which had determination coefficients $R^2 > 96\%$, were obtained with indices based on the

distance matrix Pyka (^0B, ^1B), with electrotopological state dssC and with index based on information theory I_{SA}, $\overline{I}_{SA}$ (only for $R_{M(1)}$ values obtained on silica gel). For example, the best equations of relationships between R_M values ($R_{M(1)}$ from silica gel and $R_{M(2)}$ from mixture of silica gel and kieselguhr) and structural descriptors of esters and dipole moments of mobile phases are given below:

$$\begin{aligned} R_{M(1)} &= -0.108(\pm 0.288) - 1.097(\pm 0.030) \times \mu_{mph} \\ &\quad + 0.806(\pm 0.121) \times {}^0B \\ n &= 42;\ R^2 = 97.20\%;\ F = 676.9; \\ s &= 0.076;\ p < 0.0001 \end{aligned} \tag{8}$$

$$\begin{aligned} R_{M(2)} &= -0.081(\pm 0.163) - 1.081(\pm 0.032) \times \mu_{mph} \\ &\quad - 4.108(0.484) \times \text{dssC} \\ n &= 36;\ R^2 = 97.35\%;\ F = 605.2; \\ s &= 0.081;\ p < 0.0001 \end{aligned} \tag{9}$$

The correlation Eqs. 8 and 9 can be used to calculate $R_{M(1)}$ and $R_{M(2)}$ values of investigated esters on silica gel and on mixture of silica gel and kieselguhr, respectively. For example, the relationship between R_M values measured experimentally on silica gel and values calculated by use of Eq. 8 is presented in Fig. 2.

Eqs. 8 and 9 can also be used to predict the R_M values of the esters of nicotinic acid, the measurement points of which have not been taken into consideration in the equation. A test was performed on Eqs. 8 and 9 to determine how well they predict R_M values of points not included in the training set. Two values were removed from the training sets (Eqs. 8 and 9). Butyl nicotinate separated in *n*-hexane:acetone, 6 + 4, v/v, and ethyl nicotinate separated in *n*-hexane:acetone, 3 + 7, v/v, were removed from Eq. 8. Hexyl nicotinate separated in *n*-hexane:acetone, 4 + 6, v/v, and butyl nicotinate separated in *n*-hexane:acetone, 6 + 4, v/v, were removed from Eq. 9. These subsets of two-parametric equations were recalculated as:

$$\begin{aligned} R_{M(1)} &= -0.110(\pm 0.300) - 1.097(\pm 0.032) \times \mu_{mph} \\ &\quad + 0.807(\pm 0.125) \times {}^0B \\ n &= 40;\ R^2 = 97.15\%;\ F = 630.0; \\ s &= 0.078;\ p < 0.0001 \end{aligned} \tag{10}$$

$$\begin{aligned} R_{M(2)} &= -0.078(\pm 0.174) - 1.081(\pm 0.034) \times \mu_{mph} \\ &\quad - 4.097(\pm 0.525) \times \text{dssC} \\ n &= 34;\ R^2 = 97.10\%;\ F = 518.8; \\ s &= 0.084;\ p < 0.0001 \end{aligned} \tag{11}$$

The $R_{M(1)}$ and $R_{M(2)}$ values for esters of nicotinic acids, omitted during the derivation of Eqs. 10 and 11 and subsequently predicted by use of these equations, are listed in Table 2.

Similarly, the dipole moments (or permittivity) of mobile phases and the topological indices have also been used to predict the R_M values of α-, β-, γ-, and δ-tocopherols separated on RP18 HPTLC plates using methanol, ethanol, *n*-propanol, and mixtures containing ethanol and water and *n*-propanol and water in the volume proportions 9.5 + 0.5 and 9 + 1 as mobile phases. The best regression equations were obtained using one topological index from among the topological indices $^2\chi^\nu$, ^0B, or C.[16]

Thirteen barbiturates have been separated by RP-HPTLC with 13 mobile phases (methanol–water in different volume compositions). The R_M values of barbiturates investigated have been correlated with the selected traditional structural descriptors, with the partition coefficients of the compounds, and with the dipole moments (μ_{mph}) or with the permittivities (ε_{mph}) of the mobile phases applied. The most accurate prediction of the R_M values of the

barbiturates in all the mobile phases investigated were achieved by use of two-parametric equations employing the dipole moments (or the permittivities) of the mobile phases, one topological index from among the topological indices ${}^0\chi$, ${}^1\chi$, ${}^0\chi^\nu$, ${}^1\chi^\nu$, R, W, A, ${}^1B$, and three-parametric equations employing the dipole moments (or the permittivities) of the mobile phases, and two topological indices (I_B and ${}^1\chi$ as well as I_B and ${}^1\chi^\nu$), or one electrotopological descriptor (SdssC or SssssC) or Gutman index (M or M^ν), and selected partition coefficient.[17]

Niestroj, Pyka, and Sliwiok[18] separated higher fatty acids, hydroxy fatty acids, and their esters by RP-HPTLC using methanol and methanol–water (9.5 + 5 and 9 + 1) as mobile phases. The R_M values of the compounds have been correlated with the numerical values of the topological indices, with electrotopological states of the atoms attached to the carboxyl group of investigated compounds, with the number of hydrogen bond donors (#HD), with the molecular weights (M_w), and the dipole moments (μ_{mph}) of the mobile phases. The most accurate prediction of the R_M values of the acids and esters, for all the mobile phases investigated, was achieved by use of four-parametric equations relating the dipole moments of the mobile phases and three other parameters. For example:

$$\begin{aligned} R_M = & -52.5342(\pm 3.3486) + 31.9676(\pm 1.9528) \times \mu_{mph} \\ & - 4.1128(\pm 1.6669) \times {}^1B \\ & - 0.006111(\pm 0.000851) \times M^v \\ & - 0.2108(\pm 0.0250) \times \#HD \\ n = & \ 36;\ R^2 = 94.26\%;\ s = 0.086; \\ F = & \ 127.26;\ p < 0.0001 \end{aligned} \quad (12)$$

Pyka and Bober[19] separated methyl laureate, methyl myristate, methyl palmitate, methyl isostearate, methyl stearate, and methyl arachidate by RP-HPTLC on kieselguhr F_{254} with different amounts of paraffin oil (10% and 15%), using two different mobile phases (methanol + water and ethanol + water in volume composition 9 + 1, v/v). The R_M values of these compounds for all the stationary phases and mobile phases investigated could be correlated with the dipole moments of the mobile phases (μ_{mph}), with the percentage impregnation of the stationary phases (imp%), and with numerical values of one topological index from among those based on the distance matrix (W, A, ${}^0B$, ${}^1B$) or on the adjacency matrix (${}^1\chi$, ${}^1\chi^\nu$). For example:

$$\begin{aligned} R_M = & -12.7715(\pm 1.2059) + 6.8712(\pm 0.7082) \times \mu_{mph} \\ & + 4.0967(\pm 0.6232) \times \text{imp}\% \\ & + 0.00235(\pm 0.00008) \times A \\ n = & \ 24;\ R^2 = 97.91\%;\ s = 0.076; \\ F = & \ 312.6;\ p < 0.0001 \end{aligned} \quad (13)$$

The R_M values of *cis*- and *trans*-9-octadecenoic and 11-octadecenoic acids in all the applied stationary phases and mobile phases could also be correlated with dipole moments (or permittivities) of mobile phases, with the impregnation percentages of stationary phases, and with numerical values of one topological index (W, A, ${}^0B$, ${}^1B$, ${}^2B$, I_B) or electrotopological state of oxygen atoms.[20]

APPLICATION OF THE TOPOLOGICAL INDICES AND THE ELECTROTOPOLOGICAL STATES TO PREDICT CHROMATOGRAPHIC LIPOPHILICITY AND THE PARTITION COEFFICIENTS OF INVESTIGATED COMPOUNDS

The lipophilicity of any substance, including drugs, is a property that affects its biological activity. *n*-Octanol–water partition coefficients, usually expressed as log*P* values, which

can be computed or determined experimentally, are used as a measure of lipophilicity. Log*P* can be determined experimentally by the classical method of the measuring partition of an organic compound between a non-polar phase and water. Measurement of partition coefficients is not as easy as might be expected from their simple definition. Measurement by use of equilibration methods is frequently made difficult, or even impossible, by impurities in or the instabilities of a compound, by strong preference of a compound for one of the two phases of the system, or by the formation of stable emulsions after shaking. Practical problems arise for polar and highly lipophilic compounds (log $P > 4$). For this reason the suitability of experimental and theoretical approaches for determination of the lipophilicity of organic compounds, including drugs, remains a focus of scientific interest. Different partition chromatographic techniques and theoretical methods have been widely used as reliable alternatives to classical determination of log*P*.

The use of the structural descriptors to predict lipophilicity of the organic compounds, including drugs, is defined as quantitative structure–activity relationships (QSAR). Lipophilicity parameters obtained using RP-HPTLC for many groups of organic compounds were correlated with the different structural descriptors.[6,16,21–27]

Pyka et al.[6,21] determined the chromatographic lipophilicities of seven bile acids by RP-HPTLC on different sorbent using organic modifier–water in different volume compositions as mobile phases. It was found that lipophilicity determined chromatographically (R_{M0} and ϕ_0), theoretical values ($A\log P_s$, $IA\log P$, $C\log P$, $\log P_{Kowwin}$, $x\log P$, and $\log P_{Rekker}$), and experimental *n*-octanol–water values determined by the classical method ($\log P_{exp}$) correlated the best with topological indices M^{ν} and *C*.

Pyka and Niestrój[16] and Kepczynska, Bojarski, and Pyka[22] correlated the R_{M0} values obtained on RP18 TLC plates using methanol–water in different volume compositions as mobile phases and the theoretical partition coefficients ($IA\log P$, $C\log P$, $\log P_{Kowwin}$, $\log P_{Rek}$) of 13 barbituric acid derivatives with the different structural descriptors. It was stated that linear dependences exist between R_{M0} values, partition coefficients, and some topological indices. The R_{M0} values were best correlated with topological indices based on an adjacency matrix ${}^0\chi$, ${}^1\chi$, χ_{012}, ${}^0\chi^{\nu}$, ${}^1\chi^{\nu}$, and χ^{ν}_{012}, as well as distance matrix *R*, *W*, *A*, ${}^1B$, and *D* ($r \geq 0.96$). For example:

$$R_{M0} = -3.941(\pm 0.305) + 0.608(\pm 0.031) \times {}^0\chi^{v}$$
$$n = 13;\ r = 0.9862;\ s = 0.131;$$
$$F = 391;\ p < 0.0001 \quad (14)$$

It was also affirmed that ${}^0\chi$, ${}^1\chi$, ${}^0\chi^{\nu}$, and ${}^1\chi^{\nu}$ indices are the best for calculation of the particular partition coefficients ($r > 0.95$). For example:

$$IA\log P = -5.370(\pm 0.659) + 0.652(\pm 0.059) \times {}^0\chi$$
$$n = 13;\ r = 0.9582;$$
$$F = 123.2;\ s = 0.251;\ p < 0.0001 \quad (15)$$

$$C\log P = -6.154(\pm 0.570) + 0.730(\pm 0.051) \times {}^0\chi$$
$$n = 13;\ r = 0.9744;\ F = 206.3;$$
$$s = 0.217;\ p < 0.0001 \quad (16)$$

$$\log P_{Kowwin} = -4.394(\pm 0.409) + 0.878(\pm 0.055) \times \chi_{012}$$
$$n = 13;\ r = 0.9788;\ F = 251.0;$$
$$s = 0.177;\ p < 0.0001 \quad (17)$$

$$\log P_{Rek} = -6.167(\pm 0.461) + 0.755(\pm 0.041) \times {}^0\chi$$
$$n = 13;\ r = 0.9841;\ F = 337.4;$$
$$s = 0.176;\ p < 0.0001 \quad (18)$$

The satisfactory correlations between partition coefficients and some topological indices based on distance matrix: *R*, *W*, *A*, ${}^1B$, and *D* ($r > 0.93$) were also obtained.[16,22]

The selected pesticides monolinuron, chlortoluron, diuron, isoproturon, linuron, dimefuron, diflubenzuron, teflubenzuron, and lufenuron were separated by RP-HPTLC on $RP18WF_{254}$ plates, using methanol and water as the mobile phases, in which proportional content of methanol was from 35% to 85%. The topological indices based on connectivity—*Gutman* (M, M^{ν}) and *Randić* (${}^0\chi$, ${}^1\chi$, ${}^2\chi$, ${}^0\chi^{\nu}$, ${}^1\chi^{\nu}$, ${}^2\chi^{\nu}$)—were calculated for the investigated compounds. Obtained parameters of lipophilicity R_{M0} and ϕ_0 were correlated with topological indices. Only Gutman index M^{ν}, from among all topological indices, was useful in QSAR analysis of studied urea pesticides:[23]

$$R_{M0} = 0.6957(\pm 0.2187) + 0.004639(\pm 0.000498) \times M^{v}$$
$$n = 9;\ r = 0.9619;\ s = 0.308;$$
$$F = 86.57;\ p < 0.0001 \quad (19)$$

Nicotinic acid, esters of nicotinic acid (methyl nicotinate, ethyl nicotinate, isopropyl nicotinate, butyl nicotinate, hexyl nicotinate, benzyl nicotinate), nicotinamide, and *N*-methylnicotinamide were separated on RP18 and $RP18WF_{254}$ plates using methanol–water in different volume proportions as the mobile phases. Satisfactory linear regression equations were obtained between chromatographic lipophilicity R_{M0} or partition coefficients ($\log P_{exp}$, $A\log P_s$, $IA\log P$, $C\log P$, $\log P_{Kowwin}$, $x\log P$) and some topological indices (${}^0\chi^{\nu}$, ${}^1\chi^{\nu}$, ${}^2\chi^{\nu}$, A, ${}^1B$, ${}^2B$, I_{SA}, and $\overline{I}_{SA}$), and between lipophilicity ϕ_0 and electrotopological states SaaN and SdO.[24,25] However, for the above-mentioned compounds and *N*,*N*-diethylnicotinamide,

3-pyridinecarboaldehyde, 3-pyridinecarbonitrile, 3-pyridylmethanol, and methyl 3-pyridyl ketone, the chromatographic lipophilicity parameters (R_{M0} and ϕ_0) and the theoretical *n*-octanol–water partition coefficients correlated the best with the topological index *A*.[26]

The topological indices were also used to predict lipophilic properties of the examined steroids: androsterone, epi-androsterone, dehydro-epi-androsterone, testosterone, stigmasterol, β-sitosterol, estradiol, hydrocortisone, and cholesterol. The lipophilicity parameters R_{M0} and φ_0 were obtained by using RP-HPTLC on RP18W plates, with the use of methanol–water as a mobile phase. It was stated that the regression equations with the greatest correlation coefficients were found with the following structural descriptors: for lipophilicity parameter R_{M0}, with indices based on the distance matrix *R*, *W*, and *A*; and for lipophilicity parameter φ_o and theoretical *n*-octanol–water partition coefficient *x*log*P*, with index based on information theory $\overline{I}_{SA}$.[27]

Niestroj[28] proposed new methods for the calculation of partition coefficient (log*P*) for α-, β-, γ-, and δ-tocopherols separated by RP-HPTLC on RP18 HPTLC plates using ethanol and mixture of ethanol and water in the volume proportion 9.5 + 0.5 as mobile phases. The selected topological indices ($^0\chi^\nu$, $^1\chi^\nu$, $^2\chi^\nu$, and ^0B) and the theoretical partition coefficient (*A*logP_s, *IA*log*P*, *mi*log*P*, KOWWIN, *x*log*P*, and logP_{Rekker}) were calculated for studied tocopherols. It was stated that the numerical values of topological indices $^2\chi^\nu$ and ^0B as well as the R_F values of tocopherols investigated decreased in the order α-tocopherol > β-tocopherol > γ-tocopherol > δ-tocopherol. However, the values of the theoretical partition coefficients for the tocopherols investigated decreased in the order α-tocopherol > β-tocopherol = γ-tocopherol > δ-tocopherol. New methods for log*P* calculation were based on the following equations:

$$\log P_1 = \frac{^0B \log P_{Rek}}{2(R_{F1} + R_{F2})} \tag{20}$$

$$\log P_2 = \frac{\log P_{Rek}}{(R_{F1} + R_{F2})} \tag{21}$$

$$\log P_3 = \frac{10 \log P_{Rek}}{^1\chi^\nu (R_{F1} + R_{F2})} \tag{22}$$

$$\log P_4 = \frac{10 \log P_{Rek}}{^2\chi^\nu (R_{F1} + R_{F2})} \tag{23}$$

$$\log P_5 = \frac{4(^0B)}{(R_{F1} + R_{F2})} \tag{24}$$

$$\log P_6 = \frac{2(^2\chi^\nu)}{^0B(R_{F1} + R_{F2})} \tag{25}$$

$$\log P_7 = \frac{^0\chi^\nu}{2(R_{F1} + R_{F2})} \tag{26}$$

Next, $\log \overline{P}$ was calculated as average value from all theoretical partition coefficients (logP_1, logP_2, logP_3, logP_4, logP_5, logP_6, and logP_7). The log $\overline{P}$ values were equal to 11.87, 10.18, 9.35, and 8.02 for α-, β-, γ-, and δ-tocopherols, respectively. It was stated that the applied above-mentioned topological indices ($^0\chi^\nu$, $^1\chi^\nu$, $^2\chi^\nu$, and ^0B) with the R_F values enable calculation of the partition coefficient, which depends on the relative retention of the tocopherols.[28]

Podgorna[29] proposed the new lipophilic parameter (*W*) for porphyrin and alkyloxy porphyrin derivatives separated by RP-HPTLC on RP18 plates using CH_2Cl_2:MeOH 6 + 4 (v/v) as the mobile phase. The lipophilic parameter *W* was calculated on the basis of the R_F values and the topological index *A* using Eq. 27:

$$W = A \cdot \frac{R_{F1} + R_{F2}}{R_{F1} \cdot 1000} \tag{27}$$

where, $R_{F1} > R_{F2}$ and *A* is the topological index of Pyka.

The R_F values, numerical values of topological index *A*, the theoretical *n*-octanol-water partition cofficients *A*logP_s, *IA*log*P*, *C*log*P*, KOWWIN, *x*log*P*, logP_{Rekker}, and new lipophilicity parameter *W* are presented in Table 3. The calculated lipophilicity parameter *W* correlates rather well with log*P* according to Rekker.

APPLICATION OF THE TOPOLOGICAL INDICES AND THE ELECTROTOPOLOGICAL STATES TO PREDICT THE WATER SOLUBILITY OF INVESTIGATED COMPOUNDS

Niestroj[30] separated long-chain acids and hydroxyl fatty acids and its esters by RP-HPTLC using three mobile phases, and she proposed a new method for the calculation of water solubility from experimental R_M values and other physiochemical data. It was stated that the most accurate prediction of log*W* values of studied compounds was achieved by using four-parameter equations relating the R_M values of the compounds, the numerical values of the Pyka topological index ^0B, the electrotopological states of oxygen atoms of the carbonyl groups or of oxygen atoms of the hydroxyl groups, and the dipole moments (μ_{mph}) of the applied mobile phases.

Table 3 R_F values and topological index A values, the log$P$ values calculated by the computer programs, and by the Rekker equation, appointed experimentally and the lipophilicity parameter W of investigated porphyrins.

Compound	R_F stationary phase:RP18 mobile phase: CH_2Cl_2:MeOH 6 + 4(v/v)	Topological index A	$A\log P_s$	$IA\log P$	$C\log P$	KOWWIN	$x\log P$	$\log P_{Rekker}$	$\log P_{exp.}$	W
P1	0.76	324	3.04	0.33	6.47	6.01	2.04	0.83	1.58	0.62

CONCLUSIONS

This work is an assessment of the possibility of using topological indices including electrotopological states in TLC. Every work quoted is a new aspect of the use of topological indices and electrotopological states. Data from the scientific literature indicate that the topological indices discussed can be used to predict and describe retention, lipophilic parameters obtained by TLC, and water solubility for the different classes of organic compounds investigated.

The results of the studies presented indicate that the topological indices and electrotopological states discussed have significance in analytical and physicochemical investigations of organic compounds. Theoretical determination of the R_M or R_F values and lipophilic parameters of organic compounds has special significance if standards are not available. This entry indicates that further investigations on the application of the topological indices in TLC are justifiable.

Topological Indices: Use in HPLC

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

Abstract
This entry is an assessment of the possibility of using topological indices with the high-performance liquid chromatography (HPLC) technique. Every quoted work is a new aspect of the use of topological indices. Data from the scientific literature indicate that the discussed topological indices can be used to predict and describe retention and lipophilic parameters obtained by HPLC for the different classes of organic compounds. The results of the studies presented here indicate that the topological indices have significance in analytical and physicochemical investigations of organic compounds.

INTRODUCTION

A tendency in chemical investigations is to predict physicochemical and biological properties of chemical compounds from their structural parameters. The fundamental establishment of these investigations is based on the fact that the structure of a molecule determines its properties. The prediction of physicochemical and toxicological properties of organic compounds with selected topological indices has been reviewed in monographs and dedicated entries. The first topological indices used for the prediction of selected physicochemical properties (boiling point, heat of formation, heat of vaporization, molar volume, and molar refraction) were the Wiener index, polarity number, and Platt's index. The Wiener index has been continuously modified.

MOLECULAR STRUCTURE AND PROPERTIES

Only quantum mechanics completely describes the structure of a molecule, characterizing its geometric and electronic structures. In many cases, the structural description of a molecule is shown by type and order of the connections of atoms, and by the form and size of a molecule. The topological indices, which are derived from graph theory, are the simplest means of describing the structure of a molecule. The topological indices encode the structural information of a molecule. The topological index characterizes a molecule by a single number.[1–3]

The applications of the topological indices in investigations—quantitative structure–activity relationship (QSAR), quantitative structure–property relationship (QSPR), and quantitative structure–retention relationship (QSRR)—for organic compounds have been described in the scientific literature. The compounds investigated were homologous series or mixtures of compounds from different classes of organic compounds. The topological indices have been applied in chromatographic investigations. The short distance traveled by a solute on a chromatographic column is the reason for the limited application of topological high-performance liquid chromatography (HPLC).

The range and field of application of topological indices are limited.[1,2] The topological indices can be applied as a descriptor, only when the correlated property is primarily dependent on the structure of a molecule. Often, the monoparametric and multiparametric equations have low values for correlation coefficients. In such circumstances, the authors introduce the correlation or modification in the way of the topological indices calculation. Such procedures lead to correlation equations with high values of correlation coefficients.[1–3]

The application of the topological indices is an important field in theoretical chromatography. Topological indices open a new field of investigation in chromatographic science. Many scientists have reported the application of topological indices for the prediction of the retention data for different groups of organic compounds. The extent of this application in recent years has been unexpectedly large and includes the application of the topological indices in liquid chromatography [thin-layer chromatography (TLC) and HPLC].

In previous work, Pyka[3] described the possibility of using topological indices in TLC. The objectives of this review are to describe the use of topological indices in HPLC investigations reported in scientific literature and to discuss the significance of such works.

PRESENTATION AND DISCUSSION

The investigation of chromatographic retention is one of the most active areas for the QSRR studies using various topological indices. Many papers have been written on this important area of analytical chemistry.[1–30] The first

topological indices used for the prediction of retention parameters or lipophilic parameters were the Randić indices (molecular connectivity indices), the Wiener index, and the Balaban (I_B) index. Selected applications of topological indices for the prediction of retention parameters of compounds separated by HPLC are covered later in this entry.

Jinno and Kawasaki[4] correlated log k' with the connectivity index χ of 26 polycyclic aromatic hydrocarbons (PAHs) separated on phenyl ($r = 0.9926$), ethyl ($r = 0.9905$), octyl ($r = 0.9944$), and octadecyl ($r = 0.9912$) columns. Hurtubise, Allen, and Silver[5] separated 34 PAHs by reversed-phase(RP)-HPLC and correlated their log k' with the connectivity index χ:

$$\log k' = -0.55\chi + 0.30,\ r = 0.97 \tag{1}$$

Jinno and Kawasaki[6] also obtained the best correlations between log k' and the topological index χ, van der Waals volume (V_w), and hydrophobic parameter (log P) for alkylbenzenes separated on RP C_2, C_8, and C_{18} columns by HPLC ($r > 0.94$). In addition, Smith[7] presented the relationships between log k' and connectivity index χ for alkylbenzenes and *n*-alkylbenzenes separated by RP-HPLC on SAS-Hypersil and ODS-Hypersil columns ($r > 0.97$).

Burda et al.[8] separated 54 alkanes (C_5–C_{11}), with different degrees of branching, by RP-HPLC on an octadecyl-silica Lichrosorb R18 column, by using a mixture of methanol and water (80:20) as mobile phase. The connectivity index χ was used to correlate the structures of investigated alkanes with their obtained retention parameter log k'.

Wells, Clark, and Patterson[9] investigated 16 C_1–C_5 *n*-alkylbenzamides by RP-HPLC on a Partisil ODS column using methanol and water, as well as acetonitrile and water, in different volume compositions as mobile phases. The values of log k' and log k'_w were correlated with topological indices ${}^m\chi_t$ and ${}^m\chi_t{}^\nu$ values. The highest correlations were obtained with the connectivity data that describe molecular bulk, branching in the hydrocarbon portion of the molecule. For example, for log k'_w values for 0%, acetonitrile in mobile phase on Partisil ODS-2 and Ultrasphere ODS, the following correlation equations were obtained:

1) For Partisil ODS-2:

$$\begin{aligned}\log k'_w = {} & 0.070(\pm 0.013)({}^5\chi^v_{pc})^2 \\ & + 20.930(\pm 0.917)({}^6\chi^\nu_p)^2 \\ & + 2.154(\pm 0.082),\ r = 0.9885\end{aligned} \tag{2}$$

2) For Ultrasphere ODS:

$$\begin{aligned}\log k'_w = {} & 0.834(\pm 0.026)({}^o\chi^v) \\ & + 0.326(\pm 0.031)({}^6\chi^v_{pc})^{-1} \\ & - 3.991(\pm 0.267),\ r = 0.995\end{aligned} \tag{3}$$

Adler, Babic, and Trinajstic[10] applied the Wiener index for calculating HPLC parameters for polycyclic hydrocarbons. Retention index (I) was correlated with the Wiener index for 10 PAHs:

$$\log I = 0.225(\pm 0.026)W^{(0.460\pm 0.019)} \tag{4}$$

Siwek and Sliwiok[11] applied connectivity, Wiener index, and Balaban index to evaluate hydrophobicities (log k'_w) of selected isomer ketones, by using an RP-HPLC technique. Topological indices do not correlate well with log k'_w for a large group of compounds[11]:

$$\log k'_w = 0.015W + 0.50,\ n = 10;\ r = 0.804 \tag{5}$$

$$\log k'_w = 1.62\chi + 1.0,\ n = 10;\ r = 0.787 \tag{6}$$

$$\log k'_w = -0.28I_B + 3.41,\ n = 10;\ r = 0.616 \tag{7}$$

However, they can be used successfully for qualitative comparisons of hydrophobicity within the field of isomer pairs.

Kakoulidou and Rekker[12] predicted capacity factors (k') for 14 selected alkyl-substituted benzophenones and four halogen-substituted benzophenones (separated by RP-HPLC) based on connectivity indices ${}^o\chi^\nu$ and ${}^4\chi^\nu_{pc}$:

For alkyl-substituted benzophenones:

$$\begin{aligned}\log k' = {} & 0.215(\pm 0.022)({}^o\chi^v) \\ & - 0.223(\pm 0.091)\left({}^4\chi^v_{pc}\right) \\ & - 1.458(\pm 0.143),\ n = 14; \\ & r = 0.9939;\ s = 0.037;\ F = 483\end{aligned} \tag{8}$$

For halogen-substituted benzophenones:

$$\begin{aligned}\log k' = {} & 0.491(\pm 0.085)({}^o\chi^v) \\ & - 0.695(\pm 0.231),\ n = 4; \\ & r = 0.9965;\ s = 0.051;\ F = 281\end{aligned} \tag{9}$$

Wells, Clark, and Patterson[13] investigated a series of twenty-three 5,5-dialkylbarbituric acid derivatives by RP-HPLC on Partisil ODS and Partisil ODS-2 columns using mixtures of methanol and water in volume compositions 30:70 and 50:50. The same three molecular connectivity indices were selected: ${}^1\chi$, ${}^3\chi_p$, and ${}^3\chi^\nu_p$ in the chromatographic process at both 30% and 50% v/v methanol in water and on two different columns:

For Partisil ODS:

$$\begin{aligned}\log k'_{30\%MeOH} = {} & 0.033(\pm 0.002)\left({}^1\chi\right)^2 \\ & - 0.059(\pm 0.004)\left({}^3\chi_p\right)^2 \\ & + 0.708(\pm 0.040)\left({}^3\chi^v_p\right) \\ & + 1.294(\pm 0.085),\ r = 0.990\end{aligned} \tag{10}$$

$$\log k'_{50\%\text{MeOH}} = 0.018(\pm 0.001)\left({}^{1}\chi\right)^{2} - 0.036(\pm 0.002)\left({}^{3}\chi_{\text{p}}\right)^{2} + 0.431(\pm 0.020)\left({}^{3}\chi_{\text{p}}^{v}\right) - 0.886(\pm 0.042),\ r = 0.991 \quad (11)$$

For Partisil ODS-2:

$$\log k'_{50\%\text{MeOH}} = 0.034(\pm 0.002)\left({}^{1}\chi_{\text{p}}\right)^{2} - 0.064(\pm 0.004)\left({}^{3}\chi_{\text{p}}\right)^{2} + 0.773(\pm 0.035)\left({}^{3}\chi_{\text{p}}^{v}\right) + 1.526(\pm 0.075),\ r = 0.992 \quad (12)$$

This implies that the topological indices ${}^{1}\chi$, ${}^{3}\chi_{\text{p}}$, and ${}^{3}\chi_{\text{p}}^{\nu}$ define those molecular features that govern the RP-HPLC retention of barbiturates. The topological index ${}^{1}\chi$ decreased with increased branching of an alkyl group. The topological indices ${}^{3}\chi_{\text{p}}$ and ${}^{3}\chi_{\text{p}}^{\nu}$ described the exact position of branching for the investigated barbiturates.[13]

Wells, Clark, and Patterson[14] also used the combination of topological indices ${}^{0}\chi$, ${}^{0}\chi^{\nu}$, ${}^{4}\chi_{\text{pc}}$, and ${}^{4}\chi_{\text{pc}}^{\nu}$ to predict retention of the hydrocarbons on various C_{18} stationary phases in aqueous methanol and acetonitrile.

Lehtonen[15–17] used molecular connectivity indices to correlate chromatographic parameters with molecular structure for *n*-ethylbenzamides, amines, and dansylamines separated by HPLC. The best regression equation for 22 isolated amines from wines is[15]

$$\log k' = -22.1\left({}^{1}\chi^{v}\right)^{-2} - 5.08\left({}^{4}\chi_{\text{pc}}^{v}\right)^{-2} - 0.049\left({}^{6}\chi_{\text{pc}}\right) + 2.61,\ r = 0.991 \quad (13)$$

For example, the regression equation for 16 dansyl derivatives of amines (dansylamides) separated on a Nucleosil 5 C_{18} column using the mobile phase at 39% of propanol in water is[16]

$$\log k' = 0.00894\left({}^{1}\chi^{v}\right)^{2} + 0.604\left({}^{\text{o}}\chi^{v}\right)^{2} - 2.138,\ r = 0.9910 \quad (14)$$

Lehtonen[17] also calculated molecular connectivity indices to the third order, and a high degree of correlation was observed between the measured log k' and the topological indices for 16 *n*-ethylbenzamides:

For Spherisorb S5 ODS-2 column:

$$\log k' = 1.207(\pm 0.039)\left({}^{1}\chi^{v}\right) - 0.550(\pm 0.066)\left({}^{1}\chi\right) - 1.406(\pm 0.072),\ r = 0.9935 \quad (15)$$

For μBondapak C_{18} column:

$$\log k' = 1.074(\pm 0.086)\left({}^{1}\chi^{v}\right) - 0.482(\pm 0.059)\left({}^{1}\chi\right) - 1.173(\pm 0.064),\ r = 0.9937 \quad (16)$$

The selected pesticides, monolinuron, chlortoluron, diuron, isoproturon, linuron, dimefuron, diflubenzuron, teflubenzuron, and lufenuron were separated by an isocratic RP-HPLC technique using methanol and water as mobile phase, in which the proportional content of methanol was from 45% to 90%. *n*-Hexane was selected for determining the retention time of an unretained compound. The topological indices based on connectivity Gutman (M, M^{ν}) and Randić (${}^{0}\chi$, ${}^{1}\chi$, ${}^{2}\chi$, ${}^{0}\chi^{\nu}$, ${}^{1}\chi^{\nu}$, ${}^{2}\chi^{\nu}$) were calculated for the investigated compounds. The log k values obtained for the all investigated urea pesticides were extrapolated to pure water (to 0% v/v of methanol in mobile) according to the equations of Soczewinski and Wachtmeister. The obtained parameters of lipophilicity log k_{w} and $\varphi_{\text{o(HPLC)}}$ were correlated with topological indices. Only the Gutman index M^{ν} from among all topological indices was useful in the QSAR analysis of studied urea pesticides:[18]

$$\log k_{\text{w}} = 1.0383(\pm 0.3290) + 0.005267(\pm 0.000750)\ M^{v},\ n = 9;\ r = 0.9358;\ s = 0.463;\ F = 49.33;\ P < 0.0005$$

The Gutman index M^{ν} correlates worse with $\varphi_{\text{o(HPLC)}}$ ($r = 0.8861$) in comparison with log k_{w}.

Amic, Davidovic-Amic, and Trinajstic[19] developed a simple relationship between experimental retention time by HPLC and the Wiener index (W), polarity number (p), and number of OH groups (n_{OH}) in flavyliums:

$$t_{\text{R}} = a\left[\frac{W}{(pn_{\text{OH}})}\right] + b \quad (18)$$

where a and b are statistical parameters to be determined by least squares regression. Three groups of flavyliums were investigated and three correlation equations were obtained:

For anthocyanins:

$$t_{\text{R}} = 7.1794(\pm 0.1870)\left[\frac{W}{(pn_{\text{OH}})}\right] - 17.7954(\pm 0.7309),\ n = 6;\ r = 0.9986;\ F = 1474.6;\ s = 0.32 \quad (19)$$

For anthocyanin 3-glucosides:

$$t_{\text{R}} = 19.1354(\pm 0.7039)\left[\frac{W}{(pn_{\text{OH}})}\right] - 41.7504(\pm 4.6820),\ n = 10;\ r = 0.9946;\ F = 739.1;\ s = 4.25 \quad (20)$$

For anthocyanin 3,5-diglucosides:

$$t_R = 13.6883(\pm 0.5346)\left[\frac{W}{(pn_{OH})}\right] - 41.6262(\pm 3.7626),\ n = 10;\quad r = 0.9940;\ F = 655.6;\ s = 2.66 \tag{21}$$

Amic, Davidovic-Amic, and Trinajstic[19] also correlated the Schultz index [molecular topological index (MTI)] for anthocyanins. They suggest that the QSRR with MTI index should be identical to those with the Wiener index.

Martorell et al.[20] separated a series of twenty-two 6-fluoroquinolones by ion-pair RP-HPLC. The multiple linear correlation that best fits the experimental data is

$$\log k' = 6.8448(\pm 1.3184)QX_{24} - 0.2249(\pm 0.0933)DM - 4.0366(\pm 2.1135)DIF^3\chi_c + 5.0421,\ n = 22;\ r = 0.8543 \tag{22}$$

where QX_{24} is the negative net charge associated with the heteroatom X situated at position 4 of the heterocyclic aliphatic ring that functionalizes position C_7, DM is the dipolar moment, and $DIF^3\chi_c$ is the difference between the molecular connectivity index of valency and the nonvalency of the order 3 cluster.

In recent years, topological indices have become prominent on several different fronts. Many new topological indices were described after 1990.[1,2] Some among them were also applied in QSRR analyses of compounds investigated by the HPLC technique.[1,18,19,21–30]

De Julian-Ortiz et al.[21] calculated connectivity indices to the fourth order and proposed charge indices (G_k, J_k) for racemic hydantoins, racemic α-amino acids, and racemic arylamides. The best correlation equation for racemic hydantoins separated on β-cyclodextrin column using 10% methanol as a mobile phase is[21]

$$\log k' = -1.314 + 1.280\left({}^4\chi_p^v\right) - 0.185G_3^v,\ n = 17;\ r = 0.9426;\ F = 55.76;\ P < 0.001 \tag{23}$$

The best correlation equation for racemic α-amino acids separated on α-cyclodextrin column using 1% triethylamine acetate (pH = 5.1) as a mobile phase is[21]

$$k' = -8.262 + 0.2935G_2 - 12.187G_4 + 13.701G_4^v,\ n = 15;\ r = 0.9702;\ s = 0.62;\ F = 58.70;\ P < 0.001 \tag{24}$$

The best correlation equation for racemic arylamides separated on 1-(α-naphthyl)ethylamine column using *n*-hexane-tetrahydrofuran (75:25, v/v) as a mobile phase is[21]

$$\log k' = 3.264 - 0.209\ Pr_0 + 1.289\left({}^1\chi - {}^1\chi^v\right) - 1.943\frac{{}^4\chi_{pc}}{{}^4\chi_{pv}^v},\ n = 14;\ r = 0.9554;\ s = 0.12;\ F = 38.3;\ P < 0.001 \tag{25}$$

where Pr_0 is the number of vertices showing topological valence equal to 4.

Pyka[22] separated six selected steroids (corticosterone acetate, 11-dehydrocorticosterone acetate, corticosterone, 11-dehydrocorticosterone, hydrocortisone, and cortisone) by RP-HPLC on Separon Six C_{18} column. Column void time was determined using the peak derived from a solution of sodium nitrite in methanol. The mobile phase was prepared from analytical grade methanol and redistilled water (3:2, v/v). The Randić ($^0\chi$, $^0\chi^v$, $^1\chi$, $^1\chi^v$), Wiener (W), Balaban (I_B), and Pyka (A, ^0B) indices were calculated for the investigated compounds. The chromatographic data, log k', and partition coefficient log P values, of the compounds have been correlated with the numerical values of topological indices. The most accurate predictions of the log k' and log P values of the selected steroids were achieved by using monoparametric equations employing the topological indices ^0B:

$$\log k' = 18.5859(\pm 2.2622) - 7.0362(\pm 0.8882)^0B,\ n = 6;\quad r = -0.9696;\ s = 0.053;\ F = 62.75;\ P = 0.0014 \tag{26}$$

$$\log P = 106.454(\pm 3.332) - 41.464(\pm 1.308)^0B,\ n = 6;\quad r = -0.9980;\ s = 0.078;\ F = 1004.23;\ P = 0.0000 \tag{27}$$

Pyka and Sliwiok[23]separated six esters of nicotinic acids: methyl nicotinate, ethyl nicotinate, isopropyl nicotinate, butyl nicotinate, hexyl nicotinate, and benzyl nicotinate by adsorption HPLC on a LiChrospher Si 60 column. The mixtures containing benzene and methanol in volume proportions (0 + 10, 1 + 9, 2 + 8, 3 + 7, 4 + 6, and 5 + 5) were used as the mobile phases. The t_R (min) values of esters investigated have been correlated with the dipole moments (μ_{mph}) of the mobile phases applied, with numerical values of one topological index from among those based on the distance matrix (A, W, ^0B, ^1B, ^2B) or the adjacency matrix ($^0\chi^v$, $^1\chi^v$, $^2\chi^v$) with electrotopological states SaaCH, aaN, aasC, dO, ssO, and dssC, and structural descriptors based on information theory (I_{AC} and $\bar{I}_{AC}$). Dipole moments were used to characterize mobile phases. The correlation equations that enable the calculation of t_R

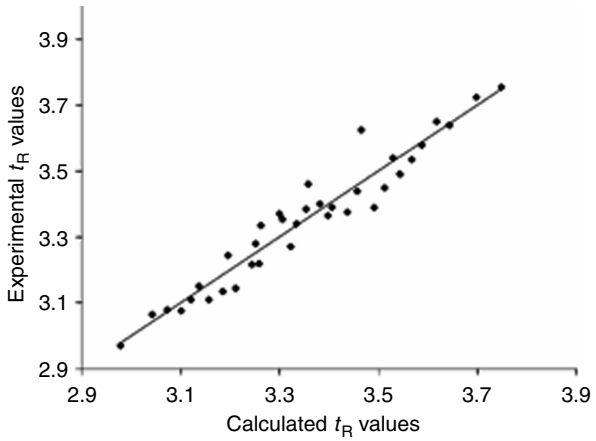

Fig. 1 Relationship between the experimental t_R (min) values of nicotinic acid esters and the t_R values calculated using Eq. 29. **Source:** From Use of traditional structural descriptors in QSRR analysis of nicotinic acid esters, in J. Liq. Chromatogr. Relat. Technol.[23]

values were obtained with topological indices based on adjacency matrices ${}^0\chi^\nu$ and ${}^1\chi^\nu$, with indices based on distance matrices ${}^1B$ and ${}^2B$, with index based on information theory (I_{AC} and $\bar{I}_{AC}$), and with electrotopological state aaN. All the equations are characterized by determination coefficients $R^2 > 90\%$. The best correlation equations were obtained with topological indices based on information theory I_{AC} and $\bar{I}_{AC}$, as well as based on distance matrices ${}^1B$ and ${}^2B$. For example,

$$t_R = -0.766(\pm 0.165) + 0.546(\pm 0.043)\mu_{mph} + 2.179(\pm 0.100)\bar{I}_{AC},\ n = 36;$$
$$R^2 = 95.08\%;\ F = 318.6;\ s = 0.046;\ P < 0.0001 \quad (28)$$

$$t_R = 1.838(\pm 0.082) + 0.546(\pm 0.050)\mu_{mph} + 1.600(\pm 0.087){}^1B,\ n = 36;$$
$$R^2 = 93.30\%;\ F = 230.0;\ s = 0.053;\ P < 0.0001 \quad (29)$$

The correlation equations (Eqs. 28 and 29) can be used to calculate t_R values of investigated esters. For example, the relationship between t_R (min) values measured experimentally and values calculated using Eq. 29 is shown in Fig. 1.

Eqs. 28 and 29 can also be used to predict the t_R values of the esters of nicotinic acid, whose measurement points have not been taken into consideration in the equation. A test was performed on Eqs. 28 and 29 to determine how well they predict t_R values of points not included in the training set. Three values were removed from the training sets (Eqs. 28 and 29). Isopropyl nicotinate (separated in benzene:methanol, 5:5, v/v) and ethyl nicotinate (separated in benzene:methanol, 4:6, and 0:10, v/v) from Eqs. 28 and 29 were removed. This subset of two parametric equations was recalculated as

$$t_R = -0.753(\pm 0.175) + 0.533(\pm 0.048)\mu_{mph} + 2.183(\pm 0.105)\bar{I}_{AC},\ n = 33;$$
$$R^2 = 94.85\%;\ F = 276.2;\ s = 0.047;\ P < 0.0001 \quad (30)$$

$$t_R = 1.872(\pm 0.090) + 0.522(\pm 0.056)\mu_{mph} + 1.604(\pm 0.090){}^1B,\ n = 33;$$
$$R^2 = 93.07\%;\ F = 201.6;\ s = 0.055;\ P < 0.0001 \quad (31)$$

The t_R values for esters of nicotinic acids, omitted during the derivation of Eqs. 30 and 31 and subsequently predicted using these equations, are listed in Table 1.

These equations are statistically significant and can be used for a reasonably good prediction of t_R values of the investigated esters of nicotinic acid. The high compatibility between experimental and predicted t_R values for esters omitted in the considered correlation equations was stated.

Djakovic-Sekulic, Perišic-Janjic, and Pyka[24] separated eight anilides of 2,2-dimethylpropanoic acid, nine anilides of benzoic acid, and nine anilides of α-phenyl acetic acid by RP-18 HPLC using mixtures containing methanol and water in volume proportions 6 + 4, 6.5 + 3.5, and 7 + 3 as the mobile phases. The log k values of investigated anilides have been correlated with the dipole moments (μ_{mph}) or permittivities (ε_{mph}) of the mobile phases applied, with numerical values of one topological index from among those based on the distance matrix (R, W, A, ${}^0B$, ${}^1B$, ${}^2B$) or on the adjacency matrix (M, M^ν, ${}^0\chi$, ${}^1\chi$, ${}^2\chi$, ${}^0\chi^\nu$, ${}^1\chi^\nu$, ${}^2\chi^\nu$), with partition coefficient by Rekker (log P_{Rek}), or with the number of hydrogen acceptors (HA), or with the solubility (log S), or with the molecular weight (M_w). Authors found 77 multiparametric equations with $R^2 > 90\%$. The best

Table 1 The t_R values (min) of nicotinic acid esters omitted from Eqs. 30 and 31, and predicted by these equations.

	t_R				
Omitted point	**Experimental**	**Predicted by Eq. 30**	**$\lvert\Delta t_R\rvert$**	**Predicted by Eq. 31**	**$\lvert\Delta t_R\rvert$**
isopropyl nicotinate (benzene:methanol, 5:5, v/v)	3.220	3.226	0.006	3.266	0.046
ethyl nicotinate (benzene:methanol, 4:6, v/v)	3.365	3.406	0.041	3.402	0.037
ethyl nicotinate (benzene:methanol, 0:10, v/v)	3.650	3.621	0.029	3.614	0.036

Source: From Use of traditional structural descriptors in QSRR analysis of nicotinic acid esters, in J. Liq. Chromatogr. Relat. Technol.[23]

equations for these groups of investigated anilides are as follows:

For anilides of 2,2-dimethyl propanoic acid:

$$\begin{aligned}\log k_{\mathrm{p}} &= -46.7031(\pm 2.5201) \\ &\quad + 25.7452(\pm 1.4278)\mu_{\mathrm{mph}} \\ &\quad + 0.002877(\pm 0.000467)M_W \\ &\quad + 0.2711(\pm 0.0230)\log P_{\mathrm{Rek}},\ n = 24; \\ R^2 &= 97.31\%;\ F = 240.8;\ s = 0.0471;\ P < 0.0001 \end{aligned} \quad (32)$$

For anilides of benzoic acid:

$$\begin{aligned}\log k_{\mathrm{b}} &= -6.7551(\pm 0.5235) \\ &\quad + 0.09581(\pm 0.00874)\varepsilon_{\mathrm{mph}} \\ &\quad + 0.007500(\pm 0.00164)M \\ &\quad + 0.4211(\pm 0.0344)\log P_{\mathrm{Rek}}, \\ n &= 27;\ R^2 = 92.16\%;\ F = 90.1; \\ s &= 0.0848;\ P < 0.0001 \end{aligned} \quad (33)$$

For anilides of α-phenyl acetic acid:

$$\begin{aligned}\log k_{\mathrm{ph}} &= -46.9896(\pm 2.2419) \\ &\quad + 25.6156(\pm 1.2646)\mu_{\mathrm{mph}} \\ &\quad + 0.004629(\pm 0.001086)M \\ &\quad + 0.3965(\pm 0.0208)\log \mathrm{P}_{\mathrm{Rek}},\ n = 27; \\ R^2 &= 97.36\%;\ F = 283.1;\ s = 0.0443;\ P < 0.0001 \end{aligned} \quad (34)$$

For all anilides investigated:

$$\begin{aligned}\log k_{\mathrm{all}} &= -52.7102(\pm 1.8869) \\ &\quad + 25.9835(\pm 1.0372)\mu_{\mathrm{mph}} \\ &\quad + 0.07725(\pm 0.01892)\left({}^2\chi^v\right) \\ &\quad + 2.2767(\pm 0.1816)^0B \\ &\quad + 0.002736(\pm 0.000360)M \\ &\quad + 0.3222(\pm 0.0142)\log P_{\mathrm{Rek}},\ n = 78; \\ R^2 &= 95.06\%;\ F = 277.6;\ s = 0.0671;\ P < 0.0001 \end{aligned} \quad (35)$$

Eqs. 32–35 can also be used for log k value prediction of anilides investigated, whose measurement points have not been taken into consideration in the equation. Four of the tests of predictive equations, such as 32–35, show how well they predict values of points not included in the training set.

From Eq. 32, log k for $(CH_3)_3C$–CO–NH–C_6H_4–CF_3 [separated with methanol and water, 7 + 3 (v/v)] was omitted, and the best subset equation using three parameters was recalculated as follows:

$$\begin{aligned}\log k_{\mathrm{p}} &= -46.3329(\pm 2.6616) \\ &\quad + 25.5281(\pm 1.5118)\mu_{\mathrm{mph}} \\ &\quad + 0.00290007(\pm 0.000480)M_{\mathrm{W}} \\ &\quad + 0.2738(\pm 0.0240)\log P_{\mathrm{Rek}}, \\ n &= 23;\ R^2 = 97.34\%;\ F = 231.4; \\ s &= 0.0480;\ P < 0.0001. \end{aligned} \quad (36)$$

From Eq. 33, log k for C_6H_5–CO–NH–C_6H_4–F [separated with methanol and water, 6 + 4 (v/v)] was omitted, and the best subset equation using three parameters was recalculated as follows:

$$\begin{aligned}\log k_{\mathrm{b}} &= -6.7834(\pm 0.5360) \\ &\quad + 0.09685(\pm 0.00917)\varepsilon_{\mathrm{mph}} \\ &\quad + 0.007390(\pm 0.00169)M \\ &\quad + 0.4199(\pm 0.0351)\log P_{\mathrm{Rek}},\ n = 26; \\ R^2 &= 92.19\%;\ F = 86.5;\ s = 0.086;\ P < 0.0001 \end{aligned} \quad (37)$$

From Eq. 34, log k for C_6H_5–CH_2–CO–NH–C_6H_4–F [separated with methanol and water, 7 + 3 (v/v)] was omitted, and the best subset equation using three parameters was recalculated as follows:

$$\begin{aligned}\log k_{\mathrm{ph}} &= -46.6855(\pm 2.3584) \\ &\quad + 25.4532(\pm 1.3258)\mu_{\mathrm{mph}} \\ &\quad + 0.004548(\pm 0.001116)M \\ &\quad + 0.3954(\pm 0.0213)\log P_{\mathrm{Rek}}, \\ n &= 26;\ R^2 = 97.26\%;\ F = 260.5; \\ s &= 0.0450;\ P < 0.0001 \end{aligned} \quad (38)$$

From Eq. 35, log k values for C_6H_5–CH_2–CO–NH–C_6H_4–CH_3, C_6H_5–CH_2–CO–NH–C_6H_4–CN, $(CH_3)_3C$–CO–NH–C_6H_4–$COCH_3$ [separated with methanol and water, 7 + 3 (v/v)], C_6H_5–CO–NH–C_6H_4–Cl, $(CH_3)_3C$–CO–NH–C_6H_4–Br [separated with methanol and water, 6.5 + 3.5 (v/v)], and $(CH_3)_3C$–CO–NH–C_6H_4–CF_3 [separated with methanol and water, 6 + 4 (v/v)] were omitted, and the best subset equation using five parameters was recalculated as follows:

$$\begin{aligned}\log k_{\mathrm{p}} &= -52.6507(\pm 2.0879) \\ &\quad + 25.9692(\pm 1.1317)\mu_{\mathrm{mph}} \\ &\quad + 0.07771(\pm 0.02096)\left({}^2\chi^v\right) \\ &\quad + 2.2620(\pm 0.2002)^0B \\ &\quad + 0.002742(\pm 0.000385)M \\ &\quad + 0.3213(\pm 0.0156)\log P_{\mathrm{Rek}},\ n = 72; \\ R^2 &= 94.32\%;\ F = 219.1;\ s = 0.0644;\ P < 0.0001 \end{aligned} \quad (39)$$

The experimental and predicted log k values calculated by 36–39 are presented in Tables 2 and 3. The differences

between experimental and predicted values $|\Delta \log k|$ were small.

Pyka[25] separated 16 PAHs (naphthalene, acenaphthylene, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene, dibenzo[*a,h*]anthracene, benzo[*g,h,i*]perylene, and indeno[1,2,3-*cd*]pyrene) according to the Environmental Protection Agency (EPA) by gradient HPLC on a LiChrospher® PAH column using acetonitrile and water as mobile phases. Retention times tr (sec) of investigated PAHs were correlated with topological indices based on the adjacency matrix (M, ${}^0\chi^\nu$, ${}^1\chi^\nu$, ${}^2\chi^\nu$, χ_{012}) and the distance matrix (W, A, C, D), and correlation equations were obtained, as follows (Table 4):

$$t_R = -564.65(\pm 75.78) + 8.649(\pm 0.379)M^\nu \quad (40)$$

$$t_R = -822.91(\pm 92.82) + 209.86(\pm 9.84)^0\chi^\nu \quad (41)$$

$$t_R = -866.18(\pm 105.10) + 335.35(\pm 17.43)^1\chi^\nu \quad (42)$$

$$t_R = -660.57(\pm 115.41) + 391.63(\pm 24.82)^2\chi^\nu \quad (43)$$

$$t_R = -308.08(\pm 62.44) + 2.413(\pm 0.166)W \quad (44)$$

$$t_R = -155.71(\pm 68.04) + 6.074(\pm 0.395)A \quad (45)$$

$$t_R = -400.5(\pm 105.6) + 116.03(\pm 7.81)C \quad (46)$$

$$t_R = -16.497(\pm 62.750) + 28.61(\pm 1.53)D \quad (47)$$

$$t_R = -792.9(\pm 97.2) + 304.1(\pm 14.7)\chi_{012} \quad (48)$$

The equations with the highest statistical parameters were obtained with topological indices based on the adjacency matrix. The relationship between t_R values and Gutman M^ν index according to Eq. 40 is presented in Fig. 2.

Pyka and Sliwiok[26] separated α-tocopherols, β-tocopherols, γ-tocopherols, and δ-tocopherols by normal-phase (NP)-HPLC and RP-C_{18}-HPLC. The selected topological indices based on connectivity (M^ν, ${}^1\chi^\nu$), distance matrix (W, ${}^0B$, MTI), and information theory (I_{AC}, $\bar{I}_{AC}$) were

calculated for these tocopherols. As presented in Table 5, the topological indices clearly show that β-tocopherols and γ-tocopherols, as positional isomers, possess the same numerical values of topological indices $^1\chi^v$, M, I_{AC}, and $\bar{I}_{AC}$. In addition, the retention times have the same values for β-tocopherols and γ-tocopherols investigated by RP-C_{18}-HPLC. Instead, the numerical values of the topological indices W and MTI for α-tocopherols, γ-tocopherols, β-tocopherols, and δ-tocopherols in the given sequence grow smaller (decrease). Only the numerical values of the topological indices ^0B grow smaller (decrease) in the following order: α-tocopherols, β-tocopherols, γ-tocopherols, and δ-tocopherols. But the difference between the numerical values of the topological index ^0B is very small for β-tocopherols and γ-tocopherols. The definite dependence between the numerical values of topological index ^0B and the chromatographic separation of the investigated tocopherols was obtained. In the given sequence, grow retention times of tocopherols were investigated by NP-HPLC.[26]

Luhua et al.[27] separated by RP-HPLC and performance liquid chromatography–mass spectrometry chromatography (HPLC–MS) (–)-ephedrine and (+)-pseudoephedrine. The topological indices based on connectivity and distance matrix A, W, and $^h\chi^v$ were calculated. The structures particularly of (–)-ephedrine and (+)-pseudoephedrine were described by topological indices $^h\chi^v$, which were applied to interpret the chromatographic separations.

Lee et al.[28] separated 18 L-amino acids by RP-HPLC. Binding energy (E_b), hydrophobicity (log P), molecular refractivity (MR), polarizability (α), total energy (E_t), water solubility (log S), connectivity index (χ) of different orders and Wiener index (W) were also theoretically calculated. The retention factors with various physicochemical and structural properties of L-amino acids were represented. After investigating the effect of descriptors on the retention factors, the five major ones were found to be E_b, MR, E_t, $^1\chi$, and W. The correlation coefficient was more than 0.95.

The Wiener index (W) was also used for calculating the HPLC retention time of PAHs,[29] n-alkanes, and cycloalkanes.[30]

CONCLUSIONS

Topological index is indirectly connected with the structures of chemical compounds. Topological indices, as well as retention parameters, are most important for physicochemical characteristics of organic compounds. Chromatography is applied to the separation of chemical compounds both for analytical and for preparative aims. Correlation of retention parameters of organic compounds with selected topological indices (with structures of compounds studied) permits assignment of definite rules, which enable the prediction of chromatographic separations.

This work is an assessment of the possibility of using topological indices with the HPLC technique. Every quoted work is a new aspect of the use of topological indices. Data from the scientific literature indicate that the discussed topological indices can be used to predict and describe retention and lipophilic parameters obtained by HPLC for the different classes of organic compounds.

The results of the studies presented here indicate that the topological indices have significance in analytical and physicochemical investigations of organic compounds. These results indicate the capacity of molecular topology to identify and predict different structural features that determine HPLC data for a variety of organic compounds. The application of topological indices in the physicochemical investigation of organic compounds is constantly

increasing. One reason for this is, among others, the use of computer programs to calculate topological indices.[1]

This review indicates that further investigations on the application of topological indices in HPLC are warranted.

Trace Enrichment

Fred M. Rabel
EMD Chemicals, Inc., Gibbstown, New Jersey, U.S.A.

INTRODUCTION

Very few chromatographic determinations using high-performance liquid chromatography (HPLC) can be done without first cleaning up the sample or sample solution in some way. The cleanup accomplishes many things, including removing extraneous matrix components and concentrating many of the components of interest so that they can more easily be detected. Many of these cleanup techniques are done off-line, which can increase analysis time by 50% or more.

Trace enrichment (TE) is a sample preparation technique using a minicolumn filled with a packing selected for its properties of attracting wanted components while eliminating unwanted ones. It is connected to the valve ahead of the analytical column, which traditionally is used only for sample injection. The sample solution is pumped (with a second pump) onto the TE column in one mobile phase, and usually washed with a second mobile phase to elute some unwanted components. Then, with a change in the flow path, it is backflushed to place the sample at the head of the analytical column, where separation begins. This speeds up the complete analysis, avoids many interferences for unwanted impurities, and when automated, runs unattended.

DESCRIPTION OF METHOD

Trace enrichment is a sample precleaning procedure that is performed prior to sample analysis. The purpose of any sample preparation procedure is twofold. First, such a procedure must selectively collect and concentrate the components of interest. Second, the method should eliminate any other components that would interfere with the analysis or would contaminate an analytical gas chromatography (GC) or HPLC column to shorten its useful analytical life.

There are many sample preparation techniques listed in texts, from simple filtration or centrifugation to many other kinds of extraction procedures, including both liquid–liquid and solid-phase extraction (SPE). When any type of sample preparation is used, it often is done manually if only a few samples are involved. If a large number of samples are to be analyzed, the entire procedure should lend itself to automation. Regardless of the number of samples, most sample preparation is done off-line; that is, the samples are prepared first with one of the methods listed, and then placed into an automated sample injection system for sequential analysis of all samples.

Trace enrichment is a sample preparation procedure that is performed by passing a "crude" sample through a special "collection" column, but with a couple of added features. It is often done online, one at a time, just prior to the analytical procedure. It usually involves a minicolumn very similar to the familiar off-line SPE tube, but packed into a stainless steel column and attached to the injection valve. This is called a "trace enrichment" column in many published procedures. Another name that is often given to this technique in the title or keywords of published entries is "column switching." This is because this technique involves valves that must be switched from one solvent flow path to another. The valve, in its initial position, allows the "crude" sample to be passed through the TE column with pump 1, whereas the mobile phase is passed only through the analytical column with pump 2 (Fig. 1). After the TE column has collected the sample components of interest, these components are backflushed onto the analytical column by switching the valve to its alternative position (Fig. 2).

The complete procedure for using a TE column is as follows:

1. The TE column is equilibrated with a minimum of two solvent combinations. The first solvent is strong, to wash the TE column free of impurities it may have accumulated from a previous sample (remember, this column is used over and over, so this step is critical so that there is no sample carry-over). This solvent is probably pure methanol or acetonitrile if using a bonded reversed-phase packing filled TE column. The second solvent is not strong; it is used to bring the TE column to equilibrium to accept the sample components of interest. Again, if a bonded reversed-phase packing filled TE column is used, this could even be pure water. The valving would be as shown in Fig. 1.
2. The "crude" sample is injected (if a small volume) or pumped (if a larger volume) onto the TE column. (*Note*: Even a "crude" sample requires membrane filtration and/or centrifugation to prevent shortened column life of the TE column.) The TE column attracts the components of interest, depending on the nature of the bonded phase packing in the TE column, the solvent in which the sample is dissolved,

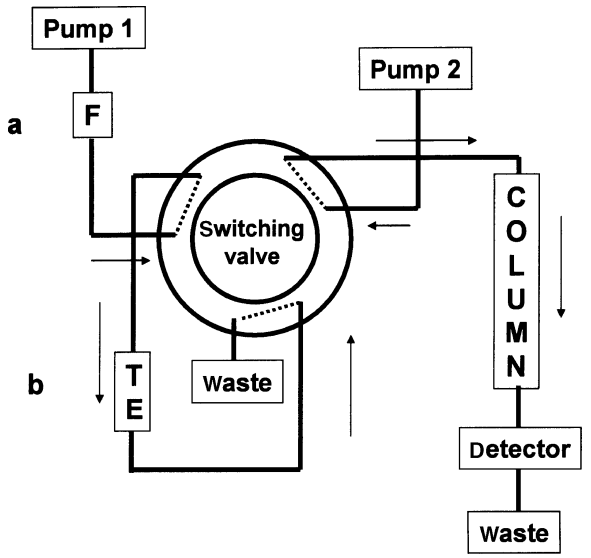

Fig. 1 Trace enrichment valving for the collection of the sample components. a, In-line filter (F) to increase the life of the TE column; b, trace enrichment column (TE). Note that the solvent from pump 2 is equilibrating the analytical column on the right while the TE column is being loaded with sample.

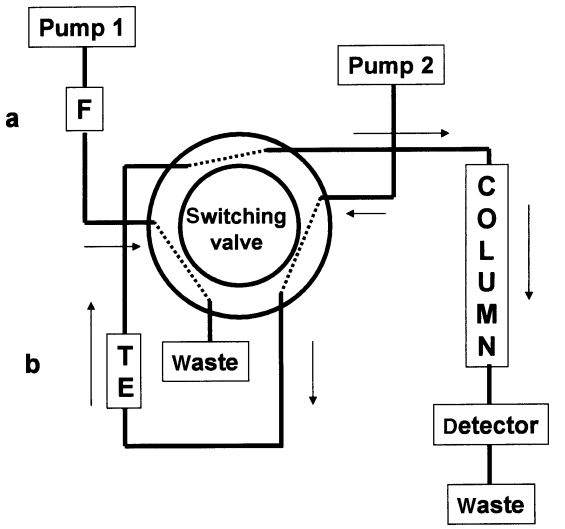

Fig. 2 Trace enrichment valving for the transfer of the prepared sample to the analytical column. a, In-line filter (F) to increase the life of the TE column; b, trace enrichment column (TE). Note that the sample is backflushed onto the analytical column. After a few seconds, the valve can be turned to the position in Fig. 1. The TE column is washed with a cleaning mobile phase, then conditioned back to the collection mobile phase, and another sample put on. See text for complete details.

and the solvent with which the TE column has been equilibrated. The TE column, most likely, will remove more than the components of interest and, thus, might need an additional solvent wash sequence to remove other unwanted collected impurities. This would be done before the final step described below. The valving would continue to be in the position shown in Fig. 1.

3. Finally, when the entire sample has been passed through the TE column, the valve is switched so that the final solvent mixture is passed, with reversed flow direction, through the TE column. This is usually a stronger eluting solvent combination that elutes the collected components to be chromatographed from the TE column. It is often the chromatographic mobile phase, which will also perform the actual analysis on the HPLC analytical column. Once the components are on the analytical column, the separation begins. This valving is shown in Fig. 2. After 5–10 sec, the valving can be set as in Fig. 1, repeat the sample preparation step for the second sample on the TE column while the separation of the first sample is proceeding on the analytical column.

Again, a strong solvent wash of the TE column and then the equilibrium sample wash precede injection of the second sample onto this column. The TE process on the minicolumn is usually accomplished within 2–3 min, and the actual separation might take 10 min. Thus, the time-limiting factor is the actual analysis, not the TE process itself. Shortening the analysis time with a shorter, more efficient HPLC column would lead to greater productivity as long as the actual analysis time is at least 1 min longer than the TE step.

The TE column ideally collects only the components of interest, permitting all unwanted impurities to pass through it. As mentioned, this is seldom completely true in practice, so the details of the entire TE have to be experimentally determined. These details involve determining which minicolumn packing to use and, perhaps, up to three solvent combinations. The first of these combinations is a solvent (or group of solvents) that dissolves the sample so that it carries the sample onto the TE column and simultaneously allows capture of the desired components. With solvent experiments, this first solvent combination can be designed to simultaneously remove some unwanted components as the components of interest are being sorbed onto the TE packing.

A second solvent combination is used to wash more of the remaining impurities out of the minicolumn. Finally, the third solvent combination is used to backflush the captured components from the TE column onto the analytical column. As mentioned, this is often the mobile phase used for the separation and is polar enough to also elute the collected compounds from the TE column.

When beginning the development of a TE column procedure, an excellent source of SPE information may be found in SPE device manufacturers' literature (or on their websites). Most manufacturers offer at least 25 years

of literature references on their products. Their procedures often provide useful information about compound types and the SPE chemistry used and the solvents for cleanup and elution. The same packing material may be used in the TE column, either the same size (usually 40–63 μm for SPE tubes) or a 5 or 10 μm version of it. Buying the TE packing material from the company that makes the SPE tubes allows the SPE solvent information previously determined to be used with the online work. Other bonded-phase chemistries from other manufacturers give *different* capture capacities and efficiencies, so the solvent to capture or elute would be completely different. If in doubt about the equivalency of the chemistries, again, manufacturers are a good source of information.

Some of the most difficult types of sample cleanup are those derived from serum, plasma, urine, or other plant or animal matrices. Proteins or other high-molecular-weight biopolymers quickly contaminate a HPLC column if they are not removed from samples. Such off-line procedures might involve multiple steps. However, another type of packing with special bonding has been used for this type of sample cleanup. It is called *restricted access material*, or RAM. This packing material has an outer surface diol-bonded phase and an internal bonded reversed phase. Biopolymers cannot penetrate into the smaller pores and are repelled by the diol phase and, thus, pass completely through the TE column. However, the components of interest, which are usually much lower-molecular-weight drug substances, are able to pass into the inner pores and attach themselves to the reversed phase. As mentioned earlier, it is still necessary to filter and centrifuge the sample before it is introduced onto the TE column, but these columns can often handle up to two thousand 50 μl injections before having to be replaced. They are available with different internal chemistries—C4, C8, C18, and ion exchangers—to allow different selectivities based on hydrophobic and ion-exchange interactions.

If biological samples are being purified, studies should also be conducted to see under what conditions any compounds of interest are released from the proteins being eluted from the typical RAM column mentioned above. This is due to the strong binding experienced with many compounds onto proteins. If 50% remains bound to the protein as it is washed away, there is 50% less compound collected for making a measurement. One might never achieve 100% release, but an extra 10–20% might be helpful in trace work.

The size of the TE column can be as small as 2–3 mm × 10–25 mm. It simply has to have sufficient capacity to capture all, or a major percentage, of the components of interest. It should be remembered that a TE column usually captures structurally related compounds and, perhaps, some impurities; hence, it might be assumed that only 15–25% of the capacity is taken up by the compound(s) of interest. Because a relatively strong mobile phase is used for backflushing, band broadening is not generally a problem in a TE method, regardless of the size of the column.

The way most TE columns are used with a valve-loop injector is that the sample solution first flows in one direction for capture, and then is backflushed onto the analytical column. This process of backflushing can also push particles captured on the inlet frit back onto the analytical column; therefore, this is another reason for filtration/centrifugation of samples before introducing them onto the TE column. Any in-line filter can also prevent particulates from migrating to places in the HPLC system where they can cause problems.

CONCLUSIONS

Trace enrichment is a valuable tool to use to simplify any laborious sample preparation technique. It is basically automation of the well-known SPE method of sample preparation. As such, it saves the analyst time, money, and solvent, and all but eliminates sources of analytical error. In addition to the traditional bonded reversed phase and ion exchange packings, newer packings have been developed with different surface and inner pore bonded phases. These RAMs have polar outer surfaces that repel biopolymers and non-polar or ionic inner surfaces that collect drugs and other smaller-molecular-weight components.

Although it takes some thought, experimentation, and additional equipment (a special valve and an additional pump), it can be a way of increasing productivity in the analytical laboratory and removing sample preparation errors.

Two-Dimensional TLC

Simion Gocan
Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania

INTRODUCTION

The two-dimensional (2-D) thin-layer chromatography (TLC) technique is one of the more versatile methods of TLC development. The first application of the 2-D chromatographic method to paper chromatography was reported in 1944 by Consden, Gordon, and Martin.[1] Since that time, this method has been mostly used for the separation of a large number of compounds that cannot be separated in a one-dimensional (1-D) TLC experiment. In 2-D TLC, separation is on one surface spread along the entire area of the plate. The resolving power of the 2-D TLC method has great application, especially in the areas of biochemistry, biology, natural products, pharmaceuticals, and environmental analysis.

TWO-DIMENSIONAL DEVELOPMENT

Two-dimensional TLC is performed by spotting the sample in one corner of a square thin-layer plate and developing in the usual manner with the first eluent. The chromatographic plate is then removed from the developing chamber and the solvent is allowed to evaporate from the layer. Then, the plate is placed in the second eluent so that development can take place in a second direction which is perpendicular to that of the first direction of development. In 2-D TLC, usually, the layer is of continuous composition, but two different eluents must be employed to obtain a better separation of a mixture. The success of the separation will depend on the ability to modify the selectivity of the second eluent compared to the selectivity of the first eluent. Fig. 1 shows the scheme of spot distribution on a 2-D TLC plate, following two developments for a theoretical case. In 2-D TLC, any spot can be identified by a pair of x_i and y_i coordinates or $R_{f,i1}$ and $R_{f,i2}$, respectively, where x_i divided by $Z_{f,1}$ is equal to $R_{f,i1}$ for the first eluent and $y_i/Z_{f,2}$ is equal $R_{f,i2}$ for the second eluent. The final position of the spot can be determined by the coordinates (x_i,y_i), in which $R_{f,i2\text{-}D}$ can be expressed as $(R_{f,i1},R_{f,i2})$.

A very good method for selection of the appropriate mobile phase for 2-D TLC separations is with the use of the "Prisma" system.[2]

The indole group of compounds is conveniently divided into the so-called "simple" indole derivatives and the indole alkaloids, which often have complicated structures, and indole dyes. Thus it was demonstrated that not all compounds are completely separated by either the basic eluent, methyl acetate–isopropanol–25% ammonia (45 : 35 : 20, v/v), or the acidic eluent, chloroform–96% acetic acid (95 : 5, v/v). Therefore one combines the effects of both of these eluent systems in the 2-D TLC method; in this way, 14 simple indole derivatives and anthranilic acid can be separated. Compounds are separated into groups according to their polarities.[3]

The 2-D TLC was successfully applied to the separation of amino acids as early as the beginning of TLC. Separation efficiency is, by far, best with chloroform–methanol–17% ammonium hydroxide (40 : 40 : 20, v/v), *n*-butanol–glacial acetic acid–water (80 : 20 : 20, v/v) in combination with phenol–water (75 : 25, g/g).[4] A novel 2-D TLC method has been elaborated and found suitable for the chromatographic identification of 52 amino acids. This method is based on three 2-D TLC developments on cellulose (CMN 300; 50 μ) using the same solvent system I for the first dimension and three different systems (II–IV) of suitable properties for the second dimension. System I: *n*-butanol–acetone –diethylamine–water (10 : 10 : 2 : 5, v/v); system II: 2-propanol–formic acid–water (40 : 2 : 10, v/v); system III: *sec*-butanol–methyl ethyl ketone–dicyclohexylamine–water (10 : 10 : 2 : 5, v/v); and system IV: phenol–water (75 : 25, g/g) (+ 7.5 mg Na-cyanide) with 3% ammonia. With this technique, all amino acids can be differentiated and characterized by their fixed positions and also by some color reactions. Moreover, the relative merits of cellulose and silica gel are discussed in relation to separation efficiency, reproducibility, and detection sensitivity.[5] Two-dimensional TLC separation of a performic acid oxidized mixture of 20 protein amino acids plus β-alanine and γ-amino-*n*-butyric acid was performed in the first direction with chloroform–methanol–ammonia (17%) (40 : 40 : 20, v/v) and in the second direction with phenol–water (75 : 25, g/g). Detection was performed via ninhydrin reagent spray.[6]

The TLC method was developed for amino acids; therefore, in principle, it is equally applicable to peptides. Peptides, such as amino acids, are generally hydrophilic. There are, however, limits to this analogy. Dinitrophenylamino acid derivatives (DNP amino acids) and phenylthiohydantoin derivatives (PTH amino acids) are obtained when reaction of peptides or proteins with dinitrofluorobenzene or phenyl mustards are properly degraded.[7,8] Their separation from reaction mixtures and their identification are considerable practical importance because they constitute essential steps

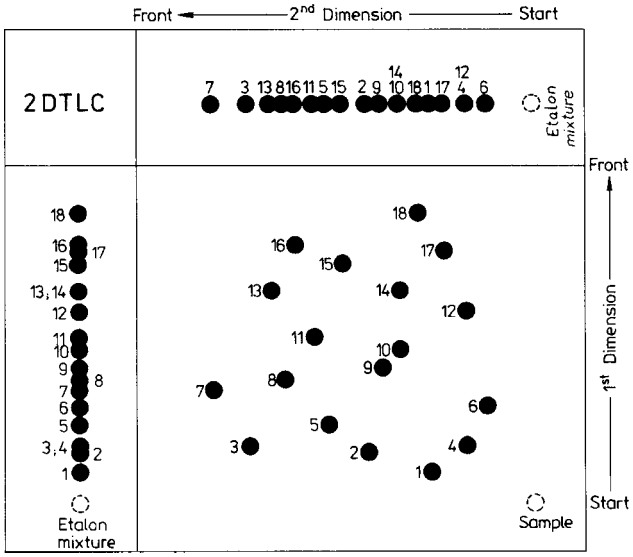

Fig. 1 Scheme of spot distribution on a 2-D TLC plate.

in the process of sequential analysis of peptide and protein structures. Generally, the run in the first direction is carried out in a toluene system. For the run in the second direction, there are many eluent systems that may be selected. Two-dimensional TLC was used to perform separation of DNP amino acids, using toluene as eluent for first direction and chloroform–benzylalcohol–glacial acetic acid (70 : 30 : 3, v/v),[9] chloroform–methanol–glacial acetic acid (95 :75 : 1, v/v), or benzene–pyridine–glacial acetic acid (80 : 20 : 2, v/v) as eluent for the second direction.[10] The majority of DNP amino acids are colored yellow.

The 2-D TLC separation of PTH amino acids may be performed with chloroform–methanol (90 : 10, v/v) and with chloroform-formic acid (100 : 5, v/v) as eluents in the first and the second developments, respectively.[11] There are many other systems of eluents that can be used to obtain good resolution. The chlorine/tolidine reagent is very useful for detection of PTH amino acids. An alternative is offered by fluorescence quenching.

A very complex mononucleotide mixture can be separated by 2-D TLC on poly(ethyleneimine)-cellulose anionexchange thin layers. After applying the nucleotide solution at the starting point, the chromatogram is developed in a closed rectangular jar by stepwise elution with LiCl solution of 0.2, 1.0, and, finally, 1.6 *M*. In order to remove LiCl, the plate is placed in a flat dish filled with anhydrous methanol. Then, the chromatogram is developed in the second direction with formic acid–sodium formate buffers, pH 3–4, by a stepwise elution with buffers of 0.5, 2.0, and 4.0 *M*. The complete resolution of a model mixture containing DPA, TPN, six nucleotide sugars, and 14 common nucleoside-5′-mono-, di-, and triphosphates takes less than 3 hr.[12]

The separation and identification of plant phospholipids and glycolipids was performed by 2-D TLC silica gel using chloroform–methanol–water (65 : 25 : 4, v/v) and diisobutyl ketone–acetic acid–water (80 : 50 : 10, v/v) as eluents for the first and the second dimensions, respectively.[13]

Amino-modified high-performance TLC (HPTLC) silica gel layers (NH_2 F_{254s} HPTLC) was used for identification of 13 amphetamine derivatives by unidimensional multiple development (UDM) in the 2-D TLC mode. The mobile phases used were ethanol–triethylamine–*n*-hexane (15 : 9 : 76, v/v) and acetone–triethylamine–*n*-hexane (23 : 9 : 68, v/v) in the first and the second directions, respectively. Because 1-D HP-TLC was not effective, UDM with the same solvent system and development distance and with two development steps was investigated. The resolution of separation was higher in the low hR_f compared to that predicted by the UDM theory.[14]

In the first direction, the development is isocratic; in the second direction, it is automated multiple development (AMD). The instrumental chromatographic method, AMD, provides a mean of normal-phase gradient developed in HPTLC. A maximum of 25 steps can be used to form an AMD gradient. The development distances increase as the solvent polarity is reduced. The plates are dried by vacuum between consecutive steps. The bands on the plate will be compressed by repeated developments, resulting in increased sensitivity and resolution. For the functional principle of the AMD device, one should consult Ref.[15] The developed distance was 8 cm. Isocratic TLC was performed with one typical eluent as the mobile phase in normal chambers previously equilibrated with the mobile phase. The AMD system was performed in a Camag device (Muttenz, Switzerland), but the gradient systems must have a different selectivity compared to isocratic development. The number of compounds separated by this method was greater than with isocratic TLC or with 1-D AMD.[16] The use of 2-D AMD with two gradients of different selectivities is a powerful method that can improve the separation of samples containing an unknown number of constituents in hydroalcoholic plant extracts.[17] The plant extract "fingerprint" is better for authenticity certification of the respective extract.

Two-dimensional TLC is a simple method that makes possible the rapid recognition of changes in individual components of a mixture. For this purpose, separations must be carried out in both directions, under exactly identical conditions. In such circumstances, a slight increase in resolution might occur because of an increase by a significant factor of the distance of migration of the zone which is a diagonal line ($Z_{f,2}$). However, this method of development indicates alterations of compounds during chromatography if the resulting spots do not lie on a diagonal line bisecting the plate. Between the first and the second developments, the compounds that suffer several structural transformations under physical agent (action of radiation) or from chemical reaction can be detected. This method can be used in photochemistry and stability control.[4]

TWO-DIMENSIONAL DEVELOPMENT ON BILAYERS

There are many reports concerning the placement of two adsorbents on the same plate.

An apparatus for simultaneously coating a plate with two adjacent layers of different adsorbents was accomplished by placing a plastic insert into a commercial spreader, thus forming two independent chambers. For this reason, combinations of two adsorbents, such as cellulose, silica gel, alumina, charcoal, silicic acid, magnesium silicate, etc. as a function of the sample were used. Then, the two eluents systems were optimized for the two development directions, e.g., 2-D separation of some ketones on a bilayer (charcoal/silicic acid) with benzene–ether–acetic acid (82:9:9, v/v) in the first direction (on charcoal) and with benzene–ether (85:15, v/v) in the second direction (on silicic acid).[18] In another paper,[19] the first adsorbent was silica gel (air-dried) and the second adsorbent was deactivated aluminum oxide. The same solvent system, toluene–ethyl acetate (3:1, v/v), was used in the two directions. In this condition, a mixture of 2,4-dinitrophenylhydrazine derivatives of hydroxycarbonyl compounds was resolved.

Silver nitrate-impregnated silica gel has also been used successfully in the separation of some classes of compounds that contain double bonds in their structures. Thus it was used in the separation of glycerides and isomers of unsaturated fatty acid esters. The 2-D TLC on adjacent layers of silica gel G and silica G impregnated with 5% of silver nitrate was used for development. The silica gel G layer covered a surface of 3×20 cm and the difference of the surface of 17×20 cm was covered with silica gel G impregnated with 5% $AgNO_3$. The first direction was performed on silica gel G with petroleum ether–diethyl ether (9:1, v/v) as eluent. The second direction was carried out on the impregnated silica gel G and developed twice with the same eluent as in the first direction. After the first direction, the mixture was fractioned into four groups of compounds (trialkyl glyceryl ethers, dialkoxy glycerides, alkoxy diglycerides, and triglycerides). After the second direction, each group was fractioned for another period into three or four compounds.[20] Thus the efficiency of the impregnated layer was demonstrated.

A method for the complete structural analysis of complex mixtures of methyl esters of saturated and unsaturated fatty acids has been performed by 2-D TLC. Adsorbent silica gel impregnated with a 10% solution of dodecane was used for the first direction with acetonitrile–acetone (1:1, v/v) as eluent. The silica gel for the second direction was impregnated with a 20% $AgNO_3$ and dipropyl ether–hexane (2:3, v/v) was used as eluent. In this way, complete separation of a standard mixture of the methyl esters of six saturated, nine monoethylenic, and three polyenic esters were achieved.[21]

The 2-D TLC on bilayers, silica gel for normal-phase (NP) and reversed-phase (RP), offer the special possibility to carry out two different separation processes on the same plate. Normal-phase chromatography can be performed in the first direction on silica gel; after the evaporation of the solvent, the plate was impregnated with paraffin oil dissolved in petroleum ether. After removal of the excess solvent, the plate was reversed phase developed in the second direction.

Another approach may also be performed by transferring the spots from one plate to another plate.[18] In such circumstances, the development in the first direction was carried out on a narrow 2 cm strip. After drying, it was clipped face to face to a 20×20 or 10×10 cm plate for development in the second direction. Close contact has to be maintained between the two layers for a proper development. In this case, the first plate can be used with a silica gel layer and the second plate can be used with a silica gel RP-C_{18} or vice versa.[22] In this way, the analysis of saponins in *Silene vulgaris* Gracke was carried out in the first direction on RP-18W HPTLC plates with 1.0% aqueous formic acid–methanol (30:70, v/v) as mobile phase and in the second, perpendicular, direction on silica gel Si 60 HPTLC with chloroform–methanol–formic acid–water (100:40:10:10, v/v) as mobile phase. With the use of 2-D TLC bilayers, the saponin mixture could be separated into 18 components, while conventional TLC could separate the mixture into nine components only.[23]

TWO-DIMENSIONAL SEPARATION BY TLC/ELECTROPHORESIS

Peptide maps of the tryptic digest of myosin have been performed on thin-layer plates (20×20 cm) by successive TLC and electrophoresis. In the first-dimension TLC with chloroform–methanol–ammonium hydroxide 34% (40:40:20, v/v) as eluent, the time was as long as 60 min. The second-dimension electrophoresis with pyridine–glacial acetic acid–water (1:10:489, v/v) buffer and 980 V, 30 mA current, the time was 1 hr. The peptide mixture is applied in amounts of 0.05 to 0.5 mg per peptide map.[24] In another paper,[25] electrophoresis was applied in one direction on buffered adsorbents, followed by chromatography in the second dimension. Here, phosphate esters were separated by TLC development twice with *n*-propanol–ammonium hydroxide–water (60:30:1, v/v), and electrophoresis was carried out in 0.28 *M* acetate buffer (pH 3.6), 1000 V, 35 mA, and 16 min.

CHROMATOGRAM EVALUATION

The best 2-D TLC separation is when all the components are separated and distributed on the entire surface of the chromatographic plate. The estimation of this separation can be made by an objective function. Generally, a good

agreement between visual evaluation of a chromatogram and computer evaluation using these objective functions was noticed.[26] On the other hand, a function is needed which can predict R_f value of the one-component function of the composition from the mobile phase.

There are programs for simulated chromatograms which are comparable to that obtained with experimental chromatograms.[26] Other details concerning the strategy of optimization of the mobile phase can be found in Ref.[22]

CONCLUSIONS

In conclusion, for difficulty separation problems the application of 2-D TLC is necessary because the power of 1-D TLC is often inadequate for complete separation of the complex samples with a high number of compounds. The main advantage of 2-D TLC separation process is that compounds are distributed widely over two-dimensional space with high zone (peak) capacity (~1500). The separation efficiency of 2-D TLC can be substantially increased in the future by a combination of the stationary and mobile phases of different polarity with automated multiple development.

Two-Phase Solvent Systems, Aqueous: CCC

Jean-Michel Menet
Aventis Pharma, Vitry-sur-Seine, France

INTRODUCTION

Aqueous two-phase solvent (ATPS) systems are made of two aqueous liquid phases containing various polymers. Such systems are gentle toward biological materials and they can be used for the partition of biomolecules, membrane vesicles, cellular organites, and whole cells. They are characterized by a high content of water in each phase, by very close densities and refraction indices of the two phases, by a very low interfacial tension, and by high viscosities of the phases. As a result, settling times are particularly long and may last up to 1 hr or longer.

The partition of a substance between the two phases depends on many factors. Theoretical studies have been carried out in order to better understand the reasons for the separation in two aqueous phases, thanks to the introduction of various polymers, and the role of various factors on the partition of the substances. However, no global theory is available to predict the observed behaviors. Hopefully, some empirical knowledge has been acquired which will help in the use of these unique solvent systems.

Various devices have been used for the partition of substances in ATPS systems. Countercurrent chromatography (CCC) has again revealed its unique features, because it has enabled the use of such very viscous systems at relatively high flow rates while obtaining a satisfactory efficiency and a good resolution for the separation. Many applications have been described in the literature for the use of ATPS systems with CCC devices.

ATPS SYSTEMS

For further information on ATPS systems and the partitioning, we strongly recommend the books by Albertson[1] and Walter et al.,[2] as reference books in this area.

Polymers Used for ATPS Systems

Many ATPS systems contain a polymer which is sugar based and a second one that is of hydrocarbon ether type. Sugar-based polymers include dextran (Dx), hydroxy propyl dextran (HPDx), Ficoll (Fi) (a polysaccharide), methyl cellulose (MC), or ethylhydroxyethyl cellulose (EHEC). Hydrocarbon ether-type polymers include poly(ethylene glycol) (PEG), poly(propylene glycol) (PPG), or the copolymer of PEG and PPG. Derivatized polymers can also be useful, such as PEG-fatty acids or di-ethylaminoethyl-dextran (Dx-DEAE).

Dextran, or α-1,6-glucose, is available in a mass range from 10,000 to 2,000,000. Dx T500 fractions, also called Dx 48 from Pharmacia (Uppsala, Sweden), are among the best known: their weight-average molecular weight (M_w) varies from 450,000 to 500,000. These white powders contain about 5–10% of water. PEG is a linear synthetic polymer which is available in many molecular weights, the most common being between 300 and 20,000.

Physical Properties of the ATPS Phases

Common characteristics of ATPS phases are their high content of water for both phases, typically 85–99% by weight and very close densities and refraction indices for the two phases. Moreover, both phases are viscous and the interfacial tension is low, from 0.1 to 0.001 dynes/cm. The settling times in the Earth's gravitational field range from 5 min to 1 hr.

PRACTICAL USE OF ATPS

Because ATPS systems are particularly suited for protein separations, many research workers have worked in this area and have tried to model their behavior when varying the composition of these systems. However, there are still no theoretical models to calculate, a priori, the partition coefficient of a protein for a wide range of molecular weights of polymers and concentrations in salts and polymers. However, it remains possible to have qualitative explanations of the role of key factors on the partition of the substances.

CHOICE OF THE ATPS SYSTEM

The general principle for designing an ATPS system is to try various systems, either made from two phases containing polymers or from one phase containing a polymer and the other component a salt. The nature of the substances to

be separated shall be taken into account: Fragile solutes may be denaturated by a too high interfacial tension, as encountered in aqueous polymer–salt systems. Some substances may even aggregate in an irreversible way, or be altered in other ways by their contact with some polymers or salts. Moreover, some substances can require the specific use of given salts, or pH, or temperature. When all the previous considerations have been taken into account, the partition coefficients can then be determined in test-tube experiments. Afterward, the composition of the phases can be adjusted.

Systems Suited for the Separation of Molecules

A simple way consists in testing two ATPS systems, dextran 40/PEG-8000 and dextran 500/PEG-8000, which lead to a relatively quick settling and allow reproducible results. For charged macromolecules, the two key parameters are the pH with regard to the isoelectric point of the product and the nature and concentration of the chosen salt. The composition in polymer has a smaller influence, except for some neutral compounds.

Systems Suited for the Separation of Cells and Particles

The main parameter for such separations is the difference of concentrations of each polymer between the two phases. If the concentrations in polymer are quite high, particles tend to adsorb at the interface of the two phases, without any specificity. For instance, all human erythrocytes adsorb at the interface of the dextran 500/PEG-8000 systems with respective concentrations higher than 7.0% and 4.4% (w/w).

The goal is to find a system close to the critical point (in the phase diagram) to achieve the separation, as the partition coefficients all become close to one. However, this requires increased attention to the experimental conditions in order to obtain reproducible results. If necessary, a change in the molecular weight of one of the polymers allows one to choose the aqueous phase in which the particle tends to accumulate. For instance, most mammalian cells partition between the interface and the upper-phase rich in PEG in dextran 500/PEG-8000 systems, whereas they partition between the interface and the lower phase rich in dextran 40/PEG-8000 systems.

ADJUSTMENT OF THE PARTITION COEFFICIENT

We note that the partition coefficient K is defined as the ratio of the concentration of the substance in the upper phase to its concentration in the lower phase. As cells and particles tend to partition between one phase and the interface, only molecules, such as proteins, are the subject of this section.

First, the partition coefficient of the substance should be determined in a standard system, such as dextran 500 (7.0%, w/w)/PEG-8000 (5.0%, w/w) with 5–10 mM of buffer added. Then, the following empirical laws can be used for the adjustment:

1. K is increased by diminishing the molecular weight of the polymer which is predominant in the upper phase (e.g., PEG) or by increasing the molecular weight of the polymer which is predominant in the lower phase (e.g., dextran). Reversing these changes decreases K.
2. K is significantly different than the unit value only if the concentrations of the polymers are high. K tends to the unit value when the concentrations of the polymers are decreased.
3. K can be adjusted by the addition of a salt, as long as the proteins are not close to their isoelectric points. For a negatively charged protein, K is decreased by following the series: phosphate $<$ sulfate $<$ acetate $<$ chloride $<$ thiocyanate $<$ perchlorate and lithium $<$ ammonium $<$ sodium $<$ potassium (for instance, lithium decreases K by a smaller amount than sodium). The influence of the nature of the salt may be amplified by an increase of the pH, which increases the negative net charge of the molecule. Positively charged proteins exhibit the opposite behavior. All these rules apply only for low concentrations of salts. Higher concentrations could, however, be used to favor the partition of the molecules in the upper phase.
4. Charged polymers can also be used; their influence is greater than that of the salts. The most common include charged polymers derived from PEG, such as PEG–TMA (trimethylamino) or PEG–S (sulfonate). Dextran can also be modified.
5. The derivatization by hydrophobic groups can also facilitate the extraction of molecules containing hydrophobic sites. The most common polymer is PEG–P (PEG–palmitate).

K depends on the temperature, but in a complex way, so that its use is difficult for common cases.

Optimization of the Selectivity

Some general rules apply to proteins in PEG/dextran systems and are summarized as follows:

1. The concentration of the polymer is important: Decreasing the concentrations brings the system closer to the critical point (in the phase diagram), smoothing K values toward the unit value and finally decreasing the selectivity.

2. The nature of the salt is important. The most important effects are encountered for $NaClO_4$, which extracts positively charged molecules in the upper phase, and tetrabutyl ammonium phosphate, which extracts negatively charged proteins in the upper phase.

APPLICATIONS

These aqueous two-phase solvent systems are more difficult to handle than organic-based solvent systems, so that the number of applications in the literature is quite small as compared to the other systems. However, these applications are really specific, quite often striking in their separation power, and they truly reveal some unique features of counter current chromatography (CCC).

Former applications of ATPS systems on CCC devices were gathered by Sutherland et al.[3] For instance, both toroidal and type J [also called a high-speed countercurrent chromatography (HSCCC)] CCC were successfully applied for the fractionation of subcellular particles. Using standard rat liver homogenates, plasma membranes, lysosomes, and endoplasmic reticulum were separated by a 3.3% (w/w) dextran T500, 5.4% PEG-6000, 10 m*M* sodium phosphate–phosphoric acid buffer (pH 7.4), 0.26 *M* sucrose, 0.05 m*M* Na_2EDTA, and 1 m*M* ethanol. Purification of torpedo electroplax membranes were also carried out, and the separation of various bacterial cells were also described, including the purification of different strains of *Escherichia coli* and the separation of *Salmonella typhirum* cells, using PEG–dextran ATPS systems. Moreover, these CCC devices were also applied to larger cells, such as the separation of various species of red blood cells.

In the same way, the separation of cytochrome-*c* and lysozyme was achieved in 1988 by Ito and Oka[4] using the type J (or HSCCC) device. The chosen ATPS system consisted of 12.5% (w/w) PEG-1000 and 12.5% (w/w) dibasic potassium phosphate in water. The two peaks were resolved in 5 hr using a 1 ml/min flow rate, but the retention of the stationary phase was as low as 26%. The limitation of this type of apparatus is definitely the low retention of the stationary phase for ATPS systems.

Several ATPS systems were also used with a centrifugal partition chromatograph (also called Sanki-type from the name of its unique manufacturer). Foucault and Nakanishi[5] tested PEG-1000/ammonium sulfate, PEG-8000/dextran, and other PEG-8000/hydoxypropylated starch on a test separation of crude albumin using a model LLN centrifugal partition chromatography (CPC) containing six partition cartridges. They demonstrated that the systems could be used with the CPC apparatus, but the efficiency was particularly low (due to very poor mass transfer) and the flow rate was quickly limited by a strong decrease in the retention of the stationary phase (and not by the back-pressure). Afterward, CPC was then not considered as really suited for ATPS systems.

The third type, which is close in principle to the type J high-speed countercurrent chromatography, was designed in the early 1980s and is named "cross-axis coil planet centrifuge." Such a new design has led to successful results with highly viscous polymer phase systems.[6] Indeed, it allows satisfactory retention of the stationary phase of ATPS systems, either in the polymer–salt form or the polymer–polymer form. Such an apparatus eliminates the main drawback of the previous CCC devices, as it allows one to maintain a good retention of the stationary phase with a sufficient flow rate to ensure an acceptable separation or purification time. Using such solvent systems, it has been applied to the separation and purification of various protein samples:

- Mixture of cytochrome-*c*, myoglobin, ovalbumin, and hemoglobin.[7]
- Histones and serum proteins.[8]
- Recombinant uridine phosphorylase from *E. coli* lysate.[9]
- Human lipoproteins from serum.[10]
- Lactic acid dehydrogenase from a crude bovine heat extract.[11]
- Profilin–actin complex from *Acanthamoeba* extract.[12]
- Lyzozyme, ovalbumin, and ovotransferrin from chicken egg white.[13]
- Acidic fibroblast growth factor from *E. coli* lysate.[14]

The cross-axis coil planet centrifuge, consequently, has been demonstrated to be particularly suited for the use of ATPS systems, leading to satisfactory retention of the stationary phase while keeping a sufficient flow rate of the mobile phase to limit the duration of the experiments.

Two-Phase Solvent Systems: Settling Time in CCC

Jean-Michel Menet
Aventis Pharma, Vitry-sur-Seine, France

INTRODUCTION

Countercurrent chromatography (CCC) is based on the use of two-phase liquid solvent systems. One of the characteristics of a two-phase system is its settling time, which is the time required for the mixture of both phases to be completely separated into two layers, usually in the Earth's gravitational field. The measurement of the settling time itself is helpful in preparing the experiment, for instance, when preparing the mobile and stationary phases in the same vessel. However, it is also intrinsically linked to the hydrodynamic behavior of the two-phase system and, therefore, to its physical parameters such as densities, viscosities, and interfacial tension. It was, therefore, used as a parameter for predicting the hydrodynamic behavior of various solvent systems in J-type CCC devices.

HOW TO MEASURE THE SETTLING TIME

The settling time depends not only on the nature of the solvent system but also on the experimental environment. As its definition is the time needed for the two phases to completely separate into two layers, the worker has to precisely choose the experimental conditions for the measurement. For instance, Ito[1] chose the following:

- Equilibrate the two-phase solvent system in a separatory funnel at room temperature.
- Separate the two phases.
- Take an aliquot of each phase.
- Put each aliquot in a graduated cylinder, which is then sealed with a glass stopper.
- Gently mix the two-phase system by inverting the cylinder five times.
- Place the cylinder immediately on a flat table in an upright position.
- Measure the time required for the two phases to settle.
- Repeat the experiment several times and take the mean time.

It is necessary to perform several experiments, as significant differences in the values are observed. A second set of tests may be performed by vigorously shaking the graduated cylinder five times and then averaging the times measured on several experiments.

The described experimental environment can be summarized as a 1 : 1 ratio of both phases, the choice of a graduated cylinder, room temperature, five-time inversion of the cylinder in a gentle or a vigorous manner, and the Earth's gravitational field. This should be only considered as an example of measuring the settling time, but what is important is to remain with a single definition in order to then use the resultant values in a comparative way.

VALUES OF SETTLING TIMES FOR USUAL CCC SOLVENT SYSTEMS

Ito has carried out the experiments, as described earlier, for 15 solvent systems. All mean values for gentle mixing and for vigorous mixing are gathered in Table 1 in the T and T' columns, respectively.[1]

The T and T' values are close; thus, they both can be considered as reliable measurements of the settling time for each solvent system. The values range from a few seconds (i.e., 3–5 sec) to about 1 min.

Other types of solvent system can be used in CCC. For instance, aqueous two-phase polymer systems (discussed elsewhere in this volume) are made of two aqueous liquid phases containing various polymers. Such systems are gentle toward biological materials and they can be used for the partition of biomolecules, membrane vesicles, cellular organites, and whole cells. They are characterized by a high content of water in each phase, very close densities, very low interfacial tension, and high viscosities of the phases. Settling times are particularly long and may last up to 1 hr. We refer the reader to the ATPS entry (see *Two-Phase Solvent Systems, Aqueous: CCC*, p. 2368) for further information on these systems.

HYDRODYNAMIC BEHAVIOR AND SETTLING TIME

The true purpose of Ito's study was to build a classification among the 15 solvent systems, based on their hydrodynamic behavior inside the column, measured through the retention of the stationary phase for various experimental conditions, on a J-type CCC device.

The first three solvent systems of Table 1 define the "hydrophobic" group, because they require the same

Table 1 Values of the settling times for 15 solvent systems.

Two-phase solvent system	Volume ratio	Settling time	
		T (sec)	T' (sec)
Hexane-water	1 : 1	<1	8
Ethyl acetate-water	1 : 1	15.5	21
Chloroform-water	1:1	3.5	5.5
Hexane-methanol		5.5	6
Ethyl acetate-acetic acid-water	4 : 1 : 4	15	16
Chloroform-acetic acid-water	2 : 2 : 1	29	27.5
Butanol-1-water	1 : 1	18	14
Butanol-1-0.1 *M* NaCl	1 : 1	16	14.5
Butanol-1-1 *M* NaCl	1 : 1	23.5	21.5
Butanol-1-acetic acid-water	4 : 1 : 5	38.5	37.5
Butanol-1-acetic acid-0.1 *M* NaCl	4 : 1 : 5	32	30.5
Butanol-1-acetic acid-1 *M* NaCl	4 : 1 : 5	26.5	24.5
Butanol-2-water	1 : 1	57	58
Butanol-2-0.1 *M* NaCl	1 : 1	46.5	49.5
Butanol-2-1 *M* NaCl	1 : 1	34	33.5

Note: T is the average value after five gentle mixings, and T' stands for five vigorous mixings.

given combination of two experimental parameters [choice of a lighter or heavier phase as stationary one, and choice of the pumping direction (i.e., from the head to the tail of the column or vice versa)] to achieve a good retention of the stationary phase and because their organic phase is hydrophobic. The last six solvent systems define the "hydrophilic" group, based on the same combination of two experimental conditions, which are reversed as compared to "hydrophobic" systems, because their organic phase can be considered as hydrophilic. There remains six solvent systems whose hydrodynamic behavior is more complicated, as it depends on the ratio of the radius of the coil on the rotation radius of the apparatus. They define the "intermediate" group.

Table 1 reveals that the classification may be defined from the values of the settling times. Indeed, the settling times of the hydrophobic solvent systems are the shortest ones, ranging from 1 to 20 sec, whereas those of hydrophilic systems are in the 25–60 sec range. Solvent systems belonging to the intermediate group exhibit moderate settling times, ranging from 6 to 30 sec.

Consequently, the measurement of the settling time for a solvent system which is different from the 15 studied is a simple way of roughly classifying it among the 3 groups defined by Ito and then to know the best experimental combinations to obtain the highest retention of the stationary phase on a J-type device.

Increasing the temperature or the concentration of a salt in the aqueous phase are known ways of reducing the settling time. This is interesting, as systems with low settling times are easier to handle and are characterized by a "hydrophobic" hydrodynamic behavior in J-type CCC devices, which leads to high values of the retention of the stationary phase.

HYDRODYNAMICS AND SETTLING TIME

Three theoretical parameters were introduced by Menet et al. in order to better understand the hydrodynamic behaviors of two-phase solvent systems.[2] We will not discuss, here, the capillary wavelength, as it only enables the description of the formation of droplets of one liquid in another liquid. The two other parameters were introduced because it appeared interesting to introduce other "theoretical" parameters to better describe the dynamic phenomena occurring inside a CCC column (i.e., after the formation of the droplet described by the capillary wavelength). Two of these are presented here, namely V_{low} for the fall of a droplet of the heavier liquid phase (lower) in the continuous lighter one (upper) and V_{up} for the rise of a droplet of the lighter liquid phase in the continuous heavier one, and are defined as follows:

$$V_{low} = \gamma \left(\eta_{up} \frac{2 + 3(\eta_{low}/\eta_{up})}{3 + 3(\eta_{low}/\eta_{up})} \right)^{-1} \quad \text{and}$$

$$V_{up} = \gamma \left(\eta_{low} \frac{2 + 3(\eta_{up}/\eta_{low})}{3 + 3(\eta_{up}/\eta_{low})} \right)^{-1}$$

with γ the interfacial tension between the two liquid phases, η_{up} the dynamic viscosity of the lighter phase, and η_{low} the dynamic viscosity of the heavier phase.

It is interesting to note that as neither V_{up} nor V_{low} depend on g, these velocities do not depend on the selected angular velocity of rotation. This is because the field intensity influences in the same way the size of the capillary wavelength and the sedimentation velocity of the droplet.

Menet et al. have computed the V_{low} and V_{up} values for the 15 solvent systems studied by Ito, along with 6 not previously studied [i.e., dimethyl sulfoxide (DMSO)–heptane (1:1, v/v), dimethyl formamide (DMF)–heptane (1:1, v/v), toluene–water (1:1, v/v), *O*-xylene–water (1:1, v/v), heptane–acetic acid–methanol (1:1:1, v/v) and chloroform–ethyl acetate–water–methanol (2:2:2:3, v/v)]. All the results have allowed them to define ranges of settling velocities linked to the hydrophobic, intermediate, or hydrophilic behavior of the solvent system. They have demonstrated the most reliable scale was that based on V_{up}, which is the description of the rise of a droplet of the lighter phase in a continuous heavier one.

It was further demonstrated that this theoretical parameter was the right one to use, as Menet et al. have carried out experiments on the evolution of the hydrodynamic behavior of the butanol-1–water system with the temperature.[3] They showed that the observed change in behavior was explained by an increase in the V_{up} settling velocity with the temperature, and, thus, a decrease of the settling time, explaining the "hydrophobic" behavior of the solvent system.

As a conclusion, the research worker can use the settling time for both purposes. One is the knowledge of the solvent system, mainly its ease of use, as long settling times complicate the use of the solvent system. The other one is to roughly predict the hydrodynamic behavior inside a J-type CCC device, in order to know the best combinations of some experimental conditions to obtain the highest retention of the stationary phase. For this purpose, the research worker may also use the theoretical settling velocity of a droplet of a lighter phase inside the heavier continuous liquid phase. It was demonstrated to be the better way of predicting the hydrodynamic behavior and, consequently, the best combination of experimental parameters for the highest retention of the stationary phase.

INTRODUCTION

Electrophoretic separation of double-stranded DNA (dsDNA) molecules, such as RFLP fragments or polymerase chain reaction (PCR) products, is usually accomplished in agarose, polyacrylamide, or composite agarose–polyacrylamide gels.[1] Agarose gels are extensively used to analyze DNA fragments from hundreds of base pairs (bp) to tens of thousands of bp, and polyacrylamide gels are regularly used for high-resolution DNA fragment analysis from several bp up to a thousand bp. In spite of numerous refinements in electrophoresis techniques during the past decade, agarose gel electrophoresis is still not efficient enough. The existing methodology requires multiple steps, such as gel casting, sample loading, staining, and imaging/documentation/data evaluation, making it very tedious and time-consuming because these tasks are not readily integrated and automated for highthroughput applications. Although several attempts have been made for automation, dsDNA fragment analysis in most laboratories is still done in a very conventional way: using submarine format agarose gel electrophoresis separation with ethidium bromide staining.[2] Some of the large, automated DNA sequencing systems are recently reported to be used for genotyping and STR profiling using cross-linked polyacrylamide gels and fluorescently labeled primers, and the configuration of these devices does not accommodate the use of agarose gels as separation medium.

DISCUSSION

Attempts to discover higher-resolution and faster electrophoresis separation techniques and media started in the 1960s, when miniaturized methods[3] were described as microelectrophoresis, but imaging technologies were not yet quite as adequate to be able to capture separations on such a minute scale. Later, polyacrylamide gels contained in glass capillaries were employed in order to separate both DNA and RNA molecules, but this progress was ultimately hampered by the inability to control extra-Joule heat. Recently emerging capillary-electrophoresis (CE) based methods are much less susceptible to the effects of Joule heat, due to the ability to dissipate heat via the large surface-to-volume ratios typical of narrow-bore capillary columns. Obtaining similarly high surface-to-volume ratios in planar-format electrophoretic systems require very thin layers, preferably reaching thickness in the capillary dimension (i.e., no greater than 0.25 mm).

The most recent advances in the electrophoretic separation of nucleic acids come from exploration of new separation matrices. Linear, non-cross-linked polymers, such as polyacrylamide, derivatized celluloses, and polyethylene oxides, have all been demonstrated to be effective in the size separation of biopolymers.[4] The advantages of these non-cross-linked polymers were proven almost entirely in high-performance CE applications;[5] however, it has been shown that very high-concentration non-cross-linked polymers can also be used in planar slab–gel format[6] for the separation of dsDNA molecules. Chemically modified agarose gels or composite agarose–non-cross-linked polymer gels capable of resolving differences of merely a few bases in DNA fragments of several hundreds of bases in length have also been developed.[7] The use of highly concentrated non-cross-linked polymers for DNA fragment analysis applications may be advantageous in several respects. First, it has been shown that non-cross-linked polymers may be supplied in a dessicated, dry form, providing a long shelf life.[8] Second, planar-form non-cross-linked polymer gels can be rehydrated to any of the range of final gel concentrations, buffer compositions, and/or ionic strengths. In addition to that, lower viscosity non-cross-linked polymers can be easily replaced in the separation platform; therefore,

cassettes supporting repetitive work with non-cross-linked polymers can be readily used with these matrices.

Visualization by covalent labeling of nucleic acids with fluorescent tags, such as fluorescein, tetramethylrodamine, Texas Red, and so forth, has been practiced for years.[9] This approach can be used for high-sensitivity DNA fragment analysis provided that the analyte is labeled by the appropriate fluorophore prior to the separation step. The approach reported in this work uses affinity binding (e.g., intercalation) dyes for *in migratio* labeling of the dsDNA fragments during the course of their electrophoretic separation. This method is beneficial in two aspects. First, unlabeled DNA fragments can be readily analyzed, because they become labeled during the separation process. Second, the complexation phenomenon usually increases the separation selectivity, resulting in a higher resolution.[10]

Large-scale, high-resolution DNA fragment analysis (e.g., mapping) requires an affordable, fully automated high-throughput agarose gel-electrophoresis based separation device that enables rapid, high-performance separations in a wide molecular-weight range. Here, we describe a system that greatly enhances the productivity of DNA fragment analysis by automating the current manual procedure and also reducing the separation time and human intervention from sample loading to data analysis.

SEPARATION PLATFORM

Fig. 1 shows the block diagram of the automated ultrathin-layer agarose gel electrophoresis system consisting of a high-voltage power supply (1); platinum electrodes (2 and 3); ultrathin layer separation platform with built-in buffer reservoirs (4), and a fiber-optic-bundle-based detection system (5). A lens set (7) connected to the illumination/detection system via the fiber-optic bundle, scans across the gel by means of a translation stage (6). A 532 nm frequency doubled Nd:YAG laser excitation source (8) and an avalanche photodiode detector (9) are connected to the central excitation fiber and the surrounding collecting fibers of the fiber-optic bundle, respectively. Interface electronics (10) is used to digitize the analog output of the detector and to connect the system to a personal computer. The separation platform also includes a positional heat sink holding the gel-filled cassette in horizontal position. This heat sink also eliminates local heat-spot-generated separation irregularities by means of homogenous dissipation of any extra heat over the gel surface during the separation. Three heating cartridges and a high-speed fan control the temperature (above ambient) of the separation platform at a preprogrammed level. The preheated (40–45°C) separation cassettes (18 cm × 7.5 cm × 190 mm) are filled with melted 2% agarose. After a few minutes of cooling/solidification, the gel-filled cartridge is ready to be used. The effective separation length of the agarose-gel-filled ultrathin-layer cartridge is 6 cm. The applied separation voltage is 750 V, generating 5–7 mA of current.

REUSABLE GEL CASSETTES AND MEMBRANE-MEDIATED SAMPLE LOADING

The reusable separation cassette has a flat bottom and top plate joined and secured in parallel, spaced 190 μm apart,

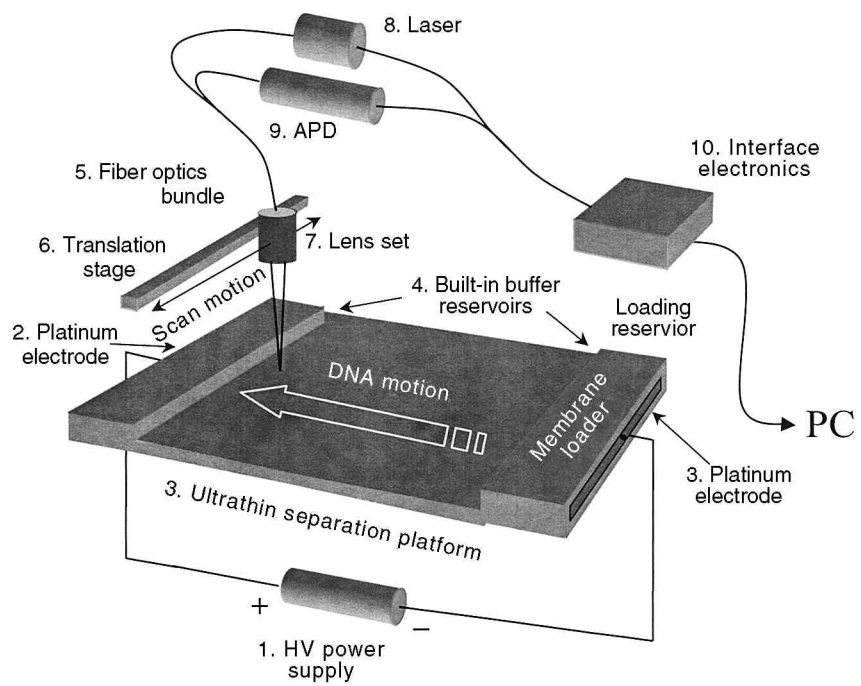

Fig. 1 Block diagram of the automated ultrathin-layer agarose gel electrophoresis system.

with buffer reservoirs permanently fixed to both ends. Two spacers run along the innerface edges of the plates to assure consistent distance between the glass plates (see the cassette in Fig. 1). For filling the cassette, a pump (e.g., large syringe) is used with a sealing applicator nozzle that matches to the top of the buffer reservoirs. To introduce the melted agarose gel into the cassette, the gel nozzle is placed at the top of one of the reservoirs, and the gel is pumped into the platform. The cassette should be preheated to approximately 40–45°C prior to the introduction of the melted agarose gel, in order to prevent premature solidification of the separation matrix. An appropriate amount of DNA staining dye [e.g., ethidium bromide (10–50 n*M*)] should be added to the melted agarose solution just before filling into the cassette.

Membrane-mediated sample loading provides a rugged, easy loading mechanism for ultrathin-layer electrophoresis gels, conveniently applicable for both vertical and horizontal formats.[11] The samples are spotted manually or automatically (robots) onto the surface of the loading membrane tabs, outside of the separation platform.The sample spotted membrane is then placed into the injection (cathode) side of the separation cassette, in intimate contact with the gel edge. By the application of the electric field, the sample components migrate into the gel. There is no need to form individual injection wells in the separation gel and loading is accomplished easily on the bench top. This novel sample injection method could be readily applied to most high-throughput gel electrophoresis based DNA analysis applications.

IN MIGRATIO FLUORESCENT LABELING

The use of fluorophore labeling of DNA fragments in gel electrophoresis expands the detection sensitivity and separation potential. Complex formation with fluorophores enables *in migratio* labeling [i.e., the migrating DNA fragments (negatively charged) complex with the countermigrating fluorophore intercalator dye (positively charged) which is dissolved in the separation matrix]. Using this method, high-sensitivity detection of the migrating DNA fragments as well as the high resolution of closely migrating components can be simultaneously obtained in a broad molecular-weight range. The appropriate concentration and type of the fluorophore complexing dye should be optimized for the wavelength of the excitation laser used in the illumination/detection system. For a 532-nm laser, ethidium bromide provides a good match (EX_{max} = 512 nm), but other high sensitivity dyes can also be used.[12]

AGAROSE-BASED REPLACEABLE SEPARATION MATRIX

In the ultrathin-layer slab–gel format described in this entry, dsDNA fragment analysis was accomplished using 2% agarose gel, filled into the separation cassette at 60°C and used for electrophoresis separation at room temperature. The advantage of employing liquefied agarose above its gelling temperature is that the gel can be easily replaced in the separation platform by simply pumping fresh melted gel into the cassette (i.e., it can be easily filled, rinsed, and refilled). The inner surface of the separation platform was coated with linear polyacrylamide in order to avoid the formation of an electric double layer and concomitant electro-osmotic-flow generation.[13]

MUTATION SCREENING BY ULTRATHIN-LAYER AGAROSE ELECTROPHORESIS

Screening of 10 patients for the dopamine D_4 receptor (D4DR) gene polymorphism was used as a model system to demonstrate the capability of this device.[14] D4DR is the major receptor type in the limbic system. Its gene contains a 48-base-pair sequence repeat in exon 3 with a variable (twofold to eightfold) repeat number in individuals. This polymorphism is believed to be associated with personality characteristics, such as novelty seeking and extravertation/introvertation. The fragment containing the polymorphic site was amplified by PCR using two primers that anneal upstream and downstream of this region, resulting in products different in length (359 and 475 bp) which were then separated by ultrathin-layer agarose gel electrophoresis (Fig. 2).

CONCLUSIONS

In this entry, we reported the use of an automated, high-performance DNA fragment analyzer for high-throughput applications, employing replaceable agarose gels in

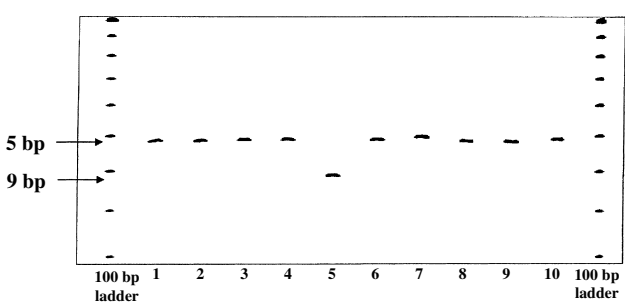

Fig. 2 Real-time electrophoretic image of the screening of 10 patients for the dopamine D_4 receptor (D4DR) gene polymorphism. Lanes 1–4 and 6–10 exhibit the 475-bp PCR product representing the common fourfold repeat alelle in homozygous form, whereas lane 5 shows a 359-bp fragment representing a patient homozygous for the twofold repeat polymorphism. [PCR was done in 35 cycles (95°C/min, 60°C/min, 72°C/min) using primers P1: 5′-GCG ACT ACG TGG TCT ACT CG-3′ and P2: 5′-AGG ACC CTC ATG GCC TTG-3′].

conjunction with a reusable ultrathin-layer separation cassette format in horizontal configuration. Sample loading onto the ultrathin separation platform was accomplished by membrane-mediated loading technology, which also enabled robotic spotting of multiple samples.[15] The sample loading membranes also allow bar coding for identification and cataloging purposes and can be stored for several days between spotting and analysis. The analyte DNA fragments were stained during the separation process by *in migratio* complexation with appropriate fluorophore intercalator dyes and detected by a scanning fiber-optic-bundle-based integrated laser-induced fluorescence–avalanche photodiode imaging system.

Cost-effectiveness for high-throughput applications was assured by simple replacement of the separation matrix by pumping fresh melted gel composition into the cassette for each consequent analysis. After a few minutes of solidification, the gel-filled cassette was ready to be used again. When compared to regular submarine agarose gel electrophoresis, the separation performance and detection sensitivity of this new method utilizing the ultrathin-layer electrophoresis platform were found to be far superior, allowing significantly faster and higher-resolution analysis (more than 10-fold). With full system integration and automation, a high-throughput automated dsDNA analysis system can be developed by simply coupling DNA sample preparation, PCR amplification, restriction digestion, sample loading, electrophoresis separation, data analysis, and map construction.

Unified Chromatography

Fernando M. Lanças
Institute of Chemistry of São Carlos (USP), University of São Paulo, São Carlos, Brazil

INTRODUCTION

Gas chromatography (GC) was the first instrumental chromatographic mode to be demonstrated, back in the beginning of the 1950s.[1] Golay[2] proposed, in the same decade, the miniaturization of the technique by introducing the so-called capillary gas chromatography (CGC). It took almost two decades (1960s and 1970s) to spread out worldwide, particularly due to the problems in handling fragile glass columns, however in the 1980s and 1990s, CGC became the preferred GC mode using wall-coated open-tubular (WCOT) columns.

Supercritical fluid chromatography (SFC) was first demonstrated in the 1960s,[3] but became popular only after the 1980s. Two different approaches were developed: one using packed columns of large inner diameter (I.D.) similar to those used in liquid chromatography (LC), and the other one using non-packed or open-tubular capillary columns similar to those used in CGC. Although open-tubular columns offer the same advantages over packed columns already perceived in CGC, packed columns are still, by far, used more than open-tubular columns in SFC.

LC was the first chromatographic mode to be developed almost one century ago.[4] Its instrumental version [usually referred as high-performance liquid chromatography (HPLC)] was developed during the end of the 1960s. Although its miniaturization has been discussed since then, its development has not followed the same successful route as CGC. The first step in the miniaturization of LC was the development of 1.0 mm I.D. columns,[5] nowadays usually termed "microbore columns." The next attempt in this direction was the introduction of capillary LC with columns of inner diameter smaller than 0.5 mm.[6] This approach is still far from being developed to a satisfactory extent in order to become as widely accepted routine technique as its GC counterpart (CGC). Although slower to develop as than it should, the miniaturization of chromatographic techniques is mandatory for the development of unified chromatography.

THE CONCEPT OF UNIFIED CHROMATOGRAPHY

Although the chromatographic techniques—namely GC, LC, and SFC—have been developed in a completely independent way, there are no theoretical boundaries between these techniques, as pointed out by Giddings in 1965.[7] Based on this concept Ishii later proposed and demonstrated in practice the idea of unified chromatography.[8] According to him,[8] it is possible to demonstrate different-mode separations (viz. LC, SFC, and GC separation) using a single chromatographic system. Further, the separation mode could be selected, changing the column temperature and pressure.[8] Shortly after the early experiments on unified chromatography by Ishii and coworkers, Yang proposed that the practice of GC, SFC, and microcolumn HPLC become more similar as the column diameter becomes smaller.[9] He also proposed that in this case, the injector, column, and detector may all be the same. In the same year, Bartle and coworkers pointed out that unified microcolumn chromatography allows high-resolution separations that make use of the same chromatographic components (injector, column, and detector) for capillary GC, microcolumn SFC, and HPLC.[10]

A few reviews on unified chromatography have been published since its initial development.[11–13] To those readers interested in these techniques, it is highly recommended to consult the pioneer work described in these reviews because there is also, in the literature, some confusion about unified chromatography and multidimensional chromatography, as will be discussed next.

UNIFIED CHROMATOGRAPHY OR MULTIDIMENSIONAL CHROMATOGRAPHY?

As discussed in the previous section, the concept of unified chromatography as agreed upon by the pioneers of this technique includes the use of the same chromatographic components (injector, column, and detector) performing GC, SFC, and LC separations. Because it is very common from the beginning, unified chromatography allows several combinations of chromatographic techniques, such as GC combined with LC, GC combined with SFC, SFC combined with GC, and so on. In this case, the separation is performed in such a way that the sample is introduced into the column and a fraction of it is eluted using one of the chromatographic modes (for instance, GC). After that, the conditions (in the single-substance mobile-phase mode) or the chemical nature (in the multisubstance mobile-phase mode) of the mobile phase is changed in order to perform another chromatographic mode to elute the analytes still retained in the column (for instance, using SFC).

In this example, the first step will allow the elution of the more volatile compounds in the GC mode while the less volatile will be eluted in the SFC mode. If these two modes

were not enough to elute all analytes, it would have been possible to later perform a LC separation using the same instrument with a fraction of the sample still in the column. This is the original concept of unified chromatography. This concept has been confused with multidimensional chromatography that uses different columns to perform the separation. In this case, several publications deal with techniques such as GC/GC, LC/LC, SFC/SFC, GC/SFC, LC/GC, and so on. In this approach, either the total or a fraction of the analytes leaving a chromatographic column is transferred to a second column in order to obtain another dimension of analysis (thus the name "multidimensional chromatography"). In unified chromatography, there is no column transfer (switch) and the second dimension of the separation is provided by the change in the mobile-phase characteristics.

TERMINOLOGY OF UNIFIED CHROMATOGRAPHY

Several terms have been used to identify this technique, including the following:

- Unified Approach to Chromatography
- Unified Capillary Chromatography
- Unified Microcolumn Chromatography
- Unified GC and SFC
- Unified Chromatography for GC, SFC, and LC
- Unified Chromatography

The last term is more general and appropriate to the actual stage of the technique.

INSTRUMENTATION

The instrumentation used in unified chromatography is based on the ones used for GC, LC, and SFC with minor modifications.

SINGLE-SUBSTANCE MOBILE-PHASE APPROACH

Using a single substance as the mobile phase makes the instrumentation much easier than a multisubstance approach. In this case, the instrument could be a simple modification of HPLC equipment to also deal with a supercritical fluid, as used originally by Ishii. In this case, simply adjusting the mobile-phase pressure and temperature in order to be either in the SFC or LC mode can make the selection of the chromatographic mode (LC or SFC). This is the easiest way to perform unified chromatography but also the more limited one because it is difficult to find a single substance that presents good behavior as a chromatographic mobile phase in the GC mode as well as in the HPLC mode.

MULTISUBSTANCE MOBILE-PHASE APPROACH

In this approach, the mobile-phase chemical nature is changed during the analysis when going from one chromatographic mode to the other. The elution of the sample components can start in the GC mode by introducing the mobile phase (usually a gas) into the column and providing the elution of the volatile compounds. After finishing this step the mobile-phase supply is interrupted and a second eluent (for instance, a supercritical fluid or a liquid) is introduced into the column in order to perform the second separation step. If a third mode is intended, the second eluent is interrupted and the third one is introduced into the column. As a consequence of this approach, a more complex and expensive instrument will have to be built, but results will be more interesting because each one of the modes will have the mobile phase optimized independently. While the first approach can be used for simple procedures, the multisubstance mobile-phase approach might be necessary for more demanding and complex ones.

SELECTED APPLICATIONS

Although unified chromatography still has to find its own applications niche, it has already been used for the analysis of a wide variety of samples from aromatic hydrocarbons, styrene, esters, phthalates, crude oil, amines, household wax, pesticides in vegetable oils and many others.[11,14–16] Its major application in the near future will certainly be centered in the analysis of complex samples such as environmental samples, biological fluids, forensic chemistry, and so forth. In this case, there is a need for more than one separation mode because the sample might contain volatile, semivolatile, and nonvolatile compounds of interest, thus requiring different chromatographic conditions.

PROJECTED ENLARGEMENT OF THE UNIFIED CHROMATOGRAPHY CONCEPT

When unified chromatography was first proposed, the chromatographic techniques were divided into GC, SFC, and LC. Nowadays, there has been a general acceptance that GC and LC are extreme mobile-phase conditions and that several intermediate conditions are possible. This includes solvated GC enhanced LC, and subcritical fluid chromatography, among other possibilities. Considering

this fact, we can expect that in the near future, all these modes will be performed in the same instrument designed for unified chromatography. This will not only enlarge the theoretical concept of this technique but will also broaden its application range.

LIMITATIONS

The major limitation of unified chromatography is that there is no commercial instrument currently available to those interested in the techniques. The few existing instruments are basically located in universities and are built in-house to attend to the purpose of the investigator. Another considerable limitation of the techniques is the difficulty in making columns that can show good performance in more than two chromatographic modes. WCOT columns made for SFC can usually operate well in the capillary GC mode; packed columns for SFC can operate in the LC modes. However, a column that operates in an optimized way in the GC and LC mode is still to be developed. Although some attempts have been made in research laboratories, they are not commercially available. Another difficulty is related to the identification mode. Nowadays, mass spectrometry (MS) is the most powerful detector for all chromatographic modes. However, the interfaces for GC/MS and LC/MS (the extreme modes used in unified chromatography) are completely different. More research has to be developed in this field in order to fulfill this gap in the identification of the peaks eluted in unified chromatography.

CONCLUSIONS

Unified chromatography is an infant technique that combines all chromatographic modes in just one instrument. Although it is fascinating from the theoretical point of view, in practice it still presents several limitations. A major one is the absence of commercial instruments, which hinders the development of further applications. It is expected that in the near future, the technique will be fully developed and the frontiers within the chromatographic world will be removed.

Uremic Toxins in Biofluids: HPLC Analysis

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

During the 1960s, target substances for removal in the blood of uremic patients were *small molecules*, such as urea, creatinine, and guanidine compounds. In the 1970s, "middle molecular substances," i.e., substances with molecular weights ranging from 300 to 5000 Da, were also included in the list of substances that have to be removed. Hemodiafiltration was developed as a more efficient method for removing middle molecular toxins, and separation and identification of such substances in uremic serum were actively attempted by many researchers worldwide.

UREMIA

The term "uremia" was initially proposed by Piorry and L'Heritier in 1840 to mean "urine in the blood." *Uremia*, or azotemia, is a condition resulting from advanced stages of kidney failure, in which urea and other nitrogen-containing wastes are found in the blood. Lethargy, mental depression, loss of appetite, and edema are some of the early signs of uremia, while subsequent symptoms include diarrhea, anemia, convulsions, coma, and a gray-brown coloration.

Treatment of uremia is usually performed with dialysis and/or renal transplantation. Since 1840, more than 2000 toxic substances were reported in uremic blood.[1,2]

UREMIC TOXINS

Uremic toxins are chemicals and waste products normally excreted by the kidneys; they are responsible for many of the signs of kidney disease. Blood urea nitrogen (BUN) is one of those substances, but it is not the only one. Early definitions (in 1978) proposed the following as minimal for the identification of uremic toxins:

1. They should be chemically identifiable and quantifiable in biological fluids.
2. The concentration in uremic subjects should exceed that in non-uremic subjects.
3. The concentration should correlate with specific uremic symptoms that disappear at the normal concentration.
4. Toxic effects in a test system should be demonstrable at the concentration found in uremic subjects.

Nowadays, this definition can be considered as classical. Because all of these criteria are rarely met simultaneously, the concept of uremic toxins has changed. In the new concept, substances that damage normal physiological functions, or interfere with physiological defense mechanisms in renal failure, have also been recognized as "uremic toxins." Some may play a role in the progression of renal disease, inducing uremic symptoms, and may contribute to dialysis-related complications.

As already mentioned, one way to treat uremia is through dialysis. Uremic toxins and excess fluid are removed by hemodialysis, which is accomplished by using a dialyzer. This is a convenient configuration, incorporating a semipermeable dialysis membrane with provisions for the flow of blood and dialysate on either side of the membrane. Blood is removed for purification from the patient's body via the blood access, pumped by the blood pump through blood tubing into the dialyzer, and is then pumped back to the patient. Dialysate of the desired chemical composition is prepared through the dialysate delivery system, by mixing water and concentrate in the appropriate ratio. Dialysate is pumped through the dialyzer to remove toxins and fluid crossing over from blood. An anticoagulant, such as heparin, is infused into the extracorporeal blood circuit to prevent blood clotting by a pump. Patients usually receive hemodialysis three times weekly for 4 hr each time.

Table 1 summarizes substances considered as possible uremic toxins. Fig. 1 illustrates the chemical structures of some of the most important uremic toxins that are determined by high-performance liquid chromatography (HPLC). In this entry, some of the most important uremic toxins are discussed (concerning their chromatographic determination).

DETERMINATION BY HPLC

Creatine–Creatinine

Molecules serving as effective biomarkers in clinical fluids are often low-molecular-mass metabolic end products. These small molecules can often be directly determined

Table 1 Possible uremic toxins.

Small water-soluble compounds
Guanidines
Asymmetric dimethylarginine
Creatinine
Purines
Oxalate
Phosphorus
Urea
Middle, large molecules
Advanced glycosylated end products
Parathyroid hormone
Oxidation products
Peptides (beta-endorphin, methionine-enkephalin, beta-lipotropin, granulocyte inhibiting proteins I and II, degranulation-inhibiting protein, adrenomedullin)
Beta 2-microglobulin
Complement factor D
Protein-bound compounds
Indoles
3-Carboxy-4-methyl-5-propyl-2-furanpropionic acid
Hippuric acid
Homocysteine
Indoxyl sulfate
p-cresol
Polyamines

in urine; however, their determination in plasma or serum often requires some form of protein removal. Creatinine is the most widely used clinical marker to assess renal function.

The reliable determination of uremic toxins, creatine, and creatinine in biofluids is a matter of great importance in clinical chemistry.

Creatine is present in muscle, brain, and blood and, although not present in large amounts in normal urine from adults, it is abundantly present in the urine of adults who have recently ingested creatine supplements. Ingestion of a creatine supplement has been shown to increase the level of phosphocreatine, and this has become extremely popular in recent years with many athletes who want to increase muscular power and to enhance their performance. Because of this, analysis for creatine has become more important in the clinical setting. Additionally, elevated serum concentrations of creatine can be observed in some cases of muscle catabolism such as primary myopathy, myositis, and muskelatrophie, as well as in the case of hyperthyroidism.

Creatinine is the end product of creatine catabolism. It is found in muscle tissue, blood, and urine as it is formed from the breakdown of muscle creatinine, and is proportional to the muscle mass. It results from the irreversible non-enzymatic dehydration and loss of phosphate from phosphocreatine, as shown in Fig. 2. Creatinine concentrations are very useful indices for evaluating glomerular filtration rate and, in general, are an important clinical marker of renal function.

Although creatinine concentration should be stable from day to day, it is a function of the amount of creatinine entering the blood from muscle, its volume of distribution, and its rate of excretion. Because the first two are usually constant, changes in the serum creatinine level would usually be a result of a change in the glomerular filtration rate (GFR). Abrupt cessation of glomerular filtration causes the serum creatinine to rise by 1–3 mg/dl daily. The blood urea nitrogen also rises with renal dysfunction, but is influenced by extrarenal factors as well.

Urine creatinine is used to adjust the values of urinary biological indicators; for example, creatinine measurements are necessary for correction of vanilmandelic and homovanillic acids, which indicate neuroblastoma and pheochromocytoma, when excreted in urine in abnormally increased concentrations. Ratios of vanilmandelic and homovanillic acids to creatinine have been utilized as a diagnostic index of these diseases.

Measurement of creatinine in serum and urine is routinely performed by photometric methods such as the Jaffé reaction, which is widely accepted and involves the formation of an adduct of creatinine with picric acid in alkaline solution, whose absorbance is measured at 500 nm. However, this method is unspecific and subject to perturbation by many interfering substances from endogenous and exogenous origins.

Therefore great efforts were undertaken to improve existing methods or to develop new measurement principles, using enzymatic and HPLC-based methods. Chromatographic techniques are attractive for clinical analysis because of their inherent ability to analyze multiple component biofluids and determine the analytes of interest with minimal interference from other species. Chemical methods give higher values because of the presence of endogenous and exogenous substances. HPLC methods for the determination of creatinine that can be found in literature involve ion exchange, ion-pairing, and reversed phase (RP). Most of these require deproteinization before analysis, but direct analysis of serum reatinine can also be achieved by column switching liquid chromatography (LC). Liquid–liquid extraction (LLE) for isolation of creatinine among other compounds has been reported. Capillary electrophoretic methods are also reported for the determination of creatine and creatinine.[3–9]

PURINE METABOLITES

Oxypurines: Allantoin, Uric Acid, Hypoxanthine, and Xanthine

Purines are metabolized in a series of reactions involving hypoxanthine, xanthine, uric acid, and allantoin as end products that are subsequently excreted in urine. Fig. 3 shows the metabolic pathways for xanthine. Measurement of urinary excretion of purine metabolites,

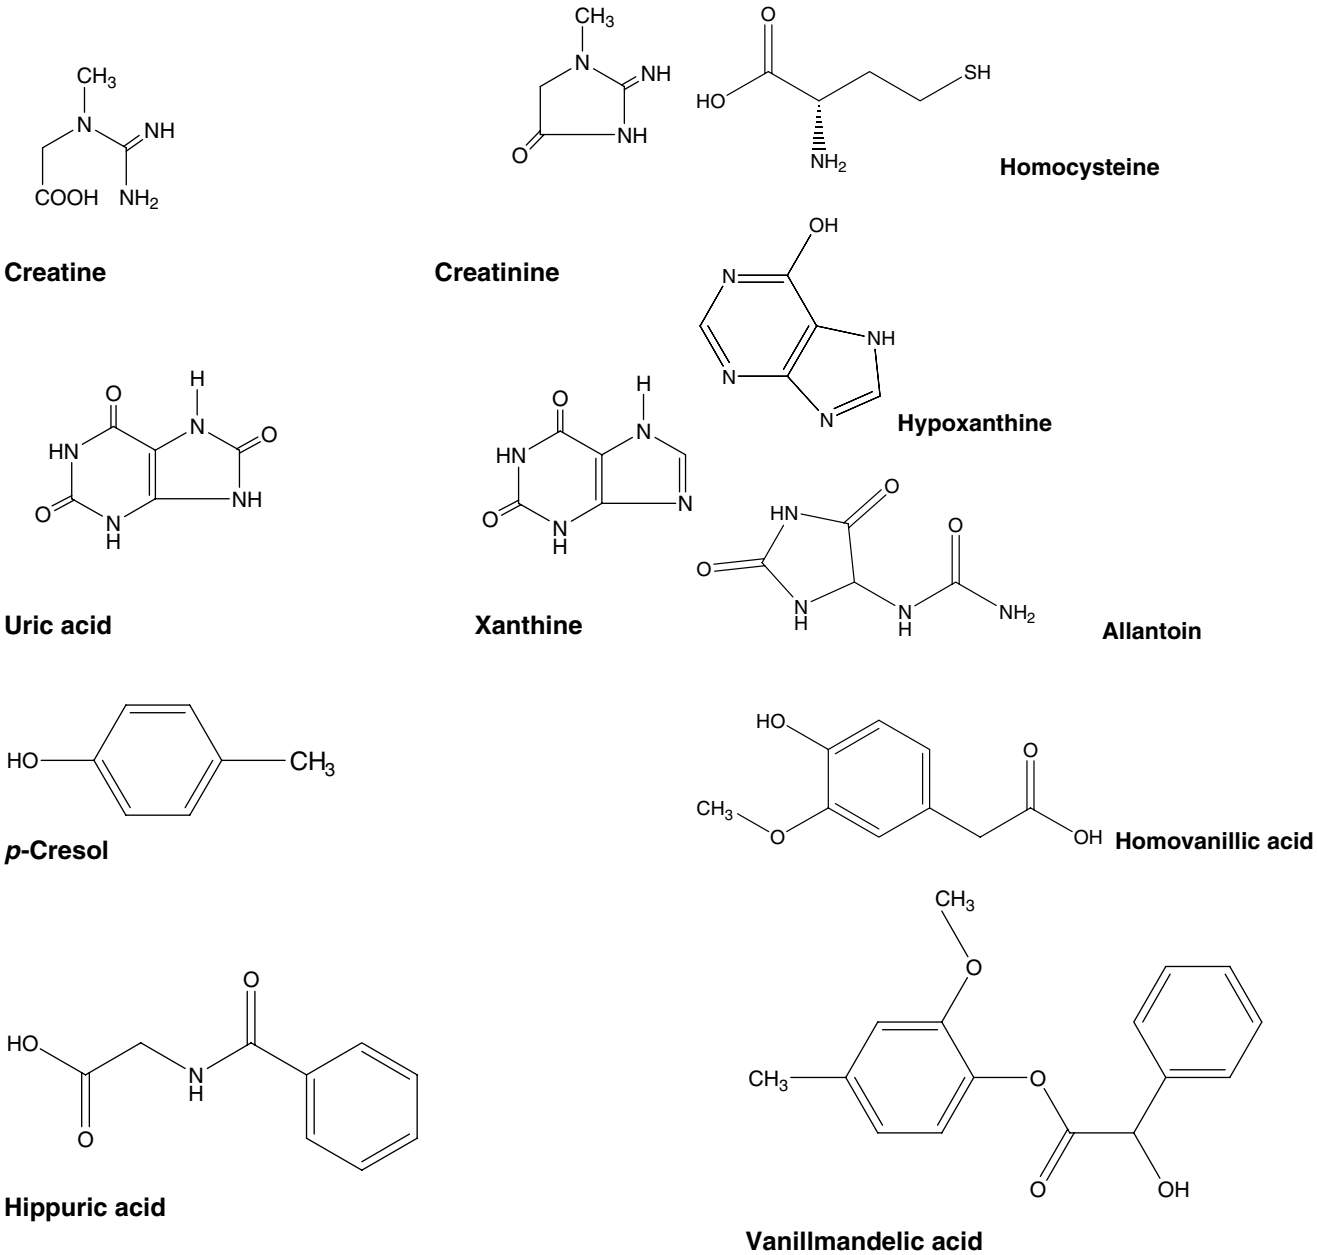

Fig. 1 Chemical structures of possible uremic toxins that are determined by HPLC.

primarily allantoin or, additionally, uric acid, xanthine, and hypoxanthine, has been proposed as a marker for microbial protein synthesis. The problem of non-specificity of the colorimetric assay for purine metabolites can be overcome by using a multitude of methods, with or without derivatization. HPLC determination of these compounds can be performed in urine samples directly after dilution.

Uric acid is a primary end product of urine metabolism in the kidney. Uric acid levels in human urine are like creatinine as an important parameter of renal function and a marker for renal failure as well as toxicity. As shown in Fig. 3, uric acid is the final product of catabolization of the purine nucleosides, adenosine, and guanosine.[10]

Xanthines, e.g., hypoxanthine and xanthine, are intermediates of the metabolism of adenine and guanine to uric acid and are, therefore, important analytes for diagnosis of certain types of metabolic disease.

Uric acid and xanthines are markers for metabolic disorders such as gout, Lesch–Nyman syndrome, and xanthinuria. Measurements of urinary excretion of purine metabolites, among them uric acid and xanthine, have been proposed as a marker for microbial protein synthesis. Their simultaneous determination is useful for diagnosis and treatment of hyperuricemia. In addition to xanthine and hypoxanthine, notable members of the xanthine class include caffeine, theophylline, and theobromine.[11–15]

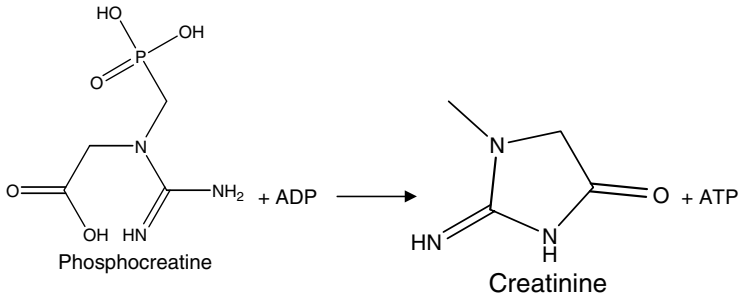

Fig. 2 Phosphocreatine metabolism.

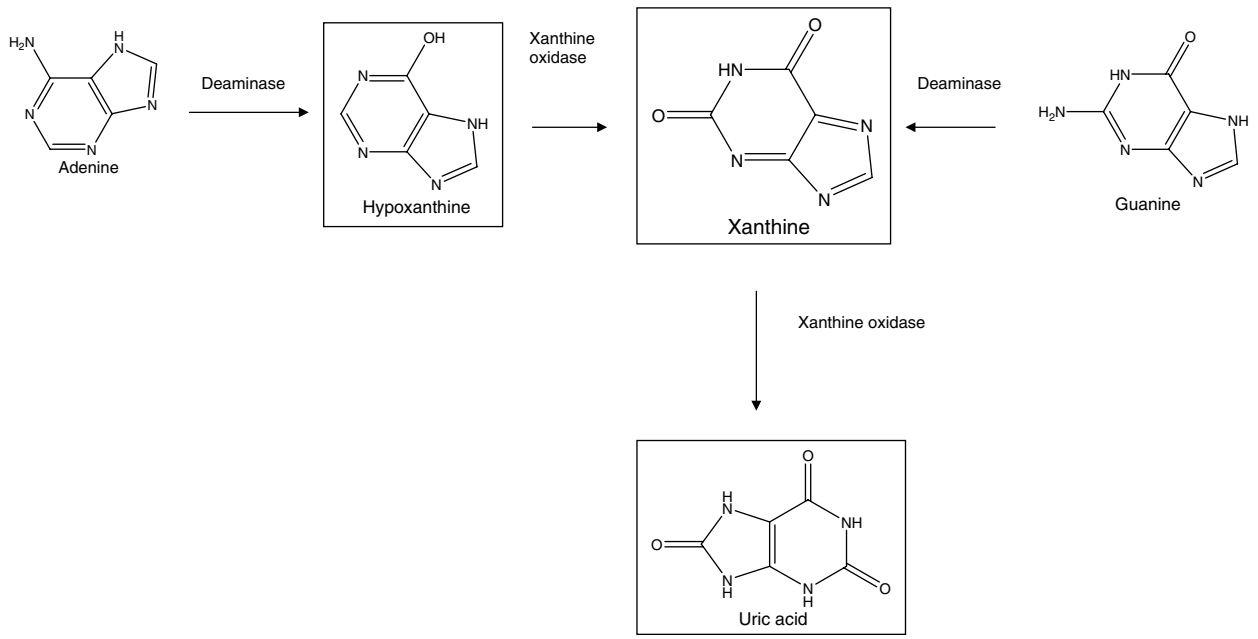

Fig. 3 Xanthine metabolic pathways.

Clearly, the determination of such compounds is crucial for diagnosis and monitoring of renal disease and metabolic disorders. The concentration of oxypurines in blood serum is among the most important parameters in biochemistry and clinical chemistry. Determination of uric acid is performed by enzymatic methods or colorimetrically by reduction of phosphotungstate.

The combination of HPLC RP C_8 columns with monitoring of the effluent at 205 nm provides an acceptable analytical tool for quantification of purine metabolites in the urine. Detection at short ultraviolet (UV) wavelengths up to 215 nm results in compromised method selectivity and, therefore, longer and more specific detection wavelengths were applied in recent methods. The combination of the direct separation and determination using a RP HPLC system, coupled with photodiode array detection, is found to be accurate and more precise and selective than previously published methods for the determination of purine metabolites in urine.

HPLC methods for the determination of uric acid found in literature include ion exchange, ion-pairing, RP, and size exclusion. Most of these require deproteinization before analysis, but direct analysis of serumuric acid was also successful by column switching LC.

In recent years, a number of methods based on HPLC, isocratic or gradient, have been reported for the quantification of allantoin and purine metabolites in biological fluids.

Various analytical methods for determining purine metabolites in biological samples, such as urine or blood plasma, have been described. These procedures are based mainly on separation by HPLC methods using RP C_{18} columns and monitoring at wavelengths ranging from 200 to 218 nm, or at 254 nm for compounds other than allantoin. The main advantage of these methods is that urine samples are analyzed directly, while the plasma samples only need acid deproteinization. Unfortunately, UV detection at short wavelengths (i.e., up to 218 nm) is not selective enough. Because allantoin is poorly retained on a C_8 column and has a very low molar absorptivity at wavelengths above 220 nm, allantoin may be converted to a derivative containing a chromophore group (Rimini–Schryver reaction). Some research groups removed the

Table 2 Chromatographic and sample preparation conditions for the simultaneous determination of creatine, creatinine uric acid and xanthine.

Chromatographic conditions
Mobile phase: 10 mmol/L KH_2PO_4
Analytical column: Kromasil C_8, 250 × 4 mm (I.D.), 5 μm
Pressure: 110–120 kg/cm^2
Flow rate: 0.8 ml/min
Detection: 200 nm

Sample preparation
Serum samples
1) 500 μl serum sample +1 ml acetonitrile to precipitate proteins
2) Centrifugation at 3500 rpm for 15 min
3) Evaporation of acetonitrile
4) Dilution of residual 10–20 times with deionized water
5) Direct analysis or spiking with stock solutions to apply standard addition technique

Human urine samples
1) Collection from healthy volunteers and storage at −20°C until analysis
2) Filtration through 0.2 μm membrane filters to remove cells and other particulate matter
3) Dilution, 400–500 times with deionized water
4) Direct analysis or spiking with stock solutions to apply standard addition technique

uric acid prior to the derivatization of allantoin; however, these methods are time-consuming and labor-intensive.

Simultaneous Determination of Creatine, Creatinine, Uric Acid, and Xanthine

Although several papers can be found in the literature dealing with the determination of single analytes or simultaneous determination of creatinine and uric acid, only a few have reported on the simultaneous determination of creatine, creatinine, uric acid, and xanthine in human biofluids. One of them reports about an HPLC method with UV detection permitting the analysis of human serum and urine for the determination of these substances in a single run. Low-wavelength UV detection is achieved at 200 nm using 10 mmol/L KH_2PO_4, as mobile phase, at a flow rate 0.8 ml/min and a Kromasil C_8, 250 × 4 mm, analytical column. Analysis is completed within approximately 8 min. Table 2 summarizes the chromatography and the sample preparation conditions. Fig. 4 shows a typical chromatogram obtained under the described chromatographic conditions.[16]

The limits of detection obtained by this method are 4 pg for creatine and creatinine, 20 pg for uric acid, and 6 pg for xanthine, while the limits of quantitation are 10 pg for creatine and creatinine, 60 pg for uric acid, and 20 pg for xanthine, when 20 μl are injected onto the column. A rectilinear relationship is observed up to 2 ng/μl for

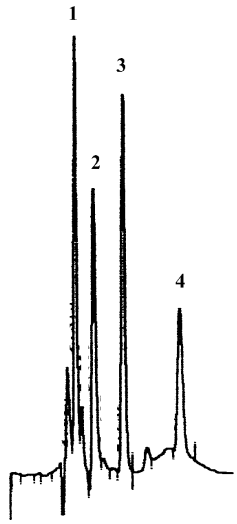

Fig. 4 High-performance liquid chromatogram of standard solution containing: 1) creatine, 2.631 min; 2) creatinine, 3.400 min; 3) uric acid, 4.645 min; and 4) xanthine, 7.014 min. Chromatographic conditions are described in Table 2.
Source: From http://www.embbs.com/cr/rf/rf3.htm[1]

creatine and creatinine, 12 ng/μl for uric acid and 5 ng/μl for xanthine.

The statistical evaluation of the method was examined by performing day-to-day ($n = 8$) and within-day ($n = 8$) calibration and was found to be satisfactory with high accuracy and precision results. Relative Standard Deviation (RSD) values were in the range of 0.4–4.3% for within-day measurements and 3.5–7.4% for day-to-day precision measurements.

This method was applied to serum and urine, simply after dilution. A typical chromatogram of creatine, creatinine, uric acid, and xanthine in serum and urine are

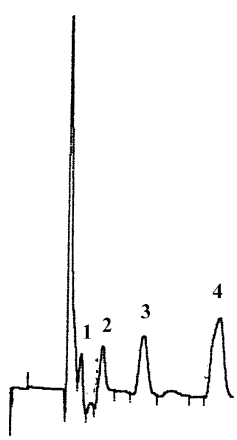

Fig. 5 High-performance liquid chromatogram of spiked human blood serum sample (after 20-fold dilution) containing: 1) creatine, 2.760 min; 2) creatinine, 3.615 min; 3) uric acid, 5.232 min; and 4) xanthine, 7.488 min. Chromatographic conditions are described in Table 2.
Source: From http://www.embbs.com/cr/rf/rf3.htm[1]

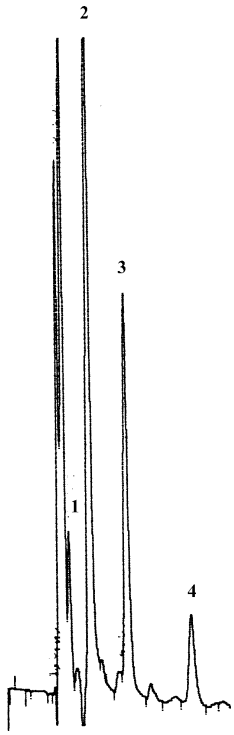

Fig. 6 High-performance liquid chromatogram of urine sample (after 400-fold dilution) containing: 1) creatine, 2.774 min; 2) creatinine, 3.675 min; 3) uric acid, 5.365 min; and 4) xanthine, 7.494 min. Chromatographic conditions are described in Table 2. **Source:** From http://www.embbs.com/cr/rf/rf3.htm[1]

shown in Figs. 5 and 6, respectively. The sensitivity of this method was high enough to determine the concentration of creatinine and uric acid in diluted serum (10- to 20-fold dilution) and urine (400- to 500-fold dilution) samples. Percentage recovery of analytes in spiked samples was in the range 91–105%. No interference was observed from endogenous compounds of human serum and urine. Correlation of analyzed samples using the developed method and conventional routine methods for creatinine and uric acid gave significantly similar results. The method appears to be a very useful tool for routine analysis of clinical samples, for simultaneous determination of creatinine, creatine, uric acid, and xanthine levels in serum and urine.

Phenol and Cresols

Urinary phenol, cresols, *p*-nitrophenol, and *p*-aminophenol are biological indicators of human exposure to aromatic hydrocarbons. Fig. 7 illustrates the scheme of phase 1 and phase 2 metabolism of inhaled benzene and toluene vapors, while Fig. 8 shows the metabolism of inhaled xylene and ethyl benzene vapors.

The determination of urinary cresols, particularly *O*-cresol, has been proposed as a biological monitoring method for toluene, as a fraction of the inhaled vapor is oxidized at the aromatic ring with the production of cresols.[17–19]

p-Cresol and hippuric acid are included among uremic toxins. *p*-Cresol (4-methylphenol) is a volatile, low-molecular-weight phenolic compound that is largely protein-bound, mainly to albumin, with partial lipophilic properties. It is related to several biochemical, biological, and physiological functions at concentrations currently observed in uremia.

p-Cresol can be considered as a prototype of protein-bound uremic retention solutes, with a protein binding of >99% in healthy subjects and approximately 90% in uremic patients. Several recent studies suggest that *p*-cresol interferes with various biochemical and physiological functions at concentrations currently observed in uremia. Concentrations of phenol and *p*-cresol in uremic serum are significantly higher than those in normal serum.

The present concept of dialysis focuses mainly on the removal of small water-soluble compounds, and the currently applied kinetic parameters of dialysis adequacy are also based on the behavior of water-soluble compounds. Nevertheless, many of the currently known biological effects in uremia are attributable to compounds with different physicochemical characteristics and, among these, protein-bound solutes may play an important role. Hippuric acid, homocysteine, and *p*-cresol are considered.[20]

Phenol and *p*-cresol noticeably accumulate in the serum of undialyzed and dialyzed uremic patients; they play a role in the development of uremic coma and defective platelet aggregation. They are synthesized in the small intestine from phenylalanine and tyrosine through 4-hydroxybenzoic acid and 4-hydroxyphenylacetic acid, respectively, by intestinal bacteria, as shown in Fig. 9. Aerobic bacteria tend to produce phenol from tyrosine, whereas anaerobic bacteria produce *p*-cresol. These phenols are absorbed from intestine and normally excreted into urine. In uremia, renal clearance of the phenols is impaired, leading to accumulation of the phenols in the blood. Compared to healthy controls, the serum *p*-cresol levels are 7–10 times higher in continuous ambulatory peritoneal dialysis patients, uremic outpatients, and hemodialysis patients.[21]

Only a few methods are available for the determination of *p*-cresol concentration in serum. In addition, these methods have only been used for the determination of total *p*-cresol. In particular, the evolution of free (non-protein-bound) *p*-cresol is of concern because, conceivably, this is the biologically active fraction. However, the concentration of free *p*-cresol is markedly lower than that of total *p*-cresol, in view of its important protein binding. Methods enabling the measurement of total and free *p*-cresol concentration in the serum of

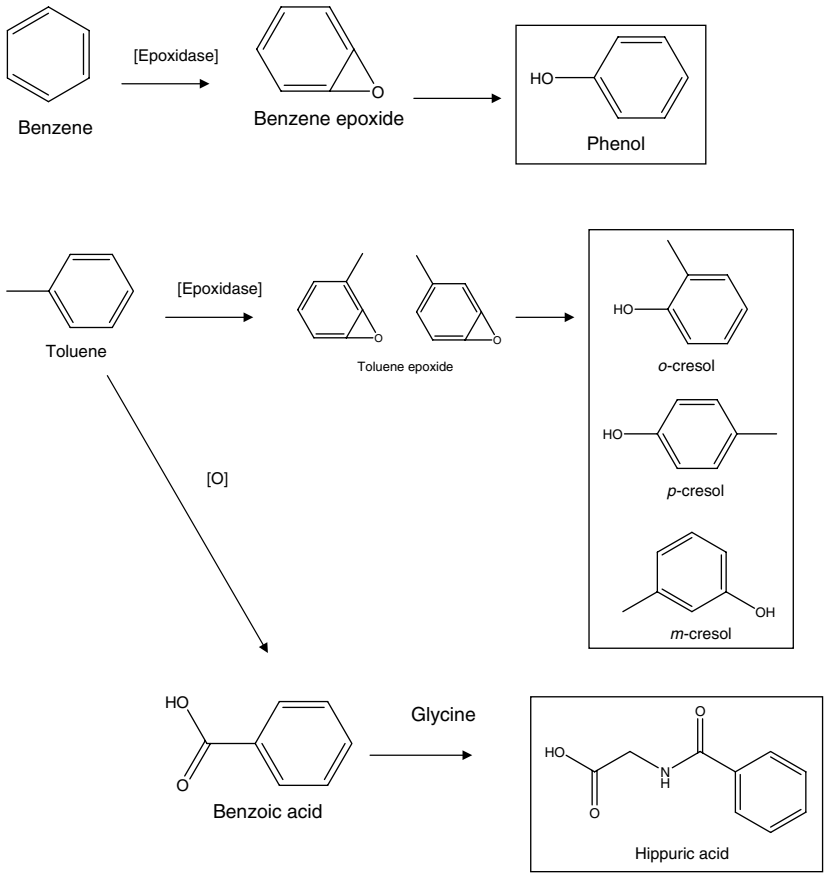

Fig. 7 Scheme of phase 1 and phase 2 metabolism of inhaled benzene and toluene vapors.

healthy controls and uremic patients are also reported in literature.

Deproteinization, extraction, and HPLC procedures are efficient, without interference of other protein bound ligands and/or precursors of *p*-cresol or phenol, via spiking experiments, and measurement of the UV absorbance over the 200–400 nm wavelength range.

HPLC methods can use fluorescence as a detector for quantifying serum phenol and *p*-cresol in uremic patients on hemodialysis.

Fluorescence detection at 284/310 nm (extinction/emission wavelengths) leads to a detection limit of 1.3 mmol/L (0.14 mg/ml for *p*-cresol). Identification of phenol and *p*-cresol may be confirmed by LC/MS. Because HPLC methods require only simple extraction, e.g., by ethyl acetate, and do not require further steps such as derivatization, they are simple and rapid compared with GC or GC/MS. Such methods are useful for monitoring serum phenols in dialyzed patients as an index of hemodialysis adequacy. However, the separation of the three isomers of cresol can only be performed by adding β-cyclodextrin to the liquid phase.

Hippuric Acid

Toluene and *o*-, *m*-, and *p*-xylene have been widely used, separately and as mixtures, as organic solvents, ingredients of thinners, and in the synthesis of chemicals. Toluene is widely used in industry as a replacement for the carcinogenic benzene, but toluene also exhibits considerable toxicity. In vivo, toluene is oxidized; the main metabolite in man is benzoic acid, which is then conjugated with glycine and excreted in urine as hippuric acid. Although hippuric acid is an endogenous metabolite commonly found in human urine, on exposure to toluene, the level is enhanced.[19–21] The three isomers of xylene in a mixture are commonly called "xylol." In vivo, these isomers are oxidized to isomeric toluic acids, then conjugated with glycine and excreted in urine as *o*-, *m*-, and *p*-methylhippuric acid.

Hippuric acid has been recognized as a potential marker of uremic toxicity in chronic renal failure. Additionally, hippuric acid and *o*-, *m*-, and *p*-methylhippuric acids are used as biological markers in studies of occupational exposure to diesel industrial solvents, because they show a good correlation with the level of exposure to toluene and xylenes. In urinary biological monitoring, expressing the amount of urinary metabolite per gram of creatinine has been used for spot samples of urine. This correction is thought to be particularly applicable for very concentrated and dilute samples. Therefore the biological exposure indices of urinary hippuric acid in toluene exposure, methylhippuric acid in xylene exposure, and mandelic acid in styrene exposure are expressed as metabolite concentrations in urine, corrected for creatinine.

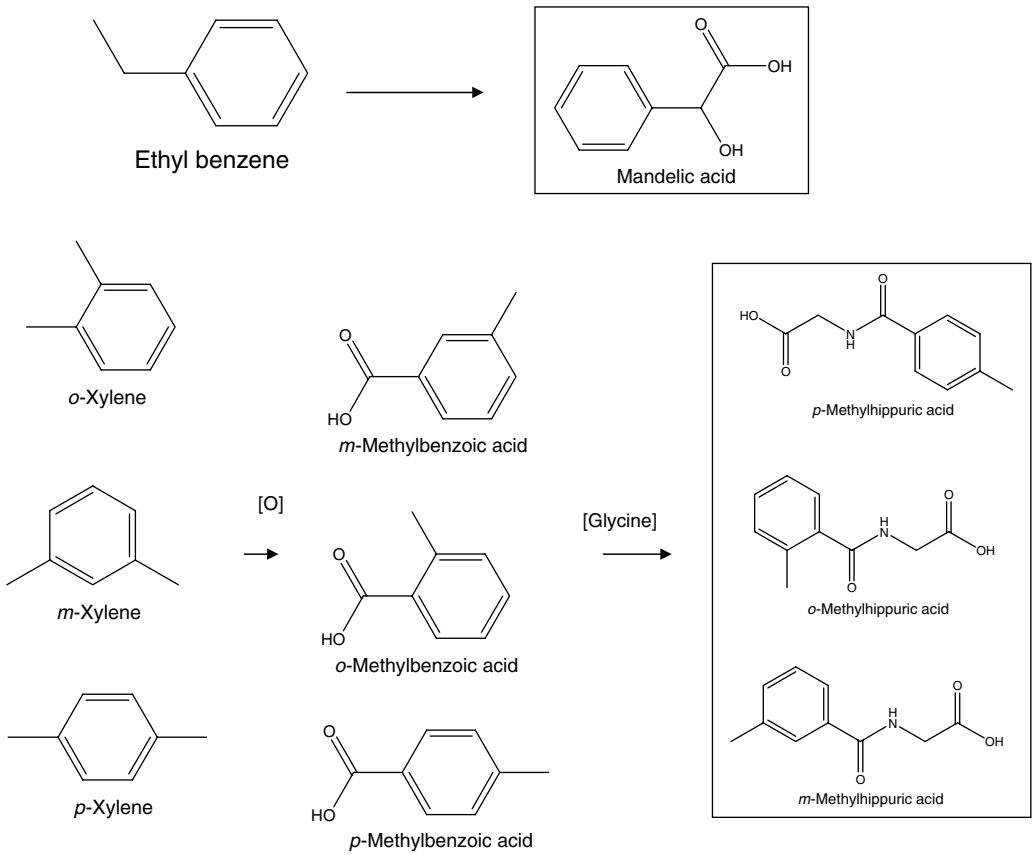

Fig. 8 Scheme of phase 1 and phase 2 metabolism of inhaled xylene and ethylbenzene vapors.

For the simultaneous determination of metabolite concentrations in the urine of workers exposed to aromatic solvents, HPLC has been widely used to obtain accurate and reliable results. Also, GC has been used for the determination of metabolite concentrations.

HPLC methods are considered by the National Institute for Occupational Safety and Health (NIOSH) to be the reference methods (e.g., NIOSH #8301). However, these methods cannot separately quantify each isomer of hippuric acid and methylhippuric acids.

GC methods are considered to be specific for determination of hippuric acid and methylhippuric acid, although they require a derivatization procedure with various reagents; for example, several investigators have used diazomethane; others have used trimethyl–silyl derivatives.

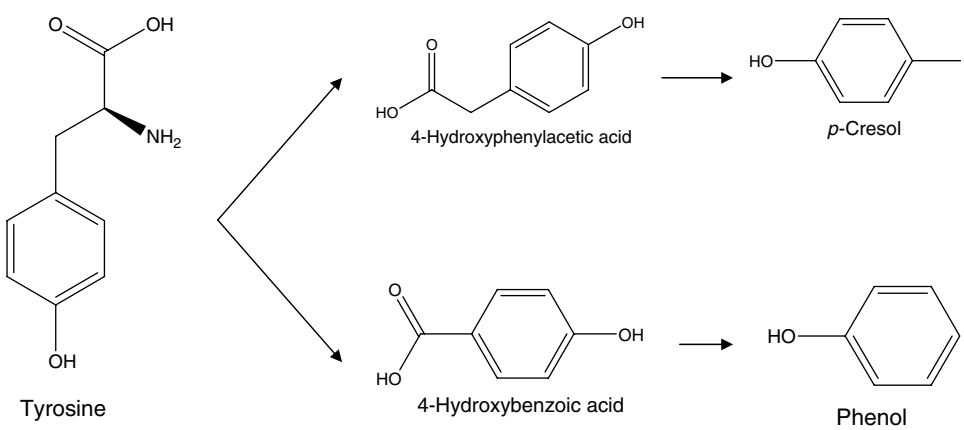

Fig. 9 Tyrosine metabolism.

RP–HPLC has been used without derivatization with ultraviolet or electrochemical detection. Liquid–liquid extraction can be performed, as well as solid-phase extraction (SPE), for sample preparation after acidification with HCl 1 mol/L (pH 1). Removal of the homovanillic acid from the variable salt concentration of the sample enhances the control of the ion exchange step. This is accomplished by SPE using a C_8 cartridge. This first stage also helps to reduce the number of anionic compounds from the matrix that will be loaded onto the strong anion exchange cartridge.[22] Recently, high-performance capillary electrophoresis (HPCE) has developed into a powerful analytical technique in diverse fields, and shows a high separation power with a short analysis time. In the field of occupational health, there are not many HPCE methods for the determination of metabolites in the urine of workers exposed to aromatic solvents, although HPCE methods have been used for hippuric acid (HA) in human urine and human serum, and for creatinine and uric acid.

Protein-bound uremic solutes play a role in the inhibition of drug protein binding. Substantial changes in protein binding of drugs occur during the progression of renal insufficiency. It has been suggested that hippuric acid in uremic ultrafiltrate is an inhibitor of theophylline protein binding. The inhibitory effect on theophylline protein binding of the deproteinized uremic serum has been shown to be higher than with ultrafiltrate ($p < 0.05$).[23]

Dose–response curves with the characterized compounds revealed that the most important role in binding inhibition could be attributed to hippuric acid. The identified uremic compounds are not entirely representative for the decreased protein binding of theophylline, indicating that additional factors than those identified in this study affect the protein binding as well.

Homocysteine

The absence of a chromophore for sensitive detection is a problem which is met with HPLC determination of these thiol analytes. However, two approaches are possible to resolve this point: 1) direct detection using electrochemistry, either amperometry on gold/mercury amalgamated electrodes or coulometry on porous graphite electrodes; 2) derivatization coupled with UV or spectrofluorometric detection. The derivatization reactions, either precolumn or postcolumn, involve different thiol selective reagents: ammonium 7-fluorobenzo-2-oxa-l,3-diazole-4-sulphonate (SBD-F), *O*-phthalaldehyde (OPA), etc.

RP–HPLC with fluorescence detection, after derivatization of plasma thiols with ammonium 7-fluorobenzo-2-oxa-l,3-diazole-4-sulphonate (SBD-F), is the most widely used method to determine total plasma amino thiols (cysteine, cysteinylglycine, and homocysteine). The time required for sample preparation (thiolic reduction, deproteinization, and precolumn derivatization with SBD-F) and for thiol derivatives separation is nearly 2 hr per sample.

Catecholamine Metabolites: Homovanillic and Vanillylmandelic Acid

Homovanillic and vanillylmandelic acids, the major metabolites of catecholamines, are often tested in urine for neurological diagnosis and for monitoring the response to therapy in diseases such as phaeochromocytoma and neuroblastoma.

Various HPLC methods have been described, mainly employing ion-pair RP chromatography, with electrochemical or fluorimetric detection, most of them including sample pretreatment with solid-phase or liquid extraction.

The determination of catecholamines requires a highly sensitive and selective assay procedure capable of measuring very low levels of catecholamines that may be present. In past years, a number of methods have been reported for measurement of catecholamines in both plasma and body tissues. A few of these papers have reported simultaneous measurement of more than two catecholamine analytes. One of them utilized lised UV for end-point detection and the samples were chromatographed on a RP phenyl analytical column. The procedure was slow and cumbersome because ofdue to the use of a complicated liquid–liquid extraction and each chromatographic run lasted more than 25 min with a detection limit of 5–10 ng on-column. Other sensitive HPLC methods reported in the literature use electrochemical detection with detection limits 12, 6, 12, 18, and 12 pg for noradrenaline, dopamine, serotonin, 5-hydroxyindoleacetic acid, and homovanillic acid, respectively. The method used very a complicated mobile phase in terms of its composition whilewhilst the low pH of 3.1 used might jeopardize the chemical stability of the column. Analysis time was approximately 30 min. Recently reported HPLC methods utilize amperometric end-point detection.[22,24]

CONCLUSIONS

Uremic toxins are chemicals and waste products normally excreted by the kidneys and are responsible for many of the signs of kidney disease. Since 1840, more than 2000 toxic substances were reported in uremic blood. Obviously, the determination of such compounds is crucial for diagnosis and monitoring of renal disease and metabolic disorders. The concentrations of several uremic toxins in blood serum and urine are among the most important parameters in biochemistry and clinical chemistry.

UV-Visible Detection Including Multiple Wavelengths

José Almiro da Paixão
Department of Nutrition, Center of Health Sciences,
Federal University of Pernambuco, Recife, Brazil

Abstract
This entry covers the principles of UV detection coupled with high-performance liquid chromatography (HPLC) as a separation and detection technique that combines specific parameters in order to meet suitable applications involving UV–Visible and fluorescence detectors. The main subtopics deal with the specific chemical and physical properties of compounds for ideal separation by identification and quantification procedures using UV–Visible in combination with HPLC, through single and program wavelength in distinct standards and matrices. In order to choose a detector system, the compatibility of selected compounds with a detection system emphasizing molecule benzoic acid (single λ) and fat-soluble vitamins (program wavelength) is evaluated. If the compound does not absorb roughly UV–Visible and non-fluorescent light without sufficient chromophore units, other properties should be chosen. The detection of UV–Visible can be performed using single λ, optimized through various channels or using program wavelength for chemical compounds with any similarity. The closest association between detection and quantification systems to complete the quantification procedure is also indicated. The outcomes of the principles of detection by UV–HPLC are outlined and discussed, especially those involving standards and complex matrices. Contemporary means of achieving complete validation are identified and discussed. UV–Visible detection always requires concise steps to ensure complete transferability between complex matrices.

INTRODUCTION

UV detection coupled with high-performance liquid chromatography (HPLC) is a separation technique that combines specific mobile and stationary phases to meet the requirements of a suitably selective, non-destructive detection system. Recent techniques of this kind have utilized the properties of both organic and inorganic compounds, thereby providing sufficient characterization for appropriate identification and quantification procedures. In order to improve the current performance of the separation technique and to provide compatible alternative procedures at specific stationary phases, further knowledge is needed about molecular mass, clearly established chromophore units, polarity, ionic or non-ionic charges, and the solubility index. In addition, parameters should be followed in analytical separation, such as capacity factor (k) between 1 and 10, resolution (R_s) greater than 1.5, separation factor (α) greater than 1.5, and symmetry factor ideally not more than 1.2.[1]

Of the non-destructive detectors, UV–Visible, fluorescence, light scattering and refractive index are frequently used for various biochemical, chemical, clinical, pharmaceutical, and nutritional applications, as well as in the analysis of supplements and functional ingredients. Of these detectors, candidates of universal grade but still poorly understood are refractive index and light scattering, which exhibit responses that vary according to assay conditions, chiefly those involving temperature conditions. On the other hand, detectors most commonly used in combination with HPLC are UV–Visible and fluorescence. HPLC coupled with mass spectrometry is sufficient for obtaining identification and quantification procedures, which simultaneously uses appropriate fragmentation rules.[1–4] However, care should be taken, especially in the case of quantification procedures, because HPLC is a destructive system. Nevertheless, it is worth completing the characterization of chemical compounds using HPLC.[1–4]

As far as UV–Visible detection is concerned, this system involves orientation (M $\Leftrightarrow$ M*) that indicates the level of energy (in electron volts, ergs, joules, or calories) certain isolated chemical compounds require to bring about excitation, resulting 1) in a spectrum (determining the maximum wavelength) when results have been obtained using spectrometry and 2) in peaks found using single λ and program wavelength (if multiple λ) when results have been obtained using chromatography, obeyed accurate correlation between concentration and units of absorbance.[1–4]

This entry deals with the chemical and physical properties of compounds that help in accomplishing ideal separation through identification and quantification procedures

particularly using UV–Visible in combination with HPLC and involving single λ and program wavelength in distinct standards and matrices—which are some of the subjects discussed in this encyclopedia.

CHOOSING A DETECTOR SYSTEM

To meet the requirements of ideal separation, identification, and subsequent quantification procedures, the compatibility between selected compounds and a detection system should be checked.

Whether a detector linked to an HPLC system is suitable is determined by the properties of compounds. If the compound does not absorb UV–Visible and non-fluorescent light, other properties should be chosen in combination with mobile-phase properties, such as refractive index and light scattering.[1–3] Alternatively, if the compound absorbs UV–Visible and fluorescent light, both properties can be measured using tandem detection.[1–4]

The detection system involves measuring different properties of the mobile phase or, alternatively, compound properties, such as differences in maximum wavelength at a particular molar extinction coefficient. The molecular and normal absorptivities thus serve as complementary criteria for identification and quantification using both HPLC and spectrophotometric techniques.[1–4] One specific disadvantage of this system is that various organic compounds absorb at similar λ values. If the compounds are soluble in an organic solvent and exhibit good compatibility, then specific mobile and stationary phases are usually recommended. On the other hand, if the compounds are volatile and do not absorb UV, then scatter radiation is recommended.[1,3,4]

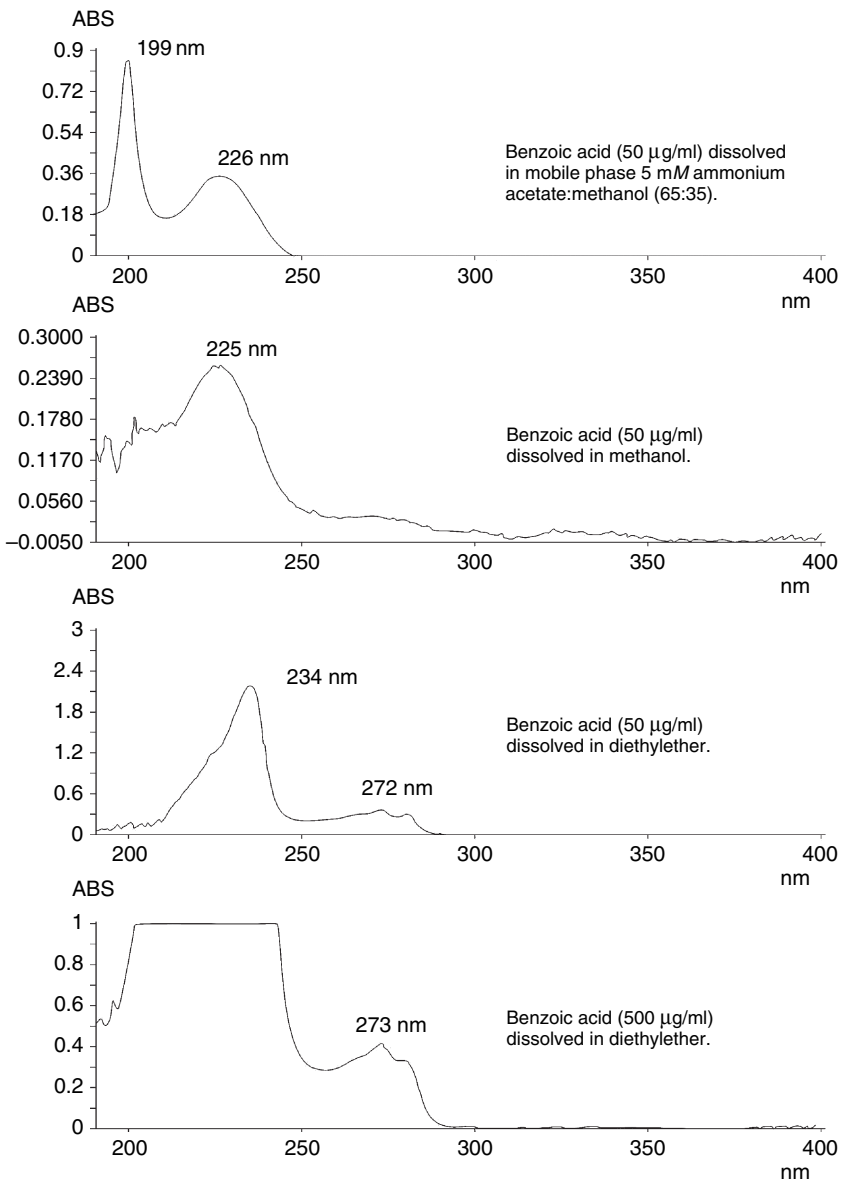

Fig. 1 Adjusting maximum λ wavelength through spectrophotometric assay before HPLC analysis.

If there is a real difficulty in selecting λ because of erroneous results in the literature or unreported results, operational conditions should be provided in such a way so as to set a maximum wavelength, taking into consideration the solubility of the compound in the mobile phase, a UV–Visible spectrum, and a particular composition of solvents as a point of reference. To demonstrate this, our research group conducted an experiment using benzoic acid (C_6H_5COOH), an ionic model compound that absorbs UV. Benzoic acid was well dissolved in an alcohol, diethyl ether, and alcohol-buffered media, whereas the mobile phase most recommended is methanol:ammonium acetate buffer 5 m*M* (65:35) in which solubility occurs easily.

The results of this experiment are shown in Fig. 1, which depicts how benzoic acid with the same concentration (50 μg/ml) performs well in particular solvent systems. It was, of course, to be expected that each solvent interferes with absorption, suggesting that it is also a good test for estimating the solubility index when for each solvent maximum wavelength varies with units of absorbance.

The detection of UV–Visible can be performed using single λ optimized through various channels (usually of 2–8) or, alternatively, using program wavelength (if multiple λ) for chemical compounds with any similarity, according to the functional group, such as benzene compounds with aldehydes, acids, alcohols, olefins, hydrocarbon chain, and others. If fluorescence is used, particularly for compounds derived from a reaction or originated directly from structural clusters, a different λ excitation or λ emission can be programed over time using the appropriate channel. Therefore, programing wavelength for UV–Visible and fluorescent light detection can alternatively be combined with pumps to achieve better performance of the mobile phase using reversed-phase and normal-phase HPLC. This removes specific effects of the mobile phase by carrying out baseline correction for each detection system.[1–4]

To select the ideal λ, chromophore units of a particular compound need to be well recognized, such as conjugated dienes coupled to an acid group ($\sigma \rightarrow \sigma^*$ and $\pi \rightarrow \pi^*$, respectively), since these are associated with electron valences C=C, C–C, C=O, particularly those involved in the benzoic acid molecule.[1,3,5,6]

For comparative measurements, the spectral index for UV–Visible accompanied by the Merck solubility index data needs to be established. If these values cannot be found in the literature, it is usually recommended to take a spectrum using a spectrophotometer or, alternatively, using an HPLC–diode array detector. There are two ways of combining this information to achieve a better quantification system by adjusting distinct channels: single λ is recommended when only one compound is used, and program wavelength is recommended for any series of chemical compounds with certain similarities, requiring multiple channels.[1–3,5–7]

PRINCIPLES OF UV–VISIBLE DETECTION

The relationship between energy (E, electron volts) and λ, $E = h\nu/\eta\lambda$, produces a response to the detection criteria, giving an direct relationship between energy and frequency (ν) associated with the particular spectral refractive index of solution (n) resolving main bands around maximum wavelength and absorption coefficient. These two criteria are used as detection principles for obtaining identification and quantification procedures by way of a linear response range, using any mode of regression (linear and non-linear effects) analysis coupled with spectrophotometric and HPLC assays. As compounds dissolve easily below a concentration of 10 m*M*, they are particularly suitable for chemicals with a molecular mass of less than 2000 Da.[1,3,4]

The chromophore units consist of a series of chemical compounds that produce molecular excitement at an appropriate energy level (electron volts) and a certain frequency (ν), causing the excitation of the molecule from a base level (M) to an excited level ($M + h\nu \Rightarrow M^*$). Returning of the molecule to the same energy level ($M^* \Rightarrow M$) is demonstrated in the form of spectral bands in which chemical groups roughly correspond to the spectral plots of wavelength vs. units of absorbance. Because this system produces heat, there is no need for any relaxation mechanism as required for the fluorescence detector.[1,3,4]

Various types of chemical changes at the valence stage of molecules that occur in the spectral mode involving the UV–Visible spectrum are as follows: η (non-ligands), σ, and π linkages that cause excitation; heteroatom carbon chains (–C≡O–); carbon–carbon chains (–C–C–); and unsaturated carbon chains, such as conjugated dienes (–C≡C–) and trienes (–C≡C–), plus amidines (–C≡N–) and nitriles (–C≡N–). The main transitions usually involve *d* and *f* orbitals and electron charge transfer. Therefore, the level of absorption of various chromophore units is suitable for defining structural properties using conjugated series of units. The UV–Visible detection is the most commonly used method, although a sufficiently accurate chemical characterization has not yet been achieved mainly because of the poorly defined rules that link most organic compounds that absorb at 190–800 nm.[1,3,4]

The maximum wavelength criterion can be adequately defined as the level of energy that excites molecular orbits, bringing the electron valences to a transitional level and returning to the same baseline energy level, in turn giving rise to particular spectral bands between 190 and 400 nm (if UV mode) and between 400 and 800 nm (if visible mode). This allows for the characterization of both organic and inorganic chemical

compounds. An adequate identification requires other techniques to confirm the result, such as infrared (0.8–300 μm), scatter light, and nuclear magnetic resonance, which are comparatively non-destructive methods that produce an accurate characterization of distinct chemical compounds.[1–4]

HPLC coupled with a mass detector has been shown to be suitable for determining minor differences in molecular masses, and thus can satisfactorily replace the UV–Visible detection method. In this destructive detection system, ideal separation (resolution below 1.5) is not required for completing the validation of identification and quantification procedures. However, the HPLC–mass-mass technique is not cost-effective and is more suitable for research centers. However, at present, the HPLC–UV technique is easily affordable in both developed and developing countries.

Maximum wavelength is a suitable criterion for quantification because the main response, concentration vs. units of absorbance, depends on chromophore units and the molecular absorption coefficient. The HPLC equipment is usually linked to software that programs various channels of signal output in order to select the best maximum wavelength, which is usually not known. However, if it is well known then various channels can be used for evaluation of the absorbance ratio, which is an additional criterion for the identification procedure involving comparative measurements using ultrapure analytical standards and real samples. This topic is discussed in detail below in the section on "Identification and Quantification Procedures Using Distinct Standards."

Fig. 2 demonstrates the main changes brought about by the absorbance ratio at $\lambda = 226$ nm (Channel A), $\lambda = 235$ nm (Channel B), and other λ for a single-compound detection system. Therefore the response of standard maximum wavelength using an HPLC technique is provided if is confirmed by a suitable spectrophotometric assay for adjusting maximum value. In this experiment, the benzoic acid standard gives an absorbance ratio of about 1.15, rendering maximum wavelength = 226 nm. This value is appropriate for use in comparing results of complex matrices, such as foods, animal feed, and drugs, and has been established as a specific reference value for unknown samples and analytical standards.[2,5–10]

The multipoint concentration varying from nano- to micrograms in quantities allows for the determination of a concentration range that lies within the minimum limits of detection (LOD) and maximum limits of quantification (LOQ)—both detection and quantification being performed using the HPLC assays. The compounds with low molar absorption (below 100 moles/L/cm) produce a narrow range of quantification, while those with medium-to-high absorption (100–1000 moles/L/cm) give better results. Besides, higher concentrations (more than 10 m*M*) usually produce overloaded peaks, reflecting the extra-polation of the column capacity (k) and hence non-ideal conditions for adequate quantification. An example of this case, particularly concerning partial validation, is depicted in Fig. 2.[1–4]

Any quantitative experiment at a particular λ (obtained from an HPLC technique and confirmed by a spectrophotometer) and absorbance ratio should be confirmed after a blank run of the mobile phase; this is illustrated in Fig. 3. Non-ideal blanks always exhibit accentuated baseline drift. This requirement is sufficient to provide analytical reliability in terms of the basic criteria for the determination of LOD and LOQ in order to validate the procedure. In addition, increase in units of absorbance from 1 to 2000 milliunits depends on an isolated threshold. If the solubility of the solvents involved in the mobile phase is good, then care should be taken with maximum wavelength when minor changes are performed using both HPLC and spectrophotometric assays.

Fig. 4 shows that benzoic acid depends on the pH of the ammonium acetate/methanol buffer (pH 4.4–5.1), providing effective reduction for a particular separation (retention time decreased from 8.0 to 3.4 min) in addition to decrease in asymmetry (2.32 to 1.81). The main effect on absorption, including that affecting the separation property, is as yet unknown. The probable explanation is that the absorption coefficient tends to decrease during the ionic phase and that the intrinsic relationship is demonstrated by the pH of the medium. The mobile and stationary phases for ideal separation that provide the best characterization of interaction are as yet unknown, mainly because the asymmetry is too large, as can be seen in Fig. 4. It has been assumed that a particular composition of the mobile phase interferes with both the absorption coefficient and the adjusted retention time (k).

When a spectral plot is not available, the absorbance ratio method is a satisfactory method for characterizing a real sample, using both spectrophotometric and HPLC assays. In addition, better performance needs to be achieved in carrying out advanced experiments, such as solid-phase extraction and other purification techniques coupled with HPLC quantification, in order to improve the separation properties.[1,3,4]

To improve any quantification system, it should be established that all points on the standard curve are injected in a similar loop according to rising or random order, and at least five points should be traced between minimum (LOD) and maximum (LOQ) concentrations. After defining the linear range response for particular compounds, a comparative analysis should be carried out for a similar group of samples and products in accordance with the regression analysis ($R^2 \geq 0.99$). For example, foods and animal feed having differences in lipid and water content and samples exploiting natural differences should arrive differently at this single identification and quantification procedure.[1–9]

An analytical approach has been developed that determines fat-soluble vitamins[2,7–10] in order to satisfy the ideal

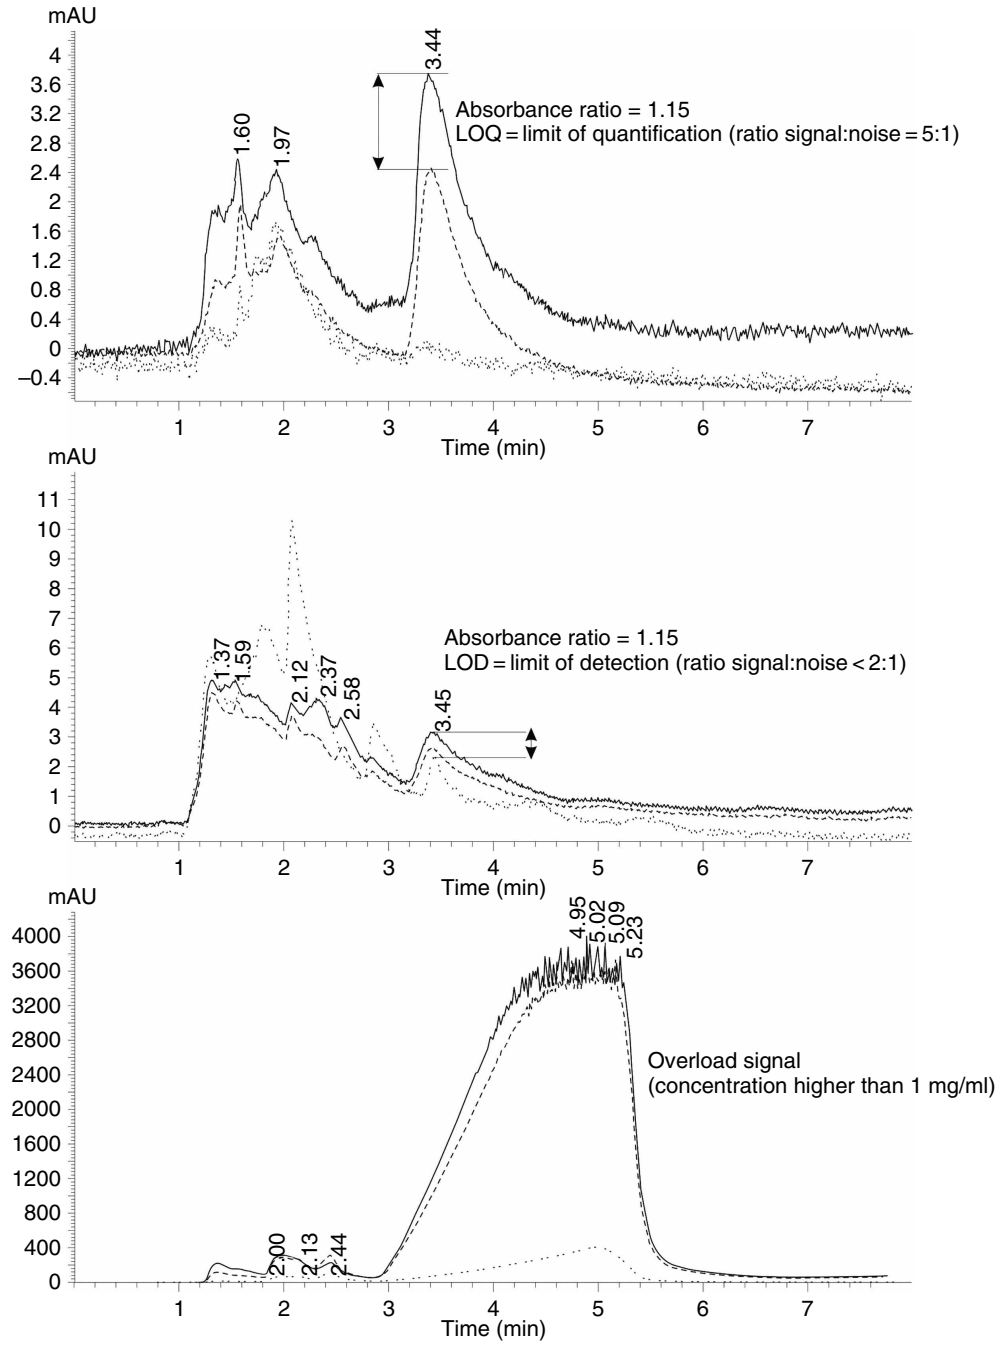

Fig. 2 Adjusting detection conditions of benzoic acid at different λ. Column: SPHERISORB ODS-2, 150 × 3.2 mm, 5 μm; mobile phase: 5 m*M* ammonium acetate:methanol (65:35); flow rate: 0.5 ml/min. Key: $\lambda = 226$ nm, —; $\lambda = 235$ nm, - - - -; $\lambda = 280$ nm, ...

requirements for using UV detection directly through programing wavelength. This has been concluded from numerous experiments using the new protocol for extraction in combination with maximum wavelength for each vitamin compound, which has adequately provided complete validation for individual groups of foods.[2,7–9]

To maximize the analytical performance of HPLC–UV methods, detection programing of various compounds that exhibit a fat-soluble vitamin function can be carried out. Improvements have recently been made to specific methods and other steps involved in optimizing the saponification conditions, thereby making it possible to separate, using the reversed-phase HPLC, majority of compounds that contain fat-soluble vitamins. And following the saponification procedure, only a minority of compounds can be detected. Irrespective of whether they use saponification or

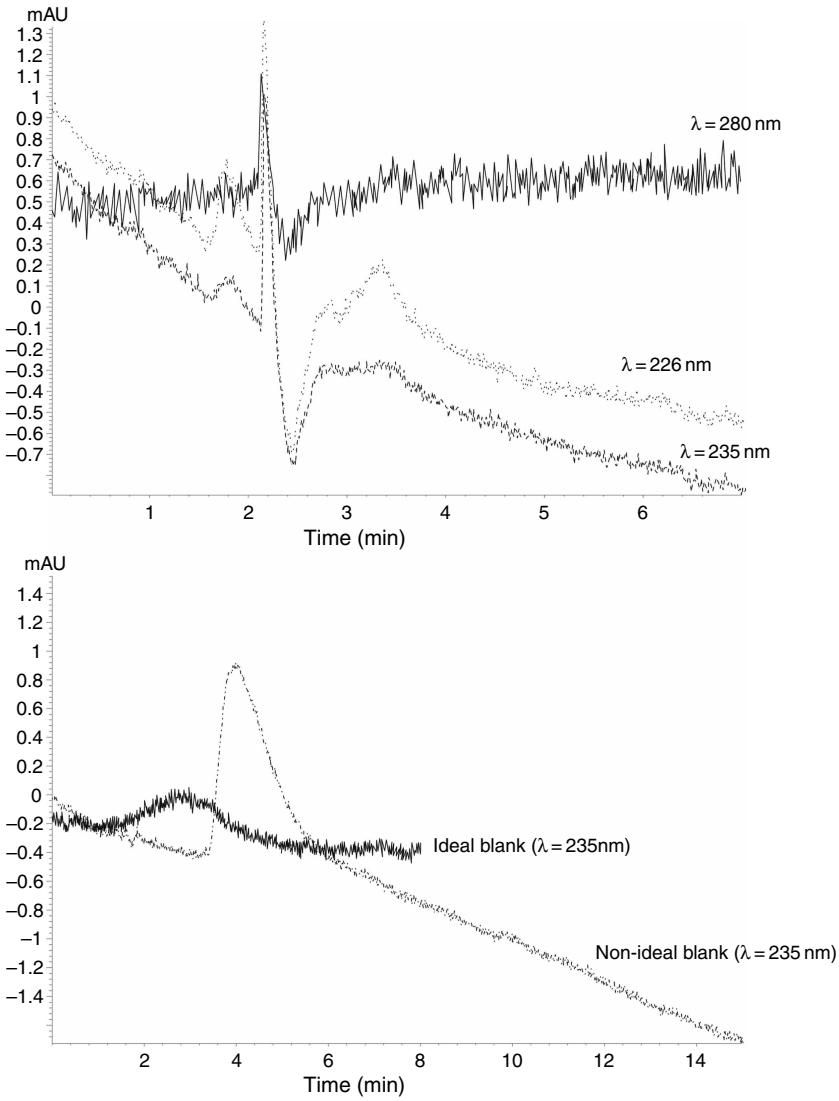

Fig. 3 Adjusting blank conditions of a particular mobile phase at different λ. Column: SPHERISORB ODS-2, 150 × 3.2 mm, 5 μm; mobile phase: 5 m*M* ammonium acetate:methanol (65:35); flow rate: 0.5 ml/min. Key: $\lambda = 226$ nm, —; $\lambda = 235$ nm, - - - - .

not, these methods may provide an estimate of the real quantities of fat-soluble vitamins. Chemical compounds containing fat-soluble vitamins belong to distinct groups of chemicals, such as alcohols, olefins, steroids, and quinones. Alcohol forms of vitamins A and E and their respective esterified forms are separate and can be quantified using an extraction procedure without saponification (Fig. 5A), while non-esterified vitamins A and E, D_2, D_3, and K_1, produce a good resolution of the vitamin value once the saponification procedure has been optimized[7–10] (Fig. 5B).

An improvement in identification and quantification procedures for fat-soluble vitamins in milk can be achieved through microcolumn associated with solid-phase extraction,[11] which, when coupled with the mass-mass–HPLC by chemical ionization at atmospheric pressure, can improve the resolution of D_2 and D_3 in the presence of vitamins A and E.[12] By contrast, if the vitamin is an ionic compound such as water-soluble vitamins, electrospray ionization is recommended.[13] Studies using a scattering radiation detector have proved to be less selective and to have poor resolution when compared to UV detection performed on isomers α- and γ-tocopherols.[14]

Since UV–Visible and fluorescence detection can determine the valence electrons of particular compounds, there is a particular λ for each compound. If detection using various channels is suggested, it is likewise recommended that maximum wavelength should be adjusted before program wavelength is being defined. This recommendation should be applied only to specific channels.

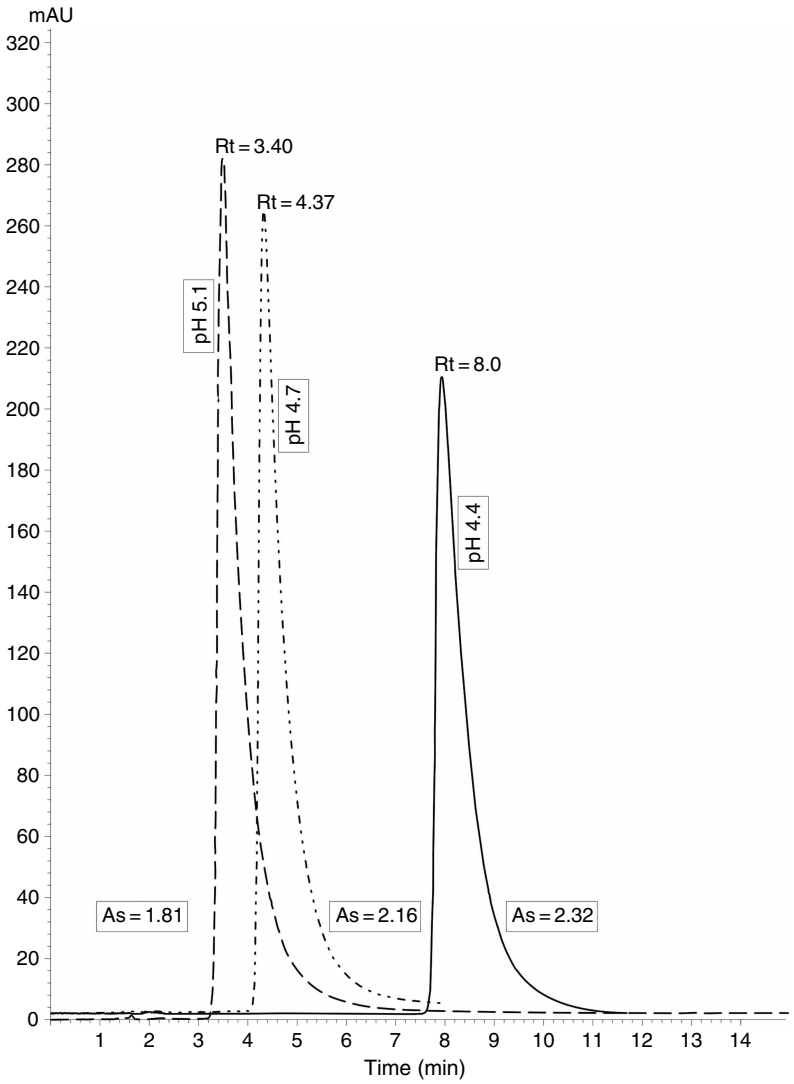

Fig. 4 Influence of pH mobile phase on k (adjusted retention time) of benzoic acid at λ = 226 nm. Column: ODS-2: 150 × 3.2 mm, 5 μm; mobile phase: 5 m*M* ammonium acetate:methanol (65:35); flow rate: 0.5 ml/min. Key: As = Asymmetry, Rt = Retention time.

SINGLE AND PROGRAM WAVELENGTH USING A COMPLEX MATRIX

The main problems regarding the baseline drift result instead are resulting from an incoherent signal that can be related to a particular mobile-phase composition, such as acid, acid buffer, acidified water, ionization agent, air bubbles, unidentified compounds, a failure of the reference material, excessive signal noise, and the natural difficulty of most biological materials to be free of compounds that absorb UV, among other factors.[1–4] Therefore, particular attention should be paid to sensitivity while using the units of absorbance described in the original method (that firstly described maximum wavelength). When developing a new protocol for the selection of a better mobile phase, efforts should be made to ensure that analytical standards are appropriately quantified using a blank run, in which the mobile phase passes through the column, in order to correct troubleshoot by monitoring baseline drift at a different threshold.

In this case, experiments were carried out and ideal and non-ideal conditions were outlined in order to initiate quantitative experiments, as shown in Fig. 6. Depending on the threshold selected (about 1 mAU), one blank run was carried out under ideal conditions for quantification of LOD and LOQ by way of a linear response range. The principal effects on the separation of vitamins A and E led to doubts regarding some chromatograms because of the non-ideal drift. The accommodation effect on the column may be an explanation for this.

An appropriate calibration of blank experiments has been performed using biological materials free of analytical compounds, such non-fatty milk, thereby making it necessary to certify these values by contrasting to reference materials too.[1,2] This is commonly found in the case of feedstuffs and pharmaceuticals, while it is less frequent in clinical chemistry, biological fluids, and other materials such as foods. Suitable and selective reference materials are required to simultaneously

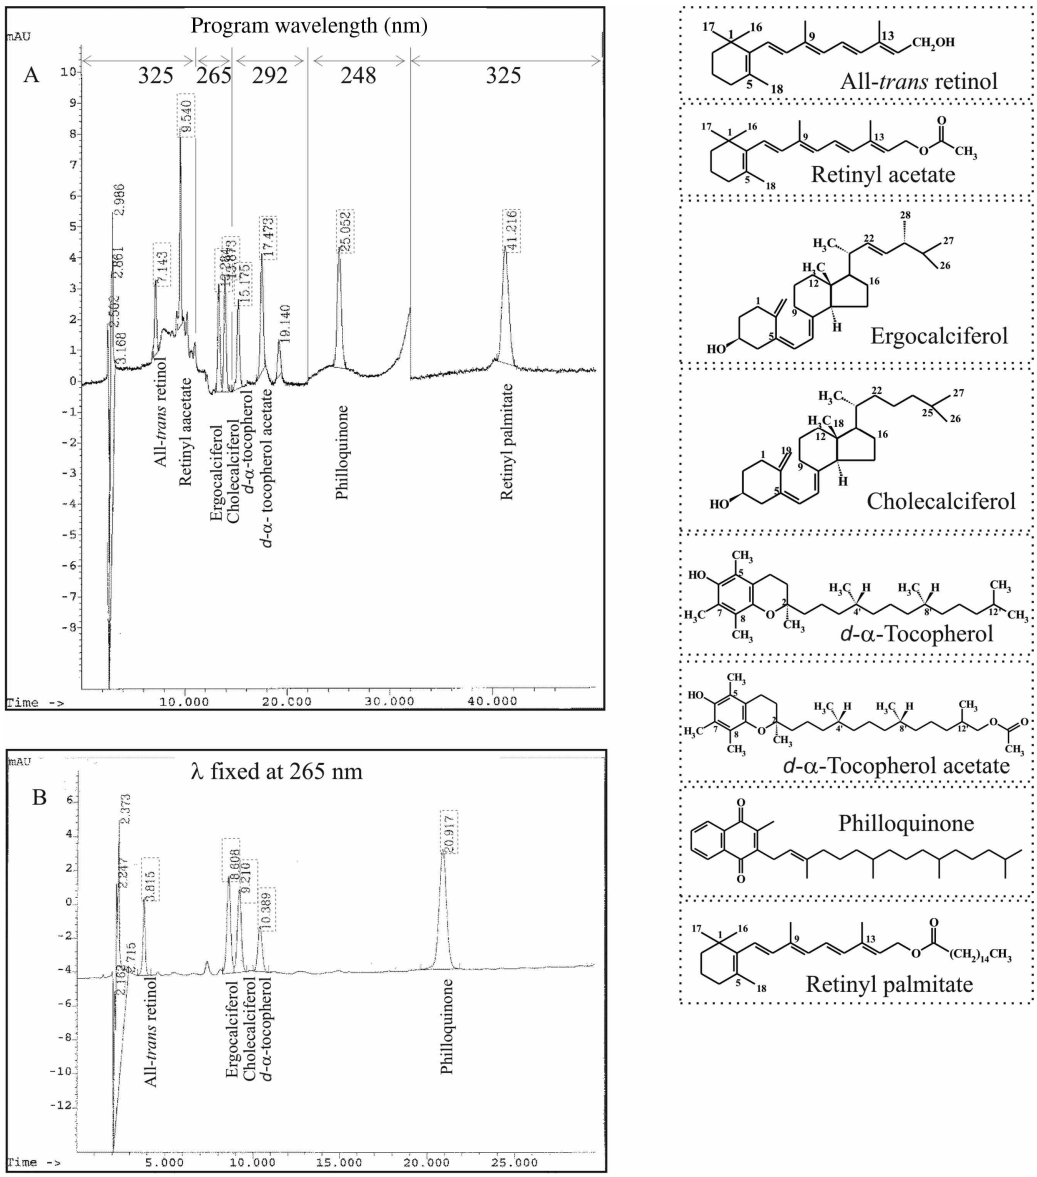

Fig. 5 Adjusted program wavelength in order to obtain detection of fat-soluble vitamins. A, Included esterified chemical forms (flow rate: 1.1 ml/min); B, Only non-esterified chemical forms (flow rate: 1.4 ml/min). Column: SPHERISORB ODS-2, 250 × 4.6 mm, 5 μm; mobile phase: methanol:water (99:1).

determine precision and accuracy. In addition, precision can be defined for particular groups of products. However, disappointing results have been obtained with certain biological materials, particularly those that are more heterogeneous than analytical standards required for some stages in the preparation of samples, such as dissolution, chemical reactions to remove interference, and chemical reactions needed to achieve a good level of purification.[1,5,6]

Different samples or matrices require suitable adaptation to the quantification system, such as fat-soluble vitamin determination in serum,[15,16] human milk,[16–18] nutritional supplements,[18] and infant formulas,[19] using external and internal standards. In fact, the complexity of matrices reveals innumerable compounds that differ in terms of modes of spread and linkage, such as liquid, semiliquid, and solid materials.[19–22] For example, liquid samples have shown high oxi-reduction potential compared to solid samples, while both have shown cross-linkage of heterogeneous compounds. Good dissolution in the mobile phase is always linked to an ideal separation technique when it is subjected to liquid–liquid and solid–liquid extraction, both of which are recommended to account for differences between matrices. When simultaneously linked to reversed-phase and normal-phase HPLC, from ideal analytical separation, both the

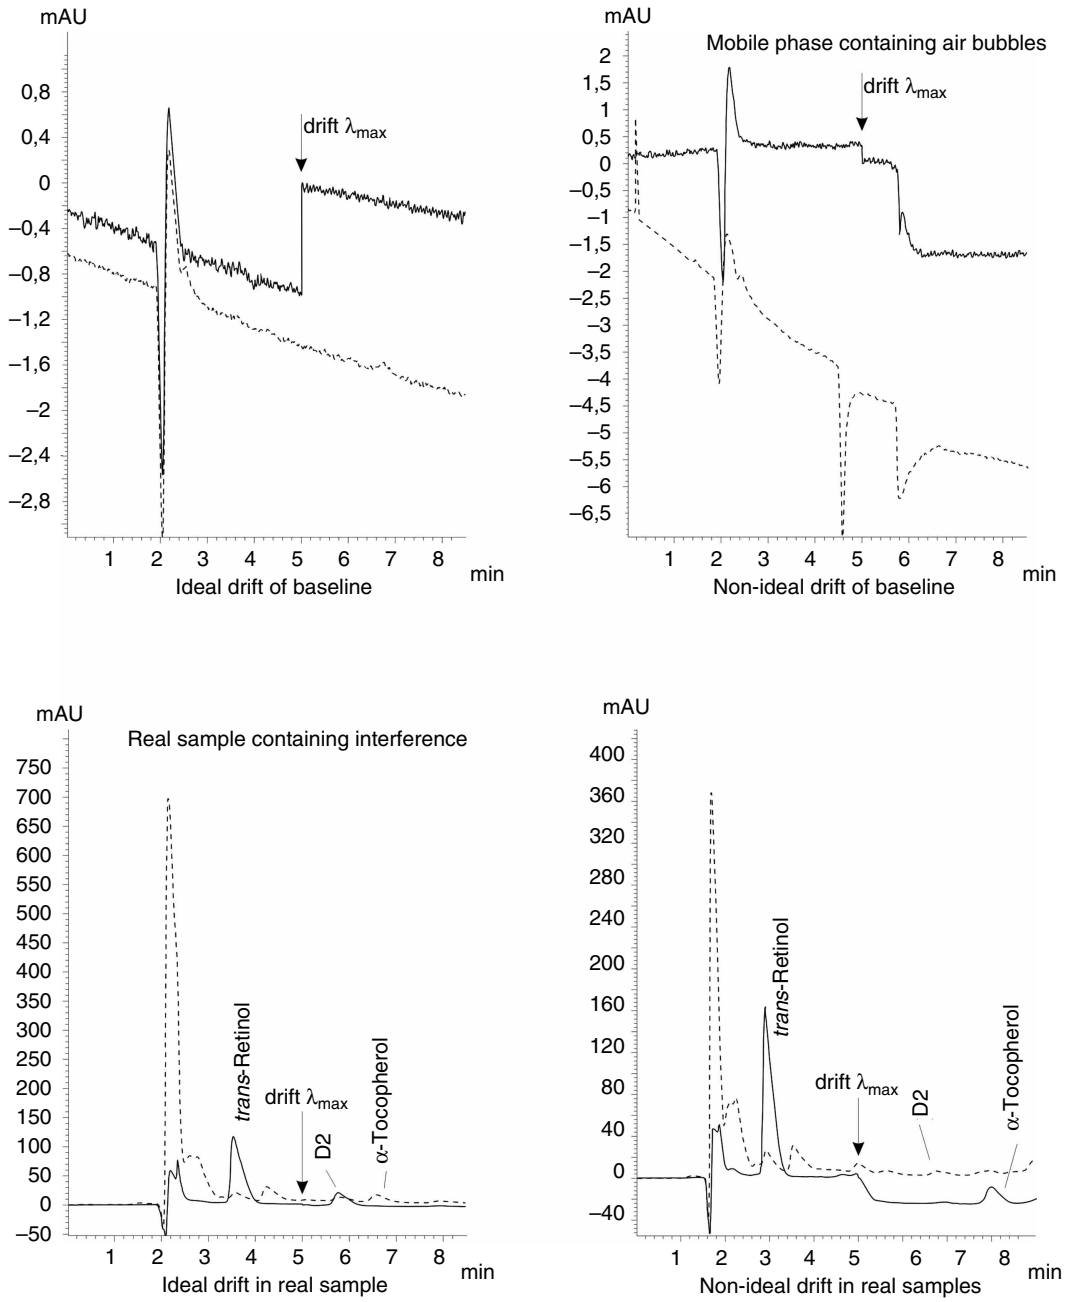

Fig. 6 Adjusted detection conditions in two channels (if multiple λ). Column: SPHERISORB ODS-2, 150 × 3.2 mm, 5 μm; mobile phase: methanol; flow rate: 0.5 ml/min. Key: Program wavelength = 325 nm until 5 min; from 5.01 min, λ = 292 nm, —; λ fixed at 265 nm, - - - -.

extraction methods have been shown to be compatible with the quantification, which is recommended as an additional criterion for accuracy studies.[1–4,22–25]

Interferences such as air bubbles, a mobile-phase composition, and a poorly conditioned column should be corrected before removing matrix interference, which subsequently helps in developing an appropriate procedure for extraction. It is worth considering the favorable conditions for detection: proper λ adjustment to mobile-phase interference.[1–4]

A few articles claim that chemical derivations are easy and must be done prior to the analytical separation procedure. In particular, there is a need for complete knowledge of the steps in the chemical reactions (i.e., the interaction between reagents and products) that helps in monitoring the characterization of compounds through a specific separation procedure. In the case of particular applications using HPLC techniques, unsatisfactory outcomes occur because unstable products (reduced or oxidized, neutralized or poorly dissociated

near pK_a) increase the capacity of buffering and dissociation,[1–6] thus affecting the separation properties.

To verify the suitability of an approach that ensures transferability through recovery rates for complete validation of the extraction and quantification steps, high levels of accuracy should always be accompanied by ideal repeatability in different samples combining precision and accuracy. Good recovery rates (higher than 80%) usually provide a rough indication of accuracy, and may therefore be distinguished in particular matrices, at least at two distinct points (low and high level). A reference material is also an additional criterion for complementary accuracy studies, providing complete validation.[1–3,22–25]

An extensive analytical approach can be developed using applications for distinct matrices. Earlier validation

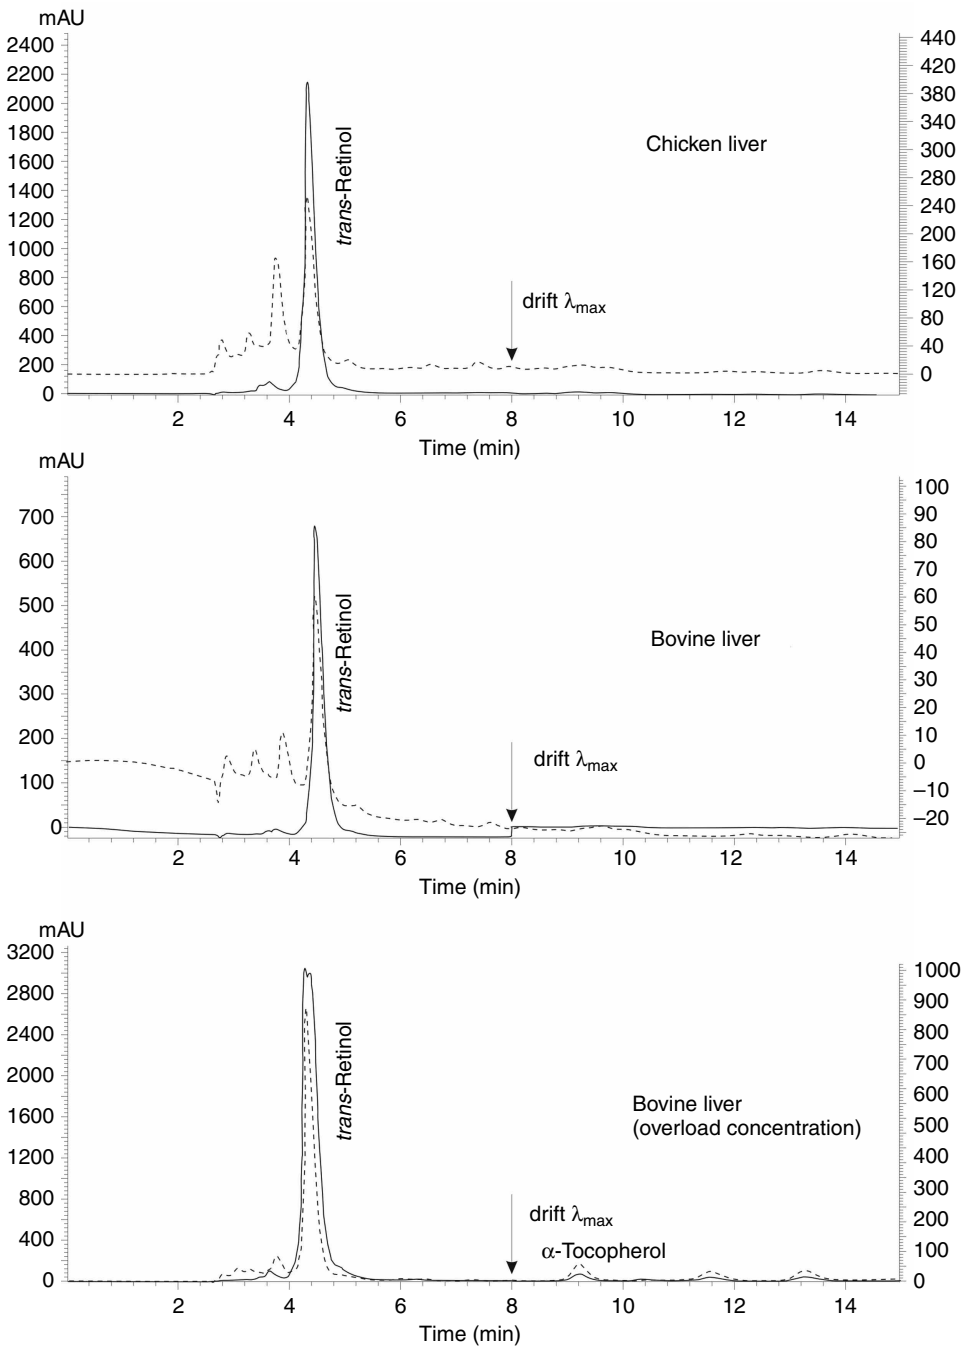

Fig. 7 Typical chromatograms of different complex matrices. Column: SPHERISORB ODS-2, 250 × 4.6 mm, 5 μm; mobile phase: methanol; flow rate: 1.0 ml/min. Key: Program wavelength = 325 nm until 8 min; from 8.01 min, λ = 292 nm, —; λ fixed at 265 nm, - - - -.

experiments can be used to ascertain the extent of transferability of a particular extraction, involving a complex matrix such as animal liver (see Fig. 7) and human milk, using fat-soluble vitamins as reference.[2,8–10,16,18–22] Recent studies in our laboratory that examined different stages of human lactation have shown that fat-soluble vitamins vary during transition of colostrums to mature milk,[22] as can be seen in Fig. 8. In this case representing a few obstacles to the quantitative analysis, which simultaneously evaluated the absorbance ratio (Table 1) and adjusted retention time (Table 2), confirming suitable transferability involving extraction and quantification steps. Therefore, it is beneficial to use a particular extraction method, initially developed for lacteal matrices and now extended to other matrices, as recommended by publications on infant formulae and fortified milk,[19] cheese and salami,[20] cooked meals and milk products,[21] and transition of colostrums to mature human milk.[22]

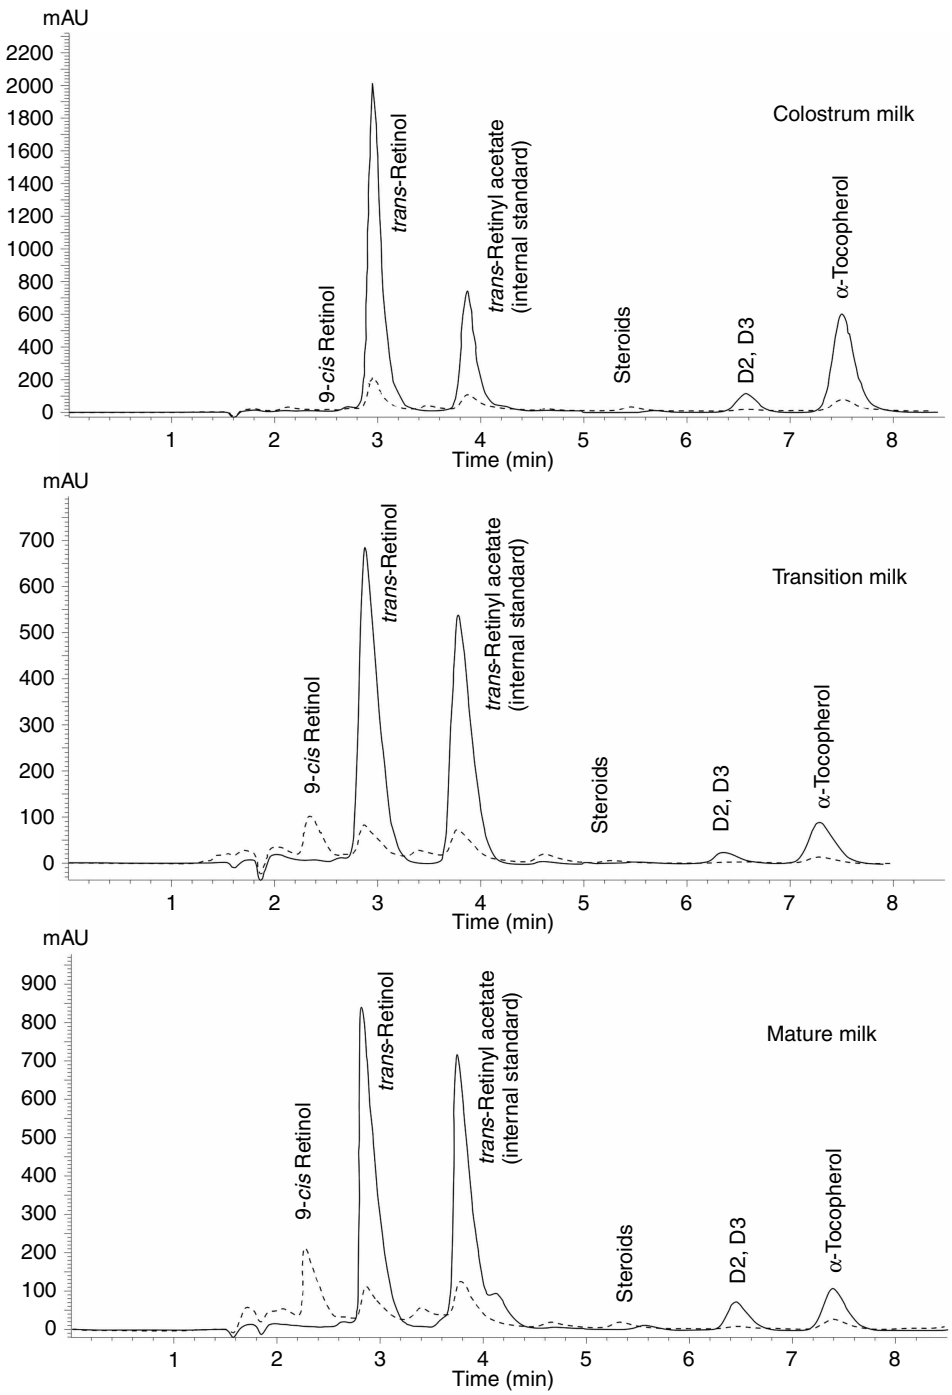

Fig. 8 Typical chromatograms of fat-soluble vitamins from different phases of lactation obtained from primiparous mothers. Column: ODS-2, 150 × 3.2 mm, 5 μm; mobile phase: methanol; flow rate: 0.5 ml/min. Key: Program wavelength = 325 nm until 5 min; from 5.01 min, λ = 292 nm, —; λ fixed at 265 nm - - - -.

	292	6.99 ± 1.35	4.23 – 9.00	7.50	7.43
Multiparous mothers ($N = 27$)	325	10.18 ± 0.47	8.66 – 10.97	10.25	10.17
	292	7.98 ± 1.03	6.00 – 10.42	8.04	8.07

All standards and samples were injected in triplicate.

IDENTIFICATION AND QUANTIFICATION PROCEDURES USING DISTINCT STANDARDS

Recent advances in the HPLC technique are highly recommended for identification. These include infrared spectroscopy coupled with Fourier transform,[1,3] light scattering,[14] or electrochemical detectors.[1,3,4] It is of particular interest that detector systems cover most organic and inorganic compounds. They require an extremely stable power supply, but without exhaustive chemical derivation requirements. The most useful non-destructive detectors are UV–Visible and fluorescence, while UV is less selective. It should be pointed out that a close association between detection and quantification systems suggests that it would be appropriate to combine these systems with accurate rules.[1,2,4]

Usually more than two channels are required to determine the ideal quantification procedure, and the use of external and internal standards is the most highly recommended way of producing the calibration curve. The particular example of benzoic acid was taken to demonstrate how LOD was determined (analytical signal-to-noise ratio $\leq$2:1; Fig. 2) in combination with the low variability observed between replicate analyses. Fig. 2 also clearly illustrates the establishment of minimum and maximum concentrations in order to define the response linear range for each compound using the UV detection system involving single λ. Comparative measurements were taken to complete quantitative experiments exhibited in Figs. 3–5, using single and program wavelength.

Given the complexity of the biological matrix, all experiments that are recommended for primary validation[23–24] and system suitability[25] should be carried out. In addition to criteria for suitable transferability, absorbance ratio is a complementary criterion that has been suggested for comparative measurements of distinct matrices using statistical parameters. Therefore the absorbance ratio taken directly from the peak (Table 1) and adjusted retention time (Table 2) measured at maximum wavelength have worked as complementary criteria for the identification procedure. When the absorbance ratio is clearly established, it is recommended that recovery rates should be determined.[23–25] The choice of matrix should have specific criteria according to the complexity, such as lipid and water content and nutrient content of a sample, as validated in our experiments using lacteal matrices of different chemical compositions.[2,7–10,22–25] Values of different samples should approximate to those established for distinct standards as shown in Tables 1 and 2.

In addition, the absorbance ratio has been shown to be a satisfactory substitute for the diode array detector because it monitors the intrinsic variability of methods, allowing for the development of a new protocol for distinct matrices. It should be borne in mind that minor variations required in the λ obviously depend on grooves originating from a prism or comb, which are the principal determining factors

Table 2 Adjusted retention time (k) as a criterion for separation and identification of vitamins A and E at maximum wavelength 325 and 292 nm, respectively.

Treatment of standards/samples	λ_{max} (nm)	Mean ± SD	Min – max	Mode	Median
All standards ($N = 36$)	325	0.64 ± 0.03	0.57 – 0.80	0.66	0.65
	292	3.14 ± 0.20	2.70 – 3.64	2.87	3.21

	292	3.13 ± 0.18	2.82 – 3.41	3.12	3.12

All standards and samples were injected in triplicate.

Table 3 Measurements of linear regression analysis obtaining different quantification methods involving external (ES) and internal standards (IS).

Pooled calibration curve	λ_{max} (nm)	Correlation coefficient *R*	Angular coefficient *B*	Linear coefficient *A*
Random order (ES)	325	0.9998	317.91650	138.28900
	292	0.9998	17.24770	75.96220
Rising order (ES)	325	0.9997	313.43390	101.04920
	292	0.9998	16.81200	64.65770
Internal standard (IS)	325	0.9991	0.05436	0.02564
	292	0.9992	0.00295	0.01388

for the variability achieved when quantitative procedures are used.[1–4,7,8] Lower resolution for maximum wavelength can be achieved using spectrophotometer-type filter optics in contrast in order to get maximum efficiency make use of a diffraction comb (usually with more than 2000 grooves), leading to an appropriate increase in the resolution of wavelength.[1,3,4]

Our recent research, in which multiparous and primiparous donors were compared during the initial phase (up to the 30th day) of human lactation, the quantities of fat-soluble vitamins were determined in colostrums, transition milk, and mature milk.[10,22] It was not possible to trace the recovery rate, because biological material was obtained in minimal quantities, especially at the colostrum phase. In addition, such complexity was bypassed to the absorbance ratio and adjusted retention time (k), both being used as complementary criteria for identification.

Table 1 shows similar variations in the absorbance ratio measured at maximum wavelength for vitamins A (325 nm) and E (292 nm), with the alternative λ set at 265 nm. Minor differences were also observed when real samples were compared to analytical standards using similar statistical parameters (such as mean, mode, and median), thereby providing sufficient transferability for a new matrix. Table 2 shows that the adjusted retention time (k) measured at maximum wavelength for vitamins A (325 nm) and E (292 nm) were sufficient to distinguish different materials. Minor differences were registered using statistical parameters, suggesting good transferability.

Standardization of areas at different peaks or a single normalization is the oldest technique. It differs greatly from the use of the external standard, although both require minimum disturbance of the baseline and reliable resolution of maximum wavelength. On the other hand, the internal standard requires the addition of particular compounds and it is usually difficult to determine what kind of compound is most appropriate and which steps should be added. It is therefore worth choosing the best procedure before determining which quantification system should be applied.[23–25]

Table 3 provides measurements of the regression analysis, allowing for the selection of the best procedure when comparing injection order, either random or rising order, using external and internal standards. However, no significant differences were registered in any of the modes evaluated. In this case, it was expected that the residual effect on the column would mask the particular way of constructing the calibration curve, especially when compared to the random injection order, because of the effect on the k value.

The addition of a standard is less used because it is difficult to achieve a matrix free of analytical compounds that absorb UV–Visible whereas any extraction procedure steps usually containing distinct chromophores that increase and modify parameters of absorption.

CONCLUSIONS

The outcomes of the principles of the UV–HPLC detection have been outlined and discussed, mainly those involving interferences of standards and complex matrices.

The single λ (maximum, or other set) and programed maximum wavelength criteria are the main ways of improving the performance of UV detection, particularly when linked to the absorbance ratio, recommended for use when coupled with a spectrophotometer or an HPLC.

Contemporary ways of achieving complete validation have been identified and discussed: programed maximum wavelength, absorption coefficient, adjusted retention time, and absorbance ratio measured at different λ.

Operational problems, such as baseline shift, and different ways of building up and injecting the standards and different matrices have also been discussed.

UV–Visible detection always requires small steps to complete validation, such as using complementary criteria for suitable identification and quantification coupled with the HPLC technique.

ACKNOWLEDGMENT

I express my gratitude to the Central Analítica, Departamento de Química Fundamental, Universidade Federal de Pernambuco, for the use of the HPLC equipment (Agilent Technologies, Inc., California, U.S.A.).

van't Hoff Curves

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

van't Hoff curves are strictly graphs of log[distribution coefficient (K)] against the reciprocal of the absolute temperature, but, in practice, log[capacity factor (k')] or log [corrected retention volume (V')] are used as alternatives (see *Plate Theory*, p. 1829). van't Hoff curves can be very informative and explain both the nature of the separation and the importance of temperature in achieving an adequate resolution. An example of two van't Hoff curves relating log(V') against $1/T$ for two different types of distribution system are shown in Fig. 1. The two curves are highly exaggerated for the sake of emphasis and clarity.

DISCUSSION

It is seen that distribution system A has a large enthalpy value ($\Delta H_0/RT$) and a low-entropy contribution [($\Delta S_0/R$)-V_S]$_A$ The large value of ($\Delta H_0/RT$)$_A$ means that the distribution is *predominantly controlled by molecular forces*. The solute is preferentially distributed in the stationary phase as a result of the interactive forces between the solute molecules and those of the stationary phase being much greater than the interactive forces between the solute molecules and those of the mobile phase. Because the change in enthalpy is the major contribution to the change in free energy, *the distribution, in thermodynamic terms, is said to be "energy driven."*

In contrast, it is seen that for distribution system B, there is only a small enthalpy change ($\Delta H_0/RT$)$_B$, but in this case, a high-entropy contribution [($\Delta S_0/R$)-V_S]$_B$. This means that the distribution is *not* predominantly controlled by molecular forces. The entropy change reflects the degree of randomness that a solute molecule experiences in a particular phase. The more random and "more free" the solute molecule is to move in a particular phase, the greater its entropy. A large entropy change means that the solute molecules are more restricted or less random in the stationary phase in system B. This loss of freedom is responsible for the greater distribution of the solute in the stationary phase and, thus, greater solute retention. Because the change in entropy in system B is the major contribution to the change in free energy, *the distribution, in thermodynamic terms, is said to be "entropically driven."*

Separations dominated by size exclusion are examples of entropically driven systems. Chromatographic separation need not be exclusively "energetically driven" or "entropically driven"; in fact, very few are. In most cases, retention has both "energetic" and "entropic" components, which, by careful adjustment, can be made to achieve very difficult and subtle separations.

It is very rare, if at all, in GC that two solutes have identical standard free energies. Even when considering enantiomeric pairs, they will have differing standard free enthalpies and standard free entropies and, consequently, differing standard free energies. Accepting these facts, the van't Hoff curve provides critical information for the chromatographer. If two solutes (e.g., a pair of enantiomers) have different standard free enthalpies, then the linear van't Hoff curves must have different slopes and, therefore, they must intersect. As a consequence, there must be a temperature where the two curves intersect and there will be a specific temperature at which the two solutes must coelute. The coelution temperature may, or may not, be in the practical operating range of the chromatographic system, but it is clear that temperature is an essential operating variable. Temperature does not merely control the elution rate and allow the analysis to be achieved more rapidly, but also critically determines the column selectivity for closely eluting peaks. In fact, this is also true for LC.

There are some examples in the literature that purport to show non-linear van't Hoff curves. Taking an example from LC, a graph relating log(V_r') against $1/T$ for solutes eluted by a mixed solvent from a reverse bonded phase will often be non-linear. However, it must be emphasized that graphs relating log(V_r') against $1/T$ can only be termed van't Hoff curves, and be treated as such if they apply to an *established distribution system*, where the nature of *both* phases does not change with *temperature*. If a mixed-solvent system is employed as the mobile phase, the *solvents themselves* are distributed between the two phases *as well* as the solute. Depending on the actual concentration of solvent, as the temperature changes, so may the relative amount of solvent adsorbed on the stationary-phase surface, and so the nature of the distribution system will also change. Consequently, the curves relating log(V_r') against $1/T$ may not be linear and, as the distribution system is varying, will not constitute van't Hoff curves. This effect has been known for many years and an early example is afforded in some early work carried out by Scott and Lawrence,[1] who investigated the effect of water vapor

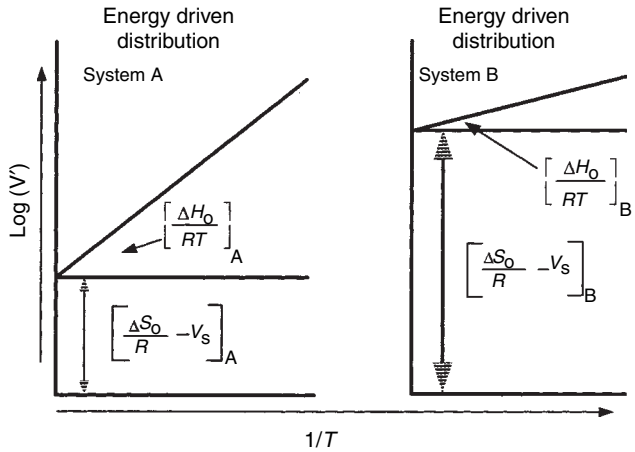

Fig. 1 van't Hoff curves for two distribution systems.

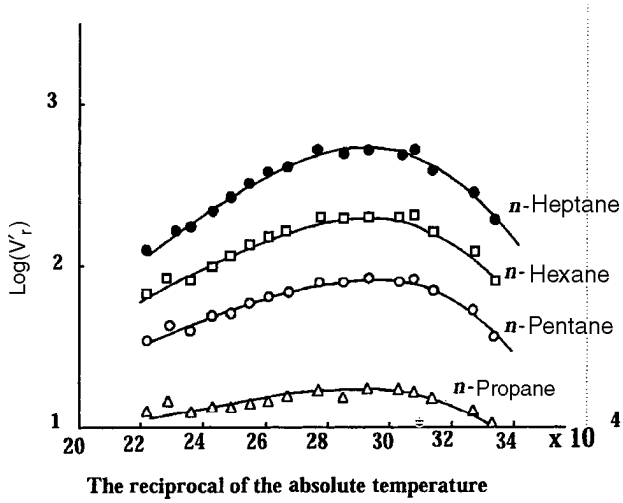

Fig. 2 Graphs of $\log(V_r')$ against $1/T$ for some *n*-alkanes separated on water-vapor-moderated alumina.

as a moderator on the surface of alumina in some gas–solid separations of some *n*-alkanes. Examples of the results obtained by those authors are shown in Fig. 2. The alumina column was moderated by a constant concentration of water vapor in the carrier gas. As the temperature of the distribution system was increased, less of the water moderator was adsorbed on the surface. As a consequence, the alumina became more active and the distribution system changed. Thus, initially, as the temperature was raised, the retention volume of each solute increased. When all the water was desorbed and the alumina surface assumed a constant interactive character and the distribution system also remained the same, the retention volume began to fall again in the expected manner and this part of the curve would then be a van't Hoff curve.

INTRODUCTION

Polyvinylpyrrolidone (PVP) is a synthetic polymer derived from the Reppe chemistry and is widely used in the pharmaceutical, personal care, cosmetic, agriculture, beverage, and many industrial applications. PVP is a polar and amorphous polymer which is soluble in water and some organic solvents, such as alcohols, chlorinated hydrocarbons, dimethyl formamide, dimethyl acetamide, and *N*-methyl pyrrolidone.

Non-ionic, anionic, and cationic VP copolymers are all available commercially to enhance the hydrophilic, hydrophobic, and ionic properties of PVP for specific applications. Important comonomers include vinyl acetate (VA), acrylic acid (AA), vinyl alcohol, dimethylaminoethylmethacrylate (DMAEMA), styrene, maleic anhydride, acrylamide, methyl methacrylate, lauryl methacrylate (LM), α–olefins, methacrylamidopropyltrimethyl ammonium chloride (MAPTAC), vinyl caprolactam (VCL), and dimethylaminopropylmethacrylamide (DMAPMA).

MOLECULAR WEIGHT AND MOLECULAR DISTRIBUTION OF PVP BY SIZE-EXCLUSION CHROMATOGRAPHY

Commercial PVP are available in five grades, K-15, K-30, K-60, K-90, and K-120 with the respective range of M_W 7000–12,000, 40,000–65,000, 350,000–450,000, 900,000–1,500,000 and 2,000,000–3,000,000. Interactions between PVP and columns, such as adsorption, partition, and electrostatic interactions, have to be eliminated by prudent choice of column and mobile phase in order to obtain true separation by size and 100% recovery.

Belenkii et al. reported in 1975[1] the size-exclusion chromatography (SEC) of PVP using Pharmacia Sephadex G-75 and G-100 columns and 0.3% sodium chloride solution as the mobile phase. Hashimoto et al. reported in 1978[2] the SEC of PVP K-30 and K-90 using TSK-PW 3000 and two 5000 columns and 0.08 *M* Tris-HCl buffer (pH = 7.94) as the mobile phase.

By using an E. Merck LiChrospher SI300 column, modified with an amide group (–NH–CO–CH_3) chemically bonded to the surface, Englehardt and Mathesn reported in 1979[3] the SEC of PVP. Herman et al. synthesized monomeric diol onto E. Merck Lichrospher SI-500 and reported in 1981[4] the SEC of PVP. Mori reported in 1983[5] the SEC of PVP K-15 to K-90 using two Shodex AD-80M/S columns with DMF and 0.01 *M* LiBr as the eluent at 60°C. Domard and Rinaudo grafted quaternized ammonium groups onto silica gels with pore diameters of 150, 300, 600, 1250, and 2000 Å and reported in 1984[6] the SEC of PVP.

Malawer et al.[7] reported in 1984 the SEC of PVP K-15, K-30, K-60, and K-90 using diol-derivatized silica gel column sets and aqueous mobile phase modified with various polar organic solvents. Senak et al. reported in 1987[8] the determination of the absolute molecular weight and molecular-weight distribution of PVP by SEC–LALLS and SEC with universal calibration. The column set used consists of TSK-PW 6000, 5000, 3000, and 2000 columns and a mobile phase of water-methanol (50:50, v/v) with 0.1 *M* $LiNO_3$. One hundred percent recovery was reported. The results showed good agreement in M_w from SEC–LALLS and from SEC with universal calibration for PVP K-30, K-60, and K-90.

Size-exclusion chromatography of PVP K-15, K-30, K-60, K-90, and K-120 using linear aqueous columns such as the Showa Denko Shodex OH pack, Toyo Soda TSK-PW, and Waters Ultrahydrogel has been reported in 1995 by Wu et al.[9] Using single linear columns also greatly reduces analysis time and solvent consumption, making SEC a practical method for quality assurance. A comparison of four commercial linear aqueous columns and four sets of commercial PEO standards for SEC of PVP K-15, K30, K-60, K-90, and K-120 was reported by Wu et al. in 1999.[10] In recent years, SEC–MALLS has also been applied in this laboratory to PVP. Fig. 1 shows an overlay of SEC–MALLS chromatograms of all commercial grades of PVP using a linear aqueous column. The excellent overlap of absolute M_w vs. retention volume plots for all commercial grades of PVP in Fig. 1 demonstrates that there is no significant difference in branching among all

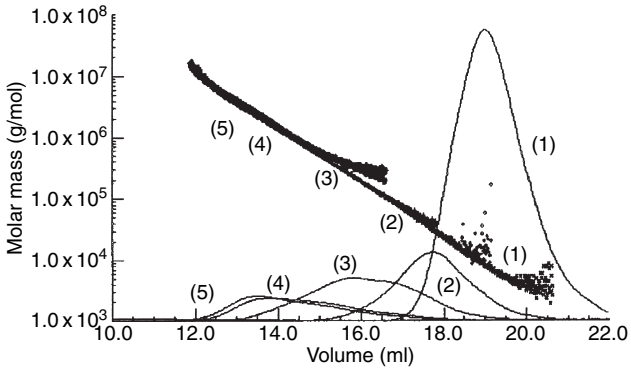

Fig. 1 Overlay of SEC chromatograms and M_w vs. retention volume plots by MALLS for PVP grades: (1) K-15; (2) K-30; (3) K-60; (4) K-90; (5) K-120.

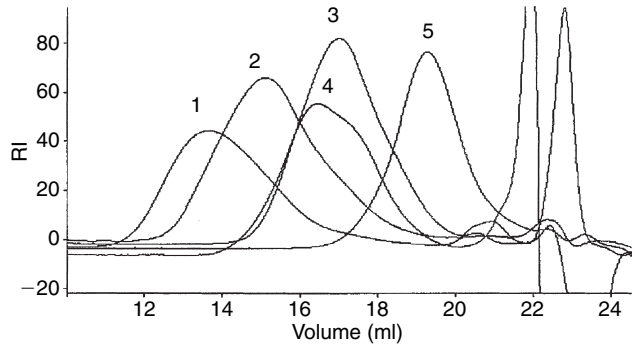

Fig. 2 Overlay of SEC chromatograms of VP-based copolymers in water–methanol (50:50) with 0.1 *M* lithium nitrate: 1, VP–DMAPMA; 2, VP–DMAPMA–AA–LM; 3, VP–VCL–DMAPMA; 4, VP–AA–LM; 5, VP–VA.

commercial grades of PVP, despite the different methods used to make them.

Finally, the following SEC columns, which have been introduced in recent years, have been demonstrated by the vendors to be successful with PVP: Jordi DVB Glucose BR linear column [in dimethyl sulfoxide (DMSO)], PL aquagel-OH column (in 0.1 *M*–0.3 *M* salt-buffer with 20% methanol); PSS Suprema column (in 0.1 *M* Tris pH 7 buffer), and PSS SDV column (in DMAC, 0.1% LiBr).[11–13]

MOLECULAR WEIGHTS AND MOLECULAR-WEIGHT DISTRIBUTIONS OF VP-BASED COPOLYMERS BY SEC

Wu et al. reported in 1991[14] the SEC of a non-ionic copolymer, such as copolymers of vinyl pyrrolidone and vinyl acetate (VP–VA) with different mole ratios and molecular weights, and a terpolymer of vinyl pyrrolidone, dimethylaminoethyl methacrylate and vinyl caprolactam (VP–DMAEMA–VC) in both aqueous and non-aqueous systems. For the aqueous system the column set used consisted of four Waters Ultrahydrogel columns of pore sizes 120, 500, 1000, and 2000 Å, and the mobile phase was water–methanol (1:1, v/v) with 0.1 *M* $LiNO_3$. For the non-aqueous system, the column sets were Shodex KD-80M plus Ultrahydrogel 120 Å, Shodex KD-80M plus PL gel 100 Å, and PL gel 10^4 Å plus 500 Å and the mobile phase was DMF with 0.1 *M* $LiNO_3$. However, it is the aqueous system that showed the best separation at the low-molecular-weight end. Fig. 2 shows the overlay of SEC chromatograms of VP-based copolymers in water–methanol (50:50) with 0.1 *M* lithium nitrate and a linear Shodex OHPAK column.

Wu and Senak reported in 1990[15] absolute molecular-weights and molecular-weight distributions of a quaternized copolymer of vinyl pyrrolidone and dimethylaminoethylmethacrylate (PVP–DMAEMA) by SEC–LALLS and SEC with universal calibration using Waters Ultrahydrogel 120, 500, 1000, and 2000 Å columns and a 0.1 *M* Tris, pH 7 buffer with 0.5 *M* $LiNO_3$ as the mobile phase. Due to the cationic charges on the molecules, a much higher salt content (0.5 *M* $LiNO_3$) is needed in the SEC mobile phase to improve the separation and recovery of the polymer.The water–methanol (1:1, v/v) mobile phase with 0.4 *M* lithium nitrate has also been used in this laboratory for SEC of this cationic copolymers with the Shodex OH pak or Ultrahydrogel linear columns with good results. Fig. 3 shows the overlay of SEC chromatograms of this cationic copolymers in a pH 7 buffer and a linear Shodex OH-PAK column.

Wu et al. reported in 1991[14] the SEC of anionic copolymers, vinyl pyrrolidone and acrylic acid (VP–AA) with different mole ratios and molecular weights, using a 0.1 *M* pH 9 Tris-buffer with 0.2 *M* $LiNO_3$ as the mobile phase and the Ultrahydrogel 120, 500, 1000, and 2000 Å column set. Fig. 4 shows overlay of SEC chromatograms of anionic copolymers in a pH 9 buffer and a linear Shodex OH–PAK column.

Copolymers and grafted copolymers of vinyl pyrrolidone and α–olefins, with α–olefins' contents higher than 60%, are not soluble in water or the water–methanol mixture. They should be analyzed in tetrahydrofuran using cross-linked

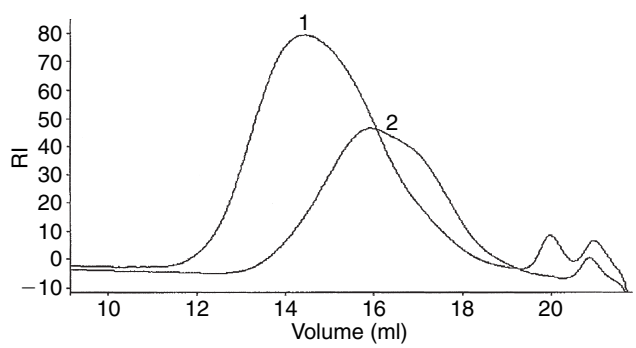

Fig. 3 Overlay of SEC chromatograms of VP-based copolymers in a pH 7 buffer: 1, high–MW VP–DMAEMA cationic copolymer; 2, medium MW VP–DMAEMA cationic copolymer.

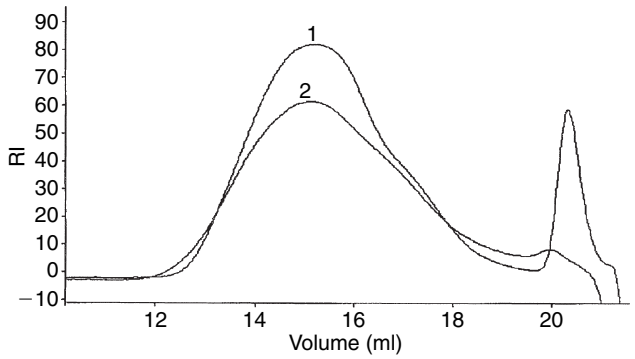

Fig. 4 Overlay of SEC chromatograms of VP–based copolymers in a pH 9 buffer: 1, VP–AA anionic copolymer; 2, VP–AA–LM anionic copolymer.

polystyrene columns. However, copolymers and grafted copolymers of vinylpyrrolidone and α–olefins, with only 10% aolefins, can be analyzed in the water–methanol mixture (50:50) with 0.1 *M* lithium nitrate.

CONCLUSIONS

With a proper choice of mobile phase (aqueous or non-aqueous), many commercially columns are available for SEC of PVP and VP-based copolymers. Mobile-phase modifiers (such as methanol, salt, and buffer) are normally required to eliminate interactions with columns. A single linear or mixed-bed column has been found to provide good separation of PVP and VP–based copolymers with a molecular weight range of from a few thousands to several millions. In general, the aqueous SEC system has better long-term stability and provides better separation than the non-aqueous SEC system, especially at the low-molecular-weight end. Hydroxylated methyl-methacrylate-type columns and water–methanol mobile phase (50:50, with salt) is a good first choice for SEC of PVP and many VP–based copolymers. New columns have been introduced to the marketplace in recent years; hopefully, they will offer better separation, solvent compatibility, stability, and minimal interactions.

Viscometric Detection in GPC/SEC

James Lesec
National Center for Scientific Research (CNRS), City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

At the beginning of gel permeation chromatography (GPC), in the early 1960s, there was only one detector at the outlet of GPC columns, generally a differential refractometer, to continuously measure the concentration of eluents. This detection provided a chromatographic peak corresponding, roughly, to the mass distribution. In addition, it was possible to build a calibration curve corresponding to the response of the column set $\log(M) = F(V_e)$ (M being the molecular weight and V_e being the elution volume), which was roughly linear, by multiple injections of narrow standards with known molecular weights and very narrow molecular-weight distributions. At each increment of elution volume, the slice concentration C_i was calculated using the polymer peak intensity and the slice molecular weight M_i, using the calibration curve. Then, it was possible to calculate, by integration

$$\frac{\sum C_i}{\sum (C_i/M_i)} = M_n$$
$$\frac{\sum C_i M_i}{\sum C_i} = M_w$$
$$\left(\frac{\sum C_i {M_i}^a}{\sum C_i}\right)^{1/a} = M_v$$
$$\frac{\sum C_i {M_i}^2}{\sum C_i M_i} = M_z$$

[a being the viscosity-law (Mark–Houwink) exponent], the different average molecular weights (in number, M_n; in viscosity, M_v; in weight, M_w; in z, M_z), in a single experiment.

The use of the GPC technique spread very quickly but, very soon, it became obvious that this method was imperfect. Every polymer has its own calibration curve which differs from one polymer to another. Moreover, for copolymers or branched polymers, the molecular weight calibration curve does not work correctly.

In 1966, the "universal calibration" method was established at the University of Strasbourg, France.[1] It used, as a parameter, not molecular weight M, but the hydrodynamic volume represented by the product $[\eta]M$, $[\eta]$ being the intrinsic viscosity. This universal calibration curve $\log([\eta]M) = F(V_e)$ was supposed to be applied to every polymer and copolymer, linear or branched, as a unique calibration curve; it worked very well.

From that point, the necessity of continuously measuring viscosity, in addition to polymer concentration, became obvious. Several attempts were made to adapt existing viscometers as GPC detectors, but the problem of internal volume was critical. Ouano[2] published the first design of a single-capillary viscometer which was based on pressure measurement. Several similar designs[3–9] were published and a commercially available instrument, the Waters Model 150CV (Waters Associates, Milford, Massachusetts, U.S.A.), based on a design described in Ref.[4], became commercially available.

SINGLE-CAPILLARY VISCOMETER

The single-capillary viscometer (SCV) is represented in Fig. 1a. Its design is a direct extrapolation of classical viscometry measurement. It is composed of a small capillary, through which the solvent flows at a constant flow rate, and a differential pressure transducer (DPT), which measures the pressure drop across the capillary. SCV obeys Poiseuille's law and the pressure drop ΔP across the capillary depends on the geometry of the capillary, on flow rate Q, and on viscosity of the fluid η according to

$$\Delta P = \left(\frac{8}{\pi}\right)\left(\frac{l}{r^4}\right)\eta Q$$

where l and r are the length and radius of the capillary, respectively.

Classical viscometers maintain ΔP constant and calculate h by measuring the variations of flow rate Q. By contrast, the SCV uses the advantage of GPC, which already has a constant flow rate Q and allows the calculation of η by measuring the pressure drop variations ΔP across the capillary. At constant flow rate Q, the pressure drop is proportional to viscosity η, and at constant viscosity η, the pressure drop is proportional to flow rate Q. Consequently, in order to use the SCV as an accurate viscometer, the flow rate must be maintained absolutely constant during the GPC experiment. Conversely, SCV allows perfect control of flow rate and can also be used as a very accurate flow meter when only pure solvent

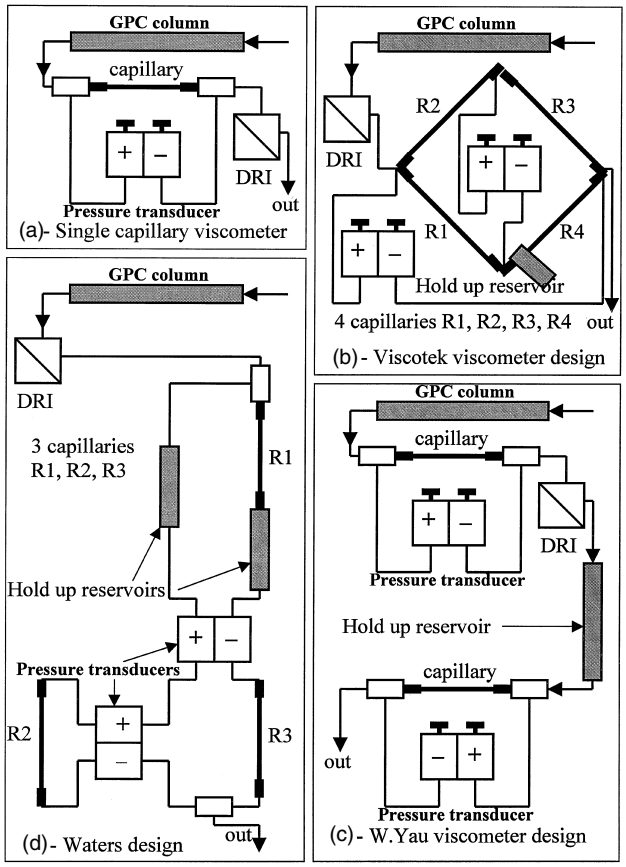

Fig. 1 Various designs of viscometric detection.

comes out of columns. At the outlet of the GPC columns, the polymer concentration is very small and the increase of solvent viscosity η is very small as well. When measuring ΔP proportional to ηQ, Q should be maintained extremely constant; this requires pulse dampeners in the flow system to smooth small flow variations due the pumping system design.

For that reason, some other, more complicated, viscometers, which are insensitive to small flow variations, were designed using multiple capillaries and pressure transducers.

MULTIPLE-CAPILLARY VISCOMETERS

The general purpose of multiple-capillary viscometers is to simultaneously measure the polymer solution in one part of the detector and pure solvent in a second part of the detector. In order to have these two parts at the same time, it is necessary to include a holdup reservoir to delay the polymer passing through the second part of the detector. One needs to wait until the delayed polymer comes out of the detector before reinjecting another sample. The basic principle is that one part of the detector measures polymer plus flow and the other part measures only flow. By obtaining the difference, the result is a signal which is proportional to polymer viscosity and insensitive to flow rate variations.

The first multiple-capillary viscometer was designed by the Viscotek Company (Houston, TX, U.S.A.).[11] It is represented in Fig. 1b. It is composed of four identical capillaries, assembled as a bridge. Here, the difference is generated by the bridge itself as a differential viscometer. The central DPT provides a differential viscosity signal DP and the second, DPT, provides inlet pressure IP. The intrinsic viscosity $[\eta]$ can be calculated by the formula

$$[\eta] = \frac{1}{C}\left(\frac{4\mathrm{DP}}{\mathrm{IP} - 2\mathrm{DP}}\right)$$

Another design was described by the Dupont Company.[12] It is represented in Fig. 1c. It is composed of two single-capillary viscometers. The first one (measure) is located as a normal SCV (Fig. 1a) and measures polymer plus flow. The second one (reference), identical to the first one, is located after a holdup reservoir which is connected after the refractometer and measures only the flow with pure solvent. It is just necessary to obtain the difference between the two signals to obtain the polymer signal with no flow contribution.

The last differential viscometer design is the Waters Corporation detector,[13] which is in the Alliance GPCV2000 high-temperature instrument. It is composed of three capillaries, two differential pressure transducers, and two holdup reservoirs; it is represented in Fig. 1d. The pressure transducers are connected flow-through; this eliminates the need for frequent purges. This detector provides, at the same time, "relative viscosity information" and "relative flow information." This design does not require a perfect matching of the capillaries.

THE USE OF VISCOMETRIC DETECTION

The first purpose of viscometric detection in GPC is to use a "universal calibration curve." At every slice, the concentration C_i is obtained through refractometric data, intrinsic viscosity $[\eta]_i$ is obtained through refractometric and viscometric data, and hydrodynamic volume $[\eta]M_i$ is obtained from the universal calibration curve. It is just necessary to divide $[\eta]M_i$ by $[\eta]_i$ to get M_i and obtain the couple C_iM_i that is necessary to calculate the various average molecular weights, as shown at the beginning of this entry, independently of the chemical nature of the sample and the standards used for calibration.

The secondary use of viscometric detection is for the determination of long-chain branching. At the same

molecular weight, a long-chain branched polymer has a more compact molecular structure than the linear one; consequently, it also has a smaller intrinsic viscosity. Therefore, it is eluted at a higher elution volume with a linear polymer of smaller molecular weight. That means that at a given elution volume, there is a mixture of polymers with different molecular weights and different degrees of branching eluting from the GPC column.

As intrinsic viscosity is affected by long-chain branching, viscometric detection provides branching information, just by comparing polymer viscosity laws. Fig. 2a represents the viscosity-law plot of a linear polymer, polyethylene (NBS1475), with a linear viscosity law and an exponent of 0.71. Conversely, Fig. 2b represents the viscosity-law plot of a branched polymer, polyethylene (NBS1476), with a curved viscosity law, under the linear polymer law (linear viscosity law). At every molecular weight, the branching distribution g_i' is calculated by

$$g_i' = \frac{[\eta]\mathrm{br}_i}{[\eta]\mathrm{lin}_i}$$

where $[\eta]\mathrm{br}_i$ and $[\eta]\mathrm{lin}_i$ are the slice intrinsic viscosities of the branched and the linear polymer, respectively.

CONCLUSIONS

Viscometric detection in GPC–SEC is extremely useful. It allows continuous viscosity measurements, which, in turn, permits the use of a unique calibration curve for all polymers (universal calibration). In addition, the viscosity law is determined for linear polymers and long-chain-branching information can be obtained for branched polymers.

Vitamins, Hydrophobic: TLC Analysis

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

Abstract
The use of thin-layer chromatography (TLC) in the investigation of hydrophobic vitamins has been discussed. The use of TLC as a separation method allows for the qualitative and quantitative investigation of hydrophobic vitamins. The use of TLC technique together with densitometry gives precise and sensitive quantification of vitamins A, D, E, and K compounds on TLC plates. It was proven that TLC is an important investigative technique for the analysis of hydrophobic vitamins. This entry shows the progress of investigations of hydrophobic vitamins.

INTRODUCTION

Vitamins are biologically active organic compounds, controlling agents that are essential for an organism's normal health and growth, not synthesized within the organism, available in the diet in small amounts, and carried in the circulatory system in low concentrations to act on target organs or tissues. Vitamins are classified according to their solubility in water and in fats. Hydrophobic vitamins include vitamins A, D, E, and K. Chromatography is useful for the identification and determination of vitamins in pharmaceutical preparations, the identification and determination of vitamins and related substances in natural materials and foodstuffs, and the chemical and biochemical determination of vitamins and their metabolites in fats and tissues. The isolation of the vitamins, their metabolites, and related substances from natural material is the most difficult task.[1–3] The aim of this entry is to present selected works that describe the analytical investigations of hydrophobic vitamins by means of thin-layer chromatography (TLC).

VITAMIN A

Physiological forms of vitamin A include retinol (vitamin A_1) and its esters, 3-dehydroretinol (vitamin A_2) and its esters, retinal (retinene, vitamin A aldehyde), 3-dehydroretinal (retine-2), retinoic acid, neovitamin A, and neo-b-vitamin A_1. Active analogues and related compounds, known as vitamins A are α-, β-, and γ-carotene, neo-β-carotene B, cryptoxanthine, myxoxanthine, torularhodin, aphanicin, and echinenone. Foods of plant origin do not contain vitamin A, but are rich sources of previtamin A. About 50 of the 500 known carotenoids can be converted to vitamin A. β-Carotene is the most important of all the carotenoids that occur in nature. β-Carotene (provitamin A), precursor of vitamin A, is found in plants.

Sliwiok, Podgorny, and Siwek[4] used TLC and high-performance liquid chromatography (HPLC) to compare the hydrophobicity of vitamin A derivatives (all-*trans* retinic acid, all-*trans* retinal, vitamin A acetate, and vitamin A palmitate). TLC was performed on RP-2 F_{254} and Kieselguhr F_{254} (impregnated with 10% paraffin oil in cyclohexane) with methanol–water (95:5, v/v). Chromatographic data for vitamin A derivatives are listed in Table 1. The separations of the vitamin A derivatives on the paraffin oil-impregnated plates were better than those on the RP-2 plates. Log *P* values from fragmental constants for the all-*trans* retinic acid, all-*trans* retinal, vitamin A acetate, and vitamin A palmitate were calculated (log *P* 4.85, 6.48, 7.92, 15.30, respectively). The relationship obtained by the authors confirms the following sequence of increasing hydrophobicity: all-*trans* retinic acid < all-*trans* retinal < vitamin A acetate < vitamin A palmitate.

Perisic-Janjic, Petrovic, and Hadzić[5] described a method for the quantitative separation of vitamin A acetate and A palmitate by thin-layer chromatography on starch, cellulose, and talc impregnated with paraffin oil using acetone-concentrated acetic acid (3:2, v/v) as the mobile phase (Table 1).

Small amounts of intensely colored pigments can be detected in ultraviolet (UV) light and also in visible light; the limit of detection is 0.01 μg for carotenoids. Retinal (0.02–0.03 μg) can be detected after spraying with rhodanine (orange-red spot of retinal). Many vitamin A compounds fluoresce yellow-green in light at 365 nm (limit of detection 0.05 μg). Vitamin A compounds can be detected with antimony(III) chloride (Carr-Price reagent) and antimony(V) chloride (blue spots), with concentrated sulfuric acid (blue color of spot),[10] with molybdophosphoric acid (green-blue spots), and with potassium dichromate in sulfuric acid (limits of detection 0.1–0.3 μg). The limit of detection of retinol isomers converted to 2,4-dinitrophenylhydrazones of retinals is 1 μg.[1,2,5] Bromophenol blue was also used for detection of vitamin A (3 μg) after adsorption TLC.[11]

Table 1 R_F values of hydrophobic vitamins and metabolites of vitamin D_3 separated in different chromatographic conditions.

VITAMIN D

Physiological forms of vitamin D include vitamin D_2 (calciferol, ergocalciferol), vitamin D_3 (cholecalciferol), phosphate esters of D_2, D_3, 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol, and 5,25-dihydroxycholecalciferol. Vitamins D_2 and D_3 are 9,10-secosteroids that differ structurally in the degree of saturation of an isoprenoid side chain. The biological activity of vitamin D_3 is greater than that of vitamin D_2. Vitamin D_2 is of vegetable origin, whereas D_3 is formed in the skin of humans and animals. From the chemical standpoint, ergocalciferol (vitamin D_2) is a relatively stable vitamin. Vitamins D_2 and D_3 are precursors of hormones. Vitamin D_3, which has little biological activity, is converted to biologically active metabolites by oxidation.

Kocjan and Sliwiok[6] determined the hydrophobicities of vitamins D_2 and D_3 by reversed-phase thin-layer chromatography (RPTLC), thin-layer adsorption chromatography, and infra red (IR) spectrometry. Partition TLC separations of vitamins D_2 and D_3 were done on TLC plates precoated with Kieselguhr $F_{254,}$ impregnated with 10% paraffin oil in benzene and developed to 10 cm with binary mixtures of methanol–water and acetonitrile–water. The R_F values of the best separation of vitamins are listed in Table 1. Adsorption TLC was done on glass plates precoated with activated silica gel 60 F_{254}, with a mobile phase of benzene–methanol (9:1, v/v). Measurement of the surfaces of the chromatographic spots obtained by adsorption TLC gave hydrophobicity coefficients (h_f 6.09 and 9.05 for vitamins D_2 and D_3, respectively). The results indicate that the hydrophobicity of vitamin D_3 is greater than that of vitamin D_2. This conclusion was proved by the lower R_F values for vitamin D_3 obtained by partition chromatography, the higher values of the respective hydrophobicity coefficients, and by the greater relative decreases in the ratio of free to bonded OH groups (obtained by spectrometric measurement).

Justova and Starka[7] described TLC separations of vitamin D_3 and its hydroxymetabolites. They tested three stationary phases (three commercial silica gel sorbents, namely, Kieselgel 60 F_{254}, Silufol UV 254, and silica gel 6061, and one relatively polar mobile phase (chloroform–ethanol–water, 183:16:1, v/v). R_F values of vitamin D_3 and its functional hydroxymetabolites are listed in Table 1. The optimal separation was achieved on Kieselgel 60 F_{254} foils produced by E. Merck, Germany. In biological samples, the vitamin D_3 hydroxymetabolite contents are at nanogram levels, which is below the limit of sensitivity of the applied visualization methods (UV light and the anisaldehyde reagent). Therefore, the hydroxycholecalciferols were localized with corresponding metabolites used as markers. Vitamin D_3 and 25-OH–D_3 were then scraped off the plate and extracted with ethanol; eluates were examined for radioactivity. The recovery of the markers in five replicate determinations was 97.8 ± 2.9% for vitamin D_3 and 98.7 ± 1.5% for 25-OH–D_3, respectively, when the effect of elution was verified. The effect of the complete chromatographic procedure was characterized by the accuracy and precision of the determination. These methods of TLC separation and determination of vitamin D_3 and its hydroxymetabolites are accurate and precise.[7]

Spots of vitamin D derivatives can be inspected in short-wavelength UV light (limit of detection 0.025–0.500 μg). The mono- and dihydroxycholecalciferols can be visualized under UV light at 254 nm or by spraying the foil with a solution of anisaldehyde in sulfuric acid (2%, w/v) mixed with glacial acetic acid (1:10, v/v) at 40°C. Vitamins D_2 and D_3 can be detected with antimony(III) chloride (Carr-Price reagent) and antimony(V) chloride (gray-blue and orange-red spots, respectively; limit of detection 0.025–0.300 μg), with concentrated sulfuric acid (brown and green spots, respectively, of vitamins D_2 and D_3; limit of detection 30 μg), with tungstophosphoric acid (gray-brown spots; limit of detection 0.2 μg), with molybdophosphoric acid (gray-blue spots; limit of detection 0.3 μg),and with trichloroacetic and trifluoroacetic acids (limit of detection 0.1–0.2 μg).[1–3,10] Vitamins D_2 and D_3 separated by adsorption TLC were visualized with 0.005% aqueous new fuchsine solution.[6] Vitamin D_3 was also detected with sodium hydroxide (yellow and orange spots in visible and UV light, respectively; limit of detection 1–8 μg), with iron(III) chloride (brown-red spot in visible light; limit of detection 8 μg), with iodoplatinate (black and brown spots in visible and UV light, respectively; limit of detection 1–8 μg), and with phosphomolybdate (pinkish brown spot in visible light; limit of detection 8 μg).[1–3] Bromocresol green, bromothymol blue, and helasol green can be used for detection of vitamins D_2 and D_3 after adsorption TLC (limit of detection 5 μg) and partition TLC (limit of detection 50 μg), respectively.[11] Jork et al.[10] obtained the fluorescence scan (λ_{exc} = 436 nm and λ_{fl} > 560 nm) of a chromatogram track with 50 ng vitamin D_3 per chromatogram zone after its separation on high-performance thin-layer chromatography (HPTLC) Kieselgel 60 (E. Merck) plates using cyclohexane–diethylether (40:20, v/v).

VITAMIN E

In nature, vitamin E occurs in eight different forms (α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols), with varying biological activities. The biological properties of α-tocopherol are of particular importance. Of these eight compounds, α-tocopherol has the highest biological activity. The relative affinity (%) is 100, 38.1 ± 9.3, 8.9 ± 0.6, and 1.6 ± 0.3, respectively, for α-, β-, γ-, and δ-tocopherols.[8] Tocopherol possesses three asymmetric carbon atoms, and there are eight possible stereoisomeric tocopherols. Natural α-tocopherol occurs as the enantiomer about the configuration 2R, 4′R, and 8′R. Semisynthetic α-tocopherol is a mixture of the diasteroisomers about the configuration 2R/S, 4′R, and 8′R. The antioxidative effect of the different tocopherols may not be identical. It has been shown in antioxidation tests with foodstuffs that the antioxidative activity of the tocopherols increases in the order γ-, δ-, β-, and α-tocopherols. Vitamin E occurs principally in wheat germ, vegetable oil, and vegetables.

Tocopherols, α-, β-, γ-, and δ-, were separated (R_M values 0.438, 0.037, 0.008, and –0.275, respectively) on Kieselguhr G plates impregnated with a 10% solution paraffin oil in hexane with a mobile phase of methanol–water (9.5:0.5, v/v) by Sliwiok and Kocjan.[12] They correlated their results with those of quantum-mechanical

calculations and respective steric effects, and observed steric effects' influence on hydrophobic properties and biological activity of tocopherols. The percentage portion of $-CH_3$ groups in the chroman ring is 10.47, 7.21, 7.21, and 3.73, respectively, for α-, β-, γ-, and δ-tocopherols. Steric effects of the OH groups in α-, β-, γ-, and δ-tocopherols were earlier presented.[2,12] Hydrophobic constants (h_f values 20.5, 17.2, 16.6, and 14.8, respectively, for α-, β-, γ-, and δ-tocopherols) were determined by adsorption TLC (Kieselgel G plates and benzene–acetone, 9:1, v/v, as the mobile phase) and the partition coefficient by Rekker (log P 12.37, 11.86, 11.86, and 11.35, respectively, for α-, β-, γ-, and δ-tocopherols) were calculated for investigated tocopherols. It was established that the investigated tocopherols can be arranged with respect to their hydrophobic properties in the order α-tocopherol > β-tocopherol > γ-tocopherol > δ-tocopherol.[12]

However, enantiomers of DL-α-tocopherol were separated on Chiralplates (Machery–Nagel, Germany) with 2-propanol–water–methanol (17:2:1, v/v) as the mobile phase.[13] Under these conditions, two bands were generated with R_F values of 0.72 and 0.62.

Tocopherols, α-, β-, γ-, and δ-, were separated by reversed-phase high-performance thin-layer chromatography (RP-C_{18}-HPTLC), normal-phase high-performance liquid chromatography (NPHPLC), reversed-phase high-performance liquid chromatography (RP-C_{18}-HPLC), and gas chromatography (GC).[8] R_F values of the α-, β-, γ-, and δ-tocopherols separated by RP-C_{18}-HPTLC, using ethanol–water as the mobile phase, are shown in Table 1. The chromatographic conditions used allowed for the separation of the four tocopherols in various biological samples. The selected topological indices based on the connectivity–adjacency matrix (M^{ν},$^{1}\chi^{\nu}$), on distance matrix (W, ^{o}B, MTI), and on information theory (I_{AC},I_{AC}) were calculated for these tocopherols. The observed chromatographic separations of investigated tocopherols were compared. The comparison indicated that RP-C_{18}-HPTLC, HPLC, and GC are the best techniques for the separation of these tocopherols. Topological index ^{o}B was the most significant. A definite dependence between the numerical values of the topological index ^{o}B and the chromatographic separation of the investigated tocopherols was obtained.[8]

Pyka and Niestroj applied the dipole moments (or permittivity) of mobile phases and the topological indices to predict the R_M values of α-, β-, γ-, and δ-tocopherols separated on RP-C_{18}-HPTLC plates using methanol, ethanol, *n*-propanol, and mixtures containing ethanol and water, and *n*-propanol and water in the volume proportions 9.5 + 0.5, and 9 + 1 as mobile phases. The best regression equations were obtained using one topological index from among the topological indices $^{2}\chi^{\nu}$, ^{o}B, or C.[14]

Hachuła and Buhl[15] described analytical methods to determine α-tocopherol in Vitaminum E capsules (Polfa, Poznan, Poland) and soybean oil. Determination of α-tocopherol (after extraction of samples) has been performed by TLC on silica gel plates with benzene–ethanol (99:1, v/v) as the mobile phase. Levels of α-tocopherol in Vitaminum E capsules and in soybean oil were earlier presented.[2,15] The results obtained by authors indicate that they were in good agreement with those expected, and the precision of the measurements was satisfactory.

Densitometry was used for quantitative determination of α-tocopherol acetate in Vitaminum E oral fluid (Medana, Poland). The sample of Vitaminum E was prepared in absolute ethanol. Chromatography was performed on glass TLC plates with layers of silica gel 60 F_{254} (E. Merck, #1.05715) and using toluene as the mobile phase. The quantitative densitometric analysis on Camag TLC Scanner 3 was performed using analytical curve. On the basis of densitometric analysis, it was shown that the R_F value of α-tocopherol acetate is equal to 0.46 and the band characterized by absorption maximum of α-tocopherol acetate is placed at $\lambda_{max} = 203$ nm. The second densitometric band occurs on the chromatogram and has an R_F value equal to 0.33 and the band is characterized by absorption maximum at 200 nm; it is a chromatographic band of contraries that occurs in Vitaminum E preparation. It was stated that the contents of α-tocopherol acetate is equal to 104.5% in relation to the content declared by the Medana producer of Vitaminum E oral fluid. The presented method is accurate, selective, and precise, and can be used for routine quality control analysis and quantitative determination of α-tocopherol acetate in Vitaminum E preparation.[16]

Vitamin E compounds can be visualized (about 20 μg) as dark spots in UV light. They appear violet, and detection is more sensitive (0.02 μg) on layers that contain 0.02% sodium-fluorescein. Moreover, these are visible in daylight as red spots (limit of detection 2 μg). Spraying with fluorescein or dichlorofluorescein reagent produces the same effect. Non-specific visualization procedures for tocopherols and tocotrienols are based on spraying with sulfuric acid, molybdophosphoric acid, antimony(V) chloride, dipyridyl-iron reagent, nitric acid, copper(II) sulfate–phosphoric acid, or bathophenanthroline. α-Tocopherol was also visualized by a coupled redox-complexation reaction with iron(III) chloride, phenanthroline, and bromophenol blue.[1–3,10] Aniline blue, alkaline blue, and bromothymol blue can also be used for detection of vitamin E (1 μg) after adsorption TLC.[11] When β-carotene was used as a TLC spray reagent, tocopherols (10 μg) appeared as yellow spots against a white background.[1–3,10] The densitogram of D-α-tocopherol after spraying dipyridyl-iron reagent was given by Jork et al.[10] They obtained the reflectance scan ($\lambda = 520$ nm) of a chromatogram track with 200 ng D-α-tocopherol after its separation on HPTLC Kieselgel 60 (E. Merck) plates with the use of toluene–chloroform (10:10, v/v).

Six dyes as new visualizing reagents: gentian violet, methylene violet, methylene blue, methyl green, malachite green, and Janus blue, have been used to detect (±)-α-

tocopherol, and (+)-α-tocopherol acetate on silica gel 60.[17] Rhodamine B and 2,2′-bipyridine–iron(III) chloride reagent were used as the comparative visualizing reagents. The limit of detection (detectability), detection index, broadening index, modified contrast index, densitometric visualizing index, and linearity range were determined for (±)-α-tocopherol, and (+)-α-tocopherol acetate following the use of these visualizing reagents (Tables 2 and 3).[17] Among all the new visualizing reagents studied, methylene violet and methyl green are the best for detecting (±)-α-tocopherol. The densitometric bands of (±)-α-tocopherol after detection with methylene violet and methyl green are compacted (β are equal to 8° and 9°, respectively) and linearity ranges are from 0.75 to 5.76 μg. Methylene violet and methyl green are better visualizing reagents in comparison with universally applied Rhodamine and 2,2′-dipirydyl–iron(III) chloride reagent to detect (±)-α-tocopherol. The densitometric band of (±)-α-tocopherol after detection with Rhodamine has β equal to 12°; however, densitometric band of (±)-α-tocopherol after detection with 2,2′-dipirydyl–iron(III) chloride reagent is compact (β is equal to 9°), but the limit of detection of (±)-α-tocopherol is then equal to only 2.08 μg, whereas densitometric limit of detection of (±)-α-tocopherol after the use of methylene violet, methyl green, and Rhodamine B is equal to 0.30 μg. Densitometric analysis of (±)-α-tocopherol without using a visualizing reagent can also be recommended, because the limit of detection is equal to 0.45 μg; however, the linearity range is from 3.46 to 20.00 μg. The densitograms of 25.00 μg (±)-α-tocopherol without using a visualizing reagent and after detection with 2,2′-dipirydyl–iron(III) chloride reagent are presented in Fig. 1a and b, respectively. The densitograms of 25.00 μg (±)-α-tocopherol after detection with Rhodamine B and methylene violet are presented in Fig. 2a and b, respectively.[17]

The best way for detecting (+)-α-tocopherol acetate is the densitometric method without using a visualizing reagent. However, the densitometric limit of detection of (+)-α-tocopherol acetate is equal to 0.30 μg, and the linearity range is from 0.75 to 20.00 μg. However, among all studied new visualizing reagents, gentian violet, methyl green, and Janus blue are the best for detection of (+)-α-tocopherol acetate. These visualizing reagents have detection properties similar to (+)-α-tocopherol acetate in relation to Rhodamine B. The densitograms of 25.00 μg (+)-α-tocopherol acetate without using a visualizing reagent and after detection with methyl green are presented in Fig. 3a and b, respectively. The densitograms of 25.00 μg (+)-α-tocopherol acetate after detection with Rhodamine B and gentian violet are presented in Fig. 4a and b, respectively.[17]

It was stated that it was possible to obtain a linear dependence between the area of the densitometric band and the quantity of spotted (±)-α-tocopherol or (+)-α-tocopherol acetate by all apllied ways of detection. The range of linearity is different for different visualizing reagents and also depends on the detected compound.[17]

VITAMIN K

Physiological forms of vitamin K are vitamin K_1 (phylloquinone, phytonadione) and vitamin K_2 (farnoquinone). Active analogues and related compounds, known as vitamin K, are menadiol diphosphate, menadione (vitamin K_3), menadione bisulfite, phthiocol, synkayvite, menadiol (vitamin K_4), menaquinone-*n* (MK-*n*), ubiquinone (Q-*n*), and plastoquinone (PQ-*n*). Phylloquinone (K_1), and menaquinone-4 (MK-4) are natural K vitamins and are often used as medicines to prevent intracranial hemorrhage in the newborn. Vitamin K contributes to the formation and regulation of numerous proteins in the body, but most significantly to prothrombin, a protein essential for blood clotting. Vitamin K is also necessary for converting prothrombin to thrombin, which is also required for blood clotting.

Argentation TLC (on silver nitrate-impregnated silica gel plates) and hexane–ethyl acetate–di-isopropyl ether (2:2:1, v/v) as the mobile phase were used to separate vitamins K_1, K_2 K_3, ubiquinone-6, ubiquinone-9, and ubiquinone-10 (R_F values 0.71, 0.63, 0.57, 0.42, 0.21, and 0.28, respectively).[18]

Perisic-Janjic, Petrovic, and Hadzić[5] described a method for the quantitative analysis of hydrophobic vitamins K_3, K_4, and K_5 by thin-layer chromatography on starch, cellulose impregnated with paraffin oil, and talc (unimpregnated) using a mixture of water–dioxane–acetone–formaldehyde (85:20:15:25, v/v/v/v) as the mobile phase (Table 1).

Hachuła[19] developed a sensitive spectrophotometric method for the determination of vitamin K_4 in drugs (Styptobion, E. Merck) after chromatographic separation on silica gel with benzene–acetone (9:1, v/v) as the mobile phase. Beer's law was obeyed for 0.3–1.0 μg/ml vitamin K_4 ($\varepsilon = 196{,}000$). No detection limit was given. The results obtained from the proposed analytical procedure were in good agreement with those expected and the precision of the measurement was satisfactory. The proposed method is rapid and involves rather low analysis costs.

All lipoquinones at levels of 0.5 μg or more are visible as dark spots on layers containing inorganic fluorescent material when illuminated with UV light, after adding sodium-fluorescein or rhodamine B or 6G to the adsorbent, or by spraying the chromatographed layer with fluorescein or dichlorofluorescein reagent. These compounds can be detected in daylight and, with high sensitivity, in UV light. Vitamin K compounds can be detected with iodine vapor (brown spots), with concentrated sulfuric acid followed by heating (violet spots, limit of detection 3 μg), with molybdophosphoric acid (gray-blue spots, limit of detection 0.5 μg), and with potassium hexaiodoplatinate reagent. Long- and short-wave UV light were used to detect vitamin K; under shortwave UV light, vitamin K showed an intense

Table 2 Fundamental absorption band, broadening index, detection index and characteristic of densitometric band, modified contrast index, densitometric limit of detection, densitometric visualizing index, and linearity range of (±)-α-tocopherol on silica gel 60.

Detection way	Fundamental absorption band λ_{max} (nm)	Broadening index [μg/(AU)]	Detection index [μg/(AU)]	Densitometric band characteristic of 25 μg (±)-α-tocopherol			Modified contrast index (AU/deg)	Limit of detection (μg)	Densitometric visualizing index [AU/(μg.deg)]	Linearity range (μg/spot) (*r*, correlation coefficient)

purple color. Vitamin K_1 was also detected with antimony(III) chloride (pink spots in visible light, limit of detection 8 μg), with iron(III) chloride (blue spot in visible light; limit of detection 8 μg), with sulfuric acid (green-brown spot in visible light; limit of detection 8 μg), with iodoplatinate (yellow and brown spots in visible and UV light, respectively; limit of detection 1–8 μg), and with phosphomolybdate (black spot in visible light; limit of detection 8 μg).[1–3,10]

SEPARATION OF MIXTURES OF HYDROPHOBIC VITAMINS AND OF HYDROPHOBIC VITAMINS FROM OTHER COMPOUNDS

Perisic-Janjic, Petrovic, and Hadzić[5] described a method for the quantitative analysis of a mixture of hydrophobic vitamins (vitamins A acetate, A palmitate, K_1, DL-α-tocopherol, DL-α-tocopherol acetate, D_2, D_3, K_3, K_4, and K_5) by TLC on starch, cellulose, talc impregnated with paraffin oil, and on unimpregnated talc. Vitamins A acetate, A palmitate, K_1, DL-α-tocopherol, DL-α-tocopherol acetate, D_2, and D_3 were separated on starch, cellulose, talc impregnated with paraffin oil using acetone-concentrated acetic acid (3:2, v/v) (Table 1), while vitamins K_3, K_4, and K_5 migrated with the front. Differences between the R_F values were satisfactory (except for vitamin A acetate and vitamins D_2 and D_3) and allowed for accurate identification. Vitamins K_3, K_4, and K_5 can be separated on starch impregnated with paraffin oil using a mixture of water–dioxane–acetone–formaldehyde (85:20:15:25, v/v/v/v) as the mobile phase, whereas all the others remain at the start position of the chromatographic plate. Separation is good on all three supports. It is necessary to point out that vitamins K_3, K_4, and K_5 were separated on the unimpregnated talc thin layer (Table 1).

Most of the prenyl lipids, such as chlorophylls, carotenoids, and prenylquinones, as well as tocopherols and vitamin K_1, which occur in plant lipid extracts, can be separated by TLC using silica gel plates or special mixtures of silica gel with other adsorbents.[18] But, the compounds with one double bond per isoprene and others with a partially or fully unsaturated isoprenoid chain can be separated efficiently by argentation TLC.

Chromatographic systems have been developed for RPTLC separation of hydrophobic vitamins on RP-18 as the stationary phase by Baranowska and Kadziolka.[9] A mixture of hydrophobic vitamins (A acetate, E, E acetate, and D_3) was separated using acetonitrile–benzene–chloroform (10:10:1, v/v) as the mobile phase (Table 1). Applied chromatographic conditions do not permit the separation of vitamin E and vitamin E acetate. Derivative spectrometry was used to determine vitamin A acetate in mixtures with other hydrophobic or water-soluble vitamins. Spectrodensitometric analysis of hydrophobic vitamins enables determination of vitamin A-acetate in the presence of vitamins E, E-acetate, and D_3 as well as lso of C, B_1, and nicotinamide, as earlier presented.[2,9]

Wardas and Pyka[11] separated vitamins D_2, D_3, acid of vitamin A, and DL-α-tocopherol by NPTLC and RPTLC. Vitamins D_2 and D_3 could not be separated by NPTLC and RPTLC. Eleven visualizing agents were used for detection of vitamins on TLC plates. In adsorption TLC, the limits of detection found for the vitamins followed the pattern: DL-α-tocopherol > acid of vitamin A > vitamin D_2 and D_3. After separation using adsorption TLC, the best results were obtained with aniline blue, alkaline blue, phenol red, bromocresol green, brilliant cresyl blue, and bromophenol blue. After separation using partition TLC, the best results were obtained with bromothymol blue and helasol green. The R_F values and limits of detection (μg) were earlier presented.[2,11] The color formation of vitamins D_2, D_3, acid of vitamin A, and DL-α-tocopherol with these visualizing agents were presented in earlier work.[1] The spectrodensitograms of α-tocopherol acetate, α-tocopherol, and cholecalciferol, without using the visualizing reagent,

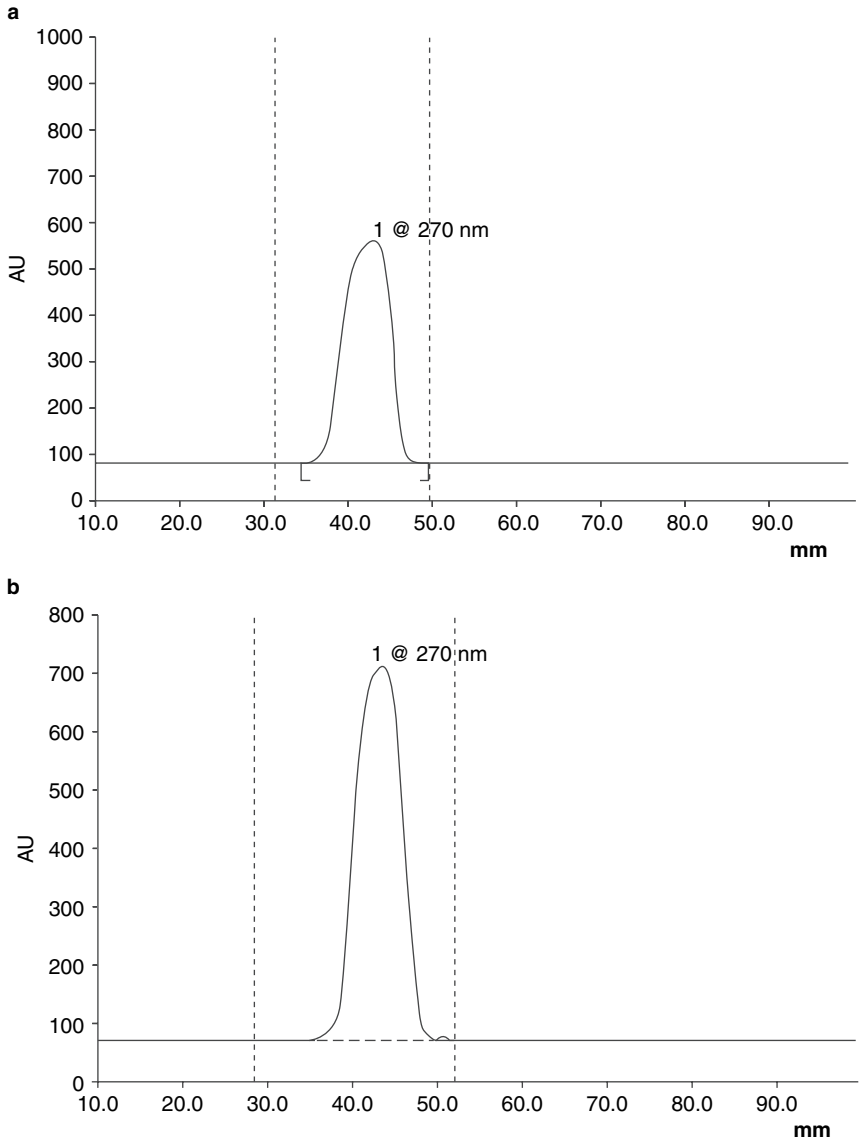

Fig. 2 Densitograms of 25.00 μg (±)-α-tocopherol after detection with (a) Rhodamine B; (b) methylene violet.
Source: From Analytical evaluation of visualizing reagents used to detect tocopherol and tocopherol acetate on thin layer, in J. Liq. Chromatogr. Relat. Technol.[17]

on different chromatographic sorbents (silica gel 60, silica gel 60 $F_{254,}$ mixture of silica gel 60 and Kieselguhr $F_{254,}$ neutral aluminum oxide $60F_{254,}$ neutral aluminum oxide $150F_{254,}$ and RP-18W) were compared.[20] The resultant spectrodensitograms of the studied compounds indicate that applied sorbents have an influence on the wavelength of the obtained fundamental absorption band (λ_{max}) and the additional absorption bands, as well as on their intensity values (AU). This fact indicates the need for standardization of the spectrodensitometric investigations regarding the applied chromatographic conditions.[20]

COMPARISON OF LIPOPHILIC PROPERTIES OF HYDROPHOBIC VITAMINS

The fat-soluble vitamins, namely, vitamin A (retinol, retinol acetate, retinol palmitate), vitamin D_2 (ergocalciferol), vitamin D_3 (cholecalciferol), vitamin E [(±)-α-tocopherol and tocopherol acetate], vitamin K_1 (phytonadione), and vitamin K_3 (menadione) were investigated by RPTLC on $RP8F_{254s}$ and $RP\text{-}18F_{254}$ plates with methanol–water mixtures of different volume compositions as the mobile phases. Linear relationships were obtained between the R_M values of the fat-soluble vitamins and the volume fraction of methanol in the mobile phase. Retention values, R_M, were extrapolated to zero methanol content and the lipophilicity values $R_{MW(RP8)}$ and $R_{MW(RP18)}$ obtained were compared with measured partition coefficients ($\log P_{exp}$) and partition coefficients ($A\log P_s$, $AC\log P$, AB/$\log P$, COSMOFRAG, milog$P$, KOWWIN, $x\log P$) were calculated using seven different software products.[21] The lipophilicity values $R_{MW(RP8)}$ and $R_{MW(RP18)}$ obtained indicate that menadione has the lowest lipophilicity. Retinol and retinol acetate have intermediate lipophilicity. However,

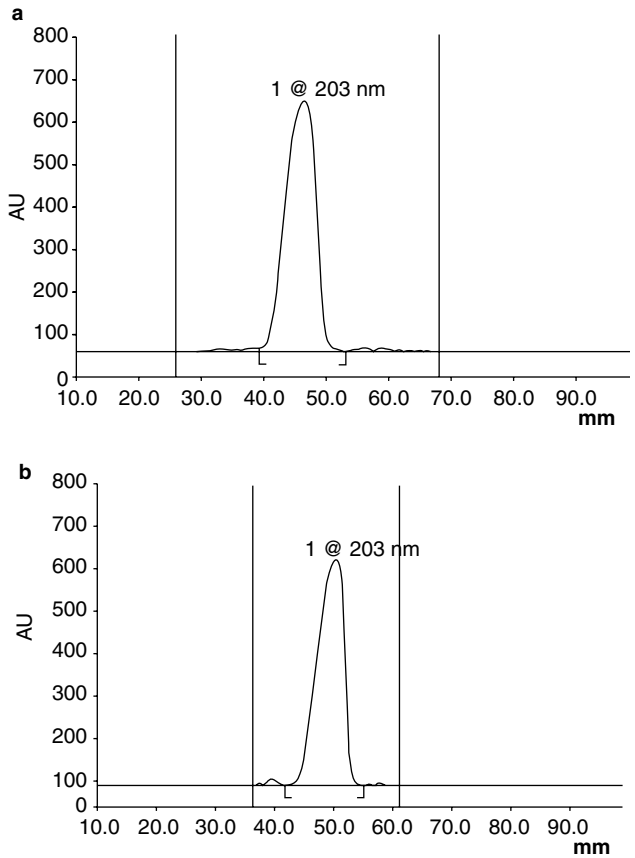

Fig. 3 Densitograms of 25.00 μg (+)-α-tocopherol acetate (a) without use a visualizing reagent; (b) after detection with methyl green.

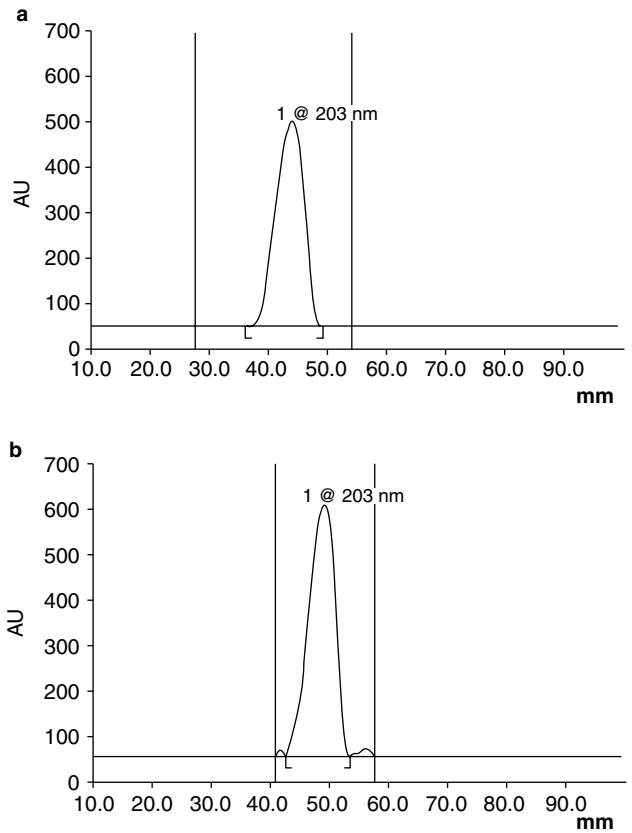

Fig. 4 Densitograms of 25.00 μg (+)-α-tocopherol acetate after detection with (a) Rhodamine B; (b) gentian violet.
Source*:* From Analytical evaluation of visualizing reagents used to detect tocopherol and tocopherol acetate on thin layer, in J. Liq. Chromatogr. Relat. Technol.[17]

ergocalciferol and cholecalciferol have higher lipophilicity and tocopherol, tocopherol acetate, phytonadione, and retinol palmitate have the highest lipophilicity. Cluster analysis was also applied for the comparison of the theoretical partition coefficients with the chromatographic lipophilicity ($R_{MW(RP8)}$ and $R_{MW(RP18)}$) of the fat-soluble vitamins. It was stated that the lipophilicity value $R_{MW(RP8)}$ shows the largest similarity to *AC*log*P*; however, $R_{MW(RP18)}$ shows the largest similarity to the theoretical partition coefficient KOWWIN. $R_{MW(RP8)}$ and $R_{MW(RP18)}$ values (i.e., values obtained on RP8F_{254s} and RP-18F_{254s} plates) well describe the lipophilic properties of fat-soluble vitamins.[21]

CONCLUSIONS

This entry has discussed the use of TLC in the investigation of hydrophobic vitamins. In earlier articles, Pyka referenced the full scientific literature for analysis of hydrophobic vitamins investigated by the TLC technique.[1–3] The use of TLC as a separation method allows for the qualitative and quantitative investigation of hydrophobic vitamins. The use of TLC techniques, together with densitometry, gives precise and sensitive quantification of vitamins A, D, E, and K compounds on TLC plates. Thin-layer chromatography is an important investigative technique for the analysis of hydrophobic vitamins.

INTRODUCTION

Cross-axis coil planet centrifuges (cross-axis CPC), which have been widely used in the separation of natural and synthetic products, are some of the most useful models among various types of countercurrent chromatographic (CCC) apparatuses.[1–3] It produces a unique mode of planetary motion such that the column holder rotates about its horizontal axis while revolving around the vertical axis of the centrifuge.[4–5] The centrifugal force field produced by the planetary motion provides stable retention of the stationary phase for polar two-phase solvent systems such as aqueous–aqueous polymer phase systems with extremely low-interfacial tension and high viscosity. Our previous studies demonstrated that cross-axis CPC, equipped with either a multilayer coil or eccentric coil assembly in the off-center position of the column holder, can be effectively applied for the separation of proteins[6–8] and sugars.[9]

This entry illustrates the CCC separation of various vitamins by means of cross-axis CPC equipped with eccentric coil assemblies.[10–11]

APPARATUS AND SEPARATION COLUMNS

All existing cross-axis CPCs are classified according to their relative column position on the rotary frame, e.g., *X*,[4–5] *XL*,[12] *XLL*,[13] and *XLLL*,[14] where *X* is the distance from the column holder axis to the central axis of the centrifuge, and *L* is the distance between the holder and the middle point of the rotary shaft. Increasing the ratio *L*/*X* improves the retention of the stationary phase by moderating phase mixing. The separations of vitamins described below were performed using the $X - 1.5L$ cross-axis CPC, which holds the separation column at $X = 10$ cm and $L = 15$ cm.

The separation column was prepared by means of a pair of eccentric coil assemblies, which were made by winding a single piece of 1 mm I.D. polytetrafluoroethylene (PTFE) tubing onto 7.6 cm long, 5 mm O.D. nylon pipes forming 20 units of serially connected left-handed coils. Then, a set of these coil units was arranged around the holder with their axes parallel to the holder axis. A pair of identical coil assemblies was connected in series to obtain a total column capacity of 26.5 ml.

CCC SEPARATION OF WATER-SOLUBLE VITAMINS

In CCC, the partition coefficient (K) is an important parameter which is used for selecting the optimal solvent system because it predicts the retention time of each component. Table 1 shows the K values of various water-soluble vitamins in the 1-butanol/aqueous 0.15 *M* monobasic potassium phosphate system. Most of the water-soluble vitamins were partitioned, almost unilaterally, into the aqueous phase in this solvent system, except that riboflavin and nicotinamide were distributed significantly into the organic phase ($K = 0.54$–1.84). Adding ethanol to the two-phase solvent system significantly increased the

Table 1 Partition coefficients of water-soluble vitamins in 1-butanol/aqueous 0.15 *M* monobasic potassium phosphate two-phase solvent systems.

1-Butanol	1	4	8
Ethanol	0	1	3
0.15 *M* KH_2PO_4	1	4	8
Thiamine nitrate (M.W. 327.36)	0.03	0.05	0.11

Riboflavin sodium phosphate (M.W. 478.33)	0.11	0.18	0.34
Pyridoxine hydrochloride (M.W. 205.64)	0.23	0.43	0.59
Cyanocobalamin (M.W. 1355.38)	0.04	0.12	0.24
L-Ascorbic acid (M.W. 176.12)	0.07	0.11	0.15
Nicotinamide (M.W. 122.13)	1.84	1.41	1.34

Partition coefficients were calculated from the absorbance of the upper phase divided by that of lower phase at 260 nm.

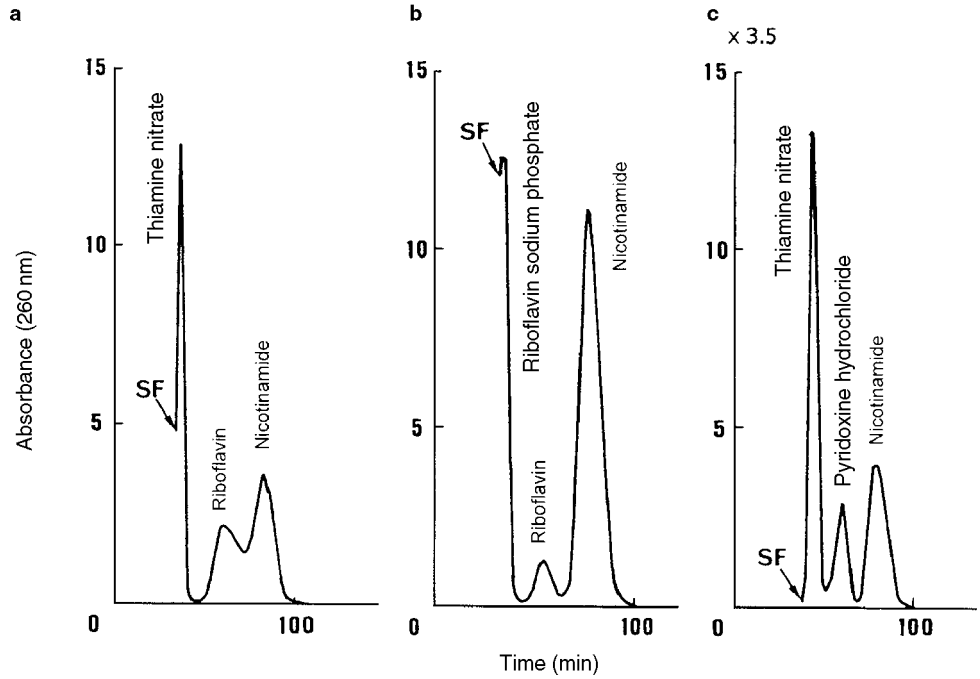

Fig. 1 CCC separation of water-soluble vitamins by cross-axis CPC. Experimental conditions: apparatus, cross-axis CPC equipped with a pair of eccentric coil assemblies, 1 mm I.D. and 26.5 ml capacity; sample. a, Thiamine nitrate (2.5 mg) + riboflavin (1.5 mg) + nicotinamide (2.5 mg). b, Riboflavin sodium phosphate (2.5 mg) + nicotinamide (2.5 mg). c, Thiamine nitrate (2.8 mg) + pyridoxine hydrochloride (4.0 mg) + nicotinamide (3.0 mg); solvent system: (a) and (b) 1-butanol/aqueous 0.15 *M* monobasic potassium phosphate (1:1) and (c) 1-butanol/ethanol/aqueous 0.15 *M* monobasic potassium phosphate (8:3:8); mobile phase: lower phase; flow rate: 0.4 ml/min; revolution: 800 rpm. SF = solvent front.

partition coefficients of riboflavin and pyridoxine hydrochloride.

Fig. 1a illustrates the CCC separation of thiamine nitrate, riboflavin, and nicotinamide by cross-axis CPC, with the 1-butanol/aqueous 0.15 *M* monobasic potassium phosphate (1:1) system. Riboflavin sodium phosphate is also resolved from riboflavin with the same solvent system (Fig. 1b). When a more polar solvent system consisting of 1-butanol/ethanol/aqueous 0.15 *M* monobasic potassium phosphate (8:3:8) is used, thiamine nitrate, pyridoxine hydrochloride, and nicotinamide are well resolved from each other, as shown in Fig. 1c.

In order to improve the separation of each water-soluble vitamin by cross-axis CPC, three ion-pair

Table 2 Effect of ion-pair reagents on partition coefficients of water-soluble vitamins in 1-butanol/aqueous 0.15 *M* KH_2PO_4 solvent systems.

Nicotinamide (M.W. 122.13)	1.32	0.78	1.46	1.39	1.49

Partition coefficients were calculated from the absorbance of the upper phase divided by that of lower phase at 260 nm.

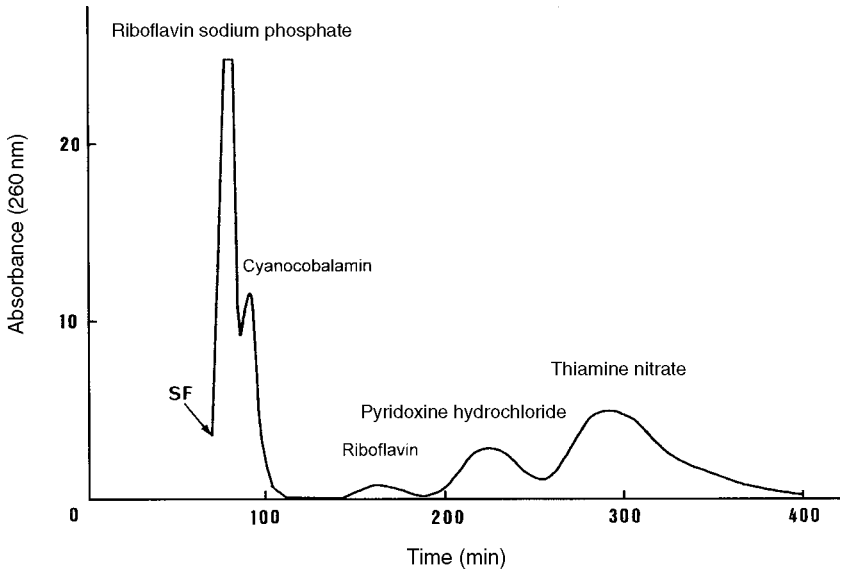

Fig. 2 CCC separation of water-soluble vitamins by cross-axis CPC. Experimental conditions: sample, riboflavin sodium phosphate (2.5 mg) + cyanocobalamin (2.5 mg) + pyridoxine hydrochloride (2.5 mg) + thiamine nitrate (2.5 mg); solvent system, 1-butanol and aqueous 0.15 *M* monobasic potassium phosphate containing 1.5% of 1-octanesulfonic acid sodium salt; mobile phase, lower phase; flow rate, 0.2 ml/min. For other experimental conditions, see Fig. 1 caption. SF = solvent front.

reagents were added to the 1-butanol/aqueous 0.15 *M* monobasic potassium phosphate system. The *K* values of the vitamins in this solvent system are summarized in Table 2. Most of the *K* values increased by increasing the concentration and carbon number of ion-pairing reagents added in the two-phase solvent system. Among these ion-pairing reagents, 1-octanesulfonic acid sodium salt was found to be most suitable and was selected for the separation of water-soluble vitamins by cross-axis CPC.

Fig. 2 illustrates the CCC chromatogram of water-soluble vitamins obtained with the above solvent system, which comprise 1-butanol and aqueous 0.15 *M* monobasic potassium phosphate, including 1.5% of 1-octanesulfonic acid sodium salt. Riboflavin sodium phosphate, cyanocobalamin, riboflavin, pyridoxine hydrochloride, and thiamine nitrate were separated using the lower phase as the mobile phase. Riboflavin was found as an impurity contained in the riboflavin sodium phosphate sample.

CCC SEPARATION OF FAT-SOLUBLE VITAMINS

The *K* values of fat-soluble vitamins obtained with four different kinds of solvent systems are summarized in Table 3. The most suitable solvent system was found to be the 2,2,4-trimethyl pentane (iso-octane)/methanol binary system.

Fig. 3a illustrates the CCC separation of fat-soluble vitamins using the cross-axis CPC equipped with eccentric coil assemblies. Calciferol, vitamin A acetate, and (±)-α-tocopherol acetate were well resolved from each other and eluted within 2.5 hr. Vitamin K_3 and Vitamin K_1 were also completely resolved with the same solvent system, as shown in Fig. 3b.

CONCLUSIONS

As described above, the cross-axis CPC, equipped with eccentric coil assemblies, can be used for the separation of both water-soluble and fat-soluble vitamins by selecting suitable two-phase solvent systems.

Table 3 Partition coefficients of fat-soluble vitamins in four different two-phase solvent systems.

	n-Hexane/aqueous 90% acetonitrile (1:1)	*n*-Hexane/ acetonitrile (1:1)	2,2,4-Trimethyl pentane/methanol (1:1)	*n*-Hexane/ethyl acetate/methanol/water (1:1:1:1)
Vitamin A acetate	5.34	1.69	1.34	130
Calciferol (M.W. 396.66)	8.14	3.29	0.83	71.2
(±)-α-Tocopherol acetate (M.W. 472.25)	48.5	10.1	3.11	62.6
Vitamin K_1 (M.W. 450.71)	61.6	5.79	3.92	9.23
Vitamin K_3 (M.W. 172.19)	0.31	0.22	0.35	2.40

Partition coefficients were calculated from the absorbance of the upper phase divided by that of lower phase at 280 nm.

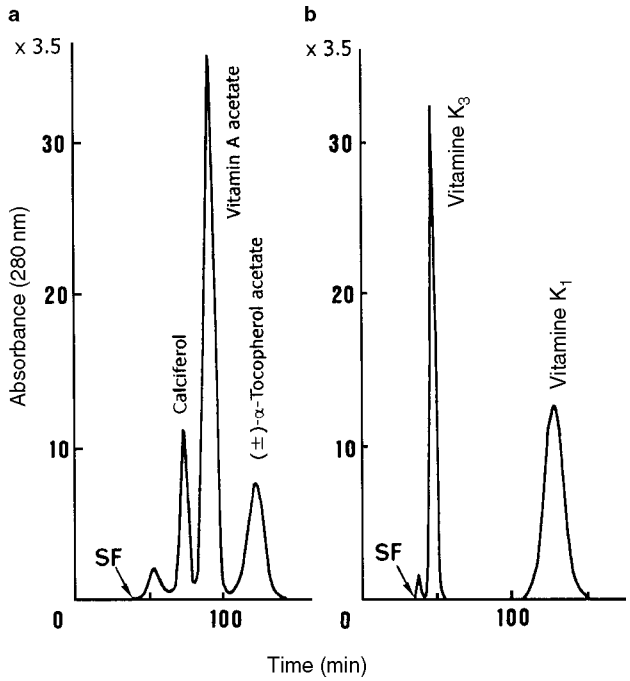

Fig. 3 CCC separation of fat-soluble vitamins by cross-axis CPC. Experimental conditions: sample, (a) calciferol (3 mg) + vitamin A acetate (30 mg) + (±)-α-tocopherol acetate (40 mg) and (b) vitamin K_3 (3 mg) + vitamin K_1 (10 mg); solvent system, 2,2,4-trimethyl pentane/methanol (1:1); mobile phase, lower phase. For other experimental conditions, see Fig. 1 caption. SF = solvent front.

Void Volume in LC

Kiyokatsu Jinno
Department of Materials Science, Toyohashi University, Toyohashi, Japan

INTRODUCTION

The column dead volume can be defined as the space in the column which is not working for the chromatographic separations (i.e., not occupied by the stationary phase and its support). Its value is generally determined by an elution time or elution volume of a non-retained solute in the chromatographic system. If the column dead volume is measured by a retention time of a non-retained solute, one can refer to this as a *column dead time* t_0.

DISCUSSION

The accurate determination of the column void time, t_0, is of fundamental importance in chromatography.[1] This is explained by the fact that a reliable estimation of this quantity is essential for the correct calculation of the retention factors (some refer to this as the *capacity factor*), k, which serves as the fundamental parameter for the comparison of retention data and for the interpretation of the physicochemical phenomena taking place within a chromatographic column. However, the determination of this parameter is very sensitive to the estimated value of the column void time, as can be seen from the equation

$$k = \frac{t_r - t_0}{t_0} \tag{1}$$

where t_r is the solute retention time and t_0 is the column dead time (Fig. 1). A precise knowledge of t_0 is also essential for the proper optimization of the chromatographic system.[2] In contrast to gas chromatography (GC), where the problem of column dead-time determination has been satisfactory solved,[3] determination of the true column void time in liquid chromatography (LC) presents both theoretical and practical difficulties and still remains an open question.

Controversial opinions exist among scientists regarding the meaning of "column dead time" in liquid chromatography (LC).[4] In its broad sense, the term "column dead time" refers to the elution volume of an unretained and unexcluded solute, but it is not easy to establish which solute (if any) can be treated as both unretained and unexcluded. In LC practice, quite a large number of solutes[5] (e.g., mobile-phase components, isotopically labeled mobile-phase components, ionic and nonionic species) had been used as void time markers. The most popular method used in reversed-phase (RP) LC is to use sodium nitrate or sodium nitrite as the probe, but the use of such compounds as the marker was termed clearly dangerous by Berendsen et al.[6] Use of small ionic species such as sodium nitrate as a void time marker was found to have the drawback that there exists a possibility of exclusion of the ionic species and, when used in small concentrations, they serve as the marker for ionic exclusion volume instead of column dead volume (Donan exclusion). Even to use higher concentrations of ionic species is now rarely utilized due to obvious shortcomings by the Donan exclusion effect. Other existing experimental methods for the determination of LC column dead time also represent a serious contradiction of opinions among scientists and, at this moment, there are no definitive methods to determine column t_0.

One promising approach to experimentally determine t_0 is the linearization method,[6] although there are opinions against this method as "undesirable," pointing out some shortcomings. The linearization approach uses the homolog series of compounds, which have various alkyl chains; their retention times are plotted against their chain lengths. Then, the resultant linear curve is extrapolated to zero chain length for the t_0 value. Some people proposed various solutes in homolog series for this purpose, but there is no confirmation

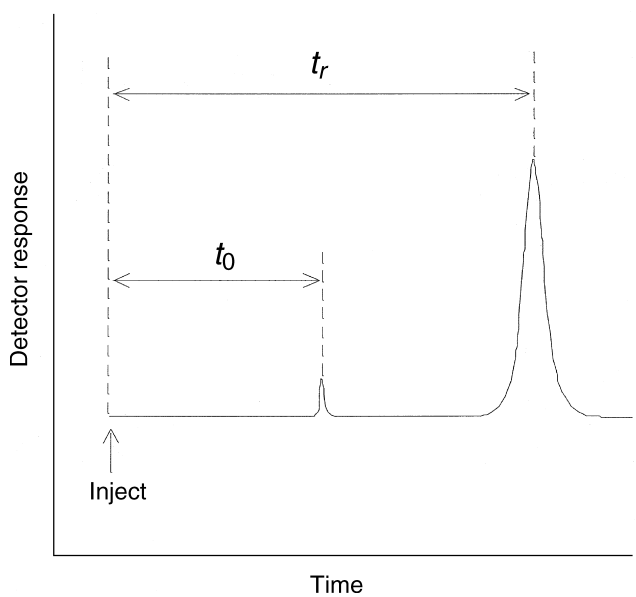

Fig. 1 Void volume determination.

concerning the accuracy of the measured t_0 value and, therefore, the opinions against on this method have also appeared in many publications. On the other hand, static methods[7] have been found to represent the upper limit of column porosity, and not the column dead volume proper.

Although the above discussions have appeared numerous times in many publications, workers always need to determine the retention factor, k, in LC separations. In order to determine t_0 experimentally, one has to state what kind of method was used to determine t_0 in his experiments. This is the only best way at this moment to recommend to all chromatographers concerning column void time, although, in the near future, the "best, reliable, theoretically well-interpreted" methods will be adopted.

Wheat Proteins: FFF

Susan G. Stevenson
N.M. Edwards
K.R. Preston
Grain Research Laboratory, Canadian Grain Commission, Winnipeg, Manitoba, Canada

INTRODUCTION

The technique of flow field-flow fractionation (FFF) has been used for size fractionation and analysis of wheat protein extracts since the mid-1990s. Since that time its application has been facilitated by improvements to instrumentation and new extraction methods allowing accurate quantification of size distribution. In addition, hyphenation of FFF systems with equipment such as refractive index (RI) and multiangle laser light-scattering (MALLS) detectors has enabled direct determination of molecular weight and radius of gyration (R_g), thus allowing estimates of protein shape. All these advances now provide the researcher with a tool that permits the quantitative and qualitative analysis of wheat proteins, and in particular, those larger polymeric proteins previously excluded in the void volume using traditional size fractionation techniques such as size exclusion HPLC (SE-HPLC), gel filtration, and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS–PAGE).

WHEAT PROTEINS

The storage proteins of wheat, collectively referred to as gluten, cover a wide molecular size range and include some of the largest known naturally occurring biological proteins.[1] The monomeric storage proteins (gliadins), as well as the salt soluble albumins and globulins, normally have molecular weights of $<$100,000. The polymeric storage proteins (glutenin) have molecular weights that extend into the millions. The size distribution of the gluten proteins, in particular, the polymeric wheat proteins, is closely related to the dough processing characteristics and quality of wheat based products.[2] Size fractionation techniques such as SE-HPLC, gel filtration, and SDS–PAGE are commonly used to characterize these proteins. These methods normally provide fractionation ranges up to molecular weights of $0.5–1 \times 10^6$ or slightly higher. However, many of the larger polymeric glutenin proteins appear in the void volume with SE-HPLC and gel filtration and are not resolved.[3] Flow FFF provides a newer tool to examine the polymeric wheat proteins, especially those constituting the highest molecular weight glutenin fraction, since its resolution is not impeded by an exclusion limit.[3]

FLOW FFF

Flow FFF is one of a family of techniques that allows fractionation of macromolecules based on size related parameters. A detailed explanation of the mechanism and theory appears elsewhere in this entry. Fractionation is achieved by the application of a field (cross-flow) perpendicular to the channel flow.[4] Components showing greater response to the force exerted by the field are displaced further from the center of the channel flow and toward the channel wall. Laminar flow through the channel produces a parabolic flow profile; therefore, the elution order of components is determined by their relative displacement. Size fractionation range, resolution, and run time can be adjusted by manipulating both the channel flow and the strength of the field. In symmetrical flow FFF, the eluent crossflow is introduced through a porous frit on one side of the channel (depletion) wall and exits through a semipermeable membrane and frit that form the other (accumulation) wall. With asymmetrical flow FFF, the upper channel wall is solid, and crossflow is generated by directing a portion of the channel flow through the accumulation wall. In both methods, components must be "relaxed" or equilibrated within the channel prior to elution. For symmetrical FFF, this is accomplished through a process referred to as "stop–flow" wherein the channel flow is "stopped" by diverting it around the channel leaving sample components exposed solely to crossflow forces. Component separation into layers within the channel occurs as equilibration is reached between crossflow and diffusion forces. In the case of asymmetrical FFF, sample focusing/relaxation is achieved through the use of switching valves to reverse the direction of flow at the channel outlet just prior to injection for the requisite focusing/relaxation period.[5] In conventional mode flow FFF, separation of macromolecules up to approximately 1 μm is based upon their diffusion coefficient.

Particles larger than 1 μm are separated in steric or hyperlayer mode and elute in reversed order (larger to

This entry is a contribution (no. M302) of the Canadian Grain Commission, Grain Research Laboratory, Canada.

smaller). In conventional mode, diffusion coefficients and the related Stokes' diameters (d_s) of separated species can be directly calculated based on elution time and channel characteristics for both symmetrical and asymmetrical flow FFF.[4]

APPLICATION OF FFF TO WHEAT PROTEIN ANALYSIS

Initial Studies

The first two reports on the use of flow FFF for separating wheat proteins appeared in the literature in 1996 when researchers from two independent laboratories reported characterization of wheat proteins from different varieties extracted by different methods and analyzed on two different types of flow FFF apparatus. Wahlund et al.[6] used asymmetrical flow FFF to examine proteins extracted from two bread wheat varieties of different protein content using sequential extraction with increasing concentrations of dilute hydrochloric acid (HCl). Stevenson and Preston[3] used symmetrical flow FFF to examine proteins extracted from Katepwa, a high quality bread wheat variety, using a modification of the traditional Osborne extraction procedure. Results from both studies showed that d_s for the monomeric gliadin-type fractions ranged in size from 8 to 10 nm while those of the polymeric glutenin fractions ranged from 15 to 35 nm in size.[3,6] Calculation of molecular weights based on hydrodynamic diameter transformations (lower limit defined by flexible random coil and upper limit by spherical protein) for the larger glutenin components resulted in values consistent with those reported in the literature for glutenins (440,000–11 million).[6]

Refinements to Equipment and FFF Techniques

A number of refinements to equipment design and techniques have been introduced since publication of the original wheat protein studies. Incorporation in the flow FFF channel of a frit inlet (FI), a small piece of permeable frit material equipped with a separate FI embedded in the depletion wall of the channel just past the sample inlet, has permitted the use of hydrodynamic relaxation as a replacement for stop–flow relaxation, thus eliminating pressure fluctuations associated with the latter.[7] FI also reduces sample adhesion to the membrane on the accumulation wall, thereby reducing the likelihood of baseline drift and artifacts. Incorporation of a frit outlet (FO) located at the depletion wall of the channel just before the channel outlet has facilitated the removal/recirculation of a high proportion of eluent buffer. The remaining eluent buffer containing the sample components is eluted in the channel outlet flow at much higher (up to 10 times)[7,8] effective concentrations resulting in much higher detector signal to noise ratios thereby eliminating the need for extremely sensitive detection methods. Recirculation of the FO flow back through the FI and that of the crossflow back through the upper frit leads to further baseline stability.[9]

Stevenson, Ueno, and Preston[9] used these refinements in channel architecture and techniques in the development of the first automated FFF procedure by using a frit inlet/frit outlet (FIFO) flow FFF channel with recirculating frit and crossflows. In addition to much higher throughput, analysis of wheat protein fractions produced by the same Osbome fractionation method and from the same flour as used for previous stop–flow studies[3] showed improved separation with more well-resolved peaks, particularly with the two polymeric glutenin protein fractions [acetic acid (HAc) extractable and sonicated HAc extractable]. As can be seen in Fig. 1a and b, the major peaks for albumins and globulins and for gliadins indicate molecular sizes <10 nm. The HAc extractable proteins (Fig. 1c) show major peaks at d_s 8 and 11 nm plus significant tailing in the 20–35 nm area, indicating the presence of some larger polymeric glutenin. The molecular size distribution in the sonicated fraction (Fig. 1d) covers a very broad range ($d_s = 12–50 + $ nm). Examination of all four fractograms (Fig. 1a–d) demonstrates that the bulk of the large polymeric material is extracted with sonication. The automated FIFO system also allows much more precise quantification of fractogram peak areas and/or size ranges. Average coefficients of variability of peak areas for six standard molecular size marker proteins were $<2\%$ while wheat protein size fractions showed values $<5\%$. The automated FFF procedure was exploited in conjunction with a simplified sequential extraction technique[10] employing dilute HAc without, then with, sonication to extract monomeric rich and polymeric rich wheat protein fractions to study the relationship of size distribution to dough strength properties. The proportion of total flour protein in the polymeric fraction and that of the larger sized (d_s) polymeric protein above 20 nm were highly correlated to dough mixing time. An extraction efficiency of about 97% compared favorably with that obtained using the same extraction protocol with 2% SDS in 0.05 *M* phosphate buffer, the buffer commonly used for polymeric wheat protein extraction. Added potential advantages of using HAc rather than SDS based buffers include easier removal from extracted protein where additional studies are to be conducted and less disruption of the secondary protein structure.

More recently, direct coupling (hyphenation) of MALLS and RI detectors to flow FFF channel has been used to provide direct, accurate determination of molecular weights, R_g and conformation of polymeric wheat proteins.[11–13] Problems such as overloading the FFF channel in order to provide sufficient signal for RI/MALLS have been addressed for both asymmetrical[11] and symmetrical[12] FFF.

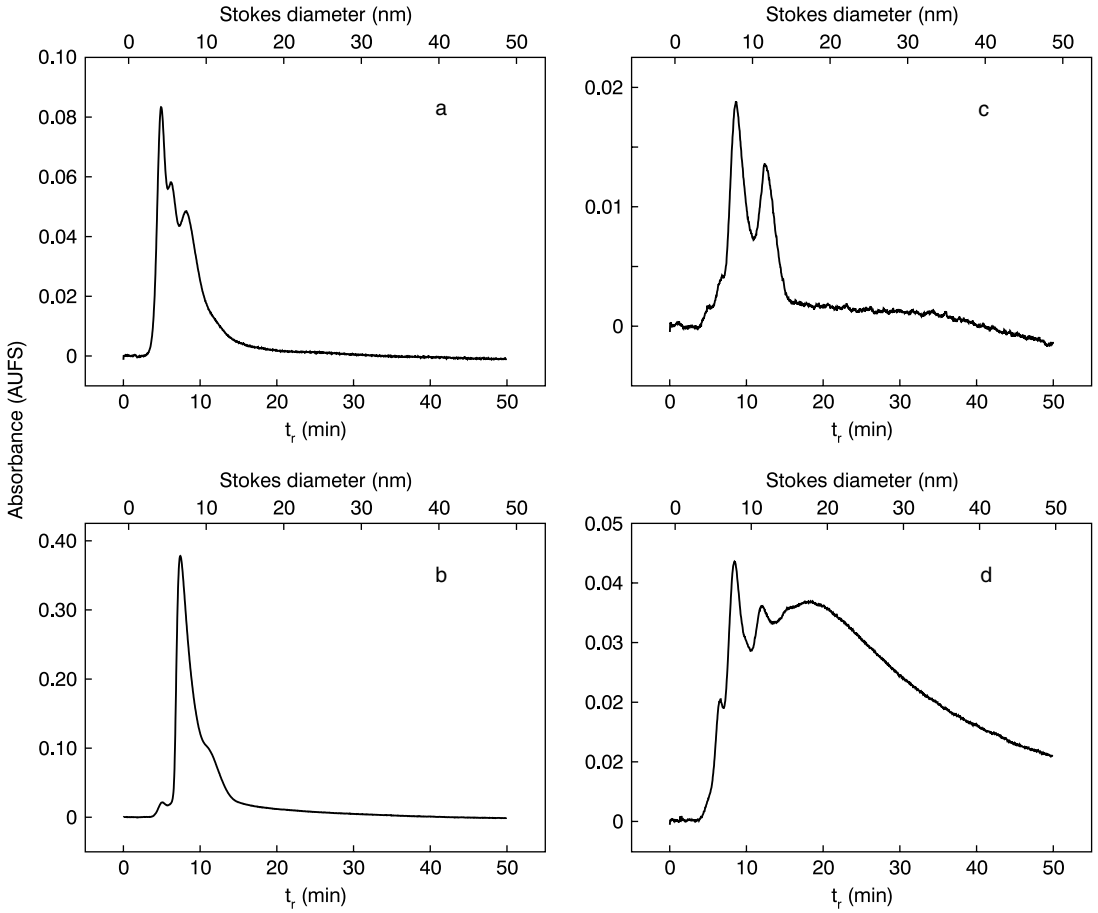

Fig. 1 Elution profiles for (a) albumin and globulin, (b) gliadin, (c) glutenin, and (d) sonicated acetic acid extractable fractions run on FIFO automated FFF channel. Normal operating conditions are $V_s = 0.2$, $V_f = 1.4$, and $V_c = 5$ ml/min.

The use of symmetrical flow FFF hyphenated with RI and MALLS detectors to assess the size and shape of sequentially dilute HAc extracted monomeric rich and sonicated HAc extracted polymeric rich wheat proteins was reported by Stevenson et al.[12] M_w values at peak for the monomeric extract varied from 31,000 to 33,000 and increased to approximately 110,000 at later elution times. Results for all five varieties of wheat included in this study were similar for the monomeric wheat protein extracts. The M_w profiles of polymeric extracts for the five wheat samples ranged from 225,000 to 300,000 at peak and increased to approximately 7×10^6 after 60 min of elution as shown in Fig. 2. R_g values for the polymeric protein fraction showed relatively small changes with increasing elution time (M_w), suggesting that the larger M_w polymeric proteins tend toward a more compact structure than the lower M_w polymeric proteins.

An asymmetrical FFF channel coupled to RI and MALLS detectors was used by Arfvidsson and Wahlund[11] to investigate the retention behavior of freeze dried HCl extractable glutenin resuspended by stirring or sonication in SDS buffer. Although sonication provided a rapid and efficient method for glutenin protein dissolution, there was evidence of physical breakdown of the largest glutenin proteins. For analysis of these proteins, the use of gentle stirring for long periods of time was preferable[11] since the average M_w increased to 2×10^7 compared to 5×10^6 with sonication.

Measuring/Monitoring Changes in Molecular Size Distribution

Field-flow fractionation has shown to be useful for systematically monitoring changes in molecular size distribution of wheat proteins, for example, those caused by treatment with oxidants or reductants. Reduction of the polymeric glutenin fractions with dithiothreitol[3] or 2-mercaptoethanol[6] produced shifts in peak positions to <10 nm, indicating release of their interchain disulfide bonded constituent subunits. Stevenson, Ueno, and Preston[9] showed that treatment of a polymeric protein extract with hydrogen peroxide resulted in an increase in the size of the polymers. Several groups[14–16] have used FFF to measure the size distribution of glutenin polymers produced through oxidation of glutenin subunits. Beasley, Blanchard, and Bekes[14] followed the oxidation of purified high- and low-molecular-weight subunits by FFF and confirmed the formation of polymeric proteins. Veraverbeke et al.[15,16] compared the size distribution of glutenin produced by polymerization of high molecular weight glutenin subunits using different oxidation protocols. Field-flow fractionation showed changes in the size distributions of the polymeric proteins over a wide oxidation range, while no significant change in distribution was evident at higher oxidation levels using SE-HPLC and multilayer SDS–PAGE. The failure to see these changes with the latter methods was attributed to their much lower exclusion limit. These researchers[15,16] also showed that the size distribution of the polymers produced by oxidation differed from one oxidant to another.

Of additional significance to wheat protein research was the separation, using flow FFF, of a wheat polymeric protein extract sample collected from the void volume of a typical SE-HPLC run.[10] Size distribution of this sample (Fig. 3) reconfirmed the presence of very large proteins (d_s 50 + nm) in the SE-HPLC void volume and also showed the presence of smaller proteins (4–12 nm), suggesting that these proteins form stable complexes with the larger proteins or among themselves. This implies that the amount of larger polymeric proteins, previously reported in samples based on SE-HPLC areas, is overestimated.[10]

CONCLUSIONS

Continued improvements in FFF instrumentation, refinements in technique and hyphenation with detectors such as MALLS have broadened the application of this method and effectively elevated it from the status of "possibly useful technique" to a reliable "applied research tool" for assessing the size and shape of wheat proteins. For additional reading concerning FFF theory, principles, and applications, the reader is referred to other sections of this encyclopedia as well as to *Field-Flow Fractionation Handbook* edited by Schimpf et al.[17] A review of the application of FFF to wheat protein analysis can also be found in Preston and Stevenson.[5]

Whey Proteins: Anion-Exchange Separation

Kyung Ho Row
Du Young Choi
Center for Advanced Bioseparation Technology and Department of Chemical Engineering, Inha University, Incheon, South Korea

INTRODUCTION

Three strong anion exchange membranes (CIM QA, Q100, and HiTrap Q) and reversed-phase high-performance liquid chromatography (RP-HPLC; 15 μm particle with a pore size of 300 μm) were investigated for the separation of major proteins, which are contained in whey, such as α-lactalbumin, bovine serum albumin (BSA), and β-lactoglobulin. Experiments were performed to determine the optimum mobile phase composition for separating the whey proteins using standard reagents for the proteins. For strong anion exchange membranes, the mobile phases were buffer A (20 mm piperazine–HCl, pH 6.4) and buffer B (buffer A + 1 *M* NaCl), with a linear gradient elution change of salt concentration applied. For RP-HPLC, the mobile phase consisted of a linear gradient of the two mixtures of 0.1% trifluoroacetic acid (TFA) in water and 0.1% TFA in acetonitrile (ACN). Standard protein reagents were used to investigate optimal mobile phase compositions with the three anion exchange membranes. From the experimental results, it was found that HiTrap Q was the most effective in separating whey proteins.

SEPARATION OF WHEY PROTEINS

Milk proteins are the most important source of bioactive peptides. The primary components of bovine milk are water, fat, lactose, and minerals; up to 6% of the mass consists of proteins and peptides, among them a number of high-value substances.[1] Particularly, milk contains two major protein groups (i.e., caseins and whey proteins), which differ greatly with respect to their physicochemical and biological properties. Normal milk contains 30–35 g/L proteins, approximately 80% of which are caseins, with the remainder being whey proteins.[2] Whey proteins can be acquired as a by-product in cheese manufacturing. The required long-term stability in functional performance of these proteins is often lacking. Although the two major proteins are scientifically significant materials, the study of the functional properties of whey proteins has attracted scientific interest for more than 20 years.[3] In general, whey is a dilute liquid composed of lactose, and a variety of proteins, minerals, vitamins, and fat. Whey contains about 6% solids, of which 70% or more is lactose and about 0.7% is proteins.[4] Whey protein components are α-lactalbumin, β-lactoglobulin, immunoglobulin A (IgA), immunoglobulin M (IgM), immunoglobulin G (IgG), BSA, lactoferrin, and lactoperoxidase. β-Lactoglobulin is the major whey protein in bovine milk. β-Lactoglobulin has a molecular mass of 18.4 kDa, possesses 162 amino acid residues, and has a concentration of 2–4 g/L. α-Lactalbumin is an albumin that has 123 amino acid residues. It possesses a molecular mass of 14.2 kDa and its concentration in milk is 0.6–1.7 g/L.[5] Bovine whey proteins have potential applications in veterinary medicine, food industries, and as supplements for cell culture media. IgG, IgA, lactoferrin, and lactoperoxidase, present in bovine whey, have high pharmaceutical value.[6] α-Lactalbumin can be used in infant formula and as a nutraceutical because of its high tryptophan content. β-Lactoglobulin is used in the production of confections.[7] Oral administration of bovine IgG is known to be an effective treatment of various infections of newborn infants.[8] Lactoferrin and lactoperoxidase are known to act as antimicrobial factors.[9] Therefore the whey proteins are used to replace other proteins, or to improve the functional properties of baby food, luncheon meat, soft drinks and milk-based drinks, ice cream, bakery, and convenience products.[10]

Traditionally, separation and purification are frequently achieved by RP-HPLC, although other HPLC methods such as ion exchange chromatography (IEC), hydrophobic interaction chromatography (HIC), size exclusion chromatography (SEC), and various types of affinity chromatography (AC) have also been used.[11] With the development of DNA recombinant techniques, HPLC has become an important tool in both quality control and process control in the production of recombinant proteins of pharmacological interest. This has contributed significantly to the development of RP-HPLC methods that can be used to carry out very rapid analyses for proteins with minimum complexity in both instrumentation and operating conditions.[12] Given the low diffusivity of biopolymers, the need to achieve fast separation of proteins by RP-HPLC has led to the development of different types of packing materials, such as non-porous microparticles (dp <5 μm) or wide-pore materials[13,14] that solve mass transfer problems in the stationary phase, allowing good separations within a reasonable time. The particles used in RP-HPLC have a porous structure of 300 μm.

Separation of whey proteins using ion exchange membranes has been investigated by many researchers and several methods have been reported.[15,16] Ion exchange separations take advantage of electrostatic interaction between surface charges of biomolecules, such as amino acids or proteins, and clusters of charged groups on a membrane. Adsorbing biomolecules displace counterions associated with the surface, discharging a complementary buffer salt in the process. Adequate buffering is required to shield native protein structures from changes in pH adjacent to exchange surfaces (Donnan effect) and pH effects induced by sorption. Selection of an appropriate buffer is critical to the success of ion exchange membranes.[17] Large molecules (>1,000,000 M_w) such as plasmid DNA are able to access charged groups, which envelope large pores of membrane adsorbers, although they would commonly be excluded from cellulose-based ion exchangers. Mobile phases and buffers employed in ion exchange bioseparations are non-denaturing to hydrophilic proteins. Elution and recovery of biologicals using ion exchange on performance are considered, as well as effects of additives and flow rate. The mobile phase composition is adjusted in the linear gradient along with NaCl concentration.

This work focused on the comparison of the separation characteristics of whey proteins using three strong anion exchange membranes (CIM QA, Q100, and HiTrap Q). In an analytical column (3.9 × 300 mm), the experiments were performed at a particle size of 15 μm with large pore sizes of 300 μm. The mobile phase was a binary system of water with 0.1% of TFA and ACN with 0.1% of TFA.

EXPERIMENTAL

Chemicals

The whey powder (from bovine milk) used in this experiment was purchased from Sigma Chemical Co. (St. Louis, Missouri, U.S.A.). The chemical composition of whey protein is shown in Table 1. Samples were prepared by diluting the appropriate amount of whey powder with water. The concentration of the samples remained at approximately 200,000 ppm. The standard chemicals of α-lactalbumin (Type III: deplete, form bovine milk, approximately 85%), β-lactoglobulin (form bovine milk, approximately 90%), and BSA were purchased from Sigma Chemical Co. Standard protein solutions were prepared in water. Standard solutions were made for each protein of 10 mg dissolved in 1 L with water. The water was filtered with HA 0.5 μm membranes (Division of Millipore, Waters Co., Milford, Massachusetts, U.S.A.) and deionized prior to use. The extra pure grade solvent of ACN was purchased from Duksan Pure Chemicals Company (Incheon, Korea). TFA was purchased from Sigma Chemical Co. The sample for injection was filtered with 0.45 μm polyvinylidene fluoride (PVDF) (Waters Co.). Sodium chloride and hydrochloric acid were purchased from Duksan Pure Chemicals Company. Piperazine was purchased from Sigma Chemical Co. For the anion exchange membrane, buffer A was 20 mm piperazine–HCl, pH 6.4, and buffer B was made by addition of 1 *M* NaCl to buffer A. The mobile phases for RP-HPLC were as follows: buffer A, 0.1% TFA in water; and buffer B, 0.1% TFA in ACN.

Table 1 Molecular masses and isoelectric points for whey proteins.

Protein	Molecular weights	Isoelectric points (p*I*)
α-Lactalbumin	14,000	4.2–4.5
β-Lactoglobulin	18,300	5.35–5.49
BSA	69,000	5.13

Equipment

The analytical column was a stainless steel μ-Bondapak™ C_{18}. The size of the analytical column was 3.9 × 300 mm, and it was packed in-house with RP-C_{18} (15 μm Merck Co.) by high-pressure pumping with solvent. The strong anion exchange membranes used in this experiment were CIM QA (BIA Separation Co.), Q100 (Sartorius), and HiTrap Q (Pharmacia). The Monolithic Convective Interaction Media (CIM) QA disk has a diameter of 16 mm and a thickness of 3 μm. The base material of CIM QA is a macroporous glycidyl methacrylate-co-ethylene dimethacrylate (GMA-EDMA) polymer matrix and the CIM QA disk bears a quaternary amine. The membrane material of Q100 is cellulose. The adsorption area of Q100 is 100 cm^2 and the binding capacity of protein is 100 μg/Q100 unit. The ion exchange media packed in HiTrap ion exchange columns are based on Sepharose high-performance material. The column volume of HiTrap Q is 1 ml. In RP-HPLC, the sample solution was passed through an Amicon 8400 (USA; maximum pressure, 75 psi) as an ultrafiltration kit and the UF membrane of cellulose discs [30,000 molecular weight cutoff (MWCO)] was utilized to extract lactose.

The analytical HPLC system was a Waters Model 600S liquid chromatography system (Waters Associates, Milford, Massachusetts, U.S.A.) equipped with a Waters 515 Multisolvent Delivery System with a 486 Tunable Absorbance Analytical Detector, and a Rheodyne injector (50 μl sample loop). The data acquisition system was a Chromate (Ver. 3.0; Interface Engineering, South Korea) installed in a PC. The flow rate of mobile phase was fixed at 4, 2, and 1 ml/min with CIM QA, Q100, and HiTrap Q, respectively. The wavelength was fixed at 260 and 280 nm and the injection volume was fixed at 20 μl. The experiment was performed at room temperature.

RESULTS AND DISCUSSION

Linear change or step change in mobile phase composition may produce differential migration of concentrated solutes. The average velocity of each desorbed solute is proportional to its fractional equilibrium mobile phase concentration. Therefore gradient elution has been normally used to remove adsorbed components from membranes. Gradient elution is convenient because it is difficult to determine, a priori, the modifier concentration required to selectively elute just the desired species.

The whey proteins α-lactalbumin and β-lactoglobulin from bovine milk were separated by RP-HPLC at room temperature using a silica-based, wide-pore C_{18} (300 μm) column and a linear binary gradient of ACN/water/0.1% TFA. However, it was observed that because of the small structural differences between α-lactalbumin and β-lactoglobulin, the desirable resolution of these proteins at the baseline was difficult to achieve. Several gradients of water–ACN, containing TFA (0.1%), were used. Fig. 1 shows the comparison of separation of the two standards of α-lactalbumin and β-lactoglobulin (dotted line) and the real whey proteins (solid line) after ultrafiltration (MWCO 30,000). The gradient condition consisted of a two-step linear binary gradient: buffer A/buffer B = 70/30–35/65 (vol.%), gradient time of 15 min.

For the anion exchanger experiment, a gradient mode with change in NaCl concentration was used to separate whey proteins of α-lactalbumin, β-lactoglobulin, and BSA. The protein standards were used and the strong anion exchange membranes used in this experiment were CIM QA (BIA Separation Co.), Q100 (Sartorius), and HiTrap Q (Pharmacia). The mobile phases were buffer A (20 mm piperazine–HCl, pH 6.4) and buffer B (buffer A + 1 *M* NaCl). In this experiment, the sample of whey was injected only with filtered 0.45 μm PVDF, without

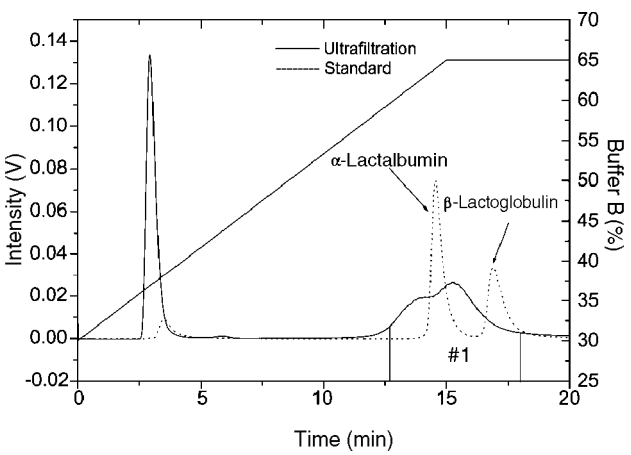

Fig. 1 Comparison of the two standard chemicals of α-lactalbumin and β-lactoglobulin and whey proteins after ultrafiltration (MWCO 30,000) by RP-HPLC (buffer A/buffer B = 70/30–35/65 vol.%, gradient time of 15 min).

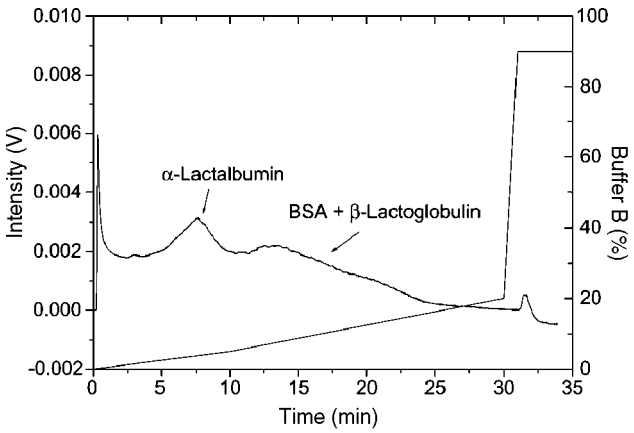

Fig. 2 Separation of standard chemicals of whey proteins using CIM QA [buffer A/buffer B: 100/0–95/5 (0–10 min), 95/5–80/20 (10–30 min), and 80/20–10/90 (30–31 min), CIM QA (BIA Separation Co.), 4 ml/min, 20 μm, 260 nm].

further pretreatment by ultrafiltration. Generally, the retention times of proteins were shorter with increasing amounts of NaCl in buffer B. The elution order of the proteins was α-lactalbumin, BSA, β-lactoglobulin B, and β-lactoglobulin A. β-Lactoglobulin was composed of β-lactoglobulin A and β-lactoglobulin B. In Fig. 2, CIM QA was used to separate whey proteins. In this case, the ratio of the volume of buffer A to the volume of buffer B in the mobile phase (buffer A/buffer B) was changed as follows: 100/0–95/5 (0–10 min), 95/5–80/20 (10–30 min), and 80/20–10/90 (30–31 min), and the flow rate of mobile phase was 4 ml/min. Although only α-lactalbumin was resolved from the other proteins, the resolution was not very good. The coeluted peak of BSA and β-lactoglobulin followed.

Fig. 3 shows the separation of whey proteins by Q100. The buffer A/buffer B ratio was changed as follows: 100/0–85/15 (0–30 min), 85/15 (30–40 min), 85/15–75/25 (40–60 min), and 75/25–10/90 (60–61 min), and the flow

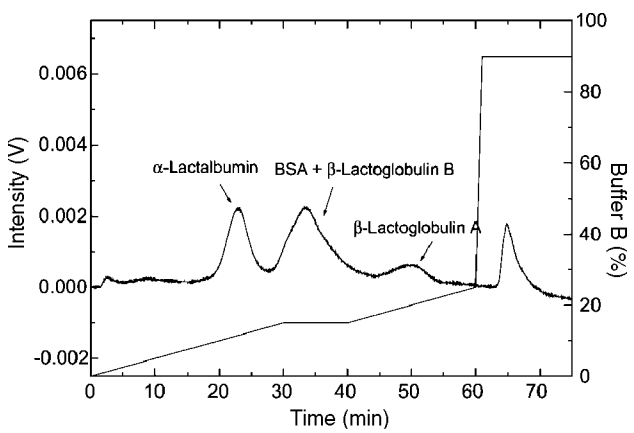

Fig. 3 Separation of standard chemicals of whey proteins using Q 100 [buffer A/buffer B: 100/0–85/15 (0–30 min), 85/15 (30–40 min), 85/15–75/25 (40–60 min), and 75/25–10/90 (60–61 min), Q100 (Sartorius), 2 ml/min].

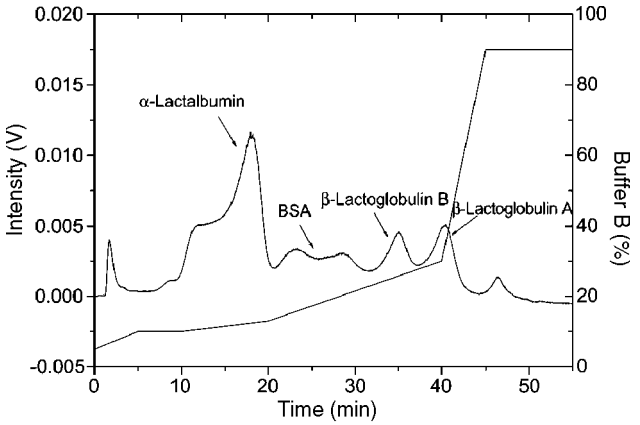

Fig. 4 Separation of standard chemicals of whey proteins using HiTrap Q [buffer A/buffer B: 95/5–90/10 (0–5 min), 90/10 (5–10 min), 90/10–87/13 (10–20 min), 87/13–70/30 (20–40 min), and 70/30–10/90 (40–45 min), HiTrap Q (Pharmacia), 1 ml/min].

rate was 2 ml/min. The resolution of α-lactalbumin was better than that using CIM QA; β-lactoglobulin A was also resolved, but BSA and β-lactoglobulin B coeluted.

The separation of whey proteins by HiTrap Q is shown in Fig. 4. The buffer A/buffer B ratio was changed as follows: 95/5–90/10 (0–5 min), 90/10 (5–10 min), 90/10–87/13 (10–20 min), 87/13–70/30 (20–40 min), and 70/30–10/90 (40–45 min), and the flow rate was 1 ml/min. The resolutions for whey proteins were quite excellent.

Real whey proteins were separated by the change of mobile phase composition obtained from Fig. 5. The injection volume was increased to 50 μl and the change of mobile phase composition was slightly modified to accommodate the larger injection volume and to improve the resolution of whey proteins. This result is shown Fig. 5.

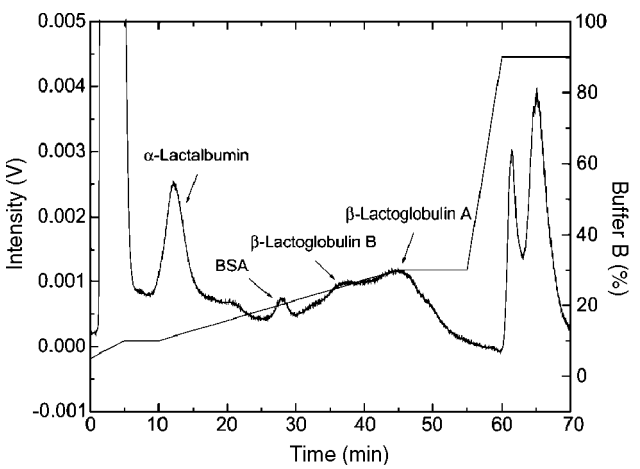

Fig. 5 Separation of the proteins contained in whey using HiTrap Q [buffer A/buffer B: 95/5–90/10 (0–5 min), 90/10 (5–10 min), 90/10–87/13 (10–20 min), 87/13–70/30 (20–40 min), and 70/30–10/90 (40–45 min), HiTrap Q (Pharmacia), 50 μm, 1 ml/min].

Although β-lactoglobulin A and β-lactoglobulin B were not satisfactorily separated, the other whey proteins were well resolved. The buffer A/buffer B ratio was changed as follows: 95/5–90/10 (0–5 min), 90/10 (5–10 min), 90/10–70/30 (10–45 min), 70/30 (45–55 min), and 70/30–10/90 (55–60 min).

In this work, three strong anion exchange membranes and RP-HPLC were used to separate whey proteins. From the result, it was found that anion exchanger and RP-HPLC were of similar separation efficiencies; in addition, HiTrap Q (Pharmacia) was the most effective anion exchange membrane for separation of whey proteins.

CONCLUSIONS

The separation characteristics of whey proteins of α-lactalbumin, BSA, and β-lactoglobulin were investigated with strong anion exchange membranes and RP-HPLC in a gradient mode. In RP-HPLC, the optimum experimental conditions of the mobile phase compositions and gradient conditions were experimentally determined to separate α-lactalbumin and β-lactoglobulins A and B contained in whey. The concentration of NaCl and the numbers of linear gradient steps were adjusted to find the optimum mobile phase with the commercially available anion exchange membranes. It was experimentally confirmed that HiTrap Q was the most effective in resolving the whey proteins. The described RP-HPLC method may be applicable to the wide application in the routine analysis of whey, fractionated whey streams, and whey protein powders produced by dairy industries.

Zeta-Potential

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

When an insulator is in contact with an aqueous solution of buffer components, the solid surface has a non-zero electric potential that decreases exponentially as a function of distance from that surface, to become zero at infinity.

DISCUSSION

Taking silica (bulk composition silicium oxide SiO_2), from which capillary material in capillary electrophoresis (CE) is manufactured, as an example, one can readily understand this when taking into account that on the silica surface, there are silicium hydroxide groups that are subject to an acid–base equilibrium according to

$$R{-}SiOH + H_2O \Leftrightarrow R{-}SiO^- + H_3O^+$$

indicating that the negative surface charge of the silica wall is pH dependent and becomes more negative as the buffer pH increases. At pH 2 or lower, the zeta-potential is virtually zero, as the above equilibrium is largely forced to the left due to an abundance of hydrogen ions. As the magnitude of the zeta-potential directly determines the electro-osmotic mobility, it is of importance to understand the effect of different buffer constituents on the zeta-potential and, hence, on the electro-osmotic flow (EOF). The electro-osmotic mobility μ_{EOF} is defined as

$$\mu_{EOF} = -\frac{\zeta\varepsilon}{\eta}$$

in which ζ is the zeta-potential, ε is the dielectric constant of the liquid, and η is the viscosity of the liquid at the plane of shear. The electro-osmotic velocity v_{EOF} is now

$$v_{EOF} = \mu_{EOF}E = -\frac{\zeta\varepsilon E}{\eta}$$

in which E is the electric field strength. Taking a more detailed look at the zeta-potential, one must realize that this potential is not really the value on the negatively charged silica surface, but rather the value on the plane of shear (i.e., at the interface between the stagnant layer of solvent molecules directly at the silica surface and the volume element that is subject to flow, caused by, for example, a longitudinal pressure drop). The combination of these is called the electric double layer.

There are several ways to dynamically change the zeta-potential and, thus, electro-osmosis. Adding a surfactant at a low concentration [generally smaller than the critical micelle concentration (CMC)] will alter the wall charge and zeta-potential due to selective adsorption on the capillary surface: sodium dodecyl sulfate (SDS) will make the zeta-potential more negative (and EOF more pronounced) and may even mask the pH dependence mentioned earlier. Cetyltrimethyl ammonium bromide (CTAB) can neutralize the wall charge, making the zeta-potential close to zero and, thus, eliminating EOF at a concentration of 5×10^{-5} *M*. A higher CTAB concentration will make the zeta-potential positive and reverse the EOF. Other additives merely decrease the zeta-potential exponentially to zero or to a small nagative value; they include polymers such as poly(vinyl alcohol), hydroxy-propylmethylcellulose, and others. Changing the liquid viscosity near the electric double layer is a usual side effect of these additives, another cause of EOF suppression. Polymers like those mentioned and many others have also been used successfully for chemical modification of the capillary surface, so that addition to the buffer (so-called dynamic coating) is not necessary.

EFFECT ON MIGRATION TIME

In uncoated fused-silica capillaries, surface charge and zeta-potential (and, consequently, EOF) can have a significant effect on migration time of anions, especially at higher pH values. As anions and EOF move in opposite directions, longer migration times are more sensitive to zeta-potential changes. This can be seen from the equation for migration time t_m:

$$t_m = \frac{L_d L_t}{(\mu_{cff} + \mu_{EOF})V}$$

where, because of opposite signs for μ_{cff} and μ_{EOF}, the denominator can be quite small. Consequently, migration time can be sensitive to slight EOF changes.

In the example in Fig. 1, a mixture of anions is analyzed in a Tris-acetate buffer of pH 8. A 2% change in zeta-potential, from −50 to −51 mV, results in a dramatic shift in migration time of peaks with longer migration times.

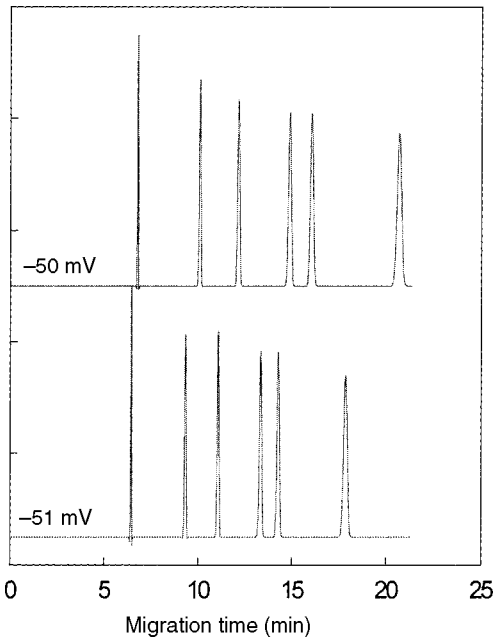

Fig. 1 Effect of capillary zeta-potential on the analysis of a mixture and anions in an uncoated fused-silica capillary in a 10 m*M* Tris-acetate buffer of pH 8. Normal zeta-potentials are around 50 mV at this pH.

Zirconia–Silica Stationary Phases for HPLC

R. Andrew Shalliker
Sindy Kayillo
Center for Biostructural and Biomolecular Research, University of Western Sydney, Sydney, New South Wales, Australia

INTRODUCTION

This review details the development of zirconia–silica stationary phases in liquid chromatography (LC). Zirconia–silica stationary phases are just one member of a group of mixed oxide materials that have recently been studied in LC. Other members of this group include alumina–silica, magnesia–silica, and titania–silica.[1,2] Each of these mixed oxide composites contains silica, which is the most widely employed stationary phase material in modern high-performance liquid chromatography (HPLC). The dominance of silica in the chromatographic industry reflects the many desirable properties that silica affords the chromatographer. Silica can be prepared in a wide variety of pore size and particle size materials, and can be easily modified to yield stationary phases with a wide range of differing selectivities. For instance, the C_{18} column displays vastly different retention behavior to that of native silica and is the most widely employed reversed-phase (RP) chromatography column. Other types of modified silica stationary phases include, but are not limited to, the C_8 column for intermediate retention of non-polar compounds in RP LC, the C_4 column for protein work, and the phenyl, nitrile, and amino columns. Silica also has a high mechanical strength, making it suitable for the preparation of columns under high pressure; when operated under suitable conditions, these columns have a long life span. Collectively, each of these attributes has made silica the material of choice as a stationary phase or stationary phase support. In many respects, the high efficiency of today's chromatography column owes much to the properties of silica. However, as a chromatographic stationary phase, silica has some limitations. The siloxane linkage is the Achilles heel in any silica-based material, being easily hydrolyzed at low pH. Furthermore, silica has a high solubility in an alkaline environment, especially at higher temperatures, leading to a loss in column bed integrity. This, in general, limits the use of silica and modified silica to pH regions between 2 and 8. Another limitation of silica is the strong and often irreversible adsorption of basic species, occurring as a consequence of the hydrogen bonding between the solute and the surface silanol groups. This belies one of the most desirable features of a stationary phase; that being good adsorption and good desorption characteristics. Many modified silica-based stationary phases are consequently subjected to rigorous procedures that attempt to protect the solute from the residual hydroxyl groups through processes such as end capping.

BACKGROUND

Resolution (R_s) in a chromatographic system is a function of three essentially independent variables: the capacity factor (k') (defined generally by the solvent strength), the number of theoretical plates (N), and the selectivity (α) according to the well-known equation given below:

$$R_s = \frac{1}{4}\sqrt{N}\left(\frac{k'}{1+k'}\right)(\alpha - 1)$$

Of these three variables, changes in the selectivity very often yield the most substantial gain in resolution, albeit with results that are often unpredictable. One of the driving forces in the development of new stationary phases is the change in selectivity to yield improvements in separation. A second driving force is developing materials that overcome the limitations of silica as noted above. One of the more successful stationary phase materials that have been developed is that of zirconia and zirconia-based stationary phases, which are now commercially available as a high-grade chromatographic product. As a stationary phase, zirconia has several important attributes. Zirconia is a highly rigid support able to withstand the rigors of conventional column-packing processes. Zirconia is temperature-stable and is insoluble in alkaline and acidic solvents, allowing mobile phases with pHs between 1 and 14 to be employed as eluents. This is particularly useful for protein work, allowing "dirty" columns to be cleaned with strong base such as NaOH. The surface of zirconia is, however, heterogeneous, containing Lewis acid, Bronsted acid, and Bronsted base sites, which leads to a multitude of retention mechanisms that may complicate the elution process.[3] However, because zirconia is highly resistant to solvent attack, virtually any mobile phase modifying agent can be employed to control any unwanted interactions. Consequently, the highly functionalized zirconia surface can be fully utilized to maximize

selectivity. Zirconia can also be synthesized in a variety of particle size and pore size materials, in much the same manner as silica. Furthermore, zirconia can be modified to yield a variety of stationary phases with different selectivities. Nawrocki et al.[3] published an excellent review on zirconia for chromatographic use, and hence a detailed discussion on zirconia is not warranted in this text.

Recent studies in stationary phase development have lead chromatographers to explore the concept of mixed oxide chromatographic supports and materials for use in LC. These include alumina–silica, magnesia–silica, titania–silica, and zirconia–silica.[1,2] The driving force behind the development of these mixed oxide supports comes from the possibility of attaining a surface with properties that exploit the best attributes of both components in the mixed oxide. For example, the band tailing of basic species on magnesia–silica columns is substantially reduced compared to silica columns due to the reduced concentration of acid sites on the surface of the magnesia–silica composite.[1] In the current text, we present an overview on the development of zirconia–silica composites as stationary phase supports and then detail some applications for which this support has been employed.

PREPARATION OF ZIRCONIA–SILICA MIXED OXIDE SUPPORTS

The demand for mixed oxide chromatographic-quality stationary phase materials is small and only a few methods that detail their preparation are available in the literature. There are, however, numerous examples of the preparation of zircon powders and Ref.[4] is an example of such a process. In general, these types of powders are unsuitable for chromatographic stationary phases because their particle sizes are in the submicron range with very broad distributions. The synthesis of mixed oxide supports for chromatographic applications can essentially be divided into two types: coprecipitation methods and coating methods.

Coprecipitation Methods

Kaneko et al.[1,2] employed a coprecipitation method, which involved a base-catalyzed procedure that precipitated irregular particles of zirconia–silica mixed oxides. Specifically, a zirconium salt (zirconyl chloride octahydrate) was added to an acidified solution of sodium metasilicate ennehydrate. The solution was made alkaline (pH 7–9) to allow the precipitation of the mixed oxide gel. The gel was aged for 10 hr, collected by filtration and washed to remove residual chloride ions. The gel was dried at 110°C and then ground to an appropriate mesh size. The resulting precipitate was regarded as an intimate mixture of silica and metal oxide gel (in this case, zirconia). The silica framework was partly occupied with a widely spread metal oxide, hence decreasing the surface area of the silica gel itself.[1,2] In this procedure, the gel was not subjected to thermal treatment above 110°C.

Zhang, Feng, and Da[5] improved on the method of Kaneko et al.[1,2] by employing an oil emulsion sol–gel procedure, resulting in the formation of mixed oxide spherical particles (spherical particles being a desirable property of a modern LC packing). In their method, sodium metasilicate pentahydrate was hydrolyzed in an acidic aqueous solution and zirconyl chloride octahydrate was added with stirring. The resulting mixture was suspended in a surfactant-stabilized oil and homogenized for 10 min at a speed calibrated to yield 5 μm spherical particles. Precipitation of the gel was initiated by the slow addition of base. The resulting hydrogel was collected and washed to remove residual solvent and dried at 120°C for 2 hr, after which the material was calcined at 600°C for 1 hr.

Coating Processes

Coating processes have been used by a number of researchers. Chicz, Shi, and Regnier[6] coated commercially available 15–20 μm Vydac silica particles with zirconia. The surface coating was obtained by reacting a combination of 2,4-pentanedione, zirconium isopropoxide, and toluene (1 : 3 : 3) (v/w/v) with silica for 1 hr. The zirconyl-clad silica was then vacuum-dried overnight and calcined at 500°C for 8 hr, after which the material was washed with 2-propanol and then vacuum-dried. The zirconyl-clad silica was further modified with polyethyleneimine (PEI) to produce an ion-exchange surface that was tested for retention of proteins. The pore diameter of the resulting zirconyl-clad silica (22.6 nm) was approximately 75% of the original Vydac silica (300 nm), while the surface area decreased marginally (~10%).

Peixoto, Gushiken, and Baccan[7] employed a similar coating process to prepare zirconized silica. Silica particles were added to a solution of $ZrCl_4$ in anhydrous ethanol. The mixture was refluxed for 8 hr under a nitrogen atmosphere. The zirconized silica was then collected and dried at approximately 125°C, before being hydrolyzed and washed in water to remove the residual chloride ions. The final product was dried at 120°C for 5 hr. The resulting zirconized silica had a 3.25% ZrO_2 surface coverage. Melo et al.[8,9] modified the method of Peixoto et al. and coated 10 μm silica particles with zirconia by reacting the silica with zirconium(IV) butoxide in toluene according to the following reaction process:[8]

$$n\text{SiOH} + \text{Zr(OBu)}_4 \rightarrow (\text{SiO})_n\text{Zr(OBu)}_{4-n} + n\text{BuOH}$$
$$(\text{SiO})_n\text{Zr(OBu)}_{4-n} + (4-n)\text{H}_2\text{O} \rightarrow (\text{SiO})_n\text{Zr(OH)}_{4-n} + (4-n)\text{BuOH}$$

where SiOH stands for silanol groups on the silica surface. Following hydrolysis, the zirconized silica contained 15.3% Zr on the surface.

More recently, a similar procedure for the preparation of zirconia-coated silica microspheres was employed by Tsurita and Nogami,[10] who coated 3 μm silica spheres with zirconia derived from zirconyl chloride octahydrate. The resulting zirconia–silica spheres were subjected to thermal treatment in order to bring about crystallization and the subsequent development of the porous structure within the material.

A coating process was also employed by Shalliker et al.[11] where zirconia–silica mixed oxide supports were prepared by coating preformed zirconia microspheres with silica, the reverse process to the methods of Chicz et al.,[6] Peixoto et al.,[7] Melo et al.,[8,9] and Tsurita and Nogami.[10] In this method,[11] zirconia microspheres were first formed using a sol–gel method. The resulting spherical zirconia hydrogels were suspended in water and a solution of hydrolyzed sodium metasilicate pentahydrate was added. The quantity of sodium metasilicate pentahydrate varied depending upon the desired Zr/Si ratio in the final composite. The solution (~200 ml) containing the zirconia microspheres and the hydrolyzed sodium metasilicate pentahydrate was heated to 60°C, allowing the slow evaporation of water to a final volume of 15% of the original amount. The microspheres were collected by filtration and then washed. Calcination of the material followed, which influenced the crystallization and resulting surface properties of the support.[11–15] Extended calcination at 1300°C resulted in the complete homogenization of the support, yielding zircon.[11]

PROPERTIES OF ZIRCONIA–SILICA MIXED OXIDE SUPPORTS

Crystallization

The crystalline nature of zirconia microspheres prepared for chromatographic purposes is dependent upon the thermal history of the zirconia. A detailed discussion on the porous nature of zirconia and silica is not warranted in this text but is covered in detail in a review by Nawrocki et al.[3] It is perhaps important to note that zirconia is amorphous until subjected to temperatures that exceed the phase transition temperature required to form the tetragonal phase (usually between 440°C and 470°C depending on the procedure used to prepare the zirconia). Once thermal treatment exceeds this phase transition temperature, a metastable tetragonal phase predominates—where, after cooling, zirconia slowly transforms to the stable monoclinic form. As thermal treatment of the zirconia is required to obtain a suitable pore-structured stationary phase, most zirconias prepared for chromatographic purposes are predominantly monoclinic, or perhaps more correctly polymorphous.[3] Complete conversion from the amorphous phase to the monoclinic phase requires a substantial degree of thermal treatment and then time to allow the tetragonal phase to form the monoclinic phase. In contrast, the most common form of silica as a stationary phase material is usually the amorphous form,[16] but, on occasion, Cristobalite has been reported.[10] Silica doping of the zirconia, however, has been shown to have a marked effect on the crystallization of the zirconia phase.[4,5,11–15] As the concentration of silica increased, the phase transition temperature from the amorphous phase to the metastable tetragonal phase increased.[12] This was independent of whether the material was prepared through a coprecipitation process[5] or by a coating process.[11] For example, the relationship between the phase transition temperature and the percentage weight of silica in the zirconia–silica composite is shown in Fig. 1. As the concentration of silica doping increased, the phase transition temperature increased monotonically and was linear until 700°C.[11] Furthermore, the addition of the silica stabilized the metastable tetragonal phase, which delayed the transformation to the monoclinic phase.[11] In general, increased silica content decreased the apparent crystallinity. Studies by Tsurita and Nogami[10] on zirconia-coated silica microspheres support the findings described above. In their work, as the concentration of Zr doping increased (or, in other words, the relative concentration of Si decreased), there was a corresponding increase in the concentration of tetragonal zirconia. Furthermore, increasing concentrations of ZrO_2 suppressed the crystallization of silica gel.

Pore Structures

Many of the most important properties of a chromatographic stationary phase relate to the pore structure, which provides a high surface area and pore volume for solute interaction for the chromatographic retention process to occur. As such, the pores should be of a suitable size to allow the solutes of interest to have unimpeded entry and exit to and from the pores. Microporous materials are of little interest in the chromatographic industry. They provide a high surface area, but one that is inaccessible to the vast majority of solutes. Mesoporous materials are the most sought after, with pore sizes between 2 and 50 nm, although macroporous materials find specialized use in the separation of macromolecules, e.g., Ref.,[16] but at the cost of a reduced surface area. Ideally, the pore shape should represent that of a cylinder and should be described by a type IV nitrogen sorption isotherm[17] as depicted in Fig. 2a. These types of isotherms are common in many industrial adsorbents with mesoporous structures. The hysteresis loop in the type IV isotherm is usually associated with capillary condensation in a mesoporous structure. These hysteresis loops can form several shapes; however, from a chromatographic aspect, the most important type of hysteresis loop is the type H1 (Fig. 2b), which represents pores that are uniform in shape and with a narrow size distribution. Many chromatographic surfaces display type H2 or intermediate H1–H2 hysteresis loops, which in a simplified form represents surfaces that have pore structures with wide bellies and narrow necks ("ink bottle" pores).[17]

In general, the pore size and subsequent surface area of zirconia-containing supports is a function of the thermal history, i.e., the crystalline nature. Calcination of the material at high temperatures leads to an increase in the pore size and a reduction in the surface area, as a consequence of particle sintering and crystallization.[3] Kaneko et al.[1] measured the physical properties (pore size distributions, specific surface areas, and pore volumes) of their stationary phases using nitrogen adsorption isotherms. The surface area and pore diameter of their stationary phase material reflected the absence of calcination at temperatures high enough to induce crystallization. Their stationary phase material was predominantly microporous, with a high surface area (122 m^2/g). No mention was made with regard to the pore shape.

In comparison, the stationary phases prepared using the coprecipitation process of Zhang, Feng, and Da[5] with thermal treatment at 600°C were mesoporous. The mean pore diameters were 8.6 nm for a composite containing 3.4% Si and 5.9 nm for a composite containing 15.8% Si. These stationary phase materials had surface areas of 29 and 76 m^2/g, respectively. It is of interest to note that the surface area for the composite containing the higher silica content was greater than the surface area for the composite with the lower silica content. The average pore diameter of the material with the low-silica content was greater than the average pore diameter of the composite with higher silica content. This reflects the decrease in crystallinity associated with an increase in the concentration of silica doping,[5] and the change in density due to the different zirconia concentrations. The composite materials prepared by Zhang, Feng, and Da[5] were reported as being type IV isotherms with H1 hysteresis loops, making them ideally suited as chromatographic adsorbents.

The pore structures of zirconia–silica composites prepared by Shalliker et al.[11–15] via a coating procedure were substantially different to those reported by Zhang, Feng, and Da.[5] In studies by Shalliker et al.[13–15] the pore characteristics were determined using inverse size-exclusion

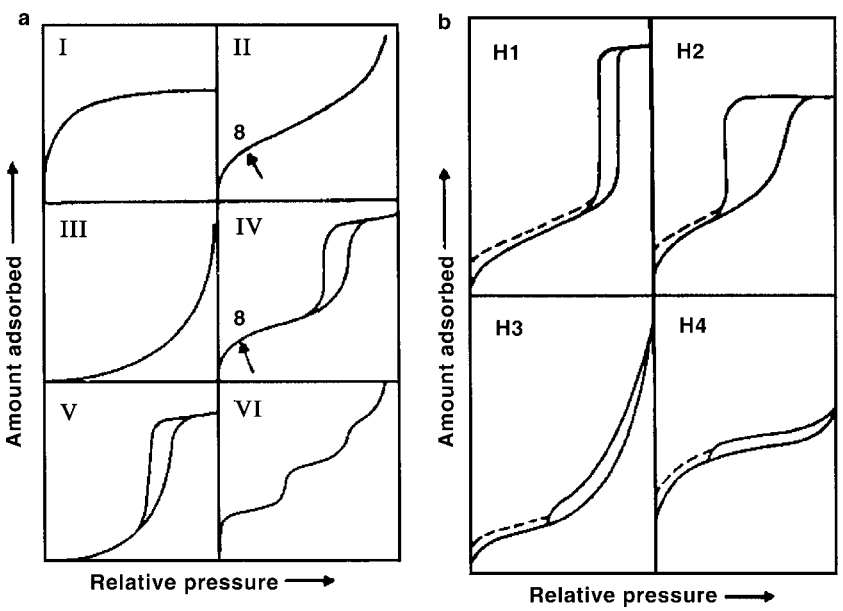

Fig. 2 (a) Types of physisorption isotherms. (b) Types of hysteresis loops.
Source: From Reporting physisorption data for gas/solid systems with special reference to the determination of surface area and porosity, in Pure Appl. Chem.[17]

chromatography (SEC) and nitrogen sorption. The inverse size exclusion technique was employed to measure the chromatographically available pore surface, while the nitrogen sorption measurements were carried out for comparative purposes with information already available in the literature. A range of composites were prepared with either 5 or 10 mol% silicon.[14,15] These composites were calcined for 1 hr at either 700°C or 810°C. Calcination of these materials at 810°C or 700°C yielded composites that were either predominantly amorphous or tetragonal depending on the concentration of the silicon doping. The increase in the phase transition temperature compared to that of native zirconia was consistent with the degree of silicon doping. For a composite material containing 10 mol% Si and calcined for 1 hr at 810°C, a type IV nitrogen sorption isotherm with an H3 hysteresis loop was obtained.[15] The type H3 hysteresis loop extended from the high relative pressure region to P/P_o approximately 0.42, indicating that the surface had a broad pore size distribution. The close proximity of the adsorption and desorption branches indicated that the entrances of the pores offered little restriction to the pore body. This type of hysteresis loop was consistent with a surface containing slit-like pores. The BET-specific surface area of the composite was 2.7 m^2/g and the pore size distribution was very broad and skewed significantly to the macroporous region, with a maximum at 3.4 nm.[15] The specific pore volume of this material was very low (0.0056 ml/g), consistent with a macroporous material. In comparison, the specific pore volume of the stationary phases prepared by Zhang, Feng, and Da[5] were 0.062 and 0.112 ml/g for the 3.4% Si and 15.8% Si composites, respectively. The specific pore volume of the stationary phase prepared by Kaneko et al.[1] was 0.17 ml/g.

The size exclusion curve for polystyrenes that eluted from a column prepared from the 10 mol% silicon composite of Shalliker et al.[14] also indicated that the material had a broad pore size distribution that extended well into the macroporous region. No exclusion limit was determined despite the elution of polymers with molecular weights in excess of 1.8 million Da. The mean pore diameter determined from the inverse size exclusion method was 56.2 nm (essentially a macroporous support) and the specific surface area agreed remarkably well with the BET-specific surface area (2.75 compared to 2.7 m^2/g). Reducing the calcination temperature from 810°C to 700°C, which was below the phase crystallization temperature for the same 10 mol% silicon phase, yielded an amorphous material. The mean pore diameter was 8.9 nm and there was a significant microporous contribution. Because of the microporous nature of this amorphous material, the surface area was almost 20-fold greater with a pore volume almost threefold higher than the predominantly tetragonal phase material obtained following calcination at 810°C.[14] Reducing the concentration of silicon to 5 mol% and calcining at 700°C yielded a very similar material to the one containing

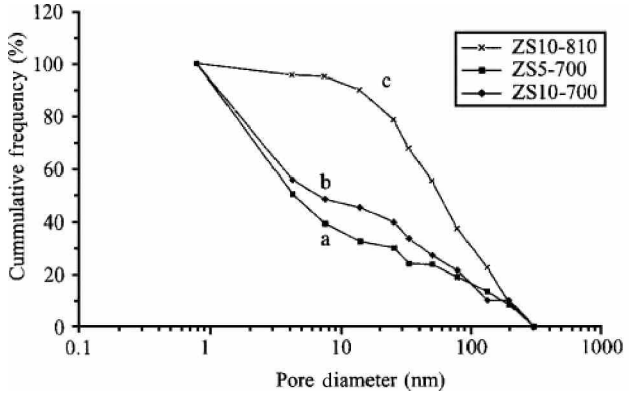

Fig. 3 Cumulative pore frequency plots of composite zirconia–silica stationary phases. a, ZS5-700; b, ZS10-700; and c, ZS10-810.
Source: From The development of stationary phase supports for liquid chromatography: I. Examination of the pore structure of zirconia–silica composites using size exclusion chromatography, in J. Liq. Chromatogr. Relat. Technol.[14]

10 mol% silicon, which was also calcined at 700°C. However, there was a significant concentration of the tetragonal phase in the 5 mol% silicon material, which was not the case for the 10 mol% silicon phase calcined at 700°C. The phase transition temperature of 5 mol% silicon support was approximately 700°C, hence the presence of the tetragonal phase. Fig. 3 illustrates the cumulative pore volumes of these three supports. This figure depicts the change in porosity as a function of the silica doping concentration and the thermal treatment of the support. For instance, for both phases calcined at 700°C, approximately 50% of the pores were less than 4 nm in diameter, whereas there were essentially no pores of this diameter for the material calcined at 810°C. The authors concluded in their study that because of the unfavorable pore shape, such supports would be unsuitable for chromatographic purposes.

Several researchers have investigated the inclusion of high melting point salts during the calcination processes in the synthesis of silica,[10,18] zirconia,[19] and zirconia–silica composites.[10,13–15] The function of the salt is to improve the pore structure of the material. The pores are homogeneously filled with a salt solution (typically sodium chloride), which is allowed to evaporate to dryness leaving behind salt deposited in the pores. Upon sufficient heating, both the salt and the stationary phase material partially liquefy and phase separation occurs.[18] The size and shape of the pores depend on the nature of the salt and on the calcination conditions. The stationary phase and salt solidify when cooled, and residual salt can be removed by washing, leaving behind widened pores. In the case of silica, this procedure has been used to prepare wide pore (>1000 nm) materials designed for bioseparations.[18] The surface structure of a LiChrosphere Si100 stationary phase that has been subjected to pore widening using a salt

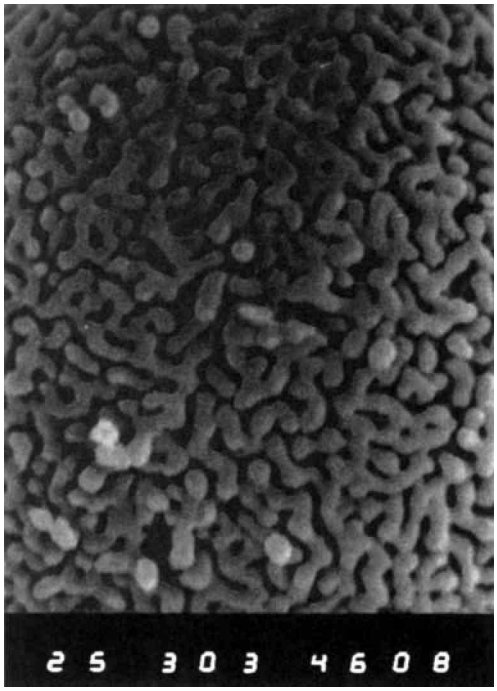

Fig. 4 Scanning electron micrograph of LiChrosphere Si100 soaked in NaCl solution and dried, heated to 800°C for 1 hr, washed out with water, and dried.

impregnation process is illustrated in Fig. 4. Salt impregnation during calcination transformed mesoporous zirconia with surfaces that had type IV nitrogen isotherms with H1–H2 hysteresis loops to surfaces with type H1 hysteresis loops. No substantial increase in the overall pore diameter was observed although the salt transformed "ink bottle"-shaped pores to cylindrical-shaped pores.[19] Salt impregnation of zirconia–silica composites resulted in materials that had type H3 hysteresis loops being transformed to materials with intermediate type H1–H2 hysteresis loops.[15] The addition of salt resulted in a more than 15-fold increase in the pore volume and a greater than sixfold increase in the surface area (measured by the BET method).[15] The pore size distribution changed from being a very broad distribution for a zirconia–silica composite calcined without salt to one being mesoporous when calcined with salt. Even with the aid of salt impregnation, evaluation of the nitrogen sorption isotherms showed evidence of pores with hindered access. The mean pore radius was 21.0 nm when measured from the adsorption branch and 10.0 nm mean pore radius when measured from the desorption branch of a nitrogen sorption isotherm. The difference between the two mean pore radii determined from the adsorption and desorption branches indicated that the pores contain wider bellies with some degree of restriction near the pore entrance. Hence, the authors' concluded that these surfaces contained a significant degree of type H2 hysteresis and the hindered pore access limited their chromatographic suitability.[15]

Surface Acidity

The surface of zirconia is known to be basic, with a pK_a of between 10.5 and 12.8. The acidity of silica is dependent upon the state of hydrolysis, typically imparting a slight acidic nature to the surface.[3] Very little information has been published with respect to the acid/base properties of zirconia–silica composites and this is not surprising given the limited experience chromatographers have with these types of stationary phases. Zhang, Feng, and Da[5] determined that the acidity of their zirconia–silica composite increased as the concentration of silica increased. This finding was consistent with an increase in the concentration of acidic hydroxyl groups associated with the increase in silica content. In contrast, Kaneko et al. measured the acid/base properties of zirconia–silica mixed oxide supports via an amine titration method.[1] They found that in a comparison between the acidity of the four mixed oxides (alumina–silica, titania–silica, magnesia–silica, and zirconia–silica), only the zirconia–silica composite contained strong acid sites—despite the fact that both alumina and silica are more acidic than zirconia.[3] All four mixed oxides exhibited stronger acidity than native silica, which is somewhat surprising given the findings of Zhang, Feng, and Da.[5] This may indicate that routine preparation of these mixed oxide supports is sensitive to the process employed including thermal treatment, dehydroxylation, and rehydroxylation.

Surface Modification

Two excellent reviews that detail procedures for the preparation of bonded phase supports have recently been published by Leonard[16] and Buchmeiser.[20] One of the most popular methods of surface chemical modification involves the use of organosilanes. These organosilanes react with the surface metal hydroxyl groups and form a surface, which may be represented as M–O–R, where R represents an alkyl chain and M represents the metal (i.e., silica, zirconia, titania, etc.). One important factor that must be stated, however, is that the order of stability of M–O–R bonds increases in the order of $M = Si > Zr > Ti > Al$.[16] Improvements in the hydrolytic stability can be achieved by shielding the siloxane bond with, for instance, polymeric phases or an intensive multivalent attachment of the bonded layer.[16]

As zirconia–silica composites are relatively new surfaces in chromatography, few studies have detailed methods that modify the surface. One research group, however, has reported the preparation of RP zirconia–silica stationary phases.[8,9] In studies by Melo et al.,[8,9] a C_8 stationary phase material was prepared by grafting

poly(methyloctasiloxane) (PMOS) to the zirconia–silica composite followed by a gamma irradiation immobilization procedure. Surface modification was achieved by drying the zirconia–silica particles in air at 120°C for 24 hr. PMOS was dissolved in dichloromethane at a concentration to yield 1 g PMOS + support per 12 ml dichloromethane, resulting in a packing material with 50% w/w PMOS. The mixture (PMOS + zirconia–silica particles + dichloromethane) was stirred for 3 hr at room temperature after which the solvent was allowed to evaporate. The PMOS-sorbed zirconia–silica microspheres were then subjected to gamma irradiation at either 80 or 120 kGy using a Co-60 source. Columns prepared from the grafted and gamma-immobilized PMOS were tested for performance and compared to PMOS-sorbed silica and PMOS-sorbed zirconia–silica stationary phases that were not subjected to gamma irradiation. The authors concluded that the gamma irradiation of the PMOS-sorbed zirconia–silica composite improved the chromatographic performance for neutral and basic species. Furthermore, the gamma-irradiated PMOS-sorbed zirconia–silica stationary phase was shown to have superior chromatographic performance following alkaline stability trials when compared to PMOS-sorbed silica or zirconia–silica stationary phases that were not subjected to gamma irradiation. This was despite there being an apparent loss in sorbed PMOS (as indicated by a reduction in the capacity factor) following washing in very basic (pH 10) solvents. No retention information was presented on the performance of gamma-irradiated PMOS-sorbed silica in comparison to gamma-irradiated PMOS-sorbed zirconia–silica.

An inorganic anion-exchange resin based on a zirconia–silica support was prepared by Chicz, Shi, and Regnier.[6] The Lewis acid sites were employed as adsorption sites that permanently retained a PEI coating which then acted as an anion-exchange ligand. In this study, a continuous film of cross-linked PEI was achieved. These surfaces were then tested for the analysis of ovabumin and bovine serum albumin.

Through chance discovery, Shalliker et al.[13,21] prepared a surface-modified normal phase zirconia–silica composite. In studies designed to optimize the pore structure of zirconia–silica composites, sodium iodide was used as a salt for pore widening experiments. However, following calcination and subsequent washing to remove residual salt, the stationary phase was left with a permanent brown-yellow discoloration, indicating the presence of iodide remaining on the surface. Elemental analysis confirmed this to be so. Consequently, the authors considered that the presence of iodide may protect the solute from the Lewis acid sites on the surface of the support.[21] Normal phase retention studies showed a reduction in the degree of retention of basic solutes together with an improvement in the peak shape of basic compounds such as pyridine and aniline.

Alkaline Stability

One of the advantages of zirconia–silica composite stationary phases is supposedly a reduction in the solubility of the surface in alkaline solvents. However, only a limited amount of information detailing the alkaline stability of the surface is currently available. Chicz, Shi, and Regnier[6] demonstrated that a zirconia–silica composite that was coated with a PEI coating was stable in boiling alkaline solvent (1 *M* KOH) for 24 hr with no visual change in the stationary phase material. In contrast, a silica phase coated with PEI dissolved within 30 min in boiling 1 *M* KOH. As mentioned above, Melo et al.[8,9] also observed stability in their RP modified support following passage of 5000 column volumes of mobile phase (NH_4^+/NH_3 buffer) at pH 10. A reduction in retention was observed, but the column efficiency and resolution remained essentially constant.

APPLICATIONS

Commercially, zirconia–silica composites have, at present, found limited use in LC due to the popularity and dominance of silica and silica-based supports. The highly competitive market and the drive to satisfy consumer demand has ensured manufacturers of silica-based supports to investigate methods that overcome or limit the shortfalls of the surface, particularly with respect to the solubility of silica in aqueous and basic solvents. The synthesis of the new generation hybrid silica (XTerra) is an example of these developments.[20] Surface protection of the silica surface, with appropriate care being taken during the dehydroxylation and rehydroxylation of the surface also improves the behavior of basic solutes. There is, at present, very limited commercial interest in developing zirconia–silica composites and, consequently, applications on these surfaces are limited to researchers who prepare their own packing materials. Nevertheless, studies that have been published so far detail differences in selectivities between silica or zirconia and zirconia–silica composites. The employment of basic test substances such as pyridine and aniline in normal phase chromatography serves as a useful indicator of selectivity and secondary adsorption effects. This is particularly true for surfaces such as zirconia as these basic compounds display strong affinity toward Lewis acid sites and are also sensitive to the presence of hydroxyl groups. With that in mind, Kaneko et al.[1] used a mixture of benzene, dimethyl phthlate, and pyridine to observe the retention characteristics of four mixed oxide supports in a hexane (99%)/methanol (1%) mobile phase. Pyridine was not observed to elute from either the column packed with silica or from the column packed with the zirconia–silica composite. The column prepared from a silica–magnesia stationary phase gave the best separation, while extreme band tailing of the pyridine was observed on columns

prepared from silica–alumina and silica–titania. Fig. 5 illustrates the results that were obtained. The authors concluded that because their zirconia–silica composite contained the highest concentration of strong acid sites, pyridine could not be eluted, whereas a broad tailing pyridine band was observed for the silica–titania and silica–alumina columns, both of which had a slightly lower concentration of strong acid sites than the zirconia–silica stationary phase. The silica–magnesia stationary phase with only weak acid sites gave the best separation and a symmetrical peak for pyridine.

In contrast, pyridine and other basic test solutes in normal phase conditions were observed to elute from zirconia–silica composites prepared by Zhang, Feng, and Da.[5] The retention of the basic solutes was greater on the zirconia–silica composite stationary phase than on a native zirconia stationary phase. The ratio k_{Si-Zr}'/k_{Zr}', where k_{Si-Zr}' and k_{Zr}' are measures of the capacity factor on the zirconia–silica stationary phase and the zirconia phase, respectively, decreased with an increase in the pK_b of the test solute, as illustrated in Fig. 6. Retention was also greater on the stationary phase containing the greater concentration of zirconia. However, the elution order of the aniline and *p*-nitroaniline was reversed when the surface concentration of zirconia increased from 3.4% to 15.3% and this was attributed to the stronger acid properties of the 15.8% zirconia–silica composite. Neutral compounds (PAHs) were also shown to be retained on the surface of the zirconia–silica composites and zirconia, and this was attributed to interactions between π electrons and Lewis acid sites.[5] The retention of acidic compounds was also studied by Zhang, Feng, and Da[5] and they suggested that the crystal structure of the support may be a factor in determining the extent of retention. In their study, retention of acidic compounds increased in the order of zirconia–silica (3.4% Zr) < zirconia < zirconia–silica (15.8%). The addition of silica to the zirconia improved the peak asymmetry.

Shalliker et al.[21] used pyridine and aniline as test solutes in normal phase chromatography. Strong retention of pyridine was observed on a native silica column ($k' = 9.5$), while the sample was only weakly retained on a native zirconia column ($k' \sim 1$). Even less retention was observed for pyridine on a zirconia–silica column ($k' = 0.86$). All pyridine bands were severely tailed with asymmetry factors as high as 2.4 for pyridine eluting from the silica column. However, elution of pyridine from a sodium iodide impregnated zirconia–silica column occurred with a capacity factor of 0.26, but most importantly, the peak tailing decreased substantially, as shown in Table 1. Similar results were observed for the elution of aniline. However, selectivity differences resulted in the elution order of pyridine and aniline being reversed between the sodium iodide impregnated zirconia–silica column and the unmodified zirconia–silica column.

Table 1 Capacity factor and asymmetry factors for pyridine in a normal phase separation on various silica and zirconia stationary phases.

Stationary phase	Capacity factor	Asymmetry factor
Silica	9.50	2.450
Zirconia	0.99	1.840
Zirconia–silica	0.86	1.795
NaI impregnated zirconia–silica	0.24	1.330

In general, iodide impregnation decreased retention, and improved peak shape.

The ion-exchange properties of zirconia–silica surfaces were utilized in a study by Peixoto, Gushiken, and Baccan.[7] In this study, zirconica–silica microcolumns were employed for the selective extraction and enrichment of chromium(VI) in a flow injection system. The hydrated zirconia–silica surface adsorbed cations or anions depending on the pH. At low pH, the surface behaved as anion exchanger by a mechanism in which OH^- was displaced from the surface according to:[7]

$$ZrOH + H^+ + Cr_2O_7^{2-} \rightarrow Zr^+Cr_2O_7^{2-} + H_2O$$

They showed that the method was suitable for the analysis of Cr(VI) in natural waters with little interference from common ions normally found in these water samples.

The ion-exchange properties of zirconia–silica surfaces were also evaluated by Chicz, Shi, and Regnier;[6] however, their study was conducted on surfaces modified with a layer of PEI. A number of different stationary phase base support materials were employed in their study including zirconia–silica. They found that retention was dependent on the amount of PEI bound to the surface, leading them to suggest that base materials with similar charge density, surface area, and pore diameter (in other words, materials with the same capacity to adsorb the PEI coating) should behave in much the same manner. The advantage of the zirconia–silica base support over silica was that the zirconia–silica phase was stable in alkaline solvents whereas the silica phase rapidly dissolved.

Only one research group has illustrated the RP retention behavior of solutes on zirconia–silica modified surfaces. In the study by Melo et al.[8,9] on PMOS gamma-irradiated modified surfaces, the RP retention behavior of a test mixture containing acetone, benzonitrile, benzene, toluene, and naphthalene was evaluated. The authors

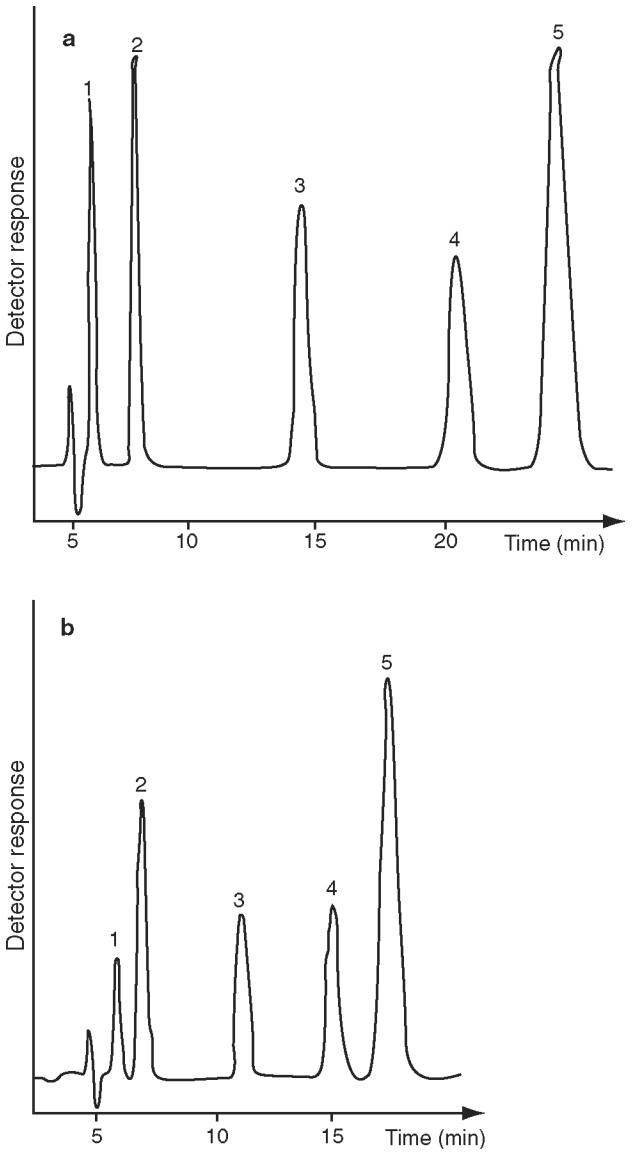

Fig. 7 Chromatograms of a mixture of acetone (1), benzonitrile (2), benzene (3), toluene (4), and naphthalene (5), obtained from a zirconized silica column with a radiation-immobilized PMOS coating (a) before initiating the stability test and (b) after completing the stability test with 5000 column volumes each of neutral and alkaline (pH 10) mobile phases.

illustrated good resolution of the five-component text mixture as shown in Fig. 7. Retention, however, decreased after the stationary phase was washed with 5000 column volumes of base (pH 10). Despite the base washing, uniform peak shape was maintained, with only a slight reduction in resolution as discussed in "Alkaline Stability" above.

CONCLUSIONS

In searching for new separation processes, the chromatographer develops new types of stationary phase materials in order to gain improvements in selectivity. The development of zirconia–silica composites is an example which—although, at present, applications on these surfaces are limited to their development—typifies the ongoing search. Whether the separations achieved on the zirconia–silica composites are better or worse than those achieved on either zirconia or silica is immaterial to the fundamental process of discovery. The important factor is that the separation is different and, therefore, an alternative separation strategy may be employed. In addition to the differences in selectivity that may be found when new surfaces are developed, beneficial surface properties may also be realized. These may be related to aspects such as the pore structure, the acidic or basic properties, or the solubility of the support.

In the specific case of zirconia–silica composites, the stationary phase could be prepared through relatively simple processes using either coprecipitation or coating methods. The addition of silica to the zirconia matrix increases the phase transition temperature from the amorphous phase to the tetragonal phase, which in turn stabilizes the tetragonal phase. The pore structure can be controlled through processes similar to those employed in the preparation of zirconia. However, the type of pore structure obtained appears to be dependent on the method of preparation. Calcination in the presence of salts improves the pore shapes. Zirconia–silica phases can also be surface-modified and C_8 and ion-exchange media have been prepared. Composite zirconia–silica stationary phases coated with PEI were shown to have a lower solubility in alkaline solvents than silica modified in the same manner. The ion-exchange properties of zirconia–silica stationary phases were utilized in the analysis of natural waters, where the concentration of chromium(VI) was enriched in a flow injection system that incorporated a microcolumn packed with zirconia–silica stationary phase. Several studies have shown the elution behavior of basic solutes on these composites, and one study illustrated that modifying the surface with a Lewis base could minimize peak tailing.

Future work in stationary phase design will probably continue to include studies on mixed oxide composites although these will continue to constitute only a small fraction of the stationary phase materials made for general purpose use. Many of the mixed oxide supports will be custom-made for specific applications, and at least in the short term, these types of stationary phases will be made by individual research groups.

Zone Dispersion in FFF

Josef Janca
Department of Chemistry, University of La Rochelle, La Rochelle, France

INTRODUCTION

All separation processes are inherently accompanied by zone broadening, which is due to the dynamic spreading processes dispersing the concentration distribution achieved by the separation.[1] As long as the relative contributions of these dispersive processes decrease, the efficiency of the separation increases. A conventional empirical parameter describing, quantitatively, the efficiency of any separation system is the number of theoretical plates per separation unit, N, or the height equivalent to a theoretical plate (the theoretical plate height) H defined by

$$N = \left(\frac{V_R}{\sigma_V}\right)^2, \quad H = \frac{L}{N} \tag{1}$$

where V_R is the retention volume, σ_V is the standard deviation of the elution curve (fractogram) of a uniform retained sample, expressed at the same retention volume units, and L is the length of the separation unit; in the case of the field-flow fractionation (FFF), it is the length of the fractionation channel. Fig. 1a shows a model fractogram and the method of graphical determination of the efficiency of the involved separation system. A more accurate procedure for the determination of the efficiency of the separation system from the experimental fractogram consists in the numerical calculation of the statistical moments of the fractogram (viz. of the first statistical moment, which corresponds to the maximum of the fractogram and, thus, to the retention volume):

$$V_R = \frac{\Sigma V_i h_i}{\Sigma h_i} \tag{2}$$

where h_i are the heights of the fractogram at the corresponding retention volumes V_i. The square root of the second central moment corresponds to the standard deviation of the fractogram and, thus, to its width:

$$\sigma_V = \left(\frac{\Sigma (V_i - V_R)^2 h_i}{\Sigma h_i}\right)^{1/2} \tag{3}$$

It must be stressed that the terms band or zone broadening, spreading, and dispersion used here are equivalent from the viewpoint of their physical meanings.

PROCESSES CONTRIBUTING TO ZONE BROADENING

Several dispersive processes contribute to zone broadening: longitudinal diffusion, non-equilibrium and relaxation processes, spreading due to the external parts of the whole separation system, such as the injector, detector, connecting capillaries, and so forth. It has theoretically been found[2] that the resulting efficiency of the FFF, characterized by the height equivalent to a theoretical plate, can very accurately be described by

$$H = \frac{2D}{R\langle v(x)\rangle} + \frac{\chi^{w^2}\langle v(x)\rangle}{D} + \sum H_{\text{ext}} \tag{4}$$

where D is the diffusion coefficient of the retained species, R is the retention ratio, $\langle v(x)\rangle$ is the average linear velocity of the carrier liquid, w is the thickness of the fractionation channel, x is the dimensionless parameter defined later, and ΣH_{ext} is the sum of all contributions to the zone broadening from the external parts of the separation channel (injector, detector cell, and connecting capillaries).

The retention ratio R is defined as

$$R = \frac{V_0}{V_R} \tag{5}$$

where V_0 and V_R are the retention volumes of the unretained and retained species, respectively. Graphical representation of the particular spreading processes, as a function of the average linear velocity of the carrier liquid and of their sum, which results in a curve exhibiting a minimum, are shown in Fig. 1b. At very low linear velocities of the carrier liquid, the longitudinal diffusion, represented by the first term on the righthand side of the Eq. 4, plays a dominant role of all zone-spreading processes. The relaxation and non-equilibrium processes, represented by the second term on the right-hand side of the Eq. 4, become more important when increasing the velocity. The result is that H passes through the above-mentioned minimum. As the diffusion coefficients of the macromolecules and particles are relatively low, the contribution of the longitudinal diffusion is almost negligible and the optimal efficiency (the minimum on the resulting curve) appears at a very low flow velocity. The zone spreading due to the external elements of the fractionation channel can be minimized by reducing their volume.

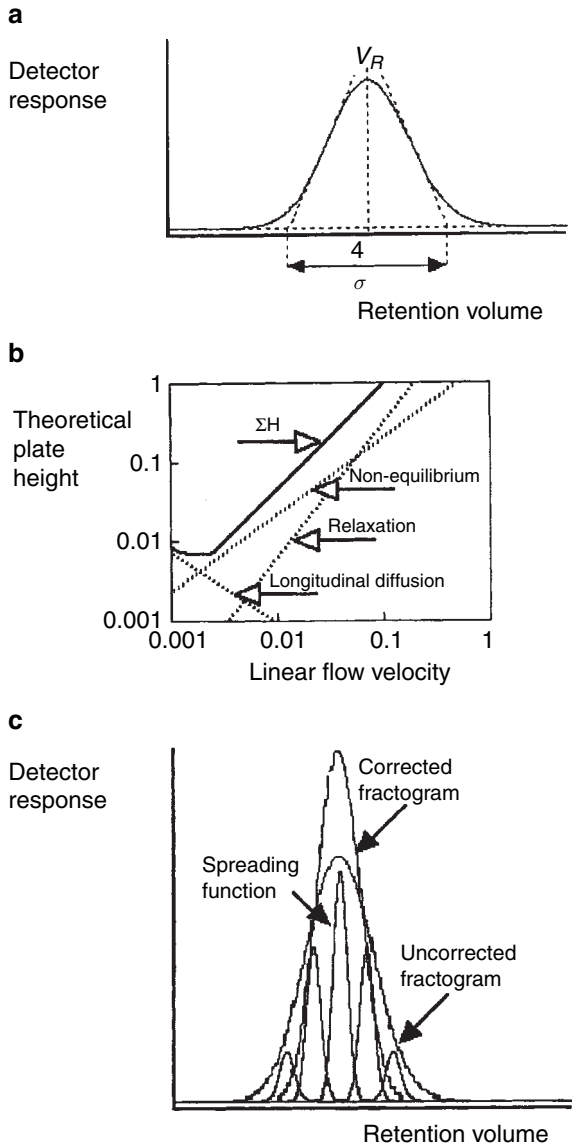

Fig. 1 Zone broadening and its correction. a, Schematic demonstration of the evaluation of the efficiency of the separation system of FFF; b, dependence of the theoretical plate height on the linear flow velocity; and c, schematic demonstration of the application of the correction for the zone broadening on a model fractogram.

The dimensionless parameter χ is a complex function of the retention parameter λ which, itself, can be approximated by the relationship

$$\lim_{\lambda \to 0} R = 6\lambda \tag{6}$$

Another approximate relationship holds between χ and λ:

$$\lim_{\lambda \to 0} \chi = 24\lambda^3 \tag{7}$$

Eq. 7 is a very important relationship because, with respect to Eq. 4, it indicates that in the most practical range of the linear flow velocities, above the optimal flow, the efficiency of the separation in FFF increases very rapidly with the retention ratio. This is rather an exceptional case among separation methods and the importance of this behavior has to be regarded with respect to the fact that the FFF methods and techniques are especially convenient for the fractionation of large and polydisperse species, such as macromolecules and particles. As the retention usually increases with the molar mass or particle size in polarization FFF, the efficiency is higher in the high molar mass or large particle size domain. This is one of the reasons why the FFF methods are particularly competitive in this field of application.

Nevertheless, the difficulty to separate the large polydisperse species enough, independently of the method or technique used, impose the necessity to introduce, and apply the powerful numerical methods, which are able to evaluate the amplitude of the zone broadening contribution to the apparent molar mass distribution (MMD) or particle size distribution (PSD), calculated by a simple data treatment of the experimental fractograms, and to correct, casually, the MMD and PSD data for zone broadening. Whenever the zone spreading attains a level not acceptable from the point of view of the analytical results obtained by a simple data treatment of the raw fractograms, a correction for the zone broadening must be applied.

RELAXATION

Relaxation represents an important contribution to the zone broadening and merits mention in particular, especially because it can be reduced by an appropriate experimental procedure.[3] The concentration distribution of the fractionated sample across the channel established immediately after the injection is far from the steady state, which is formed progressively during the elution. This leads to additional zone broadening. However, if the flow is stopped after the injection for a time necessary to achieve a steady state, the shift of the retention volume and the zone spreading can substantially be reduced. So-called secondary relaxation broadening can occur when the intensity of the field varies rapidly during the elution (e.g., by programming).

CORRECTION FOR THE ZONE BROADENING

The fractogram of a polydisperse sample is a superposition of the separation and of the zone broadening. This is shown in Fig. 1c, where the spread zones of the discrete species are overlapped and the fractogram is, in fact, a convolution of all individual zones. Whenever the zone spreading is important, the accurate MMD or PSD can be calculated from the experimental fractograms only by using a correction procedure. An efficient correction method applicable

in FFF[4] was derived from well-known correction procedures used in SEC.[5]

A raw fractogram $h(V)$ is a convolution of the fractogram corrected for the zone broadening $g(Y)$ and the spreading function $G(V, Y)$ which is a detector response to a uniform species having the elution volume Y:

$$h(V) = \int_0^\infty g(Y)G(V - Y)dY \tag{8}$$

The spreading function can be approximated by

$$G(V, Y) = \left(\frac{1}{2\pi\sigma_S{}^2}\right)^{1/2} \exp\left(-\frac{(V - Y)}{2\sigma_S{}^2}\right) \tag{9}$$

where the standard deviation should be independent of the elution volume. This independence is valid in FFF only within a not very wide range of the elution volumes. Eq. 9 can correctly be applied to the fractograms of the samples with a narrow MMD or PSD only. On the other hand, whenever a non-uniform spreading function with the dependent on the retention has to be used, the correction to be applied is

$$h(V) = \int_0^\infty g(Y)\left[\frac{1}{[2\pi(\sigma_S(Y)]^2}\right]^{1/2} \times \exp\left(-\frac{(V - Y)^2}{[2(\sigma_S Y)]^2}\right)dY \tag{10}$$

which is convenient for samples exhibiting wide MMD or PSD. Eq. 10 can be numerically solved. The graphical representation of a model result of the application of the described correction procedure is shown in Fig. 1c.

Practical utility of the described correction procedure of the experimental fractograms was demonstrated first by applying it to the real fractograms of a polymer latex obtained from sedimentation FFF[4] and was subsequently confirmed.[6–8]
