Another possible way to minimize the interaction of collagen with the capillary wall is the presence of a high concentration of surfactant (above the critical micellar concentration), i.e., by micellar electrokinetic chromatography (MEKC). A useful system consists of a 50 m*M* phosphate buffer (pH 2.5) with 50 m*M* SDS; this system has to be run in negative polarity mode. At low, submicellar concentrations, the separations are different and only reflect interactions between the peptides and with the capillary wall, but not the presence of SDS micelles in the background electrolyte.

A pluronic polymer, which is a triblock uncharged copolymer with the general formula $[\text{poly(ethylene oxide)}]_x[\text{poly(propylene oxide)}]_y[\text{poly(ethylene oxide)}]_x$, was also investigated for use in the separation of collagen fragments. Block (triblock) copolymers can self-assemble to form micelle structures in aqueous buffers and can also serve as thermo-responsive gels. Pluronics have many interesting features: they are soluble at low temperature and can gellify with a temperature increase, i.e., the polymer can be easily introduced into the capillaries at a lower temperature and the separation can be carried out at a

higher temperature. The 7.5% pluronic F127 (in a pH 2.5, 10 m*M* Tris, and 75 m*M* phosphate buffer at 20°C) can be used for the separation of CNBr fragments. The separation is probably a combination of the principles of MEKC and capillary gel electrophoresis (CGE), where it resembles the separation achieved by reversed-phase HPLC, but with a different elution order.

Collagenase Fragments

Specific enzymes for the cleavage of collagens are collagenases. There are two major types of collagenase—tissue (interstitial) and bacterial. Interstitial collagenase (EC 3.4.24.7) cleaves the triple helix of collagen at about three-quarters of the length of the molecule from the N-terminus (at 775Gly/Ile776 in the α-1(I)chain). Microbial collagenase, typically from *C. histolyticum*, (EC 3.4.24.3), digests native collagen in the triple helix region at the Gly-bonds where preference was shown for Gly at P3 and P1′; Pro and Ala at P2 and P2′; and hydroxyproline, Ala or Arg at P3′. Because glycine is every third amino acid in collagenous domains, the cleavage of collagen by microbial collagenase resulted in mainly short peptides and a complex mixture (theoretically up to 172 different peptides could arise from a naturally occurring mixture of collagen type I and III).

HPLC

The HPLC separation of peptides arising from the cleavage of collagen by bacterial collagenase is carried out in the "traditional" manner for peptide mapping. The column used is reversed-phase (C_{18}) with normal pore size (10 nm). The gradient used is water–methanol with trifluoroacetic acid as the ion-pairing agent.

Capillary Zone Electrophoresis

The separation of microbial collagenase' peptides (preferably tripeptides) is not a simple matter for CE; short peptides with proline in the carboxy terminus strongly adhere to the capillary wall. For this reason, both when separating collagenase and CNBr peptides, a very useful method is separation at acidic pH (2.5) using a fused silica capillary, or even the use of a modified capillary (inner surface) by dynamic coating (alkylamines added to the background electrolytes) at acidic pH (one of the best modifiers was 1,7-diaminoheptane).

The capillary electromigration methods can be also successfully used for the determination of the 1/4 and 3/4 fragments of collagens type I and II arising from cleavage by interstitial collagenase. The sensitivity can be enhanced by using a dynamic fluorescence labeling technique (argon ion 488 nm laser) with a running buffer containing 0.05% sodium dodecylsulfate and a non-covalent fluorescent dye for protein, NanoOrange. The collagen (type I or II) and both fragments can be separated and detected within a run time of 20 min by capillary gel electrophoresis using a gel buffer (pH 8.8) containing 4% polyacrylamide. The buffer was 50 m*M* AMPD-CACO (2-amino-2-methyl-1,3-propanediol-cacodylic acid) and a coated capillary was used.

Combination of HPLC and Capillary Electrophoresis

As was mentioned above, the cleavage of tissue consisting of collagen types I and III by bacterial collagenase can result in a rich mixture of peptides (theoretically up to 172 different peptides). The separation of this peptide set by only one analytical method was unsuccessful—with RP–HPLC only 45 peaks could be determined and only 65 peptides with CE. This resolution is not sufficient for the study of collagens and their posttranslational modification.

The off-line combination of both methods (CE and HPLC) improves separation—150 peaks were detected. In the first stage, the peptide mixture was separated by reversed-phase HPLC using gradient elution with a water–acetonitrile system with trifluoroacetic acid as the ion-pairing agent. The collagenous peptides were divided into a few (five or seven) fractions by HPLC. These fractions were further characterized by CE in an uncoated capillary using a phosphate buffer (100 m*M*, pH 2.5). This two-step peptide mapping with subsequent statistical evaluation (e.g., linear regression analysis) was shown to represent a reliable approach for revealing posttranslational modifications in collagen in vivo.

Coupling of HPLC and Capillary Zone Electrophoresis with Mass Spectrometry

The coupling of HPLC or capillary electrophoresis and mass spectrometry for peptide/protein analysis is a promising technique which will have a significant impact on protein research. Surprisingly, this method is only rarely used for the analysis of collagen. Because collagens are high-molecular-mass proteins, only the peptidic fragments can be analyzed by mass spectrometry.

The HPLC method uses the procedure described in the section on the separation of collagenase digest—a reversed-phase column (normal pore C_{18}) eluted by a water–acetonitrile gradient with formic acid as the additive. Alternatively, formic acid can be substituted with trifluoroacetic acid (due to its "ion-killing" properties at lower concentrations, e.g., 3 m*M*). Separation and resolution is slightly better with trifluoroacetic acid as the ion-pairing agent.

Capillary electrophoresis was carried out in a fused-silica capillary (100 cm × 75 μm I.D.) with a background electrolyte consisting of 0.25 *M* acetic acid, at an applied voltage of

20 kV. The mass spectrometer used was a quadrupole or trap (MS/MS) type. The sheath liquid used was 5 m*M* ammonium acetate/isopropanol 1:1 (v/v) at a flow-rate of 3 μl/min. This method enables the identification of typical collagenous tripeptides in the collagenase digest, as well as CNBr/trypsin and proteinase K digests.

CONCLUSION

Collagen is a broad group of the most abundant proteins in the human body that encompasses at least 28 known types in vertebrates. These proteins are poorly soluble (if at all) and, therefore, they are often split into shorter peptides by enzymatic or non-enzymatic methods before analysis. Collagenous peptides can be successfully separated by high-performance analytical methods—HPLC and CE. The HPLC methods use, most frequently, reversed-phase columns with ion-pairing. Various types of capillary electromigration methods can be used for the separation of collagens and their fragments. The main problem with capillary electrophoretic methods is adhesion of collagenous peptides to the surface of a fused-silica capillary. It can be eliminated by the use of acidic background electrolytes and/or use of surfactants in the separation medium. The high-performance method for analysis is combination of HPLC and CE. Nowadays, the high-performance approach is combination of HPLC and CE with MS.

Because collagens are highly important proteins, we can expect that studies of these proteins will be intensified in the future. For these researches we need, and we have, a broad spectrum of analytical methods. However, we can assume that new high-performance methods will be continuously developed.

Colloids: Adhesion on Solid Surfaces by FFF

George Karaiskakis
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

The adhesion of colloids on solid surfaces, which is of great significance in filtration, corrosion, detergency, coatings, and so forth, depends on the total potential energy of interaction between the colloidal particles and the solid surfaces. The latter, which is the sum of the attraction potential energy and that of repulsion, depends on particle size, the Hamaker constant, the surface potential, and the Debye–Huckel reciprocal distance, which is immediately related to the ionic strength of carrier solution. With the aid of the field-flow fractionation (FFF) technique, the adhesion and detachment processes of colloidal materials on and from solid surfaces can be studied. As model samples for the adhesion of colloids on solid surfaces (e.g., Hastelloy-C), hematite (a-Fe_2O_3) and titanium dioxide (TiO_2) submicron spherical particles, as well as hydroxyapatite [$Ca_5(PO_4)_3OH$] submicron irregular particles were used. The experimental conditions favoring the adhesion process were those decreasing the surface potential of the particles through the pH and ionic strength variation, as well as increasing the effective Hamaker constant between the particles and the solid surfaces through the surface-tension variation. On the other hand, the detachment of the same colloids from the solid surfaces can be favored under the experimental conditions decreasing the potential energy of attraction and increasing the repulsion potential energy.

METHODOLOGY

FFF technology is applicable to the characterization and separation of particulate species and macromolecules. Separations in FFF take place in an open flow channel over which a field is applied perpendicular to the flow. Among the various FFF subtechniques, depending on the kind of the applied external fields, sedimentation FFF (SdFFF) is the most versatile and accurate, as it is based on simple physical phenomena that can be accurately described mathematically. SdFFF, which uses a centrifugal gravitational force field, is a flow-modified equilibrium sedimentation-separation method. Solute layers that are poorly resolved under static equilibrium sedimentation become well separated as they are eluted by the laminar flow profile in the SdFFF channel. In normal SdFFF, where the colloidal particles under study do not interact with the channel wall, the potential energy of a spherical particle, $\varphi(x)$, is related to the particle radius, a, to the density difference, $\Delta\rho$, between the particle (ρ_s) and the liquid phase (ρ), and to the sedimentation field strength expressed in acceleration, G:

$$\varphi(x) = \frac{4}{3}\pi a^3 \rho G x \tag{1}$$

where x is the coordinate position of the center of particle mass.

When the colloidal particles interact with the SdFFF channel wall, the total potential energy, φ_{tot}, of a spherical particle is given by

$$\varphi_{\text{tot}} = \frac{4}{3}\pi a^3 \Delta\rho G x + \frac{A_{132}}{6}\left[\ln\left(\frac{h+2a}{h}\right) - \frac{2a(h+a)}{h(h+a)}\right] + 16\varepsilon a\left(\frac{kT}{e}\right)^2 \tan h\left(\frac{e\psi_1}{4kT}\right)\tan h\left(\frac{e\psi_2}{4kT}\right)e^{-\kappa x} \tag{2}$$

where the second and third terms of Eq. 2 accounts for the contribution of the van der Waals attraction potential and of the double-layer repulsion potential between the particle and the wall, respectively, A_{132} is the effective Hamaker constant for media 1 and 2 interacing across medium 3, h is the separation distance between the sphere and the channel wall, e is the dielectric constant of the suspending medium, e is the electronic charge, ψ_1 and ψ_2 are the surface potentials of the particles and the solid wall, respectively, k is Boltzmann's constant, T is the absolute temperature, and κ is the Debye–Huckel reciprocal length, which is immediately related to the ionic strength, I, of the medium.

Eq. 2 shows that the total potential energy of interaction between a colloidal particle and a solid substrate is a function of the particle radius and surface potential, the ionic strength and dielectric constant of the suspending medium, the value of the effective Hamaker constant, and the temperature. Adhesion of colloidal particles on solid surfaces is increased by a decrease in the particle radius, surface potential, the dielectric constant of the medium and by an increase in the effective Hamaker constant, the ionic strength of the dispersing liquid, or the temperature. For a given particle and a medium with a known dielectric constant, the adhesion and detachment processes depend on the following three parameters:

1. The surface potential of the particles, which can be varied experimentally by various quantities one of which is the suspension pH.
2. The ionic strength of the solution, which can be varied by adding to the suspension various amounts of an indifferent electrolyte.
3. The Hamaker constant, which can be easily varied by adding to the suspending medium various amounts of a detergent. The later results in a variation of the medium surface tension.

APPLICATIONS

The critical electrolyte (KNO_3) concentrations found by SdFFF for the adhesion of a-Fe_2O_3(I) (with nominal diameter 0.148 μm), a-Fe_2O_3(II) (with nominal diameter 0.248 μm), and TiO_2 (with nominal diameter 0.298 μm) monodisperse spherical particles on the Hastelloy-C channel wall were 8×10^{-2}, 3×10^{-2}, and 3×10^{-2} *M*, respectively. The values for the same sample (a-Fe_2O_3) depend on the particle size, in accordance with the theoretical predictions, whereas the same values are identical for various samples [a-Fe_2O_3(II) and TiO_2] having different particle diameters. The latter indicates that these values depend also, apart from the size, on the sample's physicochemical properties, as is predicted by Eq. 2. The detachment of the whole number of particles of the above samples from the channel wall was succeeded by decreasing the ionic strength of the carrier solution.

The critical KNO_3 concentration for the detachment process was 3×10^{-2} *M* for the a-Fe_2O_3(I) sample and 1×10^{-2} *M* for the samples of a-Fe_2O_3(II) and TiO_2. Those obtained by SdFFF particle diameters after the detachment of the adherent particles [0.148 μm for a-Fe_2O_3(I), 0.245 μm for a-Fe_2O_3(II), and 0.302 μm for TiO_2] are in excellent agreement with the corresponding nominal particle diameters obtained by transmission electron microscopy. The desorption of all of the adherent particles was verified by the fact that no elution peak was obtained, even when the field strength was reduced to zero. A second indication for the desorption of all of the adherent material was that the sample peaks after adsorption and desorption emerge intact and without degradation.

In a second series of experiments, the adhesion and detachment processes of hydroxyapatite (HAP) polydisperse particles with number average diameter of 0.261 μm on and from the Hastelloy-C channel wall were succeeded by the variation of the suspension pH, whereas the medium's ionic strength was kept constant (10^{-3} *M* KNO_3). At a suspension pH of 6.8, the whole number of injected HAP particles was adhered at the beginning of the SdFFF channel wall, which was totally released when the pH increased to 9.7, showing that, except for the ionic strength, the pH of the suspending medium is also a principal quantity influencing the interaction energy between colloidal particles and solid surfaces. The number-average diameter of the HAP particles found by SdFFF after the detachment of the adherent particles ($d_N = 0.262$ μm) was also in good agreement with that obtained when the particles were injected into the channel with a carrier solution in which no adhesion occurs ($d_N = 0.261$ μm).

The variation of the potential energy of interaction between colloidal particles and solid surfaces can be also succeeded by the addition of a detergent to the suspending medium, which leads to a decrease in the Hamaker constant and, consequently, in the potential energy of attraction.

In conclusion, FFF is a relatively simple technique for the study of adhesion and detachment of submicrometer or supramicrometer colloidal particles on and from solid surfaces.

FUTURE DEVELOPMENTS

Looking to the future, it is reasonable to expect more experimental and theoretical work in order to quantitatively investigate the adhesion/detachment phenomena of colloids on and from solid surfaces by measuring the corresponding rate constants with the aid of FFF.

Colloids: Aggregation in FFF

Athanasia Koliadima
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

The separation of the components of complex colloidal materials is one of the most difficult challenges in separation science. Most chromatographic methods fail in the colloidal size range or, if operable, they perform poorly in terms of resolution, recovery, and reproducibility. Therefore, it is desirable to examine alternate means that might solve important colloidal separation and characterization problems encountered in working with biological, industrial, environmental, and geological materials. One of the most important colloidal processes that is generally quite difficult to characterize is the aggregation of single particles to form complexes made up of multiples of the individual particles. Aggregation is a common phenomenon for both natural and industrial colloids. The high degree of stability, which is frequently observed in colloidal systems, is a kinetic phenomenon in that the rate of aggregation of such systems may be practically zero. Thus, in studies of the colloidal state, the kinetics of aggregation are of paramount importance. Although the kinetics of aggregation can be described easily by a bimolecular equation, it is not an easy thing to do experimentally.

One technique for doing this is to count the particles microscopically. In addition to particle size limitation, this is an extraordinarily tedious procedure. Light scattering can be also used for the kinetic study of aggregation, but experimental turbidities must be interpreted in terms of the number and size of the scattering particles.

In the present work, it is shown that the field-flow fractionation (FFF) technique can be used with success to study the aggregation phenomena of colloids.

The techniques of FFF appear to be well suited to colloid analysis. The special subtechnique of sedimentation FFF (SdFFF) is particularly effective in dealing with colloidal particles in the diameter range from 0.02 to 1 μm, using the normal or Brownian mode of operation (up to 100 μm using the steric-hyperlayer mode). As a model sample for the observation of aggregate particles by SdFFF, of poly(methyl methacrylate) (PMMA) was used, whereas for the kinetic study of aggregation by SdFFF, the hydroxyapatite (HAP) sample [$Ca_5(PO_4)_3OH$] consisting of submicron irregularly shaped particles was used. The stability of HAP, which is of paramount importance in its applications, is dependent on the total potential energy of interaction between the HAP particles. The latter, which is the sum of the attraction potential energy and that of repulsion, depends on particle size, the Hamaker constant, the surface potential, and the Debye–Hückel reciprocal distance, which is immediately related to the ionic strength of carrier solution.

METHODOLOGY

FFF is a highly promising tool for the characterization of colloidal materials. It is a dynamic separation technique based on differential elution of the sample constituents by a laminar flow in a flat, ribbonlike channel according to their sensitivity to an external field applied in the perpendicular direction to that of the flow.

The total potential energy of interaction between two colloidal particles, U_{tot}, is given by the sum of the energy of interaction of the double layers, U_R, and the energy of interaction of the particles themselves due to van der Waals forces, U_A. Consequently,

$$U_{tot} = U_R + U_A \tag{1}$$

For identical spherical particles U_R and U_A are defined as follows:

$$U_R = \frac{\varepsilon r \psi_0^2}{2} \ln[1 + \exp(-\kappa H)] \quad (\kappa r \gg 1) \tag{2}$$

$$U_R = \frac{\varepsilon r \psi_0^2}{R} \exp(-\kappa H) \quad (\kappa r \ll 1) \tag{3}$$

$$U_A = -\frac{A_{212} r}{12 H} \tag{4}$$

where ε is the dielectric constant of the dispersing liquid, r is the radius of the particle, ψ_0 is the particle's surface potential, κ is the reciprocal double-layer thickness, R is the distance of the centers of the two particles, A_{212} is the effective Hamaker constant of two particles of type 2 separated by the medium of type 1, and H is the nearest distance between the surfaces of the particles.

Eqs. 2–4 show that the total potential energy of interaction between two colloidal spherical particles depends on the surface potential of the particles, the effective Hamaker constant, and the ionic strength of the suspending medium. It is known that the addition of an indifferent electrolyte can cause a colloid to undergo aggregation. Furthermore, for a particular salt, a fairly sharply defined

concentration, called "critical aggregation concentration" (CAC), is needed to induce aggregation.

The following equation gives the rate of diffusion-controlled aggregation, u_r, of spherical particles in a disperse system as a result of collisions in the absence of any energy barrier to aggregate:

$$u_r = -k_r {N_0}^2 \tag{5}$$

where k_r is the second-order rate constant for diffusion-controlled rapid aggregation and N_0 is the initial number of particles per unit volume.

In the presence of an energy barrier to aggregate, the rate of aggregation, u_s, is

$$u_s = -k_s {N_0}^2 \tag{6}$$

where k_s is the rate constant of slow aggregation in the presence of an energy barrier.

The stability ratio, w, of a dispersion is defined as the ratio of the rate constants for aggregation in the absence, k_r and the presence, k_s, of an energy barrier, respectively:

$$w = \frac{k_r}{k_s} \tag{7}$$

The aggregation process is described by the bimolecular kinetic equation

$$\frac{1}{N_i} = \frac{1}{N_0} + k_{\text{app}} t_i \tag{8}$$

where N_i is the total number of particles per unit volume at time t_i and k_{app} is the apparent rate constant for the aggregation process. The measurement of the independent kinetic units per unit volume, N_i, at different times t_i can give the rate constant for the aggregation process.

Considering that d_{N_0} and d_{N_i} are the measured number-average diameters of the particles at times $t = 0$ and t_i, respectively, Eq. 8, for polydisperse samples, gives

$${d_{N_i}}^3 = {d_{N_0}}^3 + {d_{N_0}}^3 N_0 k_{\text{app}} t_i \tag{9}$$

Eq. 9 shows that from the slope of the linear plot of the ${d_{N_i}}^3$ versus t_i, the apparent rate constant k_{app} can be determined, as the N_0 values can be found from the ratio of the total volume of the injected sample to the volume of the particle, which can be determined from the diameter calculated from the intercept of the above plot.

APPLICATIONS

The observation of a series of peaks (Fig. 1) while analyzing samples of PMMA colloidal latex spheres by SdFFF suggests that part of the latex population has aggregated into doublets, triplets, and higher-order particle clusters. The particle diameter of the latex spheres was given as 0.207 μm. The aggregation hypothesis is confirmed by retention calculations and by electron microscopy. For this purpose, narrow fractions or cuts were collected from the first five peaks as shown in Fig. 1. A fraction was also collected for the peak which appeared after the field was turned off. The individual fractions were subjected to electron microscopy and as expected, cut No. 1 yielded singlets, cut No. 2 yielded doublets, cut No. 3 yielded triplets, cut No. 4 yielded quads, cut No. 5 yielded quints, and the cut after the field was turned off yielded clusters from six individual particles.

Sedimentation field-flow fractionation was used also for the kinetic study of HAP particles' aggregation in the presence of various electrolytes to determine the rate constants for the bimolecular process of aggregation and to investigate the possible aggregation mechanisms describing the experimental data. The HAP sample contained polydisperse, irregular colloidal particles with number-average diameter $d_{\text{N}} = 0.262 \pm 0.046$ μm.

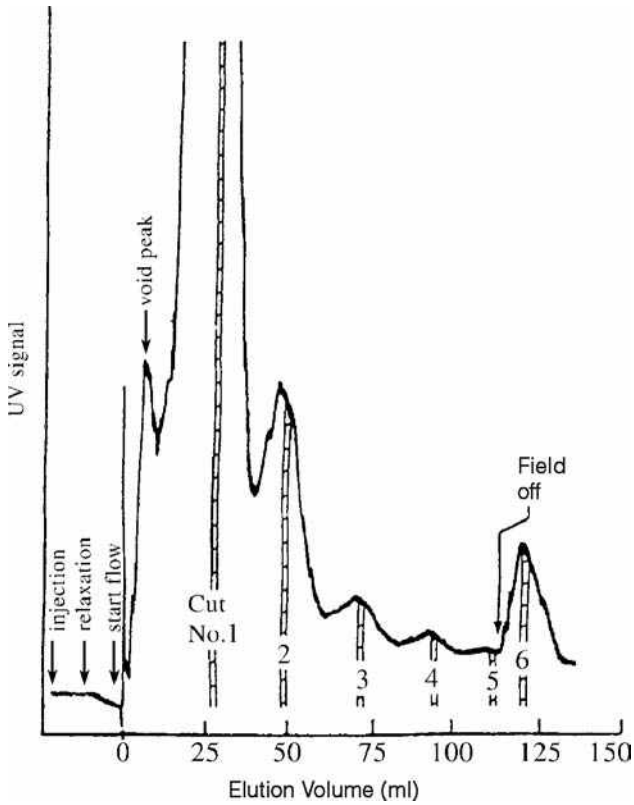

Fig. 1 SdFFF fractogram of 0.207 μm PMMA aggregate series from which six cuts were collected and analyzed by electron microscopy. Experimental conditions: field strength of 61.6 g and flow rate of 0.84 ml/min.
Source: From Resolution of colloidal latex aggregates by sedimentation field-flow fractionation, in J. Chromatogr.[1] Copyright Elsevier Science Publishers B.V.

The number-average diameter, d_N, for the HAP particles increases with the electrolyte KNO_3 concentration until the critical aggregation concentration is reached, where the d_N value remains approximately constant. The starting point of the maximum d_N corresponds to the electrolyte concentration called CAC. The last value, which depends on the electrolyte used, was found to be 1.27×10^{-2} M for the electrolyte KNO_3.

According to Eq. 9, the plot of ${d_{N_i}}^3$ versus t_i at various electrolyte concentrations determines the apparent rate constant, k_{app}, of the HAP particles' aggregation. The found k_{app} value for the aggregation of the HAP particles in the presence of 1×10^{-3} M KNO_3 is 2.5×10^{-21} cm^3/sec. It is possible to make a calculation which shows whether the value of k_{app} is determined by the rate at which two HAP particles can diffuse up to each other (diffusion control) or whether the rate of reaction is limited by other slower processes. The rate constant for the bimolecular collision (k_1) of the HAP particles, can be calculated by the Stokes–Einstein equation:

$$k_1 = \frac{8kT}{3n} \text{cm}^3/\text{sec} \tag{10}$$

where n is the viscosity of the medium. The calculated value of $k_1 = 1.1 \times 10^{-11}$ cm^3/sec is about 10 orders of magnitude greater than the value of k_{app} actually measured. So, the aggregation rates are slower than those expected if the process was simply diffusion controlled when electrostatic repulsion is absent. The latter indicates that the minimal mechanism for the aggregation process of the HAP particles would be

$$\begin{gathered} \text{Particle}_1 + \underset{2}{\text{Particle}} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \\ \text{Intermediate complex} \overset{k_2}{\rightleftarrows} \text{Stable aggregate} \end{gathered} \tag{11}$$

where k_{-1} is the rate constant for the dissociation of the intermediate aggregate and k_2 is the rate constant for the process representing the rate-determining step in the aggregation reaction. Because k_{app}, describing the overall process, is smaller than the calculated k_1 value, there must be rapid equilibration of the individual particles and their intermediate complexes followed by the slower step of irreversible aggregation. The stability factor, w, of HAP's particles found to be 4.4×10^9 is too high, indicating that the particles are very stable, even in the presence of significant quantity of the electrolyte KNO_3.

As a general conclusion, the FFF method can be used with success to study the aggregation process of colloidal materials.

FUTURE DEVELOPMENTS

Looking to the future, it is reasonable to expect continuous efforts to improve the theoretical predictions and more experimental work to investigate the aggregation phenomena of natural and industrial colloids.

Colloids: Concentration of Dilute Samples by FFF

George Karaiskakis
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

Many colloidal systems, such as those of natural water, are too dilute to be detected by the available detection systems. Thus, a simple and accurate method for the concentration and analysis of these dilute samples should be of great significance in analytical chemistry. In the present work, two methodologies of the field-flow fractionation (FFF) technique for the concentration and analysis of dilute colloidal samples are presented. Both the conventional and potential barrier methodologies of FFF are based on the "adhesion" of the samples at the beginning of the channel wall, followed by their total removal and analysis. In the conventional sedimentation FFF (SdFFF) concentration procedure, the apparent adhesion of a dilute sample is due to its strong retention, which can be achieved by applying high field strengths and low flow rates. In the potential barrier SdFFF (PBSdFFF) concentration procedure, the true adhesion of a dilute sample is due to its reverse adsorption at the beginning of the column, which can be achieved by the appropriate adjustment of various parameters influencing the interactions between the colloidal particles and the material of the channel wall. The total release of the adherent particles is accomplished either by reducing the field strength and increasing the solvent velocity (conventional SdFFF) or by varying the potential energy of interaction between the particles and the column material—for instance, by changing the ionic strength of the carrier solution (PBSdFFF).

METHODOLOGY

FFF is a one-phase chromatographic system in which an external field or gradient replaces the stationary phase. The applied field can be of any type that interacts with the sample components and causes them to move perpendicular to the flow direction in the open channel. The most highly developed of the various FFF subtechniques is sedimentation FFF (SdFFF), in which the separations of suspended particles are performed with a single, continuously flowing mobile phase in a very thin, open channel under the influence of an external centrifugal force field.

In the normal mode of the SdFFF operation, a balance is reached between the external centrifugal field, driving the particles toward the accumulation wall, and the molecular diffusion in the opposite direction. In that case, the retention volume increases with particle diameter until steric effects dominate, at which transition point there is a foldback in elution order.

PBSdFFF which has been developed recently in our laboratory, is based either on particle size differences or on Hamaker constant, surface potential, and Debye–Hückel reciprocal distance differences.

The retention volume of a component under study, in the normal SdFFF and the PBSdFFF methodologies is a function of the following parameters:

1. SdFFF:

$$V_r = f(d,\ G,\ \Delta\rho) \tag{1}$$

2. PBSdFFF:

$$V_r = f(d,\ G,\ \Delta\rho,\ \psi_1,\ \psi_2,\ A,\ I) \tag{2}$$

where d is the particle diameter, G is the field strength expressed in acceleration, $\Delta\rho$ is the density difference between solute and solvent, ψ_1 and ψ_2 are the surface potentials of the particle and of the wall, respectively, A is the Hamaker constant, and I is the ionic strength of the carrier solution.

The conventional concentration procedure in SdFFF consists of two steps: the feeding (or concentration) and the separation (or elution) step. In the feeding step, the diluted samples are fed into the column with a small flow velocity while the channel is rotated at a high field strength to ensure the "apparent adhesion" of the total number of the colloidal particles at the beginning of the channel wall as a consequence of the particles' strong retention. In the separation step, the field is reduced and the flow rate is increased to ensure the total release and the consequence elution of the adherent dilute particles.

In PBSdFFF, the concentration step consists of feeding the column with the diluted samples at such experimental conditions, so as to decrease the repulsive component and increase the attractive component of the total potential energy of the particles under study. Because the stability of a colloid varies (increases or decreases) with a number of parameters (surface potential, Hamaker constant and ionic strength of the suspending medium), the proper adjustment of one or more of these parameters

can lead not only to the adhesion of the dilute colloidal samples, which leads to their "concentration," but also to the total release of the adherent particles during the elution step.

APPLICATIONS

Conventional SdFFF

As model samples for the verification of the conventional SdFFF as a concentration methodology monodisperse polystyrene latex beads (Dow Chemical Co.) with nominal diameters of 0.357 μm (PS1) and 0.481 μm (PS2) were used. They were either used as dispersions containing 10% solids or diluted with the carrier solution [triple-distilled water + 0.1% (v/v) detergent FL-70 from Fisher Scientific Co. + 0.02% (w/w) NaN_3] to study sample dilution effects. Diluted samples in which the amount of the polystyrene was held constant (1 μml of the 10% solids) while the volume in which it was contained was varied over a 50,000-fold range (from 1 to 50 ml of carrier solution) were introduced into the SdFFF column. During the feeding step, the flow rate was 5.8 ml/hr for the PS1 polystyrene, and 7.6 ml/hr for the polystyrene PS2, and the channel was rotated at 1800 rpm for the PS1 sample and at 1400 rpm for the PS2 sample. In the separation (elution) step, the experimental conditions for the two samples were as follows:

PS1: Field strength = 880 rpm, flow rate = 12–53 ml/hr
PS2: Field strength = 500 rpm, flow rate = 24–59 ml/hr

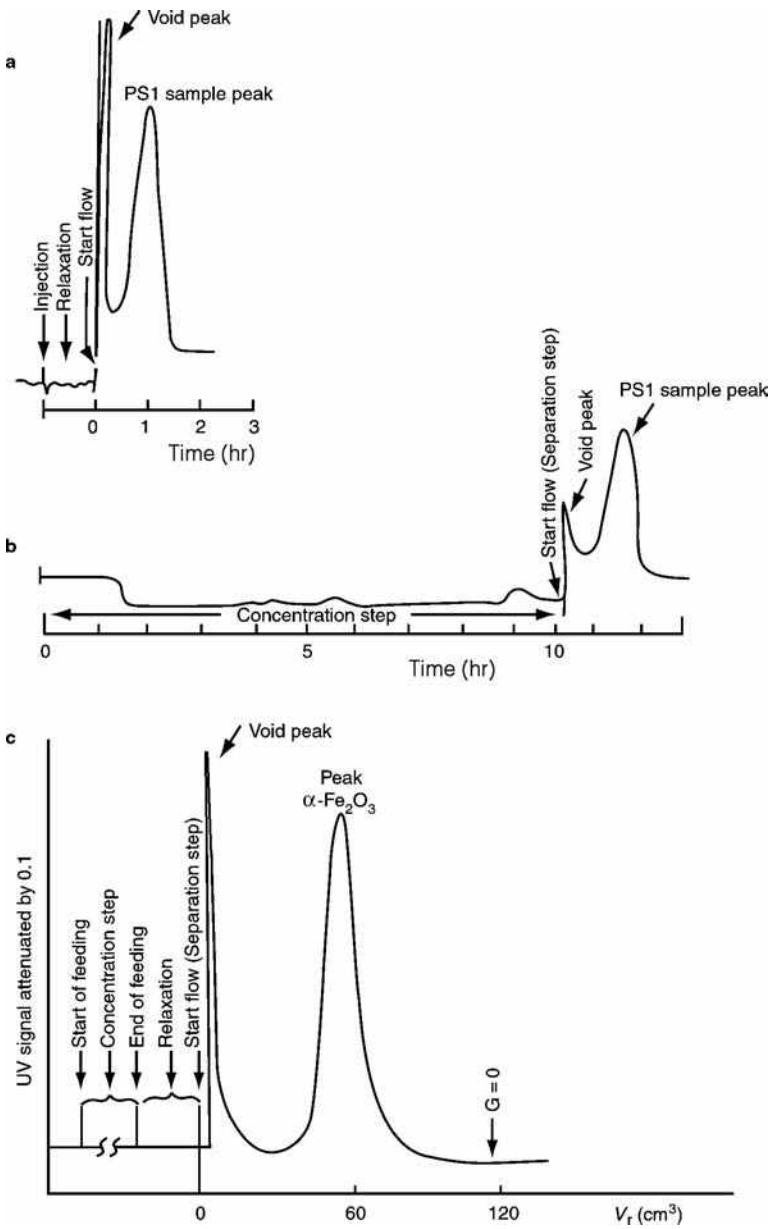

Fig. 1 Fractograms of the polystyrene latex beads of 0.357 μm (PS1) obtained by the direct injection of 1 μl of PS1 (a) and by the concentration procedure of the PS1 sample diluted in 10 ml of the carrier solution (b) using the conventional SdFFF technique, as well as of the α-Fe_2O_3 sample with nominal particle diameter of 0.271 μm diluted in 6 ml of the carrier solution obtained by the PBSdFFF concentration methodology (1c).

Fig. 1 provides a comparison of fractograms for the 0.357 μm polystyrene injected as a narrow pulse (Fig. 1a) and injected at 10 ml dilution (Fig. 1b) by the conventional SdFFF concentration procedure described previously. Fig. 1b shows that the eluted peak from the diluted sample emerges intact and without serious degradation, compared to the peak of Fig. 1a, despite the fact that the sample volume (10 ml) is over twice the channel volume (4.5 ml). The same concentration procedure was also successfully applied to the separation of the two polystyrene samples initially mixed together in a volume of 10 ml, as well as to the concentration of the colloidal particles contained in natural water samples collected from the Colorado, Green, and Price rivers in eastern Utah (U.S.A.).

As a general conclusion, the on-column concentration procedure of the conventional SdFFF method works quite successfully in dealing with highly diluted samples. Optimization, particularly higher field strengths during the concentration step, would allow higher flow rates and increased analysis speed. However, experimental confirmation would be necessary to give assurance that the particle–wall adhesion is not irreversible at higher spin rates.

Potential Barrier SdFFF

As model samples to test the validity of the PBSdFFF as a concentration procedure of diluted samples the monodisperse colloidal particles of α-Fe_2O_3 with nominal diameters of 0.271 μm were used. Diluted samples of containing 2 μl of the 10% solid, in which the volume was varied over a 10,000-fold range (from 2 to 20 ml), were introduced into the column with a carrier solution containing 0.5% (v/v) detergent FL-70 + 3×10^{-2} *M* KNO_3 to ensure the total adhesion of the particles at the beginning of the SdFFF Hastelloy-C channel wall. In the separation step, the carrier solution was changed to one containing only 0.5% (v/v) detergent FL-70 (without electrolyte) to ensure the total detachment of the adherent particles. In that case, a sample peak appeared (cf. Fig. 1c) as a consequence of the desorption of the α-Fe_2O_3 particles. The mean diameter of the particles (0.280 mm) obtained by the proposed PBSdFFF methodology for the ion_channel concentration procedure of the sample diluted in 8 ml of the carrier solution is very close to that found (0.271 μm) by the direct injection of the same particles into the channel, using a carrier in which no adsorption occurs.

As a general conclusion, one could say that the proposed PBSdFFF concentration procedure works quite successfully in dealing with highly dilute samples, separating them according to size, surface potential, and Hamaker constant. At the same time, as separation occurs, the particle sizes of the colloidal materials of the diluted mixture can be determined. The major advantage of the proposed concentration procedure is that the method can concentrate and analyze dilute mixtures of colloidal particles even of the same size but with different surface potentials and/or Hamaker constants. The method has considerable promise for the separation and characterization, in terms of particle size, of dilute complex colloidal materials, where particles are present in low concentration.

FUTURE DEVELOPMENTS

Looking to the future, we believe that the efforts of the researchers will be focused on the extension of the FFF concentration methodologies to the ranges of more dilute and complex colloidal samples, without lengthening the analysis time.

Column Switching: Fast Analysis

Toshihiko Hanai
Health Research Foundation, Pasteur Institut, Kyoto, Japan

Abstract
Column-switching separation based on the selectivity and retention capacity of packing materials is an ideal chromatographic condition for obtaining stable, highly sensitive, and reproducible results. A column-switching system is used for trace enrichment, sample cleanup, and the so-called heart-cut, where target fractions from the first column are transferred online to a second column having different properties for further separation. The second method is also called two(multi)-dimensional chromatography. The applications are classified depending on the difference in hydrophobicity, Coulombic force, molecular size, or steric hindrance of the analytes, affinity, and enzyme reactions, and application to mass spectrophotometric analysis. Some typical examples are given from selected references.

INTRODUCTION

High-pressure and high-flow-rate separation are not ideal chromatographic conditions for obtaining stable, sensitive, and reproducible results. Gradient elution is commonly used for fast separation. The separation time in gradient elution is short, but this method requires a period of re-equilibration and, in general, is not suitable for highly sensitive detection. The column-switching method is complicated because of the instrumentation needed. Once a system is established, however, a stable, reproducible, and highly sensitive chromatography can be achieved.

A double-column amino acid analyzer is considered to have been the first column-switching instrument. Once the same sample had been applied to columns of anion- and cation-exchange resins, acidic and basic amino acids were separated in parallel and detected. The system was modified for a single injection using a switching valve.

The applications of column switching are classified into two types: the use of a short column for trace enrichment in environmental analyses and for sample cleanup in biomedical analyses; and the so-called heart-cut, where target fractions from the first column are transferred online to a second column having different properties for further separation. The second method is also called two-dimensional chromatography. The fast, two-dimensional chromatographic system is built around gas chromatography and, with the addition of a mass spectrometer, it is called three-dimensional chromatography. Enantiomeric separation and ionic separation are typical examples of heart-cut. Furthermore, the same category of compounds is continuously separated using the different retention powers of packing materials. This entry describes a methodology for preparing a successful column-switching system based on the properties of analytes.

METHODOLOGY

The success of column switching depends on the molecular properties of analytes and packing materials. A packing material can selectively separate a certain group of compounds among analytes. The selection of the packing material depends on factors of retention in chromatography. These factors are the same as the parameters of solubility such as van der Waals force, Coulombic force, and steric hindrance. Hydrogen bonding and charge-transfer interaction, such as Lewis acid–base interaction, can be treated as weak Coulombic force.[1] Applications of column-switching separation are classified as follows:

1. Dependent on the difference in hydrophobicity of analytes.
2. Dependent on the difference in Coulombic force of analytes.
3. Dependent on the molecular size of analytes.
4. Dependent on the steric hindrance of analytes.
5. Affinity and enzyme reactions.
6. Application to mass spectrophotometric analysis.

Resolution can be improved by increasing the column plate number, N, and/or the separation factor (selectivity of packing materials), α [α = the ratio of the capacity ratios (retention factors) of the two compounds]. N is the physical parameter and α is the chemical parameter for the separation.[1]

Column switching utilizes the selectivity, α, of packing materials, but not the theoretical plate number of the column. Understanding the chemistry of retention in liquid chromatography is key to preparing a column-switching system. Details on packing materials and their structures are given by Hanai.[2] A diagram of the system is shown in Fig. 1. A variety of compounds have been effectively

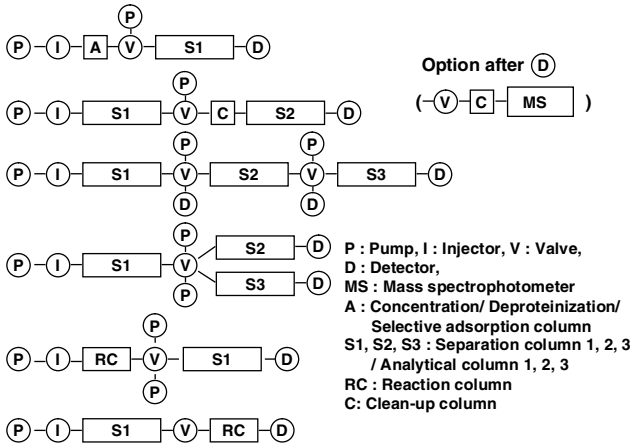

Fig. 1 Column-switching systems.

analyzed using column switching. All applications cannot be summarized in a few pages. Typical examples are given with selected references.

APPLICATIONS OF COLUMN-SWITCHING CHROMATOGRAPHY

Dependent on the Difference in Hydrophobicity of Analytes

Preconcentration on a hydrophobic cartridge is a commonly used pretreatment in trace analyses. A variety of precolumns have been used for reversed-phase liquid chromatography for prefiltration and preconcentration online. A small column for solid-phase extraction is used for the preconcentration of trace amounts of relatively hydrophobic compounds, especially in environmental analyses. Trace metals are derivatized and concentrated in a hydrophobic phase, then transferred to a separation column.[3] Peptides, drugs, and relatively hydrophobic compounds in environmental water samples were also concentrated in a hydrophobic phase and separated on a separation (analytical) column. The selection of packing material permits the selective concentration of a certain range of hydrophobic compounds. Biological samples require deproteinization before applying the sample solution for chromatographic analysis. A variety of chemicals in urine, serum, and tissues can be concentrated on hydrophobic phases after deproteinization, and then separated in an analytical column. Numerous reports have been published on the concentration of trace compounds. Some modifications to the packing materials for solid-phase extraction have been made for the direct injection of biological samples without deproteinization.

Restricted access packing materials (RAMs) have both hydrophobic and hydrophilic sites.[2] Also called internal-surface reversed-phase packing materials, RAMs have two functions: the surfaces of particles (the end groups of bonded phases) are polar to reflect the adsorption of, e.g., proteins, while the surfaces within the pores (the inner compartment of bonded phases) are relatively non-polar to support the hydrophobic adsorption of, e.g., drugs. Such a solid phase (packing material) is also called a shielded hydrophobic phase, mixed-functional phase, or dual-zone phase. This type of material can be prepared by coating proteins and cellulose. Relatively polar organic porous polymers are also used for this purpose. New bonded phases have been developed. The hydrophilic phase of the particle surface prevents the adsorption of proteins, and the hydrophobic site adsorbs hydrophobic compounds. The hydrophobicity is designed using different ligands. A column packed with inner hydrophobic packing materials is used for online prefiltration of proteins in biological samples. Relatively hydrophobic compounds are trapped inside the hydrophobic sites of the packing material and are transferred to an analytical column for further separation. Insertion of a small concentration column before the second analytical column is useful for trace analysis.

Biological samples are injected directly, and drugs and their metabolites are analyzed: for example, loxoprofen in human serum for pharmacokinetic studies;[4] propiverine in human plasma;[5] parabens, triclosan, and other environmental phenols in human milk;[6] phenols in animal feed;[7] *S*-phenylmercapturic acid and *S*-benzylmercapturic acid in urine;[8] and DNA fragments[9] and voriconazole in human plasma.[10] A longer first column is also used to purify target compounds, and the fractions are transferred to a second column for further separation of drugs in blood and urine. Baicalein, rhein, and berberine in rat plasma[11] and sulfamethoxazole and trimethoprim in whole egg[12] were analyzed using the two-column system.

The major application of column switching is sample cleanup using a small column. A combination of different hydrophobic columns in parallel permits the fast separation of a variety of hydrophobic mixtures with isocratic elution. Free amino acids are a mixture of very polar, polar, and hydrophobic amino acids. These three groups were separated in parallel using three types of hydrophobic columns by the formation of a copper complex online.[13] Very polar compounds, e.g., guanidino compounds, were also separated by reversed-phase ion-pair liquid chromatography using a very hydrophobic packing material, a carbon column.[14]

Catecholamine-related compounds—metabolites of hydrophobic aromatic amino acids—were also effectively separated using a combination of different hydrophobic packing materials.[15]

Dependent on the Difference in Coulombic Force of Analytes

The matrices of biological samples are very complicated. The selective concentration of target compounds, therefore, has been performed using ion-exchange trap columns. Sample components are separated into three groups, i.e., acidic, basic, and neutral. Further separation is carried

out using reversed-phase liquid chromatography or ion-exchange liquid chromatography with a longer ion-exchange column. Conversely, the first separation is carried out using reversed-phase liquid chromatography, and then further separation is performed by ion-exchange liquid chromatography. Utilization of ion exchangers expands the capability of a simple cleanup. Proteins[16] and peptides in human blood[17] were separated by ion exchange. Piritramide,[18] vancomycin,[19] and acidic compounds[20] in human plasma, nutrients in the presence of high chloride concentrations,[21] and inorganic selenium[22] were also analyzed using ion exchange. Ionized compounds were eluted rapidly from a reversed-phase column. A RAM column was used for direct injection of urine, and then methamphetamine and amphetamine were analyzed using ion-exchange liquid chromatography.[23] Reversed-phase ion-pair liquid chromatography was, thus, used to separate a mixture of hydrophobic and ionic compounds. The column-switching method for reversed-phase ion-pair liquid chromatography is the same as that for reversed-phase liquid chromatography. A very common application, due to Coulombic force, is sample pretreatment. Removing ionic compounds for the analysis of neutral compounds, such as saccharides, is an example. The separation of acidic and basic drugs is another example.

Dependent on the Molecular Sizes of Analytes

This approach has been applied to the separation of polymers, oligomers, and monomers. Each fraction is then further separated using a suitable separation method. One example is the separation of saccharides in exploded wood.[24] Proteins, peptides, and amino acids were analyzed, step by step, and an automated column-switching separation was studied. However, the separation of proteins does not compete with that achieved by two-dimensional electrophoresis.

A size-exclusion column is also used for sample pretreatment in biomedical analyses. Mainly, larger molecules like proteins are eluted within the exclusion limit. Then small molecules, the target molecules, are further separated by either reversed-phase liquid chromatography or ion-exchange liquid chromatography. Proteins and non-target fractions are eluted, and the target fraction is transferred to an analytical column. This system was applied to a pharmacokinetic study of omeprazole and rabeprazole,[25] and rabeprazole and its metabolites.[26] A variety of newly developed restricted access packing materials have partly replaced size-exclusion columns.

Dependent on the Steric Hindrance of Analytes

The molecular size effect is used in size-exclusion liquid chromatography. The steric effect, a difference in molecular shape, is mainly applied to normal-phase liquid chromatography. Enantiomeric separation is usually carried out with normal-phase liquid chromatography, using specially designed packing materials such as the Pirkle-type[27] and modified cyclodextrins.[28] Natural polymers having steric selectivity are also used for enantiomeric separation, using the natural form or a modified form like α-1-acid glycoprotein,[29] amylose *tris*(3,5-dimethylphenylcarbamate),[30] modified cellulose,[31] and ovomucoid.[32] Enantiomeric separation columns do not have high separation power, according to their theoretical plate number. First, the mixtures are separated using reversed-phase liquid chromatography; then the target fraction is transferred from the reversed phase to the enantiomeric separation column.

The difficulty experienced in the transfer from the reversed phase to the separation column owes to unmatched eluent components. Some technical solution is required to establish this system. When an aqueous eluent is used for the first column, a small amount of aqueous solution should be miscible in the non-aqueous eluent of the enantiomeric column. Another solution is to use a small trap column to reduce the excess aqueous solution and then back flush into an enantiomeric separation column using a suitable solvent (eluent).

Affinity and Enzymatic Reaction

Proteins attract molecules selectively. This selectivity, or affinity, is made use of after the immobilization of proteins on packing materials. Affinity is not 100% effective; therefore, affinity-based mixtures are further purified using a second column. Polyclonal antibodies,[33] monoclonal antibodies,[34] and β-cyclodextrin[35] were immobilized for specific purifications. The immobilization technique is applied to immunoassays, even if the precision of the quantitative analysis is less than that of liquid chromatography. Man-made affinity polymers, molecularly imprinted packing materials, have been developed for the selective concentration of targeted compounds. The key compounds are 17β-estradiol,[36] bisphenol,[37] atropine, propranolol, [*S*]-naproxen, and [*S*]-ibuprofen.[38] The difficulty experienced in synthesizing a suitable imprinted polymer owes to the molecular shape of the targeted compounds in the synthesis of packing materials and the extraction from the sample solution.

Quantitative analysis of enzyme reactivity is performed using an immobilized enzyme column. Given the difficulty in obtaining a relatively large amount of enzyme and retaining the enzymatic activity after the immobilization, several reaction columns are synthesized, such as monoamine oxidase,[39] β-glucuronidase,[40] lipase,[41] phenylethanol amine *N*-methyltransferase,[42] horse liver alcohol dehydrogenase,[43] and nicotinic acetylcholine receptor.[44] An enzyme column was developed for online trypsin digestion to analyze components of proteins.[45] An inorganic catalytic Pt–Rh alumina column was used to determine nitropyrene metabolites with chemiluminescence detection.[46] These online sample treatments improve the

quantitative analysis of the targeted compounds and their automated analysis.

Application to Mass Spectrometric Analysis

Mass spectrometer is a powerful tool for the identification of analytes; however, a direct free connection between liquid chromatography and mass spectrometry is not permitted. At the very least, inorganic salts should be eliminated before the use of a mass spectrometer. One approach is to collect the target fraction in a small trapped column, and then wash off the unwanted components before introduction to the mass spectrometer. Even if one uses a small column with a volatile salt, one must wash the mass chamber very often to maintain its sensitivity.

Polar compounds are separated using ion-exchange liquid chromatography; however, the inorganic salt should be eliminated before the mass spectroscopic analysis. The targeted fraction is collected on a small trap column, then the salt is removed with a volatile ion-pair reagent, and the compounds are introduced into the mass spectrometer.[47] Utilization of a miniaturized separation column with a volatile eluent and a desalting column is ideal when using a mass spectrometer as a detector.

CONCLUSION

We have seen how column switching can expedite separation of substances of interest, using techniques that take advantage of the differences in hydrophobicity, Coulombic force, molecular size, or steric hindrance of the analytes; affinity and enzymatic reactions; and the application of mass spectrophotometric analysis.

Columns: CEC Measurement and Calculation of Basic Electrochemical Properties

Michael P. Henry
Chitra K. Ratnayake
Advanced Technology Center, Beckman Coulter, Inc., Fullerton, California, U.S.A.

INTRODUCTION

In general, the structures of capillary columns in capillary electrochromatography (CEC) consist of a packed region or segment and an open, unpacked length, whose electrochemical properties may differ markedly from each other. The primary difference between the packed and open segments is their electrical resistivities. Measurements of electrochemical properties of the column as a whole, however, do not give information about the individual resistivity contributions of these two segments. Resistivity of the packed segment is fundamental in determining electroosmotic and electrophoretic flow velocities (explained in the section titled "Theory"), which in turn influence the speed of analysis and chromatographic efficiency and resolution. It is, therefore, important to know specific electrochemical properties of the two major segments to control, ultimately, the chromatographic performance of the CEC system. In this entry, a method of determining certain basic individual electrochemical properties for each segment is described.

These segmental properties do, in fact, add together in various mathematical ways to give the total property value for the column as a whole. This entry also deals with how this can be determined.

THEORY

Measurement and Calculation of Segmental Electrochemical Properties

We first consider the case of an open, but buffer-filled capillary column (Type A, shown schematically in Fig. 1), which is similar to that used in capillary electrophoresis. This is typically made of polyimide-coated fused silica. Let its length be L (cm) with an interior cross-sectional area as A (cm^2). If a voltage, V (Volts), is applied across the ends of the column and the current I (Amps) is measured, the resistance, R (Ohms), of the buffer can be calculated from Ohm's law, as given in Eq. 1:

$$R = \frac{V}{I} \tag{1}$$

R is proportional to L/A and, therefore, R is $\rho L/A$, where ρ is the electrical resistivity (units of Ω cm) of the buffer solution and can be calculated from Eq. 2:

$$\rho = \frac{RA}{L} = \frac{VA}{IL} \tag{2}$$

Eq. 3 gives the electrical conductivity [σ, (1/Ω cm)] of the buffer solution:

$$\sigma = \frac{1}{\rho} \tag{3}$$

Electrical conductance [λ, (1/Ω)] of the buffer solution is given by Eq. 4:

$$\lambda = \sigma \frac{A}{L} \tag{4}$$

or, more simply, by Eq. 5:

$$\lambda = \frac{1}{R} \tag{5}$$

The field strength, E(V/cm), over the filled capillary length is calculated from Eq. 6:

$$E = \frac{V}{L} \tag{6}$$

Voltage, current, resistance, resistivity, conductivity, conductance, and field strength are some of the purely electrochemical properties of the open, buffer-filled capillary, when an emf is placed across its ends.

We next consider the case of typical CEC columns, B and C (shown schematically in Fig. 1). The columns have the same internal diameter as column A and the packed length is L_{pack} (cm), and the open length is L_{open} (cm). Columns B and C are equilibrated with the same buffer used to fill column A. A voltage (V_T, V) applied across the ends of the capillary will cause a current (I_T, A) to flow, depending upon the total column resistance (R_T, Ω) according to Ohm's law (Eq. 1). The current that flows in either the open or the packed segment of the CEC columns will be the same, because the charge will not accumulate at any point in the circuit.

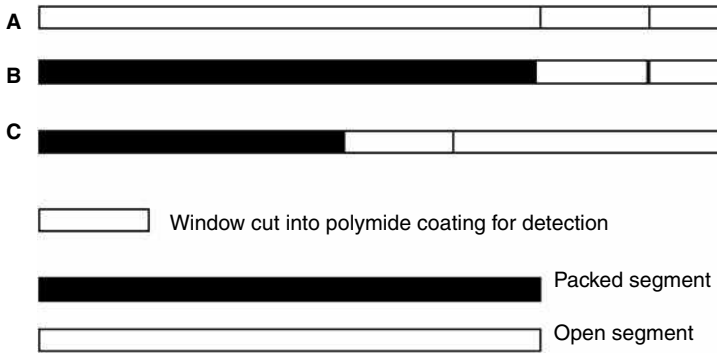

Fig. 1 Schematic diagrams of columns A–C, illustrating the locations of packed and open segments.

The total voltage drop across the capillary will be equal to the sum of the voltage drops across the packed and open segments, as shown in Eq. 7:

$$V_T = V_{open} + V_{pack} \tag{7}$$

V_{open} can be calculated from Eq. 8, where ρ_{open} is the resistivity of the buffer solution (calculated from Eq. 2) in the segment:

$$V_{open} = I_T R = \frac{I_T \rho_{open} L_{open}}{A} \tag{8}$$

Subtraction of V_{open} from V_T gives V_{pack} (Eq. 7).

Further, from Eq. 9, the resistivity of the packed segment, ρ_{pack}, can be calculated:

$$V_{pack} = \frac{I_T \rho_{pack} L_{pack}}{A} \tag{9}$$

Now that V_{open} and V_{pack} are known (Eqs. 8 and 9), the field strengths for the open and packed segments (E_{open}, E_{pack}) can be calculated from Eqs. 10 and 11:

$$E_{open} = \frac{V_{open}}{L_{open}} \tag{10}$$

$$E_{pack} = \frac{V_{pack}}{L_e} \tag{11}$$

where L_e is the "equivalent" length of the packed segment, as defined by Rathore and Horváth.[1] This parameter is the total length traveled by an unretained, neutral marker molecule, and can be calculated from Eq. 12, using electrochemical properties only, which is as follows:

$$L_e = L\left[\frac{I_{open}}{I_{pack}}\right]^{\frac{1}{2}} - L_{open} \tag{12}$$

where L is the total capillary length, and I_{open} and I_{pack} are the currents flowing through the column, in the absence and presence of packing, respectively.

Eqs. 1–12, therefore, allow the calculation of V, R, ρ, σ, λ, and E for the total column (T) and the individual open and packed segments, by the appropriate substitution of calculated values.

Linear Flow of Mobile Phase and Electric Field Strength, *E*

The axial flow of a stream of ions in an electric field formed within a capillary is generally made up of both electro-osmotic and electrophoretic components.[2] Both are directly proportional to field strength or change of voltage per centimeter. The Smoluchowski relationship[3] (Eq. 13) describes the electro-osmotic property:

$$u_{eo} = \varepsilon_o \varepsilon_r \frac{\zeta E}{\eta} \tag{13}$$

where u_{eo} is the linear velocity of the mobile phase, ε_o the permittivity of a vacuum, ε_r the dielectric constant of the buffer, ζ the zeta potential of capillary surface, E the field strength along the capillary, and η the viscosity of the mobile phase.

The linear velocity of the mobile phase is an important determinant of both speed of analysis and the chromatographic plate number, which affects peak resolution. Both are critical features of the values of chromatographic analysis.

Additivities of Segment Properties to Give Total Column Properties

Resistivities

Expressing Eq. 7 in terms of resistivities and measured parameters, we obtain the following:

$$\frac{I_T \rho_T L}{A} = \frac{I_T \rho_{open} L_{open}}{A} + \frac{I_T \rho_{pack} L_{pack}}{A} \tag{14}$$

Therefore,

$$\rho_T L = \rho_{open} L_{open} + \rho_{pack} L_{pack} \quad (15)$$

or

$$\rho_T = \rho_{open}\left(\frac{L_{open}}{L}\right) + \rho_{pack}\left(\frac{L_{pack}}{L}\right) \quad (16)$$

Thus, resistivities multiplied by the fractional length of the segment type, compared to the whole column, are additive along a column.

Resistances

Similarly, and more simply, resistances of each segment can be added as shown here:

$$V_T = I_T R_T = I_T R_{open} + I_T R_{pack} \quad (17)$$

Thus,

$$R_T = R_{open} + R_{pack} \quad (18)$$

Conductivities

As conductivity is the simple reciprocal of resistivity, substitution into Eq. 15 gives Eq. 19.

$$\frac{1}{\sigma_T} = (1/\sigma_{open})\frac{L_{open}}{L} + (1/\sigma_{pack})\frac{L_{pack}}{L} \quad (19)$$

Additivity of conductivities, therefore, occurs via the product of their reciprocals and the fractional length of segment type.

Conductances

Conductance is the simple reciprocal of resistance; therefore, Eq. 20 follows directly from Eq. 18.

$$\frac{1}{\lambda_T} = \frac{1}{\lambda_{open}} + \frac{1}{\lambda_{pack}} \quad (20)$$

Field strengths

1. With values of L_{open} and L_{pack}

$$E_T = \frac{V_T}{L} = \frac{V_{open} + V_{pack}}{L_{open} + L_{pack}} \quad (21)$$

Dividing numerator and denominator by L_{open} and putting the ratio L_{pack}/L_{open} as r,

$$E_T = \frac{E_{open} + E_{pack} r}{1 + r} \quad (22)$$

2. With values of L_{open} and L_e

Here L_{pack} is simply replaced by L_e in Eq. 22, with $r = L_e/L_{open}$

The above explanations and Eqs. 1–22 enable the calculation of many basic electrochemical properties of CEC columns. In the next section, we take data from the literature to see how the mathematics are applied to actual CEC systems.

EXPERIMENTAL DATA AND RESULTS

Ratnayake, Oh, and Henry[4] have measured currents at specific set voltages passing through CEC columns of several configurations of monolithic columns that they prepared. The three columns A (unpacked), B, and C are shown schematically in Fig. 1. The 75 μm I.D. columns were packed with 3 μm C_{18} bonded silica particles embedded in a silica gel and fitted into cartridges compatible with Beckman Coulter's P/ACE TM MDQ Capillary Electrophoresis System. The columns were equilibrated with 70/30 v/v acetonitrile/morpholino ethane sulfonic (MES) acid buffer (25 m*M*, pH 6.2).

We have used some of their data to calculate values for an expanded number of electrochemical properties of three of these columns, and the results are given in Table 1.

DISCUSSION

Column Configurations, Dimensions, and Buffers

Open and packed capillary dimensions were chosen to be the same so that Joule heating effects, if any, were similar, and column temperatures were, therefore, considered to be the same for all columns. This is an important requirement for the validity of Eqs. 8–22. The length of the packed segments was different in columns B and C to test the reproducibility of the monolithic bed preparations. The electrochemical properties in Table 1 were calculated using the same applied voltage polarity for all columns. No sample injections were needed. The choice of organic/aqueous mobile phase was made by Ratnayake, Oh, and Henry[4] in their chromatographic work such that the column functions as a standard reversed-phase packing.

Total Column Voltages, Currents, and Resistances

Similar voltages (20 kV) were applied to all columns to simplify comparisons of data. Currents were measured by

Table 1 Measured values of current, I, voltage, V, L_{open}, and L_{pack}, and calculated values of basic electrochemical properties of columns A–C.

Parameter (open) (units) (name)	Column A	Column B	Column C	Calculated	Equations
L_{open} (cm)	30	10	20	Measured	
L_{pack} (cm)	NA	21.5	10	Measured	
V_T (kV)	20	20	20	Measured

E_{open} (V/cm) (field strength)	667	309	417	Calculated	(10)
E_{pack} (V/cm) (field strength)	NA	491	657	Calculated	(11)

A (cm^2) $= 44 \times 10^{-6}$ cm^2.
[a]Field strength calculated using values of L_{open} and L_{pack}.
[b]Field strength calculated using values of L_e.

the instrument and total column resistance, R_T, was calculated using Ohm's law (Eq. 1). Resistance to current flow varied because of the different packed and open lengths in the three columns. The selection of a low buffer ionic strength, a zwitterionic buffer type, the presence of nonconducting acetonitrile, a small column cross-sectional area, and moderate column length contributed to the very low currents observed.)

Segmental Resistances, *R*, Resistivities, ρ, Conductivities, σ, and Conductances, λ

Resistivity (and its reciprocal, conductivity) of open segments, ρ_{open}, is assumed to be the same in all three columns. This will be true provided the composition of the buffer is the same. In principle, the resistivity of the mobile phase inside the packed segments will also be ρ_{open}.

The resistivities of the packed segments in columns B and C are very close, indicating that their preparation is quite reproducible. This property, ρ_{pack}, is, therefore, a good indicator of the reproducibility of manufacture in a commercial setting.

In qualitative terms, it can be gathered from the fact that if very small currents (I in μA) are generated from large voltages (V in kV), then column resistances must be high (R in billions of Ω) and conductances must be very low (λ in 1/nΩ). Values of resistivity (ρ in kΩ cm) and conductivity [σ in (1/mΩ cm)] are seen to be intermediate between these limits. The reason for this intermediate nature is a direct result of the configuration of the standard capillary used in CEC. In other words, the ratio of the column length to the interior cross-sectional area, L/A (1/cm) is very high, at about 450,000 to 1. Thus, when a low conductance is multiplied by this ratio, an intermediate value is obtained for conductivity. Similarly, the intermediate values of resistivity arise when the large column resistances are divided by the L/A ratio.

It can also be noted from Table 1 that conductances of both the packed and open segments are halved when their lengths are doubled.

Segment Voltages and Field Strengths

The relationship between linear velocity and field strength (Eq. 13) is analogous to the linear velocity of, for example, a stream of water under the force of gravity along an inclined plane. The steeper the plane, the faster the flow will be.

The flow of ions in the open column A is unimpeded by any solid resistance and, so, has the largest current flow (5.6 μA). Column B offers the highest resistance to current flow and has the lowest field strength in all segments and, consequently, the column generates the smallest current (2.6 μA). Column C is intermediate between A and B in field strength and current.

CONCLUSIONS

This entry is a short tutorial on the basics of electrochemistry that is applied to CEC columns. Because the typical CEC columns consist of a packed and an open segment, their individual electrochemical properties are quite different. The application of basic principles of electricity (Ohm's law) and knowledge of the lengths and cross-sectional area of the capillary are all that is necessary to calculate most of the basic electrochemical properties of the CEC column. These include voltage, V, current, I, resistance, R, resistivity, ρ, conductivity, σ, conductance, λ, and field strength, E, for each segment type and for the column as a whole. It has also been shown how the individual segment properties can be added together to produce the total column property. Voltages and resistances add simply, but other properties are more complex in the way that they add and involve reciprocal functions and ratios of segment lengths.

Columns: Resolving Power

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Two solutes will be resolved if their peaks are moved apart in the column and maintained sufficiently narrow to permit them to be eluted as discrete peaks. Resolution is usually defined as the ratio of the distance between the peaks to the peak width at the points of inflection. It is generally accepted that a separation of 4σ is adequate for accurate quantitative analysis, particularly when employing peak heights measurements. It is, therefore, necessary to derive an expression for the peak width in order to equate to the peak separation.

APPLICATION

The plate theory gives an expression for the elution curve of a solute as

$$X_{m(n)} = \frac{X_0 e^{-\upsilon} \upsilon^n}{n!} \tag{1}$$

where $X_{m(n)}$ is the concentration of solute in the nth plate on elution, X_0 is the concentration placed on the first plate on injection, n is the number of plates in the column, and υ is the flow of mobile phase in plate volumes.

By differentiating and equating Eq. 1 to zero gives the following expression for the retention volume of a solute:

$$V_r = n(\upsilon_m + K\upsilon_s)$$

Now, by equating the second differential of the elution equation to zero and solving for υ, an expression for the peak width at the points of inflexion can obtained:

$$\frac{d_2\left(X_0 \frac{e^{-\upsilon}\upsilon^n}{n!}\right)}{d\upsilon^2} = X_0 e^{-\upsilon}\upsilon^n - e^{-\upsilon} n\upsilon^{n-1} - e^{-\upsilon} n\upsilon^{n-1}, \underline{\qquad +e^{-\upsilon} n(n-1)\upsilon^{n-2}} \over n!$$

Thus,

$$\frac{d_2(X_0(e^{-\upsilon}\upsilon^n/n!))}{d\upsilon^2} = X_0 \frac{e^{-\upsilon}\upsilon^{n-2}(\upsilon^2 - 2n\upsilon + n(n-1))}{n!} \tag{2}$$

Now, at the points of inflexion,

$$\frac{d_2(X_0(e^{-\upsilon}\upsilon^n/n!))}{d\upsilon^2} = 0$$

Hence,

$$\upsilon^2 - 2n\upsilon + n(n-1) = 0$$

and

$$\upsilon = \frac{2n \pm \sqrt{4n^2 - 4n(n-1)}}{2} = \frac{2n \pm \sqrt{4n}}{2} = n \pm \sqrt{n}$$

It is seen that the points of inflexion occur after $n - \sqrt{n}$ and $n + \sqrt{n}$ plate volumes of mobile phase have passed through the column. Thus, the volume of the mobile phase that has passed through the column *between* the inflexion points will be

$$n + \sqrt{n}\ n + \sqrt{n} = 2\sqrt{n} \tag{3}$$

Thus, the peak width at the points of inflexion of the elution curve will be $2\sqrt{n}$ plate volumes which, in milliliters of mobile phase, will be obtained by multiplying by the *plate volume*; that is,

$$\text{Peak width} = 2\sqrt{n}(\upsilon_m + K\upsilon_s) \tag{4}$$

The peak width at the points of inflexion of the elution curve is twice the standard deviation, and, thus, from Eq. 4, it is seen that the variance (the square of the standard deviation) is equal to n, the total number of plates in the column. Consequently, the variance of the band (σ^2) in milliliters of mobile phase is given by

$$\sigma^2 = n(\upsilon_m + K\upsilon_s)^2$$

Now,

$$V_r = n(\upsilon_m + K\upsilon_s)$$

Thus,

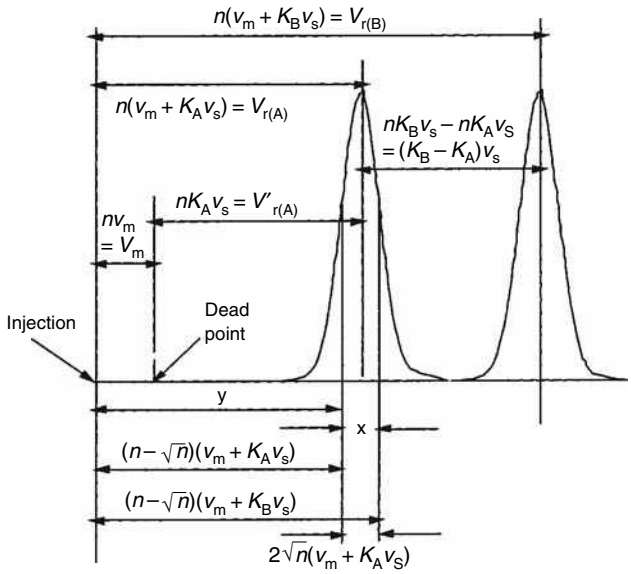

Fig. 1 A chromatogram showing two resolved solute peaks.

$$\sigma^2 = \frac{V_r{}^2}{n}$$

Let the distance between the injection point and the peak maximum (the retention distance on the chromatogram) be y cm and the peak width at the points of inflexion be x cm. If the chromatographic data are computer processed, then the equivalent retention times can be used. Then, as the retention volume is $n(\upsilon_m + K\upsilon_s)$ and twice the peak standard deviation at the points of inflexion is $2\sqrt{n}(\upsilon_m + K\upsilon_s)$ then

$$\frac{\text{Ret. distance}}{\text{Peak width}} = \frac{y}{x} = \frac{n(\upsilon_m + K\upsilon_s)}{2\sqrt{n}(\upsilon_m + K\upsilon_s)} = \frac{\sqrt{n}}{2}$$

Thus,

$$n = 4\left(\frac{y}{x}\right)^2 \tag{5}$$

Eq. 5 allows the efficiency of any solute peak, from any column, to be calculated from measurements taken directly from the chromatogram.

Consider the two peaks depicted in Fig. 1. The difference between the two peaks, for solutes A and B (see *Plate Theory*, p. 1829), measured in volume flow of mobile phase, will be

$$n(\upsilon_m + K_B\upsilon_s) - n(\upsilon_m + K_A\upsilon_s) = n(K_B + K_A)\upsilon_s \tag{6}$$

Assuming the widths of the two peaks are the same, then the peak width in volume flow of mobile phase will be

$$2\sigma = 2\sqrt{n}(\upsilon_m + K_A\upsilon_s) \tag{7}$$

where K_A is the distribution coefficient of the first of the eluted pair of solutes between the two phases. Taking the already discussed criterion that resolution is achieved when the peak maxima of the pair of solutes are 4σ apart, then

$$4\sqrt{n}(\upsilon_m + K_A\upsilon_s) = n(K_B + K_A)\upsilon_s$$

Rearranging,

$$\sqrt{n} = \frac{4(\upsilon_m + K_A\upsilon_s)}{(K_B - K_A)\upsilon_s}$$

dividing through by υ_m,

$$\sqrt{n} = \frac{4(1 + k_A{}')}{(k_B{}' - k_A{}')\upsilon_s}$$

Now, as α, the separation ratio between the two solutes, has been defined as

$$\alpha = \frac{k_B{}'}{k_A{}'}$$

then

$$\sqrt{n} = \frac{4(1 + k_A{}')}{k_A{}'(\alpha - 1)}$$

and

$$n = \left(\frac{4(1 + k_A{}')}{k_A{}'(\alpha - 1)}\right)^2 = 16\frac{(1 + k_A{}')^2}{k_A{}'^2(\alpha - 1)^2} \tag{8}$$

Eq. 8 is extremely important and was first developed by Purnell[1] in 1959. It allows the necessary efficiency to achieve a given separation to be calculated from a knowledge of the capacity factor of the first eluted peak of the pair and their separation ratio.

Conductivity Detection in CE

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

In contrast to component-specific detectors, such as ultraviolet (UV) absorbance and fluorescence, conductivity detection is a universal detection method. This means that a bulk property (conductivity) of the buffer solution is continuously measured. A migrating ionic component locally changes the conductivity and this change is monitored. As such, conductivity detection is universally sensitive because, in principle, all migrating ionic compounds show detector response, although not to the same extent.

TYPES OF CONDUCTIVITY DETECTION

Two kinds of conductivity detector are distinguished: contact detectors and contactless detectors. Both types were originally developed for isotachophoresis in 0.2–0.5-mm-inner diameter (I.D.) PTFE tubes. Contactless detectors are based on the measurement of high-frequency cell resistance and, as such, inversely proportional to the conductivity. The advantage is that electrodes do not make contact with the buffer solution and are, therefore, outside the electric field. As these types of detectors are difficult to miniaturize down to the usual 50–75 μm capillar inner diameter, their actual application in capillary electrophoresis (CE) is limited.

Contact detectors are somewhat easier to miniaturize. There are generally two subtypes: those with twin axially mounted electrodes and those with twin or quadruple radially mounted electrodes. The former can be operated in DC mode or AC mode. In the DC mode, the detector signal directly originates from the field strength between the electrodes and, given the current, is inversely proportional to the detector cell resistance. In the AC mode, both axially and radially mounted electrodes form part of a closed primary circuit of an isolation transformer, the output of which is also inversely proportional to the cell conductivity. Alternatively, the output can be linearized with respect to the conductivity.

CONDUCTIVITY DETECTOR RESPONSE

As mentioned, the detector continually measures the conductivity of the buffer solution in the capillary. If an ionic component enters the detector cell, the local conductivity will change. At first glance, one would expect the conductivity to increase, because of additional ionic material. This is a simplified and incorrect approach, however. Suppose, in a buffer consisting of 0.01 *M* potassium and 0.02 *M* acetate (pH 4.7), a 10^{-4} *M* sodium solution is analyzed. Electroneutrality requires that with an increase of the sodium concentration from zero to, in this case, initially 10^{-4} *M*, the potassium and/or charged acetate concentration cannot remain unchanged. This process is governed by the so-called Kohlrausch law. For strong ions, this equation reads

$$\Lambda = \sum_i \frac{c_i}{\mu_i}$$

in which Λ is the so-called Kohlrausch regulating function, c_i is the concentration of component i, and μ_i is the mobility of component i. Generally speaking, potassium will be partly displaced by sodium, whereas acetate will remain approximately (but not, by definition, exactly) constant. In the example given, the conductivity detector will give a negative response (see line A in Fig. 1), because potassium (with a high mobility and, hence, a higher contribution to conductivity) is, to some extent, replaced with sodium which has a ~30% lower mobility. From this example, it automatically follows that a potassium peak in a sodium acetate buffer, by contrast, will yield a positive amplitude. This makes interpretation of conductivity detector signals less straightforward.

SENSITIVITY OF CONDUCTIVITY DETECTION

A further example will illustrate aspects related to sensitivity. Suppose a 100 times more concentrated (10 m*M*) solution of ammonium is coseparated in the potassium–acetate system mentioned earlier. Naturally, ammonium will displace potassium, but as the mobilities of potassium and ammonium are almost equal, the resulting change in conductivity is minor. Sensitivity in this example is, consequently, very low (line A in Fig. 1). On the other hand, 0.005 m*M* lithium has a much lower conductivity than sodium and, consequently, shows a higher specific response (line A in Fig. 1).

Generally, one cannot expect a high sensitivity anyhow, as the background signal (originating from the buffer) is generally much higher than the eventual change

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120039929

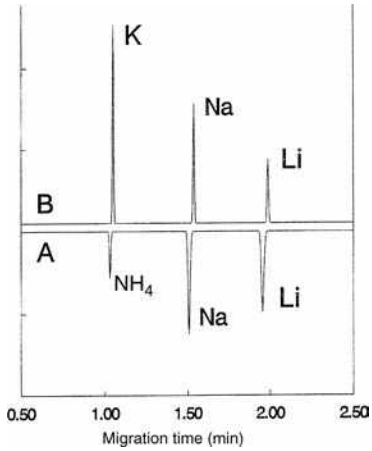

Fig. 1 Relative sensitivities in conductivity detection in CE. Trace A: sample of 10 m*M* NH_4, 0.1 m*M* Na, and 0.005 m*M* Li in a 0.01 *M* potassium–acetate buffer; trace B: sample of 0.1 m*M* each of K, Na, and Li in a 10 m*M* Tris–acetate buffer.

superimposed upon that background. One might argue that background conductivity can easily be decreased by diluting the buffer. Potential gain with this approach is very limited, because diluting the buffer below an ionic strength of 1 m*M* will lead to unacceptable loss in buffering capacity and, moreover, in severe sample overload. Another possibility to decrease the background conductivity is to use buffer components with lower mobility, such as GOOD buffers. This, however, will sooner lead to non-symmetric peaks on sample overload (peak triangulation). Using low-mobility Tris as a buffer co-ion will lead to positive peaks for 0.1 m*M* potassium, sodium, and lithium alike (line B in Fig. 1).

Conductivity Detection in HPLC

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Conductivity detection is used to detect inorganic and organic ionic species in liquid chromatography (LC). As all ionic species are electrically conducting, conductometric detection is a universal detection technique, considered as the mainstay in high-pressure ion chromatography, in the same way as is ultraviolet (UV) detection in high-performance liquid chromatography (HPLC).

DISCUSSION

The principle of operation of a conductivity detector lies in differential measurement of mobile-phase conductivity prior to and during solute ion elution. The conductivity cell is either placed directly after an analytical column or after a suppression device required to reduce background conductivity, in order to increase the signal-to-noise ratio and, thus, sensitivity. In the first mode, known as *non-suppressed* or *single-column ion chromatography*, aromatic acid eluents are used, with low-capacity fixed-site ion exchangers and dynamically or permanently coated reversed-phase columns. In the second mode, known as *eluent-suppressed ion chromatography*, the separated ions are detected by conductance after passing through a suppression column or a membrane, to convert the solute ions to higher conducting species (e.g., hydrochloric acid in the case of chloride ions and sodium hydroxide in the case of sodium ions). In the meantime, the eluent ions are converted to a low-residual-conductivity medium such as carbonic acid or water, thus reducing background noise.

Conductance G is the ability of electrolyte solutions in an electric field applied between two electrodes to transport current by ion migration. According to Ohm's law, ohmic resistance R is given by

$$R = \frac{U}{I} \tag{1}$$

where U is the voltage (V) and I is the current intensity (A). The reciprocal of ohmic resistance is the conductance G, where

$$G = \frac{1}{R} \tag{2}$$

expressed in Siemens in the International System of Units (SI), formerly reported in the literature as mho The measured conductance of a solution is related to the inter-electrode distance d (cm) and the microscopic surface area (A) (geometric area × roughness factor) of each electrode (A is assumed identical for the two electrodes) as well as the ionic concentration, given by

$$G = \frac{kA}{d} \tag{3}$$

where k is the specific conductance or conductivity. The ratio d/A is a constant for a particular cell, referred as the cell constant K_c (cm^{-1}) and is determined by calibration. The usual measured variable in conductometry is conductivity k (S/cm)

$$k = GK_c \tag{4}$$

The conductance G (in μS) of a solution is given by

$$G = \frac{(\lambda^+ + \lambda^-)CI}{10^{-3}K_c} \tag{5}$$

where λ^+ and λ^- are limiting molar conductivities of the cation and anion, respectively, and C is the molarity and I the fraction of eluent that is ionized. If the eluent and solute are fully ionized, the conductance change accompanying solute elution is

$$\Delta G = \frac{(\lambda_s - \lambda_e)C_s}{10^{-3}K_c} \tag{6}$$

The specific conductance/conductivity k (S/cm) of salts measured by a conductivity detector is given by

$$k = \frac{(\lambda_{s+} + \lambda_{s-})C_s + (\lambda_{e+} + \lambda_{e-})C_e}{1000} = \frac{\Lambda_s C_s + \Lambda_e C_e}{1000} \tag{7}$$

where C_s and C_e are the concentration (mol/L) of the solute and eluent ions, respectively, and Λ is the molar conductivity of the electrolyte.

The change in conductance when a sample solute band passes through the detector results from replacement of some of the eluent ions by solute ions, although the total ion concentration C_{tot} remains constant:

$$C_{tot} = C_s + C_e \tag{8}$$

The background ion conductivity when $C_s = 0$ is

$$k_1 = \frac{\Lambda_e C_{\text{tot}}}{1000} \tag{9}$$

When a solute band is eluted, the ion conductivity k_2 is given by

$$k_2 = \frac{\Lambda_e C_{\text{tot}}}{1000} + \frac{(\Lambda_s - \Lambda_e)C_s}{1000} \tag{10}$$

The difference in conductivity is obtained after subtraction of the first equation from the second:

$$\Delta k = k_2 - k_1 = \frac{(\Lambda_s - \Lambda_e)C_s}{1000} \tag{11}$$

From Eq. (11), it is obvious that when a sample band is eluted, the observed difference in conductivity is proportional to the concentration of the sample solute C_s. However, the linear relation holds only for dilute solutions, as Λ is itself dependent on concentration, according to Kohlrausch's law:

$$\Lambda = \Lambda - A\sqrt{C} \tag{12}$$

where A is a constant and Λ° is the limiting molar conductivity in an infinitely dilute solution, given by the sum

$$\Lambda = \Lambda^+ + \Lambda^- \tag{13}$$

or

$$\Lambda = v_+\lambda_+ + v_-\lambda \tag{14}$$

where v_+ and v_- represent stoichiometric coefficients for the cation and anion, respectively, in the electrolyte.

Eq. 11 shows that the signal observed during solute ion elution is also proportional to the difference in limiting molar ionic conductivities between the eluent and the solute ions.

Values of limiting molar ionic conductivities for a few common ions are shown in Table 1. The data tabulated are referred to 25°C temperature. The term *limiting molar ionic conductivity* is used according to International union of pure and applied chemistry (IUPAC) recommendation, rather than the formerly used *limiting ionic equivalent conductivity*. The molar and equivalent values are interconvertible through stoichiometric coefficient z.

Conductivity is measured by applying an alternating voltage to two electrodes of various geometric shapes in a flow-through cell, which results in anion migration, as negatively charged, toward the anode (positive electrode) and cation migration, as positively charged, toward the negative electrode (cathode). An AC potential (frequency 1000–5000 Hz) is required in order to avoid electrode polarization. The cell current is measured and the solution's resistance (or more strictly the impedance) is calculated by Ohm's law. Conductance is further corrected by the conductivity cell constant, thus giving conductivity.

Table 1 Limiting molar ionic conductivities of some anions and cations at 25°C.

Anions	λ^-	Cations	λ^+
OH^-	199.1	H^+	349.6
F^-	55.4	Li^+	38.7
Cl^-	76.4	Na^+	50.1
Br^-	78.1	K^+	73.5
I^-	76.8	NH_4^+	73.5
NO_3^-	71.46	Mg^{2+}	106
NO_2^-	71.8	Cu^{2+}	107.2
SO_4^{2-}	160.0	Ca^{2+}	120
$Benzoate^-$	32.4	Sr^{2+}	118.9
$Phthalate^{2-}$	76	Ba^{2+}	127.2
$Citrate^{3-}$	168	Ethylammonium	47.2
CO_3^{2-}	138.6	Diethylammonium	42.0
$C_2O_4^{2-}$	148.2	Triethylammonium	34.3
PO_4^{3-}	207	Tetraethylammonium	32.6
CH_3COO^-	40.9	Trimethylammonium	47.2
$HCOO^-$	54.6	Tetramethylammonium	44.9

The requirements for a typical conductivity detection cell are small volume (to eliminate dispersion effects), high sensitivity, wide linear range, rapid response, and acceptable stability. The cell generally consists of a small-volume chamber (<5 μl) fitted with two or more electrodes constructed of platinum, stainless steel, or gold.

Most conductivity detectors function according to the Wheatstone Bridge principle. What is actually measured is resistance of the solution. Electronically, the electrodes are arranged in that way to constitute one arm of a Wheatstone Bridge. Eluting ions from chromatographic column subsequently enter the detector cell, leading to a change of electrical resistance and the out-of-balance signal is rectified with a precision rectifier. The DC signal is either digitized and sent to a computer data acquisition system or is passed to a potentiometric recorder, by means of a linearizing amplifier, which modifies the signal so that the output is linearly related to ion concentration. Sometimes, a variable resistance is situated in one of the other arms of the bridge and is used for zero adjustment to compensate for any signal from mobile-phase ions. As mentioned earlier, at constant voltage applied to the cell, the current will be proportional to the conductivity (Fig. 1).

The conductivity k is a characteristic property of the solution rather than a property of the cell used. It contains all the chemical information available from the measurement, such as concentration and mobilities of the ions present. Accordingly, the conductivity detector is a bulk property detector and, as such, it responds to all electrolytes present in the mobile phase as well as the solutes.

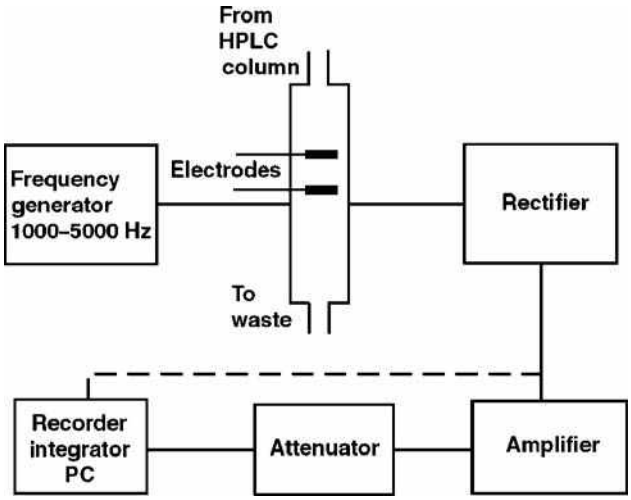

Fig. 1 Block diagram of electrical conductivity detector in HPLC.

Thus, the experimentally determined conductivity is the sum of the contributions from all ions present in the solution. The sensitivity of the conductivity detector depends on the difference between the limiting ionic conductivities of the solute and eluent ions.

The differential mode of detection is mostly effective, provided there is a significant difference in the values of the measured property between the eluent and solute ions. This difference may be either positive or negative. The former case refers to lower conductivity of the eluent ion, described as *direct detection method*, the latter to greater conductivity of the eluent ion, described as *indirect detection method* (Fig. 2).

The thermal stability of a conductivity detector is of great importance. Effective thermostating is highly required, as the temperature greatly affects the mobility of ions and, therefore, conductivity. A 0.5–3% increase of conductivity is usually expected per degree Celsius. Close temperature control is necessary to minimize background noise and maximize sensitivity; this is an especially important issue if non-suppressed eluents are used.

Typical specifications for an electrical conductivity detector are as follows: sensitivity, 5×10^{-9} g/ml; linear dynamic range, 5×10^{-9} to 1×10^{-6} g/ml; response index, 0.97–1.03.

CONCLUSIONS

Conductivity detection in HPLC or, more precisely HPIC, can be applied to ionic species, including all anions and cations of strong acids and bases (e.g., chloride, sulfate, sodium, potassium, etc.). Ions of weaker acids and bases are detected provided that the pH value of the eluent is chosen to maximize the analyte's ionization so as to increase sensitivity. The relatively simple design requirements, accuracy, and low cost contribute to its utility and popularity; thus, it is almost used in over 95% of analyses, where ion-exchange separation procedures are involved.

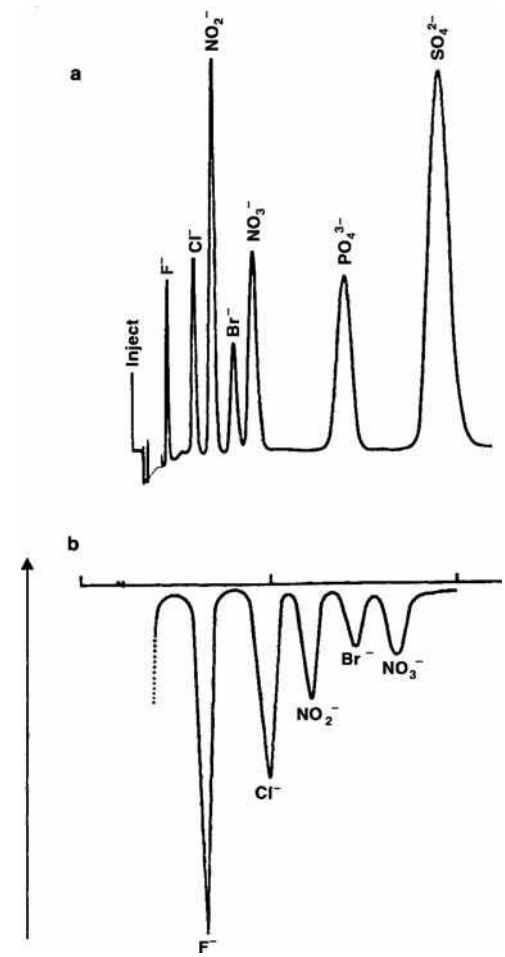

Fig. 2 Conductivity detection of anions in non-suppressed (single column) ion chromatography using an eluent of (a) low-background conductance (direct detection) and (b) high-background conductance (indirect detection). The direction of the arrow indicates the increase of conductivity.

Congener-Specific PCB Analysis

George M. Frame II
Wadsworth Laboratory, New York State Department of Health, Albany, New York, U.S.A.

INTRODUCTION

Polychlorinated biphenyls (PCBs) are complex mixtures of 209 possible chlorinated biphenyl molecules, referred to as congeners. There are from 3 to 46 isomers at each of the 10 possible levels of chlorination. Isomers of a given chlorination level are referred to as homologs. About 150 of these congeners appear at significant levels in commercial mixtures. These mixtures, trade named Aroclor (U.S.A.), Clophen (Germany), Kanechlor (Japan), and so forth, found use as electrical insulating fluids in transformers and capacitors and as binders for a wide variety of uncontained applications. Although their manufacture has been largely discontinued, their long-term stability, dispersion into the environment by prior uncontrolled releases, lipophilicity (resulting in biomagnification up food chains), and potential toxicity to humans and biota have sparked extensive research and the requirement for detailed analytical characterization of these mixtures.

DISCUSSION

This entry does not discuss the extensive literature on sample preparation, cleanup, and proper instrumental operation. Adsorption column chromatography and HPLC procedures find application here, and the book by Erickson[1] provides exhaustive discussions of these and of the history of PCB use and analysis. Methods for measuring total PCB content or measuring and reporting the mixtures by their commercial designation are not detailed. Congener-specific PCB analysis demands separation and quantitation either of shortlists of priority PCB congeners or of the PCB content of all chromatographic PCB peaks that can be separated in particular system(s). This latter mode is referred to as comprehensive, quantitative, congener-specific analysis (CQCS). The methods of choice for CQCS PCB analysis employ high-resolution GC (HRGC) on capillary columns with sensitive and selective detection by electron-capture detectors (ECD), selected ion monitoring-MS (MS-SIM), or full-scan, ion-trap MS (ITMS). The most complete discussion of target congeners for specific research applications is in Ref.[2] A descriptive overview of CQCS PCB analysis appears in an Analytical Chemistry A-page article,[3] and extensive reviews[4–6] provide detailed discussions and large bibliographies.

Fig. 1 summarizes PCB congener structure, nomenclature, the Ballschmiter and Zell (BZ) congener numbering system, and the relative abundances in the commercial Aroclor mixtures as a function of single-ring chlorine-substitution patterns. The BZ numbers in the matrix correspond to the chlorine-substitution positions in each ring of the biphenyl structure, which are listed along the top and right sides of the figure matrix. The abbreviated nomenclature (e.g., 234–245 = PCB #138) defines each congener by the substitution pattern in each ring, with the dash representing the bond between the two phenyl rings. Rotation about this bond is possible except in congeners with three or four chlorines in the ortho (2 or 6) positions.

In the United States, commercial mixtures were manufactured until 1977 by Monsanto under the trade name Aroclor. In the four-digit Aroclor designations (e.g., Aroclor 1242), the 12 indicates a biphenyl nucleus and the 42 the weight percentage of chlorine in the mixture. Reference to the matrix in Fig. 1 reveals congeners in black cells which never exceed 0.1 wt% in the mixtures. These "non-Aroclor" congeners are absent due to unfavored or improbable formation in the electrophilic chlorination process employed in the manufacture of Aroclors.[7] Conversely, the ring chlorine-substitution patterns giving rise to the congeners in gray cells are especially favored.

Whereas three or more *ortho*-chlorines block rotation about the ring-connecting bond, congeners with no, or only one, *ortho*-chlorine can relatively easily achieve a planar configuration (colloquially referred to as "coplanars") and may behave as isosteres (compounds with similar shape, functionality, and polarity) to 2,3,7,8-tetrachlorodibenzodioxin (TCDD). These bind significantly to the "dioxin receptor," and measurement of their concentrations can be combined with their "dioxin-like toxic equivalency factors" (TEFs) to give an estimate of a PCB mixture's "dioxin-like toxic equivalency" (TEQ).[2] Thus, one "shortlist" analysis specified by the World Health Organization (WHO) is for 12 such congeners found in commercial mixtures, namely PCBs 77, 81, 105, 114, 118, 123, 126, 156, 157, 167, 169, and 189. Although PCB 126 is generally a trace component, it has such a high TEF that it often dominates the TEQ calculation.

In the United States, the initial regulatory methods were the USEPA 8080 series. In 8080, packed column gas chromatography-electron capture detection (GC-ECD) was recommended and calibration was against Aroclor mixtures and results were reported as Aroclor

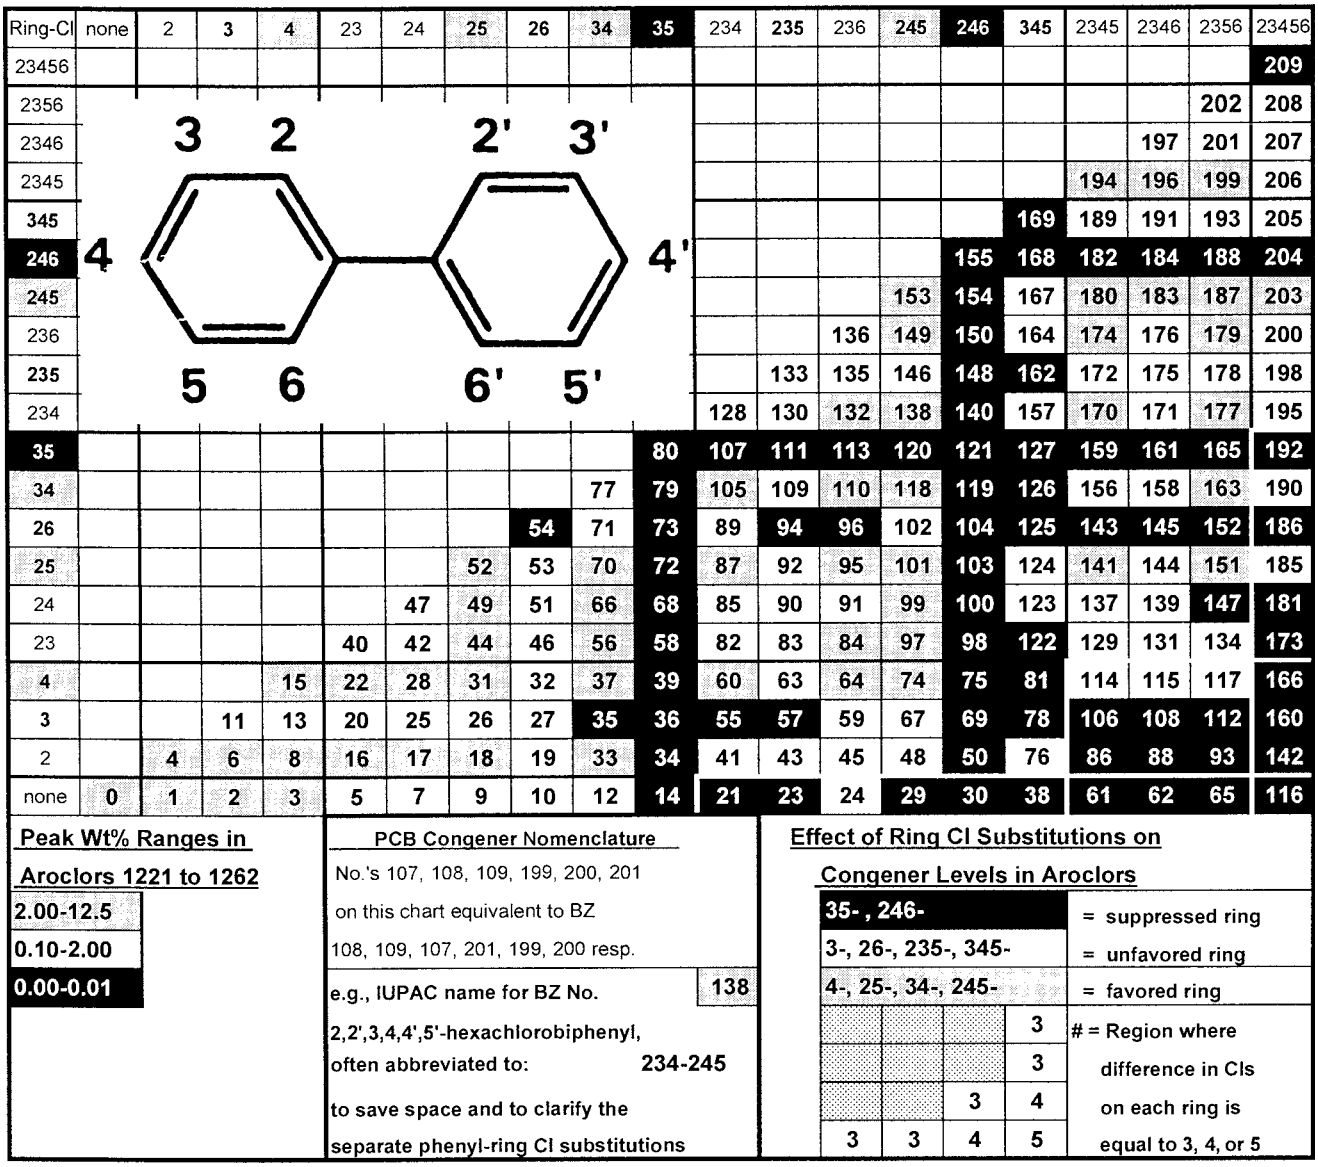

Fig. 1 PCB congener structure, nomenclature, BZ congener numbering system, and relative abundances in Aroclor mixtures.

equivalents. Method 8081 encouraged use of higher resolution capillary GC columns and MS-SIM detection, and the current version, 8082, extends this to suggest measuring some individual congeners against primary standards. An early version of CQCS analysis is EPA Method 680, which employs MS-SIM detection at the molecular ion cluster mass for each homolog level. It does not provide for actually identifying all congeners by determining their elution times and is, thus, not classified as congener-specific, but rather homolog-class-specific. It is quantitatively calibrated against an average response at each level, resulting in less precise measurement of individual congeners, but it detects and measures all PCB-containing peaks whether Aroclor derived or not. It is thus superior to the 8080 series when a PCB mixture arising from a non-Aroclor source or a substantially altered Aroclor congener distribution is encountered. In Europe, the Community Bureau of Reference (BCR) specifies measurement of a shortlist of major persistent "indicator congeners," namely PCBs 28, 52, 101, 118, 138, 153, and 180. A number of other congener shortlists are detailed in Refs.[2,3] A powerful but expensive and difficult-to-implement congener-specific PCB analysis method is USEPA Method 1668. The target list is the WHO list of coplanar PCBs with dioxin-like TEQs. The methodology is HRGC with >10,000 resolution high-resolution MS (HRMS) detection and ^{13}C-isotope dilution internal standards for all the analytes. The procedures are modeled on the well-established HRGC/HRMS USEPA Method 1613 for PCDD/Fs. The newer USEPA Method 1668 Revision A (December 1999) describes procedures for extending the analyte list to all 209 congeners that can be resolved on

either an SPB-octyl capillary column or a DB-1 (100% methyl silicone) capillary. Primary standards for all 209 congeners are distributed among five calibration solutions, which avoid any isomer coelutions on the SPB-octyl column.

No single column, nor any pair of columns, can completely separate all 209 congeners, or even the 150 or so found in Aroclors. Analysts developing CQCS or even "shortlist" congener-specific PCB analyses must select GC stationary phases capable of resolving congeners in their target list. Many analysts have employed 5% phenyl-, 95% methyl-substituted silicone polymers (e.g., DB-5) since a very similar phase was the first one for which the relative retention times for all 209 PCB congeners were published.[3] Methyl silicone phases with 50% *n*-octyl or *n*-octadecyl substituents have PCB retention characteristics similar to those of hydrocarbon columns such as Apeizon L or Apolane, but much greater stability and higher temperature limits than the latter. They permit resolution of many pairs of lower homologs, which coelute on the more polar phases. This feature is valuable for characterizing the products of dechlorination by anaerobic bacteria.[7] Phases with arylene or carborane units substituted in the silicone backbone to decrease column bleed (e.g., DB-5MS, DB-XLB, HT-8) have been found to have particularly useful congener-separation capabilities.[3,7–9] Column manufacturers Restek and SGE have subsequently modified capillary columns of this type (Rtx-PCB and HT-8-PCB, respectively) to specifically support maximal resolution of PCBs in CQCS analysis.

A database of relative retention times and coelutions for all 209 congeners on 20 different stationary phases has been published.[8] For 12 of the most useful of these phases, the elution orders of 9 solutions of all 209 congeners are available from a standard supplier, which markets these solutions (AccuStandard, New Haven, Connecticut, U.S.A.). By surveying the database, one can determine the most suitable column(s) for a particular application and can quickly establish a method component table by nine injections of the standard mixtures. This greatly facilitates the development of new CQCS PCB analyses. Tables of the weight percentages of all congeners in each of the numbered Aroclor mixtures, from which the information condensed in the figure matrix was derived, are available.[7,8] These help reduce the number of congeners that a CQCS method is required to separate when one anticipates analyzing only relatively unaltered Aroclor congener mixtures.

Prior to the availability of all 209 congeners in well-designed primary standard mixtures, much effort was expended to use structure–retention relationships on various phases to predict retention for congeners for which standards were not available.[5] In general, PCB retention times increase with chlorination level, and within chlorination levels, with less chlorine substitution in the ortho position (i.e., "coplanar PCBs" are more strongly retained). These relationships are of theoretical interest but are of less use now that accurate retention time assignments are possible with actual standards. The use of commercial mixtures such as Aroclors as quantitative secondary standards for CQCS PCB analysis is now to be discouraged,[4] as detailed studies of congener distributions show significantly different proportions among different lots.[7] In the case of Aroclor 1254, there are actually two different mixtures of radically different composition produced by totally different synthetic processes.[9]

The other major factor affecting the capability of CQCS PCB analyses is the selection of the GC detector. Initially, the ECD has been most useful for this application. It is selective for halogenated compounds, and its sensitivity is outstanding for the more chlorinated ($Cl \geq 4$) congeners. Its drawbacks are twofold: It has a limited linear range, necessitating multilevel calibration, and the relative response factors vary widely from instrument to instrument and among congeners even at the same chlorination level.[3] For mono- and dichloro-substituted congeners, it is less sensitive than the corresponding MS detectors. Other halogenated compounds such as organochlorine pesticides produce ECD responsive peaks that may interfere by coelution with certain PCB congeners. For these reasons, CQCS PCB analyses with ECD detection often employ a procedure of splitting the injected sample to two columns (each with an ECD detector) of different polarity and PCB congener elution order.[3,7] To be reported, a congener must be measured on at least one column without coelution of PCB or another interfering compound. If separately measurable on each column, the quantities found must match within a preset limit to preclude the possibility of an unexpected coeluting contaminant on one of the columns. Given the large number of congeners that may need to be measured, the data reduction algorithm for such a procedure is complex and not easily automated.

Another approach to providing a second dimension to CQCS PCB analysis is to employ much more selective mass spectrometric detection.[3,6–8] In electrospray ionization-mass spectroscopy (EI-MS), the spectra consist of a molecular ion cluster of chlorine isotope MS peaks and similar fragment ion clusters resulting from the successive loss of chlorine atoms. Congeners differing by one chlorine substituent that coelute on the GC column may often be separately quantitated by MS detection, if the more chlorinated one is not in great excess. This is because the $[M - 1Cl]^+$ fragment that interferes with the lower congener's signal is from a ^{13}C isotope peak and typically has 0.5–12% the signal level of its M^+ peak.[9] In contrast to the ECD, the sensitivity of MS-SIM or full-scan ITMS is greater for the less chlorinated congeners, as their electron affinity is lower and the positive charge of the ions is distributed over a smaller number of fragments. The linearity of the MS detectors is better than that of ECDs, and the ions monitored are more specific for PCBs and less

prone to interference from non-PCB compounds. Electron-capture detectors continue to hold the edge in absolute sensitivity (for the higher chlorinated congeners), and the dual-column/ECD detector systems are slightly less expensive than comparable bench-top, unit-mass-resolution, single-column GC/MS systems. Application to PCB analysis of more advanced (and expensive) MS detection systems, such as HRMS, MS/MS, and negative-ion MS, is described in several reviews.[4,6] Even higher throughput or more comprehensive CQCS PCB congener separations have recently been demonstrated using the latest capillary GC instrumental refinements. These are, respectively, fast GC with time-of-flight (TOF) MS detection,[10] and comprehensive 2D-GC with ECD detection.[11]

A final refinement of congener-specific PCB analysis arises from the fact that 19 of the congeners actually exist as stable enantiomeric pairs, either component of which can withstand racemization even at the elevated temperatures required to elute them from a capillary GC separation.[6] Some congeners containing either a 236- or a 2346-chlorine-substituted ring and three or more chlorines in the ortho position exist in two mirror-image forms by virtue of their inability to rotate around the bond between the two rings. These so-called atropisomers do not contain asymmetric carbon centers. They are PCB numbers 45, 84, 91, 95, 132, 135, 136, 149, 174, and 176 (containing the 236-ring), as well as PCB numbers 88, 131, 139, 144, 171, 175, 176, 183, 196, and 197 (containing the 2346-ring). They may be separated on chiral GC stationary phases, primarily those employing a family of modified cyclodextrins. A series of seven such columns have been found, which among them can achieve resolution of all 19 stable PCB atropisomers as well as separation of 11 of them from other possible coeluting PCBs if MS detection is employed.[12] Observation of PCB enantiomeric ratios significantly different from 1 is a certain indication of the action of an enzyme-mediated biological process operating on these congeners.

CONCLUSIONS

Comprehensive, quantitative, congener-specific PCB analysis requires use of high-resolution capillary GC separations, aided by selective ECD or MS detection. The availability of a range of well-documented stationary phases, complete sets of calibration and retention time standards for all 209 PCB congeners, and databases of retention data facilitates the efficient development of a CQCS assay procedure suitable for specific applications. The "holy grail" of a single system that can reliably and unambiguously identify and quantify any and all of the 209 congeners in a single run has not quite been achieved, but is being approached closely. Polychlorinated biphenyl-tailored stationary phases, fast TOF-MS detection, and comprehensive 2D-GC separations may well combine to achieve this goal.

Copolymers: Composition by GPC/SEC

Sadao Mori
PAC Research Institute, Mie University, Nagoya, Japan

INTRODUCTION

Determination of the average chemical composition and polymer composition by size-exclusion chromatography (SEC) has been reported in the literature. Two different types of concentration detectors or two different absorption wavelengths of an ultraviolet or an infrared detectors are employed; the composition at each retention volume is calculated by measuring peak responses at the identical retention points of the two chromatograms.

DISCUSSION

Synthetic copolymers have both molecular-weight and chemical composition distributions and copolymer molecules of the same molecular size, which are eluted at the same retention volume in SEC, may have different molecular weights in addition to different compositions. This is because separation in SEC is achieved according to the sizes of molecules in solution, not according to their molecular weights or chemical compositions.

Molecules that appear at the same retention volume may have different compositions, so that accurate information on chemical heterogeneity cannot be obtained by SEC alone. When the chemical heterogeneity of a copolymer, as a function of molecular weight, is observed, the copolymer is said to have a heterogeneous composition, but, even though it shows constant composition over the entire range of molecular weights, it cannot be concluded that it has a homogeneous composition.[1] Nevertheless, SEC is still extremely useful in copolymer analysis, due to its rapidity, simplicity, and wide applicability.

When one of the constituents, A or B of a copolymer A–B, has an ultraviolet (UV) absorption and the other does not, a UV detector–refractive index (RI) combined detector system can be used for the determination of chemical composition or heterogeneity of the copolymer. A point-to-point composition, with respect to retention volume, is calculated from two chromatograms and a variation of composition is plotted as a function of molecular weight. The response factors of the two components in the two detectors must first be calibrated.

Let A be a constituent that has UV absorption. K_A and K_B are defined as the response factors of an RI detector for the A and B constituents, and K_A' as the response of the UV detector for A. These response factors are calculated by injecting known amounts of homopolymers A and B into the SEC dual-detector system, calculating the areas of the corresponding chromatograms, and dividing the areas by the weights of homopolymers injected as

$$F_A = K_A G_A, \quad F_B = K_B G_B, \quad F_A' = K_A' G_A$$

where F_A, F_B, and F_A' are areas of homopolymers A and B in the RI detector and of homopolymer A in the UV detector, and G_A and G_B are the weights of homopolymers A and B injected into the SEC system.

The weight fraction $W_{A,I}$ of constituent A, at each retention volume I of the chromatogram for the copolymer, is given by

$$W_{A,I} = \frac{K_B}{R_I K_A' - K_A + K_B}$$

where $R_I = F_{RI,I}/F_{UV,I}$ for the copolymer at retention volume I. Retention volume I for the RI detector is not equal to the retention volume I for the UV detector. Usually, the UV detector is connected to the column outlet and is followed by an RI detector, and the dead volume between these two detectors must be corrected. The dead volume can normally be measured by injecting a polymer sample having a narrow molecular-weight distribution and by measuring the retention difference between the two peak maxima.

Because the additivity of the RI increments of homopolymers is valid for copolymers, the additivity of the response factors is also valid:

$$K_C = W_A K_A + W_B K_B$$

where K_C is the response factor for the copolymer in the RI detector. If the response factors of one or two homopolymers that comprise a copolymer cannot be measured because of insolubility of the homopolymer(s), then this equation is employed.

Alternatively, the extrapolation of the plot of RI response factors of copolymers of known compositions can be used. An example is that the RI response for polystyrene was 2800 and that for polyacrylonitrile was 2250.

Although the values of these response factors are dependent on several parameters, the ratio of to K_A to K_B is almost constant in the same mobile phase.

An infrared detector can be used, at an appropriate wavelength, for detecting one component in copolymers or terpolymers and, thus, expand its range of applicability to copolymers analysis. Information on composition can be obtained by repeating runs, using different wavelengths to monitor different functional groups. A single-detector system is more advantageous than a dual-detector system, such as a combination of UV and RI detectors.

Instead of measuring chromatograms two or three times at different wavelengths for different functional groups, operation in a stop-and-go fashion was introduced for rapid determination of copolymer composition as a function of molecular weight.[2]

Pyrolysis gas chromatography has been widely used for copolymer analysis. This technique may offer many advantages over other detection techniques for copolymer analysis by SEC. One obvious advantage is the small sample size required. Another is the capability of application to copolymers which cannot utilize UV or IR detectors.[3]

Combination with other liquid chromatographic techniques is also reported by several workers. Orthogonal coupling of an SEC system to another high-performance liquid chromatography (HPLC) system K_B, K_A to achieve a desired cross-fractionation was proposed.[4] It was an SEC–SEC mode, using the same polystyrene column, but the mobile phase in the first system was chosen to accomplish only a hydrodynamic volume separation, and the mobile phase in the second system was chosen so as to be a thermodynamically poorer solvent for one of the monomer types in the copolymer, in order to fractionate by composition under adsorption or partition modes as well as size exclusion.

A combination of liquid adsorption chromatography with SEC has recently been developed by several workers. Poly(styrene–methyl methacrylate) copolymers were fractionated according to chemical composition by liquid adsorption chromatography and the molecular weight averages of each fraction were measured by SEC.[5,6]

Copolymers: Molecular Weights by GPC/SEC

Sadao Mori
PAC Research Institute, Mie University, Nagoya, Japan

INTRODUCTION

It is well known that most copolymers have both molecular weight and composition distributions and that copolymer properties are affected by both distributions. Therefore, we must know the average values of molecular weights and composition, and their distributions. These two distributions are inherently independent of each other. However, it is not easy to determine the molecular-weight distribution independently of the composition, even by modern techniques.

DISCUSSION

Size exclusion chromatography (SEC) is a rapid technique used to obtain the molecular-weight averages and the molecular-weight distributions of synthetic polymers. The objective of SEC for copolymer analysis must not only be the determination of molecular-weight averages and its distribution but also the measurement of average copolymer composition and its distribution. However, separation by SEC is achieved according to the sizes of molecules in the solution, not according to their molecular weights. Therefore, the retention volume of a copolymer molecule obtained by SEC reflects not the molecular weight, as in the case of a homopolymer, but simply the molecular size.

For example, the elution order of polystyrene (PS), poly(methyl methacrylate) (PMMA), and their copolymers [P(S–MMA)], both random and block, all having the same molecular weight are as follows: random copolymer of P(S–MMA), PS, block copolymer (MMA-S-MMA), and PMMA.[1] Copolymers having the same molecular weight but different composition are different in molecular size and elute at different retention volumes. Therefore, the accurate determination of the values of molecular-weight averages and the molecular-weight distribution for a copolymer by SEC might be limited to the case when the copolymer has the homogeneous composition across the whole range of molecular weights.

A calibration curve for a copolymer consisting of components A and B can be constructed from those for the two homopolymers A and B, if the relationships of the molecular weights and the molecular sizes of the two homopolymers are the same as their copolymer and if the size of the copolymer molecules in the solution is the sum of the sizes of the two homopolymers times the corresponding weight fractions. The molecular weight of the copolymer at retention volume I, $M_{C,I}$, is calculated using

$$\log M_{C,I} = W_{A,I} \log M_{A,I} + W_{B,I} \log M_{B,I}$$

where $M_{A,I}$ and $M_{B,I}$ are the molecular weights of homopolymers A and B, respectively, and $W_{A,I}$ and $W_{B,I}$ are the weight fractions of components A and B, respectively, in the copolymer at retention volume I. This equation was empirically postulated for block copolymers.[2]

The use of the so-called "universal calibration" is a theoretically reliable procedure for calibration. For ethylene–propylene (EP) copolymers, Mark–Houwink parameters in *O*-dichlorobenzene at 135°C are calculated as[3]

$$a_{EP} = (a_{PE} a_{pp})^{1/2}$$
$$K_{EP} = W_E K_{PE} + W_P K_{PP} - 2(K_{PE} K_{PP})^{1/2} W_E W_P$$

where W_E and W_P are the weight fractions of the ethylene and propylene units of the copolymer, respectively.

Calculated Mark–Houwink parameters for P(S–MMA) block and statistical copolymers at several compositions in tetrahydrofuran at 25°C are listed in Table 1.[4] The parameters for PS and PMMA used in the calculation are as follows:

$$PS : K = 0.682 \times 10^{-2} \mathrm{ml}/g, a = 0.766$$
$$PMMA : K = 1.28 \times 10^{-2} \mathrm{ml}/g, a = 0.69$$

If copolymer molecules and PS molecules are eluted at the same retention volume, then

$$[\mu]_C M_C = [\mu]_S M_S$$

where M_C and M_S are the molecular weights of the copolymer and PS, respectively, and $[\mu]_C$ and $[\mu]_S$ are the intrinsic viscosities of the copolymer and PS, respectively. A differential pressure viscometer can measure intrinsic viscosities for the fractions of the copolymer and PS continuously, followed by the determination of M_C of the copolymer fraction at retention volume I.

The application of a light-scattering detector in SEC does not require the construction of a calibration curve using narrow molecular-weight distribution polymers. However, this method is not generally applicable to

Table 1 Calculated Mark–Houwink parameters for P(S–MMA) block and statistical copolymers at several compositions in tetrahydrofuran at 25°C.

	Block copolymer		Statistical copolymer	
Composition (styrene wt %)	$K \times 10^2$ **(ml/g)**	a	$K \times 10^2$ **(ml/g)**	a
20	1.124	0.705	1.044	0.718
30	1.054	0.714	0.953	0.731
40	0.989	0.721	0.879	0.742
50	0.929	0.729	0.821	0.750
60	0.872	0.736	0.779	0.756
70	0.820	0.744	0.747	0.760
80	0.771	0.751	0.722	0.763

copolymers because the intensity of light scattering is a function not only of molecular weight but also of the specific refractive index (the refractive index increment) of the copolymer in the mobile phase. The refractive index increment is also a function of composition. In the case of a styrene–butyl acrylate (30 : 70) emulsion copolymer, the apparent molecular weight of the copolymer in tetrahydrofuran was only 7% lower than true one.[5] A recent study concluded that if refractive index increments of the corresponding homopolymers do not differ widely, SEC measurements combined with light scattering and concentration detectors yield good approximations to molecular weight and its distribution, even if the chemical composition distribution is very broad.[6]

Coriolis Force in CCC

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

Kazufusa Shinomiya
College of Pharmacy, Nihon University, Chiba, Japan

INTRODUCTION

Coriolis force acts on a moving object on a rotating body such as the Earth or a centrifuge bowl. It was first analyzed by a French engineer and mathematician, Gaspard de Coriolis (1835).[1] The effect of the Coriolis force produced by the Earth's rotation is weak, whereas that on a rotating centrifuge is strong and easily detected. Fig. 1 illustrates the effect of Coriolis force on moving droplets in a rotating centrifuge, where the path of the sinking droplets shifts toward the direction opposite to the rotation (left); this effect is reversed for floating droplets (right).[2] Moving droplets in a rotating centrifuge have been photographed under stroboscopic illumination.[3,4] The effects of Coriolis force on countercurrent chromatography (CCC) have been demonstrated in the toroidal coil centrifuge, which uses a coiled tube mounted around the periphery of the centrifuge bowl.[2,5] When a protein mixture containing cytochrome *c*, myoglobin, and lysozyme was separated on an aqueous/aqueous polymer phase system composed of 12.5% (w/w) polyethylene glycol 1000 and 12.5% (w/w) dibasic potassium phosphate, the direction of elution through the toroidal coil had substantial effects on peak resolution, as shown in Fig. 2 and Table 1.[2,5] Since the toroidal coil separation column has a symmetrical orientation except for the handedness, the above effect is best explained on the basis of Coriolis force as follows: If the Coriolis force acts parallel to the effective coil segments (parallel orientation), the two phases form multiple droplets, which provide a broad interface area to enhance the mass transfer process, hence improving the partition efficiency (Fig. 3A). When the Coriolis force acts across the effecting coil segments, the two phases form a streaming flow, minimizing the interfacial area for mass transfer and resulting in lower partition efficiency (Fig. 3B). It is interesting to note that the above effects have not been observed during the separation of low molecular weight compounds such as dipeptides[2] and dinitrophenyl (DNP) amino acids[6] on conventional organic/aqueous two-phase solvent systems in the toroidal coil CCC centrifuge, except that at a relatively low revolution speed, the Coriolis force acting across the effective coil segments slightly improves the partition efficiency, probably due to substantially higher retention of the stationary phase.

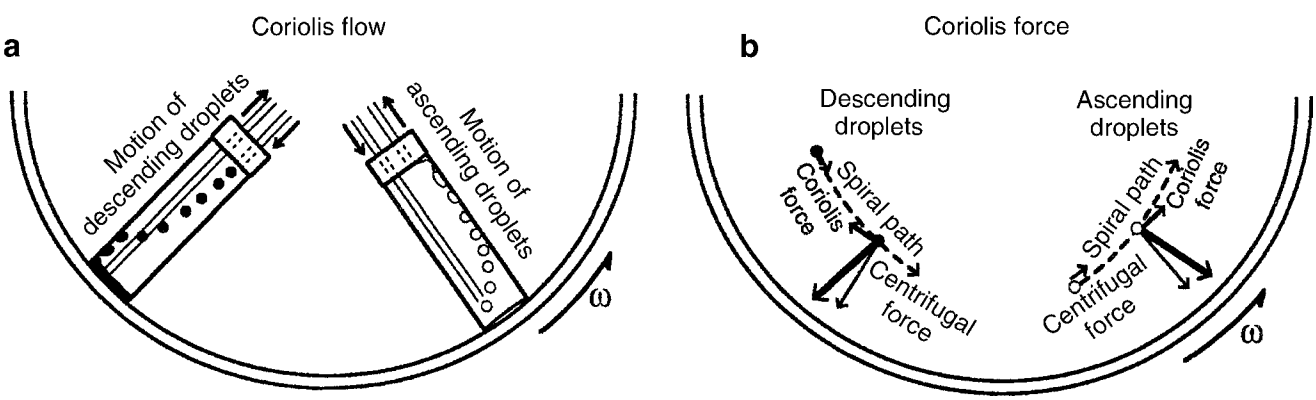

Fig. 1 Effects of Coriolis force on moving droplets in a rotating centrifuge. A. Motion of droplets in a flow through cell in a rotating centrifuge. B. Direction of Coriolis force acting on droplets on rotating centrifuge bowl.

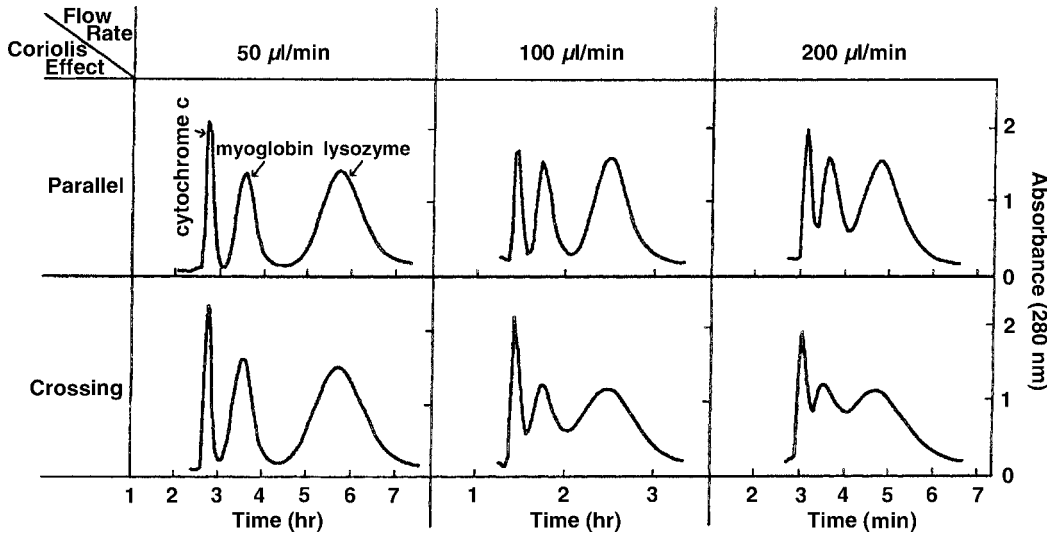

Fig. 2 Effects of Coriolis force on partition efficiency and retention of stationary phase in protein separation by toroidal coil centrifuge.

Table 1 Effects of Coriolis force on partition efficiencies of three stable proteins in toroidal coil CCC.

Flow-rate (μl/min)	Analyte peak	TP (parallel/crossing)	R_s (parallel/crossing)	Retention (%) (parallel/crossing)
50	Cytochrome *c*	1860/1490		29.2/32.0
			1.62/1.39	
	Myoglobin	365/266		
			1.66/1.40	
	Lysozyme	156/104		
100	Cytochrome *c*	1760/821		30.0/30.3
			1.27/0.86	
	Myoglobin	433/172		
			1.39/0.84	
	Lysozyme	172/63		
200	Cytochrome *c*	1296/–		22.8/21.3
			0.84/–	
	Myoglobin	330/–		
			0.92/–	
	Lysozyme	123/–		

More recently, the effect of Coriolis force was demonstrated in the separation of organic acids with organic/aqueous two-phase solvent systems in a centrifugal partition chromatograph equipped with a separation column consisting of rectangular partition compartments connected in series.[6] As shown in Fig. 4, clockwise column rotation (CW) shows substantially better peak resolution than counterclockwise column rotation (CCW), especially in the separation of *p*-methyl hippuric acid and hippuric acid (middle column) with a two-phase solvent system composed of methyl *t*-butyl ether/aqueous 0.1% trifluoroacetic acid (1 : 1, v/v). Mathematical analysis is carried out to elucidate the effect of Coriolis force on the motion of the mobile-phase droplets.[6]

Corrected Retention Time and Corrected Retention Volume

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The corrected retention time of a solute is the elapsed time between the dead point and the peak maximum of the solute. The different properties of the chromatogram are shown in Fig. 1. The volume of mobile phase that passes through the column between the dead point and the peak maximum is called the corrected retention volume.

DISCUSSION

If the mobile phase is incompressible, as in liquid chromatography, the retention volume (as so far defined) will be the simple product of the exit flow-rate and the corrected retention time.

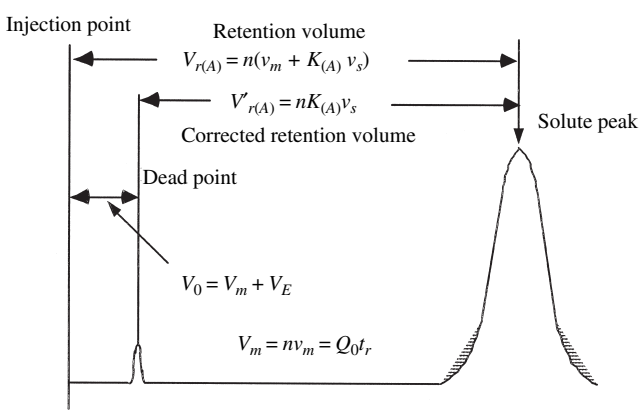

Fig. 1 Diagram depicting the retention volume, corrected retention volume, dead point, dead volume, and dead time of a chromatogram. V_0: total volume passed through the column between the point of injection and the peak maximum of a completely unretained peak; V_m: total volume of mobile phase in the column; $V_{r(A)}$: retention volume of solute A; $V_{r(A)}'$: corrected retention volume of solute A; V_E: extra column volume of mobile phase; v_m: volume of mobile phase, per theoretical plate; V_s: volume of stationary phase per theoretical plate; $K_{(A)}$: distribution coefficient of the solute between the two phases; n: number of theoretical plates in the column; Q: column flow rate measured at the exit.

If the mobile phase is compressible, the simple product of the corrected retention time and flow rate will be incorrect, and the corrected retention volume must be taken as the product of the corrected retention time and the *mean* flow rate. The true corrected retention volume has been shown to be given

$$V_r' = V_{r'}'\left(\frac{\gamma^2 - 1}{\gamma^2 - 1}\right) = Q_0 t_r' \frac{2}{3}\left(\frac{\gamma^2 - 1}{\gamma^2 - 1}\right)$$

where the symbols have the meaning defined in Fig. 1, and $V_{r'}'$ is the corrected retention volume measured at the column exit and γ is the inlet/outlet pressure ratio.

The corrected retention volume, V_r', will be the difference between the retention volume and the dead volume V_0, which, in turn, will include the actual dead volume V_m and the extra column volume V_E. Thus,

$$V_r' = V_r - (V_E + V_m)$$

The retention time can be taken as the product of the distance on the chart between the dead point and the peak maximum and the chart speed, using appropriate units. As in the case of the retention time, it can be more accurately measured with a stopwatch. Again, the most accurate method of measuring V_r' for a non-compressible mobile phase, although considered antiquated, is to attach an accurate burette to the detector exit and measure the retention volume in volume units. This is an absolute method of measurement and does not depend on the accurate calibration of the pump, chart speed, or computer acquisition level and processing.

Coumarins: TLC Analysis

Kazimierz Glowniak
Jaroslaw Widelski
Department of Pharmacognosy, Medical University of Lublin, Lublin, Poland

INTRODUCTION

Coumarins are natural compounds that contain the characteristic benzo[α]pyrone (2H-benzopyran-2-one) moiety. They are especially abundant in Umbelliferae, Rutaceae, Leguminosae, Compositae, and other plant families. Usually the substituents are at the positions C_5, C_6, C_7, and C_8 [e.g., umbelliferone (7-hydroxycoumarin), hierniarin (7-methoxycoumarin), esculetin (6,7-dihydroxycoumarin), scopoletin (6-methoxy-7-hydroxycoumarin), and others].

In addition to simple coumarin derivatives, furano- and pyranocoumarins are also commonly encountered in the Umbelliferae and Rutaceae families. The essential chemical moiety of linear furanocoumarins consists of a 2H-furan[3.2-g]-benzo[b]pyran-2-one ring called psolaren (its derivatives include, e.g., bergapten, xanthotoxin, isopimpinelin, imperatorin, isoimperatorin, oxypeucedanin, and others). The second type of furanocoumarins (the angular type of angelicin) has a 2H-furan[2.3 h]-benzo[β]pyran-2-one structure (isobergapten, pimpinelin, sphondin). There are also both linear and angular types of pyranocoumarins. In the linear type, which is named alloxanthiletin, the 2H,8H-pyran[3.2 h]-benzo[β]pyran-2-one ring is characteristic, whereas in the angular type called seselin, the 2H,8H-pyran[2.3 h]-benzo[β]pyran-2-one moiety is typical.

THIN-LAYER CHROMATOGRAPHY

Thin-layer chromatography (TLC) is a very useful method for the separation of natural coumarins, furanocoumarins, and pyranocoumarins. Natural coumarins exhibit fluorescence properties, which they display in ultraviolet (UV) light (365 nm). Their spots can be easily detected on paper and thin-layer chromatograms without the use of any chromogenic reagents. It is often possible to recognize the structural class of coumarin from the color it displays under UV detection (Table 1). Purple fluorescence generally signifies 7-alkoxycoumarins, whereas 7-hydroxycoumarins and 5,7-dioxygenated coumarins tend to fluoresce blue. In general, furanocoumarins possess a dull yellow or ocher fluorescence, except for psolaren, sphondin, and angelicin. Spot fluorescence is more intense or its color is changed after spraying the TLC chromatogram with ammonia (Table 1).[1]

Thin-layer chromatograms can also be detected by several non-specific chromatogenic reactions:

1. 1% Aqueous solution of iron (III) chloride.
2. 1% Aqueous solution of potassium ferricyanide.
3. Diazotized sulfanilic acid and diazotized *p*-nitro-aniline.

None of these reagents is very specific for hydroxycoumarins and their confirmation should be substantiated by other methods. Exposed groups present in many natural coumarins can be detected due to their susceptibility to cleavage by acids and applied over a phosphoric acid spot on a silica TLC plate.

The linear (psolarens) and angular (angelicins) furanocoumarins can be readily differentiated with the Emerson reagent. It is also used for detection of pyranocoumarins (selinidin, pteryxin) on TLC chromatograms.

CONVENTIONAL TLC

Conventional TLC is a well-known technique, used for many years in systematic research on the coumarin content of numerous plant species, as well as for chemotaxonomic relationships between those species. Great progress in the optimization of the TLC separation process was made by the design of modern, horizontal chambers for TLC. It is a universal design offering the possibility of developing chromatograms in the space saturated or non-saturated with mobile-phase vapors. Moreover, it is possible to perform gradient elution, stepwise or continuous, or to accomplish micropreparative separation of chemical compound composites (e.g., plant extracts).[2]

Gradient elution in TLC can be obtained in several ways:[1]

1. Multizonal development: the use of multicomponent eluents that are partially separated during development (frontal chromatography), forming an eluent strength gradient along the layer.
2. Development with a strong solvent (e.g., acetone) of an adsorbent layer exposed to vapors of a less polar solvent.
3. The use of mixed layers of varying surface area and activity (compare silica and Florisil®).
4. Delivery of an eluent whose composition is varied in a continuous or stepwise manner by introducing small volumes of more polar eluent fractions (e.g., 0.2 ml).

Table 1 Chromatographic methods of coumarin identification: Fluorescence colors of coumarins under UV irradiation (365 nm).

Fluorescence color	Fluorescence color with ammonia	Coumarin or coumarin type
Blue	L. blue	7-Hydroxycoumarin
B. blue	V. blue	7-Hydroxycoumarins
Blue	B. blue	7-Hydroxy-6-alkoxycoumarins
Blue	Blue	5,7-Dialkoxycoumarins
B. blue	B. blue	6,7-Dialkoxycoumarins
Blue	Blue	6,7,8-Trialkoxycoumarins
W. blue	W. blue	5,6,7-Trialkoxycoumarins
W. blue	B. blue	7-Hydroxy-5,6-dialkoxycoumarins
Blue		Psolaren
Blue	B. blue	6-Methoxyangelicin
Blue	Green	7,8-Dihydroxycoumarin
Pink	Yellow	6-Hydroxy-7-glucosyloxycoumarin
Purple	Purple	8-Hydroxy-5-alkoxypsolarens
W. purple	Pink	6-Hydroxy-7-alkoxycoumarins
Purple	Green	Angelicin, coumestrol
Green		5-Methoxyangelicin
Green		8-Hydroxy-6,7-dimethoxycoumarin
Green	Yellow	7,8-Dihydroxy-6-methoxycoumarin
Yellow		3,4,5-Trimethoxypsolaren
Yellow		6-Hydroxy-5,7-dimethoxycoumarin
Yellow	Yellow	5-Hydroxy-6,7-dimethoxycoumarin
Yellow	Yellow	5-Hydroxypsolaren
Yellow	Yellow	5,6-Dimethoxyangelicin
Yellow	Yellow	8-Alkoxypsolarens
Yellow-green	Yellow-green	5-Alkoxypsolarens
B. yellow	B. yellow	5,8-Dialkoxypsolarens

B. = bright; V. = very bright; L. = light; W. = weak.

The possibility of zonal sample dosage in equilibrium conditions (after a front of mobile phase and continuous-chromatogram development, which is provided by a horizontal "sandwich" chamber) was utilized by Glowniak, Soczewinski, and Wawrzynowicz[3] in preparative chromatography of simple coumarins and furanocoumarins found in *Archangelica* fruits, performed with a short-bed continuous development (SB-CD) technique.

The latter possibility was employed by Wawrzynowicz and Waksmundzka-Hajnos for micropreparative TLC isolation of furanocoumarins from *Archangelica*, *Pastinaca*, and *Heracleum* fruits on silica gel, silanized gel, and Florisil.

Superior coumarin compound separation with use of the described flat "sandwich" chambers is achieved with gradient chromatography on silica gel and stepwise variation of polar modifier concentrations in mobile phase, as less polar solvents (hexane, cyclohexane, toluene, or dichloromethane) and polar modifiers (acetonitrile, diisopropyl ether, ethyl acetate) are used.

Complex pyranocoumarin mixtures can be separated with the TLC technique by alternative use of two different polar adsorbents (silica gel, Florisil) and various binary and ternary eluents with different mechanisms of adsorption center effect on the molecules to be separated.[4] Improved separation can be achieved by high-performance TLC (HPTLC), which employs new, highly effective adsorbent of narrow particle size distribution, or with chemically modified surface. Because of its similarity, HPTLC is applied in designing optimal HPLC systems. Another gradient technique in coumarin compound separation is programed multiple development (PMD), also called the "reversed gradient" technique, in which chromatograms are developed to increasing distances by a sequence of eluents with decreasing polarity, with eluent evaporation after each stage.

Two-dimensional TLC (2D-TLC) is particularly effective in the case of complex extracts when one-dimensional developing yields partial separation. Moreover, it offers the possibility of modifying separation procedures when the development direction is changed.

OVERPRESSURED LAYER CHROMATOGRAPHY

The term "overpressured layer chromatography" (OPLC) was originally introduced by Tyihak, Mincsovisc, and Kalasz[5] in the late 1970s. The crucial factor is pressurized mobile-phase flow through the planar medium. Short analysis time, low solvent consumption, high resolution, and availability of online and off-line modes are the main advantages of OPLC in comparison with the classical TLC techniques. Overpressured layer chromatography was proved effective in qualitative and quantitative analysis of furanocoumarins by densitometric online detection. Overpressured layer chromatography can also be performed in two-dimensional mode (2D-OPLC). This technique was used by Harmala et al.[6] for the separation of 16 closely related coumarins from *Angelica* genus.

Long-distance OPLC is a novel form of OPLC, in which chromatograms are developed over a long distance with optimal (empiric) mobile-phase flow. Used in combination with specialized equipment designs, it produces high-performance (70,000–80,000 of theoretic plates) and excellent resolution. Botz, Nyiredy, and Sticher,[7] who initiated long-distance OPLC, proved its efficiency in the separation of eight furanocoumarin isomers and in the isolation of the furanocoumarin complex from *Peucedanum palustre* roots raw extract. This technique was used by Galand et al.[8] as well.

ROTATION PLANAR CHROMATOGRAPHY

Rotation planar chromatography (RPC), as with OPLC, is another thin-layer technique with forced eluent flow, employing a centrifugal force of a revolving rotor to move the mobile phase and separate chemical compounds. The RPC equipment can vary in chamber size, operative mode (analytical or preparative), separation type (circular, anticircular, or linear), and detection mode (off-line or online). The described technique was applied in analytical and micropreparative separation of coumarin compounds from plant extracts.

AUTOMATED MULTIPLE DEVELOPMENT

Automated multiple development (AMD), providing automatic chromatogram development and drying, is a novel form of the PMD technique. Automated multiple development as an instrumental technique can be used to perform normal-phase chromatography with solvent gradients on HPTLC plates. Most of the AMD applications use typical gradients: Starting with a very polar solvent, the polarity is varied by means of "base" solvent of medium polarity to a non-polar solvent. Instrumentation for AMD was introduced by Camag (Switzerland) and provides a means for normal-phase gradient development in HPTLC. The developing distance increases while the solvent polarity decreases. Repeated development compresses the band on the plate, resulting in increased sensitivity and resolution.[9]

CONCLUSIONS

TLC is a suitable method of separation, characterization, and quantitative evaluation for any kind of coumarin compound. Modern TLC techniques such as AMD, HPTLC, and OPLC have been in use since many years in systematic research on the coumarin content of numerous plant species, as well as for chemotaxonomic relationships between those species.

Counterfeit Drugs: TLC Analysis

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Counterfeit and substandard drug products and active pharmaceutical ingredients are a great problem for government regulatory agencies, pharmaceutical companies, healthcare providers, and consumers, leading to morbidity, mortality, and drug resistance. The drugs that are most counterfeited are those used to treat infections (antibiotics), malaria (e.g., artesunate), tuberculosis (TB), and HIV/AIDS. The U.S. Center for Medicine in the Public Interest has predicted that global counterfeit drug sales will reach $75 billion in 2010, a 95% increase since 2005. All countries, regardless of efforts in drug regulation, are affected by this increase, especially in the light of the ease of purchase of questionable drugs on the internet; however, developing countries are at greatest risk, so the costs of analytical screening methods are critically important. The problems caused by counterfeit medicines are described in more detail in earlier entries.[1,2]

This entry describes the three most important drug-screening methods in use at this time, for TB, macrolide antibiotics, and drugs from the World Health Organization (WHO) Essential Drug List. All of these are based on thin-layer chromatography (TLC).

OVERVIEW OF TLC METHODS

According to the WHO, counterfeit drugs are defined as mislabeled medicines manufactured with substandard safety, quality, and effectiveness. They include products with a different drug, but none of the labeled active ingredient, the correct active ingredient at the wrong level, or the correct drug and amounts in the wrong packaging. TLC is the main screening method used today to decide if a drug product meets label specifications and is legal. Drug-screening TLC methods are simple, inexpensive, selective, and semiquantitative, and they can be used in the laboratory or in the field in locations such as a port of entry, distribution center, clinic, pharmacy, or hospital. TLC can give an indication whether the active ingredient is present and its level of content, and, therefore, if the product is qualified or authorized or legal on this basis. Some related substances might also be detected and quantified. However, TLC will not detect counterfeits that have wrong active or inactive ingredients if they are not visualized by the detection method being used for the correct active drug.

SPEEDY TLC KIT

In a series of papers starting in 1989, Kenyon, Layloff, and coworkers developed simple and inexpensive TLC methods for rapid screening of counterfeit drugs that can be used either in a well-equipped laboratory or in remote areas with or without electricity and by personnel with limited technical background and training. Balances are not necessary if standard tablets of the drugs are available, the procedure can be performed safely in the open air with no hood, and estimates are made from visual inspections in daylight without electronic measurements. These entries described methods for analysis of theophylline tablets prescribed to treat respiratory disease;[3] 10 commonly used pharmaceuticals (ampicillin, benzylpenicillin, chloramphenicol, chloroquine diphosphate, estradiol cypionate, paracetamol, praziquantel, sulfamethoxazole, theophylline, and trifluoperazone HCl);[4] 13 drugs, including three on the WHO Essential Drug List;[5] and diethylene glycol/ethylene glycol in pharmaceutical elixirs.[6]

The apparatus and procedures that evolved from these earlier studies were described in detail[7] for the rapid screening of TB pharmaceuticals in underdeveloped countries in the field. The "Speedy TLC" apparatus (available from Granite Engineering, Inc., Granite City, Illinois, U.S.A.) is used for screening a single content of particular TB pharmaceuticals at a given concentration. Two reference solutions representing the upper and lower dosage limits depending on the legal specification of the drug being analyzed are spotted on the plate, 2 cm up from the bottom edge, in 3.0 μl aliquots with a sample solution representing 100% spotted between the standards. After development, the spots are examined visually under ultraviolet (UV) light and in visible light after detection by KI–iodine solution.

No analytical balance is required for sample or standard solution preparation. A sample tablet is ground to a fine powder in a small polyethylene bag, and the bag and powder are transferred to a suitable vessel (e.g., a beaker, flask, or bottle); the contents of capsules are simply emptied into a vessel. The proper volume of solvent is added, and the vessel is shaken vigorously to dissolve the powder

to prepare a concentrated solution from which the TLC sample solution is prepared by dilution.

The high reference solution, equivalent to 115% or 120% when the sample is prepared to be 100%, is prepared by dissolving a reference standard tablet containing a predetermined quantity of the drug in a fixed volume of solvent; reference tablets are formulated to dissolve completely in the solvent without grinding. The low reference solution (85.0% relative to the sample) is prepared by dilution of the high reference solution.

TLC analysis is performed using the Speedy TLC kit supplied with plastic bags, holders, and all other required accessories. Plastic-backed silica gel 60 F_{254} 5 × 10 cm sheets are required for use in the kit apparatus; the presence of fluorescent indicator in the layer is necessary for detection of drugs that quench fluorescence under 254 nm UV light. The specified mobile phases will provide the required separation for each analysis with drug R_F values between 0.2 and 0.8.

The rigid aluminum TLC frame, 10 cm plastic bag, filter paper saturator strips, aluminum developing tray, and clamp and fishhook are assembled, and the mobile phase is added. The TLC sheet is attached to the aluminum frame with the clip and lowered into the plastic bag with the fishhook. Paper clips are placed behind the sheet (between the sheet and the aluminum frame). The sheet is essentially suspended in space and is held only with the clip. The mobile phase will advance in a straight line. The sheet is allowed to stay in the bag without contacting the mobile phase for about 5 min to reach equilibrium, after which the plastic bag is pulled down to allow the mobile phase to contact the lower 1 cm of the layer. Development is carried out to within 1 cm of the top of the sheet with 15–18 ml of the mobile phase specified for the particular drug being analyzed: methanol–conc. ammonium hydroxide (25:0.38), methanol–acetone–conc. ammonium hydroxide (13:17:1), or ethyl acetate–glacial acetic acid–conc. ammonium hydroxide–water (12:12:4:4). The development bag and back-to-back aluminum trays will accommodate two sheets at a time.

The spots for all drugs can be detected, after drying the layer, under 245 nm UV light in a TLC viewing box or in an unlighted room, and/or by iodine staining. The KI–iodine staining solution is placed in a plastic bag, the sheets are immersed in the reagent, and they are then removed and the spots observed after excess reagent is evaporated. Most drugs are detectable using the iodine reagent, so this method is applicable when UV light is unavailable (e.g., absence of electricity or batteries to power a UV lamp).

After detection, visual inspection is made to assure that the sample spot size and intensity are between those of the standards. Other criteria for an acceptable drug analysis include no additional, unexplained spots in the sample and exact line up of standard and sample spots (identical R_F values).

The recipe for the KI–crystalline iodine reagent containing water, ethanol, and HCl and the preparation and use of the plastic bags are described in detail in the original paper,[7] along with drug R_F values in the three mobile phases. Experimental details are given in the paper for standard and sample preparation and TLC analysis of ethambutol hydrochloride (100 and 400 mg tablets), isoniazid (100 and 300 mg tablets), pyrazinamide (400 mg tablets), rifampin (150 mg capsules), streptomycin sulfate (200 mg/ml injectable), and various fixed combinations of two or three of these drugs.

FAST CHEMICAL IDENTIFICATION SYSTEM (FCIS)

The FCIS[8] was developed in China for determination in a drug testing laboratory of 10 macrolide antibiotics in different preparations, including erythromycin, roxithromycin, clarithromycin, azithromycin, erythromycin ethylsuccinate, midecamycin, meleumycin, kitasamycin, acetyl-kitasamycin, and acetylspiramycin. The system comprises two color reactions based on functional groups in the molecules and two TLC methods for screening of fake macrolide antibiotics after preparing test solutions by dissolving of tablet, granule, capsule powder, and dry suspension samples in absolute ethanol. For the color reactions, sulfuric acid as a common reaction of macrolides is first used to distinguish them from other types of drugs, then 14- and 16-membered macrolides are classified by potassium permanganate reactions depending on the time for loss of color in the test solution. Two TLC analyses on silica gel GF_{254} plates are used for further identification by comparison of sample and standard spots; the mobile phase is ethyl acetate–hexane–conc. ammonium hydroxide (100:15:15) for 14-membered macrolides and trichloromethane–methanol–conc. ammonium hydroxide (100:5:1) for 16-membered macrolides. Mobile phase development and spot detection with iodine vapor are carried out in closed TLC tanks. A suspected counterfeit macrolide preparation can be identified within 40 min.

MINILAB TLC SYSTEM

The main field screening method in use today is based on the portable Minilab kit, developed by the German Pharma Health Fund (GPHF).[1] The Minilab uses TLC procedures similar to those in the Speedy TLC system (above) except for crushing tablets inside aluminum foil instead of a plastic bag, development of layers and detection of spots in bottles instead of plastic bags, and detection with iodine vapor sublimed from crystals rather than KI–iodine solution. All necessary apparatus, reagents, and standards are included to test for 40 drugs on the WHO Essential Drug List (Table 1). This list features antibiotics and

Table 1 Drugs analyzed by the Minilab TLC kit.

acetylsalicylic acid	aminophylline	amodiaquine	amoxicillin
ampicillin	artemether	artesunate	cefalexin
chloramphenicol	chloroquine	ciprofloxacin	cloxacillin
cotrimoxazole	didanosine	erythromycin	ethambutol
furosemide	glibenclamide	griseofulvin	indinavir
isoniazid	lamivudine	lumefantrine	mebendazole
mefloquine	metamizole	metronidazole	nevirapine
paracetamol	Phenoxymethylpenicillin	prednisolone	primaquine
pyrazinamide	Quinine	rifampicin	salbutamol
stavudine	sulfadoxine/pyrimethamine	tetracycline	zidovudine

chemotherapeutical agents frequently used in the developing countries of the southern hemisphere, which when counterfeited can be a serious threat to patients' lives. The original Minilab TLC manual, dated 1998, and subsequent supplements (1999–2004) with detailed instructions covering analysis of the 40 drugs are available on the GPHF website.[9]

The first step in the Minilab protocol for screening counterfeit drugs is visual inspection of the product (e.g., size, shape, color) and its labeling and packaging, and comparison with a genuine example. Many fake medicines have been found at this step, but in some cases they are becoming harder to spot in this way because of an improved quality of copying the genuine packaging in the illicit manufacturing process. A dissolution and disintegration test is then carried out by dropping a tablet or capsule in warm (37°C) water contained in a 100 ml wide neck bottle and swirling periodically. Unless the product is labeled "slow release" or "enteric," it should disintegrate within 30 min, measured with a preset timer, or be suspected of being illegal.

The third stage is the use of simplified test tube color reactions for a quick check of the presence of any amount of a drug active ingredient in the sample. An example is a colorimetric field assay for artesunate based on the reaction of fast red TR salt with an alkali decomposition product of the drug to produce a distinct yellow color. Screening tests based on color reactions can be fooled by addition of another ingredient reacting the same as the active ingredient, or a small amount of the genuine pharmaceutically active substance, into the counterfeit drug product. In this case, a yes/no response is not adequate, and the method must be at least semiquantitative, like TLC.

In support of the TLC drug assays, the Minilab supplies a collection of authentic secondary standard tablets and capsules in sealed plastic tubes. The standard and the sample from a sachet or in the form of a hard gelatin capsule, soft gelatin capsule, or tablet are placed into glass bottles, and a designated volume of extraction solvent is added from a calibrated measuring pipette to prepare the stock solutions. The working solutions are prepared in 10 ml vials by appropriate dilution using pipettes. The origin and mobile phase line are marked using a soft pencil on an aluminum-backed 5×10 cm silica gel 60 F_{254} layer (called a "chromatoplate"), and disposable 2 μl glass micropipettes are used to spot the standards and sample 1.5 cm up from the bottom edge. The uniformity of the initial spots (they should be circular and evenly spaced) is checked under a 254 nm UV lamp. Layers are developed in glass jars with lids and lined with filter paper on all sides; the mobile phase is added, and after 15 min of equilibration the jar is opened and the spotted layer is quickly inserted so that the initial spots are above the mobile phase level. After development up to the marked line (about three quarters of the layer length), the chromatoplate is removed, and the mobile phase is evaporated with the help of a hotplate (a travel iron placed upside down). The spots are viewed under battery-operated 254 nm and 366 nm UV lamps. If necessary, spots not detected under UV light are detected as yellowish brown spots by placing the layer inside a capped jar containing iodine crystals and heating for about 30 sec on the hotplate. The spots detected with iodine and the spots seen under the UV lamps are marked with the soft pencil for documentation. After each analysis, all components of the kit must be thoroughly cleaned and dried and returned to the protective airtight and waterproof carrying case, and solutions must be disposed of properly.

The Minilab TLC analysis identifies the active ingredient by comparison of distance of travel (R_F value) between the sample spot and an authentic standard spotted on the same plate, and semiquantitative proof of content is made by visually comparing the color, size, and intensity between the sample spot and reference spots for each method of detection. Every drug has a detailed individual monograph for its analysis. As an example, the monograph for cotrimoxazole has the following sections: principle, equipment and reagents, preparation of the stock standard solution from the reference tablet, preparation of the 100% working standard solution (upper working limit), preparation of the 80% working standard solution (lower working limit), preparation of stock standard solution from a tablet

claiming a potency of 120 or 240 mg cotrimoxazole per unit, preparation of the working sample solution, spotting, development (including the mobile phase composition and development time), detection, example of the chromatoplate observed at 254 nm (containing four chromatograms: cotrimoxazole's upper limit representing 100% of total drug, a drug of good quality, a drug of poor quality, and cotrimoxazole's lower working limit representing 80% of total drug), observations to be made at 254 nm, observations to be made during iodine staining, and results and actions to be taken. Some drug monographs include a third detection method, e.g., anisaldehyde solution for artesunate.

A proficiency test was carried out recently to assess the performance of Minilab visual TLC quantification estimates.[10] Samples were made at 0%, 40%, and 100% from a drug reference tablet and given, unidentified, to inspectors with the Minilab protocol for quality screening. In round 1 of the proficiency test, only 3 of 28 substandard samples were correctly identified. Round 2, administered after a performance qualification test for the analytical method, showed improvement: 19 of 27 substandard drugs were correctly identified, while 5 out of 9 inspectors made the correct inference on the quality of 45 samples. In both rounds, two inspectors failed to identify substandard samples. These results show the need to have competent, well-trained users and to include a proficiency test in the Minilab screening program to obtain reliable results.

CONCLUSION

The TLC assays described here are a valuable aid in protecting patients from taking counterfeit and substandard quality medicines. They are more informative than visual inspection, dissociation tests, or simple color reaction tests, and their standardized format, ease of performance in the laboratory or in the field by persons without extensive technical training, and low cost are of great benefit to developing countries throughout the world in screening medicines used for fighting diseases such as TB and malaria. More costly analyses in a fully equipped analytical laboratory, such as infrared or mass spectrometry, electrophoresis, or high-performance column liquid chromatography,[11] are required only if the TLC-screening results are ambiguous. This application of TLC is arguably the most significantly important one being carried out in the world today.

CPC

M.-C. Rolet-Menet
Analytical Chemistry Laboratory, Unit of Formation and Research (UFR) of Pharmaceutical and Biological Sciences, Paris, France

INTRODUCTION

Centrifugal partition chromatography (CPC) is a method based on countercurrent chromatography (CCC). Separation is based on the differences in partitioning behavior of components between two immiscible liquids. Like high-performance liquid chromatography (HPLC), the phase retained in the column is called the stationary phase, and the other one, the mobile phase. In CCC, there are two modes by which to equilibrate the two immiscible phases. They depend on the characteristics of the centrifugal force field, which permits retention of the stationary phase inside the column. Devices that equilibrate the phases according to the so-called "hydrodynamic mode" were developed by Mandava and Ito.[1] They use a centrifugal force variable in intensity and direction. Alternating zones of agitation and settling of both phases are present along the column. In contrast, CPC uses a so-called "hydrostatic mode," owing to a centrifugal force constant in intensity and direction. Therefore, the mobile phase penetrates the stationary phase either by forming droplets, or by jets stuck to the channel walls, broken jets, or atomization. The more or less vigorous agitation of both phases depends on the intensity of the centrifugal force, the flow rate of the mobile phase, and the physical properties of the solvent system. Chromatographic separations obtained in hydrostatic mode are less efficient than those in the hydrodynamic one. But the retention of the stationary phase is less sensitive to the physical properties of solvents systems, such as viscosity, density, and interfacial tension. This particularity justifies the wide application field of CPC.

APPARATUS

The CPC column is made of channels engraved in plates of an inert polymer (Fig. 1), and they are connected by narrow ducts. Several plates are put together to form a cartridge. The cartridges are placed in the rotor of a centrifuge and connected to form the chromatographic column. The mobile phase enters and leaves the column via rotary seals. Since two immiscible liquids are present in the channel, the denser liquid moves away from the axis because of the centrifugal force. The less dense liquid is pushed toward the axis. The mobile phase can be either the lighter or the denser phase. In the latter case, the mobile-phase flows through the channels from the axis to the outside of the rotor. This is called the descending mode. The other case, where the mobile-phase flows toward the axis, is called the ascending mode.

Hydrostatic apparatuses are manufactured by Sanki Engineering Limited (Kyoto, Japan). They include two types of devices: The first is designed for analytical or semipreparative scale applications, and the second for scale-up at industrial scale. Centrifugal partitioning chromatograph type LLN was introduced in 1984 but is no longer available since 1992. It could be thermostatted from 15 to 35°C in an ambient temperature of 25°C. Type high-performance centrifugal partition chromatography (HPCPC) or Series 1000 supersedes type LLN. The HPCPC main frame is a 31 × 47 × 50 cm centrifuge operating in the range 0–2000 rpm; it cannot be thermoregulated. The rotor consists of two packs of six disks each, connected through a 1/16 in. tubing, and easily removable. Larger instruments have internal volumes from 1.4 to 30 L, can be used with flow rates ranging from 20 to 700 ml/min, and are custom designed for specific separation processes at a small industrial scale.

RETENTION OF STATIONARY PHASE

Before any use, the column is first filled with stationary phase and then rotated at the desired rotational speed. The mobile phase is then pumped into the cartridge at the desired flow rate and pushes out of the column a certain volume of stationary phase. Hydrostatic equilibrium is reached when the mobile phase is expelled at the column outlet. The retention of stationary phase, S_F, is defined as $S_F = V_s/V_t$, where V_s is the stationary phase volume in the column after equilibrium and V_t the total volume of the column.

The value of S_F depends on several parameters,[2,3] including the hydrodynamic properties of the channels, the centrifugal force (S_F increases to reach a maximum with the centrifugal force), the Coriolis force defined by the clockwise or counterclockwise column rotation[4] (higher retention of stationary phase is obtained with counterclockwise rotation), the mobile-phase flow rate (S_F decreases linearly with mobile-phase flow-rate), the physical properties of the solvent system (such as viscosity, density, interfacial tension), the sample volume, the sample concentration, the tensioactive properties of the

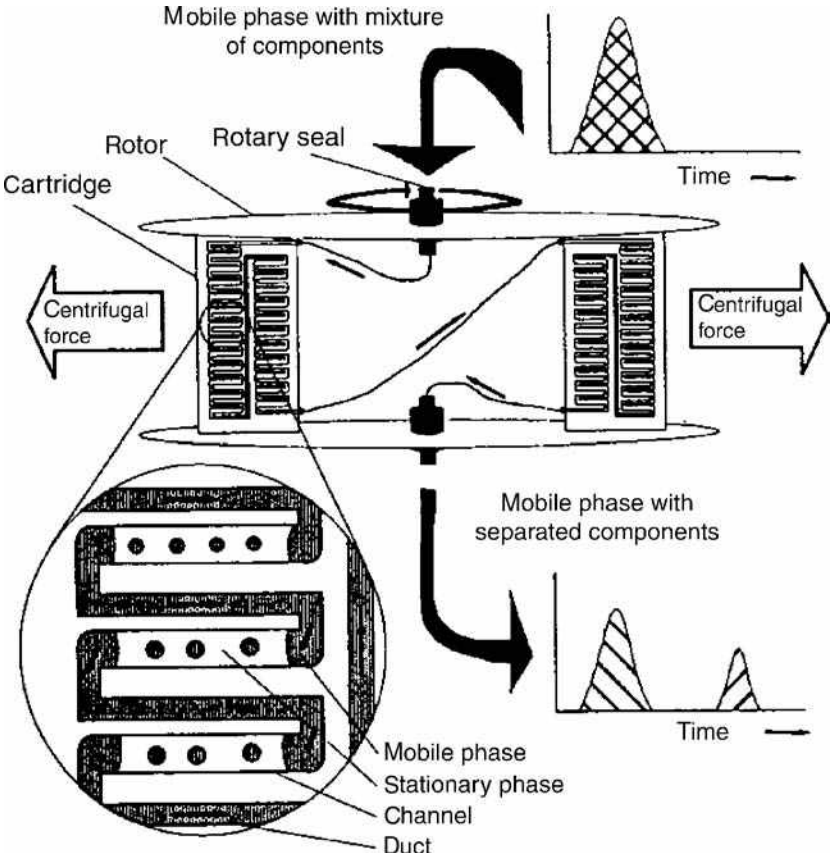

Fig. 1 Schematic representation of the CPC apparatus.
Source: From Pressure drop in centrifugal partition chromatography, in *Centrifugal Partition Chromatography*.[8]

solutes to be separated, etc. It is necessary to precisely monitor S_F because various chromatographic parameters depend on it, in particular the efficiency, the retention factor, and the resolution. Foucault[3] proposed an explanation for the variation of S_F with the various parameters described previously. He modeled the mobile phase in a channel as a droplet and applied the Stokes law, which relies on the density difference between the two phases, the viscosity of the stationary phase, and the centrifugal force. Then, he applied the Bond number derived from the capillary wavelength, which was formerly introduced for the hydrodynamic mode[5] and which relies on the density difference between the two phases, the interfacial tension, and the centrifugal force.

PRESSURE DROP

Van Buel, Van der Wielen, and Luyben[6] have proposed a model to explain the considerable pressure drop arising in the column during CPC separation. The overall pressure drop is the sum of the hydrostatic pressure drop term and the hydrodynamic pressure drop terms over the individual parts of the system. The hydrostatic contribution is caused by the difference in density between the liquids in the ducts and in the channels ($\Delta P_{stat} = nl\Delta\rho\omega^2 R$, where n is the number of channels, l the height of stationary phase in the channel, $\Delta\rho$ the density difference between the phases, ω the rotational speed, and R the average rotational radius of the cartridge). The hydrodynamic contribution (ΔP_{hydr}) is caused by the friction of the mobile phase with the walls of the channels and ducts. This latter, in a channel and a duct, is proportional to the mobile-phase density, the square of its linear velocity, the lengths of channel and duct, and the inverse of channel and duct diameter. Consequently, the overall pressure drop depends on the flow rate and rotational speed (input variables), the physical properties of the two-phase solvent system (variables), the geometry of the channels and ducts, the number of channel–duct combinations (apparatus variables), and the hold-up of stationary phase in the channel. The maximum pressure is limited by the rotary seals, which can support about 60 bars before leaking. Resolution and efficiency depend on the same variables as the pressure drop. Therefore, it is important to determine which combinations of input variables and liquid two-phases systems can be applied, with respect to the maximum pressure that can be supported by the rotary seal.

EFFICIENCY

For a symmetrical peak, Efficiency (N) in CCC can be defined as in HPLC by

$$N = 16\left(\frac{V_r}{\omega}\right)^2$$

where V_r is retention volume of the solute and ω the peak base width expressed in volume units as V_r. For an asymmetrical peak, efficiency can be defined according to the Foley–Dorsey formula

$$N = 41.7 \frac{(t_r/\omega_{0.1})^2}{(A/B) + 1.25}$$

where $\omega_{0.1}$ is the peak width at 10% of the peak height and A/B the asymmetry factor, with $A + B = \omega_{0.1}$.

Centrifugal partition chromatography apparatuses are still generally regarded as lacking efficiency (compensated by high, selectivity and S_F). The efficiency variation shows a minimum when the flow rate of the mobile phase is increased, which is the opposite of the usual HPLC Van Deemter plot. This observation has been modeled by Armstrong, Bertrand, and Berthod.[7] The mobile phase, when it comes out of the duct, flows very quickly to reach an intermediate emulsified layer and then settles in a third step before being transferred to another channel. In these conditions

$$\mathrm{In}(1 - E) = \frac{A}{F} - BF^b$$

where

$$E = \frac{C_{m,t} - C_{m,0}}{C_{m,eq} - C_{m,0}}$$

$C_{m,t}$, $C_{m,0}$ and $C_{m,eq}$ are the solute concentrations in the mobile phase at a moment t, before equilibrium, and after equilibrium, respectively, and A depends on S_F, B on the physical properties of the solvent system, and b on the solute and solvent systems. This variation is very interesting because it shows that a high-mobile-phase flow rate decreases the retention time without decreasing efficiency. However, it is observed that S_F decreases with the flow rate and the resolution R_s also decreases, as described in the following section. The flow rate of the mobile phase may be increased to lower the separation time but on condition that S_F remains adequate to maintain a sufficient R_s and consequently the quality of separation remains satisfactory.[2] Van Buel, Van der Wielen, and Luyben[8] first improved the understanding of the influence of flow patterns on the mass transfer between the two liquid phases and the chromatographic efficiency of CPC instruments. They directly visualized the mobile-phase flow through the stationary phase (in a plane parallel to the rotation axis) as a function of the rotational speed and flow rate of the mobile phase. Four main types of flow states were observed: large droplets, jets stuck along the channel walls, broken jets, and atomization. Marchal et al.[9] visualized the mobile-phase flow in a plane perpendicular to the rotation axis for different solvent systems [heptane/methanol (heptane/MeOH), chloroform/*n*-propanol/methanol/water (chloroform/*n*-ProOH/MeOH/W), heptane/chloroform/*n*-ProOH/MeOH/W, *n*-butanol/acetic acid/water (n-ButOH/acetic acid/W), aqueous two-phase systems]. They confirmed the observations of Van Buel et al. and observed deviations of jets or droplets from the radial direction caused by the Coriolis force. They correlated the chromatographic efficiency to the flow pattern observed: non-Gaussian peak corresponding to the jets stuck along the channel wall, and increase of efficiency when jets come unstuck from the walls. Increase of flow rate and rotation speed generally yielded better efficiencies.

RESOLUTION

Resolution (R_s) in CCC can be defined as in HPLC by

$$R_s = 2 \frac{V_{r2} - V_{r1}}{\omega_1 + \omega_2} = 2V_s \frac{K_2 - K_1}{\omega_1 + \omega_2}$$

where V_{r1} and V_{r2}, ω_1 and ω_2, and K_1 and K_2 are, respectively, the retention volumes, the peak base widths expressed in volume units as V_r, and the partition coefficients of the first and second eluted solutes. R_s is directly proportional to volume V_s of the stationary phase and hence on the flow rate of the mobile phase and the centrifugal force.[2,10] Resolution in CCC, as in HPLC, is governed by the Purnell relation

$$R_s = \frac{\sqrt{N}}{4} \frac{k_2'}{1 + k_2'} \frac{1 - \alpha}{\alpha}$$

where k_2' is the retention factor of the second solute and α the separation factor. N is controlled by F, the centrifugal force, S_F, and the physical properties of solvent system, k' by the nature of the solvent system (through the partition coefficient, K, and S_F), and α mainly by the solvent system. This relation shows that it is essential in CCC to control technical parameters and to judiciously choose the solvent system to separate the products. Moreover, Ikehata et al.[4] showed that partition coefficients, efficiencies, and Rs were improved by rotating the column in the clockwise direction.

SOLVENT SYSTEMS

The choice of the solvent system is the key parameter to good separation. On one hand, its physical properties define S_F, N, and R_s, on the other hand, the relative polarities of its two phases define the partition coefficients of the solutes and, as a result, the selectivities and the retention factors. The usual solvent systems are biphasic and made of three solvents, two of which are immiscible. We only give guidelines for the choice of solvent system. If the

polarities of the solutes are known, the classification established by Ito[1] can be taken as a first approach. He classified the solvent systems into three groups, according to their suitability for non-polar molecules ("non-polar" systems), intermediary polarity molecules ("intermediary" system), and polar molecules ("polar" system). The molecule must have a high solubility in one of the two immiscible solvents. The addition of a third solvent enables better adjustment of the partition coefficients. When the polarity of the solutes is not known, the Oka[11] approach uses mixtures of *n*-hexane (HEX), ethyl acetate (EtOAc), *n*-ButOH, MeOH, and water ranging from the HEX/MeOH/W (2:1:1; v/v/v) to the *n*-ButOH/W (1:1; v/v) systems and mixtures of chloroform, MeOH, and water. This solvent series covers a wide range of hydrophobicities, from the non-polar HEX/MeOH/W system to the polar *n*-ButOH/W system. Moreover, all these solvent systems are volatile and yield a desirable two-phase volume ratio of about 1. The solvent system leading to partition coefficients close to 1 is selected.

APPLICATIONS

Numerous applications using CPC are described in reference books,[1,3] covering organic and mineral solutes (Table 1). We only give key examples extracted from the CPC literature.

Polyphenols and Tannins

Open column chromatography with silica gel and alumina is not applicable to the fractionation of tannins because of their strong binding to these adsorbents, which induces extensive loss of the compounds. Such losses do not occur with CCC, as it does not use a solid stationary phase. Such molecules are very polar, so that butanol-based solvent systems can be used. Centrifugal partition chromatography is more appropriate in this case compared to hydrodynamic CCC thanks to the good retention of the stationary phase of this solvent system. Okuda, Yoshida, and Hatano[14] separated castalagin from vescalagin by using the solvent system *n*-ButOH/*n*-ProOH/W (4:1:5; v/v/v). They are diastereoisomers that differ only in the configuration of the hydroxyl group of the central carbohydrate moiety. In the same way, these authors have separated oligomeric hydrolysable macrocyclic tannins oenothein B and woodfordins by using *n*-ButOH/*n*-ProOH/W (4:1:5; v/v/v). In spite of a small structural difference (presence or absence of a galloyl group), these dimers showed a considerable difference of partition coefficients in this solvent system (0.36 for woodfordin C and 0.19 for oenothein B).

Preparative Separation of Raw Materials

One of the major applications of CPC is the purification of natural products from vegetal extracts (flowers, roots, etc.) or crude extracts from fermentation broth without previous sample preparation. Hostettmann and coworkers[12] have described many examples of isolation of natural products by CPC. Some flavonoids are, for instance, purified by using solvent systems containing chloroform, some coumarins by using solvent systems containing HEX and EtOAc, and more polar products, such as tannins, by butanol-based systems. The main interest of this technique lies, however, in the possibility to overload its column so that all the applications of semipreparative chromatography are available. For instance, Menet and Thiébaut[15] have separated 140 mg of an antibiotic from a crude extract of a fermentation broth. Some fractions of up to 95% purity were collected, while the original extract contained only 7% of the molecule of interest. They have also compared the performances of CPC, preparative LC, and hydrodynamic mode CCC. They finally showed that the solvent consumption is the lowest for CPC, while the enrichment is the best.

The pH-zone refining mode was introduced by Ito.[16] It is a variant of displacement chromatography. It is devoted to the purification of compounds whose electric charge depends on pH. For example, a mixture of free acids is injected in the organic stationary phase along with an acid stronger than all the compounds to be separated. The

Table 1 Applications in CPC.

Species	Solvents system
Polyphenols and tannins[3]	$CHCl_3$/MeOH/W (7:13:8; v/v/v), $CHCl_3$/MeOH/ *n*-ProOH/W (9:12:2:8; v/v/v/v), *n*-ButOH/*n*-ProOH/W (4:1:5; v/v/v)
Triptolide and tripdiolide[3]	HEX/EtOAc/CH_2Cl_2/MeCN/MeOH/W (12:10:3:10:5:6; v/v/v/v/v/v)
Lanthanoids[3]	HEX containing *bis*(2-ethylhexyl)phosphoric/0.1 mol/L (H, Na)Cl_2CHCOO to an appropriate pH
Flavonoids[12]	$CHCl_3$/MeOH/W (5:6:4; v/v/v)

Tannins[12]	*n*-ButOH/*n*-ProOH/W (2:1:3; v/v/v)
Naphthoquinones[12]	HEX/MeCN/MeOH (8:5:2; v/v/v)
Retinals[12]	C_6H_6/*n*-C_5H_{12}/MeCN/MeOH (500:200:200:11; v/v/v/v)
Chiral compounds[13]	Various systems containing chiral selectors

compounds are moved along the column by pumping a basic aqueous mobile phase. Pure products are eluted from the column as salts, by contiguous rectangularly shaped peaks arranged according to the pK_a values and partition coefficients. This mode allowed a preparative isolation of indole alkaloids from *Catharanthus roseus*[17] The solvent system consisted of a mixture of methyl-*tert*-butyl ether, acetonitrile, and water. The upper organic phase was made basic with triethylamine and used as the mobile phase. The lower aqueous phase was acidified by hydrochloric acid.

log $P_{oct/water}$[18,19]

Octanol–water partition coefficients ($K_{o,w}$) have been established as the most relevant quantitative physical property correlated with biological activity. Centrifugal partition chromatography using octanol and water as the two phases is a useful alternative for providing octanol–water partition coefficients ($K_{o,w}$). It offers automation advantages compared to HPLC and the shake-flask method. Three approaches for determining $K_{o,w}$ by CPC have been described. The normal mode consists in equilibrating the CPC column according to a normal equilibrium and the overloading mode by artificially decreasing the volume of the stationary phase. $K_{o,w}$ is calculated according to the classical formula $K = k'(V_t - V_s)/V_s$ The second procedure is the dual-mode method,[20] which is based on the exchange of the role of the mobile and stationary phases during the experiment. Therefore, the determination range of partition coefficients can be extended. The third procedure, the cocurrent mode, relies on the simultaneous pumping of a mixture of a small flow of octanol and a larger flow of water to elute strongly retained compounds.

Elution Gradient[21,22]

Another way to extend the polarity range of analyzed compounds is the elution gradient. During the separation, the composition of the mobile phase is modified, while the composition of the stationary is kept constant. But in CPC, when the composition of the mobile phase is modified, the composition of the stationary phase changes. To prevent instability of the stationary phase during a gradient run, the change in stationary phase composition should be lower than 20% (v/v). Not all ternary two-phase systems are suitable for elution gradient. Foucault and Nakanishi[23] gave an overview of two-phase systems that are suitable for gradient elution.

CONCLUSIONS

Centrifugal partition chromatography is a method based on CCC. Devices equilibrate the phases according to a so-called "hydrostatic mode" owing to a centrifugal force constant in intensity and direction. So, the retention of the stationary phase is less sensitive to the physical properties of solvent systems compared to the "hydrodynamic mode." This particularity justifies the wide application field of CPC: use of *n*-But OH solvent systems, aqueous two-phase systems, and elution gradient. Moreover, the largest instruments have an internal volume from 1.4 to 30 L and are custom designed for specific separation processes at a small industrial scale. Finally, a better understanding of CPC (influence of Coriolis force) shows that the geometry of channel and duct are critical. A new CPC apparatus could take this into account.

Abstract
Creatinine and purine derivatives are frequently analyzed in human and veterinary clinical chemistry laboratories. We present here an overview of high-performance liquid chromatography (HPLC) and other current analytical methods, including photometric and enzymatic determinations, capillary electrophoresis (CE), and gas chromatography–mass spectrometry (GC–MS) for the measurement of these compounds.

INTRODUCTION

Creatinine and purine derivatives—allantoin, uric acid, hypoxanthine, and xanthine present in biological samples—are important analytes for diagnoses of certain types of metabolic diseases and can serve as markers for these processes. Analyses for such substances are crucial for diagnosis and the monitoring of renal diseases, metabolic disorders, and various types of tumorigenic activity. On the contrary, these compounds are very important in the field of animal nutrition, because the measurement of their urinary excretion is being used as an internal marker for microbial protein synthesis.

OVERVIEW

Creatinine is an important analyte of clinical significance that results from the irreversible, non-enzymatic dehydration and loss of phosphate from phosphocreatine (Fig. 1). Creatine is synthesized from amino acids in the kidney, liver, and pancreas. The creatine is then transported in the blood to other organs where it is synthesized into creatinine. Creatinine detection in biological fluids is a clinical test for thyroid and muscular function and for detection of myocardial infarction. Urine and serum creatinine concentrations are used to adjust the values of urinary biological indicators, and its concentrations are very useful indexes for evaluating glomerular filtration rate of the kidneys and, in general, for indicating renal function.

Allantoin is the catabolic end product of purines in most mammals. It is formed by the action of the enzyme uricase on urate. Humans and other primates lack uricase and excrete urate as the final product of purine metabolism. However, small amounts of allantoin are present in human serum. Some authors demonstrated that free radical attack on urate generates allantoin. Therefore, small amounts of allantoin detected in human serum may provide a marker of free radical activity in vivo. In humans, the allantoin to uric acid ratio in plasma increases during oxidative stress, and thus this ratio has been suggested to be an in vivo marker for oxidative stress in humans.

Uric acid is the major product of purine metabolism, and it is degraded to allantoin in most mammals by hepatic enzyme, the urate oxidase, and excreted with the urine. Hypoxanthine and xanthine are intermediates along this pathway (Fig. 2). Under normal conditions, they reflect the balance between the synthesis and breakdown of nucleotides. Levels of these compounds change in various situations (e.g., they decrease in experimental tumors), when synthesis prevails over catabolism, and are enhanced during oxidative stress and hypoxia. Uric acid is considered an important antioxidant in human adult plasma because it can directly react with free radicals. Uric acid has been employed as a biomarker of health and nutritional status. The regular measurement of its plasma and urine concentrations has important clinical utility in disease diagnoses such as gout, hyperuricemia, the Lesch–Nyhan syndrome, and the Down syndrome. Xanthines are also markers for metabolic disorders such as xanthinuria and for several central nervous system disorders such as hypoxia, hepatic encephalopathy. Nowadays in forensic toxicology the hypoxanthine levels in vitreous humor are being applied to the estimation of postmortem interval.

In ruminants, the concentration ratio of purine derivatives to creatinine (PD:C) has been widely used in metabolism studies to determine the nutrient utilization by these animals and by the ruminal microbes.

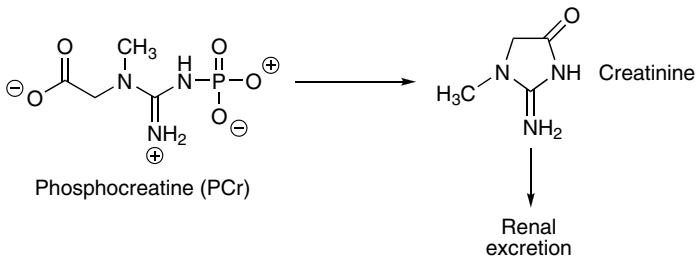

Fig. 1 Degradation of purine nucleotides and formation of purine derivatives.

SAMPLE PREPARATION

Determination of these compounds is carried out frequently in biological fluids. Analysis in urine and saliva requires previous filtration to remove cells and other particulate matter; then, the samples are diluted and directly injected onto the column. With cerebrospinal fluid, the samples are obtained by lumbar puncture; each aliquot is centrifuged and decanted before analysis. Often in plasma or serum, some form of protein removal is needed because the presence of these compounds in injected samples can cause modifications of the column and bias in chromatographic results. Protein removal can be performed by various methods, such as protein precipitation, ultrafiltration, centrifugation, liquid-phase or solid-phase extraction, and column-switching techniques. Vitreous humor samples were collected in tubes containing sodium fluoride to block the enzymes involved in glycolysis. Each sample was centrifuged and only the supernatant was used for analysis.

ANALYSIS OF CREATININE

The common spectrophotometric method for creatinine detection is based on the Jaffé reaction between creatinine and picric acid in alkaline solution to form a red-yellow complex. However, substances of endogenous and exogenous origin usually cause interference. In spite of these problems, the colorimetric method of Jaffé is still used today for the determination of creatinine in biological samples.[1] A batchwise kinetic procedure and flow injection analysis have shown the possibility to determine creatinine in human urine samples by this reaction, free from any systematic error.[2] Enzymatic methods have been reported to increase specificity/selectivity but still suffer from interferences. To avoid these problems, new analytical methods were developed. Several electroanalytical techniques, based on potentiometric or amperometric detection, are available. Potentiometric methods using several sensors and biosensors were known for the

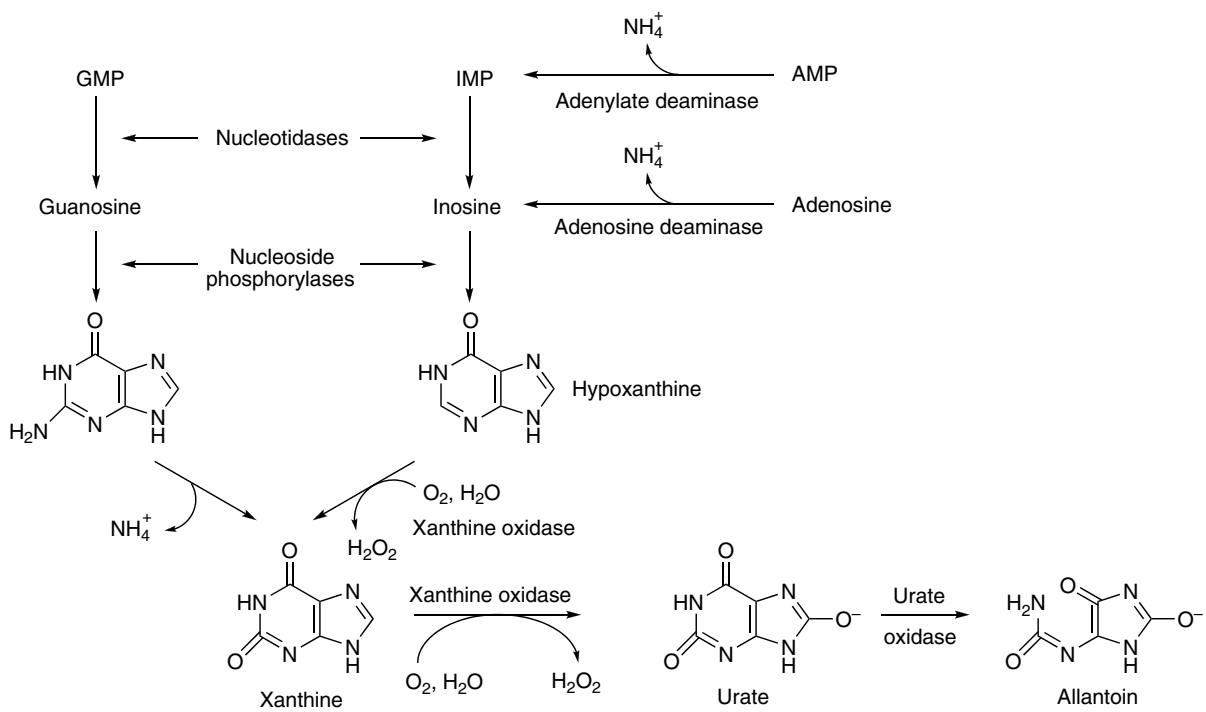

Fig. 2 Phosphocreatine metabolism.

determination of creatinine among other metabolites in biological fluids.[3–4] Capillary electrophoresis (CE), capillary zone electrophoresis (CZE), and isotope dilution–gas chromatography–mass spectrometry (ID–GC–MS),[5] proposed as a reference method, have also been used in the analysis of creatinine in human serum and urine. The advantages of CE techniques, such as a relatively short time of analysis, a usually high efficiency of resolution obtained, and a minimal amount of sample required, make electromigration techniques especially valuables in creatinine determination.[6]

Chromatographic techniques have been very useful for clinical analysis, with advantages of simultaneous measurements of different components and the elimination of interfering species. Previous reviews have been realized for the determination of creatinine.[7] High-performance liquid chromatographic (HPLC) methods include ion-exchange chromatography, reversed-phase (RP) chromatography, ion-pair chromatography, and micellar electrokinetic capillary chromatography (MEKC), and more complicated column-switching and tandem methods[8] have been described as well.

Some authors compare different methods such as electrochemical, electrophoretic, enzymatic, chromatographic, and spectrophotometric, proving that, in general, the colorimetric assays overestimated creatinine measurements.

Urinary creatinine can be analyzed by HPLC using a variety of columns. Detection methods include absorption, fluorescence after postcolumn derivatization, MS, and some other methods. The application of biosensors in HPLC could improve detection, and, in many cases, allows the detection of solutes otherwise undetectable by the common method. Review of the recent literature revealed that the method of choice for the measurement of creatinine has been RP-HPLC. C_8 and C_{18} columns and UV or electrochemical detection (ED) with isocratic elution or gradient elution were mostly used.[9]

In most cases, RP ion-pairing HPLC with UV-photometric detection was used. The advantage of this technique is the broad range of parameters that may be conveniently adjusted to optimize the separation method; they include the concentration of organic modifier in the mobile phase, the type and concentration of buffer in the mobile phase, and the type and concentration of the counterion.[10] In addition to ion-exchange methods, some authors have developed a procedure for the determination of creatinine and a wide range of amino acids that provides for fixed-site ion exchangers that eliminates the addition of ion-pairing agent in the mobile phase.[11] Creatinine has been analyzed in sera and tissues using HPLC and CE methods. Many of these determinations could also be applied to urinary creatinine analysis.

Various papers related to the simultaneous determination of creatinine and uric acid can be found in the literature. Several authors have developed CZE methods for the simultaneous analysis of these compounds in urine. The CE analysis of these renal markers offers some advantages when compared with chromatography, such as shortened separation time, reduced reagent consumption, and increased resolution. Micellar electrokinetic capillary chromatography has been applied to the simultaneous separation of creatinine and uric acid in human plasma and urine. However, chromatographic techniques are widely accepted for the determination of these compounds. Reversed-phase and ion-pair HPLC methods were applied for the simultaneous determination of these compounds in sera. These methods were consistent with the ID–GC–MS reference method. An anion-exchange HPLC-ED method using disposable electrodes has been proposed for the simultaneous determination of creatinine, uric acid, and other urinary metabolites. It requires only a small amount of urine and no sample preparation is needed. Disposable electrodes make it possible to avoid reconditioning, which are required with non-disposable electrodes.[12]

PURINE DERIVATIVES: ALLANTOIN, URIC ACID, XANTHINE, AND HYPOXANTHINE

Traditionally, oxypurines allantoin, uric acid, and, in some cases, xanthines have been analyzed in biofluids by colorimetric methods. The analysis of allantoin was based on the Rimini–Schriver reaction, in which allantoin is converted to glyoxylic acid by sequential hydrolysis under alkaline and acidic conditions, and then derivatizated with 2,4-dinitrophenylhidrazine to obtain the chromophore glyoxylate-2,4-dinitrophenylhydrazone.

The two predominant analyses of uric acid are the phosphotungstic acid (PTA) method and the uricase method. In the PTA method, urate reduces PTA to form a blue product. In the uricase analysis method, urate is oxidized by uricase oxidoreductase.

Xanthine and hypoxanthine have often been quantified colorimetrically or as uric acid following enzymatic conversion. Both approaches were problematic due to interference by compounds contained in biological fluids, whereas enzymatic conversion to uric acid has often been incomplete.

These photometric and enzymatic methods suffer from interferences by endogenous and exogenous compounds and can lead to inaccurate results. To avoid these problems, in recent years, other methods involving ED, biosensors, CZE, GC–MS, and HPLC methodology have been developed. Reversed-phase, normal-phase, ion-exchange, ion-pair, column-switching, MEKC, and size-exclusion chromatography were used for determining purine derivatives.

Different methods, mostly colorimetric and chromatographic, for the determination of allantoin have been reviewed by Chen.[13] The chromatographic procedures are mainly based on separation by HPLC using C_{18} RP columns and monitoring at wavelengths around 200 nm. Many compounds present in plasma and urine also exhibit absorbance at these

wavelengths; therefore, the detection of allantoin is not selective enough when the concentration is low (<60 μmol/L).[13] To avoid this problem, allantoin can be converted, before elution, to a derivative, which can be monitored at a more specific detection wavelength. However, allantoin is an extremely polar compound that has poor retention on C_{18} RP columns. To achieve a good separation from other polar compounds, the column length often needs to be extended. Another way to overcome the problem is the use of ion-pairing agents to slow down the elution.

For uric acid, ID–GC–MS[5] has been proposed as the candidate reference method. RP methods have been most widely employed. RP C_8 and C_{18} columns ranging from 150 to 250 mm in length and usually with an internal diameter 3.9–4.6 mm were used. Both isocratic elution and gradient elution were applied. Variable-wavelength UV or diode array detectors are the most commonly used, in the range 210–292 nm. Electrochemical and online combination of UV with ED improves the selectivity and sensitivity of analysis and decreases the probability of interfering substances being present in analyte peaks. Some methods make use of ion-exchange HPLC for the determination of uric acid and other organic compounds. In most cases, RP ion-pairing HPLC methods were used to determine uric acid in biological samples. One of these has been proposed as candidate reference method for the determination of uric acid.[14] Data obtained by this method were compared with those from ID–GC–MS using [1,3-$^{15}N_2$] uric acid as internal standard.

The main advantage of these methods is that they allow direct determination of urine samples, whereas plasma samples only need deproteinization; in addition, they offer the possibility to simultaneously determine other purine derivatives. In recent years some alternatives to HPLC involving amperometric biosensors and miniaturized CE have been proposed. The microchip CE has opened new levels in performance, functionality, and throughput.[15]

Various methods have been proposed for the simultaneous determination of uric acid and allantoin in different biological matrices. For urine samples, GC–MS was applied for the determination of both compounds.[16] However, HPLC methods are still widely accepted.

Several HPLC methods have been reported for the determination of xanthine and hypoxanthine. Different RP-HPLC methods using gradient elution and UV detection have been described to determine these metabolites and other methylated purines. To improve the determination of xanthines in urine samples, analyses were carried out with two columns—RP and anion-exchange column—connected by a column switch.[17] With this method, urinary hypoxanthine and xanthine can be measured without any sample preparation other than filtration.

Simultaneous determination of uric acid, hypoxanthine, and xanthine in different biological matrices such as urine, urinary calculi, cerebrospinal fluid, and plasma was carried out by RP-HPLC with isocratic elution and UV detection. Various analytical methods for the simultaneous determination of allantoin, uric acid, and xanthines in biological samples, such as urine, blood plasma, and serum, have been described. These procedures are mainly based on separation by HPLC using RP C_{18} columns, UV detection, and isocratic elution or gradient elution. In some cases, allantoin was converted to a derivative with a chomophoric group, but other authors avoid the disadvantages of the allantoin derivatization process.[18] The HPLC and CE methods have been compared for the determination of these compounds on plasma and atherosclerotic plaque. Comparison of results showed that CZE may have analytical performance similar, or even superior, to HPLC, especially for the determination of allantoin in biological samples.[19]

SIMULTANEOUS DETERMINATION OF CREATININE AND PURINE DERIVATIVES

Several papers can be found in the literature concerning the simultaneous determination of creatinine and uric acid or various purine metabolites; however, only a few have reported the simultaneous determination of creatinine and purine derivatives. Kochansky and Strein[20] reviewed recent developments in chromatography and CE methods for the determination of creatinine, uric acid, and xanthines in biological fluids.

RP-HPLC procedures for the determination of creatinine and purine metabolites, such as allantoin, uric acid, xanthine, and hypoxanthine in ruminant urine, were described. Chromatography was achieved with a C_{18} column under isocratic conditions, and detection at 218 nm without allantoin derivatization. The chromatographic conditions were a compromise between the sensitivity and specificity of the measurements of each analyte, analysis time, and resolution of all analyte peaks from interfering compounds.[21] This method has been improved for the simultaneous determination of allantoin, uric acid, and creatinine in cattle urine taking into account the variations in urine pH, because they could alter the retention time of analytes in RP-HPLC systems.[22] Uremic toxins creatine, creatinine, uric acid, and xanthine were simultaneously determined in human biofluids, simply after dilution, with UV detection at 200 nm. This method was compared for creatinine and uric acid with conventional routine methods and did not give significantly different results.[23]

An ion-pair HPLC method for the determination of creatinine and purine derivatives (allantoin, uric acid, and hypoxanthine in sheep urine) using allopurinol as the internal standard is described.[24] In this work, various variables were tested to optimize the simultaneous determination of these compounds, including alkyl chain length of the ion-pairing agent (C_6, C_8, and C_{10}), buffer concentration, pH, percentage of methanol of the mobile phase, and column

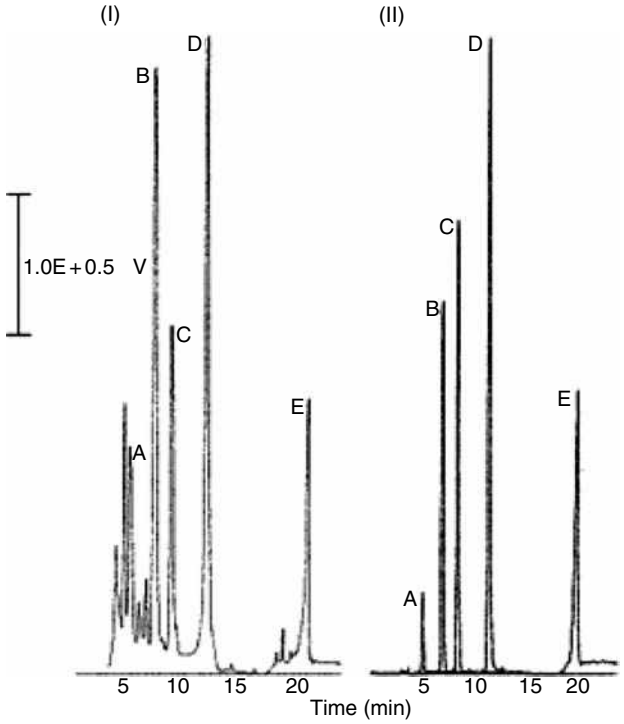

Fig. 3 (I) Chromatogram of tenfold-diluted sheep urine. (II) Chromatographic separation of standard solutions. Peaks: A, allantoin; B, uric acid; C, hypoxanthine; D, allopurinol (IS); E, creatinine.

temperature. The mobile-phase composition was phosphate buffer 10 m*M* with 3 m*M* 1-octanesulfonic acid, sodium salt, pH 4, mixed with methanol:eluent A (5%) and eluent B (20%). The gradient program was 0–13 min, 0–100% B, flow rate 0.5 ml/min; 13–25 min, 100–0% B, flow rate of 1.5 ml/min; re-equilibration time at 0% B, 10 min. The injection volume was 20 μl. The column temperature was set at 30°C. The chromatographic conditions adopted represented a compromise between good separation and reasonable analysis time. Fig. 3 shows the chromatograms resulting from the injection of pure standards and tenfold-diluted sheep urine sample under adopted chromatographic conditions. Under these conditions, there were no other endogenous urinary components that can interfere with the analyte peaks. This method was applied to check the validation of a new method that uses an electrochemical sensor for the determination of creatinine in urine samples. The precision and the accuracy of the results are very similar in both methods.[25]

CONCLUSIONS

HPLC, when compared to other instrumental methods, presents significant advantages in the simultaneous analysis of creatinine and purine derivatives. The variety of instrumental and experimental conditions (columns, buffers, organic modifiers, detectors, etc.) of these methods reported in the literature offer versatility and flexibility. Chromatographic conditions for these analytes are not complicated when RP columns are applied. New stationary phases with high separation power provide short analysis time. The mobile phases used are also very simple (organic–water mixtures with controlled pH); both isocratic elution and gradient elution are recommended. Different sensitivity detectors (UV, electrochemical, fluorescence, the combined techniques such as HPLC–MS and the new biosensors) are very valuable for the possible identification of all analyzed compounds. In some cases, only CE shows some advantages over HPLC, such as short analysis time, reduced reagent consumption, and increased resolution. However, detection limits are often inferior when using UV absorbance detectors.

Cyanobacterial Hepatotoxin Microcystins: Affinity Chromatography Purification

Fumio Kondo
Aichi Prefectural Institute of Public Health, Nagoya, Japan

INTRODUCTION

Freshwater cyanobacteria *Microcystis*, *Oscillatoria*, *Anabaena*, and *Nostoc* produce several types of toxins, among which the most commonly detected are the hepatotoxic peptides microcystins. The general structure of the microcystins is cyclo-(D-Ala^1-*X*^{2}-D-MeAsp^3-*Z*^{4}-Adda^5-D-Glu^6-Mdha^7), in which *X* and *Z* represent variable L-amino acids, D-MeAsp^3 is D-*erythro*-β-methylaspartic acid, Mdha is *N*-methyldehydroalanine, and Adda is the unusual C_{20} amino acid, (2*S*, 3*S*, 8*S*, 9*S*)-3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4(*E*),6(*E*)-dienoic acid (Fig. 1).[1] The structural differences in the microcystins mainly depend on the variability of the two L-amino acids (denoted *X* and *Z*), and secondarily on the methylation or demethylation of D-MeAsp and/or Mdha.[1] More than 60 microcystins have been isolated from bloom samples and isolated strains of cyanobacteria.[1]

Microcystins have caused the poisoning of wild and domestic animals worldwide, and in 1996, they caused the death of 76 people in Caruaru, Brazil, which was attributed to the use of microcystin-contaminated hemodialysis water.[2] Microcystins, like the well-documented tumor promoter, okadaic acid, strongly and specifically inhibit the protein phosphatases 1 and 2A and have a tumor-promoting activity in the rat liver.[3] In addition to acute hepatotoxicity, microcystins pose problems to human health—which could result from low-level, chronic exposure to microcystins in drinking water, as suggested by the high incidence of primary liver cancer in the Qidong and Haimen regions of China.[4] In 1998, the World Health Organization (WHO) proposed a provisional guideline level of 1.0 μg/L for microcystin-LR in drinking water.[4]

OVERVIEW

In order to achieve the rapid and precise determination of microcystins in complicated matrices, a systematic procedure is seriously required. This may include screening, sample purification, identification, and quantification processes.[5] Screening is intended to rapidly check for the presence of microcystins in a small amount of sample, through sensitive and simple methods. If a sample proves positive in the screening test, it will be necessary to follow through with sample purification, identification, and quantification analyses. The purpose of sample purification is to eliminate coexisting substances by a simple operation without the loss of any analyte and, considering that the microcystin concentration may be low, it also enables the enrichment of the analyte. Octadecyl silanized (ODS) silica gel has been extensively employed for this process because it retains microcystins and allows coexisting substances to pass through.[5] A method using ODS silica gel extraction followed by a purification on silica gel has been established to effectively eliminate the coexisting substances in lake water.[6] Although this method has been successfully applied to the analysis of microcystins in lake water samples, it had several problems. The method required a large water sample (5 L) to accumulate the low level of microcystins, resulting in a laborious and time-consuming extraction process. It was also shown that less hydrophobic coexisting substances still remained even after purification on silica gel,[6] indicating that a more effective purification method is required.

Recently, an immunoaffinity purification method using antimicrocystin-LR monoclonal antibodies (named M8H5) has been developed.[7] This purification method was found to be remarkably effective in the removal of coexisting substances and in the enrichment of microcystins in samples.[7–12] This work will focus on the immunoaffinity purification methods for microcystins in lake[10] and tap water samples,[11] and the analysis methods for microcystins and their metabolites in mouse and rat livers.[7–9] It will also cover the reuse of the immunoaffinity column.[12]

IMMUNOAFFINITY COLUMN

Preparation of Immunoaffinity Column

M8H5 antimicrocystin-LR monoclonal antibodies were produced by Nagata et al. as follows:[13,14] female BALB/c mice were immunized with microcystin-LR conjugated proteins (e.g., bovine serum albumin [BSA]). The spleen cells of the immunized mice and SP2/O-Ag14 cells were

	X	Z	R_1	R_2	MW
microcystin-LA	Leu	Ala	CH_3	CH_3	909
microcystin-LR	Leu	Arg	CH_3	CH_3	994
microcystin-YR	Tyr	Arg	CH_3	CH_3	1044
microcystin-RR	Arg	Arg	CH_3	CH_3	1037
microcystin-YM	Tyr	Met	CH_3	CH_3	1019
[D-Asp^3]microcystin LR	Leu	Arg	H	CH_3	980
[Dha^7]microcystin LR	Leu	Arg	CH_3	H	980

Fig. 1 Chemical structures of microcystins.

fused with polyethylene glycol. From the serum-free cultured supernatants of the generated hybridomas, the M8H5 monoclonal antibodies were prepared by membrane ultrafiltration, ammonium sulfate, which were then finally purified using a protein G column (Pharmacia, Stockholm, Sweden). This monoclonal antibody shows extensive cross-reactivity to various microcystins and nodularin (pentapeptide sharing many common features with microcystins). Based on concentrations capable of inducing 50% inhibition of antibodies in a competitive enzyme-linked immunosorbent assay (ELISA), the cross-reactivities were 100% for microcystin-LR, 109% for microcystin-RR, 51% for [D-Asp^3]microcystin-LR, 48% for [Dha^7]microcystin-LR, 44% for microcystin-YR, 26% for microcystin-LA, and 20% for nodularin.

The antimicrocystin-LR monoclonal antibody-combined gel was prepared as follows:[7] Affi-Gel 10 (25 ml, Bio-Rad, Hercules, California, U.S.A.) was washed with distilled ice water (250 ml) and mixed with an equal volume of 10 mg/ml of M8H5 antimicrocystin-LR monoclonal antibody in phosphate buffer saline (PBS) (pH 7.4). The gel mixture was incubated at 4°C for 24 hr with gentle rocking. After the addition of 1 *M* ethanolamine hydrochloride (2.5 ml), the gel mixture was washed with distilled water (250 ml), followed by PBS (500 ml). The obtained gel cake was suspended in PBS containing 0.1% sodium azide (50 ml) and stored at 4°C. The gel mixture (0.5 ml) was transferred to a polypropylene cartridge (Muromac column; Muromachi Kagaku Kogyo Kaisha, Tokyo, Japan) when used.

Protocol for Immunoaffinity Purification

The general protocol for immunoaffinity purification of the microcystins is as follows: sample extracts dissolved in PBS are loaded onto the immunoaffinity column and passed through the column. Gravity flow is usually used. After washing with PBS and distilled water, the microcystin fraction is eluted with 100% methanol.[7,10]

Direct immunoaffinity purification of the microcystins in complicated matrices is difficult because the coexisting substances in the sample occupy the column head, so that the process ends in failure.[10] Thus preliminary semipurification is indispensable when it comes to analyzing trace amounts of microcystins in samples containing substantial amounts of coexisting substances.

DETERMINATION OF MICROCYSTINS

Lake Water

A purification method for microcystins in lake water consists of solid-phase extraction (SPE) on a Sep-Pak PS2® (styrene–divinylbenzene copolymer) or Excelpak SPE-GLF® (polymethacrylate) cartridge, followed by immunoaffinity purification.[10] A 1 L sample of lake water is filtered through a glass GF/C microfiber filter (Whatman, Maidstone, U.K.), and the filtrate is applied to a Sep-Pak PS-2 or Excelpak SPE-GLF cartridge at a flow rate of about 20 ml/min. The cartridge is washed with distilled water

(10 ml), followed by 20% methanol–water (10 ml). Finally, the eluate from the cartridge with 100% methanol (10 ml) is collected and then evaporated to dryness under reduced pressure at 35°C. The resulting residue is dissolved in PBS containing 0.1% BSA (5 ml). Bovine serum albumin is used to prevent non-specific binding of the microcystins with the immunoaffinity support Affi-Gel 10. The solution is subjected to an immunoaffinity column, which is preconditioned with PBS (5 ml), methanol (5 ml), distilled water (5 ml), and PBS containing 0.1% BSA (5 ml). After washing with PBS (5 ml) and distilled water (5 ml), the microcystin fraction is eluted with 100% methanol (10 ml). The eluate is then evaporated to dryness under reduced pressure at 35°C. The residue is dissolved in 0.5 ml of 30% methanol–water and then subjected to high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection and liquid chromatography/mass spectrometry (LC/MS) analyses.

When an extract is prepared with a solid-phase extraction cartridge alone, the microcystins in lake water cannot be precisely detected because of the unstable baseline and many peaks on the chromatograms from coexisting substances (Fig. 2a). When this extract is further purified with the immunoaffinity column, the microcystin peaks are clearly detected (Fig. 2b) and effectively quantified because the coexisting substances are virtually eliminated. The recoveries from lake water (1 L) spiked with 100 ng each of microcystins-LR, -YR, and -RR are 92.2%, 89.2%, and 85.5%, respectively, with coefficients of variation of 3.3–7.6%. One of the advantages of this method is its speed; it took only 3 hr to complete the entire procedure, starting from the microcystin extraction, the immunoaffinity purification, and the quantification, whereas the previous procedures (tandem use of ODS silica gel and silica gel cartridges) took a day to complete. The detection limit for all of the three microcystins in lake water is 0.005 μg/L.

Fig. 2c shows a chromatogram of a sample taken from Lake Suwa, Japan, where water blooms occurred. Two peaks with retention times of 8.0 min (peak 1) and 17.5 min (peak 2) correspond to those of microcystins-RR and -LR, respectively, and they show the typical spectra of the respective microcystins with an absorption maximum at 238 nm (Fig. 2d), affording further confirmation.

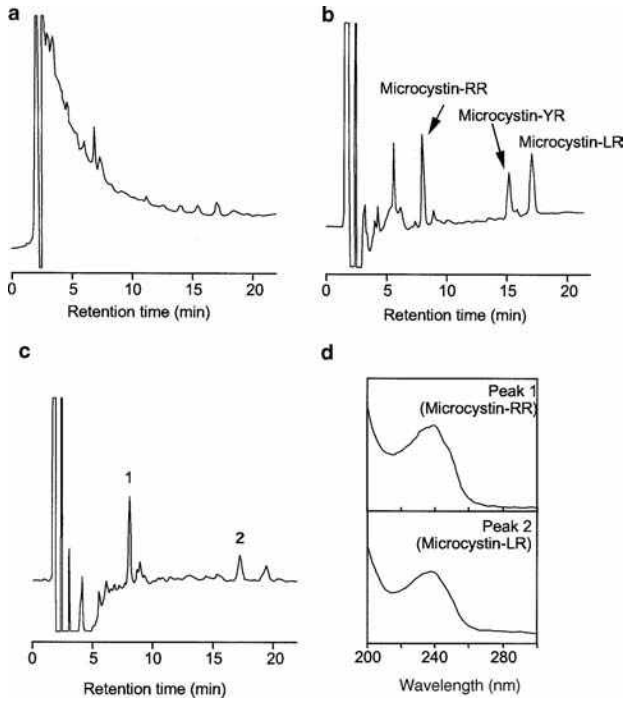

Fig. 2 HPLC analysis of lake water extracts. Microcystin-*free* lake water spiked with microcystins-LR, -YR, and -RR (100 ng each) was analyzed before (a) and after (b) purification with immunoaffinity column. (c) A water sample taken from Lake Suwa, Japan, in 1998 was analyzed after purification with the immunoaffinity column.

Tap Water and Cyanobacterial Cells

Direct purification of the microcystins in tap water with immunoaffinity columns can be achieved because the tap water contains relatively smaller amounts of coexisting substances.[11] A tap water sample is filtered through glass GF/C microfiber filters, to which a 1/10 volume of 11 × PBS is added. The sample solution is loaded onto the immunoaffinity column and passed through the column. After washing with PBS (10 ml) and distilled water (10 ml), the microcystin fraction is eluted with 100% methanol (10 ml). The eluate is evaporated to dryness and the residue is dissolved in 0.05 ml of methanol for HPLC analysis. The chromatograms of the microcystin-added tap water with immunoaffinity purification show effective elimination of the coexisting substances compared to that with the ODS cartridge (data not shown). The mean recoveries of microcystin-LR, -YR, and -RR added to tap water are 91.8%, 86.4%, and 77.3%, respectively, in the range 2.5–100 μg/L.

Microcystins in cyanobacterial cells can also be directly purified via immunoaffinity columns. A 1 L sample of lake water containing cyanobacterial cells is filtered through a glass GF/C microfiber filter (Whatman), and the cells on the filter are suspended in distilled water (10 ml). The cell containing suspension is freeze-thawed three times and then filtered through a glass GF/C microfiber filter. After the addition of a 1/10 volume of 11 × PBS, the filtrate is loaded onto the immunoaffinity column and treated in a similar manner as described above. The HPLC chromatogram shows that the peaks of microcystins-LR and -RR are clearly detected and the peaks due to the coexisting substances are almost negligible (Fig. 3a). On the other hand, the chromatogram of the same sample purified with the ODS silica gel cartridge shows that the removal of lesshydrophobic coexisting substances is insufficient, especially in a shorter retention time area (Fig. 3b).

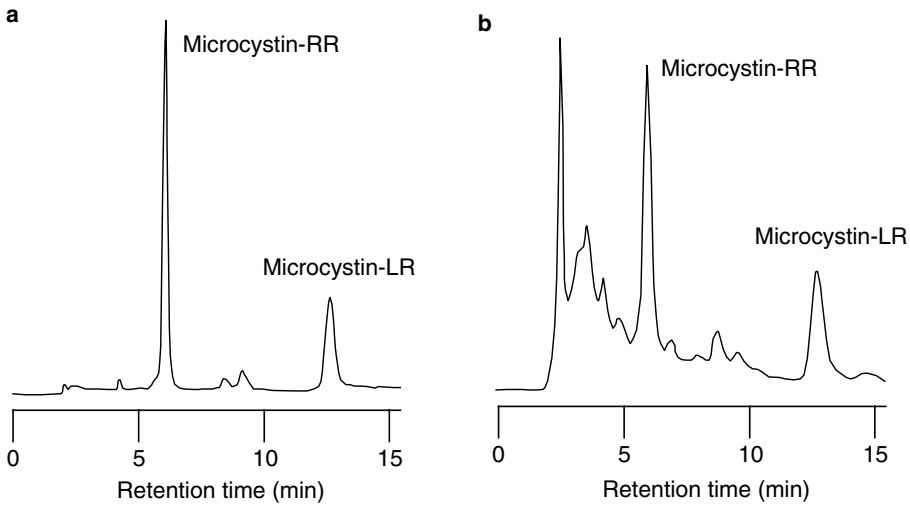

Fig. 3 HPLC analysis of cyanobacterial cells extracts. A cyanobacterial cell sample taken from Lake Suwa, Japan, in 1999 was analyzed after purification with (a) immunoaffinity column and (b) ODS silica gel cartridge.

Mouse and Rat Livers

The in vivo tissue distribution, excretion, and hepatic metabolism of microcystins have been primarily investigated using variously radiolabeled ones.[4] The amounts of the injected microcystins were too small and the amounts of the contaminants in the tissues were too large to investigate the metabolites by instrumental analysis, such as HPLC with UV detection and LC/MS. Fig. 4 shows the HPLC profiles of a cytosolic extract from mouse liver spiked with 5 μg each of microcystins-LR and -RR. When the cytosolic extract is prepared by the method described by Robinson et al.,[15] which consists of heat-denaturation, pronase digestion, and ODS silica gel treatment (Fig. 4a), the two spiked microcystins cannot be precisely analyzed because of a substantial amount of coexisting substances. When the cytosolic extract is further purified with the immunoaffinity column, the coexisting substances are effectively eliminated and the peaks of the spiked microcystins-LR and -RR are clearly detected (Fig. 4b).

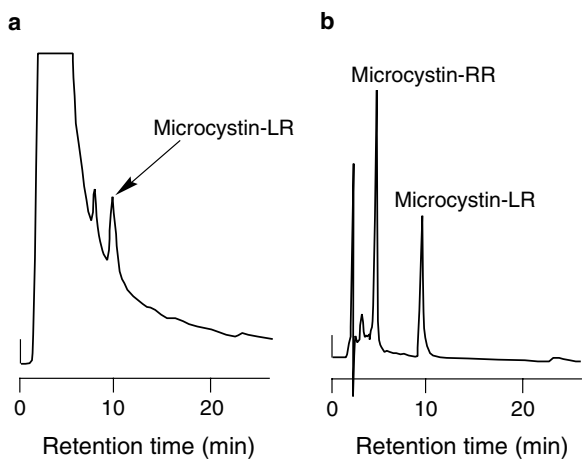

Fig. 4 HPLC analysis of a cytosolic extract from mouse liver spiked with 5 μg each of microcystins-RR and -LR. Before (a) and after (b) purification with immunoaffinity column.

The method including heat-denaturation, pronase digestion, ODS silica gel treatment, and immunoaffinity purification has been applied to the analysis of microcystins and their metabolites in hepatic cytosols from mice and rats intraperitoneally administered microcystins. A purified cytosolic extract from mouse liver at 3 hr postinjection of microcystin-RR was analyzed by Frit-FAB LC/MS. The peaks of the microcystins and related compounds can be selectively detected by monitoring the mass chromatogram at *m/z* 135, which is the characteristic ion derived from Adda, a characteristic component of microcystins.[16] The mass chromatogram shows the relatively broad peak X (Fig. 5a), which is confirmed to contain at least four peaks by using slightly modified HPLC analysis conditions. The mass spectrum of the longer retention time area of peak X shows an ion at *m/z* 1345, whose molecular weight corresponds to that of the glutathione conjugate of microcystin-RR (Fig. 5b), the thiol of GSH having been nucleophilically added to the α,β-unsaturated carbonyl of the Mdha moiety in the microcystins. The glutathione conjugate was confirmed by comparison of the retention time with that of the chemically prepared one. The mass spectrum of the shorter retention time area of peak X shows ions at *m/z* 1284, 1330, and 1459, with relatively low intensities (Fig. 5c). This area was considered to contain a conjugate of the oxidized Adda diene. The cysteine conjugate was identified in a cytosolic extract from mouse liver at 24 hr postinjection of microcystin-RR. Both the glutathione and cysteine conjugates were also identified in hepatic cytosols from the rat-administered microcystin-LR.

The immunoaffinity purification method, followed by LC/MS analysis, has also been used in other toxicological studies. When aged mice (32 weeks) were orally administered microcystin-LR at 500 μg/kg, 62% of the aged mice showed hepatic injury, whereas such changes in the liver were not found in young mice (5 weeks).[8] Upon uptake of orally administered microcystin-LR at 500 μg/kg, the

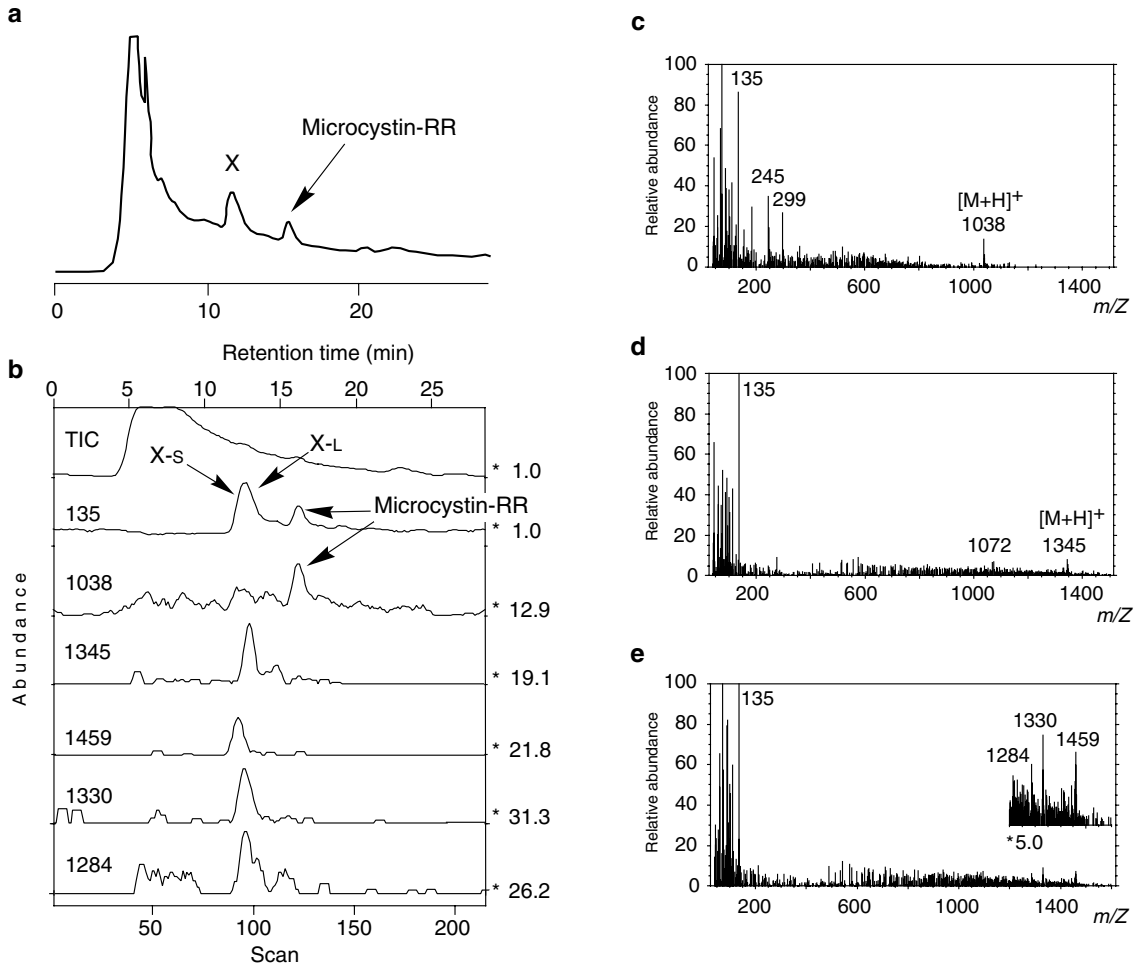

Fig. 5 Frit-FAB LC/MS analysis of a cytosolic extract from mouse liver at 3 hr postinjection of microcystin-RR. Shown are (a) simultaneously monitored UV chromatogram (238 nm), (b) total ion and mass chromatograms, (c) Frit-FAB LC/MS mass spectra of microcystin-RR, (d) longer retention time area of peak X (indicated by X-L), and (e) shorter retention time area of peak X (indicated by X-s).

toxin into the liver was confirmed by Frit-FAB LC/MS after the immunoaffinity purification. When microcystin-LR was intraperitoneally injected 100 times at 20 μg/kg into male ICR mice (5 weeks old, Charles River Japan, Atsugi, Japan) for 28 weeks, multiple hyperplastic nodules up to 5 mm in diameter were observed in every liver.[9] Microcystin-LR and its cysteine conjugate were identified from the isolated mouse livers.

REUSABLE IMMUNOAFFINITY COLUMN

Reuse of the immunoaffinity column is apparently of great value because the immunoaffinity column requires a large amount of antibodies. The immunoaffinity column using Affi-Gel 10 as the immunoaffinity support could not be repeatedly used because the applied solutions tended to stick owing to the massive bubbles produced. In order to overcome this disadvantage, a new immunoaffinity column using the immunoaffinity support Formyl-Cellulofine® has been introduced.[12] Because of the spherical shape of the immunoaffinity support Formyl-Cellulofine, the applied solutions passed through the column smoothly even when they were used repeatedly.

The purification procedure using this immunoaffinity column has been optimized as follows: After extraction with a Sep-Pak PS2 cartridge, the extract is dissolved in 25 m*M* Tris–HCl buffer (pH 7.2) containing 1 m*M* EDTA, 0.15 M sodium chloride, and 0.1% sodium azide (Tris–HCl buffer A) with 0.1% BSA (Tris–HCl buffer B) (5 ml), and the solution is loaded onto an immunoaffinity column, which is preconditioned with Tris–HCl buffer B (10 ml). After washing with Tris–HCl buffer A (10 ml) and distilled water (10 ml), the microcystin fraction is eluted with 100% dimethylformamide (DMF) (2.5 ml). The eluate is then dried on a hot block (60°C) under a constant stream of nitrogen. The residue is dissolved in 30% methanol–water (0.5 ml) and then subjected to HPLC-photodiode array (HPLC-PDA) detection and LC/MS analysis. The immunoaffinity column is regenerated by washing with Tris–HCl buffer B (10 ml) before each reuse.

Recoveries of the spiked microcystins to lake water from the first use of the column are 87–88% and 83–88% was recorded from the second and third uses. Recoveries gradually drop to 63–77% from the fourth to the fifth uses. These results indicate that the column can be repeatedly used up to three times.

CONCLUSIONS

The immunoaffinity column using antimicrocystin-LR monoclonal antibodies has proved to be an important purification tool for microcystin analysis in lake and tap water, and cyanobacterial cells and tissue samples from mice and rats. One of the advantages of the immunoaffinity purification is specificity. It enables operators to enrich the trace amounts of the microcystins and to eliminate large amounts of coexisting substances. As a result of the substantial elimination of these coexisting substances, the microcystin peaks were successfully and reliably identified with HPLC and LC/MS by excluding a few of the non-microcystin peaks that appear even after the immunoaffinity purification. On the other hand, one of the disadvantages of the analytical method using the immunoaffinity column is the requirement for large amounts of antibodies. Reuse of the immunoaffinity column is one approach to overcome this limitation. Although the immunoaffinity column for microcystins is not yet commercially available, it is believed that it will become more widely used within the next 2–3 years.

Cyclodextrins in GC

Tibor Cserháti
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

Abstract
Cyclodextrins are cyclic oligosaccharides forming inclusion complexes with a wide variety of organic and inorganic compounds. The formation of inclusion complexes modifies the physicochemical parameters of the guest molecule, resulting in modified retention behavior. The aims of this entry are to provide a short overview of the chemistry and physicochemistry of cyclodextrins and of their application for improving separation, with special emphasis on the separation of enantiomer pairs of pharmaceuticals and environmental pollutants.

INTRODUCTION

Chromatographic methods offer an excellent possibility for the separation and quantitative determination of a considerable number of organic, metallo-organic, and even inorganic, molecules with highly similar chemical structures. These methods have found widespread application in various fields of everyday life and scientific research. Thus, they play a considerable role in medical practice and research, pharmaceutical development, food sciences and technology, environmental protection, etc.

The basis of chromatographic separation is the partition of analytes between a stationary and a mobile phase of different polarity where the stationary phase is generally solid and the mobile phase is gas or liquid. Gas chromatography (GC), a well-known and frequently applied method, uses a solid or quasi-solid stationary phase, the mobile phase generally being a neutral gas. However, the application of GC technologies is restricted to analytes, which can be volatilized and are thermostable at the temperature of the measurement.

The objectives of this entry are the compilation, brief description, and critical evaluation of the newest GC methods using native cyclodextrins (CDs) or CD derivatives as the active component of the stationary phase. Earlier results in this rapidly developing field have been previously summarized.[1]

CHEMISTRY AND PHYSICOCHEMISTRY OF CDs

CDs are cyclic, non-reducing oligosaccharides consisting of D-glucopyranose units bonded by α-1,4 linkages. They can be formed from dextrins, the products of the partial hydrolysis of starch, by the enzyme glucosyltranferase.

The main native CDs are α-, β-, and γ-CD. α-CD (Schardinger's α-dextrin, cyclomaltohexose, cyclohexaglucan, cyclohexaamilose, or C6A) is composed of six glucose units. β- and γ-CDs are formed of seven and eight glucose units, respectively. The schematic chemical structure of unsubstituted native CDs is shown in Fig. 1. Unsubstituted native CDs are crystalline non-hygroscopic substances. The sugar units adopt a $^4C_1$ conformation, orienting so that the glucose forms a toroidal conical structure. Because of the macrocyclic ring structure, CDs can form inclusion complexes with molecules or molecular substructures that fit into the CD cavity (guest molecule). The inner wall of the CD cavity is hydrophobic, facilitating the inclusion of hydrophobic guest molecules or the hydrophobic substructures of a guest molecule. The outer part is more hydrophilic, capable of polar interactions with the guest molecules or with the polar substructures of guest molecules. The main chemical and physicochemical parameters of native CDs are listed in Table 1.[2] The inclusion of complex formation modifies the physicochemical characteristics of the guest molecule (adsorption capacity, polarity, lipophilicity, etc.). As the same characteristics play a considerable role in the retention behavior of the analyte, the complexed analyte is exposed to retention parameters different from those of the non-complexed one, facilitating separation. A large number of CD derivatives were synthesized and their separation capacities and physicochemical characteristics were intensively investigated. These studies were partially motivated by the fact that the thermal stability of the native is fairly low.

CD-ASSISTED GC SEPARATIONS

Various GC methods using CDs have been used, not only for the increase of the separation efficiency, but also for the determination of the strength of interaction between CDs and a considerable number of guest molecules. The

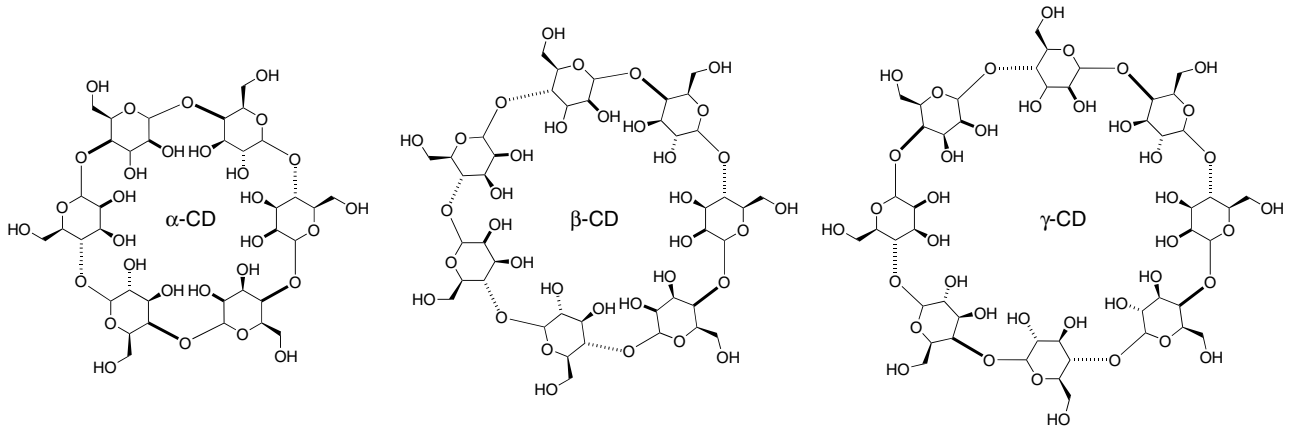

Fig. 1 Schematic structures of native α-, β-, and γ-CDs.

objectives of these investigations were the selection of the CD or CD derivative most suitable for the complexation of bioactive guest molecules or the elucidation of the molecular processes underlying inclusion complex formation. The role of CDs in separation science,[3] especially in chiral selective chromatography, has been previously reviewed[4] and discussed in detail.[5,6] A static headspace GC method and molecular modeling were employed for the study of the solubilization of chlorinated solvents by native and modified CDs. It was established that CDs effectively bind volatile pollutants.[7] Affinity capillary electrophoresis, nuclear magnetic titration, and headspace GC were applied for the measurement of the association constant between oral malodorous components and native and derivatized CDs. The binding constants are listed in Table 2. The data prove the good complexing capacity of CDs.[8]

CD-ASSISTED ENANTIOMERIC SEPARATIONS

The overwhelming majority of GC methods, employing CDs as stationary phase or as stationary phase additive, deal with the separation of optical isomers. The increasingly strong legislation regulations and the possible different biological activities of the stereoisomers motivate and promote the development and application of this type of measurement. A large variety of enantiomers was separated, including pharmaceuticals, natural products, food components, environmental pollutants.

Enantiomer Separation of Pharmaceuticals

The enantioseparation of arylpropionic non-steroidal anti-inflammatory drug methyl esters was performed with a stationary phase containing methylated and silylated-β-CD derivatives. The separation of salsolinol, levetiracetam, fluoxetine, norfluoxetine, ephedrine, methamphetamine, ephedrine type alkaloids, perfluorodiether, *N*-trifluoroacetyl-*O*-alkyl nipecotic ester, camphor, and γ-butyrolactone derivatives using different native CDs and CD derivatives were also reported.

Enantiomer Separation of Natural Compounds

The separation capacities of various stationary phases for the analysis of *R/S*-α-hydroxy fatty acid esters have been

compared. It was found that an α-CD column separated the esters with a short alkyl chain well, but was inefficient in the case of long-chain fatty acid esters. A β-CD stationary phase was applied for the successful analysis of monoterpenes, as demonstrated in Fig. 2.[9] Furan derivatives were separated on a per-*O*-methyl-β-CD column. Enantiomers of derivatized amino acids were analyzed on a stationary phase containing modified resorcinarene and β-CD. β-CD and β-CD derivatives have been further applied for the enantioseparation of monoterpenes in grapes and Scotch pines (*Pinus sylvestris*). α-CD has also found application in the separation of natural compounds. Thus, its use in monoterpenoid analysis was illustrated.[10,11]

Enantiomeric Separation of Environmental Pollutants

CD derivatives were synthesized by substituting valeryl, heptanoyl, and octanoyl groups in the 6 position of 2,3-di-*O*-pentyl-β-CD. The separation capacities of the new derivatives were tested by using 15 pairs of disubstituted benzene derivatives as analytes. The capacity factors and separation factors determined on the three stationary phases are listed in Table 3. It was concluded from the data that the separation capacity of the derivatives was markedly different; the pentyl derivative showed the best selectivity.[12] Organophosphorus pesticides were also well separated on a trimethyl-β-CD column. Because of their high toxicities, the separation possibilities of polychlorinated biphenyls have been vigorously investigated. Thus, *tert*-butylsilyl derivatives of β-CD were successfully employed for the analysis of polychlorinated biphenyls (PCB), 1,1-di(4-chlorophenyl)-2,2-dichloroethylene (DDE), and their methylsulfonyl metabolites in human adipose tissue, seal blubber, and pelican muscles. PCB atropisomers were also separated on various columns containing CD derivatives.

Two-dimensional GC was employed for the analysis of chiral PCBs in foods such as milk, cheese, and salmon.[13] A new β-CD derivative (permethylated-β-CD/hydroxy-termination silicone oil) was employed for the efficient extraction of polybrominated diphenyl ethers in soil. CDs have also been used for the analysis of toxaphene congeners. It was established that permethylated and *tert*-butyldimethylsilylated-β-CDs separate different congeners and can be applied for the study of the degradation of toxaphens. Another study applied two-dimensional GC for the successful separation of toxaphene enantiomers. It was found that the separation efficacy of β-CD containing columns showed marked differences, depending on the composition of the stationary phase. Capillary columns coated with heptakis-(2,3,6-*O*-*tert*-butyldimethylsilyl)-β-CD or octakis-(quest;2,3,6-tri-*O*-ethyl)-γ-CD were employed for the enantiomer-selective decomposition of toxaphene congeners in rats after intravenous administration. The measurement indicated the enantioselectivity of the decomposition. Other environmental pollutants, such as racemic sulfoxides, sulfinate esters, phenolic compounds, and cresol and xylene isomers, have also been analyzed by GC using various native and derivatized CDs. Interestingly, the majority of methods apply β-CD or β-CD derivatives; the use of α- and γ-CD and their derivatives is of secondary importance. CDs have been employed, not only for the enantioseparation of environmental pollutants, but also for the enhancement of the extraction efficacy.

Enantiomeric Separation of Other Compounds

The separation characteristics of the mixtures of permethylated-β-CD and heptakis-(2,6-di-*O*-pentyl-3-trifluoroacetyl)-β-CD were investigated using various organic compounds such as analytes. It was established that a synergistic effect occurs between the two CD derivatives, depending on the chemical structures of the analytes and on the ratio of the CD derivatives. Another study found a synergistic effect between the separation capacity of permethylated and perpentylated-β-CD. A gas chromatography–mass spectrometry (GC–MS) method using 2,3-di-*O*-methyl-6-*O*-*tert*-butyl-dimethylsilyl-β-CD was applied to the chiral separation of 3-hydroxyisobutyric- and 3-aminoisobutyric acids. The separation of a set of organic compounds proves the good retention capacity of CD phenyl carbamate derivatives, as illustrated in Fig. 3. The separation ability and complex stability of native α- and β-CDs were compared using a wide variety of analytes, such as dimethylnaphthalenes, α- and β-pinenes, *cis/trans* decalins, anetholes, isosafroles, (+/−)-α-pinenes, and (+/−)-camphenes. The measurements indicated that not only the stability of the inclusion complex but also the stoichiometry exerts a considerable influence on the separation. Two new enantioselective stationary phases were synthesized, i.e., heptakis(2,6-di-*O*-nonyl-3-*O*-trifluoroacetyl)-β-CD and heptakis(2,6-*O*-dodecyl-3-*O*-trifluoroacetyl)-β-CD; their separation characteristics were investigated using amines, alcohols, diols, carboxylic acids, amino acids, epoxides, halohydrocarbons, and ketones. It was proven again that the separation capacity depends on the structures of both CD derivatives and analytes. The same conclusion was drawn from the investigation of mono-ester permethylated β-CD derivatives. The application of β-CD-based chiral stationary phase for the semipreparative separation of *all-trans*-perhydrotriphenylene enantiomers in the milligram range has also been reported.

CONCLUSIONS

The development of new CD-based enantioselective stationary phases was mainly motivated by the different biological activities (both beneficial and toxic) of

many enantiomeric pairs. It was shown that native and derivatized CDs can be used successfully for the enantiomeric separation of a wide variety of enantiomer pairs. Moreover, native CDs and CD derivatives modify the retention characteristics of the GC stationary phases, resulting in improved separation parameters. The application of CDs may facilitate, not only the solution of various practical separation problems, but also the promotion of a better understanding of the underlying physicochemical principles governing both inclusion complex formation and retention.

Cyclodextrins in HPLC

Tibor Cserháti
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

Abstract
The application of cyclodextrins (CDs) in high-performance liquid chromatography (HPLC) as mobile-phase additives and components of stationary phases is briefly discussed. The advantageous separation characteristics of CDs in various HPLC technologies are demonstrated using pharmaceuticals, environmental pollutants as analytes.

INTRODUCTION

Because of the high separation power, reliability, and reproducibility, various high-performance liquid chromatographic (HPLC) methods have been extensively employed for the separation and quantitative determination of a considerable number of compounds, including pharmaceuticals, food components, environmental pollutants.

Cyclodextrins (CDs) are cyclic oligosaccharides suitable for the formation of inclusion (host–guest) complexes with many organic and inorganic compounds. The formation of inclusion complexes modifies the physicochemical characteristics of the guest molecule, resulting in different interactions with the mobile and stationary phases of the HPLC system, thereby increasing separation capacity. The complex formation influences not only the chromatographic behavior of the guest molecule, but also the solubility, uptake, decomposition rate, bioavailability, and the biological activity. These effects were demonstrated in the case of raloxifene, ketoprofene, an intestinal metabolite of ginseng saponin, pratosin hydrochloride, celecoxib, etc. The character of the various binding forces involved in the complex formation has been vigorously discussed. It has been established that, besides the decisive role of steric correspondence between the guest molecule and the dimensions of the CD cavity, hydrophobic interactive forces occur between the apolar substructures of the guest molecule and the lipophilic inner wall of the CD cavity. Moreover, the dissociable polar molecular parts pointing outside of the cavity readily interact with the polar hydroxyl groups on the outside of the cavity. These electrostatic interactions may enhance the stability of the inclusion complex. The chemistry and physicochemistry of CDs are discussed in detail in this entry. Similar to gas chromatography (GC), the overwhelming majority of the applications of CDs in HPLC deal with the separation of enantiomers. Because of their biological importance, method developments has concentrated mainly on the enantioseparation of synthetic pharmaceuticals, components of herbal medicines and food products, as well as environmental pollutants.

The aim of this work is the collection, short description, and critical survey of modern HPLC technologies applying natural CDs and various CD derivatives, both as components of the stationary phase and as additives in the mobile phase. Earlier results in the application of CDs in HPLC measurements have been previously summarized.[1]

HPLC ANALYSIS OF CYCLODEXTRINS

Because the purity of CD preparations and the character of its impurities exert a considerable influence on the complex-forming capacity, several HPLC methods were developed and successfully applied for the separation of CD mixtures. Thus, the composition of the new methylated β-CD derivatives with a low degree of substitution was investigated by matrix-assisted laser desorption/ionization mass spectrometry and HPLC, using various reversed-phase columns. Analytes were detected by evaporative light scattering detection (ELSD). Gradient elution was started at 5 vol% MeCN in distilled water and finished at 45 vol% MeCN within 40 min. The chromatograms showed good separation capacity of the HPLC system.[2]

New stationary phases were synthesized by binding substituted aromatic groups to silica. Their separation capacity was determined by using various native CDs and CD derivatives. The mobile phase for the gradient elution consisted of a mixture of MeCN, H_2O, and formic acid. CDs were detected with a refractive index detector and ELSD. The measurements indicated that the *N*-(4-nitrophenyl)-carbamide group-bonded silica was the most effective.[3]

The purity of heptakis(2,3,6-tri-*O*-methyl)-β-CD preparations was checked by reversed-phase (RP)-HPLC using the isocratic mobile phase, methanol–water 85/15, v/v. Analytes were detected by atmospheric pressure chemical ionization–mass spectrometry (APCI–MS). The measurements illustrated that the purity of the CD derivatives markedly influences the enantioselectivity of the preparation.

CYCLODEXTRINS AS MOBILE-PHASE ADDITIVES

Although CDs are generally used in the mobile phase as additives to improve separation, their application as extracting agent and sensitivity enhancer of the detection was also reported. Thus, a saturated solution of β-CD was employed for the extraction of five polycyclic aromatic hydrocarbons (PAHs) from environmental samples. The application of β-CD enhanced the efficacy of extraction and increased the sensitivity of fluorescence detection. The capacity of β-CD to enhance the sensitivity of the chemiluminscence detection of tetracyclines (oxytetracycline, tetracycline, and metacycline) has also been established.

Pharmaceuticals

A considerable number of racemic pharmaceuticals were enantioseparated by using native CDs and CD derivatives as mobile-phase additives; the optimal conditions of the enantioseparation were determined. The study of the structural features and thermodynamic parameters influencing the HPLC behavior of tolfenamic acid and ketoprofen inclusion complexes established that the decisive factor of the measurement is the entropy change in the system. The addition of β-CD to the mobile phase reduced the extent of non-specific adsorption of imipravine, desipramine, propranolol, and naproxen and enhanced the sensitivity of electrospray MS detection.[4] Norgesterol enantiomers were separated with a C_8 column using MeCN:phosphate buffer (pH 5.0, 20 m*M*) containing 25 m*M* hydroxypropyl-β-CD (HP-β-CD), 30/70, v/v. It was established that the method can be employed for the study of the stereoselectivity of the skin permeation of norgesterol. The structural isomers of madecassic acid and terminolic acid extracted from the medicinal plant *Centella asiatica* (L) Urban were separated on a C_{18} column. The mobile phase consisted of methanol:water (65/35, v/v) at pH 4. The measurements indicated that the separation efficacy increases with increasing concentration of β-CD in the mobile phase. The dependence of the retention of *S*(-)bupivacaine on the concentration of HP-β-CD in the mobile phase has been applied for the study of their interactions. Measurements were carried out on a C_{18} column using MeCN–phosphate buffer pH 7.4 (10 m*M*), 45/55, v/v. It was stated that the method can be employed for the characterization of inclusion complexes.[5]

Other Analytes

The inclusion complex formation between *trans*-resveratrol and β-CD was investigated using a C_{18} column as stationary phase and methanol–water mixtures as mobile phases. The apparent formation constants were calculated under different chromatographic conditions. The dependence of the formation constant on the concentration of methanol in the mobile phase and on the temperature of the column has been established.[6]

CYCLODEXTRINS IN STATIONARY PHASES

Pharmaceuticals

It was previously reported that a CD solution can be employed as extraction solution. Another study prepared a composite consisting of polydimethylsiloxane and β-CD and was used for stir bar sorptive extraction. It was found that the presence of β-CD increased the adsorption capacity and showed better selectivity toward polar compounds. The technique has been successfully applied for the extraction of estrogens from environmental water, bisphenol A in drinking water, and in leachate of one-off dishware. Oligo-β-CD was prepared and coupled to polyacrylate beads. This new stationary phase separated the isoflavonoid puerarin from other isoflavonoids present in the extract of *Radix puerariae* (root of the plant *Pueraria lobata*).[7] Aromatic carboxylic acid isomers and their derivatives are important metabolites of toxic compounds, drugs, and catecholamines. Their separation was performed using a β-CD-bonded phase with the s-triazine ring in the spacer. The mobile phase consisted of 4 m*M* potassium phosphate buffer and methanol (50:50, v/v). A good separation of toluic, aminobenzoic, nitrobenzoic, and hydroxybenzoic isomers was achieved. The results emphasized the importance of $\pi-\pi$ interaction and hydrogen bonding in the retention. The CD chiral stationary phases have also been employed for the enantioseparation of *cis* and *trans* nucleosides and aromatic analogues of stavudine. A β-CD capillary has been employed for the microextraction of nonsteroidal anti-inflammatory drugs (ketoprofen, fenbufen, ibuprofen) in urine. The good extraction efficacy and stability of the capillary were established. CD-based chiral stationary phases were used for the enantioseparation of furan derivatives. The retention parameters of the analytes are compiled in Table 1. It was concluded, from the data, that steric bulk, hydrogen-bonding ability, and geometry play a decisive role in the formation of inclusion complexes.[8] Similar CD-based chiral stationary phases were applied for the resolution of thioridazine enantiomers. The efficacy of a CD stationary phase to separate diastereomeric thymine derivatives has also been demonstrated, as shown in Fig. 1.[9]

Miscellaneous Analytes

Besides the separation of pharmaceuticals, CD-containing stationary phases have found application in the analysis of foods and food products, environmental pollutants, and other organic compounds. The baseline separation of lactobionic acid, sorbitol, lactose, and fructose on a β-CD phase was achieved using MeCN–sodium dihydrogen phosphate 10 m*M* (70/30, v/v) as isocratic mobile phase. Racemic 2,4-

[a]Separation of diastereomers.

Source: From Separation of chiral furan derivatives by liquid chromatography using cyclodextrin-based chiral stationary phases, in J. Chromatogr. A.[8]

dinitrophenyl amino acids were also separated on a β-CD-hexamethylene diisocyanate copolymer-coated zirconia stationary phase. Interestingly, a β-CD stationary phase has also been the normal-phase separation mode for the determination of polycyclic aromatic compounds. The retention factors measured on various stationary phases are compiled in Table 2. The data demonstrated that the best separation was achieved with the β-CD stationary phase.[10] Two novel β-CD derivatives were synthesized (mono-2^A-deoxyperphenylcarbamoylated β-CD and mono-2^A-azido-2^A-deoxyperacetylated β-CD) and used for the separation of a wide variety of analytes. The parameters of enantioseparation measured under reversed-phase conditions are listed in Table 3. The measurements proved again that the efficacy of enantioseparation depends on both the structure of the stationary phase and the analyte.[11] A novel stationary phase was prepared by immobilizing poly-β-CD on a silica surface. It was established that the retention behavior of monomethoxypoly (ethylene glycols) is governed by the hydrophobic interactions between the cavity of the β-CD and the lipophilic substructures of the analytes. A perphenylcarbamoylated β-CD derivative was bonded to silica particles and the enantioselectivity of this novel chiral stationary phase was tested by using racemic α-amidophosphonates as model analytes. It was assumed that hydrophobic interaction, steric effects, and π–π interaction are involved in the retention behavior.

4-Methyldibenzothiophene	2.98	0.82	2.13
2,4-Dimethyldibenzothiophene	2.38	0.69	3.55
4,6-Dimethyldibenzothiophene	2.88	0.76	4.02
1,3,7-Trimethyldibenzothiophene	3.01	0.81	3.96
1,4,6-Trimethyldibenzothiophene	2.77	0.72	5.36
1,4,7-Trimethyldibenzothiophene	3.07	0.78	5.55
1,4,8-Trimethyldibenzothiophene	3.33	0.78	5.56

(Continued)

Table 2 Retention factors for some polycyclic aromatic sulfur heterocycles on a β-cyclodextrin, an aminopropano, and a TCP stationary phase with cyclohexane as eluent. *(Continued)*

	β-CD	AP	TCP
2,4,6-Trimethyldibenzothiophene	2.80	0.76	6.19
3,4,7-Trimethyldibenzothiophene	2.76	0.80	3.82
2,4-Dimethyl-6-ethyldibenzothiophene	2.44	0.69	3.97
2,3,4,7-Tetramethyldibenzothiophene	1.62	0.52	3.89
2,3,7,8-Tetramethyldibenzothiophene	3.65	0.90	5.84
2,4,6,8-Tetramethyldibenzothiophene	3.02	0.71	9.99
2-Octyldibenzothiophene	1.58	0.46	1.00
4-Octyldibenzothiophene	1.86	0.61	1.06
Naphtho(2,3-*b*)thiophene	4.32	1.17	1.76
2-(1-Naphthylethano)thiophene	3.37	1.08	0.55
3-[(4-Butylphenyl)ethano]benzo(*b*)thiophene	2.59	0.82	0.38
More than three aromatic rings			
Phenanthro(4,5-*bcd*)thiophene	5.81	1.08	2.39
Benzo(*b*)naphtho(1,2-*d*)thiophene	7.01	1.41	3.29
2-(1-Naphthalenyl)benzothiophene	4.41	1.15	0.63

For the three stationary phases here, the order of selectivity toward parent aromatic rings is in the order TCP > β-CD > AP. This might point to TCP as the more favorable phase, but retention on TCP is more sensitive to the alkylation than the other phases.

Source: From Novel combined stir bar sorptive extraction coupled with ultrasonic assisted extraction for the determination of brominated flame retardants in environmental samples using high performance liquid chromatography, in J. Chromatogr. A.[12]

A CD-modified extraction method was successfully applied for the analysis of brominated flame retardants, as illustrated in Fig. 2.[12] The enantioseparation of α-hydroxy-3-phenoxybenzeneacetonitrile and its *n*-butyl esters has also been reported and visualized in Fig. 3.[13]

CONCLUSIONS

Although native CDs show acceptable enantioselectivity toward a large number of enantiomer pairs in many HPLC systems, their separation capacity is not always enough for the baseline separation of enantiomers, which is the prerequisite for reliable quantitative analysis. To overcome this difficulty, a considerable number of CD derivatives were synthesized and their separation capacities were tested using enantiomer pairs that are not well separated by native CDs. Unfortunately, the theoretical basis of the inclusion formation of new CD derivatives and the effect of new inclusion complexes on the enantioseparation of a given isomer pair are not well understood. This type of theoretical investigation is urgently needed for further development of the application of CDs and CD derivatives in HPLC.

Dead Point: Volume or Time

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The *injection point* on a chromatogram is that position where the sample is injected. The *dead point* on a chromatogram is the position of the peak maximum of a completely unretained solute. The different attributes of the chromatogram are shown in Fig. 1. The *dead time* is the elapsed time between the injection point and the dead point. The volume that passes through the column between the injection point and the dead point is called the *dead volume*.

DISCUSSION

If the mobile phase is *incompressible*, as in liquid chromatography (LC), the *dead volume* (as so far defined) will be the simple product of the *exit* flow rate and the dead time. However, in LC, where the stationary phase is a porous matrix, the dead volume can be a very ambiguous column property and requires closer inspection and a tighter definition.

If the mobile phase is compressible, the simple product of dead time and flow rate will be incorrect, and the dead volume must be taken as the product of the dead time and the *mean* flow rate. The dead volume has been shown to be given by[1]

$$V_0 = V_0' \frac{3}{2}\left(\frac{\gamma^2 - 1}{\gamma^3 - 1}\right) = Q_0 t_0 \frac{3}{2}\left(\frac{\gamma^2 - 1}{\gamma^3 - 1}\right)$$

where the symbols have the meaning defined in Fig. 1, and V_0' is the dead volume measured at the column exit and γ is the inlet/outlet pressure ratio.

The dead volume will not simply be the total volume of mobile phase in the column system (V_m) but will include extra-column dead volumes (V_E) comprising volumes involved in the sample valve, connecting tubes, and detector. If these volumes are significant, then they must be taken into account when measuring the dead volume.

There are two types of dead volume (i.e., the *dynamic* dead volume and the *thermodynamic* dead volume.[2]) The dynamic dead volume is the volume of the *moving phase* in the column and is used in kinetic studies to calculate mobile-phase velocities. In gas chromatography, both the dynamic dead volume and the thermodynamic dead volume can be taken as the difference between the dead volume and the extra-column volume. In LC, however, where a porous packing is involved, some of the mobile phase will be in pores (the *pore volume*) and some between the particles (the *interstitial volume*). In addition, some of the mobile phase in the interstitial volume which is close to the points of contact of the particles will also be stationary. The dynamic dead volume (i.e., the volume of the moving phase) is best taken as the retention volume of a relatively large inorganic salt such as potassiun nitroprusside. This salt will be excluded from the pores of the packing by ionic exclusion and will only explore the moving volumes of the mobile phase.[2] The thermodynamic dead volume will include all the mobile phase that is available to

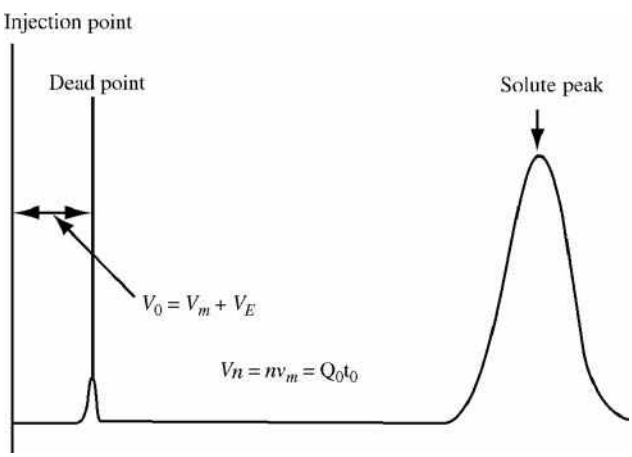

Fig. 1 Diagram depicting the dead point, dead volume, and dead time of a chromatogram. If the mobile phase is not compressible, then V_0 is the total volume passed through the column between the point of injection and the peak maximum of a completely unretained peak, V_m is the total volume of the mobile phase in the column, V_E is the extra column volume of the mobile phase, v_m is the volume of the mobile phase per theoretical plate, t_0 is the time elapsed between the time of injection and the retention time of a completely unretained peak, n is the number of theoretical plates in the column, and Q is the column flow rate measured at the exit.

the solute that is under thermodynamic examination. It is best measured as the retention volume of a solvent sample of very similar type to that of the mobile phase and of small molecular weight. If a binary solvent mixture is used (which is the more common situation), then one component of the mobile phase, in pure form, can be used to measure the thermodynamic dead volume. Careful consideration must be given to the measurement of the column dead volume when determining thermodynamic data by LC using columns packed with porous materials.

Dendrimers and Hyperbranched Polymers: GPC/SEC Analysis

Nikolay Vladimirov
Research Center, Hercules Inc., Wilmington, Delaware, U.S.A.

INTRODUCTION

Dendrimers and hyperbranched polymers are globular macromolecules having a highly branched structure, in which all bonds converge to a focal point or core, and a multiplicity of reactive chain ends. Because of the obvious similarity of their building blocks, many assume that the properties of these two families of dendritic macromolecules are almost identical and that the terms "dendrimer" and "hyperbranched polymer" can be used interchangeably. These assumptions are incorrect because only dendrimers have a precise end-group multiplicity and functionality. Furthermore, they exhibit properties totally unlike that of other families of macromolecules.

HISTORICAL BACKGROUND

Highly branched and generally irregular dendritic structures have been known for some time, being found, for example, in polysaccharides, such as amylopectin, glycogen, and some other biopolymers. In the area of synthetic structures, Flory discussed, as early as 1952, the theoretical growth of highly branched polymers obtained by the polycondensation of AB_x structures in which x is at least equal to 2. Such highly branched structures are now known as "hyperbranched polymers."

Today, regular dendrimers can only be prepared using rather tedious, multistep syntheses that require intermediate purifications. In contrast, hyperbranched polymers are easily obtained using a variety of one-pot procedures, some of which mimic, but do not truly achieve, regular dendritic growth.[1] The presence of such a large number of atoms within each dendritic or hyperbranched macromolecule permits an enormous variety of conformations with different shapes and sizes. The distribution of molecular weights focuses on the polydispersity index (M_w/M_n), and the requirements for gelation (or avoidance of gelation) when multimodal monomers are incorporated into the macromolecule. Each of these topics are discussed in Newcome's monograph.[2] Lists of reviews between 1986 and 1996 and Advances series are also given.

Buchard[3] outlined some properties of hyperbranched chains. The dilute solution properties of branched macromolecules are governed by the higher segment density found with linear chains. The dimensions appear to be shrunk when compared with linear chains of the same molar mass and composition. It is shown that the apparent shrinking has an influence also on the intrinsic viscosity and the second virial coefficient. The broad molecular-weight distribution (MWD) has a strong influence on these shrinking factors, which can be defined and used for quantitative determination of the branching density (i.e., the number of branching points in a macromolecule). Here, the branching density can be determined only by size-exclusion chromatography (SEC) in online combination with light-scattering and viscosity detectors. The technique and possibilities are discussed in detail.

DISCUSSION

Adendritic structure generally gives rise to better solubility than the corresponding linear analog. For example, aromatic polyamide dendrimers and hyperbranched polymers are soluble in amide-type solvents and even in tetrahydrofuran. Gel-permeation chromatography (GPC) was performed on a Jasco high-performance liquid chromatography (HPLC) 880PU fitted with polystyrene–divinylbenzene columns (two Shodex KD806M and KD802) and a Shodex RI-71 refractive index detector in DMF containing 0.01 mol/L of lithium bromide as an eluent. Absolute molecular weights (M_w) of 74,600, 47,800, and 36,800 were determined by light scattering using a MiniDawn apparatus (Wyatt Technology Co.) and a Shimadzu RID-6A refractive index detector. A specific refractive index increment (dn/dc) of the polymer in DMF at 690 nm was measured to be 0.216 ml/g.[4]

Standards commonly employed[5] to calibrate SEC columns do not have a well-defined size. Carefully characterized spherical solutes in the appropriate size range are therefore of considerable interest. The chromatographic behavior of carboxylated starburst dendrimers—characterized by quasi-elastic light scattering and viscometry—on a Superose SEC column was explored. Carboxylated starburst dendrimers appear to behave as non-interacting spheres during chromatography in the presence of an appropriate mobile phase. The dependence of the retention time on the solute size seems to coincide with data collected on the same column for Ficoll. Chromatography of the dendrimers yields to a remarkable correlation of the chromatographic partition coefficient with the generation number; this result is, in part, a consequence of the exponential relationship between

the generation number and the molecular volume of these dendrimers. All measurements were made in a 9:1 mixture of pH = 5.5, 0.38 *M*, which has been previously known to minimize electrostatic interactions between a variety of proteins and this stationary phase.[4]

The SEC partition coefficient[6] (K_{SEC}) was measured on a Superose 6 column for three sets of well-characterized symmetrical solutes: the compact, densely branched non-ionic polysaccharide, Ficoll; the flexible chain non-ionic polysaccharide, pullulan; and compact, anionic synthetic polymers, carboxylated starburst dendrimers. All three solutes display a congruent dependence of K_{SEC} on solute radius, *R*. In accord with a simple geometric model for SEC, all of these data conform to the same linear plot of $K_{SEC}^{1/2}$ vs. *R*. This plot reveals the behavior of non-interacting spheres on this column. The mobile phase for the first two solutes was 0.2 *M* NaH_2PO_4–Na_2HPO_4, pH 7.0. In order to ensure the suppression of electrostatic repulsive interactions between the dendrimer and the packing, the ionic strength was increased to 0.30 *M* for that solute.

The MWD[7] is derived for polymers generated by self-condensing vinyl polymerization (SCVP) of a monomer having a vinyl and an initiator group ("inimer") in the presence of multifunctional initiator. If the monomer is added slowly to the initiator solution (semibatch process), this leads to hyperbranched polymers with a multifunctional core. If monomer and initiator are mixed simultaneously (batch process), even at vinyl group conversions as high as 99%, the total MWD consists of polymers, which have grown via reactions between inimer molecules (i.e., the normal SCVP process) and those which have reacted with the initiator. Consequently, the weight distribution, $w(M)$, is bimodal. However, the *z*-distribution, $z(M)$, equivalent to the "GPC distribution," $w(\log M)$ vs. $\log M$, is unimodal. Their theoretical studies showed that the hyperbranched polymers generated from an SCVP possess a very wide MWD $M_w/M_n \cong P_n$, where P_n is the number-average degree of polymerization. The evolution of the weight-distribution and *z*-distribution curves of the total resultant polymer during the SCVP in the presence of the core moiety with $f = 10$ is given. The weight distributions become less bimodal with increasing conversion. In contrast, all *z*-distributions are unimodal.

Striegel et al.[8] employed SEC with universal calibration to determine the molecular-weight averages, distributions, intrinsic viscosities, and structural parameters of Starburst dendrimers, dextrans, and the starch-degradation polysaccharides (maltodextrins). A comparison has been made in the dilute solution behavior of dendrimers and polysaccharides with equivalent weight-average molecular weights. Intrinsic viscosities decreased in the order $[\eta_{dexstran}] > [\eta_{dextrin}] > [\eta_{dendrimer}]$. A comparison between the molecular radii obtained from SEC data and the radii from molecular dynamics studies show that Starburst dendrimers behave as θ-stars with functionality between 1 and 4. Additionally, electrospray ionization MS was employed to determine M_w, M_n, and the PD of Astromol dendrimers.

SEC experiments were carried out on a Watters 150CV$^+$ instrument (Waters Associates, Milford, Massachusetts, U.S.A.) equipped with both differential refractive index single-capillary viscometer detectors. The solvent/mobile phase was H_2O/0.02% NaN_3, at the flow rate of 1.0 ml/min. Pump, solvent, and detector compartments were maintained at 50°C. Separation occurred over a column bank consisting of three analytical columns preceded by a guard column: Shodex KB-G, KS-802, KS-803, and KB-804 (Phenomenex, Torrance, California, U.S.A.). Universal calibration was performed using a series of oligosaccharides (Sigma, St. Louis, Missouri, U.S.A.), and Pullulan Standards (American Polymer Standards, Mentor, Ohio, U.S.A., and Polymer Laboratories, Amherst, Massachusetts, U.S.A.).

The solution behavior of several generations of Starburst poly(amido amine) dendrimers, low-molecular-weight ($M_w < 60{,}000$) dextrans, and maltodextrins was also examined by SEC, using the universal calibration. For Starburst and Astramols, supplied M_w values are theoretical average molecular weights. Weight-average molecular weights for the dendrimers determined by SEC with universal calibration using oligosaccharide and polysaccharide narrow standards were slightly, albeit consistently lower than the theoretical averages. In general, the intrinsic viscosity of polymers tends to increase with increasing molecular weight (*M*), which accompanies an increase in the size of the macromolecule. Exceptions to this are the hyperbranched polymers, in which the Mark–Houwink double logarithmic $[\eta]$ vs. *M* curve passes through a minimum in the low-molecular-weight region before steadily increasing. For solutions of the dendrimers studied in their experiments, it is evident that as *M* increases, $[\eta]$ decreases. This corresponds to the molecules growing faster in density than in radial growth. Fréchet has pointed out the special situation of this class of polymers, in which their volume increases cubically and their mass increases exponentially.[9] The exponent *a* in the Mark–Houwink equation for the dendrimers is –0.2 for convergent growth for the generation studied (located in the inverted region of the Mark–Houwink plot). This value for the Starburst dendrimers is comparable to the *a* value of –0.2 for convergent-growth dendrimers, generations 3–6, studied by Mourey et al.[9] When the results from SEC are combined with those from computer modeling by comparing the ratios of geometric to hydrodynamic radii for the trifunctional Starbursts to the ratios derived for the other molecular geometries, the dendrimers appear to resemble θ-stars.

SEC[9] with a coupled molecular-weight-sensitive detection is a simple convenient method for characterizing dendrimers for which limited sample quantities are available. The polyether dendrimers increase in hydrodynamic radius approximately linearly with generation and have a characteristic maximum in viscosity. These properties

distinguish these dendrimers from completely collapsed, globular structures. The experimental data also indicate that these structures are extended to approximately two-thirds of the theoretical, fully extended length.

Puskas and Grasmüller characterized the synthesized star-branched and hyperbranched polyisobutylenes (PIBs) by SEC–light scattering in tetrahydrofuran (THF), with the *dn/dc* measured as 0.09 ml/g. The radius of gyration gave a slope of 0.3, demonstrating the formation of a star-branched polymer.[10]

Gitsov and Fréchet[11] reported the syntheses of novel linear-dendritic triblock copolymers achieved via anionic polymerization of styrene and final quenching with reactive dendrimers. For the characterization of the products in the reaction mixture, SEC with double detection was performed at 45°C on a chromatography line consisting of a 510 pump, a U6K universal injector, three Ultrastyragel columns with pore sizes 100 and 500 Å and Linear, a DRI detector M410, and a photodiode array detector M991 (all Millipore Co., Waters Chromatography Division). THF was used as the eluent at a flow rate of 1 ml/min. SEC with coupled PDA detection proves to be particularly useful in the separation and identification of all compounds in the reaction mixture. A detailed discussion can be found in Ref.[11] SEC/VISC studies show that the ABA copolymers are not entangled and undergo a transition from an extended globular form to a statistical coil when the molecular weight of their linear central block exceeds 50,000.

The solution properties of hybrid–linear dendritic polyether copolymers are investigated by SEC with coupled viscometric detection from the same authors.[12] The results obtained show that the block copolymers are able to form monomolecular and multimolecular micelles depending on the dendrimer generation and the concentration in methanol–water (good solvent for the linear blocks).

Large macromolecular assemblies and agglomerates play an important role in living matter and its artificial reproduction. AB and ABA block copolymers are convenient tools used for modeling of these processes. Usually in a specific solvent–non-solvent system, ABA triblocks form micelles with a core consisting of insoluble B blocks and a surrounding shell of A blocks that extend into the solvent phase. Two Waters/Shodex PROTEIN KW 802.5 and 804 columns were used for the aqueous SEC measurements. The columns were calibrated with 14 PEO and PEG standards. The radius of gyration was calculated from the intrinsic viscosity $[\eta]$ and Unical 4.04 software (Viscotek). The calculated values for the Mark–Houwink–Sakurada constant a are 0.583 for PEG ($K = 9.616 \times 10^{-4}$) and 0.776 for PEO ($K = 2.042 \times 10^{-4}$). They are in close agreement with the data reported for the same polymer in other aqueous mixtures (compositions).

The significant decrease in the $[\eta]$ of the copolymer solutions and the parallel decrease in R_g of the hybrid structures containing [G-4] blocks indicate that the block copolymers are undergoing intramolecular micellization. Unimolecular micelles consisting of a small, dense, dendritic core tightly surrounded by a PEO corona are formed. The influence of the size of the dendritic block was investigated with PEO7500. The solution behavior of ABA hybrid copolymers is documented. In general, materials containing more than 30 wt% of dendritic blocks are not soluble in methanol–water. However, it should be emphasized that the solubility of copolymers is also strongly influenced by the size of the dendritic block. Obviously, an optimal balance between the size of the dendrimer and the length of the linear block is required to enable the dissolution of the copolymer in the solvent composition.

Performing SEC with dual detection (DRI and viscometry) permitted application of the concept of universal calibration.

Derivatization of Analytes: General Aspects

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

INTRODUCTION

A priori information about analytes is available for most chromatographic analyses. Depending on the amount of information available, all determinations may be classified as: 1) preferably confirmatory (determined components are known); or 2) prospective (any propositions concerning their chemical nature are very approximate). Numerous differences in the design of analytical procedures in these two cases are manifested in the features of all stages of analysis—sampling, sample preparation, analysis itself, and interpretation of results. Preferably, for procedures classified as confirmatory, the stage of sample preparation should be supplemented by chemical treatment of the sample by different reagents for the optimization of subsequent chromatographic analysis. The most widely used kind of treatment is the synthesis of various chemical derivatives of target analytes, namely derivatization.

Derivatization is a special subgroup of organic reactions used in chromatography for compounds with selected types of functional groups. Not all known reactions can be applied as methods for derivatization, because these processes should be in accordance with some specific conditions. The consideration of numerous known recommendations[1–4] permits us to underline the following most important ones:

1. The experimental operations should be as simple as possible. The mixing of sample with reagent(s) at ambient temperature, without additional treatment of the mixture, is preferable. In chromatographic practice, the time needed for the completion of the derivatization reaction may be up to 24 hr (the so-called "stay overnight"). Instead of this long time, the heating of reaction mixtures in ampoules is also permitted. Some processes (including alkylation and silylation) may be realized by injection of the reaction mixtures into the hot injector of the gas chromatography (GC) equipment.
2. The number of stages of derivatization for any functional group in organic compounds should be minimal (one or two, but no more). For multistage processes, the condition "single-pot synthesis" is necessary. Such operations as extraction or re-extraction are permitted only when the quantities of analytes are not very small or when it is necessary to isolate them from complex matrices. The large excess of derivatization reagent(s) and/or solvents should be easily removable, or have no influence on the results of the analysis. The use of high boiling solvents typically is not recommended. The possible by-products of reactions should have no influence on the results either.
3. The degree of transformation of initial compounds into products (yield, %) should be maximal and reproducible to provide for the quantitative determination of these compounds by analysis of their derivatives.
4. The chemical origin of the formed products should be strongly predictable. When a known derivatization reaction is put into practice for new compounds, this knowledge can be based on previously reported examples for the closest structural analogs of the target analytes.
5. Mutually unambiguous correspondence between the number of initial analytes and their derivatives should be assured. The optimal case for all compounds is $1 \rightarrow 1$, but numerous examples of type $1 \rightarrow 2$ are known (e.g., the derivatization of enantiomers by chiral reagents, which leads to the formation of a pair of diastereomers).[5] Similarly, the reaction of carbonyl compounds with *O*-alkoxyamines gives pairs of *syn*- and *anti*-isomers of oxime *O*-ethers, etc. All processes that lead to further uncertainty (chemical multiplication of analytical signals), such as $1 \rightarrow N$ ($N \geq 3$), are not recommended for analytical practice. In connection with this, the number of reaction by-products should be minimal.
6. The feature of structural terminology of derivatives should be noted. If the number of newly added protecting groups in the molecules is unknown for derivatives of complex polyfunctional organic compounds, they can be classified in accordance with known derivatives. For example, *N*-benzoyl glycine ($PhCONHCH_2CO_2H$) can form two trimethylsilyl (TMS) derivatives: *mono*-($PhCONHCH_2COOTMS$) and *bis*-[$PhC(OTMS) = NCH_2COOTMS$]. If precise information on their chemical origin is unavailable, both of them can be named simply "benzoylglycine TMS" or "TMS #1" and "TMS #2" in the order of chromatographic elution.

7. The foregoing remarks follow from general features of derivatization reactions. It should be noted that this method is not used for completely unknown samples, because information about the presenting analytes is needed.

In accordance with the criteria mentioned, e.g., *N*,*O*-trimethylsilyl derivatives of amino acids do not seem to be useful in analytical practice owing to the non-specific *mono*- and *bis*-silylation of primary amino groups or post-reaction hydrolysis of the resultant N–Si bonds. Even the simplest compounds of this class, $H_2N–CHR–CO_2H$, form three possible products, $H_2N–CHR–CO_2TMS$, $TMSNH–CHR–CO_2TMS$, and $(TMS)_2N–CHR–CO_2TMS$ [$TMS = Si(CH_3)_3$], with different GC retention parameters. In the case of diamino monocarboxylic acids with non-equivalent amino groups [e.g., lysine, $H_2N(CH_2)_4CH(NH_2)CO_2H$], the number of similar semi-silylated derivatives is theoretically increased up to nine.

MAIN FEATURES OF DERIVATIZATION REACTIONS

The greatest principal difference between organic reactions in general and those that can be considered chromatographic derivatization reactions is the de facto commonly accepted absence of necessity of product structure determination in the latter case. In "classical" organic chemistry, every synthesized compound must be isolated from the reaction mixture and characterized by physicochemical constants or spectral parameters for confirmation or estimation (for new objects) of its structure. Nevertheless, for the processes that have been classified as derivatization reactions, these operations are not necessary and generally not used in analytical practice. *The reaction itself is considered confirmation of the structure of the derivatives.* Of course, any exceptions to this important rule seem very dangerous and should be pronounced as special warnings for the application of any method of derivatization. Hence, in general cases, this method implies a risk in the ascribing of structures to the products formed in the chemical reactions. For new derivatives of complex organic compounds, the independent determination (or confirmation) of their structures seems desirable.

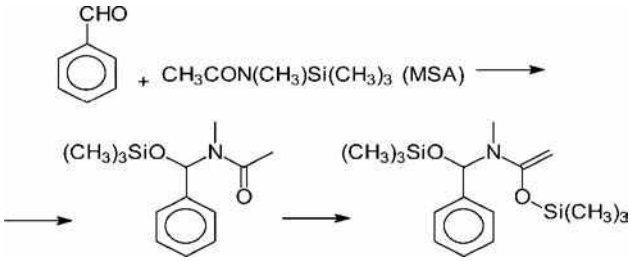
All organic reactions used for derivatization can proceed only in condensed phase, i.e., in solutions. None of these interactions are possible in gaseous media. Nevertheless, there is a special technique, flash derivatization, which involves joint (or more rarely, consecutive) injection of samples and reagents into GC equipment. It is noteworthy that in this case too, all reactions take place in the condensed phase, i.e., before evaporation of the samples. This method has been recommended for silylation, but is more often used for alkylation by a special group of chemicals—quaternized ammonium salts and hydroxides. For example, such reagents as 3,5-*bis*-(trifluoromethyl)benzyl dimethylphenylammonium fluoride have been proposed for flash conversion of hydroxy compounds (preferably phenols and carboxylic acids) into their 3,5-*bis*-(trifluoromethyl)benzyl ethers.[6]

There are many examples where well-known derivatization reactions cannot be used in specific cases owing to the absence of mutually unambiguous correspondence between initial analytes and formed derivatives. For instance, methylation by diazomethane, CH_2N_2, is not recommended for barbiturates, because of the formation of mixtures of their *N*- and/or *O*-methyl derivatives. Another example is the interaction of dimethyl disulfide with conjugate dienes,[7] which gives complex mixtures of products and indicates the absence of regioselectivity. One of the frequently used derivatization methods for carbonyl compounds [RR′CO (including the important group of ketosteroids)] is their one-step treatment by *O*-alkyl hydroxylamines ($R''ONH_2$) with the expected formation of alkyl ethers of oximes ($RR'C = NOR''$). However, this reaction has an anomaly for compounds with C = C double bonds conjugated with carbonyl groups, that is, parallel addition of reagent with active hydrogen atoms to the polarized C = C bonds (see Eq. 1 below).[8]

This means that instead of one expected product with molecular weight (MW) = $M_0 + 29$ (with *O*-methyl hydroxylamine as reagent; M_0—molecular weight of initial carbonyl compound), reaction mixtures may contain two additional products with $MW = M_0 + 47$ and $M_0 + 76$. This feature is negligible for the analysis of individual compounds, but when samples are mixtures of components of interest, the analysis becomes impossible because of the complexity of interpretation of the results.

In any case, the information about the estimated products of derivatization should be unambiguous. As an important example, it is interesting to note that for a long time, it was considered that various silylating agents could react only with compounds having active hydrogen atoms. However, only in 1999 was it shown[9] that typical reagents of this type (*N*-methyl trimethylsilyl acetamide, MSA) react with aromatic carbonyl compounds (preferably aldehydes) giving unusual products of acetamide addition to C = O bonds followed by their one- or two-step silylation. Keeping this fact in mind, it is better to name these products MSA adducts rather than TMS derivatives.

$$\begin{array}{ccc} R_2 = CR' - OR'' + CH_3ONH_2 \rightarrow & & R_2C = CR' - CR'' = NOCH_3 \\ \downarrow & & \downarrow \\ CH_3ONH - CR_2 - CHR' - COR'' & \rightarrow & CH_3ONH - CR_2 - CHR' - CR'' = NOCH_3 \end{array} \quad (1)$$



Only if the organic reaction is in accordance with all the above-mentioned criteria may it be considered a method for derivatization. Finding new appropriate processes of this type is complex and often not obvious.

One of the main, but not sole, purposes of derivatization is the transformation of non-volatile compounds into volatile derivatives. Each chromatographic method [GC, GC/mass spectrometry (MS), high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), etc.] being supplemented by derivatization of analytes permits us to solve some specific problems. The principal among them are summarized briefly in Table 1; more detailed comments follow. Some of the derivatization methods mentioned can also be used in mass spectrometry, which includes no preliminary chromatographic separation of analytes,[10] but there are special derivatization techniques never used in chromatographic methods (e.g., synthesis and analysis of isotopically labeled compounds).

Most monofunctional organic compounds [including alcohols (ROH), carboxylic acids (RCO_2H), amides ($RCONH_2$), etc.] are volatile enough for direct GC analysis. Exceptions are only those compounds with high melting points (sometimes with decomposition) because of strong intermolecular interactions in their condensed phases {e.g., thiosemicarbazones ($RR'C = N–NHCSNH_2$), guanidines [$RNH–C(=NH)–NH_2$], etc.}. Ionic compounds [e.g., quaternary ammonium salts, $(R_4N)^+X^-$] are non-volatile as well. If the compounds contain two or more functional groups with active hydrogen atoms [including the case of inner molecular ionic structures such as that seen in amino acids, $RCH(NH_3^+)CO_2^-$], their volatility decreases significantly. The purpose of derivatization of all these objects is to substitute active hydrogen atoms (better in all functional groups) by covalently bonded fragments that provide more volatile products. Direct GC analysis of highly reactive compounds {free halogens, hydrogen halides, strong inorganic acids like sulfonic acid (RSO_2OH), phosphonic acid [$RPO(OH)_2$], etc.} can be accompanied by their interaction with stationary phases of chromatographic columns and they also require derivatization.

Table 1 Principal applications of derivatization in different chromatographic techniques.

Aims of derivatization	Typical examples
GC	
Transformation of non-volatile, thermally unstable, and/or highly reactive compounds into stable volatile derivatives	$ROH \rightarrow ROSiMe_3$ $ArOH \rightarrow ArOCOCF_3$ $RR'CO \rightarrow RR'C = NOCH_3$
Synthesis of derivatives for element-specific GC detectors or conversion of non-detectable compounds into suitable products for minimization of detection limit	$ROH \rightarrow ROCOCCl_3$ (ECD) $RCO_2H \rightarrow RCO_2CH_2CCl_3$ (ECD) $HCO_2H \rightarrow HCO_2CH_2C_6H_5$ (FID)
Combination with stage of sampling (preferably in environment analyses when derivatization is used as method of chemisorption)	$RCHO \rightarrow 2,4\text{-}(NO_2)_2C_6H_3–NH–N = CHR$
Separation of enantiomeric compounds on non-chiral phases after their conversion into diastereomeric derivatives	$RR'C^*HNH_2 + C_6H_5C^*H(OMe)COCl \rightarrow RR'C^*HNH–COC^*H(OMe)C_6H_5$
GC/MS	
Determination of molecular weights of compounds with $W_M \approx 0$ at electron impact ionization (synthesis of derivatives with conjugated bond and/or atom systems)	$RR'CO \rightarrow RR'C = NNH–C_6F_5$ (π–p–π conjugation system) $RNH_2 \rightarrow RN = CH–NMe_2$ (p–π conjugation system)
Increase of specificity of molecular ion fragmentation for estimation of structure of analytes (e.g., determination of C = C double bond position in carbon skeleton of molecules)	"On-site" derivatization:[11] $RCH = CHR' \rightarrow$ R–CH(SMe)–CH(SMe)–R′ "Remote-site" derivatization:[12] $RCH = CH(CH_2)_nCO_2H + H_2NCH_2CH_2OH \rightarrow$ 2-substituted oxazolines
HPLC with UV detection and CE	
Synthesis of chromogenic derivatives (with chromophores that provide adsorption within typical range of UV detection of 190–700 nm)	$C_6H_7O(OH)_5 \rightarrow C_6H_7O(OCOC_6H_5)_5$
Conversion of hydrophilic analytes into more hydrophobic derivatives	$RCH(NH_2)CO_2H \rightarrow RCH(NHCSNHC_6H_5)CO_2H$
Various chromatographic techniques	
Determination of number of functional groups with active hydrogen atoms using mixed derivatization reagents	$X(OH)_n + [(R_1CO)_2O + (R_2CO)_2O)] \rightarrow$ mixture of miscellaneous acyl derivatives

C*—chiral carbon atoms.

Table 2 Average values of differences of GC retention indices (ΔRI) for some derivatization reactions.

$\Delta MW = MW_B - MW_A$	Scheme of reaction A → B (for monofunctional compounds only)	$\Delta RI \pm s_{\Delta RI}$
14	$RCO_2H \rightarrow RCO_2Me$	–102 ± 28
14	$ArOH \rightarrow ArOMe$	–62 ± 16
28	$RCO_2H \rightarrow RCO_2Et$	–42 ± 7
28	$RR'CO \rightarrow RR'C = NNHMe$	229 ± 23
29	$ROH \rightarrow RONO$	–6 ± 27
42	$ROH \rightarrow ROCOMe$	142 ± 18
42	$ArOH \rightarrow ArOCOMe$	97 ± 20
42	$RNH_2 \rightarrow RNHCOMe$	437 ± 29
42	$ArNH_2 \rightarrow ArNHCOMe$	401 ± 7
42	$RR'CO \rightarrow RR'C = NNMe_2$	302 ± 20
72	$ROH \rightarrow ROSiMe_3$	119 ± 18
72	$RCO_2H \rightarrow RCO_2SiMe_3$	76 ± 16
96	$ROH \rightarrow ROCOCF_3$	–85 ± 24
114	$RCO_2H \rightarrow RCO_2SiMe_2$–*tert*-Bu	288 ± 29

If the initial compound A may be analyzed together with its derivative B, the comparison of their GC retention indices is a source of important information about the nature of these compounds. The average value of $\Delta RI = RI(B) - RI(A)$ may be used for the identification of both analytes and, if necessary, the reaction itself.[13] Selected ΔRI values for GC analysis on standard non-polar polydimethyl siloxanes are presented in Table 2.

GC/MS analysis completely excludes the second item (see Table 1) from the possible aims of derivatization, insofar as the mass spectrometer itself is both a universal and selective GC detector. At the same time, two new important reasons for derivatization appear in this method. The intensities of molecular ion ($M^+ \cdot$) signals are low for compounds having no structural fragments, which provides the effective delocalization of charge and unpaired electron in these ions. These fragments are conjugate bond and/or atom systems, or isolated heteroatoms with high polarizability (S, Se, I). In accordance with this regularity, *O*-TMS derivatives of alcohols in general show no $M^+ \cdot$ peaks in mass spectra, whereas for the TMS ethers of enols of carbonyl compounds ($RCH_2COR' \rightarrow RCH = CR'$–$OSiMe_3$) and TMS ethers of their oximes ($RCH = N$–$OSiMe_3$) (π–p–d conjugation systems), they are very intensive.

The determination of positions of C = C double bonds in the carbon skeletons of molecules is very often impossible owing to uncertain charge localization in molecular ions. The solution of this problem involves the conversion of unsaturated compounds into products whose molecular ions have sufficiently fixed charge localization. There are two methods by which to accomplish this localization: 1) addition of heteroatomic reagents directly to the C = C bond (the so-called "on-site" derivatization with the formation of TMS ethers of corresponding diols, adducts with dimethyl disulfide,[11] etc.); and 2) introduction or formation of nitrogen-containing heterocycles rather far from the target C = C bond[12] ("remote-site" derivatization).

The formation of new chromophores for the optimization of UV detection of analytes in HPLC involves the synthesis of derivatives with conjugate systems in the molecule. Compared with GC, there are no restrictions on the volatilities of these derivatives for HPLC analysis. They may be synthesized before analysis (precolumn derivatization) or after chromatographic separation (postcolumn derivatization, or, in other words, reaction GC). The latter technique, as a method of identification of analytes, was highly popular until the 1970s. However, at present, this approach has practically lost its significance owing to the progress of GC/MS methods. Very few new GC applications of this method have been reported during the past dozens years or so[14], but it is still used in HPLC because it permits us to combine the measurement of retention parameters of initial analytes with detection of their derivatives.[15]

The range of most convenient hydrophobicity of organic compounds for reversed-phase (RP) HPLC separation may be estimated approximately as $-1 \leq \log P \leq +5$ ($\log P$ is the logarithm of the partition coefficient of the compound being characterized in the standard solvent system 1-octanol/water). Highly hydrophilic substances with $\log P \leq -1$ need a special choice of analysis conditions, e.g., introduction of ion-pair additives into the eluents. Another approach is their conversion to more hydrophobic derivatives by the modification of functional groups with active hydrogen atoms.

The examples mentioned here for RP-HPLC analysis of monosaccharides in the form of their perbenzoates and amino acids as *N*-phenylthiocarbamoyl derivatives (Table 1) satisfy both principal criteria: introducing the chromophores into molecules of analytes (C_6H_5CO– and C_6H_5NH–CS–NH–) and optimization of their retention parameters.

Sometimes, the generally prohibited multiplication of analytical signals of derivatives may be attained artificially for the solution of special problems. For example, the treatment of polyhydroxy compounds (phenols, phenol carboxylic acids, polyamines, etc.) [$X(OH)_n$] by equimolar mixtures (1 : 1) of acylation reagents [$(R_1CO)_2O + (R_2CO)_2O$] leads to the formation of ($n + 1$) miscellaneous acyl derivatives $X(OCOR_1)_n$, $X(OCOR_1)_{n-1}(OCOR_2)$,..., $X(OCOR_2)_n$. The relative abundances of their chromatographic peaks should be close to the binomial coefficients, i.e., 1 : 1 (at $n = 1$), 1 : 2 : 1 ($n = 2$), 1 : 3 : 3 : 1 ($n = 3$), and so forth. Moreover, the differences of retention indices of all these mixed derivatives are close to each other. These two regularities permit us to determine the number of hydroxyl groups (n) in the molecules of analytes. This mode of derivatization can be realized in both HPLC[16,17] and GC[18] conditions.

Insofar as the derivatization can be considered one of the stages of sample preparation for chromatographic analysis, it can be combined with other procedures, for instance, the preconcentration of traces of analytes. For example, the yield of solid-phase extraction or microextraction of organic compounds from aqueous solutions with modified silica gels is better for more hydrophobic substances; the preliminary conversion of acidic compounds into suitable derivatives is recommended.[19]

CONCLUSIONS

Chemical derivatization as a stage of sample preparation is a widespread approach in various chromatographic and related techniques. It is used for the conversion of compounds that cannot be analyzed directly into suitable products (derivatives). The aims of this treatment of samples are very diverse and depend on the final goals of analyses as a whole. One of the most important problems to be solved using derivatization is the transformation of nonvolatile compounds into products volatile enough for GC analysis. Other aims of this method include the optimization of detection and structure evaluation of analytes.

A disadvantageous feature of derivatives of complex organic compounds can be the uncertainty in their structures. This requires their determination (or confirmation) by independent methods (MS), or the exhaustive characterization of reactions classified as those of derivatization.

Detection in CCC

M.-C. Rolet-Menet
Analytical Chemistry Laboratory, Unit of Formation and Research (UFR) of Pharmaceutical and Biological Sciences, Paris, France

INTRODUCTION

Detection of solutes is an essential link in the separation chain. It helps to reveal solute separation by detecting them in the column effluent, and in some cases, it could permit their characterization. These objectives are based on the various physical properties of the products.

Countercurrent chromatography (CCC) is a chromatographic method that separates solutes that are more or less retained in the column by a stationary phase (liquid in this case) and are eluted at the outlet of the column by a mobile phase. Two treatments of column effluent have been used up to now in CCC. Either the column outlet is directly connected to a detector commonly used in HPLC (online detection) or fractions of mobile phase are collected and analyzed by spectrophotometric, electrophoretic, or chromatographic methods etc. (off-line detection).

The first one is more practical and rapid to carry out. It is commonly used in analytical applications of CCC and also in preparative CCC to analyze effluent continuously and to follow the steps of the separation.

The second one is often tedious because each fraction must be analyzed. However, it is of great interest in preparative applications of CCC, especially to measure the purity of fractions and the biological activity of separated compounds and also to recover a product from one fraction or some selected fractions to resolve its chemical structure.

ON-LINE DETECTION

This type of detection can be used as such in preparative CCC to monitor separations, before the fraction collector, if any, and in analytical CCC (for instance, during the determination of log $P_{\text{octanol/water}}$).

Several detectors used in high-performance liquid chromatography (HPLC) and in supercritical fluid chromatography (SFC) can be connected to the CCC column[1] to detect solutes and thus follow separation. They can be, for instance, fluorimeters (very sensitive and used without modifications in CCC), UV–Visible spectroscopes,[1] evaporative light scattering detectors,[1,2] atomic emission spectroscopes,[3] etc. Some detectors give more information than the detection of the solute, such as structural information of separated components, as in infrared spectroscopy,[4] mass spectrometry,[5] or nuclear magnetic resonance.[6] These detectors are used either online with a collector fraction or in parallel if they are destructive.

UV Detection

The UV–Visible detector is the universal detector used in analytical and preparative CCC. It does not destroy solutes. It is used to detect organic molecules with a chromophore moiety or mineral species after formation of a complex (for instance, the rare earth elements with Arsenazo III[7]). Several problems can occur in direct UV detection, as has already been described by Oka and Ito:[8] 1) carryover of the stationary phase due to improper choice of operating conditions, with appearance of stationary phase droplets in the effluent of the column; 2) overloading of the sample, vibrations, or fluctuations of the revolution speed; 3) turbidity of the mobile phase due to difference in temperature between the column and the detection cell; or 4) gas bubbling after reduction of effluent pressure. Some of these problems can be solved by optimization of the operating conditions, better control of the temperature of the mobile phase, and addition of some length of capillary tubing or a narrow-bore tube at the outlet of the column before the detector to stabilize the effluent flow and to prevent bubble formation. The problem of stationary phase carryover (especially encountered with hydrodynamic mode CCC devices) can be solved by the addition between the column outlet and UV detector of a solvent that is miscible with both stationary and mobile phases and that allows one to obtain a monophasic liquid in the cell of the detector[1] (a common example is isopropanol).

Evaporative Light-Scattering Detection

Evaporative light-scattering detection (ELSD) involves atomization of the column effluent into a gas stream via a Venturi nebulizer, evaporation of solvents by passing it through a heated tube to yield an aerosol of non-volatile solutes, and finally measurement of the intensity of light scattered by the aerosol. After a suitable evaporation step, in the worst case of segmented or emulsified mobile phase, the column effluent should always be an aerosol of the solutes before reaching the detection cell. It can be used without modifications. For molecules without chromophore or fluorophore groups or with mobile phases with a high UV cut-off

(acetone, ethyl acetate, etc.), ELSD is useful.[1] But it cannot detect fragile or easily sublimable solutes because the nebulizate is heated. Moreover, this detection method does not preserve the solutes. To collect column effluent, a split must be installed at the outlet of the column to allow ELSD detection in a parallel direction to fraction collection with consequent loss of solutes.

Atomic Emission Spectrometry[3]

This detection mode can be used during ion separation. Kitazume et al. used a direct plasma atomic emission spectrometer (DCP, Spectra-Metrics Model SpectraSpan IIIB system with fixed-wavelength channels) for observation of the elution profile during the separation of nickel, cobalt, magnesium, and copper by CCC. For profile measurement of a single element, an analog recorder signal from the DCP was converted into a digital signal. The digital data were stored in a workstation and the elution profile was plotted. For simultaneous multielement measurement, the emission signal for each channel was integrated for 10 sec at intervals of 20 sec, and the integrated data were printed out.

Infrared Spectrometry[4]

Romanach and de Haseth have used a flow cell for liquid chromatography/Fourier transform-infrared spectrometry (LC/FT-IRS) in CCC. The main difficulty is the absorbance of the liquid-mobile phase. This problem is exacerbated in LC by low solute to solvent ratios in the eluates. In contrast, CCC leads to a high solute to solvent ratio so that it can be used with a very simple interface with a CCC column without any complex solvent removal procedures. High-sample loadings are possible by using variable path length of the IR detector (from 0.025 to 1.0 mm).

Mass Spectrometry[5]

Several interfaces have been used in CCC/MS. The first employed is the thermospray (TSP). When the column is directly coupled with TSP MS, the CCC column often breaks due to the high backpressure generated by the TSP vaporizer. In contrast, other interfaces using methods such as fast atom bombardment (FAB), electron ionization (EI), and chemical ionization (CI) have been directly connected to a CCC column without generating high backpressure. Such interfaces can be applied to analytes with broad polarity. As it is suitable to introduce effluent from the column CCC into MS only at a flow rate between 1 and 5 μl/min, the effluent is usually introduced into MS through a splitting tee, which is adjusted to an adequate ratio.

Nuclear Magnetic Resonance

Nuclear magnetic resonance (NMR) gives maximum structural information and allows measurement of the relative concentrations of eluted compounds. Spraul et al.[6] experimented with coupling of pH zone refining centrifugal partition chromatography (CPC) with NMR by using a biphasic system based on D_2O and an organic solvent.

On-line pH Monitoring

In pH zone refining, solutes are not eluted as separated peaks but as contiguous blocks of constant concentrations, so that it is highly difficult to monitor the separation by means of a UV detector. Online pH monitoring is generally used, allowing the observation of transitions between solutes, since each zone has its own pH determined by the pK_a and the solute concentration. The experiment was carried out in stop–flow mode.

OFF-LINE DETECTION

The analysis of the mobile-phase fractions collected at the outlet of the column is the oldest method used in CCC (droplet CCC and rotation locular CCC) to evaluate the quality of separation and to characterize solutes. With modern CCC methods such as CPC, CCC Type J, and

Table 1 Off-line detection.

Molecules	Fraction analysis
Schisanhenol acetate 5 and 6 of *Schisandra rubriflora*[5]	TLC
	Purity control by HPLC
Bacitracin complex[5]	Absorbance measure at 234 nm Purity control by HPLC

Recombinant uridine phosphorylase[9]	SDS–PAGE Enzymatic activity by Magni method
Torpedo electroplax membranes[9]	Percentage of cholinergic receptor

cross axis, numerous applications have been described for preconcentration and preparative chromatography. Table 1 lists some applications described in reference books.[5,9] The type of detection used for each fraction depends on the isolated solute. They are TLC and HPLC on line with UV detector or mass spectrometer[10–12] (HPLC also enables an estimation of each fraction's purity,[13,14] a determination of fingerprints of medicinal plants,[15] etc.) for organic solutes, ICP–AES for mineral species, and polyacrylamide gel electrophoresis (PAGE) for biological molecules.[16,17] If the purity of the compound is satisfactory, a study by direct injection MS[18] and NMR[19] allows determination of its chemical structure. Biochemical tests are also available to verify the biological activity of biomolecules, which are often separated and collected in aqueous two-phase systems.[17]

CONCLUSIONS

High-speed CCC is mainly dedicated to preparative separations. Two types of detection are available: online and off-line detections. The first allows one to follow the quality of the separation. The second is suited to the analysis of fractions collected during preparative separation.

Detection in FFF

Martin Hassellöv
Department of Chemistry, Analytical and Marine Chemistry, Göteborg University, Göteborg, Sweden

Frank von der Kammer
Department for Environmental Science and Technology, Technical University of Hamburg-Harburg, Hamburg, Germany

INTRODUCTION

The main purpose of the detector in a field-flow fractionation (FFF) system is to quantitatively determine particle number, volume, or mass concentrations in the FFF size-sorted fractions. Consequently, a number, volume, or mass dependent size distribution of the sample can be derived from detection systems applied to FFF [e.g., (UV–Vis) fluorescence, refractive index, inductively coupled plasma ionization mass spectrometry (ICPMS)]. Further, on-line light scattering detectors can provide additional size and molecular weight distributions of the sample.

An analytical separation technique requires a detection method responding to some or all of the components eluting from the separation system. The choice of detector is determined by the demands of the sample and analysis. For FFF techniques, many of the detection systems have evolved from those used in LC techniques.

Detection can be carried out either with an online detector coupled to the eluent flow, or by collection and subsequent analysis of discrete fractions. For collected fractions, a range of analytical methods can be used, both quantitative (e.g., radioactive isotope labeling and metal analysis) and more qualitative (e.g., microscopic techniques). Online detectors suitable for coupling to the FFF channels include both non-destructive flow through cell systems and destructive analysis systems. It is often desirable to use online detection if possible since the total analysis time is much less than for discrete fraction analysis. Regardless of detector type, the dead volumes and flows in the system between the FFF channel and detector or fraction collector must be accurately determined and corrected for.

If the signal from a detector is a factor of two properties, it is possible to use another detector on line to resolve the different properties, e.g., multiangle light scattering (MALS) in combination with differential refractive index (DRI), or continuous viscosimetry + DRI. Alternatively, the two detectors may respond to two different properties of interest: In either case, it is almost as simple to acquire multiple detector signals as a single one. Multiple detectors can be arranged either in series or in parallel. A parallel detector arrangement avoids the band broadening problem encountered in the serial arrangement, where the first detector may cause significant band broadening for the second, due to the dead volume in the flow cell. For a serial detector connection, it is best to have the one with the smallest dead volume first, as long as it is not a destructive detector. Some detectors, such as DRI detectors, have restrictions regarding the maximum allowable pressure in the flow cell and must be connected last in series. For parallel coupling, the outflow from the FFF channel needs to be split to two or more detectors, and it is then essential to have control of the individual flows, since changes can induce drift in sensitivity and shifts in the dead times between the channel and detector during a run.

When choosing detector and experimental conditions, one needs to consider analyte concentration, detector sensitivity, background level, and detection limits. The maximum amount of analytes that can be injected is usually limited by sample overloading in the FFF channel (interparticle interactions), which disturbs the separation. It is necessary to have an analyte detection limit well below the overloading sample concentration to be able to quantify the peaks without too noisy a background. When using multiple detectors on line, their sensitivity may be quite different either overall or as a function of size range. An example of this is the use of a MALS detector, which has much higher sensitivity for larger particles, together with a DRI detector, which has the opposite sensitivity properties, making the small and large particle ranges difficult to cover.

OPTICAL DETECTION SYSTEMS

UV–Vis spectrophotometers are the most commonly used detectors for FFF applications mainly due to their availability, simplicity, and low cost. The majority of FFF work to date has focused on separation method development where the use of a UV–Vis detector showing the quality of the separations is sufficient. However, the quantification of the separated particles or macromolecules is not always straightforward, since the UV–Vis signal is actually a

turbidimetric measure for solid particles that is fully based on light scattering principles and an absorption measure for light-absorbing macromolecules. The absorbance contribution is only dependent on concentration, but there is a more complicated relationship involved in the light scattering signal, and both principles may be applicable if the solid particles and macromolecules are of comparable. In case of turbidity, large particles scatter light much more effectively than smaller particles, and particles with varying composition and refractive indices give rise to further complications. The correction of the detector signal according to Mie scattering theory is complicated but can often be simplified with appropriate assumptions.[1] For particles larger than 1 μm, efforts have been put into development of an absolute or standard-free quantification method using UV–Vis detection for gravitational FFF.[2] For the scattering phenomenon of nanometer sized particles, a corrective method was developed recently by evaluation of the turbidity spectrum acquired with spectral resolved UV/Diode array detector (DAD) detection.[3] In principle, the light scattering signal is dependent on particle properties such as, e.g., concentration and size, but also on the observation angle and the wavelength of the incident light. In the case of UV/DAD and fluorescence detectors, where only one fixed observation angle is available, the light scattering may be evaluated as a function of the applied wavelength. This approach was successfully applied[3] for the correction of the turbidity signal of FFF fractionated latex beads, which were smaller in size than the applied wavelength ($\lambda = 254$ nm).

The DRI detector is very common in size-exclusion chromatography (SEC) and records any change in refractive index of the sample stream relative to a reference stream. It is a general detector with the advantage of responding to almost all solutes, and it is concentration selective. The sensitivity of a DRI detector is not always the best, but new detector models offer different lengths of optical path, so that the sensitivity can be adjusted to match sample concentration. The DRI detector is not sensitive to changes in flow rate, but is highly sensitive to temperature changes. It is probably the most used detector for FFF applications after the UV detector.

Flows through fluorescence detectors are very common in LC, mainly due to the high selectivity and good signal-to-noise ratio. Only a few papers on FFF with fluorescence detectors are published, but when the analytes have suitable fluorescence properties, this is an excellent choice.

For fluorescence detectors offering excellent stray light suppression, a special mode of operation is available that turns them into simple light scattering detectors. By setting the excitation wavelength equal to the emission wavelength, the light scattered by particles is observed at 90° to the incident light. In contrast to turbidimetry in UV–Vis detectors, this is termed nephelometry and not interfered by light-absorbing substances. The problem of the dependence of the light scattering signal on sample properties other than particle concentration, such as particle size and shape, is also present with this technique.

Photon correlation spectroscopy (PCS), also called dynamic light scattering or quasielastic light scattering, correlates the short-term fluctuations of the light scattering signal to the diffusion coefficients of the sample particles. Photon correlation spectroscopy is a valuable tool in validation of FFF separations. One prerequisite of PCS is that the sample itself be at rest and show nearly no motion other than the Brownian motion of the analyte. Hence, it is too slow to be of practical use as an online detector. Recent flow-through static light scattering detectors offer a PCS option. This can only provide the PCS detection on line and "in flow" for very small macromolecules and particles, which must be present at sufficiently large concentrations. Photon correlation spectroscopy has, for example, been used for verification of the average sizes obtained from FFF theory for discrete fractions of emulsion separated using sedimentation FFF.[4]

Improvements in light scattering theory and instrumentation have been going on for decades, but the development of the MALS instrument—from the earlier low angle light scattering (LALS) technology, now incorporating up to 18 detectors measuring the scattered light at individual angles—presents a breakthrough in particle sizing. Compared to LALS instruments, multiangle detection allows more physical properties of the particles to be derived from the results. Also, the MALS instrument has higher sensitivity and is less affected by dust particles in the sample. Light scattering techniques give average values of the properties of the particle population in the sample and do not describe the property distribution of the sample, but when coupled to a particle sizing technique, such as FFF, the distributions of the different properties are derived from each size fraction.

MALS theory has been thoroughly described in several papers by Wyatt[5] and will only be mentioned briefly here. For each size fraction or batch measurement, the following applies as long as the limits of the Rayleigh–Gans–Debye approximation are fulfilled. This means that the particles are smaller than the incident light's wavelength, the refractive index is similar to that of the solvent, and no light absorption occurs:

$$\frac{Kc}{R_\theta} = \frac{1}{M_w P(\theta)} + 2A_2 c + \cdots \quad (1)$$

$$P(\theta) = 1 - a_1[2k\sin(\theta/2)]^2 + a_2[2k\sin(\theta/2)]^4 - \cdots \quad (2)$$

K is a light scattering constant including refractive index increment and wavelength of the scattering light and A_2 is the second virial coefficient. If the sample is very dilute, the second term of Eq. 1 can be neglected and the excess Rayleigh ratio, R_θ (net light scattering contribution from each component at angle θ), becomes directly proportional

to $M_wP(\theta)$. On plotting R_θ/Kc against $\sin^2(\theta/2)$, the intercept yields molecular weight (M_w) at the concentration c, and from the slope, the root mean square radius (RMS radius) can be derived. One great advantage with the MALS detector is that it does not demand calibration of the channel with reference materials. The absolute concentration of the analyte is necessary to determine the molar mass of the analyte since the signal includes a factor of concentration. The determination of the RMS radius is independent of concentration and can be achieved from the MALS signals alone. To acquire the sample concentration at each time slice, a concentration calibrated DRI detector is commonly used on line with the MALS detector. FFF/MALS/DRI is receiving much interest and attention and many applications have been developed in recent years, especially in synthetic polymer and biopolymer characterization. Thielking and Kulicke[6] have published papers on the coupling of FFF/MALS/DRI for analysis of both polystyrene particles and smaller polystyrene sulfonates (PSS). Fig. 1 shows their results of DRI derived concentration and molecular weight given from MALS data as a function of elution volume for seven PSS standards. However, for small molecules ($<$ 10 kDa), the sensitivity of the MALS detector is rather poor. The use of MALS together with FFF proved to be useful and complemented SEC/MALS techniques for polymers that could not be fractionated by SEC. After the first applications were documented,[6] several FFF subtechniques were coupled to MALS. The target analytes were mainly polysaccharides,[7] different kinds of polystyrene latex particles,[5,8] and starch polymers.[9] Nearly no characterization of natural particles using FFF/MALS is reported. Magnuson et al.[10] analyzed freshly precipitated iron oxides with FFF/MALS, and it was applied to analyze natural colloids extracted from soil.[11]

The technique complements FFF ideally, since FFF provides a prefractionation to overcome limitations of MALS on broad distributed bulk samples, and MALS delivers independent molar mass and RMS radius determination.

In an evaporative light scattering detector (ELSD), the sample is nebulized, and when the solvent in the resulting droplets is evaporated, their mass content is proportional to particle mass in the sample stream. The particles are detected with a laser light scattering detector and the signal is related to their size. The ELSD has not been extensively used in FFF. Oppenheimer and Mourey[12] showed that it can be a good complement to turbidimetric detection in sedimentation FFF for particles smaller than 0.2 μm. This detector is free from the problems associated with UV detectors when applied to a broad size range or samples with differing extinction coefficients over the size range. Further, it can be used for samples lacking absorbance characteristics. Compton, Myers, and Giddings[13] presented a single particle detector for steric FFF (1–70 μm) based on light scattering of single particles flowing through the laser light path. Today, there are several other commercial flow stream particle counters available.

The continuous viscosity detector has been shown to be a good detection tool for thermal FFF analysis of polymer solutions.[14] Due to the high sample dilution in FFF, the viscosity detector response above the solvent baseline, ΔS, is only dependent on the intrinsic viscosity of every sample point, $[\eta]$, multiplied by the concentration, c, at the corresponding points:

$$\Delta S = [\eta]c \tag{3}$$

If a concentration-selective detector, such as a DRI detector, is connected on line with the viscosity detector, the ratio of the two signals yields the intrinsic viscosity distribution of the polymer sample. In polymer characterization, the intrinsic viscosity can be a property just as important as the molecular weight distribution. Furthermore, polymer intrinsic viscosity follows the Mark–Houwink relation to the molecular weight, M, where K and a are Mark–Houwink viscosity constants:

$$[\eta] = KM^a \tag{4}$$

MASS SPECTROMETRIC DETECTION SYSTEMS

The mass spectrometry (MS) detection methods covered here are mainly a selection of commonly used liquid chromatography/mass spectrometry (LC/MS) methods, some of which have been optimized for FFF techniques or could potentially be good detection tools for FFF separations.

The issue in the coupling of a liquid-based separation method to a mass spectrometer is the ion source conversion of dissolved analytes to ions in the high vacuum mass

analyzer, which for instance can be magnetic sectors, quadrupoles, ion traps, or time-of-flight (TOF) analyzers. Different ion sources give different information depending on the ionization mechanisms and will be discussed for each method below.

In most FFF separations, a moderate concentration of dispersion agent, electrolyte, or surfactant is used to improve the separations. A common feature for most MS instruments is that salt in the liquid entering the ion source leads to deterioration of the performance of the MS by lowering the signal-to-noise ratio and by condensing on surfaces inside the MS, thus continuously increasing the background level.

Today, the most frequently used LC/MS ion source is electrospray ionization (ESI), in which the sample stream ends in a narrow capillary, put on a high voltage (positive or negative). This potential, sometimes together with a sheath gas flow, gives rise to a spray of small charged droplets ($\sim$ 1 μm). When the solvent is evaporated from these droplets, electrostatic repulsion forces smaller droplets ($\sim$ 10 nm) to leave. Before entering the semivacuum region, free analytes with one or more net charges usually due to proton transfer or ion adducts (e.g., Li^+, Na^+, or NH_4^+) dominate.

Electrospray ionization is a mild ionization method, that is, almost no fragmentation of the ions occurs. It is applicable to all organic compounds involved in proton exchange or binding to ions in the gas phase, which includes almost all biomolecules and polymers. In ESI/MS, multiple charges occur with a charge distribution for all components. This charge envelope usually has maximum intensity at *m/z* about 1000 and rarely ranging beyond 2000 in *m/z*. This has the advantage that large molecules, such as peptides, DNA molecules, or polymers, can be analyzed by all common MS analyzers, but the drawback is that the resulting spectra can be complicated to interpret. For single mass molecules such as peptides, there are numerical models to deconvolute the single charge molecular weight from the ESI/MS *m/z* spectra, but for incompletely separated polymer components, the overlapping charge distributions for the individual polymer components make the interpretation complicated. ESI/MS sensitivity is dramatically reduced due to cluster formation in the presence of more than a few millimoles per liter of the salt, and surfactants can have a devastating effect on the ESI/MS spectra. Therefore, a volatile buffer should be used if possible (e.g., ammonium acetate, ammonium nitrate). ESI/MS has been used as a detector for flow field-flow fractionation (FlFFF) analysis of low molecular weight ethylene glycol polymers,[15] where the effect of different carriers on cluster formation was investigated. ESI/MS has been coupled to SEC in several applications for polymer analysis and other applications where FFF techniques can be successfully used, including proteins, neuropeptides, and DNA molecule segments. Modern ESI/MS has a broad range of flow rates from nanoliters up to a milliliter per minute.

Atmospheric pressure chemical ionization (APCI) is a method not yet applied to FFF, but could potentially be a good alternative to ESI for semivolatile analytes lacking a natural site for a charge. The analytes are evaporated and exposed to gas phase molecules ionized by a high voltage corona discharge electrode. The analytes are subsequently ionized by a charge transfer from the gas molecules. Atmospheric pressure chemical ionization has been shown to be less sensitive to buffer salts than ESI, and no fragmentation occurs in the ion source. Mainly singly charged ions are formed, making APCI less applicable to large molecules, depending on the upper range of the MS analyzer. Atmospheric pressure chemical ionization has a good flow rate compatibility (0.3–1.5 ml/min) with FFF.

Matrix assisted laser desorption ionization (MALDI) is a frequently used ionization technique, but it is rarely used as an online detector. The sample stream is applied to a target plate, and it is allowed to cocrystallize with the matrix, which is subsequently desorbed, ionized with a laser, and analyzed in the MS. MALDI/TOF has been successfully used to determine molecular weight distributions of fractions collected after thermal FFF separation of polydisperse polymers.[16] MALDI is a good ion source, due to the soft ionization with high efficiency and simple mass spectra, even for heavier molecules, since the majority carry only a single charge.

ICPMS is an ion source for elemental analysis where the analyte stream is introduced into a high-energy plasma with efficient atomization and ionization, producing almost entirely singly charged elemental ions. It has multielement capability with excellent sensitivity and has good flow rate compatibility (0.1–1.5 ml/min) with FFF techniques. ICPMS has previously been applied to sedimentation FFF for determination of major element composition in different size fractions of suspended riverine particles and soil particles in the size range 50–800 nm,[17] and recently flow FFF coupled on line to ICPMS has been used to determine elemental size distributions for over 55 elements in freshwater colloidal material (1–50 nm).[18,19] Fig. 2 shows a selection of elements and the signal from the UV detector, coupled on line before the ICPMS, from a river water sample. An interface between the FFF channel and the ICPMS was used to supply acid, to improve the performance of the nebulizer–spray chamber system, and internal standard. The interface also serves to dilute and split away about half of the salt content. The salt is necessary for the FFF separation, but harmful to the ICPMS.

DENSITY-BASED DETECTION

A continuous density detector works on the principle of a liquid flowing through an oscillating U-shaped glass tube, where the oscillating frequency is found relating the oscillations to the density of the flowing liquid. A densimetric

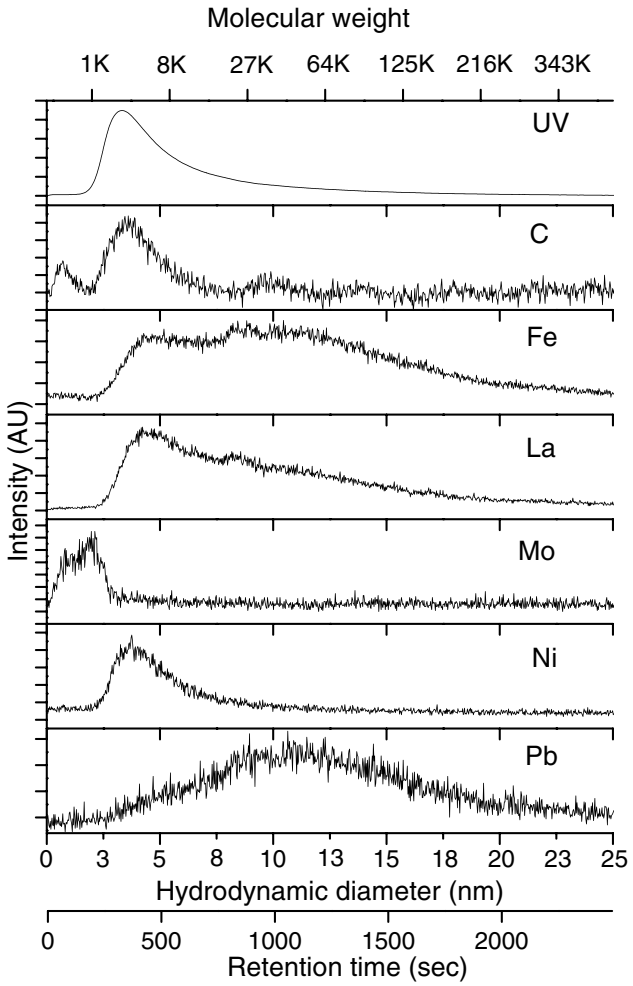

Fig. 2 Elemental size distributions of the colloidal material in a freshwater sample as given from an FlFFF coupled to ICPMS. A UV detector is placed on line prior to the ICPMS and the UV size distribution is included. The signals are plotted as a function of retention time, hydrodynamic diameter (from FFF theory), and molecular weight (from standardization with PSS standards).
Source: From Determination of continuous size and trace element distribution of colloidal material in natural water by on-line coupling of flow field-flow fractionation with ICMPS, in Anal. Chem.[18]

detector has been evaluated for sedimentation FFF,[20] and the conclusions were that it is a universal concentration-selective detector without the need for signal correction or transformation. The sensitivity is however a limiting factor, since it is dependent on the density difference between the sample and the carrier liquid. A density difference of 0.2 g ml^{-1} is sometimes sufficient, but to achieve higher sensitivity a difference up to 1.0 is desirable, making densimetric detection suitable for inorganic particles, but less appropriate for lighter organic analytes. The densimeter detector is sensitive to temperature changes, but insensitive to flow changes, making it most suitable for flow programming applications.

CONCLUSIONS

A multidetector approach is often applied in FFF since all detection systems have some advantages and limitations over some size ranges, sample types, and detection limits. For example, the most common detector, the UV–VIS, has limitations that it is selective for both absorption and turbidity but it is still widely used. Elemental analysis of FFF fractions with ICPMS has been successfully developed during recent years, but other mass spectrometric hyphenations are still very few. On-line light scattering has proven to be a very valuable system to determine molecular weight and RMS radius distributions (MALS) as well as diffusion coefficients and hydrodynamic radius (DLS).

Detection in Ion Chromatography

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
Since its introduction in 1975 ion chromatography (IC) has been used in most areas of analytical and environmental chemistry. Although the conductivity detector is still the most popular, other types of detection can be applied for different analytes. These include the following methods: electrochemical (e.g., amperometric, potentiometric), photometric (UV/Vis, chemiluminescence), and spectrometric detectors used mainly in hyphenated techniques.

INTRODUCTION

Detection methods applied in ion chromatography (IC) can be divided into electrochemical and spectrometric methods. Electrochemical detection methods include conductometric, amperometric, and potentiometric methods, while spectroscopic methods include molecular techniques (UV/Vis, chemiluminescence, fluorescence, and refractive index methods), and spectroscopic techniques such as: atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), inductively coupled plasma–optical emission spectrometry (ICP–OES), inductively coupled plasma–mass spectrometry (ICP–MS), and mass spectrometry (MS).[1]

The performance of ion chromatographic detectors has considerably increased over the last 30 years. The progress made so far has made them more sensitive and convenient in use, as well as increased detection selectivity.[2]

Fundamentals of detection methods used in IC have been comprehensively covered in several monographs.[3,4] Detection methods employed in IC can be divided into direct and indirect ones (Fig. 1) and taking into consideration the type of application (Table 1). Direct detection methods are those in which the eluate ions exhibit a much smaller value of the measured property than solute ions. Detection methods are called indirect if the eluate ions exhibit a much higher value of the property measured than solute ions.

CONDUCTIVITY DETECTION

The most widespread detection technique in IC is still conductometry, because electric conductivity of electrolytes is strongly dependent on concentration.

This technique has recently been simplified by the introduction of self-regenerating devices thanks to which electrolytically hydrolysis of water in the eluate stream takes place. This, in turn, produces the ions necessary for the regeneration of the suppressor, thus avoiding the need for a separate regenerant device.[5]

The principle of functioning of a conductivity detector lies in differential measurement of mobile phase conductivity both before and during solute ion elution. The conductivity cell is placed either directly next to an analytical column or after a suppressor device, which is required to reduce background conductivity, in order to increase the signal-to-noise ratio, and thus sensitivity. In IC, without eluate conductivity suppression the signal-to-noise ratio can be maximized if a low-conductivity mobile phase at a low concentration is used.

Electric conductivity usually increases with the increase of temperature, and viscosity of the solution exponentially decreases as the temperature rises.

The equivalent conductances of anions and cations are typically between 35 S cm^2/val and 80 S cm^2/val. The H^+ ion with 350 S cm^2/val and the OH^- ion with 198 S cm^2/val are the only significant exceptions. Consequently, detector signal depends not only on the solute ion concentration, but also on the equivalent conductances of both eluate cations and solute anions, and on their degree of dissociation. The degree of eluate and solute ion dissociation is determined by the pH value of the mobile phase.

A general problem in suppressed IC can be the fact that sensitivity is poor when the product of suppression exhibits a small degree of dissociation, for example in the case of very weak acid anions (e.g., silicate, cyanide).

Suppressed and non-suppressed conductivity methods of detection have a number of things in common. The things in common include the fact that in both cases electric conductivity of the analytes is measured. On the other hand, the most apparent difference is that one method uses a suppressor system while the other does not.

Table 1 Survey of the main detection methods used in ion chromatography.

Detection mode	Principle	Applications
Conductivity	Electrical conductivity	Anions and cations with pK_a or pK_b <7
Amperometry	Oxidation or reduction	Anions and cations with pK_a or pK_b >7
Direct and indirect UV/Vis	UV/Vis light absorption	UV-active anions and cations, heavy and transition metals after derivatization reaction
Fluorescence	Excitation and emission	Ammonium, amino acids, and primary amines after postcolumn derivatization
Refractive index	Change in refractive index	Anions and cations at higher concentrations
ICP-AES, ICP-MS	Atomic emission	Hyphenation techniques for selective and sensitive metal analysis
MS	ESI	Hyphenation technique for structural characterization of organic anions and cations

The use of suppressed conductivity detection is limited when high-capacity ion-exchange columns are used; the concentrations of hydroxide- or carbonate-based eluates needed for reasonable elution times would be too high for continuously working membrane suppressors.

Conductivity detection can be applied to ionic species including all anions and cations of strong acids and bases (e.g., fluoride, chloride, nitrite, nitrate, phosphate, sulfate, sodium, potassium, magnesium, calcium, and ammonia). Ions of weaker acids and bases can be detected provided the pH value of the eluate is chosen to maximize the ionization of analytes in order to increase sensitivity. The relatively simple construction and operation, accuracy and low cost contribute to its utility; thus, it is used in over 95% of the analytes, where ion-exchange separation procedures are involved.[6]

AMPEROMETRIC AND POTENTIOMETRIC DETECTIONS

Amperometric detection is generally used for the analysis of solutes with pK values above 7, which, owing to their

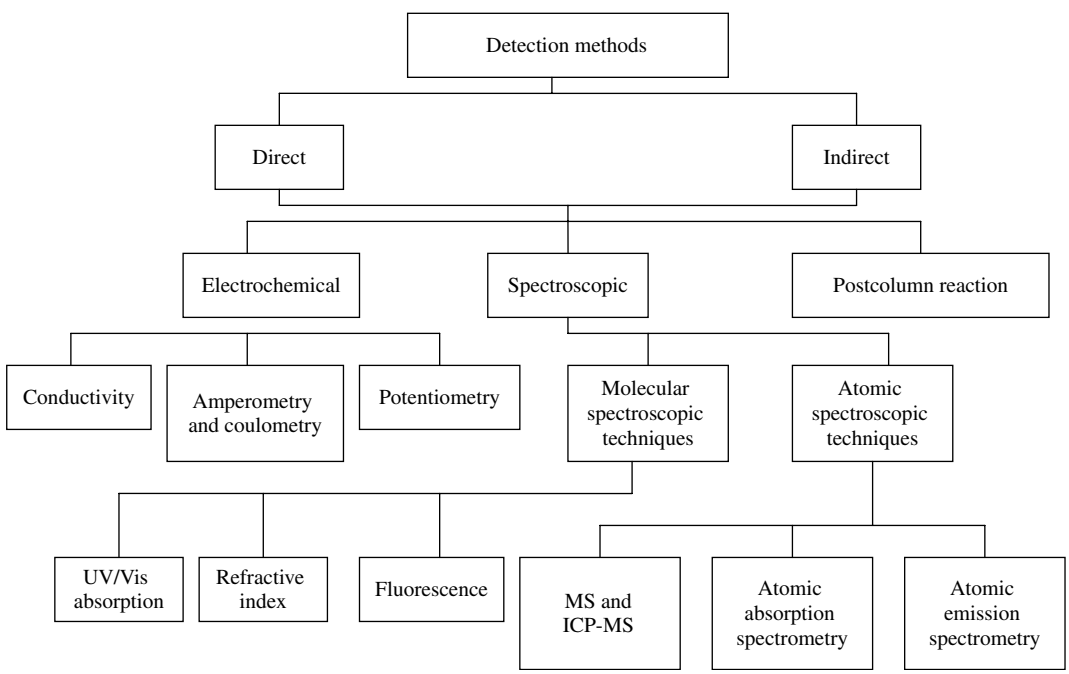

Fig. 1 Classification of detection methods for ion chromatography.

low dissociation, can hardly be detected by means of suppressed conductivity.

Conventional amperometric detectors employ a three-electrode detector cell consisting of a working electrode, a reference electrode, and a counter electrode. The electrochemical reaction at the working electrode is either oxidation or reduction. The required potential is applied to the working electrode. The electric current resulting from this electrochemical reaction serves as the analytical signal and is directly proportional to the concentration of the electrochemically active analyte. Generally, amperometric detection is carried out in a direct mode that requires electrochemically non-active coions in the mobile phase.

The potential applied to the working electrode may be constant during the period of separation or it may be applied in pulse mode. Application of this method includes determining ions like nitrite, bromide,[7] iodide, sulfite, thiosulfate, thiocyanate, cyanide, or heavy and transition metals.[8]

POTENTIOMETRIC DETECTION HAS ONLY FOUND LIMITED USE IN ROUTINE IC

The main disadvantages of potentiometric detectors in IC are: slow response of many electrodes and the fact that they respond well to only a few different species.[9]

UV/VIS DETECTION

UV/Vis detection is a very popular detection mode for high-performance liquid chromatography (HPLC) and although its significance in IC is smaller, it is considered a useful supplementary means of detection. A disadvantage of UV/Vis detection is that most inorganic anions do not have an appropriate chromophore. UV/Vis detection methods can be divided into direct and indirect methods. In UV/Vis detection, the change of absorbance during elution of an analyte ion is governed by the differences of molar absorbance of analyzed ions and coions in the mobile phase.

For direct UV/Vis detection, molar absorption of coions should be zero. UV/Vis transparent mobile phase includes alkane sulfonic acids and their salts, phosphate buffers, sodium perchlorate, and similar electrolytes that allow the direct UV detection of selected ions.[10]

Direct detection has gained great significance in determination of nitrite and nitrate,[11] as well as bromide and iodide in the presence of high chloride concentrations. Moreover, chromate, sulfide, thiocyanate, thiosulfate, and selected metal chloro- and cyano-complexes[12] can be determined by means of this method.

UV/Vis detection may also be performed indirectly. This method is called indirect photometric method. It is a more universally employed detection mode, for which a wavelength should be chosen where molar absorption of analyte is zero and high for eluate coions.[13] UV/Vis detection in combination with postcolumn reactions proves to be a versatile technique that provides enhanced sensitivity and selectivity for specific application.[14]

The instrumentation for postcolumn derivatization detection in IC is relatively simple. The effluent from the column is mixed with the reagent by means of a T-piece. The reagent is delivered by a pump or by pressure applied to the reagent bottle.

Next, a knitted polytetrafluoroethylene (PTFE) capillary can serve as the flow-through reactor, its length depending on the necessary reaction time.

OTHER SPECTROSCOPIC DETECTION METHODS

Chemiluminescence detection is another technique based on light emission. It is generally performed in a postcolumn reaction mode. The majority of chemiluminescence detection methods in IC is based on luminal reaction that involves aqueous alkaline oxidation of the luminal in the presence of a catalyst.[15]

In IC, fluorescence detection is rarely used as a detection method since very few ions fluoresce.[16] Refractive index detection is a non-selective detection. Only because of its moderate sensitivity, very poor selectivity, and sensitivity to baseline fluctuations, it is very rarely used in IC. The only advantage of refractive index detection is the ability to use comparatively concentrated eluants that allow the use of high-capacity ion exchangers.[17]

Atomic spectroscopic techniques in use for IC detection include both AAS and AES. The majority of AES detection techniques in IC is based on the ICP source.

In recent years, the coupling of IC with element-specific detection methods including AAS, ICP-AES, ICP-MS, and MS has gained significant importance.

ICP-MS offers unique advantages including element specificity, wide linear dynamic range, low detection limits and, ability to perform isotope dilution analysis.[18,19]

The most useful detection mode in IC seems to be MS. Because of its flexibility, this coupling method has numerous possible applications in ion analysis.[20,21] IC coupled with spectrometric detector (IC–MS) is a modern determination method for quantitative and qualitative analysis. Similar analytes are separated by IC and subsequently detected by a mass spectrometer. Both ionic substances (anionic and cationic) and polar substances (e.g., organic acids or sugars) can be determined with this very sensitive detection system.

Analyses using an MS detector are also characterized by a very low matrix influence and are therefore ideally suitable for cases involving coelution, eluate interference, or sample matrix influence. This means that MS represents a real alternative to conventional IC detectors such as conductivity, electrochemical or UV/Vis detectors. Because of IC–MS coupling, direct qualitative analysis of different species is possible. The mass-charge ratio is used for peak identification and resolving the molecular structure of the analyte. MS detection can be carried out in selected ion monitoring (SIM) or scan (*m/z*) mode.

In liquid chromatography with MS detection various ion sources can be used:

– electrospray ionization (ESI)
– atmospheric pressure chemical ionization (APCI)
– atmospheric pressure photochemical ionization (APPI)

ESI is a very soft ionization method. It shows the best sensitivity in IC for the polar and ionic analytes. By using ESI, in contrast to other ionization methods, multivalent ions also can be transferred to the gas phase. Further advantages of ESI are its dependability, simple handling and maintenance, and a wide range of use for polar and ionic substances in any molecular mass range.

In contrast to the conductivity detector, the MS detector is a mass-flow-dependent detector. This means that the flow rate influences the sensitivity of the signal. Flow rates below 1.0 ml/min should be used with ESI. In order to maximize the sensitivity of the detector the flow rate should be as low as possible. Various types of mass filters are used in IC–MS. Quadrupole is the most widespread one.

The advantages of IC–MS such as sensitivity and selectivity are noticeable in the analysis of drinking water (e.g., for the determination of perchlorate, the analysis of haloacetic acids or of disinfection by-products).[22] Other fields of application are: clinical and biochemical research (determination of organic acids, amines, or sugars),[23] pharmaceutical industry (peak identification and purity tests), petrochemical industry (determination of indicator substances), food industry, electroplating industry, analysis of hazardous substances, and environmental analysis.[24,25]

CONCLUSION

Of the many forms of detection used in IC, conductometric detection is still the most popular. However, all other methods such as electrochemical and spectroscopic methods are more often applied especially for the analysis of trace ions in samples with complex matrices.

The most powerful detection technique for the trace analysis in complex matrices seems to be MS, separately or with inductively coupled plasma source or an electrospray source.

Detection of TLC Zones

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

After development with the mobile phase, the thin-layer chromatography (TLC) plate is dried in a fume hood and heated, if necessary, to completely evaporate the mobile phase. Separated compounds are detected on the layer by viewing their natural color, natural fluorescence, or quenching of fluorescence. These are physical methods of detection and are non-destructive. Substances that cannot be seen in visible or ultraviolet (UV) light can be visualized with suitable detection reagents to form colored, fluorescent, or UV absorbing compounds by means of derivatization reactions carried out pre- or postchromatography. Although dependent upon the particular analyte, layer, and detection method chosen, sensitivity values are generally in the nanogram range for absorbance and picogram range for fluorescence.

Other detection methods include radioactivity for labeled compounds (a non-destructive physical method) and biological methods (e.g., immunochemical or enzymatic reactions). Coupled detection methods such as TLC/infrared spectrometry (TLC/IR) or TLC/mass spectrometry (TLC/MS) can be used for confirmation of zone identity as well as quantification in some cases.

DIRECT DETECTION

Compounds that are naturally colored (e.g., plant pigments, food colors, dyestuffs) are viewed directly on the layer in daylight, while compounds with native fluorescence (aflatoxins, polycyclic aromatic hydrocarbons, riboflavin, quinine) are viewed as bright zones on a dark background under longwave (366 nm) UV light. Compounds that absorb around 254 nm (shortwave), including most compounds with aromatic rings and conjugated double bonds and some unsaturated compounds, can be detected on an "F-layer" containing a phosphor or fluorescent indicator (often zinc silicate). When excited with 254 nm UV light, absorbing compounds diminish (quench) the uniform layer fluorescence and are detected as dark violet spots on a bright green background. Viewing cabinets or boxes (Fig. 1) incorporating 254 and 366 nm UV-emitting mercury lamps are available commercially for inspecting chromatograms in an undarkened room. Detection by natural color, fluorescence, or fluorescence quenching does not modify or destroy the compounds, and the methods are, therefore, suitable for preparative layer chromatography. Derivatization reactions modify or destroy the structure of the compounds detected, but they are often more sensitive than detection with UV radiation.

UNIVERSAL DETECTION REAGENTS

Postchromatographic universal reactions such as iodine absorption or spraying with sulfuric acid and heat treatment are quite unspecific and are valuable for completely characterizing an unknown sample. Absorption of iodine vapor from crystals in a closed chamber produces brown spots on a yellow background with almost all organic compounds except for some saturated alkanes. Iodine staining is non-destructive and reversible upon evaporation, while sulfuric acid charring is destructive. Besides sulfuric acid, 3% copper acetate in 8% phosphoric acid is a widely used charring reagent. The plate, which must contain a sorbent and binder that do not char, is typically heated at 120–130°C for 20–30 min to transform zones containing organic compounds into black to brown zones of carbon on a white background. Some charring reagents initially produce fluorescent zones at a lower temperature before the charring occurs at a higher temperature.

SELECTIVE DERIVATIZATION DETECTION

Selective derivatization reagents form colored or fluorescent compounds on a group- or substance-specific basis and aid in compound identification. They also allow the use of a TLC system with lower resolution, because interfering zones may not be detected. If the detection is to be the basis of a quantitative (densitometric) analysis, the reagent used should react with the analyte to produce the primary product in proportion to the quantity present in the zones and not produce any interfering secondary compounds.

Derivatization can be performed before or after development of the layer with the mobile phase. Prechromatographic derivatization is carried out either in solution prior to sample application or directly on the plate by applying the sample and reagents at the origin or in the preadsorbent (or concentration) area. Prechromatographic derivatization may enhance compound stability or chromatographic selectivity as well as serving for detection. Types of prechromatographic derivatization reactions that have been used include acid and

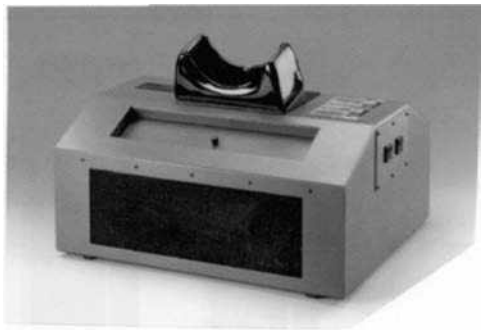

Fig. 1 Darkroom viewing cabinet with two overhead ports that accept one or two 8 W combination shortwave/longwave portable UV lamps.

alkaline hydrolysis, oxidation and reduction, halogenation, nitration and diazotization, hydrazone formation, esterification, and dansylation.

Derivatization reactions for detection are usually carried out postchromatography, and many hundreds of reagents have been reported in the literature. Selected examples are listed in Table 1.

APPLICATION OF DETECTION REAGENTS

Liquid chromogenic and fluorogenic detection reagents such as those in Table 1 can be applied by spraying or dipping the developed and dried layer. When a sequence of reagents is necessary, the layer is usually dried between each application.

Various types of aerosol sprayers that connect to air or nitrogen lines are available commercially for manual operation (Fig. 2), and this method is most widely used for reagent application. For safety purposes, spraying is carried out inside a laboratory fume hood or commercial TLC spray cabinet with a blower (fan) and exhaust hose, and protective eyeware and laboratory gloves are worn. The plate is placed on a sheet of paper or supported upright inside a cardboard spray box. The spray is applied from a distance of about 15 cm with a uniform up-and-down and side-to-side motion until the layer is completely covered. It is usually better to spray a layer two or three times lightly and evenly with intermediate drying rather than give a single, saturating application that might cause zones to become diffuse. Studies are required with each reagent to determine the optimum total amount of reagent that should be sprayed, but generally the layer is sprayed until it begins to become translucent. After visualization, zones should be marked with a soft lead pencil because zones formed with some reagents may fade or change color with time. A cordless electropneumatic sprayer with separate spray heads for low and high viscosity reagents is manufactured by Camag (Fig. 3). The ChromaJet DS 20 (Fig. 4) is a PC-controlled automatic apparatus that reproducibly sprays derivatization reagents on selected tracks of the layer; minimal reagent volumes are used, and operation can be documented in conformity with good laboratory practice (GLP) standards.

As with proper application using a fine-mist manual sprayer or an automated sprayer, dipping can provide uniform reagent application that leads to sensitive, reliable detection and reproducible results in quantitative densitometric analysis. The simplest method is to manually dip for a short time (5–10 sec) in a glass or metal dip tank. More uniform dip application of reagents can be achieved by use of a battery operated automatic, mechanical chromatogram immersion instrument (Fig. 5), which provides selectable, consistent vertical immersion and withdrawal speeds between 30 and 50 mm/sec and immersion times between 1 and 8 sec for plates with 10 or 20 cm heights. The immersion device can also be used for impregnation of layers with detection reagents prior to initial zone application and development, and for postdevelopment impregnation of chromatograms containing fluorescent zones with a fluorescence enhancement and stabilization reagent such as paraffin. Dip application to the layer cannot be used when two or more aqueous reagents must be used in sequence without intermediate drying. Dip reagents must be prepared in a solvent that does not cause the layer to be removed from the plate or the zones to be dissolved from the layer or to become diffuse; dip reagents are usually the same concentration or less concentrated than corresponding spray reagents.

Detection reagents can also be applied to the layer as a vapor, as mentioned above for iodine. Other reagents delivered to the layer by vapor exposure include *t*-butyl hypochlorite and HCl, both of which form fluorescent derivatives with a variety of compounds. The Analtech vapor-phase fluorescence (VPF) visualization chamber provides detection of compounds such as sugars, lipids, steroids, flavonoids, and antibiotics by induced fluorescence after heating the sealed chamber, containing the plate and ammonium bicarbonate crystals, on a hotplate to a temperature that decomposes the salt to ammonia.

HEATING THE LAYER

Layers often require heating to eliminate residual mobile phase after development, and again after spray or dip application of the detection reagent in order to complete the reaction upon which detection is based and ensure optimum derivative formation. Typical conditions are 5–15 min at 100–110°C. If a laboratory oven is used, the plate should be supported on a solid metal tray to help ensure uniform heat distribution. The plate heater shown in Fig. 6 usually provides more consistent heating conditions than an oven; it features a 20 × 20 cm flat, evenly

Table 1 Reagents used for postchromatographic derivatization of different classes of compounds.

Analyte(s)	Reagents and treatment	Result
Acidic or basic compounds	Solutions of pH indicators (e.g., bromocresol green, bromophenol blue)	Colored zones on pale background
Aldehydes	0.1 g 2,4-Dinitrophenylhydrazine in 100 ml methanol plus 1 ml conc. HCl	Orange-yellow or more colored zones on light-colored background
Alkaloids	0.85 g Basic bismuth nitrate, 40 ml water, and 10 ml glacial acetic acid mixed with 8 g potassium iodide in 20 ml water (Dragendorff reagent)	Yellow-brown zones
	0.3 g Hexachloroplatinic(IV) acid in 100 ml water mixed with 100 ml 6% potassium permanganate solution	Various colored and fluorescent zones; contrast of layer can be improved by heating
Amino acids	0.5% Ninhydrin in ethanol–glacial acetic acid (98 : 2); heat at 90–100°C for 5–10 min	Blue to purple zones
Amino acid derivatives	0.1% *p*-Dimethylaminobenzaldehyde in ethanol mixed (1 : 1) with conc. HCl (Ehrlich's reagent); heat at 60°C for 5 min	Different colored zones
Amphetamines	Spray with 0.5% aqueous Fast Black K salt, dry, spray with 0.5 *M* NaOH, spray again with Fast Black K solution	Orange-red and different violet colors
Antioxidants	Diazotized *p*-nitroaniline (800 mg *p*-nitroaniline in a mixture of 250 ml water and 20 ml HCl; 5 ml $NaNO_2$ added dropwise until solution is colorless)	Aromatic compounds give yellow to brown zones
Aromatic compounds	0.2 ml Formaldehyde (37%) in 10 ml conc. sulfuric acid (Marquis reagent); heat at 110°C for 20 min	Colored zones on light pink background; some may be fluorescent
Ascorbic acid	1–50 mg Cacotheline in 50 ml water, heat at 110°C for 20 min	Red-brown to violet zone on a yellow background
Carbohydrates	3% *p*-Anisidine hydrochloride in water-saturated butanol; heat at 110°C for 10 min	Red to brown zones
	1.2 g Ammonium vanadate in 95 ml water and 5 ml conc. sulfuric acid (Mandelin reagent)	Blue zones on yellow background
Flavonoids	1% Aluminum chloride solution in ethanol	Fluorescent zones
Lipids	5 g Phosphomolybdic acid in 100 ml absolute ethanol; heat at 100–150°C for 2–5 min	Blue zones on yellow layer background
Lipids and quinones	0.5–1.0 mg/ml Rhodamine 6G in ethanol	Fluorescent zones

(Continued)

Table 1 Reagents used for postchromatographic derivatization of different classes of compounds. *(Continued)*

Analyte(s)	Reagents and treatment	Result
Metal cations	0.25% Ethanol solution of alizarin, then ammonia vapor	Red-violet zones on violet background
Organic acids	100 mg 2,6-Dichloroindophenol sodium salt in 100 ml ethanol (Tillman reagent); heat at 100°C for 5 min	Red-orange zones on violet background
Pesticides (carbamates), sulfonamides, and primary amino compounds	1 g Sodium nitrite in 20 ml water diluted to 100 ml with conc. HCl–ethanol (17 : 83); dry plate; then 1% *N*-(1-naphthyl)ethylenediamine dihydrochloride in 10 ml water and 90 ml ethanol (Bratton–Marshall reagent)	Pink to violet zones
Pesticides (organophosphate)	2% 2,6-Dibromoquinone-4-chlorimide in glacial acetic acid; heat at 110°C for 10 min	Pink, orange, and brown zones on pale yellow background
Phenols	2% 4-Aminoantipyrene in 80% ethanol, then 4% potassium hexacyanoferrate(III) in ethanol–water (1 : 1) (Emerson reagent)	Red zones on light yellow background
Phenols, amino compounds, aromatic hydrocarbons, and coumarins	1% 2,6-Dibromoquinone-4-chloroimide in methanol (Gibbs reagent); heat at 110°C for 2–5 min	Different colored zones
Steroids	0.5 ml Anisaldehyde dissolved in 8 ml conc. sulfuric acid and diluted with 85 ml methanol plus 10 ml glacial acetic acid; heat at 100°C for 5–10 min	Violet-blue zones on light pink or colorless background; sometimes fluorescent zones
Sugars	5 g α-Naphthol in 160 ml ethanol, 20 ml sulfuric acid, and 13 ml water; heat at 110°C for 5 min	Blue-purple zones
Sulfonamides	15% Fluorescamine in acetone	Fluorescent zones
Terpenoids	0.5 ml Anisaldehyde mixed with 8 ml conc. sulfuric acid and diluted with 85 ml methanol and 10 ml glacial acetic acid; heat at 100°C for 5–10 min	Violet-blue zones on light pink or colorless background
	10% Antimony(III) chloride in chloroform; heat at 120°C for 5–10 min	Variously colored zones
Vitamin B_1	10 mg Potassium hexacyanoferrate and 1 g NaOH in 7 ml water and 13 ml ethanol	Bluish fluorescent zones
Vitamin E	Mixture (1 : 1) of 0.1 g iron(III) chloride hexahydrate in 50 ml ethanol with 0.25 g 2,2′-bipyridine (α,α′-dipyridyl) in 50 ml ethanol (Emmerie–Engle reagent)	Red zone

heated ceramic surface; a grid to facilitate proper positioning of TLC or high-performance TLC (HPTLC) plates; programmable temperature between 25 and 200°C; and digital display of the programmed and actual temperatures. Prolonged heating time or excessive temperature can cause decomposition of the analytes and darkening of the layer background and should be avoided.

Some reagents can be impregnated into the layer before spotting of samples if the selectivity of the separation is not affected and the mobile phase does not strip the reagent during development. Detection takes place only upon heating after development. This method has been used for detection of lipids as blue spots on a yellow background on silica gel layers preimpregnated with phosphomolybdic acid by dipping, spraying, or development. Analtech sells precoated silica gel plates impregnated with 5% ammonium sulfate; heating at 150–200°C for 30–60 min in a closed container (the VPF Chamber, described above, can be used) generates sulfuric acid for charring detection of zones.

THERMAL DETECTION WITHOUT REAGENTS

Thermal derivatization (or thermochemical reaction) allows detection of zones without the use of reagents. For example, simple heating of amino-modified silica layers causes conversion of sugars, oligosaccharides, creatine, catecholamines, steroid hormones, and other compound types to stable fluorescent compounds. Heating times of 3–45 min and temperatures of 140–200°C have been used for different substances.

BIOLOGICAL DETECTION

Several detection methods are based on the biological activities of certain compounds. Cholinesterase inhibiting pesticides (e.g., organophosphates, carbamates) are detected sensitively by treating the layer with the enzyme and a suitable substrate, which react to produce a colored product over the entire layer except where colorless pesticide zones are located due to their inhibition of the enzyme–substrate reaction.

TLC/immunostaining has been used to detect solasodine glycosides by separation of the compounds on a silica gel layer, transfer to a polyvinylidene difluoride membrane, and treatment of the membrane with sodium periodate solution followed by bovine serum albumin (BSA), resulting in a solasodine–BSA conjugate. Individual zones were stained by monoclonal antibody against solamargine.

Bioluminescence has been used for specific detection of separated bioactive compounds on thin layers (BioTLC). After development and drying of the mobile phase by evaporation, the layer is coated with micro-organisms by immersion of the plate. Single bioactive substances in multicomponent samples are located as zones of differing luminescence. The choice of the luminescent cells determines the specificity of the detection. A specific example is the use of the marine bacterium *Vibrio fischeri* with the BioTLC format. The bioluminescence of the bacterial cells is reduced by toxic substances, which are detected as dark zones on a fluorescent background with picogram level sensitivity.

BioTLC kits are commercially available from ChromaDex, Inc., (Santa Ana, California, U.S.A.).

RADIOACTIVITY DETECTION

Radioactive zones can be detected on thin layers by film autoradiography, digital autoradiography with a multiwire proportional chamber, use of charged–coupled devices, or bioimaging/phosphor imaging techniques. These methods differ in terms of factors such as simplicity, speed, sensitivity, resolution, linear range, and accuracy and precision of quantification, and the method of choice depends on the available instrumentation, the type of experiment, and the information needed.

ZONE IDENTIFICATION AND CONFIRMATION

The identity of the detected TLC zones is obtained initially by comparison of characteristic R_f values between samples and reference standards chromatographed on the same plate, where R_f equals the migration distance of the center of the zone divided by the migration distance of the mobile phase front, both measured from the start (origin). Identity is more certain if a selective chromogenic detection reagent yields the same characteristic color for sample and standard zones. Because the chromatogram is stored on the layer, multiple compatible detection reagents can be applied in sequence to confirm the identity of unknown zones. As an example, almost all lipids are detected as light green fluorescent zones by use of 2,7-dichlorofluorescein reagent, while absorption of iodine vapor differentiates between saturated and unsaturated lipids or lipids containing nitrogen. The identity of zones is confirmed further by recording UV or visible absorption spectra directly on the layer using a densitometer (in situ spectra), or by direct or indirect (after scraping and elution) measurement of fourier transform infrared (FT-IR), Raman, or mass spectra.

CONCLUSIONS

Details of reagent preparation, application and heating procedures, results, and selectivity of many hundreds of reagents for detection of all classes of compounds and ions, including those in Table 1, are available in the literature references listed.

Detection Principles

Kiyokatsu Jinno
Department of Materials Science, Toyohashi University, Toyohashi, Japan

INTRODUCTION

Various methods of detection are employed in chromatography. Each approach for the detection of solutes is based on their physical or chemical properties. Some of the more commonly used detectors are discussed here for liquid chromatography (LC), gas chromatography (GC), and supercritical fluid chromatography (SFC).

LIQUID CHROMATOGRAPHY

The most commonly used detectors in LC are concentration-sensitive. The detector output signal is a function of the concentrations of the analytes passing through the detector cell. In order to use the information for quantitation, the detector must respond linearly to changes in concentration over a wide concentration range, which is called the linear dynamic range of the detector. Criteria for the evaluation of the quality or the suitability of the detector are as follows: the magnitude of the linear dynamic range, the noise level, the sensitivity, and the selectivity. The sensitivity is determined by the specific characteristics of the analytes and by the extent to which these differ from the characteristics of the sample matrix. The most important parameters are noise, drift, detection limit (sensitivity), selectivity, stability, and compatibility with various elution modes.

Noise is the high-frequency variation of the detector signal, which becomes visible when the baseline is recorded at the higher-sensitivity settings. To determine the noise level, parallel lines are drawn around the noise envelope and the distance between these lines; the actual noise level is expressed in detector signal units (for instance, AU, mV, or μA). This parameter is dependent upon the lamp, the amplifier, and the cell geometry, and is specified differently by many manufacturers. Static measurements usually provide better values for the noise level than those obtained under flow conditions. Noise levels are calculated using the mean of the baseline envelope. A measure for the sensitivity of a detector is the minimum detectable amount of a given compound (detection limit). Most LC detectors measure optical or spectroscopic characteristics of the analytes. Other detectors use electrical (conductivity) or electrochemical characteristics, such as oxidation or reduction electrochemical detector (EcD) of the analytes. A detector is said to be more selective when it measures a more unique characteristic of an analyte.

Ultraviolet (UV) Detector

UV detection is the most popular, i.e., most commonly utilized, in the LC detection mode. Depending on instrumental design, three types of UV detectors are used today: single wavelength detectors, where a fixed wavelength is used for the absorbance monitoring of the analytes; variable wavelength detectors, with which one can choose the most appropriate wavelength for the analyte detection; and UV detectors which provide spectral information, such as fast-scanning UV detectors and diode array detectors.

UV detectors make use of the spectral absorption properties of the analytes in the UV and visible (Vis) wavelength range. The absorption measured at a given wavelength generally follows Beer's law and is transformed to a concentration-dependent signal. The change in absorption is proportional to the concentration when all parameters are kept constant. The detector cell volumes range from 5 and 10 μl; the light path typically ranges from 6 to 10 mm.

The fixed wavelength detector is the most widely used in LC. It is simple in design and, consequently, the least expensive although it is still the most sensitive. Its widespread use is historic in origin and is due to the fact that the strong emission line of the mercury lamp at 254 nm is well suited for absorption measurements of many organic compounds, provided that they possess an aromatic system. Some advantages of the fixed wavelength detector are as follows:

1. The simple design; the detector is relatively inexpensive.
2. The mercury spectral line is very strong and narrow.
3. The intensity of the light beam entering the system allows for a wide linear response range and high sensitivity.

Variable wavelength detectors use a continuous light source in combination with monochromators to select the desired detection wavelength. The monochromator, in general, is a rotating diffraction grating which is positioned in the light path of the detector cell. Some instruments possess an additional variable bandwidth. In microprocessor-driven instruments, the desired wavelength and slit width can be selected and read on a display. Almost all instruments contain "classical" optics with spectral dispersion of the light occurring prior to passage through the flow cell. "Reversed optics" UV detectors have recently become

popular. A holographic grating is placed between the flow cell and the photodiodes; it disperses the light beam through the detector cell. This design makes it possible to obtain spectral information at any point in time, which can then be further processed depending on the requirements of the analysis. Spectral information can be obtained from the diode array within 40–200 msec. Even for very narrow peaks, it is possible to scan spectra without stopping the flow. The diode array detector contains no moving parts; consequently, the spectra are of high quality in terms of resolution and reproducibility. Data can be acquired and evaluated, and relevant spectra can be stored and compared with spectral libraries via a computer. Of course, this type detector can be useful as a variable wavelength detector and, also, this provides information on peak identity and peak purity; it is routinely used in method development for separation of UV-active compounds.

Refractive Index (RI) Detectors

RI detection is the oldest in various LC detection modes and is commonly used in carbohydrate and polymer analysis. The RI (n) is a bulk property of the eluate. The RI detector is therefore a universal and rather non-specific detector but offers relatively low sensitivity. In RI detection, the specific physical parameter is the RI increment, dn/dc, which detects the differential change in the RI (n) that is a dimensionless parameter, and dn/dc is therefore expressed in ml/g. For most compounds in common solvents, dn/dc lies between 0.8–0.15 ml/g. The actual parameter used in RI detection is the RI itself, whose minute changes are transformed into a detector signal. Three types of RI detectors are commercially available: Fresnel (reflection), deflection, and interference. Fresnel RI detectors measure the difference between the RI of a glass prism with reference to the eluate. At the glass/liquid phase boundary, part of the incident beam is completely reflected. The intensity of the transmitted light is then measured at a given angle. When the RI changes, the angle and the intensity of the beam hitting the photodiode changes accordingly.

In the deflection-type RI detector, the optical system is designed differently. The light beam actually passes through the detector cell twice. After passage through the detector and the reference cell, the light beam is reflected back through the detector cell. The beam is balanced by an optical zero control, divided into two beams of equal intensity by a prism, and focuses onto two photodiodes. One half of the detector cell is filled with pure mobile phase (reference cell), while the column eluate flows through the other half. The RI (n) is the same in each cell when only mobile phase passes through the cell. When an analyte passes through the flow cell, the RI (n) in the flow cell will change with respect to the reference cell. The light beam is deflected during forward and return passage through the cells. The resulting difference in light intensity is sensed by the photodiodes and the differential signal of the diodes is amplified and passed on to signal output devices.

In the interference-type RI detector, a monochromatic coherent light beam is split and the resulting two beams are directed through a reference and a sample cell, respectively. After passage through the cells, the difference in RI between the cells causes interference of two beams, which is measured by a photodiode.

Fluorescence (FL) Detector

Absorption of UV light by certain compounds triggers the emission of light with a longer wavelength. The spectral range of the emitted light depends on the excitation wavelength. Fluorescence emission can only be triggered at wavelengths at which the analytes absorb in the UV. Not all UV-absorbing compounds are also fluorescence emitters although some compounds possess native fluorescence. Non-fluorescent compounds can be converted into fluorescent compounds by derivatization with a suitable fluoresophore before (so-called pre-column derivatization) or after (post-column derivatization) LC separation. The most selective and most flexible design contains two diffraction gratings with variable wavelength monochromators at the excitation side and at the emission side of the system. These types of detectors contain an additional cut-off filter to control stray light/light-scattering and noise. In the stopped-flow mode, excitation, as well as emission spectra, of labile compounds can be scanned, and the optimum wavelengths for routine measurements can be determined. Of course, photodiode array detection is also available for this detector type.

Electrochemical Detectors

EcDs are used for quantitation of compounds which can be easily oxidized or reduced by an applied potential. The standard reduction potential at the electrode is measured and transformed into a detector signal. The number of compounds which can be electrochemically detected is, however, considerably smaller than the number of optically detectable compounds by UV, RI, and FL. To become oxidized or reduced, a compound must possess electrochemically active groups. EcDs are mainly used in clinical, food, and environmental analysis.

Gas Chromatography

In contrast to LC detectors, GC detectors often require a specific gas, either as a reactant gas or as fuel (such as hydrogen gas as fuel for flame ionization). Most GC detectors work best when the total gas flow rate through the detector is 20–40 ml/min. Because packed columns deliver 20–40 ml/min of carrier gas, this requirement is easily met. Capillary columns deliver 0.5–10 ml/min;

thus, the total flow rate of gas is too low for optimum detector performance. In order to overcome the problem when using capillary columns, an appropriate makeup gas should be supplied at the detector. Some detectors use the reactant gas as the makeup gas, thus eliminating the need for two gases. The type and flow rate of the detector gases are dependent on the detector and can be different even for the same type of detector from different manufacturers. It is often necessary to refer the specific instrument manuals for details to obtain the information on the proper selection of gases and flow rates. All detectors are heated, primarily to keep the analytes from condensing on the detector surfaces. Some detectors require high temperatures to function properly; some detectors are very sensitive to changes in temperature although others are only affected by very large changes in temperature. Some detectors are flow-sensitive; thus, their response changes or the baseline shifts according to the total gas flow rate through the detector.

Flame Ionization Detector (FID)

The FID is the most powerful and popular detector in GC, for which a basic structure is demonstrated in Fig. 1. Hydrogen and air are used to maintain a flame at the tip of the jet and into the flame where the organic components are burned. Ions are created in this combustion process; they are attracted to the charged collector electrode. This induced ion flow generates a current that can be measured and transformed to an output voltage by an electrometer. The amount of current generated should be dependent on the concentrations of the compounds introduced into the flame. The FID responds best to compounds containing a carbon–hydrogen bond. The lack of a carbon–hydrogen bond does not completely eliminate any response; however, the response is significantly depressed. Some notable compounds such as water, carbon monoxide, and carbon dioxide are non-responding. Typical sensitivities for most organic compounds are 0.1–1 ng. The linear range is 5–6 orders magnitudes. Helium and nitrogen are typical as the makeup gases for capillary columns. Nitrogen is less costly and provides slightly better sensitivity. Near universal response, ease of use, wide linear range, and good sensitivity make the FID suitable for a wide variety of samples. Since FID is a simple detector, there is little routine maintenance required. The response of an FID is dependent on the hydrogen and gas flow rates; therefore, periodic measurement of these gas flow rates is necessary to maintain a stable performance. FIDs are not very temperature-sensitive and temperature changes of 50°C or greater are needed before any performance alterations are observed. FIDs are not sensitive to changes in the carrier gas flow rates; thus, baseline shifts or drifting is rarely found by changing the experimental conditions.

Nitrogen–Phosphorus Detector (NPD)

An alkali metal bead, usually rubidium sulfate, is positioned above the jet in NPD, as seen in Fig. 2, and the current is applied to this bead, which causes it to achieve temperatures up to 800°C. The addition of hydrogen and air generates plasma around the bead, and carrier gas containing the solutes is delivered to the tip of the jet and the plasma. Specific ions are produced in the plasma from nitrogen- or phosphorus-containing compounds. These ions move to the charged collector. This movement of ions generates a current that is measured and transformed to an output voltage by an electrometer. The amount of the current is dependent on the amount of the compound introduced into the plasma. The NPD exhibits excellent selectivity and sensitivity for nitrogen- and phosphorus-containing compounds. The sensitivity is approximately 10,000 times

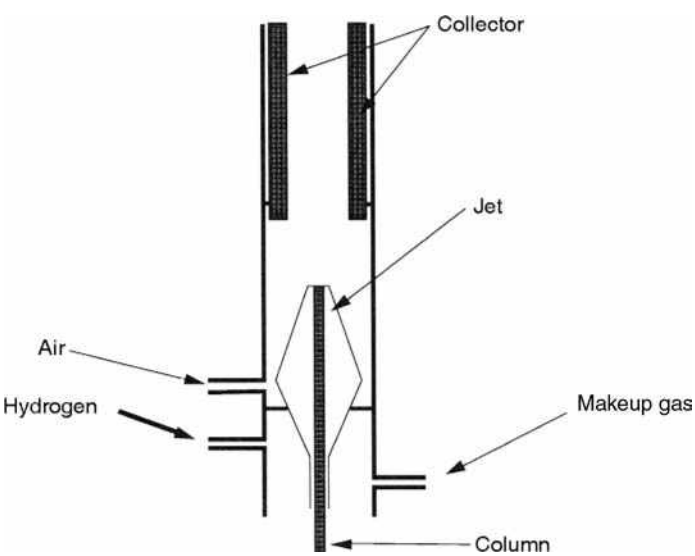

Fig. 1 Basic structure of FID for capillary GC.

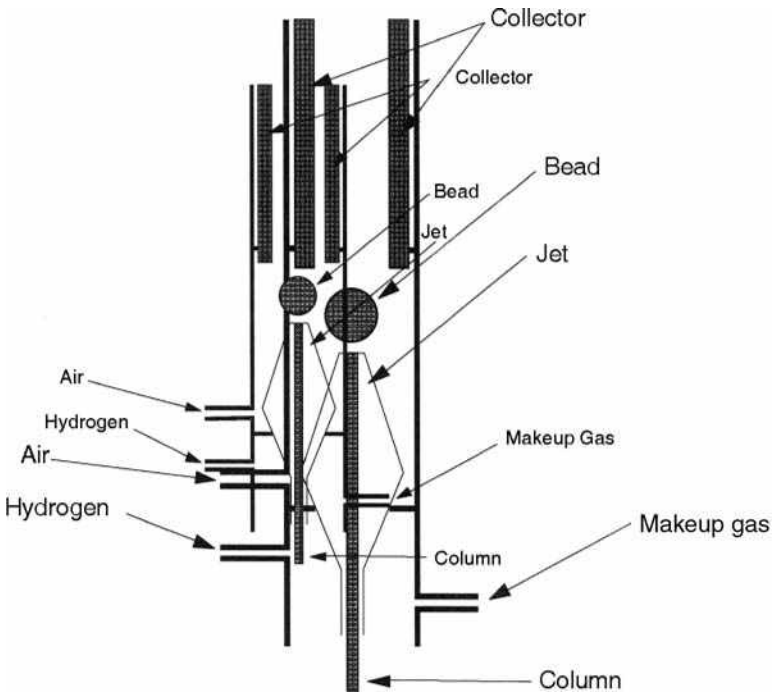

Fig. 2 Basic structure of NPD for capillary GC.

greater for nitrogen and phosphorus compounds than for hydrocarbons. Typical NPD sensitivities are in the range of 0.5–1 pg with a linear range of 5–6 orders. Helium is the preferred makeup gas. Many compounds in the sample may not contain nitrogen or phosphorus, so a response is not observed for these compounds and, therefore, specific detection for nitrogen and phosphorus can be attained. Peak separation, identification, and measurement are made much easier because there are fewer peaks in the chromatogram. Also, less preparation of the sample prior to final determination is required because fewer of the potential interferences yield a response in the detector signal. Pesticides and pharmaceuticals analysis are generally the fields of application of the NPD.

Flame Photometric Detector (FPD)

Hydrogen and air are used to maintain a flame at the tip of the jet in the FPD. The carrier gas containing the analytes is delivered to the tip of the jet and into the flame. Some FPDs use a dual jet or burner design, but the overall process is not significantly different. The solutes are burned in the flame, forming S2 and HPO. Due to excitation in the flame, light at 392 nm for S2 and at 526 nm for HPO are emitted. A photomultiplier tube is used to measure the light intensity after the optical filter. A current is generated, which can be measured and transformed to an output voltage by an electrometer. The amount of light created at each wavelength is dependent on the amount of compound introduced into the flame. The selectivity of the FPD for sulfur and phosphorus compounds is 3–4 orders of magnitude. Typical sensitivities are 10–100 pg for sulfur and 1–10 pg for phosphorus compounds. FPD responses are usually nonlinear for sulfur compounds. Nitrogen is the best makeup gas because its use results in the best sensitivity especially in the sulfur detection mode. FPDs are temperature- and flow-sensitive and, therefore, sensitivity changes are common when the temperature or carrier gas flow rates are changed. Increasing the detector temperature results in a decrease in sensitivity. FPD sensitivity for phosphorus compounds is comparable to NPD sensitivity. Due to some of the difficulties with NPDs, FPDs are frequently preferred for phosphorus-specific detection purposes. The increase of 500–1000 times in sensitivity of the FPD over the thermal conductivity detector (TCD) and FID often makes its nonlinear response behavior tolerable.

Electron-Capture Detector (ECD)

Carrier gas containing the solutes is delivered into the heated cell in the ECD. A ^{63}Ni source lining the cell acts as a source of electrons, and a moderating or auxiliary gas of nitrogen or argon/methane (95/5) is introduced into the cell to create thermal electrons which are attracted to the anode, creating a current. When an electronegative compound enters the cell, it captures thermal electrons and reduces the cell current. The amount of current reduction is measured and transformed to an output voltage by an electrometer. The size of the current loss is dependent on the amount of the compound entering the cell. The ECD primarily responds to compounds that contain a halogen, carbonyl, or nitrate group. Halogens have 100–100,000 times, nitrates have 100–1000 times, and carbonyls have 20–100 times better response than hydrocarbons.

Polyhalogenated compounds, or compounds containing multiple nitrate or carbonyl groups, yield significantly increased detector responses. Also, the response for different halogens and types of carbonyls are varied, depending upon the structures of the analytes. Sensitivities approaching 1 pg for halogens, 10 pg for nitrates, and 50 pg for carbonyls are typical. The linear range is 2–3 orders and poor; therefore, multiple-point calibration curves are required for accurate quantitation. The auxiliary gas is often used as the makeup gas in situations where makeup gas is necessary. Nitrogen is less costly and provides slightly better sensitivity than others. Argon/methane provides a slightly better linear dynamic range than nitrogen. The primary application of ECDs is for the detection of halogenated compounds. The flow rates of the carrier gas and auxiliary gas have a pronounced effect on the sensitivity and linear range of an ECD. The ECD temperature also affects the sensitivity.

Thermal Conductivity Detector (TCD)

The TCD consists of two heated cells, one of which is a sample cell and the other is a reference cell. The carrier gas containing the separated compounds enters the sample cell, while the reference cell is supplied with the same type and flow rate of carrier gas that flows into the sample cell. There is a TCD design that utilizes a single cell and a switching valve to accomplish the same task. Current is applied to the filaments, which causes them to reach an elevated equilibrium temperature when the current and gas flows are constant. When a compound that has a thermal conductivity different from that of the carrier gas is eluted from the column, it induces a change in the filament temperature. Because the reference cell filament remains at a constant temperature, the temperature difference between the two filaments is compared. The difference is measured via a Wheatstone bridge, which produces an output voltage. It is dependent on the amount of compound entering the sample cell. The best TCD sensitivity is established when the difference in thermal conductivities between the carrier gas and the component is maximized. Helium or hydrogen is usually the carrier gas of choice because these gases have thermal conductivities 10–15 times greater than that of most organic molecules, whereas nitrogen is only seven times higher than most organic molecules. This means that the TCD is a universal detector in GC although the sensitivity is relatively low, 5–50 ng per component or 10–100 times less than that of the FID. The linear range is five orders magnitude. TCDs are flow- and temperature-dependent.

Other detectors

There are a number of other GC detectors commercially available. Photoionization detectors (PIDs) are primarily used for the selective, low-level detection of the compounds which have double or triple bonds or an aromatic moiety in their structures. Electrolytic conductivity detectors (ELCDs) are used for the selective detection of chlorine-, nitrogen-, or sulfur-containing compounds at low levels. Chemiluminescence detectors are usually employed for the detection of sulfur compounds. The atomic emission detectors (AEDs) can be set up to respond only to selected atoms, or group of atoms, and they are very useful for element-specific detection and element-speciation work.

SFC

All detectors in GC and LC can be easily made useful for SFC. Basically, however, we can say that GC detectors are useful for capillary SFC, and LC detectors are useful for packed-column SFC. The most important and convenient features of SFC are that any detection systems available in chromatography can be useful and all work well.

Detector Linear Dynamic Range

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The linearity of most detectors deteriorates at high concentrations and, thus, the *linear dynamic range* of a detector will always be less than its dynamic range.

DISCUSSION

The symbol for the linear dynamic range is usually taken as (D_{LR}). As an example, the linear dynamic range of a flame ionization detector might be specified as

$$D_{LR} = 2 \times 10^5 \quad \text{for } 0.98 < r < 1.02$$

where r is the response index of the detector.

Alternatively, according to the ASTM E19 committee report on detector linearity, the linear range may also be defined as that concentration range over which the response of the detector is constant to within 5%, as determined from a linearity plot. This definition is significantly looser than that using the response index.

The lowest concentration in the linear dynamic range is usually taken as equal to the *minimum detectable concentration* or the *sensitivity* of the detector. The largest concentration in the linear dynamic range would be that where the response factor (r) falls outside the range specified, or the deviation from linearity exceeds 5% depending on how the linearity is defined. Unfortunately, many manufacturers do not differentiate between the dynamic range of the detector (D_R) and the linear dynamic range (D_{LR}) and do not quote a range for the response index (r). Some manufacturers do mark the least sensitive setting on a detector as N/L (non-linear), which, in effect, accepts that there is a difference between the linear dynamic range and the dynamic range.

Detector Linearity and Response Index

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

It is essential that any detector that is to be used directly for quantitative analysis has a linear response. A detector is said to be truly linear if the detector output (V) can be described by the simple linear function

$$V = Ac$$

where A is a constant and c is the concentration of the solute in the mobile phase (carrier gas) passing through it.

DISCUSSION

As a result of the imperfections inherent in all electromechanical and electrical devices, true linearity is a hypothetical concept, and practical detectors can only approach this ideal response. Consequently, it is essential for the analyst to have some measure of detector linearity that can be given in numerical terms. Such a specification would allow quantitative comparison between detectors and indicate how close the response of the detector was to true linearity. Fowlis and Scott[1] proposed a simple method for measuring detector linearity. They assumed that for an approximately linear detector, the response can be described by the power function

$$V = Ac^r$$

where r is defined as the response index of the detector.

For a truly linear detector, $r = 1$, and the proximity of r to unity will indicate the extent to which the response of the detector deviates from true linearity. The response of some detectors having different values for r are shown as curves relating the detector output (V) to solute concentration (c) in Fig. 1. It is seen that the individual curves appear as straight lines but the errors that occur in assuming true linearity can be quite large. The errors actually involved are shown in the following, which is an analysis of a binary mixture employing detectors with different response indices:

Solute	$r = 0.94$	$r = 0.97$	$r = 1.00$	$r = 1.03$	$r = 1.05$
1	11.25%	10.60%	10.00%	09.42%	09.05%
2	88.75%	89.40%	90.00%	90.58%	90.95%

It is clear that the magnitude of the error for the lower-level components can be as great as 12.5% (1.25% absolute) for $r = 0.94$ and 9.5% (0.95% absolute) for $r = 1.05$. In general analytical work, if reasonable linearity is assumed, then $0.98 < r < 1.03$. The basic advantage of defining linearity in this way is that if the detector is not perfectly linear, but the value for r is known, then a correction can be applied to accommodate the non-linearity.

There are alternative methods for defining linearity which, in the author's opinion, are somewhat less precise and less useful. The recommendations of the ASTM E19 committee on linearity measurement are as follows:

> The linear range of a detector is that concentration range of the test substance over which the response of the detector is constant to within 5% as determined from a linearity plot,—the linear range should be expressed as the ratio of the highest concentration on the linearity scale to the minimum detectable concentration.

This method for defining detector linearity is satisfactory up to a point and ensures a minimum linearity from the detector and, consequently, an acceptable quantitative accuracy. However, the specification is significantly "looser" than that given above, and it is not possible to correct for any non-linearity that may exist, as there is no correction factor provided that is equivalent to the response index. It is strongly advised that the response index should be determined for any detector that is to be used for quantitative analysis. In most cases, r need only be measured once, unless the detector undergoes some catastrophic event that is liable to distort its response, in which case, r may need to be checked again.

There are two methods that can be used to measure the response index of a detector: the *incremental method* of measurement and the *logarithmic dilution method* of measurement.[2] The former requires no special apparatus, but the latter requires a log-dilution vessel, which, fortunately, is relatively easy to fabricate. The incremental method of measurement is the one recommended for general use.

The apparatus necessary is the detector itself with its associated electronics and recorder or computer system, a mobile-phase supply, pump, sample valve, and virtually any kind of column. In practice, the chromatograph to be used for the subsequent analyses is normally employed. The solute is chosen as typical of the type of substances that will be analyzed and a mobile phase is chosen that will

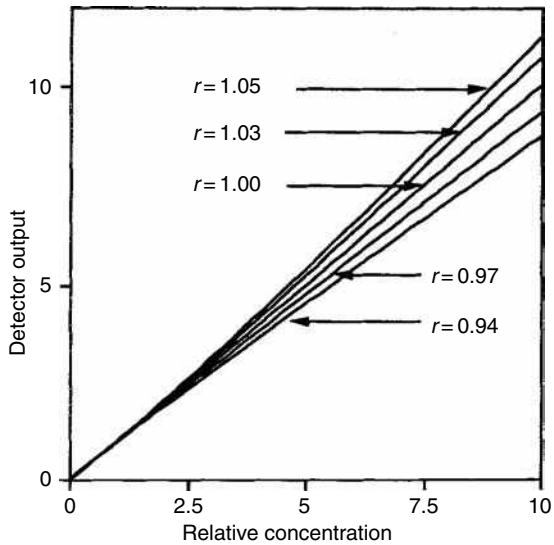

Fig. 1 Graph of detector output against solute concentration for detectors having different response indices.

elute the solute from the column in a reasonable time. Initial sample concentrations are chosen to be appropriate for the detector under examination.

Duplicate samples are placed on the column, the sample solution is diluted by a factor of 3 and duplicate samples are again placed on the column. This procedure is repeated, increasing the detector sensitivity setting where necessary until the height of the eluted peak is commensurate with the noise level. If the detector has no data acquisition and processing facilities, then the peaks from the chart recorder can be used. The width of each peak at 0.607 of the peak height is measured and the peak volume can be calculated from the chart speed and the mobile-phase flow rate. Now, the concentration at the peak maximum will be twice the average peak concentration, which can be calculated from

$$c_p = \frac{ms}{wQ}$$

where c_p is the concentration of solute in the mobile phase at the peak height (g/ml), m is the mass of solute injected, w is the peak width at 0.6067 of the peak height, s is the chart speed of the recorder or printer, and Q is the flow rate (ml/min).

The logarithm of the peak height y (where y is the peak height in millivolts) is then plotted against the log of the solute concentration at the peak maximum (c_p). Now,

$$\log(V) = \log(A) + (r)\log(c_p)$$

Thus, the slope of the $\log(V)/\log(c_p)$ curve will give the value of the response index (r). If the detector is truly linear, $r = 1$ (i.e., the slope of the curve will be sin $\pi/4 = 1$). Alternatively, if suitable software is available, the data can be curved fitted to a power function and the value of r extracted directly from the curve-fitting analysis. The same data can be employed to determine the linear range as defined by the ASTM E19 committee. In this case, however, a linear plot of detector output against solute concentration at the peak maximum should be used and the point where the line deviates from 45° by 5% determines the limit of the linear dynamic range.

Detector Noise

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Detector noise is the term given to any perturbation on the detector output that is not related to the presence of an eluted solute. As the minimum detectable concentration, or detector sensitivity, is defined as that concentration of solute that provides a signal equivalent to twice the noise, the detector noise determines the ultimate performance of the detector. Detector noise has been arbitrarily divided into three types, *short-term noise*, *long-term noise*, and *drift*, all three of which are depicted in Fig. 1.

SHORT-TERM NOISE

Short-term noise consists of baseline perturbations that have a frequency that is significantly higher than that of the eluted peak. Short-term detector noise is usually not a serious problem in practice, as it can be easily removed by appropriate electronic noise filters that do not significantly affect the profiles of the peaks. The source of this noise is usually electronic, originating from either the detector sensor system or the amplifier electronics.

LONG-TERM NOISE

Baseline perturbations that have a frequency that is similar to that of the eluted peak are termed long-term noise. This type of detector noise is the most significant and damaging, as it is often indiscernible from very small peaks in the chromatogram. Long-term noise cannot be removed by electronic filtering without affecting the profiles of the eluted peaks and, thus, destroying the integrity of the chromatogram. It is clear in Fig. 1 that the peak profile can easily be discerned above the high-frequency noise, but it is lost in the long-term noise. Long-term noise usually arises from temperature, pressure, or flow-rate changes in the sensing cell. Long-term noise can be controlled by careful detector cell design, the rigorous stabilization of operating variables such as sensor temperature, flow rate, and sensor pressure. Long-term noise is the primary factor that ultimately limits the detector *sensitivity* or the *minimum detectable concentration*.

DRIFT

Baseline perturbations that have a frequency significantly larger than that of the eluted peak are called drift. In gas chromatography (GC), drift is almost always due to either changes in detector temperature, changes in carrier gas flow rate, or column bleed. As a consequence, with certain detectors, baseline drift can become very significant at high column temperatures. Drift is easily constrained by choosing operating parameters that are within detector and column specifications.

A combination of all three sources of noise is shown by the trace at the bottom of Fig. 1. In general, the sensitivity of the detector (i.e., in most cases, the amplifier setting) should never be set above the level where the combined noise exceeds 2% of the full scale deflection (FSD) of the recorder (if one is used), or appears as more than 2% FSD of the computer simulation of the chromatogram.

MEASUREMENT OF DETECTOR NOISE

The detector noise is defined as the maximum amplitude of the combined short- and long-term noise measured over a period of 10 min (the ASTM E19 committee recommends a period of 15 min). The detector must be connected to a column and carrier gas passed through it during measurement. The detector noise is obtained by constructing parallel lines embracing the maximum excursions of the recorder trace over the defined time period. The distance between the parallel lines, measured in millivolts, is taken as the measured noise (v_n), and the noise level (N_D) is calculated in the following manner:

$$N_D = v_n A = \frac{v_n}{B}$$

where v_n is the noise measured in volts from the recorder trace, A is the attenuation factor, and B is the alternative amplification factor.

Note: Attenuation is the reciprocal of amplification; manufacturers may use either function as a control of detector sensitivity.

The noise levels of detectors that are particularly susceptible to variations in column pressure or flow rate (e.g., the katharometer) are sometimes measured under static conditions (i.e., no flow of carrier gas). Such specifications

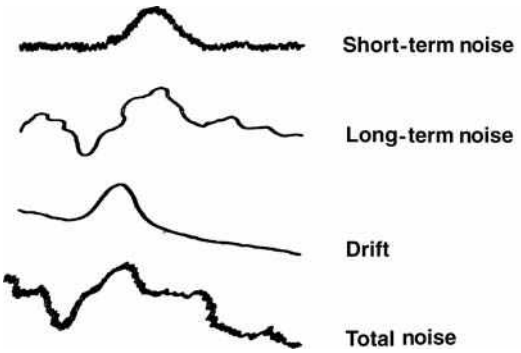

Fig. 1 Different types of detector noise.

are not really useful, as the analyst can never use the detector without a column flow. It could be argued that the manufacturer of the detector should not be held responsible for the precise control of the mobile phase, whether it may be a gas flow controller or pressure controller. However, all carrier supply systems show some variation in flow rates (and, consequently, pressure) and it is the responsibility of the detector manufacturer to design devices that are as insensitive to pressure and flow changes as possible.

At the high-sensitivity-range settings of some detectors, electronic filter circuits are automatically introduced to reduce the noise. Under such circumstances, the noise level should be determined at the lowest attenuation (or highest amplification) that does not include noise-filtering devices (or, at best, the lowest attenuation with the fastest response time) and then corrected to an attenuation of unity.

Diffusion Coefficients from GC

George Karaiskakis
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

One of the most important physicochemical applications of gas chromatography (GC) is for the measurement of diffusion coefficients of gases into gases, liquids, and on solids. The gas chromatographic subtechniques used for the measurement of diffusivities are briefly reviewed, focusing on their accuracy and precision, as well as on the corresponding sources of errors responsible for the deviation of the experimental diffusion coefficients measured by GC from those determined by other techniques or calculated from known empirical equations.

The diffusion coefficients can be determined by various gas chromatographic techniques based either on the broadening of the elution peaks, or on the perturbation imposed on the carrier gas flow rate.

DIFFUSION IN GASES

The diffusion coefficient of a gas A into another gas B, D_{AB}, is a function of temperature, T, pressure, p, and composition, x, even for binary mixtures at low pressure D_{AB} is almost independent of the gas composition. Several empirical equations describing the dependence of D_{AB} on T and p are available, among which the most important are the following:[1,2]

1. The Stefan–Maxwell equation:

$$D_{AB} = \frac{a}{n{\sigma_{AB}}^2}\left[\frac{8RT}{\pi}\left(\frac{1}{M_A}+\frac{1}{M_B}\right)\right]^{1/2} \quad (1)$$

where a is a constant taking various values ($1/3\pi$, 1/8, $1/2\pi$, and 3/32), depending on the researcher, n is the number of gas phase molecules per cubic centimeter, σ_{AB} is the collision diameter between the gas molecules A and B, R is the gas constant, T is the absolute temperature, and M_A, M_B are the molecular masses of solute A and carrier gas B, respectively.

2. The Chapman–Enskog equation:

$$D_{AB} = \frac{0.00263T^{3/2}}{p{\sigma_{AB}}^2}\left(\frac{1/M_A+1/M_B}{2}\right)^{1/2} \quad (2)$$

3. The Arnold equation:

$$D_{AB} = \frac{0.0083T^{3/2}(1/M_A+1/M_B)^{1/2}}{p({V_A}^{1/3}+{V_B}^{1/3})(1+c_{AB}/T)} \quad (3)$$

where V_A and V_B are molar volumes in cubic centimeters, at the boiling points, while c_{AB} is Sutherland's constant, which can be estimated in various ways.[1,2] The above equation, which introduces a second temperature dependent term in the denominator to account for molecular "softness," shows a dependence varying from $T^{3/2}$ to $T^{5/2}$.

4. The Gilliland equation:

$$D_{AB} = \frac{0.0043T^{3/2}(1/M_A+1/M_B)^{1/2}}{p({V_A}^{1/3}+{V_B}^{1/3})} \quad (4)$$

5. The Hirschfelder–Bird–Spotz (HBS) equation:

$$D_{AB} = \frac{0.00186T^{3/2}(1/M_A+1/M_B)^{1/2}}{p{\sigma_{AB}}^2\Omega_{AB}} \quad (5)$$

The term Ω_{AB} is the collision integral, depending in a complicated way on temperature and the interaction energy of the colliding molecules, ε_{AB}. Ω_{AB} values as a function of the reduced temperature $T^* = kT/\varepsilon_{AB}$, where k is the Boltzmann constant, have been tabulated.[3,4] The main disadvantage of the HBS equation is the difficulty encountered in evaluating σ_{AB} and Ω_{AB}.

6. Chen and Othmer provided the most explicit approximation of the HBS equation using the critical values of temperature, T_C, and volume, V_C:

$$D_{AB} = \frac{0.43(\frac{T}{100})^{1.81}(\frac{1}{M_A}+\frac{1}{M_B})^{1/2}}{p\left(\frac{T_{CA}T_{CB}}{10^4}\right)^{0.1405}\left[\left(V_{\frac{CA}{100}}\right)^{0.4}+\left(V_{\frac{CB}{100}}\right)^{0.4}\right]^2} \quad (6)$$

7. Fuller, Schettler, and Giddings[5] developed a successful equation in which atomic and structural volume increments and other parameters were obtained by a least-squares fit to over 340 measurements. In the Fuller et al. (FSG) method, which provides the best practical combination of simplicity and accuracy,

$$D_{AB} = \frac{0.00143T^{1.75}(1/M_A+1/M_B)^{1/2}}{p\left[(\sum v)_A{}^{1/3}+(\sum v)_B{}^{1/3}\right]^2} \quad (7)$$

$\sum v$ is determined by summing the relative atomic contributions given in literature.[1]

The Broadening Techniques

The GC broadening techniques for the measurement of gaseous diffusivities are the *continuous elution method*, introduced by Giddings,[2,6,7] and its *arrested elution* modification invented by Knox and McLaren.[2,6,7]

The continuous elution method is conducted in an open tube with circular cross section. The carrier gas flow rate is chosen such that the plate height, H, depends mainly on only one of the van Deemter terms, namely the longitudinal diffusion term. For correction reasons, the use of two different length columns is necessary, and the equation for H is:[2]

$$H = (L_1 - L_2)\left[\frac{t_1^2 - t_2^2}{(t_1 - t_2)^2}\right] \tag{8}$$

where L_1 and L_2 are the lengths of the two columns, respectively, while $(t_1 - t_2)$ and $(t_1^2 - t_2^2)$ are the corresponding differences for the first and second moments of the time base. Replacement of Eq. 8 by the Golay equation, describing band broadening in open tube, gives the final equation from which the diffusion coefficient D_{AB} is obtained:[2]

$$D_{AB} = \frac{v}{4}\left[H \pm \left(H^2 - \frac{r^2}{3}\right)^{1/2}\right] \tag{9}$$

where v is the average carrier gas velocity and r is the radius of the tube. When the flow velocity is slow, the determination of D_{AB} is done from the positive root, while the negative root is used at higher flow velocities. One of the main advantages of the method is the high speed of collecting data with high precision.

In a typical experiment of the arrested elution method,[2,6,7] a solute sample is injected into the column and eluted in the normal way without arresting the gas, so that its outlet velocity, v, can be obtained. Then, during the elution of the solute band, about halfway along the particular column, the flow is switched to a dummy column of equal resistance. After a delay time, t, of 1–20 min, the flow is reconnected to the column and the peak is eluted. The spreading of the band, during the delay time, can occur only by diffusion, and from the standard deviation δ (or the variance, σ^2) of the concentration profile, determined by the detector, the diffusion coefficient D_{AB} can be found from the following equation:[2]

$$\frac{d\sigma^2}{dt} = \frac{2D_{AB}}{v^2} \tag{10}$$

Eq. 10 shows that a plot of σ^2 against the delay time, t, should be a straight line with slope $2D_{AB}/v^2$, from which the D_{AB} value can be determined. The average reproducibility of the method, which is approximately $\pm 2\%$, depends mainly on the accurate measurement of v, since v is to the second power in Eq. 10.

Although the arrested elution method has two drawbacks (the need of several runs to get a D_{AB} value with a precision of 2%, and of constant flow rates over long periods for runs at various arrested times), in comparison with the continuous elution method, the former has also the following advantages: 1) Effects of zone broadening other than axial molecular diffusion and non-uniform flow profile do not affect the measurement; 2) no assumptions are made about the precise form of the flow profile, the smoothness of the column wall, or the accuracy in the knowledge of the column diameter.

Diffusion coefficients, for various binary gas mixtures, at various temperatures and pressures with their accuracy and precision, measured by gas chromatographic broadening techniques (GC-BTs; continuous, as well as arrested elution methods), are given in Table 3 of Ref.[2] and in Table 1 of Ref.[6] Representative data are collected here in Table 1.

The Flow Perturbation Techniques

The flow perturbation gas chromatographic methods used for the measurement of diffusion coefficients in gases are the *stopped-flow* and the *reversed-flow* techniques.

The stopped-flow technique[2,8] consists in stopping the carrier gas flow for short time intervals by using shut-off valves. Following each restoration of gas flow, a narrow peak (stop-peak) is recorded in the chromatographic trace, having the form of those of Fig. 2 in Ref.[2] The problem to be solved here is to determine the area under the curve of each stop-peak as a function of the time of the corresponding stop in the flow of the carrier gas. Since the stop-peaks are fairly symmetrical and have a constant half-width, their height from the baseline, H, rather than their area, is used to plot $\ln(Ht^{3/2})$ vs. the inverse time, $1/t$, according to the following equation:[8]

$$\ln(Ht^{3/2}) = \ln\left(\frac{mt_sL}{\pi^{1/2}D_{AB}^{1/2}}\right) - \frac{L^2}{4D_{AB}}\frac{1}{t} \tag{11}$$

where m is the injected amount of solute in moles, t_s the stopped-flow interval in seconds, and L the length of the diffusion column (cf. Fig. 1 of Ref.[2]) in centimeters, which permits calculation of the diffusion coefficient D_{AB} from the slope $-L^2/4D_{AB}$.

Table 1 Diffusion coefficients, D_{AB}, from GC-BTs.

[a]Precision has been defined as: $100 \times$ Deviation/D_{AB}, where for two values, the high (D_{AB}^{high}) and the low (D_{AB}^{low}), the deviation is ($D_{AB}^{high} - D_{AB}^{low}$)/2.
[b]Accuracy has been defined as: $100 \times |D_{AB} - D_{lit}|/D_{AB}$, where D_{lit} are literature[2,6] values.

Diffusion coefficients from the stopped-flow technique, which are very sensitive to the precision with which L is measured, since D_{AB} is proportional to L^2, are given in literature[2,8] for some binary gas mixtures.

The *reversed-flow GC (RF-GC) technique*, introduced in 1980,[9] is based on reversing the direction of flow of the carrier gas from time to time. Its experimental setup is very simple and consists of the following parts:[2,10,11]

1. A conventional gas chromatograph with any kind of detector capable of detecting the solute(s) contained in the carrier gas.
2. A so-called sampling column constructed from a glass or stainless steel chromatographic tube of any diameter, and having a total length 0.6–2.0 m, depending on the particular application. The sampling column, which is coiled and accommodated inside the chromatographic oven, should be completely empty of any solid material for the determination of the diffusion coefficient of gases into pure gases or mixtures of gases, or it can be filled with a common chromatographic material for the measurement of the diffusion coefficient of ternary gas mixtures into pure gases.
3. A diffusion column, which is constructed from the same material as the sampling column, is connected perpendicularly to it, usually at its midpoint. The other end of the diffusion column is closed with an injector septum and is used as the injection point of the solute under study. The diffusion column, which is empty of any solid material, is a straight or coiled, relatively short (30–80 cm) piece of empty tubing placed inside the chromatographic oven.
4. The sampling and the diffusion column form the sampling cell, and this cell must now be connected to the detector and to the carrier gas inlet in such a way that the carrier gas flow through the sampling column can be reversed in direction by a four- or six-port valve that is connected with the two ends D_1 and D_2 of the chromatographic column, as well as with the inlet of the carrier gas and the detector, as shown in Fig. 1.

If pure carrier gas passes through the sampling column, nothing happens on reversing the flow. But if a solute comes out of the diffusion column as a result of its diffusion into the carrier gas, filling the diffusion column and also running along the sampling column, the flow reversal records the concentration of the solute at the junction $x = l'$ (cf. Fig. 1) at the moment of the reversal. This concentration recording has the form of extra chromatographic peaks, called *sample peaks*, superimposed on the otherwise continuous detector signal. The loading of the carrier gas with other substance(s) is due to its (their) slow diffusion into the carrier gas passing through the sampling column. The enrichment of carrier gas in the gas(es) contained in the diffusion column depends on the rate with which gas(es) enters (enter) the sampling column at the junction

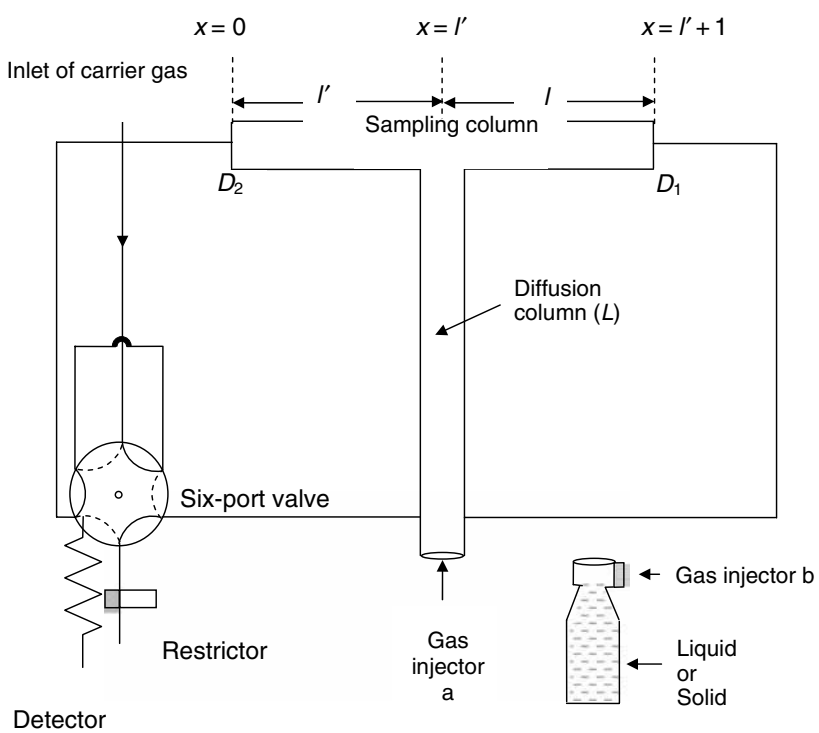

Fig. 1 Schematic representation of the reversed-flow GC technique for measuring diffusion coefficients. (a) Injection point for gaseous diffusivities; (b) injection point for liquid and solid diffusivities.

$x = l'$ of the two columns. By reversing the flow now, one can perform a sampling of the concentration of the analyte gas at this junction, each sample peak measuring (by its height H) this concentration at the time of the flow reversal. Repeating this sampling procedure at various times, t, and using suitable mathematical analysis, the following equations describing the variation of H with t, when the slow process under study is the gaseous diffusion, were derived:[10–13]

$$\ln(H^{1/M}t^{3/2}) = \ln(gN_1) - \frac{L^2}{4D_{AB}}\frac{1}{t} \tag{12}$$

$$\ln(H^{1/M}) = \ln(gN_2) - \frac{3D_{AB}}{L^2}t \tag{13}$$

where

$$N_1 = \frac{mL}{\dot{V}(\pi D_{AB})^{1/2}} \tag{14}$$

$$N_2 = \frac{\pi m D_{AB}}{\dot{V}L^2} \tag{15}$$

M is the response factor of the detector [$M = 1$ for flame ionization detector (FID)], g a proportionality constant pertaining to the detector calibration, m the injected amount of solute in moles, and V the volumetric flow-rate in cubic centimeters per second.

Plotting the left-hand side of Eq. 12, $\ln(H^{1/M}t^{3/2})$ vs. $1/t$, one can obtain the diffusion coefficient value of D_{AB} from the slope $-L^2/4D_{AB}$ of the straight line and the known value of the diffusion column length (L).

Eq. 13 shows that a plot of $\ln H$ vs. t (after the maximum of the diffusion band) is linear with the slope $-3D_{AB}/L^2$, from which the diffusion coefficient D_{AB} can be also determined.

The question that now naturally arises is: Which one of the two equations, namely Eqs. 12 and 13, is more accurate in the determination of the gaseous diffusion coefficients? The answer is not so simple and depends on both the gaseous system under study and the experimental conditions applied. Generally, Eq. 12 is used for short duration experiments and for long diffusion columns, while Eq. 13 is used for short column lengths (say 30–50 cm) and for experiments of long duration. The selection of the proper mathematical analysis to estimate the more accurate gaseous diffusion coefficient by RF-GC can also be based on the comparison of the two experimental values found from Eqs. 12 and 13 with those given in the literature or calculated from known empirical equations.

The diffusion coefficients of various gaseous hydrocarbons in carrier gases N_2, H_2, and He determined by the reversed-flow technique with the aid of Eq. 12 at various temperatures are compiled in Table 2. The values and their standard errors found by regression analysis using standard least-squares procedures are reduced to 1 atm after multiplication by the pressure of the experiment. This pressure is given in Table 2, so that one can find the actual values determined from the ratio D_{AB}/p. The precision of the method, defined as the relative standard deviation (%), can be judged from the data given for methane–helium. From the five values quoted, a precision of 0.9% is calculated. The experimental values of diffusion coefficient given in Table 2 are compared with those calculated theoretically with the equation of HBS (Eq. 5). The accuracy given in the last column of Table 2 is a measure of the deviation of the values found by the RF-GC method from the calculated ones, defined as:

$$\text{Accuracy } (\%) = \frac{\left|D_{AB}{}^{\text{found}} - D_{AB}{}^{\text{calcd}}\right|}{D_{AB}{}^{\text{found}}} \times 100 \tag{16}$$

All of the theoretical or semiempirical equations describing the dependence of the diffusion coefficient on temperature lead to the relationship[1,2,14]

$$D_{AB} = AT^n \tag{17}$$

where A is a complex function including molar masses or volumes, critical volumes or temperatures, volume increments, pressures, etc. depending on the special equation used. Eq. 17 shows that the exponent n can be found from the slope of the linear plot of $\ln D_{AB}$ against $\ln T$. The various values of n calculated from these plots, which vary between 1.59 and 1.77,[13,14] are very close to the value 1.50 suggested by the Stefan–Maxwell and the Gilliland and Arnold equations,[1] to the value 1.81 predicted by the Chen–Othmer equation,[1] and to the value 1.75 predicted by the FSG equation.[1,5]

The reversed-flow method for measurement of gas diffusion coefficients in binary mixtures can also be extended to simultaneous determination of effective diffusion coefficients for each substance in a multicomponent gas mixture.[15] This extension of the method is achieved by filling the column section l (Fig. 1) with a chromatographic material, which can affect the separation of all components of the gas mixture. Effective diffusion coefficients of various mixtures of gaseous hydrocarbons into the carrier gases N_2, H_2, and He, determined by RF-GC, with the aid of Eq. 12, can be found in the literature.[15]

Comparison of the Broadening with the Flow Perturbation Techniques

1. The accuracy of the RF-GC method, in comparison with the GC-BTs, is higher.[2] The mean percentage deviation of D_{AB} (for the binary mixtures C_2H_4–N_2 and C_2H_6–N_2 at various temperatures) determined by RF-GC[2] from the respective predicted values by means of the FSG equation is estimated at 3.4, while that of the GC-BTs is 5.7.[6]

Table 2 Diffusion coefficients of various solutes into three carrier gases at ambient temperatures and reduced to 1 atm pressure, determined by reversed-flow GC.

Carrier gas	Solute gas	T (K)	$\dot{V}$ (cm^3/sec)	p (atm)	D_{AB} ($\times 10^3$ cm^2/sec)		Accuracy[b] (%)
					D_{AB}^{found}	(D_{AB}^{calcd})[a]	
N_2	CH_4	296.0	0.260	1.96	272 ± 4	214	21.3

He	CH_4	295.7	0.250	1.78	527 ± 3	669	26.9
		295.0	0.283	2.03	520 ± 1		28.7
		296.0	0.283	2.03	522 ± 1		28.2
		296.0	0.283	2.03	514 ± 0.2		30.2
		296.7	0.283	2.03	522 ± 3		28.2
	C_2H_6	295.6	0.300	2.15	518 ± 3	507	2.1
	n-C_4H_{10}	290.0	0.283	2.03	333 ± 3	330	0.9
	C_2H_4	296.0	0.283	2.03	558 ± 4	544	2.5
	C_3H_6	291.0	0.283	2.03	412 ± 4	440	6.8

The actual values found at the pressure of the experiment, p, are simply D_{AB}/p. All errors given in this table are "standard errors" calculated by regressions analysis.
[a]This is defined by Eq. 16.
[b]Calculated by the HBS equation.

2. The precision of the RF-GC method was calculated to be 0.9%. The precision of the continuous elution technique was about 1%, while that of the arrested elution method was about 2%.[2]
3. The time needed for the determination of D_{AB} values by the continuous elution method is very short (≈5 min), while that by the arrested elution method is longer (≈3 hr), due to the requirement of repeating the experiments at a number of delay times. The corresponding time for the RF-GC method is about 30–60 min, depending on the binary gas mixture and the length of the diffusion column used.
4. The length of the empty diffusion column in RF-GC is relatively short (30–80 cm), compared to that used in the continuous elution method, where much longer (~15 m) columns are used.
5. In the continuous elution method, in order to eliminate the effect of extra zone broadening factors, the use of two columns is necessary. Such a correction procedure is not necessary in the arrested elution technique, resulting in more reliable D_{AB} values through a more time consuming procedure. RF-GC, being a dynamic technique under steady-state conditions, has also the advantage that extra zone broadening factors are not implied in D_{AB} determinations.

DIFFUSION OF GASES IN LIQUIDS

Diffusion coefficients in liquids are of great significance in many theoretical and engineering calculations involving mass transfer, such as absorption, extraction, distillation, and chemical reactions. The measurement of accurate diffusion coefficients of gases in liquids is not an easy task. Different values are often obtained from different workers in different laboratories, even by using similar measuring techniques.

GC, being a dynamic technique, has been successfully used during the last three decades for the measurement of diffusion coefficients in a large number of gas–liquid systems, especially polymer–solvent systems.

From the 1980s, the *chromatographic broadening technique* has been "substituted" in the literature by *inverse gas chromatography* (IGC). The two main IGC methods for the measurement of diffusion coefficients in liquids are *packed column IGC*[7] and *capillary column IGC*.[7]

In packed column IGC, the preparation of the column is usually done by packing the column with a chromatographic material, running a solution of the solvent through it, and removing the solvent by evaporating with a stream of an inert gas. The presence of film irregularities due to the porous character of most chromatographic supports in

packed columns is a problem that affects the accuracy of the measured diffusion coefficients.

An innovation in the use of IGC for the measurement of diffusion coefficients in liquids is the introduction of capillary columns, which solved the problem of the non-uniformity of the coating on the solid particles. A known concentration of a degassed solution is used to fill a capillary column, which is sealed at one end, and vacuum is applied to the other end. The evaporation of the solvent results in the deposition of a uniformly thin liquid layer on the capillary walls.

Data concerning diffusion coefficients of gases in liquids, determined by various IGC techniques, can be found in the literature.[2,6]

The Reversed-Flow Technique

The experimental setup of the RF-GC method for measuring diffusion coefficients of gases in liquids is similar to that of Fig. 1, the only difference being the end of the diffusion column, at which a vessel containing the liquid or the solid (when surface diffusion is studied) is placed.[16,17] Using suitable mathematical analysis, equations were derived by means of which diffusion coefficients of various gases into liquids, D_L, were determined.[16,17]

All calculations of D_L can be carried out simultaneously by a GW-BASIC personal computer program, written for non-linear least-squares regression analysis[18] and based on the experimental pair values H and t in centimeters and seconds, respectively. The experimental D_L values are of the same order of magnitude and, in some cases, very close to those obtained by other techniques or calculated theoretically from empirical equations. The precision (~13%) and the accuracy (8–47%) of the RF-GC method, as determined from the D_L values of Refs.[16,17], compared to those computed from the more accurate empirical equation of Wilke–Chang,[1] are relatively satisfactory, considering the difficulties in obtaining experimental D_L values, and the large dispersion of the predicted diffusion coefficients.[2]

SURFACE DIFFUSION

The only gas chromatographic method used for the measurement of diffusion coefficients of gases on solid surfaces is the RF-GC technique validating a recent mathematical analysis, also permitting the estimation of adsorption and desorption rate constants, local adsorbed concentrations, local isotherms, local monolayer capacities, and energy distribution functions.[19] The RF-GC technique has been successfully applied for the time-resolved determination of surface diffusion coefficients for physically adsorbed or chemisorbed species of O_2, CO, and CO_2 on heterogeneous surfaces of Pt/Rh catalysts supported on SiO_2.[19] All calculations for the surface diffusion coefficient, D_s, can be carried out simultaneously by the GW-BASIC personal computer program listed in Appendix A of Ref.[19] The D_s values clearly show their dependence on time, and are in relative agreement with those found by non-chromatographic techniques.[19]

CONCLUSIONS

The gas chromatographic broadening and flow perturbation techniques have been proven to be useful tools for the accurate measurement of diffusion coefficients of gases in gases and liquids, and on solids.

Diode Array Detectors: Peak Identification

Ioannis N. Papadoyannis
H.G. Gika
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

The diode array detector (DAD), which arose from the analyst's needs to reduce data observations times in chromatography, has become a powerful tool in a research environment and in the quality assurance laboratory. Diode array adds a new dimension of analytical capability to liquid chromatography (LC) because it allows qualitative information to be obtained beyond simple identification by retention time.

Among the three advantages that DAD provides to the high-performance liquid chromatography (HPLC) analyst, peak identification is the one that allows the identification of unknown constituents in a sample whose matrix is complex.

PEAK IDENTIFICATION

The method-development laboratory is often set with a task of identifying unknown constituents in a complex sample. The identity or quantity of analytes is not well defined at this stage. Complicated sample-preparation steps and multiple HPLC analyses may be required to ascertain the nature of a sample. The diode array detector simplifies this process. In the case that more than 15 different peaks have been separated in a analysis of a multicomponent sample of known origin; more than a full day's work might be required just to establish the retention times of the unknowns with the use of a standard absorbance detector. A number of long-run HPLC analyses would have to be made with pure standards so that retention time correlations could be determined. This necessity is accomplished by the DAD's advantage of acquiring data in both the time and spectral domain.

The DAD has brought compound identification to HPLC. Previously, mass spectrometry (MS) was the sole domain in peak identification for gas or liquid chromatography (GC/MS or LC/MS). This can now be achieved as part of the HPLC analysis, and at a lower cost, because there is the ability to use an HPLC/DAD system as a scouting technique to check the possible identity of an unknown sample.

HPLC techniques often use absolute or relative retention times to identify compounds. Under well-defined conditions, UV/Visible spectra are useful data for the confirmation of peak identity. Thus, it is possible to qualify the compounds present through the use of spectra. This mode of identification by spectral similarity is also useful when retention times shift because of changing chromatography for similar sample runs.

However, spectral identity is a necessary but not a sufficient condition for compound identification. If the instrument parameters that determine how spectra are acquired are matched suitably, the spectral match of an unknown to a known spectrum can be used as strong indication of compound similarity or confirmation of identity. In a chromatogram, the retention time of a given peak offers an obvious means of preselection of candidate spectra through the application of a retention time window. All spectra from the set of possible candidates that fall in the window are compared to the unknown spectrum. The candidate with the best match factor above a certain threshold level is then used to identify the compound for the peak. Another possibility is to weigh both the match factor and the similarity in retention times and use the combined information for identification.

Peak identification is done by comparing a spectrum from an unknown peak to a spectrum from a user-created library. The best match of spectra is the closest to the correct identification. The comparison between the reference spectrum and the unknown spectrum is realized by the appropriate software.

With the DAD, spectra can be acquired automatically for each peak during the analysis. The spectra can be compared with those stored in a library, either interactively on the computer display or mathematically with the help of microprocessors. In Fig. 1, the spectral library matching is illustrated. The standard sample is analyzed and the spectrum of the target compound is registered in the library. The spectrum of the unknown sample is compared to standard spectra in the library.

SPECTRAL LIBRARIES

The UV spectra employed in HPLC can change for the same compound, depending on the mobile-phase environment at the time of elution. To have any success in applying similar approaches to compound identification, the separation system used to acquire spectra for standards and unknown analytes needs to be the same and well

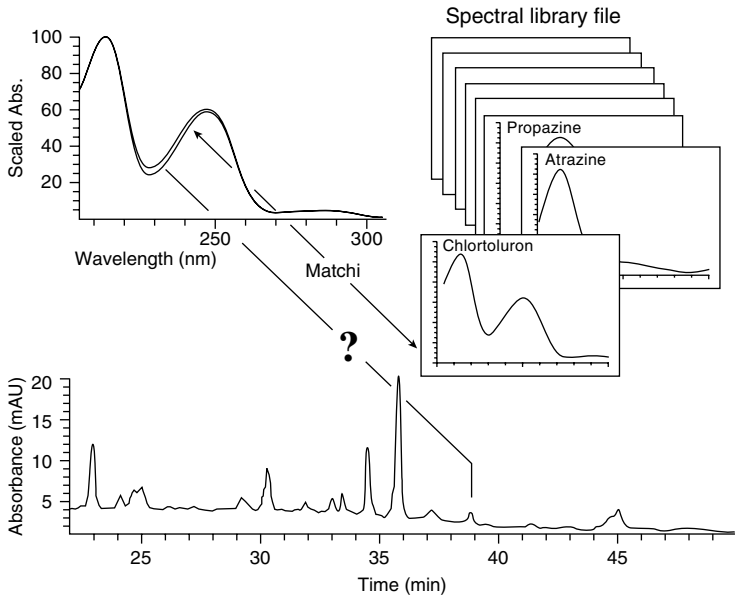

Fig. 1 Peak identification by spectral matching.

defined. Several examples taken from the recent literature make a strong case for the necessity of clearly defining the column and the mobile phase used.

Two primary approaches to the use of spectral libraries in HPLC can be described:

1. In the forward library search, an attempt is made to identify each compound in an unknown sample from a large library of standard compounds, previously recorded under defined chromatographic conditions. Each compound spectrum from the sample, analyzed under the same conditions, is searched against the library for identification. In case this is not possible, it may be classified by comparison with similar compounds from the library. Because the unknown sample may contain compounds that are not present in the library, it is desirable to obtain, at least, a list of likely matches for each unknown. In some instances, preselection of spectra is employed, based on the retention time indexing or on rough comparison of spectral features such as number and position of the primary absorbance maxima. This is done primarily to reduce the time needed to search the full compound library. In HPLC, it is found mainly in toxicological screening and drug-testing applications.
2. For reverse library searching, a limited library of standard compounds, all of which are expected to be present in the sample, is searched against the unknown spectrum in the current analysis. This search mode is an expansion of normal calibration procedures used currently in HPLC. Each peak of interest in a sample should be characterized through analysis of a standard. The spectral library, consequently, contains spectra for a limited number of compounds. In this case, we try to find the best match for each standard spectrum in the library by searching against all compound spectra identified in the current analysis. The question is to find all or some of the standard compounds in the unknown sample in a one-to-one assignment.

SPECTRAL MATCHING

Spectral matching can be defined as the process of comparing two spectra with the intention of determining their similarity. Once spectra could be digitized and the digital information manipulated mathematically, it became possible to base the comparison on a numeric evaluation of the digital data. Thus, in the modern definition, spectral matching is a procedure whereby the digital information available for a pair of spectra, each typically consisting of numerous discrete data points, is reduced to a single number indicative of the similarity between the two spectra. Ideally, this reduction in the number of data points does not involve any reduction in the information contained in the relationship of two spectra to each other. More specifically, most matching procedures presently employed are based on a point-by-point comparison of the two spectra in question to establish the presence or absence of significant differences.

Generally, there are three ways of performing spectral comparison: 1) overlay of spectra and visual determination, which is a subjective test; 2) evaluation of spectral differences between the reference spectrum and the unknown spectrum using the appropriate software. Larger differences suggest that the unknown is a different compound than the reference or that it is a mixture;

3) use of sophisticated software to calculate a numerical value that mathematically defines the closeness of the match.

Following are descriptions of the most common mathematical approaches used through spectral matching software.

Vectorial Approach to Spectral Matching

One approach that facilitates the definition and comparison of various matching procedures and eliminates the confusion associated with normalization is to view each spectrum as a vector in *N*-dimensional space. A spectrum data is considered as the group of the absorbance at each wavelength and it is represented with the vector.

$$(a(\lambda_1), (a(\lambda_2), a(\lambda_3), \ldots, a(\lambda_n))$$

where $a(\lambda_i)$ is the absorbance at the wavelength λ_i.

One spectrum corresponds to one vector:

$$\vec{S} = (a(\lambda_1), (a(\lambda_2), a(\lambda_3), \ldots, a(\lambda_n))$$

If there are two spectra, spectrum S_1 corresponds to S_1 and spectrum S_2 corresponds to S_2.

$$\vec{S}_1 = (a_1(\lambda_1), (a_1(\lambda_2), a_1(\lambda_3), \ldots, a_1(\lambda_n))$$
$$\vec{S}_2 = (a_2(\lambda_1), (a_2(\lambda_2), a_2(\lambda_3), \ldots, a_2(\lambda_n))$$

These vectors are simplified to a two-dimensional vector as shown in Fig. 2. The matching procedure can then be based either on determining the angle between the two vectors or on finding the distance between their tops. The first approach would seem to be independent of the relative magnitude of S_1 and S_2; the later definition implies normalization of S_1 and S_2 prior to the calculation of the distance.

If these spectra come from the same compound, the ratio between corresponding elements in S_1 and S_2 is constant and these vectors have the same direction. In that case, the angle θ in Fig. 2 becomes zero. As general rule, the more the angle approaches zero, the greater the similarity between the two spectra. The following equation describes the degree to which the two spectra correspond [similarity index (SI)] based on the cosine of the angle of their component vectors formed at each point of measurement:

$$\mathrm{SI} = \frac{\vec{S}_1 \cdot \vec{S}_2}{|\vec{S}_1| \cdot |\vec{S}_2|} = \cos\ \theta \tag{1}$$

or

$$\mathrm{SI} = \frac{\sum_{\lambda_i} a_1(\lambda_i) \cdot a_2(\lambda_i)}{\sqrt{\sum_{\lambda_i} a_1(\lambda_i)^2} \cdot \sqrt{\sum_{\lambda i} a_2(\lambda_i)^2}} \tag{2}$$

As the SI approaches zero, the pattern matching becomes poor (the angle θ between the vectors approaches 90°) and, conversely, as SI approaches unity, the pattern approaches a perfect match.

For easier manipulation, especially in the case of very similar spectra where differences may exist only in the third or fourth decimal place, the spectral match factor is often multiplied by 1000.

Another common measure of spectral similarity is the correlation coefficient *r* that is defined as:

$$r = \frac{\sum[(S_{1i} - \bar{S}_1)(S_{2i} - \bar{S}_2)]}{\sqrt{\sum(S_{1i} - \bar{S}_1)^2 \sum(S_{2i} - \bar{S}_2)^2}} \tag{3}$$

It expresses the correlation between paired absorbance values for the two spectra at each discrete wavelength interval. If we shift out two spectra S_1 and S_2 along the absorbance axis in a way that the mean absorbance for both spectra is zero, a process that is referred to as "mean centering," then $\bar{S}_1$ and $\bar{S}_2$ will both be zero.

Mean centering eliminates any spectral difference because of a fixed baseline offset that might be present in an individual spectrum. Eq. 3 further shows that the normalization of the spectral vectors to unit length is equivalent, in statistical terms, to the scaling of each spectrum by its standard deviation.

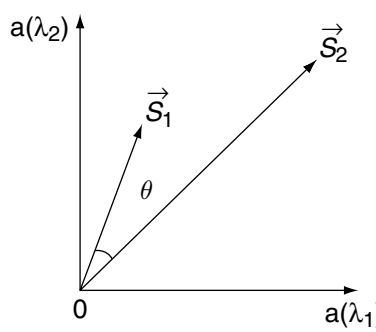

Fig. 2 Vectorial definitions of spectral matching.

Measures of Dissimilarity

Reliant on the ultimate relationship of geometry:

$$\cos^2 + \sin^2 = 1 \tag{4}$$

we can define a factor of dissimilarity of spectra. Thus, the sine square multiplied by 1000 could serve as an indicator of spectral dissimilarity.

Another possible measure of spectral dissimilarity, the Euclidean distance *e* between the tips of the two

vectors, as shown in Fig. 2, can also be related to sine and cosine:

$$e = S_1 - S_2 = \sqrt{\sin^2(S_1 - S_2) + [1 - \cos(S_1, S_2)]^2} \quad (5)$$

$$e = \sqrt{\sin^2(S_1 - S_2) + 1 - 2\cos(S_1 - S_2) + \cos^2(S_1 - S_2)} \quad (6)$$

and upon the Eq. 4

$$e = \sqrt{2 - 2\ \cos(S_1, S_2)} \quad (7)$$

$$e = \sqrt{1 - |\cos(S_1, S_2)|} \quad (8)$$

All the mathematical approaches mentioned above differ in the degree of change observed for spectral differences, most noticeably for angles below 15°. Between 0° and 10°, $\sin^2$, $\cos^2$, and cosine do not change very much, making it more difficult to differentiate among spectra with strong similarities. The rate of change varies, complicating the task of assessing the variability of the match score for different degrees of dissimilarity.

Normalization of Spectra

There are numerous procedures for the normalization of spectra, other than the one based on unit vector length. They all lead to the same result, if S_1 and S_2 differ only in concentration but there are essential differences in the case where S_1 and S_2 differ significantly.

The general normalization procedure for a given spectrum S follows the rule: $\langle S \rangle = NS$, where $\langle S \rangle$ corresponds to the normalized spectrum S and N is the appropriate normalization factor. Some of the more commonly used normalization procedures are presented below.

For vector normalization, N is defined as $N = 1/\sqrt{\sum S_i^2}$. Further, normalization to unit area can be achieved as $N = 1/\sum \mid S_i \mid$.

Vector normalization and area normalization are fairly resistant to noise because all data points are included and small random fluctuations, due to noise, tend to cancel each other.

There are also two normalization procedures that are based on the forcing of the absorbance at a specific wavelength to a specific value V. The wavelength used can be either the same for both spectra, $N = S_\lambda/V$ or the wavelength of maximum absorbance can be found over a specific wavelength range for each spectrum, $N = S_{max}/V$. In both cases, normalization is much more dependent on noise because a single absorbance value controls the normalization factor N.

FACTORS AFFECTING SPECTRAL COMPARISON

How to set a threshold level for the match factor to positively identify a compound spectrum is strongly dependent on a variety of factors. Below are mentioned those that play a major role in the success of the spectral matching procedure and are important tools in optimizing spectral comparison and threshold setting.

Wavelength Accuracy and Precision

Depending on the shape of the spectrum, small errors on the wavelength axis could translate into substantial errors on the absorbance axis and thus lead to false scores.

Detector Response Function

Initially, the optical resolution achieved by the spectrometer is governed by the size and shape of the entrance slit and determines the overall preservation of spectral fine structure. Secondly, the diode resolution obtained from the diode array is based on the geometry of the individual diodes, their spacing, and any grouping of diodes applied during processing of spectral data. Finally, stray light in the detector can cause deviations from Beer's law such that at low-light throughput absorbance no longer changes linearly with concentration. Thus, depending on the analyte's concentration, spectra will be distorted at higher absorbance values, resulting in an overall different shape when compared to a spectrum at lower concentrations.

Instrument Noise

The dissimilarity score for two identical spectra will never reach zero because of the presence of noise in the detector that cannot be compensated. There will always be some residual dissimilarity, which imposes a practical limit on the definition of a match threshold. The noise level of a given spectrum at a specific analyte concentration depends on the spectrometer, the characteristics of the diode array, and the scan speed of the detector, the lamp, and detector electronics.

Interference from Spectral Background

In most LC analyses, the spectra recorded contain some background absorption caused by either a change in the elution solvent, if a gradient system is employed, or by instabilities inherent in the instrumentation, or both. Therefore, some kind of background correction is typically indicated whenever spectra are compared, either for the purpose of determining whether a chromatographic peak contains an impurity or for the process of compound identification.

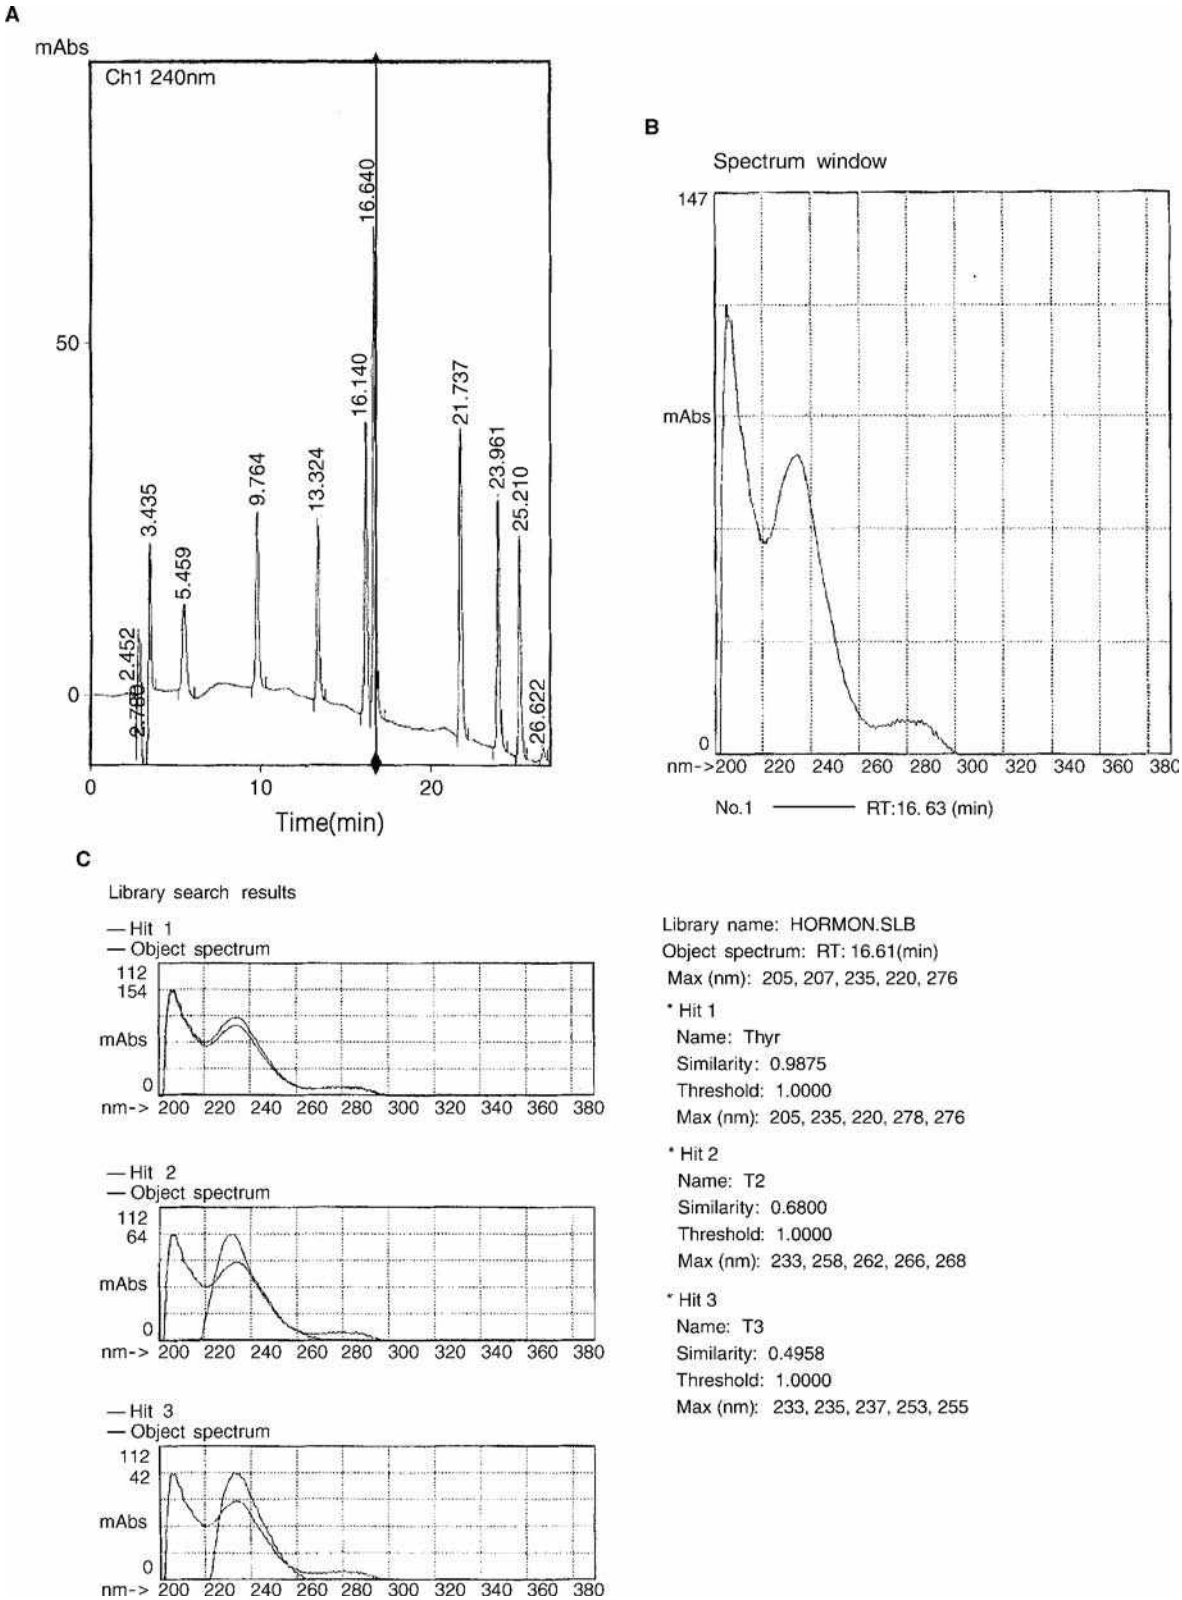

Fig. 3 A, HPLC chromatogram of standard solution containing tyrosine, thyronine, and some of their iodo derivatives. Detection was performed with a Shimadzu SPD-M6A photodiode array detector at 240 nm. The spectrum B, of the selected peak (thyronine) is acquired automatically and stored in the UV spectral library for comparison in further identification procedures. C, Normalized spectral comparison and report results of chromatogram's thyronine peak with the best matching library spectrum. The similarity index indicates the closest match.

Selection of Wavelength Range Employed for Matching

The selection of the appropriate wavelength determines the selectivity of spectral comparisons because instrument noise, which is the sum of all electronic and optical imperfections, will certainly favor some wavelength regions over others.

Processing of Spectral Data Prior to Matching

Prior to calculation of a dissimilarity score, spectra can be treated mathematically, either to improve their noise characteristics or to enhance differences for very similar spectra. One mode of pretreatment, from classical spectroscopy, involves the use of derivatives, especially of the second and higher derivatives, to enhance the fine structure of absorbance bands. Smoothing of spectral data to reduce noise is another pretreatment mode that could potentially improve the selectivity of spectral matching.

Impurities

The spectrum of the unknown compound to be identified should not contain any spectral impurities as caused by coeluting components. If a spectrum is known to contain a spectral impurity, it should be corrected for this impurity before the comparison with the standard spectra. Corrections for coeluting impurities are very difficult. If the impurity does not coelute completely, identification may still be possible, depending on the concentration and elution time of the impurity, relative to the main peak.

EXAMPLE OF APPLICATION

The identification of an unknown peak in a chromatographic analysis, performed by the Shimadzu SPD-M6A UV/Vis photodiode array detector, combined with data acquisition software Class M10A, is presented in Fig. 3A–C. The spectrum file of the selected peak is compared against reference spectra in a user-built library. Data processing through the mathematical approach mentioned above defines the best match. The numerical value of the SI indicates the spectrum of thyronine as the better match because, in this case, it is close to unity. The comparison is also made by visual evaluation through the overlaid spectra. The created spectral sublibrary consists of several iodothyronine and iodotyrosine spectra, which are those of interest in this application. Thus, the chromatographic peak, assuming it belongs to thyronine, can be identified among other related compounds by its UV spectrum, allowing qualitative analyses that are more accurate.

CONCLUSIONS

The mode of peak identification that the diode array detector provides allows identification of unknown peaks, not only by retention time but also by their UV spectra. The UV spectrum is very reproducible and its full shape is much more compound-specific than is generally assumed. It is a powerful tool that, beyond other applications, it can also be used as a scouting technique to find out the possible identity of an unknown sample. However, spectral identity is a necessary but not a sufficient precondition for compound identification. The information that is acquired by the comparison of an unknown and a known spectrum can be used as strong indication of compound similarity or confirmation of identity. Combinatorial estimation of retention time and spectral comparison results will give us a more definite idea.

Diode Array Detectors: Peak Purity Determination

Ioannis N. Papadoyannis
H. G. Gika
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Peak purity analysis is an evaluation technique for detecting the presence of coeluting impurities in high-performance liquid chromatography (HPLC) data. Running a peak purity check prior to analytical quantitation helps to ensure accuracy. In the development of analytical methods, peak purity analysis can reveal the presence of contamination during standardization and, by doing so, can prevent the subsequent generation of false analytical data.

Peak purity analysis is also a useful addition to routine quality control procedures, especially in the analysis of pharmaceuticals and food products, for which contamination and quality of results are critical.

PEAK PURITY ANALYSIS WITH DIODE ARRAY DETECTOR

Peak purity analysis is designed to detect the presence of an impurity that is coeluting with the analyte peak. For impurity detection with a single-wavelength UV/Vis detector, one must see a shoulder, valley, or excessive tailing to suspect the presence of an impurity. The absence of these features on the chromatographic peak is not a foolproof assurance of peak purity. The impurity may not be seen simply because the chromatographic resolution is low (Fig. 1). A photodiode array detector can provide additional information by using the acquisition of UV/Vis spectra to determine peak purity.

A proper peak purity determination requires access to a significant portion of the eluting compound's spectrum without interrupting the separation. For this reason, peak purity analysis is performed using a multisignal UV/Vis diode array spectrophotometer as the HPLC detector. Unlike the diode array detector (DAD), the traditional variable-wavelength detector examines only a single wavelength of the sample spectrum, providing insufficient information for peak purity determination. The diode array spectrometer illuminates the sample with the entire spectrum of wavelengths emitted by the light source. Light transmitted by the sample is then broken into its component wavelengths by a diffraction grating and directed to a bank of photodiodes, each of which is dedicated to measure a narrow band of the spectrum. As no mechanical scanning is required, spectral acquisition can be accomplished in as little as 12 msec, well within the precision limits for HPLC peak elution. The rapid spectral acquisition makes it possible to perform peak purity determinations using selected multiple spectra as inputs. Therefore, the absence of any mechanical action in the acquisition of spectra enhances the reproducibility and the accuracy of the peak purity analysis. For coeluting peaks, a DAD makes it possible to differentiate both compounds, even when their spectral absorption overlaps the entire range of captured wavelength data.[1,2]

DIFFICULTIES OF PEAK PURITY CONFIRMATION

Before the quantitative information contained in a chromatographic peak can be used, the purity of the peak should be confirmed. Only after we are sure that no coeluting impurity was present, which could have contributed to the peak response, can we convert the peak's area or height into quantitative information based on the equivalent response of a pure standard. This peak purity analysis can be based on the comparison of the various spectra recorded during the elution of the peak. If the peak is pure, then, apart from concentration differences, the spectra taken at several points during a peak's elution should all be identical and the match scores obtained should be very close to the perfect match scores. If significant deviations are encountered, this can be seen as an indication of impurity.

Unfortunately, the inverse is not necessarily true. If the spectra are identical, based on the algorithm used for comparison, the peak can still be impure for one or several of three possible reasons:

1. The impurity is present at a much lower concentration than the main compound and is not detectable.
2. The impurity has the same or a very similar spectrum, compared to the main compound.
3. The impurity exhibits the same peak profile as does the main compound; that is, it completely coelutes with the main peak, across the entire peak.

One of the most important aspects of peak purity analysis that is often overlooked is the fact that any

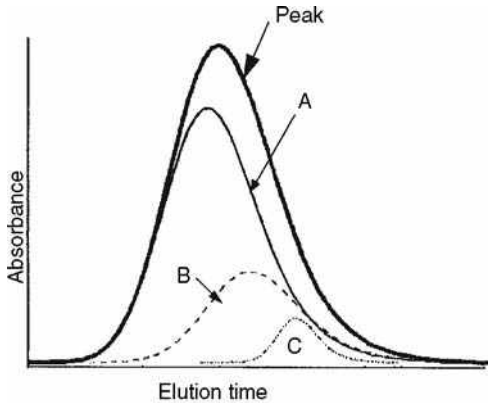

Fig. 1 Coelution of three compounds A, B, and C in the chromatographic peak. No shoulders, valleys, or excessive tailing are seen.

peak purity algorithm can only confirm the presence of impurities, but can never unambiguously prove that a peak is pure.

HPLC SIGNAL OVERLAY FOR PURITY ANALYSIS

One way of uncovering contributions because of impurities in an HPLC peak is to overlay peak profiles acquired at several wavelengths. As two different compounds are unlikely to exhibit identical absorption over multiple wavelengths, the presence of an impurity is revealed by the deviation of the profiles. To compensate for the differences in spectral intensity at different wavelengths, the signals to be compared are first normalized to the maximum absorbance value or to equal areas. Peaks free of impurities exhibit good overlap, but the presence of an impurity is indicated by a shift in the retention time maximum at different wavelengths (Fig. 2).

The signal overlay method is not considered to be very sensitive, and is highly dependent on the resolution of analyte and impurity peaks. If care is taken to correct for solvent background and if the signals are normalized to the highest absorbance value in the time range plotted, the resulting ratiogram can provide conclusive information. It is usually recommended as an additional qualifier in conjunction with other peak purity analysis methods.

In addition to signal overlap, the ratios of signals acquired at different wavelengths can be calculated and plotted. The resulting ratiograms are good *indicators* of peak purity. Any significant distortion of the ratiogram's ideally rectangular form is an indication of differential absorption and the presence of an impurity (Fig. 3). Peak purity analysis based on signals is generally limited to instances for which the spectra of both analytes and impurities are well known, a requirement for selecting the wavelengths best suited for comparison. Typical applications for this information would be routine evaluations such as quality control checks.

PEAK PURITY USING SPECTRAL DATA

Comparison of spectra is the most popular method of peak purity determination. The primary advantage of this approach is that prior knowledge of component spectra is not required. However, information derived using these techniques is not sufficient for determining the kind, number, and level of impurities present.

A number of selection criteria and data manipulation techniques can be applied prior to analysis to improve the quality of the analytical result. These include setting different spectrum acquisition modes, background corrections, normalization, and threshold settings.

Selection of Spectra for Comparison

Peak purity analysis software allows users to sample spectra at equidistant points across an HPLC peak. In

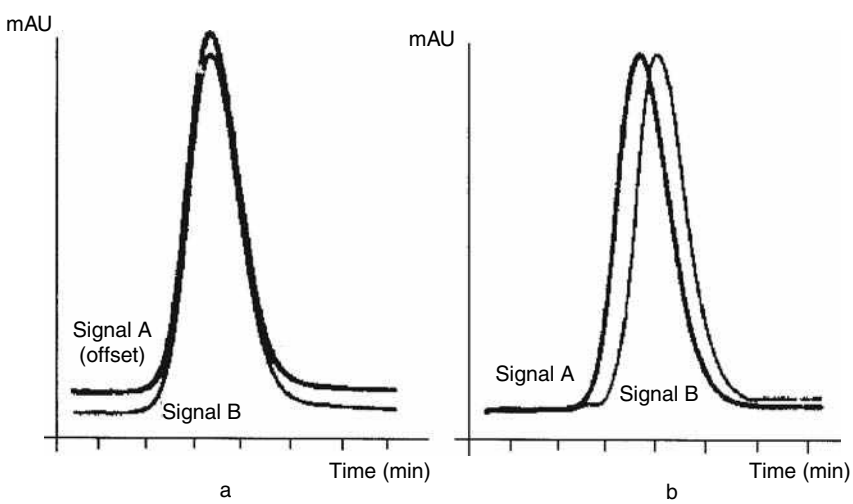

Fig. 2 Normalized signals for (a) pure and (b) impure peaks.

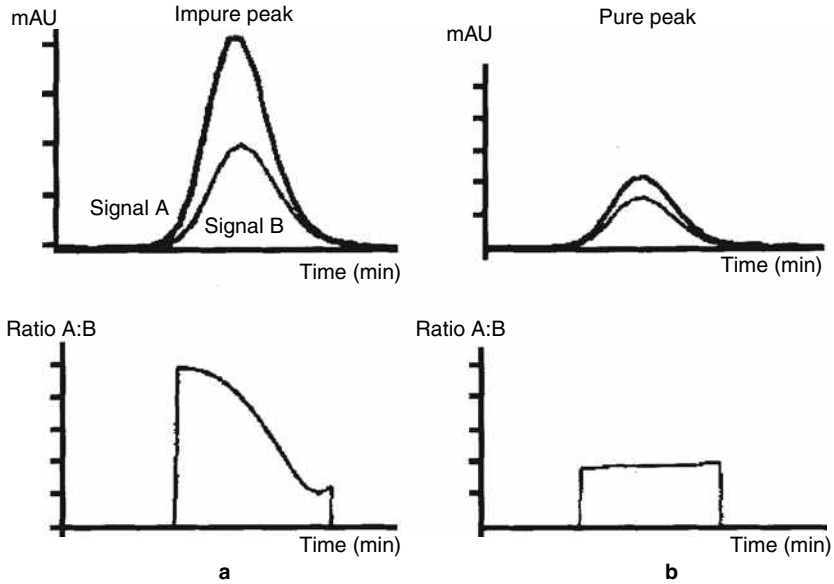

Fig. 3 Ratiograms taken from (a) an impure and (b) a pure peak.

general, the poorer the resolution between potentially coeluting peaks is, the more desirable it is to use greater numbers of data points to detect the impurity. Traditionally, spectra have been sampled upslope, at the apex, and downslope of the eluted peak. This selection pattern may overlook the presence of impurities near the peak extremities. However, acquisition of many spectra may increase calculation and display time without adding significant information.

Background Correction

A peak should not be labeled as impure because of spectral background, or because of tailing interference from a neighboring peak. Both effects can be corrected for by suitable background correction, with the understanding that spectral subtraction increases the noise of a spectrum and, thereby, lowers the ideal match factor.

Whether background correction needs to be applied depends on the separation system employed. If the instrument is balanced properly, then, for isocratic separations, the solvent background will be eliminated by the built-in automatic subtraction of the solvent spectrum, as present at the beginning of the analysis, from all recorded spectra. For gradient separations, background corrections will have to be applied after the analysis.

Different methods for correction are possible; the choice of method depends on the availability of spectra resulting from specific modes of spectral storage for different instruments. Ideally, all spectra are retained for an analysis, but because of processing and storage constraints, many instruments offer a mode of acquisition where spectra are stored only during the elution of a peak. Peak spectra can be limited to just the apex spectrum, or to a number of additional spectra across the peak, most commonly acquired at the baseline and the inflection points. If only apex spectra are available, no background correction is possible. For all other cases, the quality of background correction will depend on the availability of suitable baseline spectra.

In the simplest case, a single baseline spectrum is subtracted from all analyte spectra. This will work only for the elimination of constant spectral impurities. If several baseline spectra are available, linear combinations of those spectra can be used to generate a synthetic background spectrum at any point in the chromatogram. Ideally, the two spectra should be close to the beginning and the end of the peak being analyzed. If this is not possible because of incomplete separation of the peak from its neighbors, baseline spectra could be taken from the beginning and the end of a peak group.

If only slope and apex spectra are available, background correction is still possible, in a limited fashion, by subtracting the apex spectrum from the two slope spectra. For isocratic separations or gradient with slow changes in solvent background, this approach will produce two baseline-corrected slope spectra with a loss in signal that is equal to the difference in amplitude between slope and apex spectrum.

Spectrum Normalization

Spectra used for comparison during peak purity determination should be normalized to compensate for differences in concentration. Normalization can be based on setting equal absorbance maxima or maximum wavelength ranges, on setting equal area of spectra or spectral region of interest, or on using a matching algorithm that minimizes area differences by shifting and scaling spectra.

Absorbance Threshold

Setting an absorbance threshold improves the accuracy of spectral comparison by screening out spectra near the signal baseline. These spectra tend to have a relatively high degree of noise, which adversely affects the accuracy of both normalization and subsequent spectrum matching.

Spectrum Overlay

After spectra are acquired and processed, they are overlaid for visual evaluation (Fig. 4). Although significant deviations between the profiles can indicate the presence of an impurity, the converse is not necessarily true, and spectral profiles that match quite well may still mask the presence of an impurity. Factors that may contribute to nondetection of impurity include large concentration differences between analyte and impurity and either highly similar spectral profiles or identical chromatographic peak profiles and retention times for both analyte and impurity. As a rule of thumb, impurity concentrations in the 0.1–1% range may be detected when the spectra are dissimilar. However, if the spectra of the different components are highly similar and the HPLC peaks are not well resolved, the impurity detection limit is on the order of 5%.

ADVANCED TECHNIQUES

Simple peak purity analysis is relatively accurate when the impurity is present at significant concentration levels but, as the level of impurity diminishes, its impact on the target analyte spectrum becomes subtler and may require more sophisticated techniques. For this, statistical software routines are available for automated spectral comparisons. In these cases, peak purity determination and analysis of spectral differences are achieved using vector analysis algorithms. The more similar the spectra are, the closer the value is to 0.0°; the more spectrally different they are, the larger the value. All the spectral data points across the peak are analyzed; the data are converted into vectors, compared, and graphically plotted so that the results can be visualized. These software routines provide both numerical results and graphical representations such as similarity and threshold curves.

Similarity curves are plots of retention times versus similarity factors computed by comparing spectra across an eluted peak with one or more selected spectra. Similarity curves improve the sensitivity of detecting impurities because they extract and highlight subtle impurity-generated anomalies in an analyte spectrum that might otherwise go unnoticed.

The threshold curve is a plot of retention time versus a similarity factor threshold, below which the presence of an impurity cannot be distinguished from spectral noise. The threshold trace may be computed automatically from the standard deviation of a number of user-selected pure noise spectra. Alternatively, the threshold may be set at a fixed value. Similarity and threshold curves tend to rise at the extremities of the eluted peak, even when no impurity is present. As signal strength decreases, a larger proportion of the spectral response is caused by noise. If an impurity is present at a detectable concentration, the similarity curve will intersect the threshold (Fig. 5).

Peak purity software incorporating routines for data acquisition and reduction, extraction and comparison of spectra, and display of analytical results can be utilized in either an interactive or automated fashion. A desired sequence of operations can be recorded in a peak purity analysis method file and can run unattended after input parameters are selected. As the quality of the determination is highly dependent on the preanalysis data treatment,

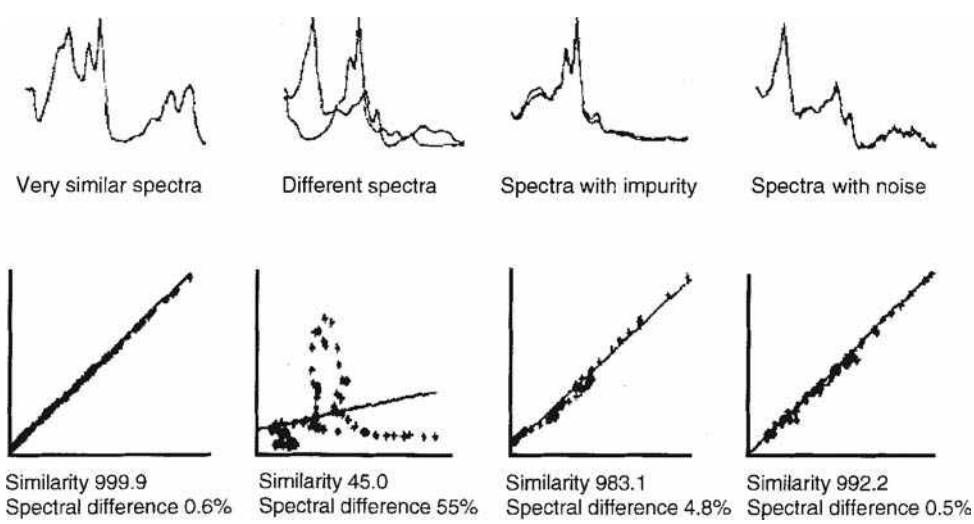

Fig. 4 Graphical display of similarity factors for different pairs of normalized spectra.

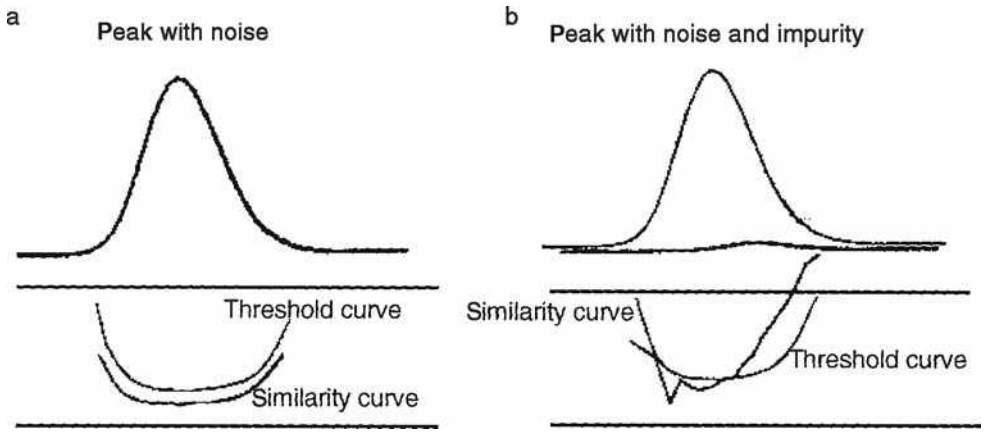

Fig. 5 Effect of impurity and noise on similarity and threshold curves of (a) a peak without impurity but with noise, and (b) a peak with impurity and noise.

results should be inspected visually to verify that peaks are properly baseline-separated and correctly integrated.

The evaluation of a peak purity analysis is assisted by a well-organized visual display of the output of various peak purity analysis techniques.[3–5]

CONCLUSIONS

Peak purity analysis is designed to detect the presence of an impurity that is coeluting with the analyte peak. A DAD, using the almost instantaneous acquisition of a considerable portion of the UV/Vis spectrum of eluted peak components, can give accurate information to determine peak purity. The spectral uniqueness of each compound is used to indicate when there are two or more components present in the peak, to identify peaks, and to assess purity.

Peak purity analysis is very useful in chromatographic method development, to confirm that all components have been chromatographically separated, and in quality control, to warn the analyst that an unexpected coeluting impurity has appeared.

Displacement Chromatography

John C. Ford
Department of Chemistry, Indiana University of Pennsylvania, Indiana, Pennsylvania, U.S.A.

INTRODUCTION

One of the three basic modes of chromatographic operation, displacement chromatography is useful for preparative separations and trace enrichment. Most liquid chromatographic methods have been performed in displacement mode. Solutes purified by displacement chromatography include metal cations, small organic molecules, antibiotics, sugars, peptides, proteins, and nucleic acids.

Displacement operation involves the introduction of a volume of sample onto the column, which has been previously equilibrated with a weak mobile phase. Since this is a weak mobile phase, the individual sample components are significantly retained by the stationary phase. Displacement occurs with the introduction of a new mobile phase containing a species with a higher affinity for the stationary phase than that of any of the solutes. The solutes are displaced from the stationary phase by this higher-affinity displacer and move further down the column, readsorbing. The solute with the highest affinity for the stationary phase moves the least before readsorbing and that solute with the lowest affinity for the stationary phase moves the most. This process repeats until a series of separated, but adjacent, bands is formed. Each band moves at the same velocity as that of the displacer front. Following elution, the column must be regenerated and re-equilibrated with the initial mobile phase before any subsequent displacement separation. This re-equilibration step can be lengthy and is frequently considered a major limitation to efficient displacement operation.

DEFINITION

Displacement chromatography is one of the three basic modes of chromatographic operation, the other two being frontal analysis and elution chromatography. Displacement chromatography is rarely, if ever, used for analytical separations, but is useful for preparative separations. It has also been used for trace enrichment.

Many, if not most, retentive chromatographic methods have been performed in the displacement mode, including normal-phase, reversed-phase, ion exchange, and metal affinity chromatographies. Much of the recent work has focused on the use of ion exchange displacement chromatography for the preparative purification of biotechnological products.[1,2] Solutes purified by displacement chromatography include metal cations, small organic molecules, antibiotics, sugars, peptides, proteins, and nucleic acids.

Tswett recognized the difference between elution and displacement development, although Tiselius was the first to clearly define these differences. While displacement was popular in the 1940s, that popularity waned in the 1950s. In the 1980s, there was a resurgence of interest in displacement operation due to the efficient utilization of the stationary phase possible in that mode. Frenz and Horvath[3] have published a comprehensive review of the history and applications of displacement chromatography.

Displacement chromatography is characterized by the introduction of a discrete volume of sample into the chromatographic column that has been previously equilibrated with a weak mobile phase, termed the carrier. This carrier is chosen so that the individual components of the sample (the solutes) are significantly retained by the stationary phase. The displacement is accomplished by following the sample with a new mobile phase containing some concentration of the displacer, a molecule with a higher affinity for the stationary phase than that of any of the solutes. The solutes are displaced from the stationary phase by the higher-affinity displacer and move further down the column, readsorbing. That solute with the highest affinity for the stationary phase moves the least before readsorbing, and that solute with the lowest affinity for the stationary phase moves the most. This process is repeated as the displacer solution moves further down the column until a series of separated, but adjacent, bands is formed, termed the isotachic train. Each component of the train moves at the same velocity as the velocity of the displacer front. Following elution of the isotachic train and the displacer solution from the column, the column must be regenerated and re-equilibrated with the carrier before any subsequent displacement separation. This re-equilibration step can be lengthy and is frequently considered a major limitation to efficient displacement operation.

Displacement chromatography requires the competitive isotherms of the solutes and the displacer to be convex upward and to not intersect each other. The isotherm of the displacer must have a higher saturation capacity than any of the solutes. The width, not the height, of the solute band within the isotachic train varies as the amount of solute in the sample varies. The height of the solute band is determined by its isotherm. The concentration of the eluted solutes can be greater than their concentrations in the

sample in displacement chromatography, unlike in isocratic elution chromatography, wherein dilution necessarily occurs.

The choice of displacer concentration is critical for successful displacement. If the displacer concentration is increased, then the solute concentrations in the isotachic train also increase. If the displacer concentration is decreased, then displacement does not occur and the solutes elute as overloaded peaks in the elution mode. Rhee and Amundson[5] have shown that there is a critical displacer concentration below which displacement cannot occur. This concentration depends primarily on the saturation capacities of the solutes and displacer.

When the solute isotherms cross one another, the situation becomes more complex. It then becomes possible to experience selectivity reversal, i.e., at one displacer concentration, the solutes elute in the order A first, then B, while at another displacer concentration, the order is B first, then A. In a study of this problem, Antia and Horvath[6] showed the existence of the separation gap. This is a region in the isotherm plane, the position of which depends on the ratio of the saturation capacities of the solutes in question. Outside the separation gap, displacement occurs in the normal fashion. However, within the separation gap, the displacement operation does not separate the displaced solutes, but results in the elution of a mixture of the solutes.

In addition to appropriate isotherm behavior and displacer concentration, other factors are important in determining the effectiveness of a displacement chromatographic method. Highly efficient columns and fast mass transfer kinetics are necessary to achieve sharp boundaries between the adjacent solute bands in the isotachic train. Diffuse boundaries mean significant regions of overlap between adjacent solute bands and thus low recovery of purified material.

Successful displacement requires the establishment of the isotachic train before elution of the solutes from the column. As might be expected, the column length is thus an important parameter in displacement chromatography. The column should be sufficiently long (or sufficiently efficient) to allow complete formation of the isotachic train, while lengths beyond that minimum do not improve the separation but increase the separation time. An inadequate length results in the elution of an incompletely formed isotachic train with inadequately resolved solute bands, again reducing the recovery yield.

Similarly, the sample size, column length, and displacer concentration jointly influence the establishment of the isotachic train and, thus, the effectiveness of the displacement separation. For a given displacer concentration and column length, increasing amounts of sample result in increasingly diffuse boundaries and, in sufficiently large samples, significant deterioration of the isotachic train. Likewise, for a given sample size and column length, increasingly high concentrations of displacer cause increasingly diffuse boundaries—termed overdisplacement.

Displacement chromatography has the attractive benefit of concentrating the solute. If the conditions are selected appropriately, large injection volumes of low concentration samples can result in isotachic trains having high solute concentrations, essentially identical to those obtained for narrow pulses of high concentration samples. This is one of the features that have caused the increased interest in displacement as a preparative mode. However, detailed comparisons of the production rates of displacement vs. overloaded elution operation are limited.[4] The limited experimental studies suggest that the displacement operation is superior, although regeneration time was not included in the production rate calculation. Alternately, extensive theoretical studies indicate that, for solutes having Langmuirian behavior, optimized overloaded elution chromatography is superior. Resolution of this issue currently awaits further studies.

Displacement TLC

Maria Bathori
Department of Pharmacognosy, University of Szeged, Szeged, Hungary

INTRODUCTION

Displacement takes place in a broad scale when a stronger species replaces a weaker one. Displacement of ligands on the receptor is a typical phenomenon in pharmacology which explains drug–drug interactions.

Displacement equilibrium is also known in chromatography, by which ligands compete for binding sites. This competition can be preferentially utilized for either analytical or preparative scale separations.

DISPLACEMENT CHROMATOGRAPHY WITH COLUMN HPLC

Chromatography may be performed as elution, frontal, or displacement. When the mode of development is not specified, a chromatographic separation is considered to be an elution.

The displacement phenomenon in chromatography was recognized from the beginning of separation processes in the present-day sense.[1] Classical displacement chromatography (DC) was used to separate biologically active compounds, such as amino acids, peptides, and fatty acids.[2] High-performance displacement chromatography (HPDC) was developed in Horváth's laboratory at Yale University. They realized displacement type of development on a microparticulate stationary phase; various applications were accomplished to demonstrate the power of HPDC in preparative scale separation of compounds of biological and medical interest.[3–6]

Experimental work of Kalász et al.[6] resulted in the statement of the characteristics and basic rules of DC. They conceived properties of the fully developed displacement train, factors affecting displacement development, efficacy of separation, analysis of displaced fractions, determination of displacement diagrams from Langmuirian isotherms, as well as selection of the column, carrier, and displacer for DC. Concentration of the sample is a particular feature of DC. However, the displacer in the carrier is also definitely concentrated through the development of the displacement train.

Furthermore, certain prerequisites of HPDC were stated, such as the limit of the mobile phase flow velocity, slight overlapping of peaks during fractionation, etc.

Displacement thin-layer chromatography (D-TLC) also stemmed from the activity of Horváth's group at Yale University. Experimental work with D-TLC has proven the validity of the rules of DC, found by using HPLC.[5,6] Kalász et al.[6–8] continued the research on D-TLC, mainly with the separation of steroids.

There are basic unique characteristics solely for DC. DC works with a mobile phase containing both the carrier and the displacer. A special front moves forward during the development; it is the front of the displacer. Of course, certain compounds are moving forward ahead of the displacer front; that is, the displacer (front) displaces the components from the binding sites of the stationary phase. This complex of the components is terminated by the displacer and the components, and also the displacer is moving forward in the form of clearly defined zone(s) instead of as the Gaussian peaks seen with elution chromatography. The concentration (zone height or peak height) of individual displaced zones is determined by the crossing point of the Langmuirian isotherm and the operating line, instead of the amount of sample components (Table 1).

DISPLACEMENT THIN-LAYER CHROMATOGRAPHY

D-TLC started with the experiments of Kalász and Horváth,[5–7] who stated the basic rules of D-TLC. A direct connection was found between the volumetric load of HPLC and the size (length) of sample in TLC. The size of displaced zones depends on the weight size of the load, but never on the volume of the injected sample with D-HPLC. Similarly, the dimensions of the displaced band are independent from that of the spotted sample. A surprisingly short distance of advancement totally developed the displacement train, e.g., a 20 mm development. It is even more surprising that 75 μg of the sample load could become part of a displacement train after having utilized about 250 mg of stationary phase.[6,7]

D-TLC has several analogs to column displacement HPLC, such as:

- A displacer is supplied after the samples have been loaded onto the stationary phase.
- A displacer front is generated in situ on the stationary phase.
- The sample components start to move because of the effect of displacer, and the displacer front forms a displacement train of adjacent spots.

Table 1 Comparison of elution and displacement modes of development.

Elution development	Displacement development
Linear and non-linear (overloaded) elution.	
The components are diluted (relative to their concentrations in the sample).	The components are concentrated (relative to their concentrations in the sample).
There is one mobile phase, consisting of the elements of the eluent. Gradient elution can also be performed by the use of several mobile phases. Either stepwise gradient or continuous gradient elution is possible.	There are two consecutively supplied mobile phases, the carrier and the displacer. This latter consists of an adequate amount of displacer in the carrier.
The components travel with different migration speeds.	Isotachic migration of the component zones in the fully developed displacement train.
Gaussian (or quasi-Gaussian) peaks.	Adjacent square-wave-shaped zones.
The peak area is proportional to the amount of the component. In some approximations, the peak height is considered instead of peak area.	The zone height is determined by the crossing of the Langmuirian isotherm of the component with the operating line. The zone width is proportional to the amount of the component.
Separation means physical removal of the peaks from each other, the maximum of peaks have to be far away from each other, the distance should be at least one peak width measured at the baseline.	The adjacent zones of a totally developed displacement train touch each other, even in the optimal separation.

- After having reached the state of a fully developed displacement train, all bands move with the same velocity, which is the velocity of the displacer front.

There are two conditions required for any component in the displacement train:

- The component has to show very moderate movement on the stationary phase from the effect of carrier.
- The displacer has to have stronger absorption to the displacement train than the component to be displaced.

There are four different migration types of any solute in the displacing system; for example,

1. The solute is displaced in the front of the displacer.
2. The solute migrates faster than the displacer front.
3. The solute migrates slower than the displacer front.
4. The solute remains at the start.

Cases 1–3 are given in Fig. 1. Case no. 1 generally represents the real displacement (bonafide displacement).[9] Further proof of the bonafide displacing process can be given by the use of spacers, varying the front distance (and, thereby, the displacement front distance), and control of the load vs. spot length principle. This latter rule means that the higher the load, the longer will be the spot length. Bonafide displacement and quasi-displacement can also be differentiated on the basis of the chromatogram. Bonafide displacement gives a homogenous peak, which consists of both the displacer front and the displaced component. In the case of quasi-displacement, the two peaks are partially separated, and the peak of the displaced component is a little bit wider. A change of carrier generally solves this problem. Participation in the displacement train is the principal assignment.

Kalász et al.[10] showed that even a very short distance (e.g., 2 cm in the case of 5% displacer) may be sufficient for the formation of a fully developed displacement train. HPDC is devoted to preparative scale separation.[3] Fractions result in HPDC; the fractions are collected and analyzed "off-line." The appropriate fractions can be combined to yield the pure compounds. D-TLC was grown into an approach for scouting the optimum conditions for HPDC. Its goals are to find the proper carrier, the proper displacer, and the appropriate displacer concentration in the carrier. A series of experiments proved that the results of D-TLC can be transferred to HPDC.[5]

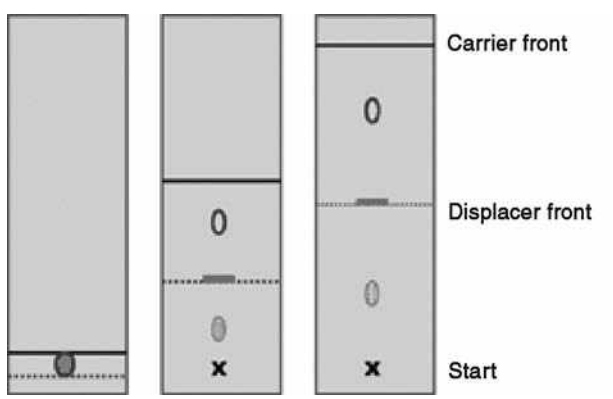

Fig. 1 Development of displacement chromatogram can take place on a plane. The faster-running front represents the carrier, and the slower-running front is the displacer in the carrier. Certain components can be eluted by the carrier (blue open circle), and another one is eluted with the displacer (green circle, shaded). If there is any component displaced, it is located just before the displacer front (red square, filled).

Even the zone-concentrating effect of the increase of displacer concentration was directly proven using off-line quantitative determination of the fractions obtained by HPDC.[5] However, the major field of application of D-TLC remains qualitative analysis, such as identification of compounds such as metabolites. D-TLC is mainly performed for such analytical purposes. On plain silica stationary phase, the 20:1:4:2 mixture of *n*-butanol–hydrochloric acid–water–methanol properly displaced several morphine derivatives, including morphine, azido-dihydroisomorphine, 14-hydroxy-dihydromorphine, dihydromorphine, 14-hydroxy-azido-dihydroisocodeine, 14-hydroxy-azido-dihydroisomorphine, codeine, azido-dihydroisocodeine, and 14-hydroxy-dihydrocodeine. Nonetheless, the adequate choice of the displacement system can alter the order of components and even the participation of the components in the displacement train. Using the same stationary phase (plain silica), the chlorinated hydrocarbon carriers (chloroform, dichloromethane, and dichloroethane) make less migration possible, as compared with the *n*-butanol–methanol–water–hydrochloric acid system. When triethanolamine displacer in chloroform carrier was used, certain otherwise eluted components became part of the displacement train. The ECAM (*O*-ethyl-*N*-cyclopropyl-norazido-dihydroisomorphine), CAM (*N*-cyclopropyl-norazido-dihydroisomorphine), norazido-dihydroisomorphine, normorphine, and nalorphine changed their situation from eluted positions to displaced ones. The most surprising change happened in the case of 6-amino-dihydromorphine, which was eluted with the carrier well before the displacer front, but it was left behind the displacer front in chlorinated hydrocarbon carrier and triethanolamine displacer. This phenomenon can be explained by the reaction of amino group to the change of acidic to basic conditions caused by substituting triethylamine for the hydrochloric acid. The change of the stationary phase from silica to alumina also altered the components, in the displacement train, and the lengths of the displaced zones were changed as well. Remarkably, certain components show faster mobility on alumina when chloroform carrier is used. In addition, the displacement zones are also generally longer.[11] The change of the stationary phase from plain silica to reversed-phase silica (TLC plate RP-18 F_{254}s, precoated, layer thickness 0.25 mm) turned the order of components upside-down (Fig. 2). Some of the components, however, remained in the displacement train, e.g., azido-dihydroisomorphine, ethylmorphine, and norazido-dihydroisomorphine. Preparative work can also be performed by scraping the spots from the plate. D-TLC separation of morphine analogs was performed using volatile mobile phases including the carrier and the displacer. The mixture of *n*-butanol–hydrochloric acid–water–methanol (20:1:4:2) can be preferentially used for preparative separation of semisynthetic

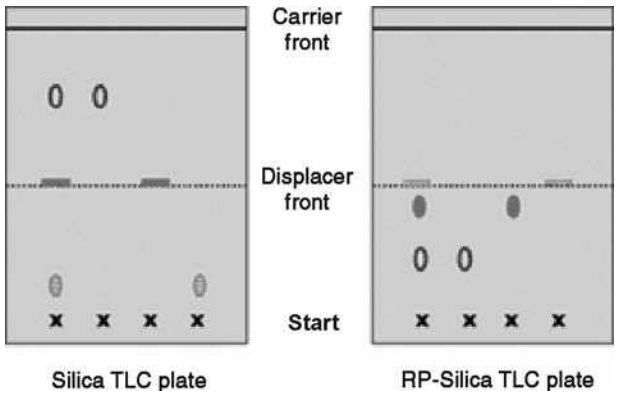

Fig. 2 The order of the spots is generally reversed when the stationary phase is changed from plain silica to reversed-phase silica.

morphine derivatives. The separation includes the removal of the intermediates of the synthesis as well as the purification of the member of metabolic pathway. Another important factor to be considered was the concentration of displacer in the carrier. The higher the displacer concentration, the larger will be the R_F of its front (i.e., R_D). The displacer front could reach the migration position of certain eluted components, which may be part of the displacement train.[9]

DC of substituted phenylisopropylamines can be easily accomplished. Both normal phase and octadecyl-substituted silica (reversed-phase) plates were used with the chloroform/triethanolamine and water–acetonitrile/tetrabutylammonium chloride carrier/displacer pairs, respectively. Only a few exceptionally behaving compounds moved faster or slower than the displacer front in the normal-phase and reversed-phase systems, respectively. The displacement chromatogram of HPDC can be characterized as series of sequentially increasing steps of the weight distribution or that of ultraviolet absorbance. This is the reason why off-line detection is used to characterize HPDC. D-TLC would have a similar profile, but specific detection may improve differentiation of the individual components. Further possibility is given by the application of spacers.

Kalász et al.[12] used spacer to improve separation of radiolabeled metabolites, and the method was called spacer D-TLC. They also constructed specific parameters of DC, especially for calculation of the resolution (R_D), yield (Y), loss (L), and efficiency (E). Displacement of radiolabeled compounds was readily visualized using X-ray film with contact autoradiography.[6,12,13] Two-dimensional chromatography can be simply arranged when a planar stationary phase is used. The stationary phase must be rotated 90° after the 1st dimensional development; then, the system is ready for the 2nd dimensional run. Elution type of development followed by displacement is an easy and useful means of two-dimensional thin-layer chromatography

(2D-TLC). The 2D-TLC method has several increments to the elution–elution developments, such as the discrimination factors are different in the 1st and in the 2nd dimensional separations. The spots are concentrated through the 2nd dimensional development. Use of a spacer may further increase the separation of the spots that are located close to each other. Extensive work was devoted to the D-TLC using forced flow of the mobile phase (FFMP)[6,14] and to the comparison of the effect of forced flow of the mobile phase to that of the classical (capillary flow) TLC.[8]

The decrease of the mobile phase flow rate from 0.6 to 0.5 and then to 0.3 caused the appearance of the doubled fronts, such as alpha and beta fronts of the carrier and also α and β fronts of the displacer. This phenomenon can be explained by a particular characteristic of planar chromatography, as the mobile phase runs on a dry stationary phase. In addition to the chromatographic occurrences, there is an additional process; it is the wetting of the stationary phase with the components of the mobile phase. If the mobile phase supply is not adequate (this is the case of slow-traveling mobile phase), the wetting of the dry stationary phase is the rate-limiting step. Such cases are unknown in either HPDC or HPLC, when the stationary phase is presaturated and extensively washed by the mobile phase prior to loading a sample. Therefore development of HPDC is restrained by the high flow velocity of the mobile phase, and that of D-TLC is limited by using a slow velocity. 2D-TLC is the proper choice for separation of a single compound from a multicomponent mixture. When the 2nd dimensional run is carried out using D-TLC, one or several components can be well separated from all others. In addition, the displaced components are extensively concentrated.[14]

When varying the conditions of D-TLC, various components can be a part of the displacement train. An interesting application of DC is given by the identification of metabolically generated radi olabeled formaldehyde from the radiolabeled (–)-deprenyl [(–)-C^{14}-*N*-methyl-*N*-propynyl-phenyl-isopropylamine]. The analysis was carried out after reacting the metabolites in a urine sample with 2,4-dinitrophenylhydrazine. The essence of the identification included the use of a standard (2,4-dinitrophenylhydrazone of formaldehyde) and comparing the urine samples with, and without, reaction of 2,4-dinitrophenylhydrazine.[15,16] This method has been called reaction-displacement thin-layer chromatography.[16] Kalász et al.[9,17] reported front deformation when the stationary phase per load mass ratio was under 10, e.g., when 0.5 or 1 mg of solute was loaded onto 2.5 mg of the stationary phase.

The list of substances subjected to planar displacement chromatography includes a broad range of organic compounds. For instance, Kalász and Horváth[5] separated three corticosteroids, Reichstein's Q, Reichstein's S, and Reichstein's H compounds. Kalász[13] also separated phenylalkylamines, e.g., deprenyl, deprenyl metabolites, and related compounds. Báthori et al.[18–21] separated ecdysteroids; Kamano et al.[22] separated toad-poison bufadienolides, such as resibufogenin, cinobufagin, bufalin, bufotalin, cinobufotalin, telocinobufagin, and gamabufotalin. Kalász et al.[10] separated morphine and semisynthetic morphine derivatives from each other. Kalász et al.[15,16] also identified formaldehyde as an efferent metabolite of *N*-demethylation.

CONCLUSIONS

There are advantages which are offered by D-TLC. The planar stationary phase offers numerous advantages which cannot easily be realized using column (or capillary) arrangements. The entire displacement process can be readily visually followed. The separation can be directly evaluated. Sensitivity of the UV/visible scanners is well suited for the concentrations of substances in the displacement train. Radioactive spots on the planar stationary phase may be easily monitored by the use of X-ray film or digital autoradiography (DAR). Spacers can be inserted between the displaced bands. The plates are disposable; therefore the regeneration process is generally ignored. Two-dimensional developments (elution displacement) can be easily performed. The actual concentration of displacer in the carrier can be calculated on the basis of its retardation. A detailed general summary of D-TLC is also given in a recently published book on TLC.[23]

ACKNOWLEDGMENTS

Distribution Coefficient

M. Caude
A. Jardy
Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

In high-performance liquid chromatography (HPLC), as in many chromatographic techniques, separations result from the great number of repetitions of the analyte distribution between the mobile and stationary phases that are linked. At each elementary step, the distribution is governed by the distribution equilibrium

$$X_M \rightleftharpoons X_S$$

where X stands for the solute and the subscripts M and S for the mobile phase and the stationary phase, respectively. Conventionally, this equilibrium is characterized by the distribution coefficient

$$K = \frac{C_S}{C_M} \tag{1}$$

where C_S and C_M are the molar concentrations of the solute X in the two phases. The distribution coefficient is also sometimes defined in terms of mole fractions of the solute in both phases. In elution analytical chromatography, concentrations are low enough to be comparable to the activities as an approximation. Although K should be dimensionless, as any thermodynamic constant, some authors use different units for the concentrations in both phases. For example, in LSC chromatography, concentrations are given in moles per square meter for the adsorbent. In such a case, K should be considered as an "apparent" constant, the dimension of which is m. However, in practice, the product in Eq. 2 must have the dimension of a volume.

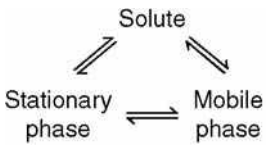
K is interrelated with the retention factor k' by

$$k' = Kq$$

where q is the phase ratio, defined as the ratio of stationary phase volume V_S to the mobile phase volume V_M. Under linear conditions, K is linked to the solute retention volume (first-order moment of the elution peak) through

$$V_R = V_M + KV_S \tag{2}$$

The distribution coefficient is the reflection of the ternary interactions schematically represented by



These interactions are as follows:

Solute ↔ stationary phase for the retention
Solute ↔ mobile phase for the solubilization
Mobile phase ↔ stationary phase because of the competition between at least one constituent of the mobile phase (the strongest, also called the modifier) and the solute toward the active sites.

For an isobaric and isothermal process, the equilibrium constant K is given by

$$\ln K = -\frac{\Delta G}{RT} \tag{3}$$

where ΔG° is the difference in standard Gibbs free energy linked with the solute transfer from the mobile phase to the stationary phase:

$$\Delta G = -\frac{\Delta G}{RT} \tag{4}$$

where H° and S° are the enthalpy and entropy, respectively.

In many cases, the value of H° is independent of temperature so that linear van't Hoff plots ($\ln K$ vs. $1/T$) are observed. However, irregular retention behaviors are often observed, in practice, due to the dependence of H° on the temperature.

Relationship (3) shows, clearly, the obtaining of reproducible results needed to thermoregulate the chromatographic apparatus, especially the column and mobile phase. Similarly, Eq. 3 explains why temperature changes implemented in order to increase efficiency can affect, drastically, the selectivity.

From Eq. 1, K can be related to the sorption isotherm, as it corresponds to the chord slope at each point. Therefore, Eq. 2 is valid only if K is constant; that is, the sorption

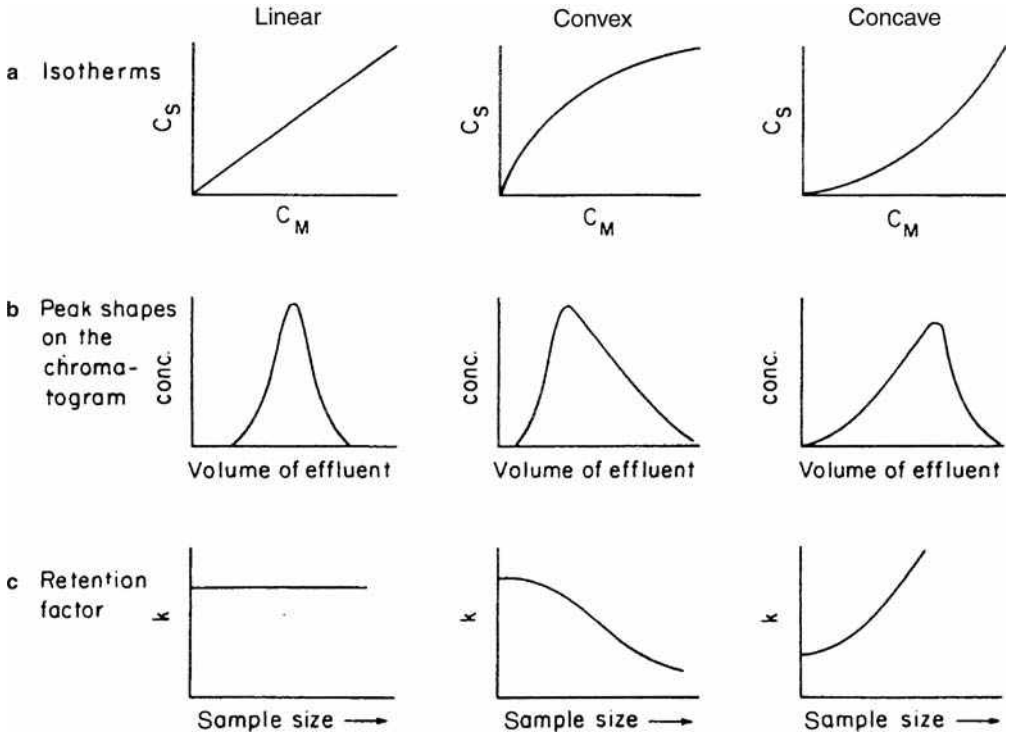


Fig. 1 Effect of isotherm shape on certain chromatographic properties. a, Three different shapes of sorption isotherms encountered in chromatography; b, peak shapes resulting from these isotherms; c, dependence of the retention factor on the amount of solute injected. **Source:** From *An Introduction to Separation Science*.[1]

isotherm is linear or, at least, is in a region where it becomes linear (i.e., if the dilution is great enough). The effect of the isotherm shape is shown in Fig. 1.

For the low concentrations used in LC, the elution peak is Gaussian in shape and its retention factor is independent of the sample size. When isotherms are non-linear (convex or concave, as illustrated in Fig. 1), an asymmetric elution peak is obtained and the retention factor measured at the peak apex is dependant on the sample size. This peak asymmetry is due to the dependence of the solute migration velocity vs. the slope of the isotherm, which varies the solution concentration in the mobile phase.

DNA Sequencing: CE

Feng Xu
Yoshinobu Baba
Department of Medicinal Chemistry, University of Tokushima, Tokushima, Japan

INTRODUCTION

Cells store their hereditary information in the form of double-stranded DNA, formed of the same four monomers—adenine (A), thymine (T), cytosine (C), and guanine (G). Using capillary electrophoresis (CE), scientists can read out the complete sequence of monomers in DNA molecules and thereby decipher the hereditary information that each organism contains. Large-scale DNA sequencing projects need instruments that generate high throughput at low cost. One approach to increase the CE throughput is to run a large number of capillaries in parallel, so-called capillary array electrophoresis (CAE). The Human Genome Project was initiated in 1990 with the goal of sequencing the 3 billion nucleotides present within human chromosomes. In 2001, the "first draft" of the entire human genome was published,[1,2] which made it possible to see for the first time exactly how genes are arranged along human chromosomes. With the appearance of the first multicapillary instrument in 1990, traditional slab gel electrophoresis was gradually replaced by CAE due to higher DNA sequencing performance. The early experimental result of sequencing of 29–512 bases with >97% accuracy was obtained in 9.5 hr at a field strength of 50 V/cm by using a laser beam scanning across a capillary array.[3] Later, the appearance of 96-capillary array electrophoresis greatly speeded the DNA sequencing in the Human Genome Project. In the meantime, the new technique of microfabricated CAE (μCAE, or microchip electrophoresis) combines the advantages of CE (system automation, reproducibility, and accurate quantification) with those of microfabrication (high speed and multiplex analysis), and will find its position in DNA sequencing.

This entry gives an overview of the fundamentals of DNA sequencing by CAE, μCAE, and four-color laser-induced fluorescence (LIF) detection, as well as some major factors (sieving matrix, sample preparation, electric field strength, etc.) influencing the sequencing accuracy and efficiency.

FOUR-COLOR LASER-INDUCED FLUORESCENCE DETECTION AND CAPILLARY ARRAY ELECTROPHORESIS

Laser-induced fluorescence is the standard CE detection method in DNA sequencing, due to its high sensitivity and the fact that the identity of the terminal base of each DNA can be encoded in the wavelength and intensity of the fluorescent emission. The DNA sequencing fragments are fluorescently labeled with four different dyes on each base, and are then detected by a four-color LIF detector.

Instrumentation design of detector systems for CAE and microfabricated devices has reached a mature stage. The two most successful LIF detector designs are the scanning confocal detector[4] and the multisheath flow detector.[5] A schematic of the scanning confocal detector (four-color planar fluorescence scanner) is shown in Fig. 1. The design adopts a scanning technology through capillaries that are illuminated by a single laser beam. The capillary bundle is placed on a planar translation stage, which moves at 1 cm/sec perpendicular to the direction of electrophoresis. The fluorescence, collected at right angles from the capillaries, is divided into four detection channels by dichroic beam splitters and band-pass filters, and then focused through a pinhole on four photomultiplier tubes and simultaneously recorded in four spectral channels. Using automated sample and gel-matrix loading, the total run time for sequencing more than 500 bases is <2 hr. The scanning confocal detector is adopted in the first commercial 96-capillary array MegaBACE 1000 system from Molecular Dynamics (Amersham-Pharmacia Biotech)[6] for DNA sequencing by CAE. The system uses linear polyacrylamide (LPA) as the separation matrix, and has a turnaround time of 2 hr per run. The capillaries have a life of ~130 runs and can be run with both dye primer and dye terminator reactions. An average read length of >550 bases at 98.5% accuracy is feasible with the M13 standard template. Another high-throughput rotary-scanner detection device was designed (as shown in Fig. 2), in order to analyze over 1000 capillaries in parallel. Currently, the device accommodates 128 capillaries. A microscope objective and a mirror assembly revolve inside a ring of capillaries, exciting fluorophores and collecting fluorescence from each capillary.

In the second detector design, multisheath flow detector, the capillaries are illuminated with a line-focused laser beam. Fluorescence is collected at right angles and imaged onto a CCD camera. The use of the CCD camera ensures that all capillaries are monitored simultaneously. To eliminate light scattering, the capillary array is inserted into a

rectangular quartz cuvette that holds the capillaries like the teeth of a comb (Fig. 3). A simple siphon pumps the sheath fluid through the interstitial spaces between the capillaries, and draws a sample from each capillary as a thin stream in the open region below the capillaries. A single laser beam

skims all flow streams. Since the laser beam only traverses the sheath fluid and DNA streams, the low-power beam can excite fluorescence from all samples simultaneously. The detector has no moving parts. This design has been incorporated in a second commercial system, ABI PRISM 3700 from PE Biosystems (Applied Biosystems).[7] The system uses four dyes, and simultaneously detects 96 capillaries with a turnaround time of 2 hr to obtain 550 bases with 98.5% accuracy using POP-6 (6% poly-*N*,*N*-dimethylacrylamide; pDMA) as the sieving matrix.

RIKEN Japan has produced an extra-high-throughput autosequencer (RISA sequencer) that consists of a 384-capillary array. Cross-linked acrylamide is used as the sieving matrix and a scanning laser fluorescence as the detector.[8] The read length, with more than 99% accuracy, is 650 bases.

MICROCHIP ELECTROPHORESIS

Microchip electrophoresis is superior to CE in that it allows facile monolithic array construction, precise controlling of picoliter sample injection amount, quick electrophoretic

separation speed, and potential for integration with sample pretreatment.

The first instance of DNA separation by microchip electrophoresis was in 1994.[9] A mixture of DNA oligomers from 10 to 15 bases was efficiently separated. Since then, microchip electrophoresis for DNA separation has developed very quickly. DNA sequencing of 200 bases by microchip takes only 10 min in cross-linked polyacrylamide gels.[10] By using 4% LPA in 7 cm-long coated microchannels, 600 bases were separated in 20 min at 160 V/cm.[11] Four-color LIF detection is feasible in micrototal analysis system (μTAS) use.

Long read lengths need long separation channels, because separation resolution scales with the square root of channel length. In order to adapt the radial chip design to modern wafer-scale fabrication for increasing the effective separation lengths, Mathies's group developed pinched turn geometries (hyperturns) in folding channels (Fig. 4).[12] A unique rotary design and a rotary confocal scanning system run 96 samples in a radial configuration at a time. DNA sequencing with an average read length of 430 bases at a rate of 1.7 kb/min was achieved in 96-lane microchip CAE. Ehrlich and coworkers[36] fabricated very long microchannels of 40 cm in large glass plates and obtained an average read length of 800 bases in 80 min with 98% accuracy (Fig. 5). Capillary array electrophoresis on a chip brings new potentials to high-throughput DNA sequencing on miniaturized CE platforms.

FACTORS INFLUENCING SEQUENCING

A key parameter of an electrophoresis system is the read length per unit time. Since the read length for the present commercial instrument is limited to 500–600 bases with >99% accuracy in 2 hr, sequencing of long read lengths, for example, >1000 bases, is very much required. Long read lengths in a short time reduce the number of sequencing reactions needed, because the number of primers required for directed sequencing strategy and the number of templates generated and sequenced in shotgun sequencing are inversely proportional to the read length. In addition, long read lengths minimize the computational effort required to assemble shotgun-generated data into finished sequences. The read length is influenced by a number of factors, e.g., polymer matrix, capillary temperature, field strength, effective channel length, base-calling algorithms, etc. but the most important is resolution. Heller[13] summarized in detail how various factors affect resolution (Fig. 6). Diffusion is thought to be an ultimate limitation to the resolution of polymer matrix-based separation. Long separation channels, modest electric fields, high temperature, and medium concentrations of polymer matrices are feasible for obtaining higher resolution and longer read length.

According to polymer theory, with a semidilute polymer solution above an overlap threshold concentration, c^*, fully entangled networks are formed by the interaction of polymer tangles, thereby forming dynamic pores in the polymer network for DNA separation. Depending on DNA size, the DNA molecules can either be sieved through the polymer network (Ogston model) or reptate in a virtual tube (reptation model).[14] The Ogston model

describes the separation of DNA molecules smaller than the polymer pore size. The reptation model can depict the electrophoresis behavior of DNA molecules larger than the polymer pore size. Larger DNA fluctuates in effective length during migration. The mobility of a DNA fragment is inversely proportional to its size (reptation without orientation). If the DNA molecule is very large, its mobility is size independent (reptation with orientation), in which case the resolution approaches zero. In DNA sequencing by electrophoresis, one can extend the

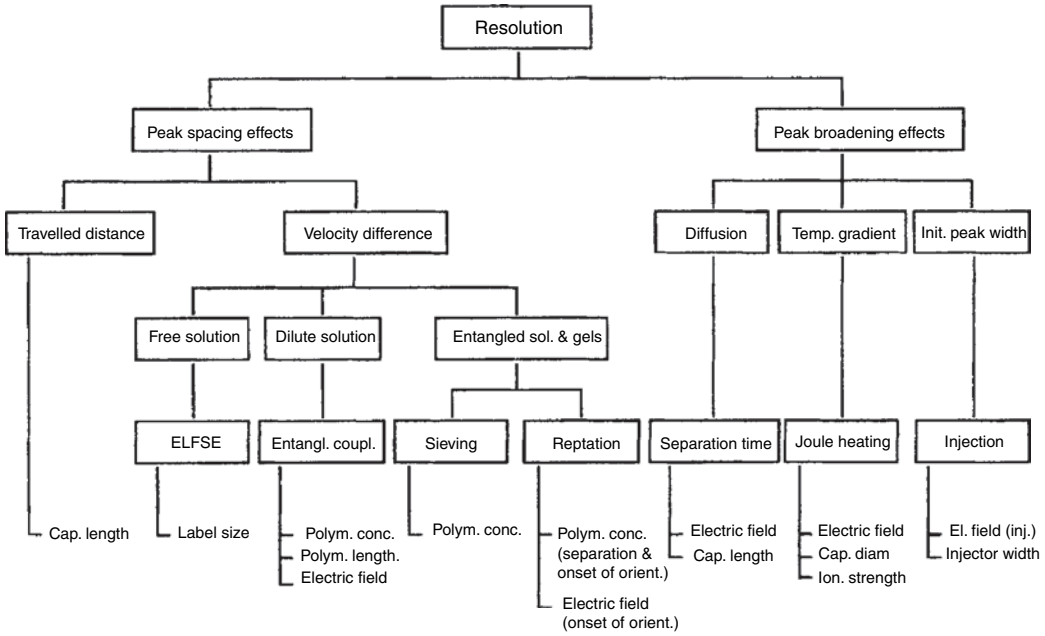

Fig. 6 Overview of the influence of different parameters on resolution during separation of DNA by CE. Only tunable parameters with strong influence are shown.
Source: From Principle of DNA separation with capillary electrophoresis, in Electrophoresis.[13]

reptation-without-orientation range by optimizing various parameters that influence resolution. Then the position of zero resolution is shifted to a higher base number.

Separation Matrix

Earlier DNA sequencing by CE used cross-linked polyacrylamide gels. The polyacrylamide capillary has a rather limited life. When the separation medium has degraded, the entire capillary must be replaced. The replacement is quite tedious because of alignment constraints of the optical system with the narrow-diameter capillaries. In contrast, low-viscosity polymers are attractive for DNA sequencing by CE. They can be pumped from the capillary and replaced with fresh matrix after each run without replacement of the capillary or realignment of the optical system. A range of polymeric solutions have been tested. LPA, pDMA, and polyethylene oxide (PEO) are the most widely used ones. Nowadays, gel-filled capillaries have almost fully been substituted by polymer solution-filled capillaries.

Linear polyacrylamide represents the best replaceable sieving polymer in terms of read length and speed. It can generate DNA sequencing read lengths beyond 1000 bases within 1 hr with a run-to-run base calling accuracy of 99.2% for the first 800 bases and 98.1% for the first 900 bases.[15] At a high polymer concentration, both long and short chains give equally good resolution for single-stranded DNA. For separating a larger size range, it is better to use long polymer chains and lower polymer concentrations. This leads to a more uniform resolution in function of DNA size. Mixing two populations of polymers, each with a narrow but different range of molar mass, has become popular. It facilitates fine-tuning of the separation performance over a broad range of DNA sizes. With a novel LPA formulation comprising 0.5% w/w 270 kDa/2% w/w 17 MDa LPAs operated at 70°C and 125 V/cm, an ultralong read length of 1300 bases was reached in 2 hr with 98.5% accuracy.[16] The high performance is attributed to better thermostability of the LPA formulation, optimized temperature and electric field, adjustment of the sequencing reaction, and refinement of the base-calling software.

PEO, pDMA, and polyvinylpyrrolidone (PVP) have self-coating abilities, which allows DNA sequencing in bare fused-silica capillaries. A mixture of two molecular mass populations of PEO is possible to separate DNA sequencing fragments over 1000 bases, too, but the separation time exceeds 7 hr.[17] pDMA[18] and PVP[19] are low-viscosity sieving matrices (<100 cP). They have moderate separation efficiencies and can provide maximum read lengths of about 500–600 bases.

Copolymers of LPA and pDMA combine the excellent sieving performance of LPA with the good self-coating property of pDMA. On uncoated capillaries at room temperature, 700 bases can be obtained with resolution $R > 0.55$.[20]

Sieving matrices with "built-in thermal viscosity switches" are alternatives in DNA sieving. The 3–5% grafted copolymer solution, which has a hydrophilic LPA backbone and comblike poly(*N*-isopropylacrylamide) (pNIPA; M_w 650–1800 kDa) side chains, exhibits a viscosity lower than

300 cP at room temperature, and a high viscosity (10,000 cP) at 66°C, suitable for DNA sequencing with a read length of 800 bases ($R > 0.5$) in less than 1 hr.[21]

In order to avoid intramolecular base pairing of DNAs, sequencing has to be run under denaturing conditions. A denaturing agent, such as urea or formamide, is added during gel polymerization or to the buffer in the case of polymer solutions. Most researchers use urea at a concentration of 7–8 *M*. The addition of formamide up to 40% increases the denaturing capacity of the matrix. The denaturing power of these agents alone is not sufficient, and the separation has to be performed at an elevated temperature. Generally, a temperature of 50–60°C is used to keep the DNA fragments completely denatured. Furthermore, higher temperature operation increases sequencing rate and read length as well as resolutions.[22] For 600-base separation, the maximum separation efficiency was also found at 60°C.[23] Temperature stability is important for DNA sequencing by CE. Even millidegree temperature oscillations have a detrimental effect on DNA read lengths.[24] Beyond a point, the efficiency diminishes seriously.

Sample Preparation

Sample preparation is an important step in the sequencing protocol. The presence of impurities [salt, proteins, unincorporated deoxynucleotides (dNTPs), dideoxynucleotides (ddNTPs), etc.] in DNA samples has deleterious effects both on the sequencing run and on capillary lifespan. DNA sequencing samples are typically synthesized following the Sanger enzymatic method.[25] Four reactions are set up, each with a different A, T, C, or G modified by replacing an H atom from the OH group in the C3 position of the sugar. This ddNTP is incapable of forming the next bond in the DNA chain; therefore, synthesis of that chain is terminated when a ddNTP is incorporated. The four reactions (with either labeled ddATP, ddTTP, ddCTP, or ddGTP) are performed, followed by ethanol precipitation to remove excess reagents and salts. The precipitated DNA is dissolved in formamide for electrophoretic injection and sequencing.

Since the beginning of DNA sequencing by CE, DNA labeled with four dyes (FAM, JOE, ROX, and TAMRA) has been standardized.[26] The four-color confocal fluorescence scanner utilizes excitation at either two laser wavelengths (e.g., 488 and 543 nm) or a single laser beam (e.g., 488 nm). New energy-transfer (ET) primers have higher molar absorbances. They contain a common donor dye at the 5′ end and an acceptor dye about 8–10 nucleotides away. Using a single laser at 488 nm, the excitation is transferred by resonance ET to the acceptor dye; then higher fluorescence intensities are observed,[27] which results in longer read lengths, higher base-calling accuracies, and reduced template amount. Now the ET primers have gained wide acceptance and are widely used for DNA sequencing in CAE.[28]

Effect of Electric Field Strength

With decreasing electric field, the onset of reptation-with-orientation is shifted to larger DNA sizes, which extends the size range to be separated. This effect is confirmed by many experiments. An electric field strength of 600 V/cm produces an ultrafast analysis time of 3–4 min, but the read length degrades to 300 bases.[29] At the expense of an analytical time of 7 hr, a low-field strength of 75 V/cm can extend the read length up to 1000 bases in PEO matrices.[17] Baba's group[30] proposed electric field step gradients, with an initial voltage ramp (up to 220 V/cm) for accelerating short fragments, followed by a voltage plateau, a voltage decrement, and a lower voltage constant of 90–130 V/cm for longer DNA fragments. A 20% extension of the read length was obtained, up to 800 bases at 60°C with high accuracy.

WALL COATING

Single-stranded DNA has a more hydrophobic character than double-stranded DNA and presents stronger interaction with the silica wall. Thus, capillary wall coating is greatly preferred. A few of polymers, such as pDMA, PEO, and PVP, as mentioned, have self-coating abilities. They can be used for DNA sequencing in bare capillaries or bare microchips. However, the life of the bare walls is limited because their performance deteriorates with repeated runs. Therefore, extensive and, sometimes, harsh rinsing is indispensable between runs.

Most polymeric matrices require an inner coating of separation channels to prevent both electro-osmotic flow (EOF) and DNA–channel wall interactions. The acrylamide coating procedure developed by Hjertén[31] is the most commonly used permanent covalent coating method. The disadvantage is that the coating cannot endure for long due to easy hydrolysis of the –Si–O–Si– bond. Hence, some more stable covalent coating procedures[32] have been developed to extend the wall-coating life.

CONCLUSIONS

Capillary array electrophoresis has become a standard method to decipher genomes within a short time, and has played an important role in large-scale DNA sequencing. With further increase of the capillary number in the array, it will become difficult to manufacture and work with. The problem is being solved by a transition to μCAE systems. The quality of sequencing separations on microchips is rapidly approaching that obtained using conventional

CAE. Hyphenation of sample automatic processing steps to μCAE will further lead to increase in efficiency and quality of DNA sequencing, reduction of overall cost, and automation of the whole process. It is plausible that high-throughput DNA sequencing by CAE and μCAE will afford a rapid means for human genetic counseling, disease diagnosis, and clinical therapy.

Drug Development: LC/MS in

Mohamed Abdel-Rehim
Research and Development, AstraZeneca, Södertälje, and Department of Chemistry, Karlstad University, Karlstad, Sweden

Eshwar Jagerdeo
Federal Bureau of Investigation Laboratory, Quantico, Virginia, U.S.A.

Abstract
Impressive progress has been made in the instrumentation and application of liquid chromatography–mass spectrometry (LC–MS) in the past few decades. In recent years, the use of LC–MS has become more important in drug discovery and development. In quantitative bioanalysis, LC–MS has become the method of choice for drug analysis in biological samples. The use of liquid chromatography in combination with mass spectrometry in routine therapeutic drug-monitoring activity is becoming more and more important. This entry will attempt to provide an overview as well as an understanding of the importance of liquid chromatography–mass spectrometry/tandem mass spectrometry (LC–MS, LC–MS/MS) in drug development. The role of LC–MS/MS in drug discovery and development will be discussed. Different sample preparation methods for plasma handling will be presented. High-throughput LC–MS/MS is summarized. Applications of LC–MS in metabolism studies and clinical studies will be presented.

INTRODUCTION

Even though the first mass spectrometer (MS) that was constructed by Sir J.J. Thomson[1] more than 110 years ago (1897) for the determination of mass-to-charge ratios (*m/z*) of ions, today it is almost a ubiquitous research instrument. A clear demonstration of MS took place in 1918–1919 by Francis W. Aston (University of Cambridge) and Arthur J. Dempster (University of Chicago). The first commercial MS instrument was introduced in the 1940s in the United States by Consolidated Engineering Corporation (Pasadena, California). In 1946, the concept of time-of-flight mass spectrometry (TOF-MS) was suggested by William E. Stephens.[1] The direct coupling of gas chromatography (GC) and TOF-MS was achieved in 1950s by Roland S. Gohlke and McLafferty.[1] The most popular type of tandem MS instrument (triple quadrupole) was invented by Richard A. Yost in 1987.[1] Two recently developed MS techniques (1980s) have had a major impact on the ability to use MS for the study of biomolecules: electrospray ionization–MS (ESI–MS)[1] and matrix-assisted laser desorption/ionization–MS (MALDI–MS).[1]

In the 1990s and 2000s, new products were designed and developed exclusively for LC–MS performance. A broader scale of application occurred with the development of LC–MS-based methods for the analysis of novel pharmaceuticals.

Today, MS is one of the most powerful analytical techniques particularly in pharmaceutical analysis where good selectivity and high sensitivity are often needed. Liquid chromatography–mass spectrometry (LC–MS) has become a highly developed tool for the determination of drugs in plasma samples. The more recent developments in ionization technologies make MS an important tool for biological research. In the pharmaceutical industry the measurement of drug level in plasma answers key questions that are asked during drug discovery and development. The more rapid these measurements the more quickly drugs progress toward regulatory approval. It is important to minimize the analysis times where possible. The enhancement of the LC–MS technique during the past few years has led to decreased analysis times and increased throughput in the bioanalytical field. Due to its selectivity the use of MS has strongly increased for applications in biological samples. The advent of modern, user-friendly MS has led to a reconsideration of the application of MS in the analytical process. In many instances this re-evaluation has resulted in an explosive increase in the use of the technique in industry, particularly for drug discovery/pharmacological and genomic/proteomic applications. MS technologies such as matrix-assisted laser desorption/ionization (MALDI) and ESI have simplified the analysis of proteins, peptides, and drug metabolites. In general, low detection limits ranging from the picomole to the femtomole level are achieved.

DISCUSSION

In recent years, there has been an explosion in the use of LC–MS/MS as a fundamental analytical tool for drug metabolism and pharmacokinetics (DMPK) applications, e.g., metabolite identification, pharmacokinetic (PK) analysis,

cytochrome P450 (CYP) inhibition/induction, parallel artificial membrane permeation assay (PAMPA), and Caco-2 permeability. The choice of ESI vs. atmospheric pressure chemical ionization (APCI) should be addressed seriously, given the well-recognized fact that ESI is not a uniform ionization method. The greater the polarity of a compound, the more likely it is to occur as an ion in solution and it can be observed using ESI. Thus, in a complex mixture only a limited number of the components of the mixture are likely to be observed. Another way to look at it is to say that there is only a certain amount of ionization available and that it will be distributed in favor of the most polar species present. For instance, it is not uncommon that the purpose of a chemical reaction is to convert a polar precursor into a less polar product, for example, the addition of a protecting group onto an amine. Here the user may have a difficult time determining the level of completion of such a reaction if trying to monitor it by ESI. On the other hand, APCI is more even in its ability to ionize a range of compounds and would therefore be suited to answering such questions. However, APCI also has disadvantages in that the ionization process is more energetic and therefore more likely to generate fragments. Also, it is limited in its molecular mass range to about 1000 Da. This mass range limitation would be highly detrimental in cases where many analytes exceed 1000 Da. Arguments can be put forward for either method, but we would recommend ESI based on the simplicity of the spectra and the very wide range of structures for which data can be obtained. Today, most applications utilize the ESI interface (about 80% of published papers) vs. atmospheric pressure chemical ionization. ESI is an interface that is relatively easy to use.

The Role of LC–MS, LC–MS/MS in Drug Discovery and Development

The main purpose of drug discovery is to generate lead compounds with suitable pharmaceutical properties for preclinical evaluation and ensure high speed and high quality. High-capacity screening and high throughput are required. It was estimated that screening of 100,000 compounds are required for the discovery of only one quality lead compound.[2] The identification and optimization of a lead compound can take up to 3–6 years.[2] Therefore, drug discovery advances need fast, selective, and high-throughput screening methods. In addition, the drug development consists of four discrete stages: 1) drug discovery; 2) preclinical development; 3) clinical development; and 4) manufacturing. Due to its sensitivity, selectivity, speed, and simplicity, the LC–MS technology is applied nearly in every stage of drug development (Table 1). Additionally, the ease of method development and operation and the achieved level of automation make LC–MS an attractive tool in drug analysis. The role of LC–MS already starts in the drug discovery stage and continues until or after the manufacturing stage (Table 1). In spite of several chromatographic techniques such as GC, supercritical fluid chromatograph (SFC), and capillary electrophoresis (CE) have been interfaced to MS, LC–MS remains dominated in bioanalysis. The use of ionization technique depends on the structure and the acidity or basicity of the analyte studied. Normally, positive and negative ion ESI is preferred for basic and acidic drugs, respectively, while APCI is more suited for the less basic/acidic or neutral molecules.

LC–MS Instrumentation

Atmospheric pressure ionization (ESI and APCI) has become the dominant technique. The development of ESI led to a huge increase in the use of LC–MS, which was established to be a capable ionization technique, especially for polar compounds, and was found to be very compatible with solvents used for reversed-phase LC. Today, numerous manufacturers offer well-integrated LC–MS systems with the best performance. The ESI sources are usually orthogonal to the analyzer, which results in the maintenance of high

Table 1 LC/MS analysis activities at every stage of drug development.

performance by reducing source contamination, for example, the "Z-spray" ESI. In the past 10 years there has been an increasing demand from the pharmaceutical industry for faster analytical methods, to accelerate the drug development process. LC–MS is the most well-known technique, with its high sensitivity and selectivity. Ultra-performance liquid chromatography (UPLC) with fast gradients of only a few minutes are now used on short columns (typically 5 cm long, 1.7–1.9 μm particle size), compared to separations formerly on 10–25 cm long columns (3–5 μm particle size) with 10–30 min gradients.[3] However, suppression effects can be a significant problem and therefore a sample preparation is needed. Fraction collection system connected with LC–MS has also been introduced by several manufacturers. Moreover, coupling of LC with UV detection in parallel with MS provides further structural information and indication of purity and may display analytes not observed on the MS because of inability to ionize or ion suppression. The fast acquisition TOF-MS gives the possibility to maximize sample throughput with multiple inlet systems into one MS. Further developments include high capacity of vacuum pumps, resulting in lower MS background and in higher sensitivity. In addition, combinatorial chemistry has led to the use of 96-well microtiter plates and their coupling with analytical systems. The applications of MS/MS stages, as available on ion-trap MS systems, can be of enormous help in structure elucidation in drug metabolism studies. The result of this improved ability to analyze many more samples in a given time and faster acquisition MS instruments is the production of large amounts of data. This is becoming a major issue, and improvements in data management using automated processing are needed. Today there are powerful software tools that have been developed and are available from all major instrument manufacturers.

High-Throughput LC–MS

The development of faster and higher-throughput analytical methods is required for speed and capable use of time in the pharmaceutical industry. The development of combinatorial chemistry techniques and other new strategies has led to an increase in the number of possible drug candidates. This has produced a need for high throughput in bioanalyses for toxicological and pharmacokinetic studies. The trace level of drugs and metabolites in plasma remains a challenge in quantitative bioanalysis. Also, the need for same-day rotate of results from large numbers of biological samples makes high-throughput bioanalysis more essential.

Due to its sensitivity, selectivity, and potential for the development of high-throughput methods of analysis, LC–MS/MS has revolutionized the strategies and achievement of modern drug discovery and development in the pharmaceutical industry. Furthermore, UPLC–MS has the advantage of increased chromatographic performance generated by sub-2 μm particle stationary phases run at high mobile phase linear velocities. This results in increased resolution, peak capacity, and more sensitive high-throughput assays. However, efforts to further improve the sample throughput capabilities of modern techniques and strategies are ongoing.[4]

The higher selectivity attainable due to the use of LC–MS/MS is frequently reduced by decreasing the quality of the sample pretreatment and/or the chromatography. The motivation of this is an increase in the sample throughput. However, this often puts serious demands on the sample pretreatment methods. Also, the off-line sample pretreatment appeared to be the rate-limiting step. Speeding up the sample preparation is one of the most important factors in bioanalysis. One of the most applied approaches is the use of SPE or LLE in a 96-well plate format. Online sample preparation in a 96-well plate format was described by different authors.[4] Off-line sample preparation seems to be preferred by many researchers.

Severe matrix problems may be experienced in quantitative bioanalysis, especially in ESI. Signal suppression due to unknown matrix interferences is often observed. Changes in the sample preparation procedures may solve the problem, but in some cases changing over to APCI, when appropriate, appears to be the only likely solution. Signal suppression is described in the next section.

ION SUPPRESSION IN MS

Although the MS technique is particularly sensitive and robust, there is potential for ion suppression,[5] particularly with ESI interface. The matrix problems may be practiced in quantitative bioanalysis, particularly in ESI. Ion suppression was also observed with APCI interface during studies on a drug compound and metabolites.[6] Ion suppression is a well-known phenomenon in LC–MS bioanalysis, and in recent years the occurrence of ion suppression has become the most important concern in quantitative bioanalysis using LC–MS. A well-defined example of signal suppression was described by Annesley[7] and Matuszewski, Constanzer, and Chavez-eng.[8] Ion suppression can give rise to incorrect data interpretation, that is, poor accuracy and precision. Weaver and Riley[5] described how the effect of ion suppression of polyethylene glycol (PEG 400) could lead to incorrectly determined PK parameters and decreased sensitivity of the analytical method. Ion suppression is not only a result of endogenous material present in biological samples but it can also be caused by LC mobile-phase additives.[9] Even typically used mobile-phase components such as triflouroacetic acid (TFA) or methanol cause ion suppression. For example, TFA has been used in HPLC–UV analyses to improve the peak shape and to reduce the retention times but for MS analyses, TFA causes signal suppression. Annesley reported that the methanol used in the mobile phase could be a source of differential ionization or ion suppression.[10] van Hout et al.[11] showed that the percentage of ion

suppression relates to the matrix/analyte ratio, in another words it depends on the analyte concentration [ion suppression degree is proportional to 1/(analyte concentration)]. Two important points can be concluded from the van Hout et al. paper, the first is decreasing the matrix/analyte ratio through more extensive sample cleanup or through better chromatographic separation and the second is the importance of performing ion suppression validations.

The frequency of ion suppression or other deleterious effects can be evaluated by different experimental methods. The most common method is the comparison of the instrument response for an injected sample prepared in the mobile phase to the same concentration added to a preextracted blank sample matrix. The second method involves postcolumn continuous infusion of the compound into the MS instrument. In the third method, standard line slope comparison is also used to evaluate ion suppression.[12–16] Full-scan mass spectra can also be a useful method to study what impurities (in the blank of extracted sample matrix or in the LC mobile phase) are responsible for ion suppression and to try to remove these compounds.

Elimination of ion suppression requires changes in: 1) the sample pretreatment procedures; 2) the LC mobile-phase composition; 3) the LC mobile phase pH; and 4) the LC column polarity. In some cases changing the ionization source (e.g., ESI over to APCI) appears to be the feasible solution. At last the studies about ion suppression may further our understanding of the fundamental chemistry and physics of the ESI process.

ROLE OF SAMPLE PREPARATION PRIOR TO INJECTION

When the analytes are present in a complex matrix, e.g., plasma, the sample preparation is of crucial importance for the analysis. Biological fluids such as plasma and urine are much more complex than many others due to the presence of proteins, salts, acids, bases, and various organic compounds with chemistry similar to that of the analytes of interest. Thus, the extraction methods for biological samples are difficult. If an unsuitable sample preparation method has been employed before the injection, the whole analytical process can be wasted. The purpose of the sample preparation is: 1) the removal of interfering substances to eliminate ion suppression; 2) the conversion of analytes into a more suitable form for injection, separation, and detection; and 3) the preconcentration of the analytes to improve sensitivity. The procedure must be highly reproducible, with a high recovery of the target analytes. Further, an ideal sample preparation method should involve a minimum number of working steps and it should be fully automated. Because of the low concentration levels of drug in plasma and the variety of metabolites, the selected extraction technique should be virtually exhaustive. In this section, we will discuss about a well-applied sample preparation for drug analysis that is used with real samples from clinical institutions or pharmaceutical industry. Commonly used sample preparation methods[4,17] in the pharmaceutical industry are solid-phase extraction (SPE), liquid–liquid extraction (LLE), and protein precipitation (PP). SPE gives both high recovery and good chromatography. LLE and SPE are the most important sample preparation methods in LC–MS. The growing number of samples to be analyzed requires high-throughput and fully automated analytical techniques. Recent developments of sample handling techniques are directed, from one side, toward automation and online coupling of sample preparation units and detection systems and, from another, toward development of more selective sorbents such as immunosorbents, molecular imprinted polymers, and restricted access materials (RAM).

The limiting step in achieving fast bioanalysis is off-line sample preparation. This indicates the clear need of online sample pretreatment for speeding up sample preparation. One of most widely applied approaches is the 96-well plate format. While off-line sample pretreatment seems to be preferred by many researchers, online strategies are described as well.[4]

Liquid–Liquid Extraction

LLE is a simple sample preparation method. It has been widely used for the preparation of aqueous samples for many decades. It is a useful and easy method to extract the analytes from plasma to an organic solvent after shaking. LLE involves mixing an immiscible organic solvent with an aqueous solvent (e.g., plasma, urine, serum) to extract the analyte into the organic phase. The organic phase may be transferred, evaporated to dryness, and reconstituted prior to analysis. This method can give good recovery and a very clean sample. Initially volume of milliliters of solvent was needed but today 100–500 μl can be used for 96-well plates.[4] The analytes are extracted in an uncharged form by adjusting the plasma pH. Using LLE the analytes can also be extracted into the organic phase as an ion pair using an ion-pair reagent. Also, the analyte can be concentrated by the evaporation of the solvent and by redissolving the analyte in less volume prior to injection. The disadvantage of the LLE method is that it is difficult to obtain high recovery for polar analytes such as metabolites and it is not easy to automate it. Also, analytes with low K_D (distribution constant, K_D = concentration in organic phase/concentration in aqua phase) give bad recovery.

New progresses to establish LLE have been done in the past 10 years and is still under development. Examples of these include single-drop-liquid-phase microextraction (SD-LPME), LPME, and supported membrane extraction (SME). Single drop-LPME is based on a drop of organic solvent hanging at the end of a syringe needle.

Solid-Phase Extraction

SPE is a simple method that uses a small volume of a solid phase (10–100 mg) to isolate desired analytes from a sample. SPE has been in use for more than 50 years. Today SPE is the most popular sample preparation method. SPE can be performed off-line or online by direct connection to the chromatographic system. However, a key SPE problem is- method development. In the development of SPE the most important goal was to obtain extracts free from matrix interferences in a few steps (conditioning of the sorbent, applying of the sample, washing and elution). The most important parameters in SPE are the selection of the type and amount of the sorbent, the determination of the sample volume that can be applied without loss in recovery, the composition and volume of the washing solution that can be applied without loss of the analytes, and finally the composition and volume of the elution solution.[18] The availability of cleaner and more reproducible sorbents, and the large choice of sorbents over past few years, has led to an increasing acceptance and growing interest in this method. Compared to LLE, SPE has a number of potential advantages: SPE can easily be automated, gives more efficient separation of interferences from analytes, reduces organic solvent consumption, and is more efficient in analyte recovery. In SPE, higher recovery takes one step, while in LLE it takes many more steps. One major disadvantage of SPE is that the cartridges tend to vary from lot to lot.

Protein Precipitation

Precipitation is a widely used sample preparation method in bioanalysis. The most common type of precipitation for proteins is salt induced or by addition of an organic solvent (methanol, acetonitrile) or by changing the sample pH by adding acids such as sulfuric acid or hydrochloric acid. Today there is a PP microplate in the 96-well format (Biotage AB and Whatman). Many applications on this technique have been published.

Microextraction-Related Techniques in Bioanalysis

Solid-Phase Microextraction

Solid-phase microextraction (SPME) was introduced in the early 1990s by Arthur and Pawliszyn.[19] SPME is a simple solvent-free sample preparation method for GC and LC. The extraction is based on the partitioning of the analyte between the organic phase on the fused silica fiber and the matrix. Many factors such as pH, temperature, salt concentration, and stirring affect the equilibrium constant and the equilibration time.[19] Fiber lifetime is a significant issue. SPME fiber is quite sensitive to complex matrix such as plasma. In addition, type of polymer, temperature, duration, and additives coming from the sample solution influence the stability of the coating. It should be noted that additives such as sodium hydroxide and salt could catalyze polymer thermal degradation. In some bioanalytical studies, fiber lifetime decreased to about 20 samplings instead of 80.[20]

Microextraction by Packed Sorbent

Microextraction by packed sorbent (MEPS) is a new development in the field of sample preparation and sample handling.[21] It entails the miniaturization of conventional SPE packed-bed devices from milliliter bed volumes to microliter volumes. MEPS can be connected online to GC or LC without any modifications. This approach to sample preparation is very promising for many reasons: 1) it is easy to use; 2) it is a fully automated online procedure; 3) it is rapid; and 4) the cost of analysis is minimal compared to conventional solid-phase extraction. In MEPS about 1 mg of the solid packing material is packed inside a syringe (100–250 μl) as a plug or between the barrel and the needle as a cartridge. Sample preparation takes place on the packed bed. The bed can be coated to provide the selective and suitable sampling conditions. MEPS differs from commercial SPE in that the packing is integrated directly into the syringe and not into a separate column. Moreover, the packed syringe can be used several times, more than 100 times using plasma or urine samples, whereas a conventional SPE column is used only once. MEPS can handle small sample volumes (10 μl plasma, urine, or water) as well as large volumes (1000 μl). The superior performance of MEPS was recently illustrated by online LC–MS and GC–MS assays of drugs and metabolites in water, urine, plasma, and blood samples.

The MEPS technique has been used to extract a wide range of analytes in different matrices (urine, plasma, blood). Several drugs such as local anesthetics and their metabolites, the anticancer drugs roscovitine, olomoucine, busulfan, cyclophosphamide, β-blockers acebutolol and metoprolol, the neurotransmitters dopamine and serotonin, methadone, and cocaine and cocaine metabolites have been extracted from biological samples such as blood, plasma, and urine using MEPS.[21–26]

APPLICATION OF LC–MS IN DRUG AND METABOLITES ANALYSIS

The most important application of LC–MS in drug development has been in drug metabolism studies. Furthermore, LC–MS has an important role in the analysis and identification of impurities, in degradation products in pharmaceuticals, and in the isolation and characterization of potential drug substances from natural or synthetic sources. Additionally, quantitative bioanalysis of drugs and

metabolites in biological samples is the most important application area of LC–MS in drug development. Quantitative bioanalysis is necessary for preclinical and clinical drug testing to make available pharmacokinetic and pharmacodynamic data. The use of LC–MS in quantitative bioanalysis is favored due to low detection limits in picograms, high selectivity against possibly interfering solutes in the biological matrix, and the capability to use isotopically labeled compounds as internal standards. As a result, LC–MS/MS has become the method of choice for quantitative bioanalysis in the pharmaceutical industry.

The metabolism of a potential new drug must be investigated before it can be considered for further development into a therapeutic agent.[27] A good drug candidate should preferably be metabolically stable and should have a good pharmacokinetic profile with high bioavailability and long half-life. Some metabolites may also be more pharmacologically active or more toxic than the parent drug. The characterization of the metabolites, major and active, helps in the discovery of new drug candidates with enhanced pharmacological activity, metabolic stability, and toxicology profile. The LC–MS technique is the preferred tool for the study of drug metabolism because of its sensitivity and selectivity. The use of LC–MS provides information about molecular weight and fragmentation patterns for structure elucidation.

In Vitro and In Vivo Drug Metabolism

Today, in vitro systems are a basic part of drug metabolism during drug discovery.[27] This has several advantages such as high speed, reduction in the use of animals, and the ability to investigate specific aspects of the metabolic disposition of a compound. Metabolic stability influences both oral bioavailability and plasma half-life of a compound, which in turn, affect its efficacy. Commonly, the initial studies of drug metabolism have been carried out in vitro with liver microsomal preparations or hepatocytes. These provide good indication of the metabolic fate of a drug.

In vivo metabolism studies entail analysis and determination of drugs and metabolites in blood, urine, and feces. These matrices contain a larger amount of endogenous compounds that could coelute and interfere with LC–MS analysis. A good sample preparation technique and capable chromatographic separation (LC, UPLC) and a selective detection technique (MS/MS) are therefore important for successful in vivo metabolism studies.

An example of the application of LC–MS and UPLC–MS in vitro and in vivo metabolism studies is the study of the metabolism of prazosin (antihypertensive agent being investigated for the treatment of posttraumatic stress disorder). The in vivo metabolism of prazosin in rat was first reported in 1977,[28] and six metabolites were characterized, though at that time analytical techniques were not as advanced, nor were the MS as sensitive as today. Studies have shown that prazosin can improve sleep and reduce severe nightmares in both civilians and military war veterans experiencing posttraumatic stress disorder (PTSD), as well as those from Operation Iraqi War, 2003.[29] The new interest in the use of prazosin in the clinic led to its metabolism being investigated in vitro using liver microsomes from rats, dogs, and humans; rat and human cryopreserved hepatocytes and more metabolites were characterized. Erve et al.[30] reinvestigated the in vivo metabolism study of prazosin in rat using a quadrupole TOF-MS coupled with UPLC, to identify metabolites revealed by in vitro studies; consequently, six new metabolites were identified (Fig. 1). The structures of the metabolites M1–M8, M10, M11, and M13 were confirmed by comparison of MS/MS spectra with those obtained from metabolites formed in vitro and reported elsewhere. For M7, nuclear magnetic resonance (NMR) spectroscopy was also performed to provide additional support for the proposed structure. For M16–M21, tentative structures were proposed based on interpretation of MS/MS spectra, H–D exchange, and accurate mass as discussed in detail.[30]

LC–MS in Clinical Applications

LC–MS determination of drugs and metabolites in clinical studies is a key function in the success and effectiveness of clinical development of drugs. LC–MS has established an obvious advantage for quantitative pharmacokinetic studies in terms of analysis time, cost, and sample throughput. LC–MS/MS has powerful capacity in quantity bioanalysis. LC–MS in clinical applications such as in the diagnosis of inherited and acquired metabolic disorders, gastrointestinal disorders, cancer and diabetes, and therapeutic drug monitoring is still frequently required.

Today LC–MS is a useful alternative to GC–MS for the analysis of biological carboxilic acids.[31] Simultaneous determination of anticancer drugs such as busulfan, cyclophosphamide, and rescovitine in patients' samples are reported using LC–MS/MS after online sample pretreatment.[22–24] Quantitation of antibiotics such as penicillins, nitrofurans, tetracyclines, cephalosporins, and sulfonamides at low concentration levels in biological samples was performed using LC–MS/MS. Salvador et al.[32] have developed an LC–MS/MS assay for the determination of a new antibacterial agent (AVE6971) and validated the assay in human white blood cells (WBC). The assay involved a lysing procedure of WBC and ultracentrifugation of the extracts. Determination of drugs with a nitrogen-containing-saturated ring such as morphine, codeine, cocaine, and 6-monoacetylmorphine in body fluids utilizing LC–MS/MS has been reported. A number of publications have also covered the application of LC–MS/MS for determination of neurosteroids and steroids such as 3-ketosteroids metandienone, nandrolone, and testosterone with limit of detection (LODs) between 2.5 and 250 fmol (in different matrices), depending on the analyte by using atmospheric pressure photoionization (APPI–MS).[33] Type-amide local anesthetics such as ropivacaine in human plasma were analyzed using LC–MS/MS. Table 2 summarizes the

Fig. 1 Proposed in vivo metabolism of prazosin. Bold indicates metabolites not previously reported in vivo.

Table 2 Operating and conditions of LC/MS/MS of different drugs.

Drug	Column	Mobile phase	Sample preparation	LOD/ LOQ	Refs.
Local anaesthetics	Hypersil Gold (100 × 2.1 mm)	Methanol and water (1:1) 0.1% HCOOH	MEPS	2 n*M*	[22]
Busulfan	Hypersil Gold (100 × 2.1 mm)	Acetonitrile and water 0.1% HCOOH	MEPS	5 μg/ml	[23]
Cyclophosphamide	Zorbax SB-C8 (50 × 2.1 mm)	Acetonitrile and water 0.1% HCOOH	MEPS	0.5 μg/ml	[24]
Roscovitine and Olomoucine	Zorbax SB-C8 (50 × 2.1 mm)	Acetonitrile/methanol/water 0.1% HCOOH	MEPS	0.5, 1.0 μg/L	[25]
Acebutolol and metoprolol	Zorbax SB-C18 (50 × 2.1 mm)	Acetonitrile and water 0.1% HCOOH	MEPS	1.0 μg/L	[26]
Immunosuppressive	CP ChromSphere (20 × 3 mm)	Methanol and 10 m*M* ammonium formate	Protein precipitation	2 n*M*	[34]
Antibiotics	Caltrex Resorcinearene (125 × 2 mm)	Formate buffer-acetonitrile (40:60, v/v)	SPE	3–18 ng/ L	[35]
Cefdinir	RP18 Waters (50 × 2.1 mm)	Methanol–water (25:75, v/v) 0.075% HCOOH	Protein precipitation	5 μg/L	[36]
Anabolic and corticosteroids	C-18 RP (50 × 2.1 mm)	Acetic acid, ammonium acetate, and methanol	LLE	0.1–2 μg/L	[37]
Amphetamines	C18 (40 × 2.1 mm)	Trifluoroacetic acid (ion paring)	SPE	1 μg/L	[38]
Amisulpride	Polar-RP (75 × 4.6 mm)	5 m*M* ammonium formate and acetonitrile (30:70, v/v)	LLE	0.5 μg/L	[39]
Ziprasidone	C8 (150 × 2.1 mm)	2 mmol L−1 Ammonium acetate in acetonitrile–water (9:1, v/v)	LLE	0.1 μg/L	[40]

conditions of LC–MS/MS for some classes of drugs in biological samples. In addition, in a clinical study Abdel-Rehim, Bielenstein, and Askemark[41] showed how the use of LC–MS/MS leads to more reliable results than the use of LC–UV/ LC–MS for the quantification of ropivacaine and its metabolites. In their investigation analysis of urine samples from a clinical study of ropivacaine and its metabolites, 3-hydroxyropivacaine (3-OH-ropivacaine) and PPX, by an LC–UV method showed high concentrations of 3-hydroxyropivacaine, 2–50 times higher than expected. In the study, the patients were treated with a number of drugs in combination with ropivacaine. These drugs were paracetamol, lidocaine, fentanyl, morphine, and trimethoprim. When the fraction of 3-hydroxyropivacaine was collected from LC–UV and analyzed by LC–MS, only a high signal with mass number 291 [3-hydroxyropivacaine (MH+)] was observed. This observation indicates that it may be a drug or a metabolite having the same mass number as 3-hydroxyropivacaine and eluting at the same retention time on the LC system that gives a high signal in UV and MS detection. The examination of the drugs given showed that trimethoprim has the same molecular weight as 3-hydroxyropivacaine. The analysis of trimethoprim by LC–UV and LC–MS showed that under the given conditions it has the same retention time as 3-hydroxyropivacaine. The tuning of 3-hydroxyropivacaine and trimethoprim by tandem MS/MS showed that both substances have the same precursor ions (*m/z*: 291) but different product ions (*m/z*: 126 and 123 for 3-hydroxyropivacaine and trimethoprim, respectively) (Fig. 2A and B).

Analysis and Identification of Impurities and Degradation Products

The impurities in pharmaceuticals are mainly produced during the synthetic process from raw chemicals, intermediates, solvents, and by-products. Raw chemicals and intermediates for drug manufacturing do not always have the same purity requirements as the final pharmaceuticals. By-products are generated during synthesis and are another source of pharmaceutical impurities. Impurities may also occur from the components used in dosage formulation and/or in the process of formulation where temperature, humidity, and light may all participate. The most common degradation processes are oxidation, hydrolysis, and dehydration; other processes include adduct formation with excipients, dimerization, and rearrangement. Thus the investigation and the evaluation of drug impurities is a demand from drug regulation authorities. It is important to ensure that the observed impurities do not have any pharmacological and toxicological effects. Study and screening of impurities and degradation products in formulated

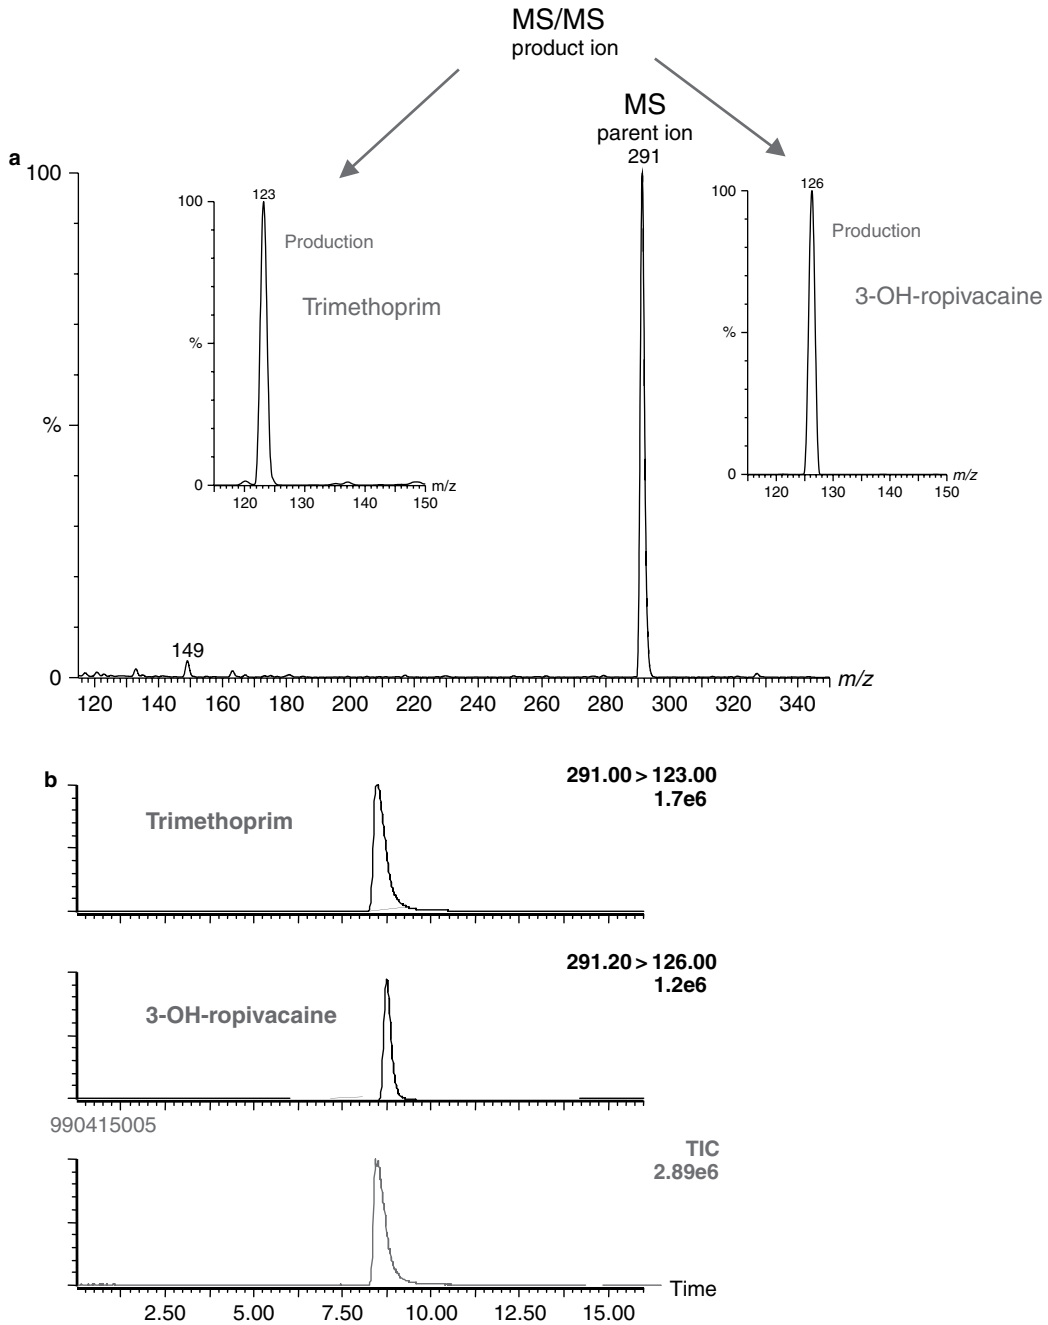

Fig. 2 a, Mass chromatogram (LC–MS and product ions from MS/MS) for the fraction of 3-OH-ropivacaine including trimethoprim collected from LC–UV. b, Mass chromatogram of patient's urine sample shows 3-OH-ropivacaine and trimethoprim by LC–MS–MS.

pharmaceuticals are necessary for ensuring that no compounds with deleterious effects are produced during their shelf life. The identification of degradation products will help in the understanding of potential side effects associated with degradation. This will also aid in the design of a more constructive formulation and for synthesis of new drugs with better stability. According to ICH (International Conference on Harmonization) guidelines on impurities in new drug products, identification of impurities below the 0.1% level is not considered to be necessary except for the potential impurities that are expected to be unusually potent or toxic.[42]

Since impurities and degradents are usually present in quite small quantities as compared to the drug, LC–MS is widely used for analysis of impurities.[43] However, it is useful to use a UV in combination with MS for the estimation and identification of impurities especially for the

unknowns. In addition, NMR and Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS) are also used for studying impurities.[42]

Additionally, LC–MS is the method of choice for the separation and detection of chiral impurities in pharmaceuticals. The analysis of chiral impurities in pharmaceuticals is of importance because the D-isomer of a drug can have a different pharmacological, metabolic, and toxicological activity from the L-isomer. Chiral impurities of amino acids, present in peptide drugs, have been separated and determined by LC–MS.[43] The selectivity of MS detection eliminated interference from other peaks that appeared when a UV detector was used for detection.

FUTURE TRENDS AND PERSPECTIVES

The combination of LC with MS has created a powerful tool for the analysis and quantitation of a variety of drugs and metabolites in complex matrices. LC–MS has turned out to be a particularly sensitive and selective technique for the analysis and quantitation of pharmaceuticals. It is a fundamental analytical tool for the studies of drug metabolism of new drug candidates and the identification and characterization of impurities and degradents in pharmaceuticals. Further transfer of the routine activity of immunosuppressants from immunoassays to LC–MS, which allows the automation of sample preparation, shortens analytical run times and is probably cost-effective despite heavy investment costs.

Technical progress in MS continues, with improvements in sensitivity and resolution. The trend is toward the further development of hybrid instruments such as Q-TOF/FTICR. Application of accurate mass measurement is a convenient tool to enable offering information about molecular weight and fragmentation patterns for structure elucidation. Further requirements for high-resolution sequencing of proteomics in pharmaceutical development will have implication for MS. The combination of online high-throughput sample preparation techniques with LC–MS/MS will lead to even faster analysis and cost-effective.

Because of the use of microfluidic systems, it might be possible in the future to use online miniaturized chip separation with miniaturized MS for rapid on-site analysis. Additionally, coupling of LC–NMR/MS will be a invaluable system that will allow the obvious identification of metabolites.

INTRODUCTION

Non-steroidal anti-inflammatory agents are of prime clinical interest in the control of pain and inflammation associated with a wide variety of rheumatoid- and non-rheumatoid-related disorders. In a continuous search for well-tolerated and effective agents for the treatment of human diseases, over 100 groups of new chemical entities have been synthesized and disclosed in the literature as potential anti-inflammatory drugs.

As their name implies, non-steroidal anti-inflammatory drugs (NSAIDs) are drugs that block or inhibit the inflammation processes without the use of steroid drugs. The most commonly used NSAIDs are aspirin, ibuprofen, and naproxen.

NSAIDs remain the mainstay of therapy for patients with chronic pain. NSAIDs are essential analgesics, especially for pain associated with inflammation. Inflammation results in increased local prostaglandin (PG) production, which also occurs in the central nervous system (CNS). Increased PGs in the CNS result in central sensitization and increased pain. The NSAIDs main mode of action is blocking the PG production by binding and inhibiting cyclooxygenase (COX), the main enzyme in the synthesis of PGs from arachidonic acid. NSAIDs inhibit PG production both at the site of injury and in the CNS, i.e., they have both a peripheral and a central action. While the result of this effect is mainly a reduction in inflammation and peripheral nociceptor sensitization, there is some evidence that NSAIDs have a central analgesic action as well, although the exact mechanism remains unclear. However, inhibition of PG synthesis does not account for the total analgesic effect of NSAIDs.

NSAID CLASSIFICATION

NSAIDs are, as a group, the most frequently consumed drugs worldwide. They also cause the most, and often dangerous, side effects reported to the US Food and Drug Administration, the majority of which are because of damage of the gastrointestinal (GI) tract and kidneys. This explains the continuous interest of pharmacologists, clinical pharmacologists, and pharmacoepidemiologists in this group of drugs.

Although NSAIDs are effective in the treatment of pain and inflammation, their routine and long-term administration is limited, because of their GI and renal side effects. COX isozymes are the main targets of NSAIDs. While the inhibition of COX-2 is related to anti-inflammatory effects, that of COX-1 is associated with the adverse effects. The idea behind developing COX-2 inhibitors was to have a NSAID devoid of GI toxicity. However, GI toxicity depends on multiple factors, not just COX-2 selectivity.

Based on an increasing body of data, Frolich[1] proposes a simple alternative to the usual chemical classification of NSAIDs, allowing one to predict a drug's major effects according to its relative inhibition of the constitutive and inducible COX isoenzymes.

According to COX enzyme selectivity,[2] NSAIDs are classified into the following:

1. COX-1 selective group-1, which include low- dose aspirin.
2. Non-selective group-2 with similar inhibition activity for COX-1 and COX-2, which includes high-dose aspirin, diclofenac, ibuprofen, indomethacin, mefenamic acid, naproxen, paracetamol, piroxicam, and others.
3. COX-2 selective group-3, which includes ketorolac, meloxicam, nabumetone, nimuselide, and others.
4. COX-2 highly selective group-4, which includes celecoxib, rofecoxib, etc.

Based on their chemical structures, NSAIDs areas follows:

1. Carboxylic acids
   a. Salicylic acids and esters (e.g., ASA, diflunisal, and benorylate)

   b. Acetic acids
      i. Phenylacetic acids (e.g., diclofenac)
      ii. Carbo- and heterocyclic acetic acids (e.g., indomethacin, ketorolac, sulindac, and tolmetin)
   c. Propionic acids (e.g., flurbiprofen, ketoprofen, tiaprofenic acid, ibuprofen, naproxen, and fenoprofen)
   d. Fenamic acids (e.g., mefenamic Acid)
2. Enolic acids
   a. Pyrazolones (e.g., phenylbutazone)
   b. Oxicams (e.g., piroxicam and meloxicam)
3. Cox-II Inhibitors (e.g., celecoxib, valdecoxib, and rofecoxib)

ANALYSIS OF NSAIDS

High-performance liquid chromatography (HPLC) possesses many of the attributes of gas chromatography, plus some of the advantages of liquid-phase separation. Without derivatization, the high polarity and low volatility of many non-steroidal anti-inflammatory agents restrict the use of gas chromatographic methods. The thermally labile compounds and their derivatives may also limit the applicability of gas chromatography for the analysis of these classes of drugs.

A great number of HPLC techniques have been developed and successfully applied for the analysis of NSAIDs from pharmaceutical forms or from biological media (urine, plasma, whole blood, etc.).

Selection of a procedure, which is most suitable for solving a specific problem, depends on the analyst's need for measuring the drugs only or the drugs and their respective metabolites.

SAMPLE PREPARATION

The most critical step in generating accurate, reliable results is good sample preparation. Only in rare instances, is cleanup not required, and the drug concentration is simply adjusted before the drug is injected directly into the chromatograph.

Most samples are not ready for direct introduction into instruments. For example, the substances have to be extracted into a solution, which can be analyzed. There might be several processes within sample preparation itself. Some steps commonly encountered are homogenization, size reduction, extraction, concentration, derivatization, the cleanup, and the analysis. These processes depend on the sample, the matrix, and the concentration level at which the analysis needs to be carried out. For instance, trace analysis requires more stringent sample preparation than major component analysis.

Considering the solubilities of the NSAIDs in solvents such as methanol or acetonitrile, for the analysis from pharmaceutical formulations (tablets, syrups, supositories, etc.), the easy way to prepare the sample is to dissolve it in the following:

1. Pure solvents
   a. Methanol[3–10] for aspirin, diclofenac, mefenamic acid, tolfenamic acid, ibuprofen, tenoxicam, nabumetone, etc.
   b. Acetonitrile[11,12] for diflunisal, indomethacin, fenoprofen, ibuprofen, ketoprofen, naproxen, mefenamic acid, diclofenac, piroxicam, etc.
2. Aqueous methanol or acetonitrile[10,13–15] for tolmetin, bufexamac, nabumetone, benzydamine, etc.
3. The mobile phase used in HPLC[16,17] for diclofenac, oxyphenbutazone, etc.
4. THF/propan-2-ol[15] (for benzydamine hydrochloride from creams).

The obtained solution can be analyzed after centrifugation and filtration.

In other cases, e.g., for pharmacokinetic studies, the NSAIDs must first be extracted from biological media (urine, plasma, serum, whole blood, tissues, etc.).

The main challenge, when dealing with the preparation of biological samples, is that they are exceedingly complex. These substances might interfere by interaction with the drug itself, or possibly with the column packing or detector of the chromatographic system. Thus, additional procedures are almost always required, prior to the chromatography, to reduce the number of interfering substances, so that HPLC can resolve the remaining components efficiently, with a lower noise level and detection limit.

The purification of the drug, once it is freed from its environment, depends upon the chemical nature of the drug and its contaminants. Those purification conditions that selectively extract the drug should be chosen leaving, as much as possible, the endogenous material unextracted, while providing quantitative recovery of the drug.

The sample preparation for the analysis of drugs in biological fluids consists of a number of operations that are used for the release of the drug from a conjugate or biological matrix; removal of endogenous compounds that could interfere with the assay; and techniques for liquid handling.

In the case of NSAIDs, the most encountered techniques are liquid–liquid extraction or solid-phase extraction (SPE).

Table 1 Salicylic acids and esters.

Stationary phase	Mobile phase	Detection	Comments	Refs.
3 μm ODS column 10 cm × 4.6 mm I.D.	0.01 *M* phosphate buffer(pH = 3) : CH_3OH (19 : 1) (0.6 ml/min)	Ultraviolet (UV), 216 nm	Linear from 40–42.5 μg aspirin/ml Detection limit: 157 ng/ml Precision ranged from 0.12 to 1.95%	[72]
Bondapak ODS C18 (30 cm × 4 mm I.D.) 10 μm	0.03 *M* sodium acetate (pH = 3.5 with glacial acetic acid) : methanol (5 : 2) (1 ml/min)	UV, 280 nm	Separation from methanolic solution Linear from 0.85–12 mg aspirin/ml Detection limit: 2.7 ng Recovery: 100.4% with RSD (n = 6) of 0.98%	[3]
Nucleosil C8 (25 cm × 4.6 mm, 5 μm	H_2O : acetonitrile : H_3PO_4 (325 : 175 : 1); 1 ml/min	UV, 225 nm	Linear for 0.2–5 μg/ml Detection limit: 0.05 μg aspirin/ml	[73]
LiChrospher 100 RP-18 (5 μm)	KH_2PO_4 (pH 2.5)/acetonitrile	UV, 234 nm	Linear from 0.1–2 μg aspirin/ml Accuracy: 99.7–101.3%; RSD: 3.3–4.3% Detection limit: 0.05 μg/ml	[74]
Nucleosil C8 (25 cm × 4.6 mm I.D.) 5 μm	H_2O : methanol : acetonitrile : OPA (650 : 200 : 150 : 1) at 1 ml/min	UV, 225 nm	SPE from plasma in acid medium (SPE PEEK column, 10 mm × 4.3 mm I.D., packed with 30 μm Hypersil C18; washed with water : OPA (1000 : 1) at pH 2.5 for 2 min at 1 ml/min) Linear from 0.1–5.00 μg aspirin/ml Detection limit 0.04 μg/ml	[75]
Develosil ODS (10 μm)	Water : methanol (4 : 6)	FTIR		[76]
Spherisorb ODS-5 (25 cm × 4.6 mm)	H_2O : methanol : acetic acid (71 : 25 : 4; pH 2.5) 1.2 ml/min	UV, 254 nm	Linear from 2.5–10 mg/L	[63]

Supercritical fluid chromatography: JASCO C18 (25 cm × 4 mm, 10 μm), 45°C	CO_2 containing 16.67% CH_3OH (3 ml/min), 9.81 MPa	UV, 220 nm	Ibuprofen from tablets	[84]
Zorbax C8 column (25 cm × 4.5 mm I.D.)	CH_3CN : 50 m*M* disodium hydrogen phosphate buffer of pH 3.3 (buffer A) (1 : 1); 1.5 ml/min	UV, 220 nm	Paracetamol, chlorzoxazone, and diclofenac sodium in drug formulations were shaken with CH_3CN; the solution is filtered and diluted with buffer A Linearity: 4–20 μg/ml diclofenac sodium; Average recovery of 50 mg is 99.24%.	[12]
Machery-Nagel-Nitrile (25 cm × 4 mm I.D.), 10 μm	H_2O : CH_3OH (17 : 3, containing 0.01 *M* sodium acetate and anhydrous acetic acid with the pH adjusted to 4.6) 2.5 ml/min	UV, 220 nm	Paracetamol, chlormezanone, and diclofenac sodium from tablets, methanolic solution Linearity: 2–200 μg/ml diclofenac sodium Recovery: 98–101.98%	[4]
Nucleosil 5C18 (10 cm × 3 mm I.D.) 5 μm	For urine: CH_3CN : 1% acetic acid (9 : 11), 0.5 ml/min For plasma: the same solvents from 48% CH_3CN (held for 8 min) to 90% CH_3CN from 8.1 to 9.9 min	UV, 220 nm	Alclofenac in plasma, extracted with ethyl ether, evaporated to dryness, and the residue dissolved in the mobile phase Alclofenac in urine, SPE on an Adsorbex C18 column with elution with CH_3OH : H_2O (4 : 1) Linearity: to 10 and 20 μg/ml with limits of quantitation of 0.1 and 1 μg/ml in plasma and urine, respectively	[19]
Hypersil C18 (10 cm × 4.6 mm I.D.), 5 μm	CH_3OH : 0.1 *M* acetic acid containing 0.01% heptanesulfonic acid (3 : 2) 1.5 ml/min	UV, 240 nm	Fenclofenac from plasma: adding 0.1 *M* phosphate buffer of pH 7.2 and H_2O; SPE on Isolute C18 preconditioned with CH_3OH and H_2O, washed with phosphate buffer and hexane and dried under reduced pressure (68 kPa) for 2 min, eluted with ethyl acetate : hexane (1 : 1), evaporated to dryness at 40°C under N_2; the residue dissolved in 0.1 ml of methanol plus 0.15 ml of phosphate buffer	[85]

Table 3 Carbo- and heterocyclic acetic acids.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Alltima C8 (10 cm × 2.1 mm I.D.), 5 μm	CH_3OH : 40 m*M* ammonium acetate buffer of pH 5.1 (4 : 1) 0.3 ml/min	Electrospray MS; m/z = 357.9/139.0	Plasma is mixed with 50 m*M* ammonium formate buffer of pH 3.5 and IS (mefanamic acid; 100 mg/L in aqueous 50% methanol); the mixture is applied to C18 SPE cartridges preconditioned with methanol and 50 m*M* ammonium formate buffer of pH 3.5; after washing with 50 m*M* ammonium formate buffer of pH 3.5, the analytes were eluted with methanol and evaporated to dryness under air flow at 40°C; the sample is reconstituted with mobile phase Linearity: 5–2,000 μg/L indomethacin	[36]
Spherisorb column (20 cm × 3.9 mm I.D.), 5 μm	CH_3CN : 0.5% acetic acid (1 : 1) 1.5 ml/min	UV, 254 nm	Tissue homogenized with 0.25 *M* Na_2HPO_4 of pH 3.5; a portion is mixed with IS then extracted with CH_2Cl_2 and centrifugated at 2,000 g for 20 min; the extract is evaporated to dryness and the residue (from liver or muscle) is redissolved in methanol. For the residue resulting from fat, it is mixed with methanol, and the unstable emulsion obtained is allowed to stand for 10 min until total phase separation occurred Linearity: 20 ng/g (detection limit) to 500 ng/g indomethacin	[67]
μ-Bondapak C18 (25 cm × 4.6 mm I.D.) 10 μm; 30°C	CH_3OH : 0.035 *M* H_3PO_4 of pH 5.5 (19 : 6), 1 ml/min	UV, 260 nm	Plasma is mixed with IS solution, phosphate buffer of pH 7, and NaCl; the mixture is extracted with ethyl acetate; the organic phase is heated at 50°C to dryness, the residue is dissolved in methanol and centrifuged at 3,000 rpm Linearity: 0.125–50 μg/ml indomethacin Detection limit: 62.5 ng/ml	[68]
Chiralpak AD (25 cm × 4.6 mm), 10 μm and Chiralpak AD guard column (5 cm × 4.6 mm)	0.05% trifluoro acetic acid (TFA) in hexane : ethanol (17 : 3) 1 ml/min	UV, 340 nm	Enantiomers of sulindac	[56]
Spherisorb S5 ODS-2 (25 cm × 4.6 mm I.D.) 5 μm	2% acetic acid of pH 3.5 : CH_3CN : THF (25 : 24 : 1) 1 ml/min	UV, 340 nm	For sulindac from urine, the sample is injected directly or after dilution, acidification to 0.2 *M* with 1 *M* HCl and addition of 10 μg indomethacin (IS)	[56]

Table 3 Carbo- and heterocyclic acetic acids. *(Continued)*

Stationary phase	Mobile phase	Detection	Comments	Refs.
Inertsil ODS-2 (15 cm × 4.6 mm), 5 μm	50 m*M* phosphate buffer(pH = 5) : CH_3CN (29 : 21), 0.9 ml/min	UV, 230 or 320 nm	Urine samples acidified to pH 5 with acetate buffer and purified by SPE on a Sep-Pak silica cartridge; the NSAIDs were eluted from the cartridge with ethyl acetate Detection limits: 0.005 μg/ml for naproxen and 0.05 μg/ml for sulindac, piroxicam, loxoprofen, ketoprofen, felbinac, fenbufen, flurbiprofen, diclofenac, ibuprofen, and mefenamic acid in human urine	[47]
Octyl column (15 cm × 4.6 mm), 5 μm	CH_3CN : CH_3COOH : H_2O (75 : 2 : 123) 2 ml/min or 1 ml/min for feces	UV, 329 nm	Plasma is mixed with 50% H_3PO_4, indomethacin solution (IS), and extracted with CH_2Cl_2; the organic phase is evaporated to dryness under N_2 at 37°C and reconstituted in mobile phase Urine is treated at 37°C for 2 hr with betaglucuronidase and extracted as for plasma Fecal supernatants were mixed with IS, evaporated to dryness and reconstituted in mobile phase; Linearity: 0.025–10, 0.02–2, and 250–100 μg/ml for active metabolite of sulindac in plasma, urine, and feces, respectively	[58]
Hypersil ODS (15 cm × 4.5 mm), 5 μm; 17°C	CH_3OH : 0.02 *M* KH_2PO_4 (pH 4.5) (57 : 43) 1.25 ml/min	UV, 245 nm	Plasma is mixed with 0.15 *M* KH_2PO_4 buffer (pH = 3), IS, and ethyl ether; after centrifugation, the organic phase is evaporated to dryness and the residue is dissolved in the mobile phase Linearity: 10–1000 ng/ml acemetacin	[37]
Nucleosil 5 C18 (12.5 cm × 4.6 mm)	0.02 *M* phosphate buffer of pH 4.5 : CH_3OH (9 : 11) 1.4 ml/min	UV, 254 nm	Acemetacin is extracted from plasma (adjusted to pH = 3) with ethyl ether, the solvent is evaporated and the residue is dissolved in the mobile phase	[30]
LiChrosorb RP-18 (25 cm × 4 mm), 7 μm	1% aqueous acetic acid : acetonitrile (1 : 1) 1.3 ml/min	UV, 227 nm	Serum or urine is mixed with IS, diluted with H_2O, adjusted to pH = 1 with 1 *M* HCl, extracted twice with isooctane/isopropanol (19 : 1); the combined organic layers were evaporated to dryness with N_2 and reconstituted in mobile phase	[35]

μ-Bondapak C18 (25 cm × 5 mm)	Methanol-aq. 1% formic acid (77 : 23)	UV, 310 nm	Fentiazac is extracted from plasma at pH = 2 into CH_2Cl_2	[31]
LiChrosorb RP-8 (25 cm × 4 mm) 7 μm	Methanol : 5 m*M* phosphate buffer of pH 3 (4 : 1) 1 ml/min	UV, 254 nm	Fentiazac from tablets and suppositories is extracted with methanol Linearity: 8–18 μg/ml fentiazac	[86]
Brownlee silica (22 cm × 4.6 mm) 5 μm (23°C) in series with a 7 μm silica precolumn (1.5 cm × 4.6 mm)	5 m*M* sodium phosphate : H_3PO_4 buffer of pH 2.6 (19 : 1) containing 0 to 10% CH_3CN 1 ml/min	UV	Indomethacin, sulindac and tolmetin were extracted from capsules or table ts using aq. 0 to 10% acetonitrile	[87]
Zorbax ODS or ultrasphere ODS (25 cm × 4.6 mm) 5 μm or μ Bondapak C18 (30 cm × 3.9 mm) 10 μm	1.36 g/L KH_2PO_4 and 3.39 g/L of PIC A in H_2O : methanol : acetic acid (350 : 650 : 1) 1 ml/min	UV, 317 nm	Tolmetin from tablets or capsule powder is dissolved in and diluted with sodium zomepirac dihydrate solution (IS) and aq. 50% methanol Linearity: 10–30 μg/ml tolmetin; Detection limit: 1 μg/ml	[13]
Spherisorb ODS (12.5 cm × 4.9 mm) 5 μm	CH_3CN : aq. 1% H_3PO_4 (1 : 1) 2 ml/min	UV, 313 nm	Urine and plasma samples were centrifuged and an aliquot of the supernatant so lution is subjected to HPLC o n a cleanup column of Spherisorb ODS (4 cm × 4.6 mm), 10 μm) with a mobile phase (1.5 ml/min) of aq. 0.5% H_3PO_4 Linearity: 0.5–100 μg/ml zomepirac sodium	[88]

Table 4 Fenamic acids.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Nucleosil C18 5 μm	H_2O : methanol (23 : 73) 0.8 ml/min	UV, 280 nm	Plasma containing flufenamic acid, mefenamic acid (IS), and 1 *M* HCl were mixed, then extracted with CH_2Cl_2 by shaking for 20 min; the organic phase is evaporated to dryness and the residue reconstituted in methanol Linearity: 0.5–15 μg/ml flufenamic acid Detection limit: 0.1 μg/ml	[41]
Supelcosil LC-8 (25 cm × 4.6 mm I.D.) 5 μm	50% acetonitrile adjusted to pH = 3.3 with CH_3COOH; 2 ml/min for 13 min then to 2.7 ml/min (held for 11 min) in 17 min	UV, 280 nm	Plasma-containing flufenamic acid is mixed with acetonitrile; after centrifugation, the supernatant is evaporated to dryness at 45°C under N2 and the residue is reconstituted in the mobile phase	[20]
LiChrosorb RP-18 (25 cm × 4 mm) 10 μm	65 m*M* ammonium acetate–methanol (1 : 3–3 : 7 in 6 min) 0.8 ml/min	UV, 282 nm	Flufenamic acid, mefenamic acid and tolfemanic acid were determined in serum, urine, and pharmaceuticals Detection limits (ng injected) were 0.5 for flufenamic acid, 0.7 for mefenamic acid, and 1.0 for tolfenamic acid	[89]
Shimpack CLC-ODS (15 cm × 6 mm)	Aq. 85% methanol containing 0.05 *M* $NaClO_4$ and 0.57% of acetic acid 0.6 ml/min	Electrochemical detection with a vitreous-carbon electrode at +1.0 V vs. Ag/AgCl	Serum is mixed with 10 m*M* phosphate buffer (pH 5.6) and *N*-phenylanthranilic acid as IS; proteins were removed by precipitation with acetonitrile, and, after centrifugation, the supernatant solution is concentrated to dryness and the residue is dissolved in methanol Serum recoveries of mefenamic acid (4–21 ng) and flufenamic acid (8–25 ng) were 96–119% and 98–103%, respectively; The corresponding detection limits were 0.4 and 6.3 pg	[21]
Nucleosil C18 (25 cm × 4.6 mm I.D.) 5 μm	H_2O adjusted to pH 3 with H_3PO_4/CH_3CN (45 : 55) 1.5 ml/mm	UV, 210 nm	Mefenamic acid sample is dissolved in methanol The method is applied in analysis of related substances in mefenamic acid	[90]
		UV, 210 nm		[5]

Hypersil ODS (20 cm × 2.1 mm I.D.) 5 μm	2 m*M* phosphate buffer of pH 3.2 : CH_3CN 19 : 1 to 1 : 1 (held for 10 min) in 20 min and then to 19 : 1 in 1 min; 0.4 ml/min		Blood containing mefenamic acid is vortex mixed with saturated NH_4Cl for 10 sec, and the mixture is extracted with ethyl acetate containing heptabarbitone (IS); the mixture is centrifuged at 2,500 rpm for 10 min, a portion of the upper organic layer is removed and evaporated to dryness; the residue is dissolved in CH_3CN and vortex mixed with CH_3CN-saturated hexane for 10 sec	
Vydac stainless steel C18 bonded-phase silica (25 cm × 4.6 mm I.D.) 5 μm	CH_3CN : 10 m*M* H_3PO_4 (3 : 2) of pH 2.6, 0.9 ml/min	UV, 280 nm	Plasma is vortex mixed with the IS (indomethacin for the determination of mefenamic acid or mefenamic acid for indomethacin in acetonitrile) and acetonitrile; the mixture is centrifuged at 9,000 g for 3 min, and a portion of the supernatant liquid is evaporated to dryness; the residue is dissolved in mobile phase Linearity: 0.1–10 μg/ml Detection limits: 0.06 and 0.08 μg/ml for indomethacin and mefenamic acid, respectively;	[22]
Spherisorb ODS (10 cm × 3 mm) 10 μm	CH_3OH : phosphate buffer (9 : 11) 0.85 ml/min	UV, 280 nm	Urine samples containing meclofenamic acid were hydrolyzed with 10 *M* NaOH, the pH is adjusted to 3 with H_3PO_4, and the analytes were extracted into CH_2Cl_2; the organic extracts were washed with citrate buffer of pH 5.2 and extracted with 0.1 *M* NaOH, the alkaline aq. phase is adjusted to pH 5.2 with H_3PO_4, and the analytes were extracted into heptane; the heptane is evaporated and the residue is dissolved in methanol	[32]
Stainless steel column (10 cm × 3.0 mm) packed with Spherisorb ODS (10 μm)	40% of methanol in phosphate buffer solution of pH 6.1, 0.8 ml/min	UV, 280 nm	Meclofenamic acid from plasma and citrate buffer solution (pH 4.6) containing diclofenac sodium (IS) were mixed with CH_2Cl_2; the mixture is centrifuged, the organic phase is evaporated to dryness, and the residue is dissolved in the mobile phase Linearity: 0.20–4.8 μg/ml meclofenamic acid	[42]
LiChrospher C18 (15 cm × 4.6 mm I.D.) 5 μm; 30°C	Methanol : 0.07 *M* phosphate buffer of pH 3 (9 : 1) 2 ml/min	UV, 286 nm	Linearity: 50–500% of the expected working assay of tolfenamic acid and RSD were <1%; Mean recoveries were 99.7%	[91]

(Continued)

Table 4 Fenamic acids. *(Continued)*

Stationary phase	Mobile phase	Detection	Comments	Refs.
LiChrospher 100 RP-18 (25 cm × 4 mm I.D.) 5 μm	CH_3CN : 10 m*M* H_3PO_4 (3 : 2) 1.1 ml/min	UV, 280 nm	Plasma containing tolfenamic acid is diluted with acetonitrile containing phenylbutazone (IS), vortex mixed for 1 min and centrifuged at 9,000 g for 3 min; the supernatant is separated and evaporated to dryness, and the residue is redissolved in mobile phase Linearity: 0.2–5 μg/ml telfenamic acid Detection limit: 50 ng/ml	[23]
LiChrosorb RP-18 (25 cm × 4 mm) 10 μm	Acetate buffer (pH 4.6) : CH_3OH (9 : 41) 1.9 ml : min	UV, 282 nm	Powdered capsule contents or suspension were dissolved in methanol; the diluted suspensions were sonicated for 10 min, centrifuged at 3,500 rpm for 10 min, and a portion of the supernatant solution is diluted with methanol. Portions of the solution. (1–3 ml for capsule contents or 10–30 ml for suspensions) were mixed with 6 ml of caffeine solution (IS) and diluted with methanol Linearity: 0.1–10.0 ng/μl tolfenamic acid	[6]
GSK ODS-2 C18 Microbore, 5 μm (15 cm × 1 mm I.D.)		UV or electrospray ionization MS	Samples containing niflumic acid is extracted with ethanol	[92]
Hypersil ODS (10 cm × 2.1 mm I.D.) 5 μm	Gradient elution with hexane : 95% propan-2-ol; 0.4 ml/min	Atmospherc pressure-ionization (API)-MS detection or PBMS detection	Urine containing flunixin is adjusted to pH 7 with 1 *M* NaOH (or 1 *M* HCl) and centrifuged at 500 g for 15 min supernatant is applied to a Bond Elut Certify II SPE ml cartridge and washed with H_2O, CH_3OH, and hexane. Flunixin is eluted with 10% acetic acid in hexane and naproxen (IS) for API-MS or ketoprofen (IS) for particle-beam (PB)-MS; the eluates were evaporated to dryness under N_2 and the residues were dissolved in methanol for API-MS or hexane : propan-2-ol (1 : 1; solvent B) for PB-MS.	[64]

Table 5 Propionic acids.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Tris-(4-methyl benzoate) cellulose covalently bound to silica gel (15 cm × 4.6 mm I.D.) (10 μm)	Methanol/0.1*M* perchlorate buffer of pH 2 1 ml/min	UV, 230; 254 nm	Benoxaprofen, carprofen, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, pirprofen, and tiaprofenic acid derivatized to their amides using 1-naphthylmethylamine or benzylamine in the presence of 1-hydroxybenzotriazole as catalyst and 1-ethyl-3-dimethylaminopropyl-carbodiimide as coupling agent	[93]
Ultron ES-OVM chiral column (15 cm × 4.6 mm) packed with ovomucoid protein chemically bonded to silica	Phosphate buffer (pH 5.8)/an organic modifier (e.g., methanol, ethanol, propanol, propan-2-ol, butanol, butan-2-ol, and 2-methylpropan-2-ol) 1 ml/min	fluorimetric (λ_{ex} = 227 nm) or UV at 214 nm	Racemic mixtures of flurbiprofen, benoxaprofen, benzoin, and verapamil	[94]
CHIRAL-AGP (50 and 10.0 cm × 4 mm I.D.) of (5 μm), CHIRAL-AGP precolumn (1 cm × 3 mm I.D.)	Buffers/uncharged modifiers such as methanol, ethanol, propan-1-ol, propan-2-ol, or acetonitrile; 0.9 ml/min	UV, 225 nm	Naproxen, tiaprofen, flurbiprofen, carprofen, ketoprofen, ibuprofen, fenoprofen, and indoprofen	[95]
Ultrasphere ODS (15 cm × 4.6 mm, 5 μm)	Gradient of 35% of acetonitrile 9 m*M* and 45 or 50% of acetonitrile 5 m*M*; 2 ml/min	λ_{em} = 365 nm, λ_{ex} = 235 or 290 nm for urine or plasma, respectively	Carprofen Plasma is acidified with H_3PO_4 and extracted with ethyl acetate, the organic phase is evaporated; residue dissolved in 28% of acetonitrile in aqueous 10 m*M* tetrabutylammonium hydrogen sulfate pH = 2.5 (solution A); Urine is mixed with solution A and centrifuged	[48]
LiChrosorb Si 60 (25 cm × 4 mm); similar precolumn (3 cm × 4 mm)	CH_2Cl_2 : methanol : acetic acid (98 : 1 : 1); 1.5 ml/min	λ_{ex} = 305 nm λ_{em} = 375 nm	Carprofen Plasma is extracted with butyl acetate in the presence of acetate buffer (pH 2.8)	[52]
C-18 Spherisorb (25 cm × 4.6 mm × 5 μm)	CH_3CN : 0.1 *M* sodium acetate (7 : 13), pH = 6.3, 1 ml/min	UV, 278 nm	Flurbiprofen and diclofenac. Plasma is spiked with IS solution, 2.5 *M O*-phosphoric acid is added, and the mixture is vortex mixed, and 1.5 ml hexane/propan-2-ol (4 : 1) is added; The mixture is vortexed and centrifuged The organic layer is separated and evaporated to dryness at 37°C under N_2 The residue is reconstituted in mobile phase	[53]

(Continued)

Table 5 Propionic acids. *(Continued)*

Stationary phase	Mobile phase	Detection	Comments	Refs.
C18 (25 cm × 4.6 mm × 5 μm)	Acetonitrile : H_2O_2 : H_3PO_4 (1200 : 800 : 1) 1.5 ml/min	$\lambda_{ex} = 250$ nm $\lambda_{em} = 285$ nm	Flurbiprofen from plasma: deproteinized by vortexing and centrifuging with acetonitrile	[24]
Spherisorb ODS2 (15 cm × 4 mm I.D.), 5 μm	Linear gradient elution with 0.1 *M* formate buffer of pH 3% methanol, (9 : 1–9 : 11 over 10 min, and to 0 : 100 over 20 min); 1.5 ml/min	UV, 254 nm	Ketoprofen, caffeine, indoprofen, fenbufen, naproxen, and ibuprofen in pharmaceutical formulations and blood plasma	[96]
YWG-C18 (25 cm × 4.6 mm I.D.)	380 mg NaH_2PO_4 and 50 mg Na_2HPO_4 in 1 L H_2O adjusted to pH 3 : methanol (1 : 3) 1 ml/min	UV, 220 nm	Ibuprofen Syrup is dissolved in and diluted with methanol. A portion of the solution is mixed with diphenylamine (IS) and the mixture is diluted with methanol	[7]
Column packed with an amide derivative made from (*R*)-1-naphthylglycine and 3,5-dinitrobenzoic acid; (25 cm × 4.6 mm I.D.)	Aqueous 70% methanol containing 0.01 *M* ammonium acetate with pH adjusted to 5.9 with acetic acid; 1 ml/min	UV, 254 nm	Ibuprofen enantiomers	[97]
Chiralcel OD column (15 cm × 4.6 mm I.D.) 25°C	Hexane : propan-2-ol, 100 : 1 containing 0.1% TFA; 1 ml/min	UV, 230 or 254 nm	Ibuprofen or flurbiprofen Plasma is applied to a Sep-pak C18 cartridge for SPE, with 10 ml H_2O for percolation and 5 ml acetonitrile for elution The eluate is evaporated then dissolved in mobile phase	[61]
LiChroCART RP-18	Acetonitrile : 10 m*M* phosphate buffer of pH 6.5 (19 : 31)	UV, 275 nm or fluorimetric $\lambda_{ex} = 275$ nm $\lambda_{em} = 433$ nm	Enantiomers of indoprofen in plasma Plasma is mixed with racemic indobufen (IS), acidified, and extracted with ethyl ether The drug is coupled with leucinamide via reaction with ethyl chloroformate; The enantiomers are then extracted into ethyl acetate and transferred into methanol	[38]

Hypersil HAS (15 cm × 4.6 mm I.D.), 7 μm; operated at 28°C	50 m*M* phosphate buffer of pH = 7.4 : acetonitrile (17 : 3); addition of 3.5% propan-2-ol and 15% acetonitrile if the phosphate concentration decreased from 50 to 25 m*M*; 0.6 ml/min	UV, 232 nm	Ketoprofen from human serum albumin. The unbound enantiomers in the mixed buffer (0.067 *M* phosphate and pH 7.4) solution of the drug racemate with human serum albumin were sampled with a microdialysis probe after 10 min incubation at 37°C After 12 min, the dialysate is collected for 30 min	[98]
Bioptic AV-1 (15 cm × 4.6 mm)	Acetonitrile : buffer pH 7, 0.1 *M* (5 : 95); 0.6 ml/min	UV, 254 nm	Ketoprofen, ibuprofen, and fenprofen enantiomers Samples were prepared in methanol	[99]
α 1 acid glycoprotein-immobilized silica	4 m*M* potassium dihydrogen phosphate buffer/propan-2-ol (199 : 1) 0.8 ml/min	UV, 263 nm	Inactive (*R*)-enantiomer in the pharmacologically active (*S*)-enantiomer of naproxen	[100]
Zorbax Sil (25 cm × 4.6 mm)	Cyclohexane : ethyl acetate (7 : 3), 0.8 ml/min	UV, 272 nm	Naproxen enantiomers	[101]
Tris-(4-methyl benzoate) cellulose covalently bound to silica gel (15 cm × 4.6 mm I.D.); 10 μm	Methanol : 0.1 *M* perchlorate buffer of pH 2; 1 ml/min	UV, 230 and 254 nm	Benoxaprofen, carprofen, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, pirprofen, and tiaprofenic acid after derivatization to their amides using 1-naphthyl methylamine or benzylamine in the presence of 1-hydroxy benzotriazole as catalyst and 1–ethyl–3–dimethyl aminopropyl-carbodiimide as coupling agent	[102]

Table 6 Other acids.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Chiralpak AD	Propan-2-ol : 90 m*M*	UV, 313 nm	Ketorolac and its enantiomers from blood	[103]
Chiral-AGP (10 cm × 4 mm, 5 μm) packed with α 1-acid glycoprotein immobilized on silica	NaH_2PO_4 : 10 m*M* Na_2HPO_4 : 2 m*M* dimethyloctylamine (pH 5.5; 17 : 183) 0.5 ml/min	UV, 320 nm	Ketorolac from plasma Plasma is spiked with S-(+)-naproxen in methanol-IS, extracted with tertbutyl methyl ether The aqueous phase is acidified to pH 1 with HCl, and backextracted into tertbutyl methyl ether The organic phase is removed, evaporated to dryness, and the residue redissolved in mobile phase Linearity : 20–20,000 ng/ml Quantitation limit: 5 ng/ml	[54]
C8 (25 cm × 4.6 mm); 10 μm	Acetonitrile : methanol : 0.01 *M* KH_2PO_4 of pH 4.2 (1 : 1 : 2)	UV, 319 nm	Ketorolac tromethamine in ophthalmic formulations after dilution with water Linearity: 20–70 μg/ml	[104]
Bondapak/μ Porasil C18 (15 cm × 3.9 mm)	Acetonitrile : 0.05 *M* H_3PO_4 (1 : 1) of pH 2, 1 ml/min	Vitreous C electrode in the pulsed mode at 0, 1000, and 12000 mV vs. Ag/AgCl	Ketorolac from tablets Linearity: 1–50 μ*M* ketorolac Detection limit: 0.359 μ*M*	[105]
Microsorb silica (15 cm × 4.6 mm), 5 μm	Ethyl acetate : hexane (2 : 3)	UV, 317 nm	Ketorolac from plasma Plasma is mixed with IS, acidified, extracted with ethyl acetate/hexane and the extract is derivatized with (+)-R-1-(1-naphthyl)ethylamine Linearity: 0.02–2 μg/ml	[50]

Chiral AGP (10 cm × 4 mm); 5 μm	Propan-2-ol : 0.05 *M* phosphate buffer of pH 5.5 (1 : 19), 0.4 ml/min	UV, 317 nm	Plasma (containing ketorolac) is mixed with IS and subjected to SPE on C18 columns using H_2O, aqueous 20% methanol, and hexane for washing and ethyl acetate : hexane (3 : 7) for elution The eluate is dried and reconstituted in mobile phase Linearity: 0.02–2 μg/ml	[44]
Waters Novapak C18 (15 cm × 3.9 mm) 4 μm	H_2O : acetonitrile : triethylamine : 85% H_3PO_4 : cyclam (800 : 200 : 10 : 3 : variable), 2 ml/min	UV, 255 nm	Analysis of tenidap	[106]
Novapak C18	Aqueous 35% methanol containing 2 m*M* triethylamine, 1 ml/min	MS	Tenidap and its stable isotope analog in serum IS solution in aqueous 75% methanol is vortex mixed with 0.05 *M* Na_2CO_3 Serum is added and the resulting mixture is again vortex mixed and extracted with ethyl acetate Following centrifugation, the organic layer is evaporated to dryness, the residue is dissolved in 2 m*M* triethylamine in methanol, sonicated and vortex mixed. Triethylamine–H_2O is added, and the solution is vortex mixed Linearity: 0.1–25 μg/ml tenidap	[55]

Table 7 Oxicams.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Haisil 120 BD C18 (12 cm × 3 mm I.D.), 5 μm; at 30°C	THF : methanol : 30 m*M* H_3PO_4 buffer containing 0.015% KCl adjusted to pH 2.7 with 4 *M* NaOH (2 : 8 : 15); 0.5 ml/min	Amperometric at +0.65 V	Extraction of piroxicam from plasma, subcutaneous tissue or synovial capsule homogenate, synovial fluid from alkaline medium with CH_2Cl_2/hexane (1 : 4) and evaporation of the extract, with the residues dissolved in mobile phase Linearity: 0.72–600 ng/ml	[44]
LiChrospher 100 RP-18 (11.9 cm × 3 mm I.D.), 5 μm	Methanol : acetate buffer of pH = 4.3 (9 : 11)	UV, 280 nm and 254 nm	Piroxicam in 2.5% NH_4OH	[107]
Kromasil C18 (15 cm × 4 mm I.D.), 5 μm	Acetonitrile : 20 m*M* phosphate buffer of pH 3.1; 1 ml/min	UV, 360 nm	Piroxicam from plasma (A) plasma is applied to a Bond-Elut C8 SPE cartridges, washed with 2 ml 0.15 m*M* phosphate buffer of pH 3.5, dried under vacuum and eluted with 0.4 ml mobile phase; (B) plasma applied to the SPE cartridges packed with 40 μm C8-bonded phase, washed with 1 ml 75 m*M* phosphate buffer of pH 3.5 and eluted with mobile phase; Linearity: 0.05–2.5 μg/ml Detection limit: 25 ng/ml (A) and 7.5 ng/ml (B)	[71]
LiChrosorb RP-C8 (25 cm × 4.6 mm I.D.); 10 μm	0.02 *M* sodium acetate (containing 5 m*M* heptane sulfonic acid sodium salt; pH = 3.5) : methanol : acetonitrile (11 : 8 : 1); 1.5 ml/min	UV, 300 nm and 375 nm	Tenoxicam from tablets Powdered tablets equivalent to one tablet dissolved in methanol	[8]
Nucleosil C18 (25 cm × 4.6 mm I.D.), 5 μm	10 m*M* NaH_2PO_4, 1 m*M* sodium lauryl sulfate and acetonitrile : H_2O (7 : 13) adjusted to pH 2.8 with H_3PO_4; 1.5 ml/min	UV, 355 nm	Tenoxicam from plasma; to 1 ml plasma is added ketorolac (IS) and 100 μl 1.5% $ZnSO_4$; the sample is vortex mixed for 2 min; 3 ml methanol is added followed by further mixing for 2 min; buffer (0.44 ml; 100 m*M* NaH_2PO_4 and 10 m*M* sodium lauryl sulfate, adjusted to pH 2.8 with H_3PO_4) is added and after mixing the solution, it is centrifuged at 2000 g for 10 min at 27°C	[26]
LiChrospher 100 RP-18 (12.5 cm × 4 mm); 5 μm	0.1 *M* phosphate buffer of pH 7.4 : methanol (3 : 2); 1.1 ml/min	UV, 355 nm	Tenoxicam from plasma; plasma is mixed with 1 ml of 1 *M* HCl, 1 ml H_2O and 100 μl of piroxicam solution (IS) The mixture is extracted with 5 ml of CH_2Cl_2, mixed 5 min and centrifugated at 1800 g for 10 min The extract is evaporated to dryness under N at 30°C and the residue is dissolved in 100 μl mobile phase Linearity: 5–2000 ng/ml Detection limit: 5 ng/ml	[43]

Viosfer LC-18 (25 cm × 4.6 mm); 10 μm	Methanol : Na_2HPO_4 buffer of pH 3 (9 : 11); 1.2 ml/min	UV, 361 nm	Tenoxicam from plasma Plasma is mixed with 1-(2-hydroxyethyl)-3-hydroxy-7-chloro-1, 3-dihydro-(*O*-fluorophenyl)-2H-1, 4–benzodiazepin-2-one solution (3 μg/ml; IS) and the mixture is applied to a Bakerbond SPE extraction column Elution with acetonitrile, evaporation to dryness, and the residue dissolved in mobile phase Linearity: 0.1–10 μg/ml Detection limit: 0.05 μg/ml;	[108]
Hypersil ODS2 (250 mm × 4.6 mm) 5 μm	Methanol : H_2O : triethylamine : acetic acid (2,5 : 1,5 : 15 : 7)	UV, 355 nm	Meloxicam from plasma Plasma is acidified with HCl and extracted with ethyl ether Linearity: 0.03–8.0 mg/L Detection limit: 2.5 ng/ml Recovery: 93.6–97.7%	[39]
LiChrosphere RP-18	*Tris*-acetic acid buffer : tetrabutylammonium reagent : THF : acetonitrile	UV, 360 nm	Analysis of tenoxicam, piroxicam, isoxicam, cinnoxicam, meloxicam, and lornoxicam from pharmaceutical preparations	[109]
LiChrospher C18 (125 mm × 4.0 mm) 5 μm	Sodium acetate buffer (pH = 3.3; 170 m*M*) : acetonitrile (62 : 38)	UV, 355 nm	Meloxicam from plasma Plasma proteins were precipitated with $HClO_4$ (70%) and acetonitrile mixture (1 : 1 v/v) Linearity: 50–1500 ng/ml	[27]
LiChroCART 125-4 LiChrospher RP-8	0.05 *M* phosphate buffer : 30% acetonitrile : 25 m*M* *t*-butylamine (pH = 7.0)	UV, 364 nm	Meloxicam from plasma Plasma is introduced on the LiChrospher alkyl-diol silica precolumn using a 0.05 *M* phosphate buffer (pH = 6.0); The precolum is washed with the buffer and is backflushed with the mobile-phase transferring the analyte to the HPLC system	[69]
YMC Cyano (50 mm × 4.6 mm)	H_2O : acetonitrile : formic acid (50 : 50 : 0.1); 1.0 ml/min	MS in positive ion ESI mode	Meloxicam from plasma Plasma is treated with potassium phosphate (1.0 *M*, pH = 7.0) and extracted with ethyl acetate : cyclohexane (9 : 1) The organic layer is evaporated and reconstituted Linearity: 50.0–3000 ng/ml	[51]

Table 8 Pyrazolidindiones.

Stationary phase	Mobile phase	Detection	Comments	Refs.
Ultracarb 5 C18 ODS (15 cm × 4.6 mm I.D.) equipped with Supelcosil LC-18DB guard column (2 cm × 4.6 mm I.D.) at 35°C	0.02 *M* sodium phosphate buffer (pH = 7) : methanol (1 : 1); 1 ml/min	UV, 264 nm	Phenylbutazone from plasma; Plasma is ultrafiltered into a 2 ml centrifugal concentrator with molecular-mass cut-off membrane The ultrafiltrates is centrifuged at 4500 g for 2 hr at 4°C Linearity: 20–2000 ng/ml Detection limit: 3.4 ng/m Recovery: 89.9–93.7%	[18]
SPS-5PM-55-100-C18 (15 cm × 4.6 mm I.D.) and similar guard column	Acetonitrile : 0.05 *M* phosphate buffer (pH = 7.5) (3 : 17) 1 ml/min	UV, 265 nm	Phenylbutazone and oxyphenbutazone in serum Direct injection after filtering; Linearity: 0.5–20 μg/ml Detection limit: 0.25 μg/ml	[110]
LiChrospher 100 RP-18 (12.5 cm × 4 mm I.D.), 5 μm; similar guard column (40 × 4 mm) at 35°C	0.1 *M* acetic acid : methanol (9 : 11); 1 ml/min	UV, 254 nm	Phenylbutazone and oxyphenbutazone from plasma and urine Plasma is deproteinized by adding acetonitrile and centrifuging Urine is acidified with 2 *M* acetate buffer (pH = 3.5) and extracted with CH_2Cl_2 : methanol (19 : 1); the organic layer is washed with saturated $NaHCO_3$, filtered, and evaporated at 40°C to dryness under N_2; the residue is dissolved in methanol Detection limit: 0.5 μg/ml Quantitation limit: 1 μg/ml	[33]
LiChrosorb RP-18 (25 cm × 4.5 mm)	80% methanol (adjusted to pH 3 with H_3PO_4); 1 ml/min	UV, 250 nm	Azapropazone and its principal 8-hydroxy-metabolite in plasma, urine, and GI mucosa Mucosa homogenate is extracted with HCl_3 : methanol (4 : 1), the extract is evaporated to dryness and the residue is dissolved in methanol This solution or acidified urine or plasma, is cleaned on Sep-Pak C18 and eluated with methanol	[57]

Ultrasphere ODS (15 cm × 4.6 mm); 5 μm and Nova-Pak precolumn	Acetonitrile : 0.02 *M* $(NH_4)_2SO_4$ (11 : 9); 1.5 ml/min	UV, 340 nm	Indomethacin, suxibuzone, phenylbutazone, and oxyphenbutazone in plasma Plasma is mixed with indomethacin solution (IS); adjusted to pH = 3.4 with 0.345 *M* citrate buffer The solution is passed through a Bond Elut cartridge of phenyl sorbent, washed with H_2O, dried and eluted with hexane : ethyl ether (1 : 1); the organic phase is evaporated to dryness under N_2 at 40°C and the residue is dissolved in methanol Linearity: up to 50 μg/ml Detection limit: 0.05 μg/ml Recovery: 90.8–101.5%	[62]
LiChrosorb RP-8 (25 cm × 4 mm, 10 μm), LiChrosorb RP-8 (3 cm × 4 mm, 7 μm) as precolumn	Acetonitrile : methanol : H_2O (5 : 1 : 4) adjusted to pH 3.5 with acetic acid; 1 ml/min	UV, 254 nm	Oxyphenbutazone from tablets Powdered tablets equivalent to ~25 mg of oxyphenbutazone were dissolved in mobile phase Linearity: 10–100 μg/ml	[17]
Nucleosil 5C18 (10 cm × 3 mm)	[H_2O : acetic acid (30 : 1)] : methanol (2 : 3); 0.4 ml/min	UV, 240 nm	Mofebutazone and its 4-hydroxy-metabolite in plasma and urine To 1 ml of plasma were added 1 ml of 1 *M* acetate buffer (pH = 5.3) and 0.1 ml of phenylbutazone in methanol : ascorbic acid (100 : 1) as IS An ethyl ether extract of the mixture is evaporated to dryness at 40°C under N_2 and the residue is dissolved in methanol Linearity: 1–25 μg/ml	[40]
LiChrosorb RP-8 or -18 (15 cm × 4.6 mm, 5 μm)	Ethanol : citrate buffer of pH = 2.5 (12 : 13); 1 ml/min	UV, 254 nm	Acidified plasma or urine is extracted with 1-chloro butane : $CHCl_3$ (1 : 1) Detection limit: 10 ng/ml	[34]
Radial-Pak C18	Acetonitrile : 0.02 *M* phosphate buffer (pH = 7) (13 : 37)	UV, 254 nm	Sulphinpyrazine and four of its metabolites in plasma Deproteinization with acetonitrile Linearity: 0.2–100 μg/ml	[25]

Table 9 Non-acids compounds.

Stationary phase	Mobile phase	Detection	Comments	Refs.
μ Bondapak C18 (30 cm × 4 mm) 8–10 μm	H_2O : methanol (40 : 60) pH = 3.0 with H_3PO_4 1 ml/min	UV, 280 nm	Bufexamac in cream and ointment About 1 g of sample, containing ~50 mg of bufexamac, is mixed with hexane and aqueous 80% methanol; the layers were separated after shaking and the extraction is repeated with aqueous methanol Recovery 91.2–103.2%	[111]
Shim-pack CLC-ODS (15 cm × 4.6 mm I.D.)	Methanol : 50 m*M* acetate buffer at pH = 3.5 (13 : 7); 1 ml/min	UV, 254 nm	Determination of nabumetone in pharmaceutical products after the sample is dissolved in methanol Linearity: 86.4–345.6 μg/ml	[9]
Supelcosil LC-8 (15 cm × 4.6 mm, 5 μm)	H_2O : acetonitrile (50 : 50) containing 1.5 ml/L triethyl amine and 8 ml/L acetic acid; pH = 4.5; 2 ml/min	UV, 270 nm	Analysis of nabumetone and its major metabolite from plasma and tablets Powdered tablets (~one tablet) were sonicated in 30 ml aqueous 50% acetonitrile containing methoxy acetophenone (IS); the resulting solution is diluted with IS solution Plasma is shaken with 10 ml *n*-hexane : ethyl acetate (1 : 1) and 0.5 ml 1 *M* HCl; the mixture is centrifuged and the organic layer is evaporated to dryness; the residue is dissolved in aqueous 50% acetonitrile	[14]

			Recovery: 99.8–100.9%	
Spherisorb C18 (15 cm × 4.6 mm, 5 μm)	H_2O : acetonitrile (45 : 55) 1 ml/min	UV, 331 nm	Determination of nabumetone from pharmaceutical products Powdered tablets were dissolved in methanol with sonication then filtered The filtrate is diluted with the mobile phase and mixed with methanolic naproxen solution (IS) Linearity: 20–90 μg/ml	[10]
Wakosil ODS 5C18 (150 × 4.6 mm, 5 μm)	0.5 g of 1-heptanesulfonic acid sodium salt in 1 Lacetonitrile : water : triethyl amine (500 : 500 : 1); pH = 3 with H_3PO_4	UV, 270 nm or fluorimetric (λ_{ex} = 280 nm, λ_{em} = 350 nm)	Determination of naproxen and nabumetone in urine and pharmaceutical products Urine is purified by SPE (Bond-Elut Certify II)	[112]
μ Bondapak C18 (30 cm × 4 mm, 10 μm)	H_2O : acetonitrile (1 : 1) pH = 3; 2.0 ml/min	UV	Determination of proquazone from serum or urine Serum or urine is mixed with 0.2 *M* Na acetate buffer (pH = 5); the proteins were precipitated with H_2SO_4/Na_2WO_4; The obtained solution is extracted with $CHCl_3$, the organic layer is evaporated to dryness and the residue is dissolved in methanol Linearity: up to 2 μ*M* Detection limit: 0.02 μ*M*	[28]

Table 10 Compounds with alkaline character.

Stationary phase	Mobile phase	Detection	Comments	Refs.
LiChrospher 60 RP Select B (10 cm × 4.6 mm, 5 μm)	Acetonitrile : 0.05 *M* ammonium acetate (pH 7) (11 : 9); 0.9 ml/min	UV, 230 nm	Benzydamine hydrochloride is dissolved in H_2O Gels were dissolved in aqueous acetonitrile Creams were dissolved in propan-2-ol/THF	[113]
μ Bondapak C18 (30 cm × 3.9 mm), 10 μm	Methanol : acetonitrile : H_2O (9 : 10 : 1) containing 0.05% of aqueous 25% NH_3; 2 ml/min	Fluorimetric $\lambda_{ex} = 303$ nm; $\lambda_{em} = 377$ nm	Benzydamine from biological fluids Extracted from plasma or urine with ethyl ether Detection limit: 0.5 ng/ml in plasma, 1 ng/ml in urine	[29]
Novapak C18 (15 cm × 3.9 mm), 5 μm at 30°C	Acetonitrile : H_2O : anhydrous acetic acid (124 : 75 : 1), containing 5 m*M* Na-dodecyl sulfate at pH = 4; 0.9 ml/min	UV, 305 nm	Benzydamine hydrochloride in pharmaceutical products Gels were dissolved in H_2O : acetonitrile (1 : 1) Creams were dissolved in THF : propan-2-ol (1 : 2) Linearity: 18.75–600 μg/ml Detection limit: 3 μg/ml (gel); 7.8 μg/ml (cream)	[15]
ODP-50 (15 cm × 4.6 mm, 5 μm) at 55°C	5 m*M* tetrabutylammonium bromide in 0.02 *M* phosphate buffer of pH = 6.5 : acetonitrile : THF (30 : 5 : 1)	UV, 295 nm	Tiaramide metabolites in urine and plasma To 5 ml urine were added 100 μl IS, and 5 ml 0.5 *M* phosphate buffer (pH = 7); the mixture is vortexed, centrifugated 5 min at 3000 rpm, and purified with a Bond-Elut PH cartridge, washing with 4 × 10 ml ice-cold 50 m*M* phosphate buffer (pH = 7); the elution is made with 5 ml ice-cold 30% aqueous methanol To 3 ml plasma were added 60 μl IS and 5 ml 0.5 *M* phosphate buffer were added and prepared as above Linearity: up to 10 μg/ml; detection limit: 20 ng/ml	[70]
ODS-bonded material	Methanol : 15 m*M* phosphate buffer of pH 8 (11 : 9)	UV, 225 nm	Tiaramide and its metabolites were extracted with $CHCl_3$ from plasma at pH = 6; the organic phase is evaporated to dryness; the residue is dissolved in the mobile phase	[46]

Table 11 Sulphoanilide analog (nimesulide).

Stationary phase	Mobile phase	Detection	Comments	Refs.
RP C18	Linear gradient	UV, 240 and 280 nm	Nimesulide from plasma Recovery: 96.0%;	[114]
Supelcosil LC-18 DB	50 m*M* sodium phosphate buffer (pH = 3.0) : acetonitrile (gradient elution); 1 ml/min;	UV, 230 nm	Analysis of main urinary metabolites Urine is purified by solvent extraction before and after enzymatic hydrolysis	[115]
Spherisorb ODS 2 (12.5 cm × 4.6 mm)	50 m*M* phosphate buffer (pH = 5.5) containing 10% methanol; 1 ml/min	UV, 280 nm	Determination of nimesulide from biological media	[116]

Table 12 COX-2 inhibitors.

Stationary phase	Mobile phase	Detection	Comments	Refs.
BDS-Hypersil C18 (10 cm × 4.6 mm, 5 μm)	H_2O : acetonitrile (65 : 35); 1.2 ml/min	Postcolumn photolysis at 254 nm; fluorimetric $\lambda_{ex} = 250$ nm; $\lambda_{em} = 375$ nm	Determination of rofecoxib from plasma 1 ml plasma is vortex mixed 50 μl acetonitrile, 25 μl of 4-(4-methanesulponylphenyl)-3-(4-methyl phenyl)-5H-furan-2-one (IS; 0.4 μg/ml in acetonitrile) and 1 ml 0.1 *M* acetate buffer The mixture is extracted with 8 ml hexane : CH_2Cl_2 (1 : 1) and centrifuged at 1500 g for 5 min The organic layer is evaporated to dryness at 50°C under N_2 and the residue is reconstituted in 1 ml mobile phase Linearity: up to 100 ng/ml; detection limit: 0.5 ng/ml	[45]
Thermohypersil-Keystone C18 (250 mm × 4.6 mm) 5 m	H_2O : acetonitrile (60 : 40), 1 ml/min	UV, 272 nm	Determination of rofecoxib from plasma 1 ml of plasma is mixed with 0.3 ml of saturated borate solution, extracted with 3 ml of ethyl acetate and centrifuged at 3000 rpm for 10 min The organic layer is evaporated to dryness under N_2, the residue is dissolved in the mobile phase Linearity: 50–450 ng/ml; quantitation limit: 50 ng/ml	[49]
C18 (100 mm × 3.0 mm)	Acetonitrile : water (1 : 1) 0.4 ml/min	MS with chemical ionization	Determination of rofecoxib after extraction from basified plasma by solvent extraction; organic extract is dried and reconstituted in mobile phase	[59]
Novapak C 8 (150 mm × 3.8 mm)	Acetonitrile : tetrahydrofuran : sodium acetate buffer (pH = 5.0) (30 : 8 : 62)	UV, 215 nm	Determination of celecoxib plasma after SPE using C18 extraction cartridges Linearity: 40–4000 ng/ml; recovery: >88%	[117]

Octadecyl-bonded phase	Mobile phase containing acetonitrile and a phosphate buffer	UV	Determination of celecoxib from acidified plasma after SPE on a poly (divinyl benzene-co-*N*-vinyl pyrrolidone) and elution with a mixture of acetonitrile : methanol (1 : 1); the eluate is evaporated to dryness and the residue is dissolved in methanol Linearity: 0.01–2 mg/L Detection limit: 0.005 mg/L Quantitation limit: 0.002 mg/L	[65]
Zorbax XDB	Acetonitrile : water (50 : 50) containing 10 m*M* 4-methyl morpholine (pH = 6.0)	MS–MS	Determination of valdecoxib, its hydroxylated metabolite and carboxylic acid metabolite in human urine after SPE (Zymark RapidTrace automation system) Linearity: 1–200 ng/ml Quantitation limit: 1 ng/ml	[118]
Zorbax XDB-C8	Acetonitrile : water (50 : 50) containing 10 m*M* ammonium acetate	MS	Determination of valdecoxib and its hydroxylated metabolite in human plasma after SPE (Zymark RapidTrace automation system); Linearity: 0.5–200 ng/ml Quantitation limit: 0.5 ng/ml	[119]

For instance, the NSAIDs are extracted from biological media with different procedures.

1. Plasma is ultrafiltered into a centrifugal concentrator with a molecular-mass cut-off membrane, and the ultrafiltrate is centrifuged.[18]
2. The proteins from biological fluids are removed with acetonitrile,[11,17,19–25] methanol,[26] $HClO_4$/acetonitrile,[27] or H_2SO_4/Na_2WO_4,[28] and, after centrifugation, the supernatant solution is evaporated to dryness and the residue is dissolved in the mobile phase [20,22,23] or in methanol.[21]
3. By liquid–liquid extraction from the following:
   a. Urine with ethyl ether,[29] CH_2Cl_2,[30–32] CH_2Cl_2/methanol,[33] $CHCl_3$/1-chlorobutane,[34] or isooctane/isopropanol[35]
   b. Plasma with ethyl ether,[29,30,36–40] CH_2Cl_2,[30,41–43] CH_2Cl_2/hexane,[44,45] $CHCl_3$,[46] $CHCl_3$/1-chlorobutane,[34] ethyl acetate,[47–49] ethyl acetate/hexane,[14,50] ethyl acetate/cyclohexane,[51] butyl acetate,[52] hexane/propan-2-ol,[53] and tert butyl methyl ether[54]
   c. Serum with isooctane/isopropanol[35,55]
   d. Blood with ethyl acetate[45]
   e. Tissue with CH_2Cl_2,[56] CH_2Cl_2/hexane,[44] and $CHCl_3$/methanol[57]

The obtained solution is evaporated and the residue is reconstituted in mobile phase,[30,35–37,42–46,53,54,58,59] acetonitrile,[5] acetonitrile/water,[14] methanol,[21,33,40,47,56,57] triethylamine in methanol,[55] 28% CH_3CN in aqueous 10 m*M* tetrabutylammonium hydrogen sulfate, pH = 2.5.[48]

4. Separation by SPE is done at a controlled pH value for absorption and for elution.

For instance, the sample, more often in an acid medium, is applied to a C_{18} cartridge, this is washed with water,[60–62] water/*O*-phthaldehyde,[63] water/methanol/hexane,[50,64] methanol/CH_3CN,[65] CH_3CN/acetate buffer,[66] phosphate buffer/hexane,[67] ammonium formate buffer,[68] or phosphate buffer.[69,70]

For elution, solutions of methanol,[57,60] methanol/water,[36,70] acetonitrile,[43,61] acetonitrile/buffer,[66] 10% acetic acid in hexane,[64] ethyl acetate,[37] ethyl acetate/hexane,[50,67] ethyl ether/hexane,[62] or mobile phase are used.[69] The obtained solution is injected directly[63] or after evaporating to dryness in the normal condition or under nitrogen, the residue being dissolved in mobile phase,[43,50,60,61,66,68] methanol/buffer,[67] methanol,[62,64,65] or hexane/propan-2-ol.[64]

If the SPE is done on a C_8-bonded phase, then the cartridge is washed with a buffer with pH value lower than 4 and eluted with mobile phase.[71]

HPLC

Reverse-phase HPLC systems most often employ aqueous buffers, methanol, or acetonitrile as part of the mobile phase. The biological samples are injected, after purification, using one of the previously methods (e.g., liquid–liquid extraction or SPE), as well as aqueous or alcoholic extracts of pharmaceutical preparations. In addition, increased specificity of spectrophotometric detectors in HPLC often obviates the need for extraction cleanup prior the injection.

Because of the large number of individual nonsteroidal anti-inflammatory agents, the analytical conditions for HPLC will be presented for a few selected compounds.

In the context of this review, the procedures for some NSAIDs are briefly presented; for adapting a particular analytical procedure to the instrumentation available in a specific laboratory, we strongly recommend using the original literature for the most complete descriptions of the methods.

For convenience of the reader and analyst, the liquid chromatographic conditions included in this entry are summarized in tabular form (Tables 1–12). All entries are listed according to their chemical structures.

Dry-Column Chromatography

Mark Moskovitz
Dynamic Adsorbents, Inc., Atlanta, Georgia, U.S.A.

INTRODUCTION

Dry-column chromatography (DCC) is a modern chromatographic technique that allows easy and rapid transfer of the operating parameters of analytical thin-layer chromatography (TLC) to preparative column chromatography (CC). The dry-column technique bridges the gap between preparative CC and analytical TLC.

DISCUSSION

TLC has become an important technique in laboratory work, because it permits the rapid determination of the composition of complex mixtures. TLC allows the isolation of substances in micro amounts. If, however, milligrams or even grams of substance are required, CC has to be applied, as TLC would involve a high cost and excessive time. In many cases, even the so-called thick layer or prep layer is but a poor choice because of time, cost, and sometimes inadequate transferability of the parameters of the analytical technique. In addition, the transfer from TLC to CC, however, often proves to be difficult because the CC adsorbent is not usually analogous to the TLC adsorbent.

It is imperative that when transferring conditions of TLC separations to preparative columns, the conditions responsible for the TLC separation be meticulously transferred. Both CC and TLC use the same principle of separation. For normal operating conditions, a TLC layer has a chromatographic activity of II–III of the Brockmann and Schodder scale. Therefore, the sorbent used for DCC has to be brought to the same grade of activity. TLC layers often contain a fluorescent indicator in which case the DCC sorbent has to contain the same phosphor.

In TLC, the silica or alumina layer is "dry" before it is used and contacts the solvent only after it has been placed into the developing chamber. This is why, in DCC, the dry column is charged with the sample. Contrary to the normal CC, DCC is a non-elution technique. Therefore, only a limited amount of eluent is used in DCC to merely fill the interstitial volume between the adsorbent particles.

Scientific Adsorbents, Inc. DCC adsorbents, which are commercially available from Scientific Adsorbents, Inc. (Atlanta, Georgia, U.S.A.) are adjusted to meet the physical-chemical properties of TLC as closely as possible. These adjustments are made during the manufacturing cycle, and the material is packaged ready to use. With similar physical-chemical properties, the values obtained for the substances under investigation from TLC are practically identical to those obtained with DCC.

Using these especially adjusted adsorbents for DCC, one can use the same sorbent and the same solvent for the column work and can transfer the TLC results to a preparative scale column operation rapidly, saving time and money. DCC materials are available corresponding with the most common thin layers: silica DCC and alumina DCC.

These DCC sorbents have found wide use when it is necessary to scale up TLC separations in order to prepare sufficient quantities of compounds for further chemical reactions and/or analytical processes. DCC can be practically used for every separation achievable by TLC (Fig. 1).

SIMPLIFIED PROCEDURE

Preparation

1. Use the same solvent system that was developed on a TLC plate.
2. Cut a Nylon tube to the desired length. To isolate 1 g of material, use approximately 300 g of sorbent in a 1 m × 740 mm tube (Fig. 2).
3. Close the tube by rolling one end and securing it by a seal or a clip/staple.
4. Insert a small pad or wad of glass wool at the bottom of the column; pierce holes at the bottom with a needle.

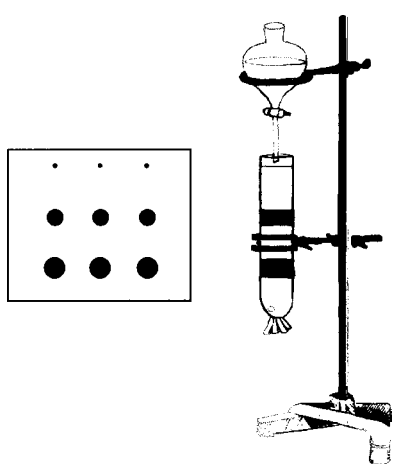

Fig. 1 Dry column chromatography (DCC).

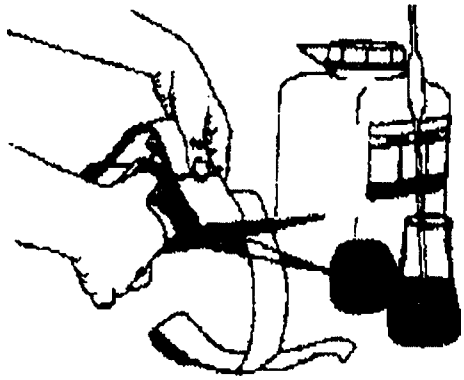

Fig. 2 Cut a nylon tube to the desired length.

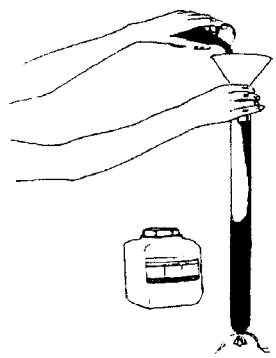

Fig. 3 Dry fill the column to three-fourths of its length.

5. Dry fill the column to three-fourths of its length (Fig. 3).
6. The sample to be separated should be combined with at least 10 times its weight of the same sorbent in a conical test tube.
7. Add an additional centimeter of sorbent on top of the sample, followed by a small pad of glass wool (Fig. 4).
8. Fasten the tube to a clamp on a stand.

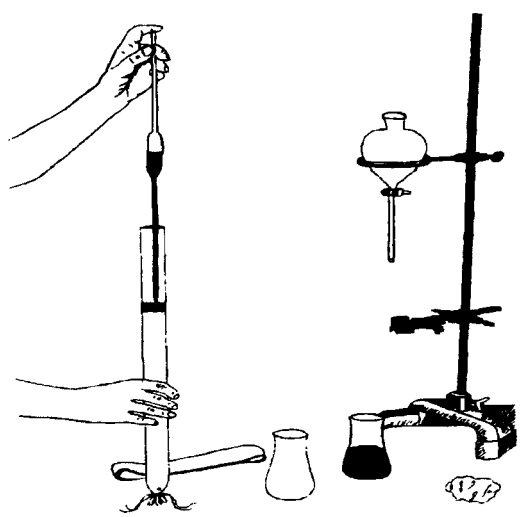

Fig. 4 Add sorbent and a small pad of glass wool.

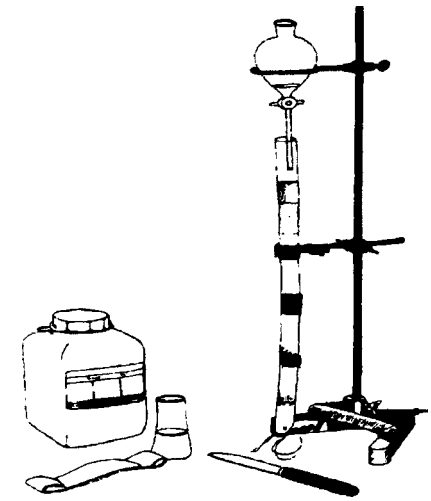

Fig. 5 Add solvent.

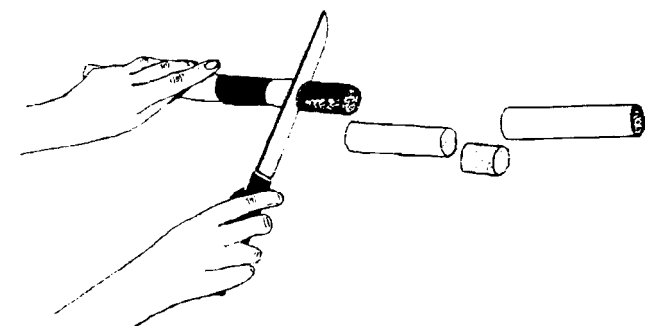

Fig. 6 Slicing the column.

9. Open the stopcock of the solvent reservoir and add solvent until it reaches the bottom of the column. Stop. Elapsed time: approximately 30 min. (Fig. 5).
10. Find the locations of the separated bands by visible, ultraviolet (UV), or UV quenching. Alternatively, cut a 1/16 in. vertical slice off the tube. Spray the exposed area with an appropriate visualization reagent and align with the untreated column to identify (mark) the separated bands.
11. Mark the location of the bands on the Nylon tube.
12. Remove the column from the clamp.
13. Slice the column into the desired sections (Fig. 6).
14. Elute the pure compounds from the sliced sections with polar solvents.

Dual CCC

David Y.W. Lee
McLean Hospital, Harvard Medical School, Belmont, Massachusetts, U.S.A.

INTRODUCTION

Dual countercurrent chromatography (DuCCC) is a powerful separation method, which allows the performance of classic countercurrent distribution in a highly efficient manner. The system consists of a multilayer coiled column integrated with two inlet and two outlet flow tubes for a non-miscible two-phase solvent system and a sample feed line, which is connected to the middle of the coiled column. Subjecting the system to a particular combination of centrifugal and planetary motions produces a unique hydrodynamic effect, which allows two immiscible liquids to flow countercurrently through the coiled column. The sample solution is fed at the middle portion of the column and eluted simultaneously through the column in opposite directions by the two solvents. This distinct feature of maintaining constant fresh two mobile phases within the coiled column permits a rich domain of applications. The principles of DuCCC and its applications in the purification of natural products and synthetic peptides are reviewed.

DISCUSSION

The development, in the 1980s, of modem high-speed countercurrent chromatography (HSCCC) based on the fundamental principles of liquid–liquid partition has caused a resurgence of interest in the separation sciences. The advantages of applying continuous liquid–liquid extraction, a process for separating of a multi-component mixture according to the differential solubility of each component in two immiscible solvents, have long been recognized. For instance, the countercurrent distribution method, which prevailed in the 1950s and 1960s, was applied successfully to fractionate commercial insulin into two subfractions, which differed only by one amide group in a molecular weight of 6000.[1] In recent years, significant improvements have been made to enhance the performance and efficiency of liquid–liquid partitioning.[2–8] The high-speed centrifugal partition chromatographic (CPC) technique utilizes a particular combination of coil orientation and planetary motion to produce a unique hydrodynamic, unilateral phase distribution of two immiscible solvents in a coiled column. The hydrodynamic properties can effectively be applied to perform a variety of liquid–liquid partition chromatographies including HSCCC,[2] foam countercurrent chromatography.[8–9] and DuCCC [10–11] In most cases, for the two-phase solvent system selected for HSCCC, one liquid phase serves as a stationary phase and the second phase is used as a mobile phase. An efficient separation can be achieved by continuous partitioning of a mixture between the stationary phase and the mobile phase.

By definition, this mode of separation should be called high-speed liquid–liquid partition chromatography or centrifugal partition chromatography, because only one solvent phase is mobile. In the case of DuCCC, for the two-phase solvents countercrossing each other inside the coiled column from opposite directions, both phases are mobile and there is no stationary phase involved.

The name "dual" countercurrent chromatography is redundant; however, it is useful to distinguish it from ordinary HSCCC. DuCCC shares several common advantages with other types of liquid–liquid partition chromatography. For instance, there are an unlimited number of two-phase solvent systems which can be employed, and there are no sample losses from irreversible adsorption or decomposition on the solid support. In addition, DuCCC is extremely powerful in separating crude natural products, which usually consist of multicomponents with an extremely wide range of polarities. In a standard operation, the crude sample is fed through the middle portion of the column. The extreme polar and non-polar components are readily eluted from the opposite ends of the column followed by components with decreasing orders of polarity in one phase and increasing order of polarity in the other phase. A component with a partition coefficient equal to 1.0 will remain inside the coiled column. Essentially, the DuCCC resembles a highly efficient performance of classic countercurrent distribution. They differ in that CCC is a dynamic process, whereas CCD is an equilibrium process. The principles, instrumentation of DuCCC, and its capabilities in natural products isolation are illustrated in the remainder of the entry.

PRINCIPLES AND MECHANISM

The fundamental principle of separation for modem DuCCC is identical to classic countercurrent distribution. It is based on the differential partitions of a multicomponent mixture between two countercrossing and immiscible solvents.The separation of a particular component within a complex mixture is based on the selection of a two-phase

solvent system, which provides an optimized partition coefficient difference between the desired component and the impurities. In other words, DuCCC and HSCCC cannot be expected to resolve all the components with one particular two-phase solvent system. Nevertheless, it is always possible to select a two-phase solvent system, which will separate the desired component. In general, the crude sample is applied to the middle of the coiled column through the sample inlet, and the extreme polar and nonpolar components are readily eluted by two immiscible solvents to opposite outlets of the column.

Contrary to the classic countercurrent distribution method, modern DuCCC allows the entire operation to be carried out in a continuous and highly efficient manner. DuCCC is based on the ingenious design of Ito.[8] A cylindrical coil holder is equipped with a planetary gear, which is coupled to an identical stationary sun gear (shaded) placed around the central axis of the centrifuge. This gear arrangement produces an epicyclic motion; the holder rotates about its own axis relative to the rotating frame and simultaneously revolves around the central axis of the centrifuge at the same angular velocity as indicated by the pair of arrows. The epicyclic rotation of the holder is necessary to unwind the twist of the five flow tubes caused by the revolution, eliminating the use of rotary seals to connect each flow tube.

As shown in Fig. 1, this unique design enables the performance of DuCCC using five flow channels connected directly to the column without using a rotational seal. When a column with a particular coil orientation is subjected to an epicyclic rotation, it produces a unique hydrodynamic phenomenon in the coiled column in which one phase entirely occupies the head side and the other phase occupies the tail side of the coil column. This unilateral phase distribution enables the performance of DuCCC in an efficient manner. A theoretical calculation of the hydrodynamic forces resulting from such an epicyclic rotation is very complicated and has not been elucidated.

METHODS AND APPARATUS

The DuCCC experiments are performed with a tabletop (type J) high-speed plant centrifuge equipped with a multilayer coiled column connected to five flow channels. The multilayer coiled column is prepared from 2.6 mm inner diameter PTFE tubing by winding it coaxilially onto the holder to a total volume capacity of 400 ml. The multilayer coiled column is subjected to an epicyclic rotation at 500–800 rpm. The fractions are collected simultaneously from both ends of the column and analyzed by thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC).[8,12]

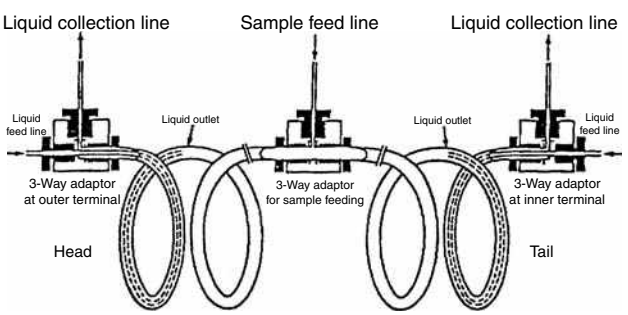

Fig. 1 Column design for DuCCC.

APPLICATIONS

In the past decade, the rapid development of sophisticated spectroscopic techniques, including various two-dimensional nuclear magnetic resonance (2D NMR) methods, automated instrumentation and routine availability of x-ray crystallography has greatly simplified structural elucidation in natural product investigations. Consequently, the challenge to today's chemists has shifted to one's capability of isolating the bioactive components from crude extracts of either plants or animals. The extract of crude natural products usually is comprised of hundreds of components over a wide range of polarities. In isolating these natural products, it is essential to preserve the biological activity while performing chromatographic purifications. DuCCC represents one of the most efficient methods for isolation of the desired compound from a complex mixture.

Dual CCC has several advantages over HSCCC or CPC[13] in dealing with crude natural products. One distinct feature of DuCCC is the capability of performing normal-phase and reversed-phase elusions simultaneously. This provides a highly efficient and unique method for separation of crude natural products. In many instances, fractions eluted from DuCCC are pure enough for recrystallization or structural study. For example, an HPLC trace of the crude ethanol extract of *Schisandra rubriflora* shows that the major bioactive lignan, schisanhenol, is closely eluted with its acetate, it has been a major problem to isolate the pure schisanhenol. The fractions collected from DuCCC after injection of a crude ethanol extract of *Schisandra rubriflora* (125 mg) were analyzed by TLC and reversed-phase HPLC. The solvent system employed for DuCCC was hexane:ethyl acetate:methanol:water (10:5:5:1).

The upper phase, being less polar than the lower phase, results in a sequence of elution similar to normal-phase chromatography, whereas the lower phase provides a sequence of elution resembling reversed-phase chromatography. The bioactive components, schisanhenol acetate and schisanhenol, were eluted in the lower phase. Reversed-phase HPLC analyses of fractions 36–40 accounted for 32 mg of almost pure schisanhenol.[6] A total of 4 mg of schisanhenol acetate was also obtained from fractions 50–57. As evidenced by this experiment, DuCCC offers an excellent method for semipreparative isolation of bioactive components from very crude natural products.[11] The

isolation of the topoisomerase inhibitor boswellic acid acetate from its triterpenoic acid mixture has also been accomplished by DuCCC.[12] As shown in Fig. 2, when an isomeric mixture of triterpenoic acids (400 mg) was subjected to DuCCC, using a hexane:ethanol:water (6:5:1) as the solvent system, 215 mg of the boswellic acid acetate and 135 mg of the corresponding boswellic acid were obtained. Some highly polar impurities were eluted immediately in the solvent front, from fraction 1 to 4. The isomeric boswellic acid was eluted in the lower-phase solvent and the less polar acetates were eluted simultaneously in the upper-phase solvent. Although the isomers were only partially resolved by DuCCC, this experiment demonstrates that DuCCC is a highly efficient system for preparative purification.

The conformationally restricted cyclic, disulfide containing, enkephalin analogue (D-Pen, D-Pen) enkephalin (DPDPE) was synthesized by solid-phase methods. Its purification was accomplished previously by partition on Sephadex G-25 block polymerizate using the solvent system (1-butanol:acetic acid:water: 4:1:5), followed by gel filtration on Sephadex G-15 with 30% acetic acid as the eluent.[14] DuCCC demonstrated a highly efficient and one step method for the purification of DPDPE. The crude DPDPE (500 mg), which contained impurities and salts, was purified by DuCCC with a two-phase solvent system consisting of 1-butanol containing 0.1% TFA and water also containing 0.1% TFA in a 1:1 (v/v) ratio. The desired DPDPE was eluted from the upper phase in fractions 15–19. The purity of each fraction collected was monitored by HPLC. A total of 24 mg pure DPDPE was obtained within 2 hr. As evidenced, DuCCC can be a highly costeffective procedure for the purification of polypeptides.

CONCLUSION

The capability and efficiency of DuCCC in performing classic countercurrent distribution has been demonstrated in the isolation of bioactive lignans and triterpenoic acids from crude natural products and in the purification of synthetic polypeptides. DuCCC provides excellent resolution and sample loading capacity. It offers a unique feature of elution of the non-polar components in the upper-phase solvent (assuming the upper phase is less polar than the lower phase) and concomitant elution of the polar components in the lower phase. This capability results in an efficient and convenient preparative method for purification of the crude complex mixture. The capability of DuCCC has not yet been fully explored. For instance, a particular solvent system can be selected to give the

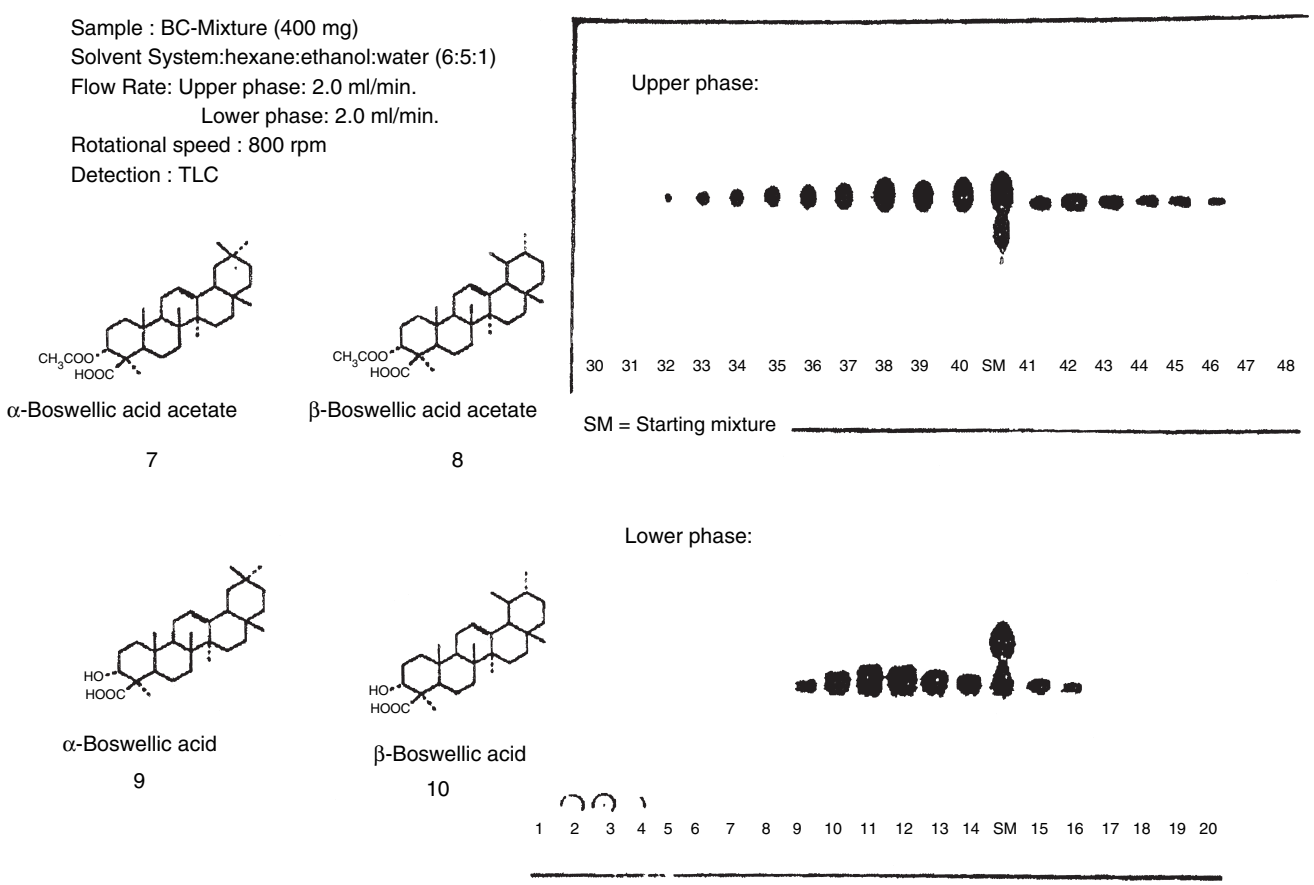

Fig. 2 DuCCC of triterpenoic acids.

desired bioactive component a partition coefficient of 1. This will allow the "stripping" of the crude extract with DuCCC to remove the impurities or inactive components. Consequently, the bioactive component will be concentrated inside the column for subsequent collection. This strategy can also be applied to extract and concentrate certain metabolites in biological fluids such as urine or plasma. Because there is no saturation of the stationary phase, a large amount of sample can also be processed by DuCCC. In addition, the system can be easily automated with computer-assisted sample injection and fractionation.

Eddy Diffusion in LC

J.E. Haky
Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.

INTRODUCTION

Among the causes of widening of peaks corresponding to components of a mixture undergoing separation by liquid chromatography (LC) is the phenomenon known as eddy diffusion. This results from molecules of a solute traversing a packed bed of a column through different pathways, in and around the stationary phase. Some molecules travel more rapidly through the column through more open, shorter pathways, whereas others will encounter longer, restricted areas and lag behind. The result is a solute band that passes through the column with a Gaussian distribution around its center.[1]

DISCUSSION

The degree of band broadening of any chromatographic peak may be described in terms of the height equivalent to a theoretical plate, H, given by

$$H = \frac{L}{N} \tag{1}$$

where L is the length of the column (usually measured in cm) and N is the number of theoretical plates, which can be calculated from Eq. 2, where t_R and W are the retention time and width of the peak of interest, respectively:

$$N = 16\left(\frac{t_R}{W}\right)^2 \tag{2}$$

Because higher values of N correspond to lower degrees of band broadening and narrower peaks, the opposite is true for H. Therefore, the goal of any chromatographic separation is to obtain the lowest possible values for H.

The contribution of eddy diffusion and other factors to band broadening in LC can be quantitatively described by the following equation, which relates the column plate height H to the linear velocity of the solute, μ:

$$H = A\mu^{0.33} + \frac{B}{\mu} + C\mu + D\mu \tag{3}$$

where A, B, C, and D are constants for a given column.[2] The linear velocity μ is related to the mobile-phase flow rate and is determined by

$$\mu = \frac{L}{t_0} \tag{4}$$

where t_0 (the so-called "dead time") is determined from the retention time of a solute which is known not to interact with the stationary phase of the column. The first term in Eq. 4, $A\mu^{0.33}$, includes the contribution of eddy diffusion to chromatographic band broadening. This term, which is dependent on the cube root of the linear velocity, is less dependent on mobilephase flow rate than the other terms in the equation, which are either directly or inversely proportional to linear velocity.

Minimizing eddy diffusion in an LC column results in a lower $A\mu^{0.33}$ term in Eq. 3, which minimizes band spreading and gives narrower chromatographic peaks. The most common methods used for this purpose, in LC, are the following: a) Using a column of the smallest practical diameter. This obviously reduces the number of alternate pathways which a solute can take through the column; b) Using a stationary phase of smallest practical particle size. Giddings[3] and others have shown that the effects of eddy diffusion are directly proportional to the average diameter of stationary-phase particles. Thus, smaller stationary-phase particles give narrower peaks; c) Making sure the column is uniformly packed. Again, this limits open space in the column, thus minimizing the number of pathways.

Those who prepare and/or manufacture LC columns must use the above methods to limit the effects of eddy diffusion on the chromatographic separations. However, there are practical limitations. Column and stationary-phase particle diameters can only be reduced to points that are compatible with the pressure limitations of the pumps used in chromatographic instruments and the required sample capacities of the columns. The degree of training and experience of those who pack the columns

may also limit the quality of the procedure used in packing the column. Nevertheless, most commercial manufacturers of LC columns have adopted column designs and packing procedures which generally reduce the effects of eddy diffusion on modern LC separations to an inconsequential level. Still, these effects may increase as a column ages, and practicing chromatographers should be on the watch for them.

Efficiency in Chromatography

Nelu Grinberg
Analytical Research Department, Merck Research Laboratories, Rahway, New Jersey, U.S.A.

Rosario LoBrutto
Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

One of the most important characteristics of a chromatographic system is the efficiency or the number of theoretical plates, *N*.

DISCUSSION

The number of theoretical plates can be defined from a chromatogram of a single band as

$$N = \left(\frac{t_R}{\sigma_t}\right)^2 = \frac{L^2}{{\sigma_t}^2} \tag{1}$$

where, for a Gaussian shaped peak, t_R is the time for elution of the band center, σ_t is the band variance in time units, and L is the column length.[1] N is a dimensionless quantity; it can also be expressed as a function of the band elution volume and variance in volume units:

$$N = \left(\frac{V_R}{\sigma_v}\right)^2 = 5.56\left(\frac{t_R}{W_{1/2}}\right)^2 \tag{2}$$

In a chromatographic system, it is desirable to have a high column plate number. The column plate number increases with several factors:[2]

- Well-packed column
- Longer columns
- Smaller column packing particles
- Lower mobile-phase viscosity and higher temperature
- Smaller sample molecules
- Minimum extracolumn effects.

In an open-bed system, N can be measured from the distance passed by a zone along the bed:

$$N = \left(\frac{d_R}{\sigma_d}\right)^2 \tag{3}$$

where d_R is the distance from the point of sample application to the point of the band center and σ_d is the variance of the band in distance units.[1]

In fact, the plate theory describes the movement of a particular zone through the chromatographic bed. As the zone is washed through the first several plates, a highly discontinuous concentration profile is obtained, with the solute being distributed in plates following the Poisson distribution.[3] At an intermediate stage (approximately 30–50 plates), much of the abrupt discontinuity disappears due to a similar concentration of the analyte in the neighboring plates. As the process continues (after 100 plates), the concentration profile is smooth and, even though the distribution is still Poisson, it can be approximated by a Gaussian curve. The standard deviation, of the Gaussian curve, which is a direct measure of the zone spreading, is found to be

$$\sigma = \sqrt{HL} \tag{4}$$

where H is the plate height and L is the distance migrated by the center of the zone. In practice, the plate height is used to describe the zone spreading, including both nonequilibrium and longitudinal effects. In a uniform column, free from concentration and velocity gradients, the plate height is defined as

$$H = \frac{\sigma^2}{L} \tag{5}$$

In a non-uniform column, the zone spreading varies from point to point and its local value is

$$H = \frac{d\sigma^2}{dL} \tag{6}$$

which represents the increment of plate height in the variance σ^2 per unit length of migration. In practice, the smaller the value of H, the smaller the magnitude of band spreading per unit length of the column. The determination of H does not require the measurement of, as long as N is known. Thus, combining Eqs. 1 and 6 yields[4]

$$H = L\left(\frac{\sigma}{L}\right)^2 = \frac{L}{N} \tag{7}$$

In practice, because the separation in a particular chromatographic column is linked to the time spent by the analyte in the stationary phase and the time spent by the analyte in the mobile phase is irrelevant for the separation, a new parameter is defined (i.e., *effective plate number*, N_{eff}). The effective plate number is related to the separation factor k' and N by

$$N_{\text{eff}} = N\left(\frac{k'}{1+k'}\right)^2 \tag{8}$$

Similarly, an expression for H_{eff} can be written

$$H_{\text{eff}} = H\left(\frac{1+k'}{k'}\right)^2 \tag{9}$$

The effective parameters are more meaningful when comparing different columns.[4]

There are several major contributions that will influence the band broadening and, consequently, H:[5] eddy diffusion, mobile-phase mass transfer, longitudinal diffusion, stagnant mobile-phase mass transfer, and stationary-phase mass transfer. The effect of each process on the band broadening and, consequently, on the plate height is related to all the experimental variables: mobile-phase velocity, u; particle diameter, d_p; sample diffusion coefficient in the mobile phase, D_m; the thickness of the stationary-phase layer, d_f; and the sample diffusion coefficient in the stationary phase, D_s. In general, H will vary with the velocity of the mobile phase, u, as it travels through the column. In a gas chromatography (GC) system, a plot of u vs. H will lead to a curve which has a hyperbolic shape,[6] characterized by the equation

$$H = A + \frac{B}{u} + Cu \tag{10}$$

Eq. 10 is known as the van Deemter equation, and no correction was made for gas compressibility. Using the reduced parameters $h = Hd_p$ and $v = ud_pD_m$, Eq. 10 becomes

$$h = a + \frac{b}{v} + cv \tag{11}$$

where A, B, C, a, b, and c are constants for a particular sample compound and set of experimental conditions as the flow rate varies. The B term in Eq. 10 relates to band broadening occurring by diffusion in the gas phase in the longitudinal direction of the column. According to Einstein's equation for diffusion,

$$\sigma^2 = 2D_m t_0 = \frac{2D_m L}{u} \tag{12}$$

Because $H = \sigma^2 L$, the B term becomes

$$B = 2\frac{D_m}{u} \tag{13}$$

The inverse velocity term in Eq. 13 becomes important at low velocities. Because the D_m in liquids is 10^5 times smaller than in gases, the longitudinal term plays no practical role in band broadening in LC. The A term in Eq. 10 describes the non-homogeneous flow, also called eddy diffusion. In this case,

$$\frac{\sigma^2}{L} = 2\lambda d_p = A \tag{14}$$

where λ is a packing correction factor of $\sim$0.5. In classical GC, the A term is a constant, representing a lower limit on column efficiency, equivalent to $H = d_p$ or $h = 1$.

At velocities above $H_{\min}$, the C term controls H and relates to non-equilibrium resulting from resistance to mass transfer in the stationary and mobile phases.[6]

In HPLC, the van Deemter equation still holds. However, Giddings[3] argued that the equation is too simplistic because it ignores the coupling that exists between the flow velocity and the radial diffusion in the void space of the packing around the particles. He suggested replacing the term A by a term $a(1 + bu^{-1})$ to account for the flow velocity, because both the eddy diffusion and the radial diffusion are responsible for the transfer of the molecules between the different flow paths of unequal velocity. To include the coupling between the laminar flow and the molecular diffusion in porous media, Horvath and Lin[7] introduced a new parameter, δ, which is the thickness of the stagnant film surrounding each stationary-phase particle. However, at high velocities required in high-performance liquid chromatography (HPLC), Horvath and Lin's model reduces to the Knox equation, which is a variation of the van Deemter equation:[8]

$$h = av^{0.33} + \frac{b}{v} + cv \tag{15}$$

where a, b, and c are empirical parameters related to the analyte and the experimental flow rate conditions.

Efficiency of a TLC Plate

Wojciech Markowski
Department of Inorganic and Analytical Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

Chromatography, by definition, is a separation methodology for a multicomponent sample mixture, which is based on differentiating movement zones of the sample. An essential feature of chromatographic separation is that the components of the sample are transported through the separation medium—in the case of thin-layer chromatography (TLC), through an open bed. Differences in interaction with the medium lead to a selective redistribution of the component zones, from overlapping zones at the start following injection, toward largely individual regions inside the separation medium. The appearance of individual component zones, after the development process, can be recorded with the aid of scanning densitometry, to convert the plate chromatogram into realistic two-dimensional representation of the chromatographic process in a form suitable for evaluation of kinetic parameters. The underlying fundamental processes responsible for chromatographic separations can be explained by thermodynamic and kinetic considerations. Thermodynamic relationships are responsible for retention and selectivity, and kinetic properties are responsible for band broadening. Thus, the position and separation of peaks in a chromatogram are thermodynamic properties, whereas the axial dimensions of the peaks are governed by kinetic considerations, and both phenomena must be considered to optimize resolution. As Giddings[1] emphases in his book, "separation is the art and science of maximizing separative transport relative to the dispersive transport."

RESOLUTION

The most useful criterion for the estimation of the quality of a separation is the resolution. The resolution is given by:[2]

$$R_s = \frac{(z_f - z_o)(R_{f(2)} - R_{f(1)})}{0.5(w_1 + w_2)} \quad (1)$$

where $R_{f(1)}$ and $R_{f(2)}$ are the R_f values of chromatographic spots 1 and 2, respectively; and w_1 and w_2 are widths of spots at the base. Eq. 1 clearly shows the two competing aspects of a chromatographic separation: the separation distance achieved by the primary separation process (numerator) is opposed by the "blurring" action of the zone broadening (denominator). Eq. 1 allows for direct calculation of R_s based on the parameters measured on the chromatogram. Eq. 1 can be transformed to the form:[3]

$$R_s = (1 - R_{f(1)})\left[1 - \frac{R_{f(1)}}{R_{f(2)}}\right]N^{0.5} \quad (2)$$

Eq. 2 demonstrates that the plate resolution, as in other forms of chromatography, depends on the number of theoretical plates N, the selectivity, and the retention coefficient of the solute for the particular layer concerned.

CONCEPT OF THEORETICAL PLATES AND THEIR MEASUREMENT

The measurement of plate efficiency is depicted in Fig. 1a and b.[4] The number of "theoretical plates" is a measure of the quality or "efficiency" of a chromatographic layer. By analogy with the theoretical plates of a distillation column, the chromatographic separations distance and the layer are divided into theoretical separation plates. For a given problem, sorbent, and solvent, a specific minimum number of theoretical plates is necessary to achieve the desired separation. For a capillary flow-controlled system, the mobile-phase velocity is not constant throughout the chromatogram and, at any position within the chromatogram, its value depends on the system variables. The mobile-phase velocity is not under external control and its range cannot be varied independently to study the relationship between the layer plate height and the mobile-phase velocity. Because all zones do not migrate the same distance in TLC, individual zones experience only those theoretical plates through which they travel and the plate height is directly dependent on the migration distance. A further complicating factor is that the size of the starting zone applied to the layer is always a finite value with respect to the size of a developed zone. Therefore, it is not adequate to use the measured zone width as the starting point from which to determine the extent of zone broadening for the layer. The plate number N can be experimentally determined via the "H value" (i.e., "height equivalent to a theoretical plate," or HETP).[5] The measured H value is an average over the separation length and the symbol H_{obs} or $\bar{H}$ is given and is obtained from the integration of the expression for the local plate height H_{loc} (quantity introduced by Giddings[1,4]):

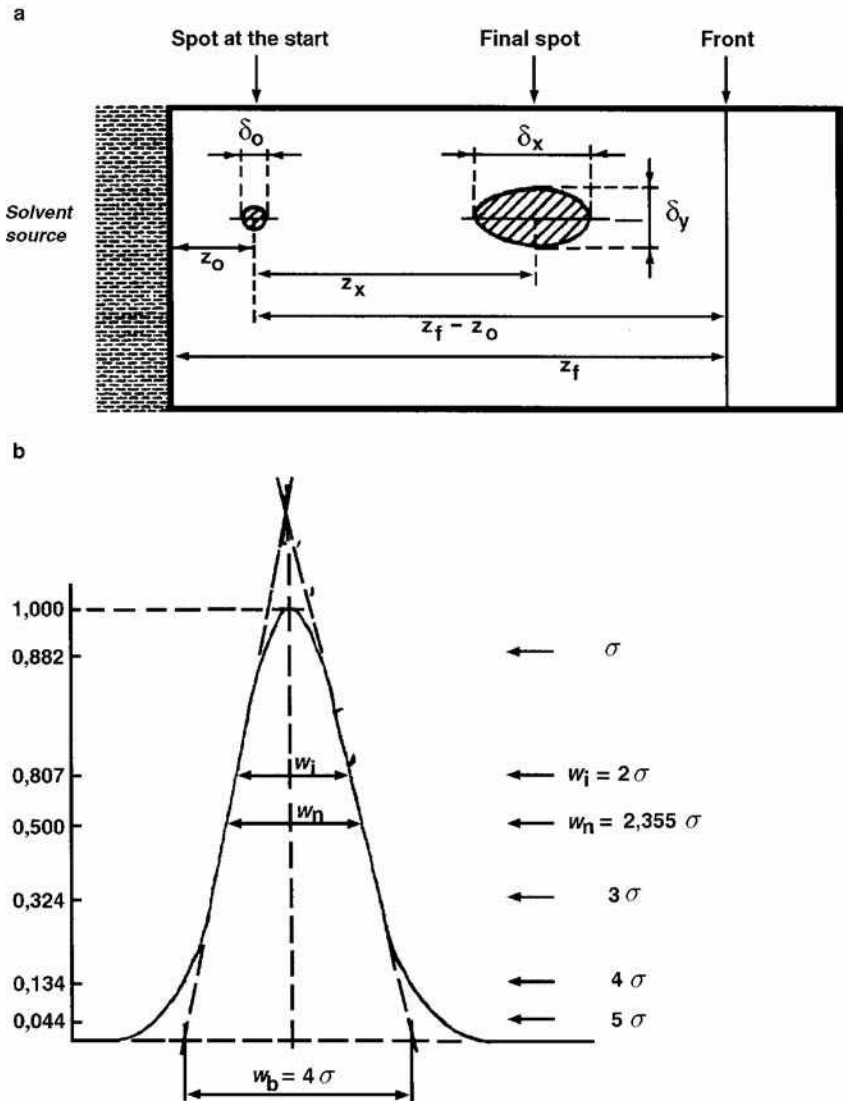

Fig. 1 a, Basic symbols for TLC spot migration. z_x is the migration length of the spot, $z_f - z_o$ is the separation length, and z_f is the front migration length; and b, Width of a Gaussian band at different percentages of maximum height.

$$N = \frac{z_f - z_o}{H} \tag{3}$$

$$H_{loc} = \frac{d\sigma_x^2}{dz} \tag{4}$$

and, in practical terms,

$$\overline{H} = H_{obs} = \frac{\int_{z_o}^{z_x} H_{loc} dz}{\int_{z_o}^{z_x} dz} = \frac{\sigma_x^2}{z_x} = \frac{b_{0.5}^2}{5.54 z_x} \tag{5}$$

The average plate number N of the whole separation length is:

$$N \approx \overline{N} = \frac{z_f - z_o}{H_{obs}} = \frac{z_x}{H_{obs} R_f} \tag{6}$$

Hence, the average theoretical plate number can be calculated from the experimental data for $b_{0.5}$ and the lengths z_f and z_x in the chromatogram. To obtain reliable H values, it is recommended that the experiment comply with the following rules:[4]

1. The band maximum should be at least 10 times greater than the detection limit.
2. Asymmetrical or poorly resolved spots should not be used for determining H.
3. Only σ_{chrom}^2 should be used.

Failure to do this results in excessively high H values. The measured zone variance σ_x^2 in the direction of flow is composed of:

$$\sigma_x^2 = \sigma_{spotting}^2 + \sigma_{chrom}^2 + \sigma_{inst}^2 + \sigma_{other}^2 \tag{7}$$

The contribution of the length of the starting zone to the length of the separated zone could be removed by considering their variances, such that:

$$\sigma_{\text{chrom}}{}^2 = \sigma_{\text{x}}{}^2 - \sigma_{\text{spotting}}{}^2 \quad (8)$$

where $\sigma_{\text{x}}{}^2$ is the variance of the developed zone, $\sigma_{\text{chrom}}{}^2$ is the variance due to the zone expansion during the migration through the layer, and $\sigma_{\text{spotting}}{}^2$ is the variance associated with sample application; here, we are assuming that the contributions to zone broadening associated with the properties of the detection and recording devices $\sigma_{\text{inst}}{}^2$ are negligible. The form of the starting zone is immaterial—only its dimension and sample distribution along its axis parallel to the direction of development (first-order approximation) are significant. It is obvious that the characteristic dimension of the starting zone in the direction of migration is never infinitely small compared with the same characteristic dimension of the zone after normal development. The determination of peak variance is straightforward for developed zones, but presents some difficulty for the undeveloped starting zone. The starting zone is applied to the dry layer. At the start of the migration process, it is contacted by the advancing mobile phase, which is moving at its highest velocity and is probably not fully saturated at its leading edge. Several processes take place quickly, which can lead to changes in the dimensions of the starting zone at the moment the chromatogram begins. The solvent front contacts the bottom portion of the starting zone first, pushing it forward with a characteristic migration velocity (which depends on the solute R_{f} value) into the upper portion of the starting zone, which is fixed in position until it is contacted by the advancing mobile phase. This causes a reconcentration of the starting zone and a reduction of its characteristic dimension in the direction of development. In addition, because the flow of mobile phase is unsaturated, all the pores holding sample will not be filled simultaneously; adsorbed samples may not be displaced from the sorbent surface instantaneously, and localized solvent saturation may limit the rate of solute dissolution in the mobile phase. The dimensions of the starting zone in the direction of migration are too large to ignore.

It can be assumed that the variance of the starting zone is equivalent to the properties of the sample zone, after it has been transported a few millimeters from its point of application by the mobile phase. In this way, some account is taken of the capacity of the mobile phase to reshape the deposited sample zone at the beginning of the chromatogram.[6]

CAPILLARY FLOW

As normally practiced in TLC, capillary forces control the migration of the mobile phase through the layer. Under these conditions, the velocity at which the solvent front moves is a function of the distance of the front from the solvent entry position and declines as this distance increases.[4] There are two consequences of this effect:

1. The mobile-phase velocity is not constant throughout the chromatogram.
2. The mobile-phase velocity is set by the system variables and cannot be independently optimized unless forced flow development conditions are used.

If the migration distance is not excessively long, then the solvent front position as a function of time is adequately described by:

$$z_{\text{f}}{}^2 = \chi t \quad (9)$$

where z_{f} is the distance of the solvent front position above the solvent entry position, χ is the mobile-phase velocity constant, and t is the elapsed time since the solvent commenced migration through the layer. At any position on the layer, the solvent front will be moving with a velocity given by:

$$u_{\text{f}} = \frac{\chi}{2z_{\text{f}}} \quad (10)$$

There are two features of importance when using Eqs. 9 and 10. The velocity constant χ depends on the identity of the solvent; layer characteristics such as average particle size, layer permeability, layer thickness, etc.; and the state of equilibrium between solvent vapors in contact with the layer and the bulk solvent moving through the layer. As the solvent permeates the layer, the channels of narrower diameter are filled first, leading to more rapid advancement of the mobile phase. Large pores below the solvent front fill more slowly, resulting in an increase in the thickness of the layer of mobile phase. The bulk mobile-phase velocity, representing saturated flow through the region occupied by the sample zones, is moving at a lower velocity than the solvent u_{f} front velocity. As a reasonable approximation, the bulk solvent velocity is usually taken to be 0.8 u_{f}.[6] The velocity constant χ is related to the experimental condition by Eq. 11:

$$\chi = 2\kappa_{\text{o}} d_{\text{p}} \frac{\gamma}{\eta} \cos\theta \quad (11)$$

where κ_{o} is the layer permeability constant, d_{p} is the average particle diameter, γ is the surface tension, η is the viscosity of the mobile phase, and θ is the contact angle. The layer permeability constant is dimensionless and takes into account the effect of porosity on the permeability of the layer and the difference between the bulk liquid velocity and the solvent front velocity. A typical value of permeability is $1 - 2 \times 10^{-3}$,[6] virtually identical

with typical column values. Assuming a narrow particle size distribution, Eq. 11 indicates that the velocity constant should increase linearly with average particle size. The solvent front velocity should be larger for coarse particle layers than for fine particle layers, in good agreement with experimental observations. In addition, from Eq. 11, we see that the velocity constant depends linearly on the ratio of the surface tension of the solvent to its viscosity, and the solvents that maximize this ratio are most useful for TLC. The contact angle for most mobile phases on polar adsorbent layers is generally close to zero and there does not exist the problem of wetting. In the case of reversed-phase layers containing bonded, long-chain, alkyl groups, it is not possible to apply the mobile phase with a content of water below 40%. The optimum mobile-phase velocity for a separation can be established by forced flow development[6] and it is considerably higher than the mobile-phase velocity obtained by the use of capillary flow under different experimental conditions. This is illustrated in Fig. 2(a) and (b).

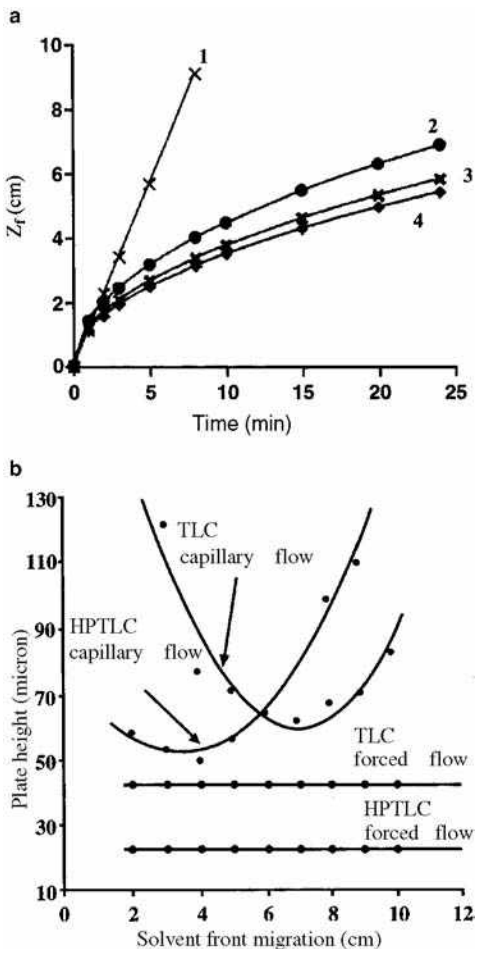

Fig. 2 a, Plot of solvent front migration distance z_f for dichloromethane on a high-performance silica gel layer as a function of time under different experimental conditions. Identification: 1 = forced flow development at u_{opt}; 2 = capillary flow in a saturated developing chamber; 3 = capillary flow in a sandwich chamber; and 4 = capillary flow in an unsaturated developing chamber; and b, Variation of the observed plate height as a function of the solvent front migration distance for conventional TLC and high-performance thin-layer chromatography (HPTLC) silica layers under capillary flow and forced flow (u_{opt}) conditions.

BAND-BROADENING INTERPRETATION

The kinetic contributions to zone broadening are evaluated by fitting data for the column plate height, as a function of the mobile-phase velocity, to a mathematical model describing the relationship between the two parameters. Several models have been used in the above experiment, but those by de Ligny and Remijnsee[7] and Knox and Pryde,[12] and developed by Guiochon and Siouffi,[9] are most widely used and, at least for a first approximation, allow for comparison and determination of the differences between TLC and column chromatography:[7–11]

$$\bar{H} = \frac{3A_k d^{5/3}\theta^{1/3}}{2(2D_m)^{1/3} z_f^{1/3}} \frac{(z_f^{2/3} - z_0^{2/3})}{z_f - z_o} + \frac{B_k D_m}{\theta d_p}(z_f - z_o) + \frac{C_k \theta d_p^{3}}{2D_m(z_f - z_o)} \lg \frac{z_f}{z_o} \quad (12)$$

where d_p is the average particle size, χ is the mobile-phase velocity constant, and D_m is the solute diffusion coefficient in the mobile phase. A_k, B_k, and C_k are dimensionless coefficients characterizing the packing quality (A_k), the diffusion in the mobile phase (B_k), and the resistance to mass transfer (C_k). Eq. 12 can be helpful in the interpretation of the influence of layer structure on plate height. Results of simulations of the relationship between plate height and different parameters are presented in Fig. 3 and parameters used in simulation are presented in Table 1.

UNIDIMENSIONAL MULTIPLE DEVELOPMENT

Unidimensional multiple development provides a complementary approach to forced flow for minimizing zone broadening.[13] All unidimensional multiple development techniques employ successive repeated development of the layer in the same direction, with removal of the mobile phase between developments. Approaches differ in the changes made (e.g., mobile-phase composition and solvent front migration distance) between consecutive development steps; the total number of successive development steps employed can also be varied. Capillary forces are responsible for migration

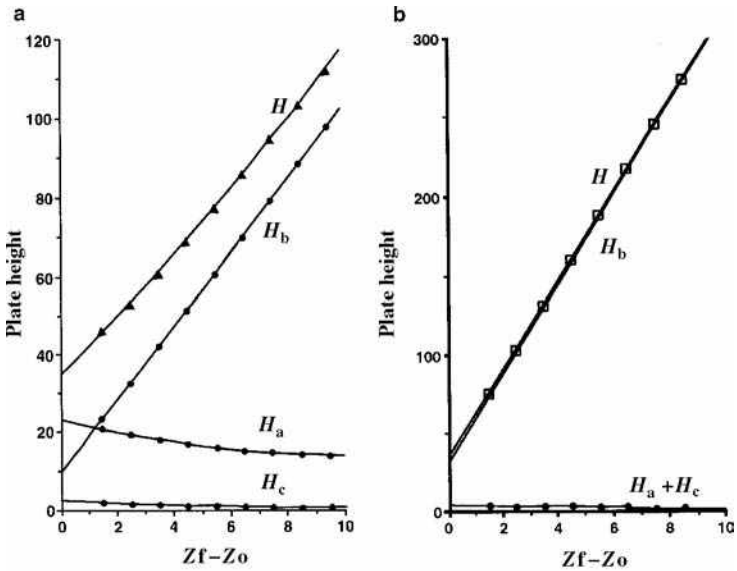

Fig. 3 a, Simulation of the average plate height for a TLC layer by use (Eq. 12) and properties listed in Table 1. The contribution from flow anisotropy is represented by H_a, that from longitudinal diffusion by H_b, and that from resistance to mass transfer by H_c; and b, Simulation of the average plate height for an HPTLC layer by use (Eq. 12) and properties listed in Table 1. The contribution from flow anisotropy is represented by H_a, that from longitudinal diffusion by H_b, and that from resistance to mass transfer by H_c.

of the mobile phase, but a zone-focusing mechanism is used to counteract the normal zone broadening that occurs in each successive development. Each time the solvent front traverses the stationary sample zone, the zone is compressed in the direction of development. The compression occurs because the mobile phase contacts the bottom edge of the zone first; here, the sample molecules start to move forward before those molecules are still ahead of the solvent front. When the solvent front has moved beyond the zone, the focused zone migrates and is subject to the normal zone-broadening mechanisms. Experiment indicates that, beyond a minimum number of development steps, zone widths converge to a constant value that is roughly independent of migration distance.

SOLVENT GRADIENTS

A similar phenomenon, compression of chromatographic zones, occurs in gradient TLC when the concentration of mobile phase delivered to the layer is varied in a stepwise manner. In the case where the concentration front traverses the sample zone, the zone is compressed in the direction of development. The compression takes place on the length equal to the diameter of the spot. Application of multicomponent eluent for the development of the layer, when the components differ in polarity, causes the creation of a natural gradient in the mobile phase. The gradient appears as multiconcentration fronts.[14] As in step gradients, the compression takes place and the widths of the spots are much smaller. This should improve resolution.

Table 1 Characteristic properties of precoated layers and HPLC columns.

Property	HPTLC	TLC	HPLC
Porosity total	0.65–0.70	0.65–0.75	0.8–0.9
Interparticle	0.35–0.45	0.35–0.45	0.4–0.5
Intraparticle	0.28	0.28	0.4–0.5
Flow resistance parameter	875–1500	600–1200	500–1000
Apparent particle size (μm)	5–7	8–10	d_p
Minimum plate height (μm)	22–25	35–45	2–3 d_p
Optimum velocity (cm/sec)	0.03–0.05	0.02–0.05	0.2
Minimum reduced plate height	3.5–4.5	3.5–4.5	1.5–3
Optimum reduced velocity	0.7–1.0	0.6–1.2	3–5
Separation impedance 9,000–70,000	10,500–19,800	11,100–60,200	2,000–9,000
Mean pore diameter (Si 60) (nm)	5.9–7.0	6.1–7.0	
Knox coefficients			
A_k	0.75	2.83	0.5–1
B_k	1.56	1.18	1–4
C_k	1.42	0.84	0.05

Adapted from Poole[6] and Knox & Pryde.[12]

Table 2 Zone capacity calculated or predicted for different separation conditions in TLC.[6]

Method	Dimensions	Zone capacity
(A) *Predictions from theory*		
Capillary flow	1	<25
Forced flow	1	<80 (up to 150, depending on pressure limit)
Capillary flow	2	<400
Forced flow	2	Several thousands
(B) *Based on experimental observations*		
Capillary flow	1	12–14
Forced flow	1	30–40
Capillary flow (AMD)	1	30–40
Capillary flow	2	~100
2		
(C) *Predictions based on results in (B)*		
Forced flow	2	~1500
Capillary flow (AMD)	2	~1500

MOVING PLATE

Changing the solvent entry position for each, or some, of the development steps enables the separation in each segment to be achieved in the shortest possible time under favorable capillary flow conditions. With as few as 10 developments, it is relatively easy to achieve 15,000–25,000 apparent theoretical plates for a zone migration distance of 6–11 cm.[6,15,16]

ZONE CAPACITY

The potential of a chromatographic system to achieve a particular separation can be estimated from its zone capacity, also referred to as the separation number (SN). It provides a method of comparison of different TLC systems and an indication of the possibility of separating a given mixture:[8]

$$\mathrm{SN} = \frac{z_\mathrm{f}}{b_0 + b_1} - 1 \qquad (13)$$

where b_0 is the extrapolated width of the starting spot at half-height of the concentration curve, and b_1 is the extrapolated width of the spot with $R_\mathrm{f} = 1$. Some typical results for the zone capacity, either predicted from theory or by experiment, are summarized in Table 2.[6] Experimental observations are indicated for zone capacity of approximately 12–14 for a single development in a capillary flow, increasing to 30–40 if forced flow is used. Use of capillary flow and the zone-focusing mechanism of multiple development leads to a zone capacity similar to that for forced flow.

CONCLUSIONS

In capillary flow conditions, there is an inadequate range of mobile-phase velocities, which does not allow working at u_opt values; the role of the binder remains not completely clear. The zone-focusing mechanism causes an increase of separation performance of the system in the most simple way. Forced flow offers a modest increase in performance with a reduction in separation time.

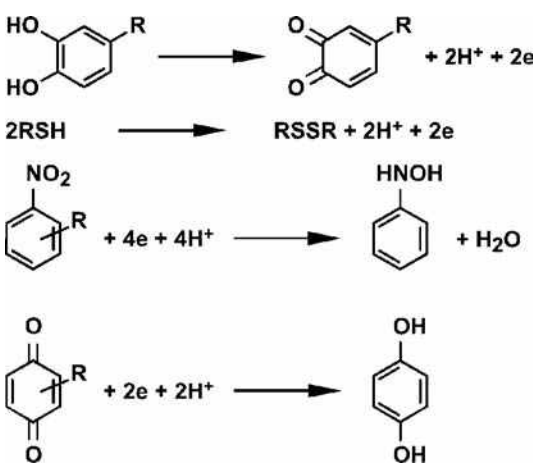
Electrochemical Detection

Peter T. Kissinger
Chairman and CEO, Bioanalytical Systems, Inc., West Lafayette, Indiana, U.S.A.

INTRODUCTION

With respect to chromatography, "electrochemical detection" means amperometric detection. Amperometry is the measurement of electrolysis current vs. time at a controlled electrode potential. It has a relationship to voltammetry similar to the relationship of a UV detector to spectroscopy. While conductometric detection is used in ion chromatography, potentiometric detection is never used in routine practice. Electrochemical detection has even been used in gas chromatography (GC) in a few unusual circumstances. It has even been attempted with thin-layer chromatography (TLC). Its practical success has only been with liquid chromatography (LC), and that will be the focus here.

Most chemists remember electrochemistry as a difficult subject they heard about in physical chemistry courses, and they regard it as having something to do with batteries. Both of these impressions are true! What is important here is to understand that: 1) redox reactions can be made to occur at surfaces (electrodes); and 2) amazingly enough, such reactions are not just the fate of metals ($Fe^{+++} \rightarrow Fe^{++}$) but actually occur quite widely among organic compounds of interest, such as drugs, pesticides, explosives, food additives, neurotransmitters, DNA, etc. There are good references for the novice wishing to understand the analytical electrochemistry of organic substances.[1] I present a few common examples below for both oxidations (electrons are lost; the process is anodic) and reductions (electrons are gained by the analyte; the process is cathodic).



While we all remember (or try not to) the confusing math associated with electrochemistry and thermodynamics, all we need here is an appreciation of the fact that current, i, is proportional to the moles, N, of analyte reacted per unit time. The latter is proportional to concentration at a constant flow rate through a detector cell. The key equation is

$$i = \frac{dQ}{dt} = nF\frac{dN}{dt}$$

where Q is the amount of electricity (charge in coulombs), n is the number of electrons, and F is the Faraday constant. As one can see from the above examples, most organic analytes are involved in reactions where $n = 1$, 2, or 4. To use an electrochemical detector, it is very important to know that i is proportional to concentration and the amount injected, just as UV absorbance is proportional to concentration or the amount injected.

LC/electrochemistry (LCEC) is now over 30 years old.[1] In recent years, an emphasis has been placed on miniaturizing the technology to accommodate the study of smaller biological samples, often with a total available volume of only a few microliters. Both LC and electrochemistry are largely controlled by surface science. Considering this fact, both technologies benefit from reducing the distance from the bulk of the solution phase to the surface. In LC, this is accomplished by using smaller diameter stationary phase particles. In electrochemistry, it is accomplished by using packed bed or porous electrodes and/or thin-layer cells with greatly restricted diffusion pathways.

For analytical purposes, there is no loss in concentration detection limit by reducing the total surface area available in both methodologies. In LC, this reduction is accomplished by using smaller diameter columns and in EC, by using smaller electrodes. With LC column diameters of 0.1–1.0 mm and radial flow thin-layer cells with dead volumes of a few tens of nanoliters, it is possible to build analytical instruments suitable for routine use by neuroscientists, drug metabolism groups, and pharmacokinetics experts. LC/electrochemistry has been used for foods, industrial chemicals, and environmental work. Nevertheless, biomedical applications have dominated. It shows no potential for preparative chromatography and is generally used when nanograms or picograms hold some appeal.

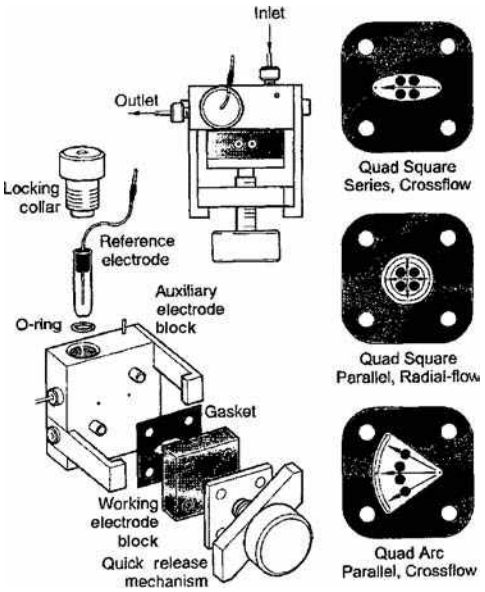


Fig. 1 One example of a sandwich type thin-layer LCEC detector with adjustable dead volume, flow pattern, and up to four channels. **Source:** From Four channel liquid chromatography/electrochemistry, in Curr. Sep.[2]

DETECTOR CELLS

A wide variety of detector cells have been used for LCEC.[1] The choice can be baffling to a non-expert. These all "work" to some degree. The key issues:

1. An electrode (the "working electrode") exposed to the mobile phase in a dead volume (small) appropriate to the column diameter chosen.
2. A place to locate at least one other electrode (a "counterelectrode") or preferentially two (an auxiliary electrode and a reference electrode).
3. The possibility for a choice of different working electrode materials (see following section).
4. The possibility of multiple channels in series or parallel.

Fig. 1 is representative of one choice that meets these criteria.[2] Such a cell is normally described as a "thin-layer sandwich configuration." The working electrode(s) is (are) in the form of an interchangeable block. Electrodes of different sizes, shapes, or materials can be accommodated with a flow pattern established by a gasket shape and thickness. Such cells can easily be adapted for LC flow rates of 5–5000 μl/min. Different designs are used for capillary separation tools such as capillary electrophoresis (CE).

ELECTRODE MATERIALS

The most common electrode material used in LCEC is carbon, either as solid "glassy carbon" disks in thin-layer cells, or as a high surface area porous matrix through which the mobile phase can flow. Gold electrodes are useful to support a mercury film, and these are primarily used to determine thiols and disulfides, and also for carbohydrates using pulsed electrochemical detection (PED) with high pH mobile phases. Platinum electrodes are occasionally useful for specific analytes, but are most frequently employed to determine hydrogen peroxide following an oxidase immobilized enzyme reactor (IMER). More recently, copper electrodes have begun to attract serious interest for determination of carbohydrates in basic mobile phases. Glassy carbon is the overwhelming favorite choice due to its wide range of applicable potentials and its rugged convenience. Bulk glassy carbon is difficult to use in geometries other than disks and plates. There are a number of other geometries that have practical interest for multiple electrode detectors. One of the more valuable recent contributions to LCEC derives from the ability to deposit conducting vitreous carbon films on silicon or quartz substrates using lithography techniques. The lithography technology makes it possible to lay down a variety of electrode geometries, which could not possibly be manufactured in small sizes by traditional machining. While such electrodes are still at the research stage, they show considerable promise. Detector cells with 2, 4, or even 16 electrodes are commercially available. There are obvious parallels with diode array detection (DAD). When two electrodes are used in series, there are similarities to fluorescence or MS/MS in the way that selectivity is often enhanced.

PULSED ELECTROCHEMICAL DETECTION

There are many substances that would appear to be good candidates for LCEC from a thermodynamic point of view, but that do not behave well due to kinetic limitations. Johnson and coworkers at Iowa State University used some fundamental ideas about electrocatalysis to revolutionize the determination of carbohydrates, nearly intractable substances that do not readily lend themselves to ultraviolet absorption (LCUV), fluorescence (LCF), or traditional d.c. amperometry (LCEC).[3] At the time this work began, the LC of carbohydrates was more or less relegated to refractive index detection (LCRI) of microgram amounts. The importance of polysaccharides and glycoproteins, as well as traditional sugars, has focused a lot of attention on PED methodology. The detection limits are not competitive with d.c. amperometry of more easily oxidized substances such as phenols and aromatic amines; however, they are far superior to optical detection approaches.

POSTCOLUMN REACTIONS

Electrochemical detection is inherently a "chemical" rather than a "physical" technique (such as ultraviolet, infrared,

fluorescence, or refractive index). It is therefore not surprising to find that many imaginative postcolumn reactions have been coupled to LCEC. These include photochemical reactions, enzymatic reactions, halogenation reactions, and Biuret reactions. In each case, the purpose is to enhance selectivity and therefore improve limits of detection. While simplicity is sacrificed with such schemes, there are many published methods that have been quite successful.

CAPILLARY ELECTROPHORESIS AND CAPILLARY ELECTROCHROMATOGRAPHY (CEC)

Since there is LCEC, it is only logical that there should be CEEC and CEC/EC. This area was pioneered by Andrew Ewing at the Pennsylvania State University. Richard Zare (Stanford University) and Susan Lunte (Kansas University) have explored this idea in a number of unique ways. The basic technology has been recently reviewed.[4] There are several fundamental problems that do not occur with LCEC. First, the capillaries must be of small diameter to properly dissipate resistive heating. Thus, the electrodes used in CEEC are normally carbon fibers or metallic wires placed in or at the capillary end. Second, the electrical current through the capillary that establishes the electroosmotic pumping is much larger than the electrolysis current measured in determining analytes of interest. The ionic and electrolytic currents need to be "decoupled" in some way. A third concern is that the flow rate in CE or CEC is not independent of the choice of "mobile phase" or even the sample, whereas in LC it is easily predetermined and maintained by a volume displacement pump. In spite of these concerns, CE is very attractive because of its high resolution per unit time and the small sample volumes required. In the case of CEEC, the concentration detection limits are frequently superior to those of optical detectors for suitable analytes. This is because electrochemical detection is a surface (not volume) dependent technique. In the grand scheme of things, at this writing, CE and CEC are very rarely used vs. LC, and therefore CEEC and CEC/EC must be considered academic curiosities until this situation changes.

CONCLUSIONS

Electrochemical detection has matured considerably in recent years and is routinely used by many laboratories, often for a very specific biomedical application. The most popular applications include acetylcholine, serotonin, catecholamines, thiols and disulfides, phenols, aromatic amines, macrocyclic antibiotics, ascorbic acid, nitro compounds, hydroxylamines, and carbohydrates. As the last century concluded, it is fair to say that many applications for which LCEC would be an obvious choice are now pursued with LC/MS/MS. This only became practical in the 1990s and is clearly a more general method applicable to a wider variety of substances. In a similar fashion, LC/MS/MS has also largely supplanted LCF for new bioanalytical methods. Nevertheless, there remain a number of key applications for these more traditional detectors, known for their selectivity (and therefore excellent detection limits). Likewise, it will be quite a few years before LC/MS/MS is affordable worldwide. An interesting recent development is the combination of electrochemical detector flow cells with MS in various configurations including EC/LC/MS/MS and LC/EC/MS/MS.[5] This enables information-rich solution phase redox chemistry to be combined with gas phase ion chemistry, adding a new dimension for complex samples. It also provides new mechanistic information on the electrochemical detection process.[6]

Electrochemical Detection in CE

Oliver Klett
Institute of Chemistry, Uppsala University, Uppsala, Sweden

INTRODUCTION

Capillary electrophoresis (CE) is a powerful separation tool which has its primary strength in the high separation efficiency and short analysis times.

DISCUSSION

By decreasing the internal diameter (I.D.) of the capillaries used, the situation can be further improved due to the possibility of using higher separation voltages. Such a miniaturization, however, often involves a challenge regarding how the detection is to be made in the narrow capillaries for sample volumes in the nanoliter to subpicoliter range. Electrochemical (EC) methods, usually based on the use of microelectrodes, are relatively inexpensive and are readily miniaturized and adapted to such low volumes and capillary sizes without loss of performance. Electrochemical detection is based on the monitoring of changes in an electrical signal due to a chemical system at an electrode surface, usually as a result of an imposed potential or current. The principles, advantages, and drawbacks of currently used EC methods will be discussed briefly below.

In a solution, the equilibrium concentrations of the reduced and oxidized forms of a redox couple are linked to the potential (E) via the Nernst equation

$$E = E^{0\prime} + \frac{RT}{nF}\ln\left(\frac{c(\text{ox})}{c(\text{red})}\right) \quad (1)$$

with $E^{0\prime}$ the standard potential and c(ox) and c(red) the concentration of the oxidized and reduced forms, respectively; the other symbols have their usual meaning.

In electrochemical detection, the potential of a working electrode can be measured versus a reference electrode, usually while no net current is flowing between the electrodes. This type of detection is referred to as "potentiometry." Alternatively, a potential is applied to the working electrode with respect to the reference electrode while the generated oxidation or reduction current is measured. This technique is referred to as "amperometry." When applying a negative potential to the working electrode, the energy of the electrons in the electrode is increased and, eventually, an electron can be transferred to the lowest unoccupied level of a species in the nearby solution. This species is thus reduced; vice versa, species can be oxidized by applying a sufficiently high positive potential. In both cases, the generated current (i) can be expressed by

$$i = -aFDnc\delta_N^{-1} \quad (2)$$

with a being the electrode area, D the diffusion coefficient, δ_N the thickness of diffusion layer; the other symbols have their usual meaning. For each redox couple, there exists a potential, the standard potential E^0, for which the reduced and oxidized forms are present in equal concentrations. By applying a potential more positive than E^0, the concentration of the reduced form is forced to decrease at the electrode surface while the concentration of the oxidized form increases. This process is the cause of the current measured in amperometric techniques. By choosing the applied potential, it is also possible to discriminate between different analytes. The range of potentials that can be applied in amperometric detection is, however, generally limited by redox processes involving the solvent [e.g., the oxidative and reductive evolution of oxygen ($2H_2O \rightarrow O_2 + 4H^+ + 4e^-$) and hydrogen ($H_2O + e^- \rightarrow 0.5\ H_2 + OH^-$), respectively, in water]. A wide range of physiologically and pharmacologically important substances, as well as many heavy metals, transition metals, and their complexes, exhibit standard potentials within this accessible potential range. In fact, many metabolic pathways involve redox processes taking place in aqueous systems. Neurotransmitters of the catechol type (*O*-dihydroxy benzene derivatives) were consequently among the first reported analytes for electrochemical detection in CE (CE/EC). Detection limits down to can be achieved in this way.

The choice of working electrode material is an important factor in amperometric detection. For catechols and similar substances, such as phenolic acids, electrodes made of glassy carbon have shown good performances. Other good detectable and biological important substances include thiols and disulfides (e.g., cysteine, glutathione, and their disulfides which are best detected on an Au/Hg amalgam electrode); amino acids and peptides, which can be detected using Cu electrodes, and carbohydrates, glycopeptides, and nucleotides, detected on Au, Cu, or Ni electrodes.

Commonly in amperometric detection, a fiber or disk microelectrode is used where the electrode is positioned in or close to the outlet of the capillary (see Fig. 1). A complication when working with EC in CE is the need for careful alignment of the electrode(s) and capillary

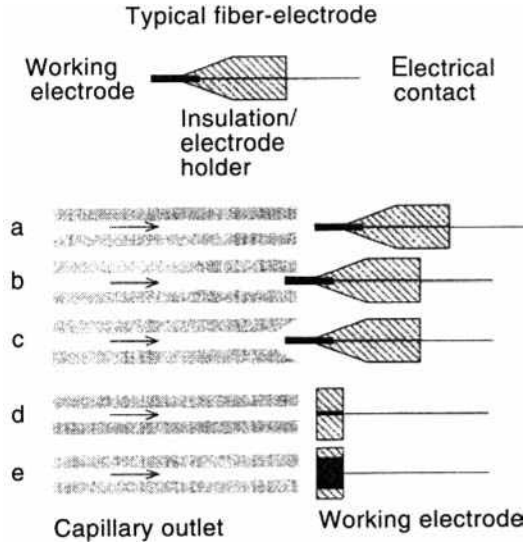

Fig. 1 Electrode setups for CE/EC with fiber microelectrodes: (a) end column, (b) on-column, (c) improved on-column, (d) wall tube, and (e) wall-jet detection.

outlet. This alignment, which mostly is carried out with micromanipulators under a microscope, is essential to ensure both a good sensitivity and reproducibility and, hence, constitutes the main challenge while adapting EC for routine CE. Another complication in CE/EC involves the interference of the high-voltage (HV) separation field on the EC detection. In the first combination of EC and CE, it was assumed that the HV field had to be totally removed from the detection area. This was done by various kinds of decouplers, which unfortunately also introduced additional band broadening and decreased sensitivities. Furthermore, the manufacturing of the decouplers requires considerable labor-intensive experience and skill.

A later approach is based on the utilization of small-inner-diameter (<25 μm) capillaries to reduce the influence of the HV field.

In potentiometry, all ions present in the solution principally contribute to the potential of the working electrode. As the ratio between the analyte concentration and that of other species in the solution generally is rather low, the analyte contribution to the detector signal is often low, which results in relatively poor detection limits. To circumvent this problem, ion-selective membranes (ISM), which permit only some ions to pass through the membranes, are commonly employed. In this way, detection limits down to 10^{-7} mol/L can be achieved. The ISM also reduces the influence from matrix components, which allows measurements in complex matrices such as blood or serum without interferences. The long-term stability of these electrode may, however, be a problem, as the electrodes might have to be replaced after a few hours or days. Common analytes are inorganic anions and cations, especially alkali and alkaline earth metals ions. A further application is the indirect detection of amino acids, where the complexing of amino acids with Cu^+ ions selectively alters the potential of a copper electrode.

In conductometry, two working electrodes placed either in or at the end of the capillary, along the capillary axis, are commonly employed. A high-frequency AC potential is applied between the working electrodes and the conductance (L) of the solution is continually monitored. In this way, the passing of any zone deviating in its ion composition from the background is detected. As the ion mobilities contribute to the magnitude of the signal as seen in Eq. 3, slowly moving large molecules and low charged biomolecules are less straightforwardly detected, whereas detection limits down to some hundred parts per thousand have been reported for small inorganic and organic ions:

$$L = \frac{FA\Sigma i|z_i|u_i c_i}{l} \tag{3}$$

with A as the cross-sectional area perpendicular to the AC field, l the electrode distance, and u the mobility. Applications have been described for ions up to a size of sulfate or Cd^+ and MES or benzylamine, respectively.

BIBLIOGRAPHY

The field of electrochemical detection in CE have been extensively reviewed in Refs.[1–3] Instructive applications can be found for amperometry in Ref.,[4] for potentiometry in Ref.,[5] and for conductometry in Ref.[6] An example of miniaturized on-chip EC/CE is given in Ref.[7] The theoretical aspects of electrochemical detection have been discussed in detail in Ref.[8]

Vince Serignese
Pharmaceutical Analysis Laboratory, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

INTRODUCTION

Separation science technology has provided the analyst with numerous methods for quantitative determinations, the more established being high-performance liquid chromatography (HPLC) and gas chromatography (GC). With huge advancements in computer technology, extremely sensitive methods have been made available to the user such as tandem mass spectrometry (MS–MS), liquid chromatography/mass spectroscopy (LC/MS), and GC/MS. However, an electrophoretic technique which has been developed through joint efforts from a number of scientific disciplines is rapidly generating interest for its wide applicability and highly sensitive assays. The field of capillary electrophoresis (CE) borrows principles from conventional electrophoresis, LC, and GC. High-performance capillary electrophoresis (HPCE) refers to all techniques that have been developed on the subject. In this entry, the electrokinetic chromatographic (EKC) analysis method will be discussed, with emphasis on micellar electrokinetic chromatographic (MEKC). Before doing so, some fundamental principles of CE will be discussed.

ELECTROPHORETIC AND ELECTRO-OSMOTIC MIGRATION

Capillary zone electrophoresis (CZE)[1] is a basic mode of HPCE and serves as a good starting point for laying the background information on EKC and MEKC. Only ionic or charged compounds are separated, based on their differential eletrophoretic mobilities. Fig. 1 illustrates the setup for a CE system. In summary, electrolyte buffer solutions and electrodes are present at both ends of the open-tube fused-silica capillary. A positive high-voltage power supply is the source of current. A sample is injected hydrostatically or electrokinetically at the positive end of the capillary (capillary head) and, in the presence of an applied voltage potential, moves toward the negative electrode, where it is detected by an ultraviolet (UV) absorbance instrument. The signal produced is recorded as a chromatogram where sample components are identified as chromatographic peaks according to their retention times, and peak areas or heights are calculated for quantitative purposes.

During analyte migration, electrophoresis and electro-osmosis are taking place. The velocity (v_s, cm/sec) and mobility (μ_s, cm^2/V sec) of the solute are defined by the following equations:

$$v_s = v_{co} + v_{cp} \tag{1}$$

$$\mu_s = \mu_{co} + \mu_{cp} \tag{2}$$

where v_{co} and μ_{co} are electro-osmotic velocity and mobility, respectively, v_{cp} and μ_{cp} and are electrophoretic velocity and mobility, respectively. The relationship between velocity and mobility is given by

$$v = \mu E \tag{3}$$

where E (V/cm) is the electric field strength. Because E is constant for all solutes in a separation analysis, the solute velocities are differentiated by their mobilities.

Electrophoresis is an electrokinetic phenomenon whereby charged compounds in an electric field move through a continuous medium and separate by preferentially obtaining different electrophoretic mobilities according to their charges and sizes. Cations move toward the negative electrode (cathode) and anions move toward the positive electrode (anode).

Electro-osmosis is created by the electric doublelayer effect.[2] A fused-silica capillary at neutral pH attains fixed negative charges at the inner wall surface as its silanol groups undergo ionization. A layer of hydrated cations will form adjacent to the inner wall to counter the fixed negative charges. An applied voltage potential will cause the positively charged layer to migrate toward the cathode with a flat velocity profile, simultaneously dragging the bulk solution inside the capillary and transporting charged compounds at the electro-osmotic flow velocity. It is assumed that v_{co} is faster than v_{cp} and determines the direction of solute migration. Hence, a cation will have its sum total (Eq. 1) greater than the individual component velocities ($v_s > v_{co}$) and the anion will migrate slower than the electro-osmotic flow ($v_s < v_{co}$).

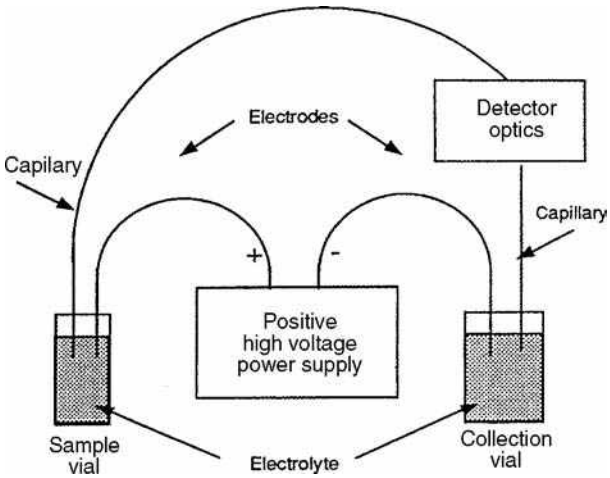

Fig. 1 Diagram of a CE system.
Source: Reprinted from Waters Quanta 4000E CE System Operator's Manual, Waters Corp., 1993.

Electro-osmosis need not be present in open-tube CE. Coatings exist that can be applied to the capillary surface to eliminate the electrical double layer. However, electro-osmotic flow can be used to reduce solute retention times, which can be advantageous for certain analyses.

As previously mentioned, electrophoretic separations using open-tube capillaries are based on solute differential mobility, which is a function of charge and molecular size. A different approach is required for separating neutral or uncharged compounds. Because charge is absent, electrophoretic mobility is zero. Electro-osmotic flow would allow them to migrate, but their velocities would be equal. Separation would not be possible with the above method.

ELECTROKINETIC CHROMATOGRAPHY

Terabe[3] developed a method that separates neutral or uncharged compounds; he named it electrokinetic chromatography. The experimental design is that of CZE (Fig. 1). The difference lies in the separation principle. In LC, a solute freely distributes itself between two phases [i.e., a mobile phase usually made of a mixture of aqueous and organic solvents and a stationary phase (a solid material packed in a steel housing known as a chromatographic column)]. Under high pressure, the mobile phase is delivered by a liquid chromatographic pump and continuously solvates the stationary phase, thereby transporting nonvolatile compounds of interest that are introduced into the system via chromatographic injection. Separation is based on their phase-distribution profiles. EKC follows the above principle but uses electro-osmosis and electrophoresis to displace analytes and "chromatographic phases" in capillaries.

The electrolyte buffer solution is analogous to the mobile phase. A charged substance, referred to as the carrier, is dissolved in the electrolyte buffer. The neutral solute present in the separation medium will partition itself between the carrier (incorporated form) and the surrounding solution (free form). The carrier ("chromatographic phase") corresponds to the stationary phase in conventional chromatography with modifications, in that it is not a fixed support and exists homogeneously in solution. For this reason, the carrier is called the "pseudo-stationary phase." As discussed in the previous section, the charged carrier will transport the incorporated solute electrophoretically (here, is the carrier velocity) at a slower velocity than the free solute migrating with the electro-osmotic flow velocity in the opposite direction. The point to keep in mind is that the carrier migrates with a different velocity than the bulk solution. The variation of the ratio of the amount of incorporated solute to the amount of total solute between separands in a sample mixture will lead to sample component separation.

MICELLES IN ELECTROKINETIC CHROMATOGRAPHY

Different types of EKC have been developed. Cyclodextrins (CDEKC) have been used to form inclusion complexes with solutes to effect their separation. Other examples of EKC include microemulsion electrokinetic chromatography (MEEKC). The MEKC technique (for a detailed treatise, the reader is referred to Ref.[4]) utilizes the presence of micelles in the electrolyte buffer solution to influence the migration time of solutes. In this case, the separation carrier is the micelle.[5]

Surfactants produce micelles. Their amphophilic nature classifies them as detergents, surface-active agents that are composed of a hydrophilic group and a hydrophobic hydrocarbon chain. In addition to what is known as the critical micelle concentration (CMC), individual surfactant molecules (monomers) interact with each other to form aggregates or micelles, establishing a state of equilibrium between a constant monomer concentration and a rapidly increasing micelle concentration.

As shown in Fig. 2, micelles are depicted as "round-like" structures with their polar moieties exteriorly located in the vicinity of the aqueous medium and their hydrophobic tails oriented inward forming a cavity. The sizes and shapes of the structures formed when monomer units aggregate is affected by electrolyte concentration, pH, temperature, and hydrocarbon chain length. During aggregation, interactions occur not only between the aggregates but also among the monomer units within the aggregate structure. Monomer unit distribution (the number of surfactant molecules in an aggregate) is characteristic of the surfactant used. Fig. 2 displays several forms of aggregates that exist in solution and Table 1 gives examples of surfactants.

Basically, MEKC is an EKC application with the micelle as the designated carrier. A surfactant at a concentration above the CMC is added to the running buffer and

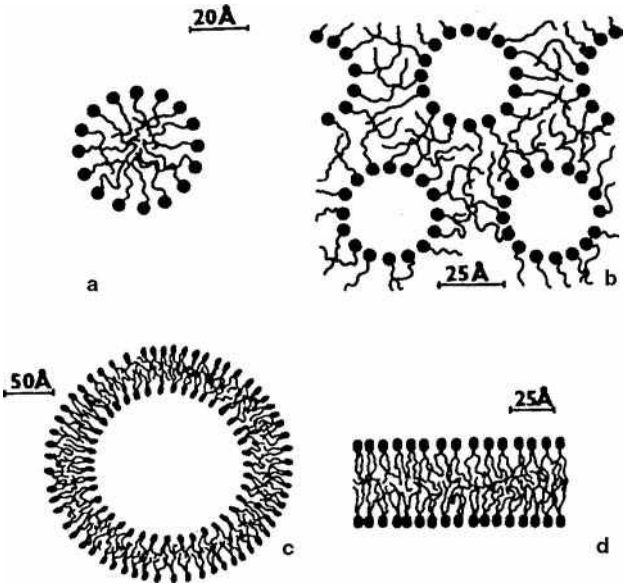

Fig. 2 Examples of aggregate structures of surfactants in solution: (a) micelle; (b) inverted micelles; (c) bilayer vesicle; (d) bilayer.
Source: From Physics of amphiphiles: micelles, vesicles and microemulsions, in Proceedings of the International School of Physics "Enrico Fermi," CourseXC.[6]

initiates micelle formation. Because the separation principle has already been dealt with and the flow scheme in Fig. 3 is an illustrative summary notated for MEKC, it is clear that a neutral analyte residing in the hydrophobic interior of a micelle (depicted as a sphere in Fig. 3) will be transported with the micelle's velocity (v_{mc}). The free analyte will migrate with the electro-osmotic flow velocity (v_{co}).

The chromatographic aspect (solute partitioning) of the separation[8] can be explained in terms of a commonly used parameter in chromatography, the retention or capacity factor. We begin with the following equation:

$$k' = \frac{n_{mc}}{n_{aq}} \tag{4}$$

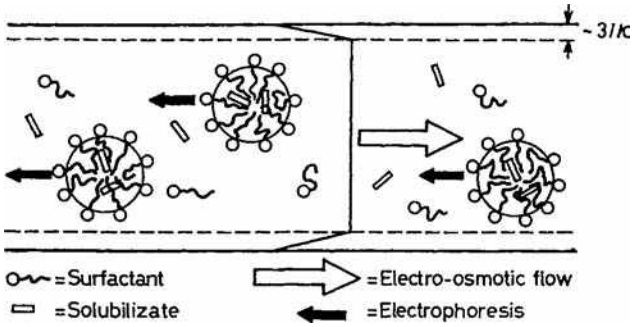

Fig. 3 Schematics of the separation principle of MEKC.
Source: From Micellar electrokinetic chromatography, in *Capillary Electrophoresis Technology*.[8]

where n_{mc} and n_{aq} are the mole amounts of the analyte in the micellar and aqueous phases, respectively. The corresponding mole fractions are given by

$$\frac{n_{mc}}{n_{mc} + n_{aq}} \text{ and } \frac{n_{aq}}{n_{mc} + n_{aq}}$$

where $n_{mc} + n_{aq}$ is the total amount of analyte present in the electrolyte buffer. The relationship in Eq. 4 and appropriate substitutions transform the above ratios into $k'/(1 + k')$ for the micelle analyte mole fraction and $1/(1 + k')$ for the aqueous analyte mole fraction. The total analyte velocity (v_s) takes the form

$$v_s = \frac{1}{1 + k'} v_{co} + \frac{k'}{1 + k'} v_{mc} \tag{5}$$

where $[1/(1 + k')]$ represents the velocity of the analyte mole fraction in the aqueous phase and $[k'/(1 + k')]v_{mc}$ is the velocity of the analyte mole fraction in the micellar phase.

Because velocity is a function of length (the capillary length from the point of injection to the detector cell) over time ($v = l/t$), we can substitute and rearrange the terms in Eq. 5 to obtain a relationship between the migration time (t_R) of the analyte and k':

Table 1 Some common surface-active agents.

Source: From *Introduction to Colloid and SurfaceChemistry*.[7]

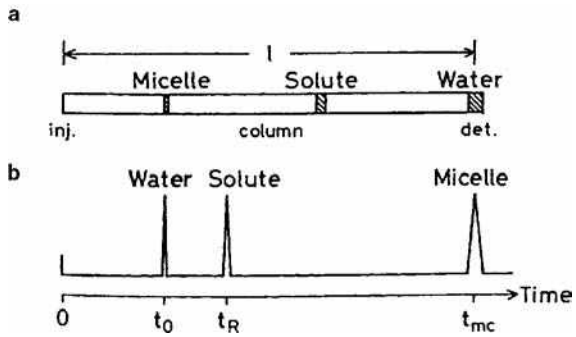

Fig. 4 (a) Representation of zone migration inside the capillary tube and (b) the corresponding chromatogram.
Source: From Electrokinetic chromatography with micellar solution and opentubular capillary, in Anal. Chem.[9]

$$T_R = \frac{1 + k'}{1 + (t_0/t_{mc})k'} t_0 \tag{6}$$

$$k' = \frac{t_R - t_0}{(1 - t_R/t_{mc})t_0} \left[\left(\frac{1 - t_R}{t_{mc}} \right) t_0 \right]^{-1} \tag{7}$$

Fig. 4a is a snapshot of the capillary tube following a sample injection at its positive end (inj.). The micelle, neutral solute, and aqueous solution (water) migrate toward the negative electrode (det.), establishing zones depicted by vertical bands, as they separate inside the capillary. The corresponding chromatogram in Fig. 4b shows the migration order where the t_R value for a neutral analyte is range bound between the migration times of the micelle (t_{mc}) and water (t_0). This limitation is reflected in the denominator of Eq. 6. When t_{mc} approaches infinity, the micelle is assumed to be stationary. The ratio t_0/t_{mc} will become zero and Eq. 6 turns into

$$t_R = 1 + k' \tag{8}$$

In this case, a neutral solute completely solubilized within the micelle will have a t_R value approaching infinity as its k' value does the same. Solute elution is assumed not to occur. Similarly, the free neutral analyte is unretained and its k' is equal to zero. Therefore, the t_R value will be equal to t_0 (Eq. 8). This explains why the neutral solute can migrate no slower than the micelle (t_{mc}) and no faster than the aqueous solution (t_0).

Although the above discussion focuses on neutral analyte separation, MEKC can be applied to ionic species which have their own electrophoretic mobilities and a broader migration time range.

CONCLUSIONS

The purpose of this entry was to provide the reader with a basic understanding of CE and to describe how a technique such as MEKC uses basic principles of chromatography to perform separations which are not possible electrophoretically. As the applications for electrokinetic chromatography rapidly expand, the future direction will develop on two fronts:

1. The development of novel separation carriers that will broaden the species range of separable analytes. EKC is suitable for separating small molecules, considering the size of the cavities of the established carriers.
2. The scope for further partition mechanisms, as new separation carriers are discovered, is promising. The separation principle is basic chromatography and with research efforts introducing new carriers in the pipeline, modified versions of the separation mechanism are possible.

Its rapid analysis time, low sample and solvent volume requirements, high resolution, and selectivity will continue to attract researchers who are involved in separation analysis.

Electron-Capture Detector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The electron-capture detector (ECD) is probably the most sensitive gas chromatography (GC) detector presently available. However, like most high-sensitivity detectors, it is also very specific and will only sense those substances that are electron capturing (e.g., *halogenated* substances, particularly fluorinated materials).

DISCUSSION

The ECD detector was invented by Lovelock[1] and functions on an entirely different principle from that of the argon detector. A low-energy β-ray source is used in the sensor to produce electrons and ions. The first source to be used was tritium absorbed onto a silver foil, but, due to its relative instability at high temperatures, this was replaced by the far more thermally stable ^{63}Ni source. The detector can be made to function in two ways: either a constant potential is applied across the sensor electrodes (the DC mode) or a pulsed potential is used (the pulsed mode).

A diagram of the ECD is shown in Fig. 1. In the DC mode, a constant electrode potential (a few volts) is employed that is just sufficient to collect all the electrons that are produced and provide a small standing current. If an electron-capturing molecule (e.g., a molecule containing a halogen atom which has only seven electrons in its outer shell) enters the sensor, the electrons are captured by the molecules and the molecules become charged. The mobility of the captured electrons are much reduced compared with the free electrons and, furthermore, are more likely to be neutralized by collision with any positive ions that are also generated. As a consequence, the electrode current falls dramatically. In the pulsed mode of operation, which is usually the preferred mode, a mixture of methane in argon is usually employed as the carrier gas. Pure argon cannot be used very effectively as the carrier gas, as the diffusion rate of electrons in argon is 10 times less than that in a 10% methane–90% argon mixture. The period of the pulsed potential is adjusted such that relatively few of the slow negatively charged molecules reach the anode, but the faster moving electrons are all collected. During the "off-period," the electrons reestablish equilibrium with the gas. In general use, the pulse width is set at about 1 μs and the frequency of the pulses at about 1 kHz. This allows about 1 ms for the sensor to reestablish equilibrium in the cell before the next electron collection occurs. The peak potential of each pulse is usually about 30 V but will depend on the geometry of the sensor and the strength of the radioactive source. The average current resulting from the electrons collected at each pulse is about 1×10^{-8} A and usually has an associated noise level of about 5×10^{-12} A. Both the standing current and the noise will also vary with the strength of the radioactive source that is used.

The sensor consists of a small chamber, 1 or 2 ml in volume, with metal ends separated by a suitable insulator. The metal ends act both as electrodes and as fluid conduits for the carrier gas to enter and leave the cell. The cell contains the radioactive source, electrically connected to the conduit through which the carrier gas enters and to the negative side of the power supply. A gauze "diffuser" is connected to the exit of the cell and to the positive side of the power supply. In the pulsed mode, the sensor operates with oxygen-free nitrogen or argon–methane mixtures. The active source is ^{63}Ni, which is stable up to 450°C. The sensor is thermostatted in a separate oven which can be operated at temperatures ranging from 100°C to 350°C. The column is connected to the sensor at the base and makeup gas can be introduced into the base of the detector. If open tubular columns are employed, the columns are operated with hydrogen or helium as the carrier gas. The ECD is extremely sensitive (i.e., minimum detectable concentration $\sim 1 \times 10^{-13}$ g/ml) and is widely used in trace analysis of halogenated compounds—in particular, pesticides.

In the DC mode, the linear dynamic range is relatively small, perhaps two orders of magnitude, with the response index lying between 0.97 and 1.03. The pulsed mode has a much wider linear dynamic range and values up to five orders of magnitude have been reported. The linear dynamic range will also depend on the strength of the radioactive source and the detector geometry. The values reported will also rest on how the linearity is measured and defined. If a response index lying between 0.98 and 1.02 is assumed, then a linear dynamic range of at least three orders of magnitude should be obtainable from most pulsed-mode ECD.

PULSED-DISCHARGE ELECTRON-CAPTURE DETECTOR

The pulsed-discharge ECD is a variant of the pulsed ECD detector, a diagram of which is shown in the lower part of

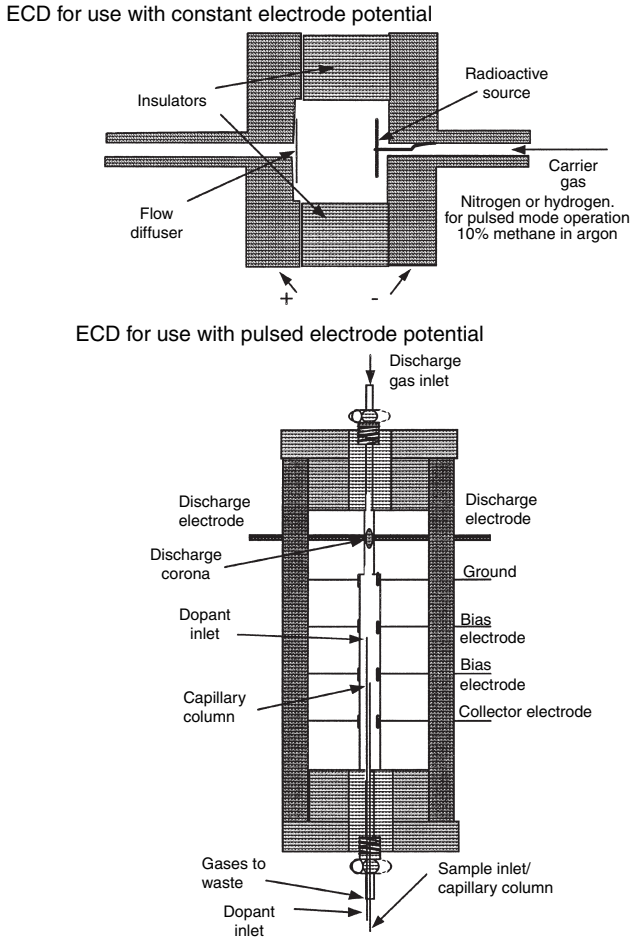

Fig. 1 The two types of electron capture detector.
Source: Courtesy of Valco Instruments Company, Inc.

Fig. 1. The detector functions in exactly the same way as that of the traditional ECD but differs in the method of electron production. The sensor consists of two sections: the upper section, where the discharge takes place, has a small diameter and the lower section where the column eluent is sensed and the electron capturing occurs, has a wider diameter. The potential across the discharge electrodes is pulsed at about 3 kHz with a discharge pulse width of about 45 μs for optimum performance. The discharge produces electrons and high-energy photons (which can also produce electrons) and some metastable helium atoms. The helium doped with propane enters just below the second electrode, metastable atoms are removed, and electrons are generated both by the decay of the metastable atoms and by the photons. The electrons are collected by appropriate potentials applied to each electrode in the section between the third and fourth electrode and, finally, collected at the fourth electrode. The collector electrode potential (the potential between the third and fourth electrodes) is pulsed at about 3 kHz with a pulse width of about 23 μs and a pulse height of 30 V.

The device functions in the same way as the conventional ECD with a radioactive source. The column eluent enters just below the third electrode, any electron-capturing substance present removes some of the free electrons, and the current collected by the fourth electrode falls. The sensitivity claimed for the detector is 0.2–1.0 ng, but this is not very informative as its significance depends on the characteristics of the column used and on the k' of the solute peak on which the measurements were made. The sensitivity should be given as that solute *concentration* that produces a signal equivalent to twice the noise. Such data allow a rational comparison between detectors. The sensitivity or minimum detectable concentration of this detector is probably similar to the conventional pulsed an estimate from the published data. The modified form of the ECD, devoid of a radioactive source, is obviously an attractive alternative to the conventional device and appears to have similar, if not better, performance characteristics.

The high sensitivity of the ECD makes it very popular for use in forensic and environmental chemistry. It is very simple to use and is one of the less expensive, high-sensitivity selective detectors available.

Electro-Osmotic Flow

Danilo Corradini
Institute of Chromatography, Rome, Italy

INTRODUCTION

Electro-osmosis refers to the movement of the liquid adjacent to a charged surface, in contact with a polar liquid, under the influence of an electric field applied parallel to the solid–liquid interface. The bulk fluid of liquid originated by this electrokinetic process is termed electro-osmotic flow (EOF). It may be produced both in open and in packed capillary tubes, as well as in planar electrophoretic systems employing a variety of supports, such as paper or hydrophilic polymers.

DISCUSSION

The formation of an electric double layer at the interfacial region between the charged surface and the surrounding liquid is of key importance in the generation of the EOF.[1–3] Most solid surfaces acquire a superficial charge when are brought into contact with a polar liquid. The acquired charge may result from dissociation of ionizable groups on the surface, adsorption of ions from solution, or by virtue of unequal dissolution of oppositely charged ions of which the surface is composed. This superficial charge causes a variation in the distribution of ions near the solid–liquid interface. Ions of opposite charge (counterions) are attracted toward the surface, whereas ions of the same charge (co-ions) are repulsed away from the surface. This, in combination with the mixing tendency of thermal motion, leads to the generation of an electric double layer formed by the charged surface and a neutralizing excess of counterion over co-ions distributed in a diffuse manner in the polar liquid. Part of the counterions are firmly held in the region of the double layer closer to the surface (the compact or Stern layer) and are believed to be less hydrated than those in the diffuse region of the double layer where ions are distributed according to the influence of electrical forces and random thermal motion. A plane (the Stern plane) located at about one ion radius from the surface separates these two regions of the electric double layer.

Certain counterions may be held in the compact region of the double layer by forces additional to those of purely electrostatic origin, resulting in their adsorption in the Stern layer. Specifically, adsorbed ions are attracted to the surface by electrostatic and/or van der Waals forces strongly enough to overcome the thermal agitation. Usually, the specific adsorption of counterions predominates over co-ion adsorption.

The variation of the electric potential in the electric double layer with the distance from the charged surface is depicted in Fig. 1. The potential at the surface (ψ_0) linearly decreases in the Stern layer with respect to the value of the zeta potential (ζ). This is the electric potential at the plane of shear between the Stern layer (plus that part of the double layer occupied by the molecules of solvent associated with the adsorbed ions) and the diffuse part of the double layer. The zeta potential decays exponentially from ζ to zero with the distance from the plane of shear between the Stern layer and the diffuse part of the double layer. The location of the plane of shear, a small distance further out from the surface than the Stern plane, renders the zeta potential marginally smaller in magnitude than the potential at the Stern plane (ψ_δ). However, in order to simplify the mathematical models describing the electric double layer, it is customary to assume identity of ψ_δ and ζ, and the bulk experimental evidence indicates that errors introduced through this approximation are usually small.

According to the Gouy–Chapman–Stern–Grahame (GCSG) model of the electric double layer,[4] the surface density of the charge in the Stern layer is related to the adsorption of the counterions, which is described by a Langmuir-type adsorption model, modified by the incorporation of a Boltzman factor. Considering only the adsorption of counterions, the surface change density σ_S of the Stern layer is related to the ion concentration C in the bulk solution by the following equation:

$$\sigma_S = zen_0 \frac{C}{V_m} \exp\left(\frac{ze\xi + \Phi}{kT}\right) \times \left[1 + \frac{C}{V_m} \exp\left(\frac{ze\xi + \Phi}{kT}\right)\right]^{-1} \quad (1)$$

where e is the elementary charge, z is the valence of the ion, k is the Boltzman constant, T is the temperature, n_0 is the number of accessible sites, V_m is the molar volume of the solvent, and Φ is the specific adsorption potential of counterions.

The surface charge density of the diffuse part of the double layer is given by the Gouy–Chapman equation

$$\sigma_G = (8\varepsilon kTc_0) \sinh\left(\frac{ze\xi}{2kT} f\right) \quad (2)$$

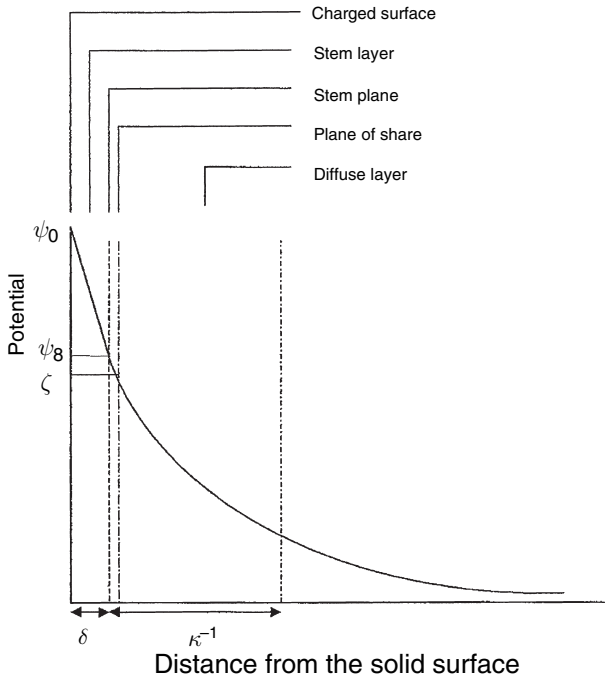

Fig. 1 Schematic representation of the electric double layer at a solid–liquid interface and variation of potential with the distance from the solid surface: ψ_0, surface potential; ψ_δ, potential at the Stern plane; ζ, potential at the plane of share (zeta potential); δ, distance of the Stern plane from the surface (thickness of the Stern layer); κ^{-1}, thickness of the diffuse region of the double layer.

where ε is the permittivity of the electrolyte solution and c_0 is the bulk concentration of each ionic species in the electrolyte solution.

At low potentials, Eq. 2 reduces to

$$\sigma_G = \frac{\varepsilon\xi}{\kappa^{-1}} \tag{3}$$

where κ^{-1} is the reciprocal Debye–Hückel parameter, which is defined as the "thickness" of the electric double layer. This quantity has the dimension of length and is given by

$$\kappa^{-1} = \left(\frac{\varepsilon kT}{2e^2 I}\right)^{1/2} \tag{4}$$

in which I is the ionic strength of the electrolyte solution.

Eq. 3 is identical to the equation that relates the charge density, voltage difference, and distance of separation of a parallel-plate capacitor. This result indicates that a diffuse double layer at low potentials behaves like a parallel capacitor, in which the separation distance between the plates is given by κ^{-1}. This explains why κ^{-1} is called the double-layer thickness.

Eq. 2 can be written in the form

$$\xi = \frac{\sigma_G \kappa^{-1}}{\varepsilon} \tag{5}$$

which indicates that the zeta potential can change due to variations in the density of the electric charge, in the permittivity of the electrolyte solution, and in the thickness of the electric double layer, which depends, throughout the ionic strength (see Eq. 4), on the concentration and valence of the ions in solution.

The dependence of the velocity of the electro-osmotic flow (v_{eo}) on the zeta potential is expressed by the Helmholtz–von Smoluchowski equation

$$v_{eo} = \frac{\varepsilon_0 \varepsilon \zeta}{\eta} E \tag{6}$$

where E is the applied electric field, ε_0 is the permittivity of vacuum, and ε and η are the dielectric constant and the viscosity of the electrolyte solution, respectively. This expression assumes that the dielectric constant and viscosity of the electrolyte solution are the same in the electric double layer as in the bulk solution.

The Helmholtz–von Smoluchowski equation indicates that under constant composition of the electrolyte solution, the EOF depends on the magnitude of the zeta potential, which is determined by the different factors influencing the formation of the electric double layer, as discussed earlier. Each of these factors depends on several variables, such as pH, specific adsorption of ionic species in the compact region of the double layer, ionic strength, and temperature.

The specific adsorption of counterions at the interface between the surface and the electrolyte solution results in a drastic variation of the charge density in the Stern layer, which reduces the zeta potential and, hence, the EOF. If the charge density of the adsorbed counterions exceeds the charge density on the surface, the zeta potential changes sign and the direction of the EOF is reversed.

The ratio of the velocity of the EOF to the applied electric field, which expresses the velocity per unit field, is defined as electro-osmotic coefficient or, more properly, electro-osmotic mobility (μ_{eo}).

$$\frac{v_{eo}}{E} = \mu_{eo} = \frac{\varepsilon_0 \varepsilon \xi}{\eta} \tag{7}$$

Using SI units, the velocity of the electro-osmotic flow is expressed in meters per second (m/sec) and the electric field in volts per meter (V/m). Consequently, in analogy to the electrophoretic mobility, the electro-osmotic mobility has the dimension square meters per volt per second. Because electro-osmotic and electrophoretic mobilities are converse manifestations of the same underlying phenomenon, the Helmholtz–von Smoluchowski equation applies to electro-osmosis as well as to electrophoresis. In fact, when an electric field is applied to an ion, this moves relative to the electrolyte solution, whereas in the case of electro-osmosis, it is the mobile diffuse layer that moves under an applied electric field, carrying the electrolyte solution with it.

According to Eq. 6, the velocity of the EOF is directly proportional to the intensity of the applied electric field. However, in practice, the non-linear dependence of the EOF on the applied electric field is obtained as a result of Joule heat production, which causes an increase of the electrolyte temperature with a consequent decrease of viscosity and variation of all other temperature-dependent parameters (protonic equilibrium, ion distribution in the double layer, etc.). The EOF can also be altered during a run by variations of the protonic and hydroxylic concentration in the anodic and cathodic electrolyte solutions as a result of electrolysis. This effect can be minimized by using electrolyte solutions with a high buffering capacity and electrolyte reservoirs of relatively large volume and by frequent replacement of the electrolyte in the electrode compartments with fresh solution.

The magnitude and direction of the EOF depend also on the composition, pH, and ionic strength of the electrolyte solution.[5–7] Both the pH and ionic strength influence the protonic equilibrium of fixed-charged groups on the surface and of ionogenic substances in the electrolyte solution which affect the charge density in the electric double layer and, consequently, the zeta potential. In addition, the ionic strength influences the thickness of the double layer (κ^{-1}). According to Eq. 4, increasing the ionic strength causes a decrease in κ^{-1}, which is currently referred to as the compression of the double layer that results in lowering the zeta potential. Consequently, increasing the ionic strength results in decreasing the EOF.

The charge density in the electric double layer and, hence, the EOF are also influenced by the adsorption of potential-determining ions in the Stern region of the electric double layer. A variety of additives can be incorporated into the electrolyte solution with the purpose of controlling the EOF by modifying the solid surface dynamically. These include simple and complex ionic compounds, ionic and zwitterionic surfactants, and neutral and charged polymers. The incorporation of these additives into the electrolyte solution may result either in increasing or in reducing the EOF, or even in reversing its direction. The impact of these additives on the EOF is generally concentration dependent. Such behavior is in accordance to the Langmuir-like adsorption model describing the variation of the charge density in the Stern layer on the concentration of adsorbing ions in the electrolyte solution (see Eq. 1).

The proper control of the EOF can be also obtained by adding organic solvents to the electrolyte solution. The influence of organic solvents on the EOF may result from a multiplicity of mechanisms. Organic solvents are expected to influence both the dielectric constant and viscosity of the bulk electrolyte solution. Generally, this leads to the variation of the ratio of the dielectric constant to the viscosity of the electrolyte solution, to which the EOF depends according to Eq. 6. In addition, the local viscosity within the electric double layer[8] can be varied by the adsorption of the organic–solvent molecules in the Stern layer, which may also influence the adsorption of counterions, depending on the different solvation properties of the organic solvent. Organic solvents may also influence the zeta potential by affecting the ionization of potential-determining ions on the surface.

Different methods can be employed to measure the magnitude of the EOF.[9] One possibility involves measuring the velocity of the EOF by measuring the change in weight or in volume in one of the electrolyte solution reservoirs. The addition of an electrically neutral dye to one electrode reservoir and its detection in the other where the EOF is directed is another possible method. Other methods based on monitoring electric current while an electrolyte solution of different conductivity is drawn into the system by electro-osmosis or determining the zeta potential from streaming potential measurements are less popular and accurate. More common is the method of calculating the electro-osmotic velocity from the migration time of an electrically neutral marker substance incorporated into the sample solution. The selected compound must be soluble in the electrolyte solution, neutral in a wide pH range, and easily detectable. In addition, it should neither become partially charged by compellation with the components of the electrolyte solution nor interact with the capillary tube, the chromatographic stationary phase, or the slab gel employed in capillary electrophoresis (CE), capillary electrochromatography, and planar electrophoresis, respectively. This method has the advantage of simplicity and can be used to monitor the EOF during analysis in any of the above techniques, provided that the analytes and the EOF are directed toward the same electrode.

Electro-Osmotic Flow in Capillary Tubes

Danilo Corradini
Institute of Chromatography, Rome, Italy

INTRODUCTION

The electro-osmotic flow in open capillary tubes is generated by the effect of the applied electric field across the tube on the uneven distribution of ions in the electric double layer at the interface between the capillary wall and the electrolyte solution. In bare fused-silica capillaries, ionizable silanol groups are present at the surface of the capillary wall, which is exposed to the electrolyte solution. In this case, the electric double layer is the result of the excess of cations in the solution in contact with the capillary tube to balance the negative charges on the wall arising from the ionization of the silanol groups. Part of the excess cations are firmly held in the region of the double layer closer to the capillary wall (the compact or Stern layer) and are believed to be less hydrated than those in the diffuse region of the double layer.[1] When an electric field is applied across the capillary, the remaining excess cations in the diffuse part of the electric double layer move toward the cathode, dragging their hydration spheres with them. Because the molecules of water associated with the cations are in direct contact with the bulk solvent, all the electrolyte solution moves toward the cathode, producing a pluglike flow having a flat velocity distribution across the capillary diameter.[2]

DISCUSSION

The flow of liquid caused by electro-osmosis displays a pluglike profile because the driving force is uniformly distributed along the capillary tube. Consequently, a uniform flow velocity vector occurs across the capillary. The flow velocity approaches zero only in the region of the double layer very close to the capillary surface. Therefore, no peak broadening is caused by sample transport carried out by the electro-osmotic flow. This is in contrast to the laminar or parabolic flow profile generated in a pressure-driven system, where there is a strong pressure drop across the capillary caused by frictional forces at the liquid–solid boundary. A schematic representation of the flow profile due to electro-osmosis in comparison to that obtained in the same capillary column in a pressure-driven system, such as a capillary high-performance liquid chromatography (HPLC), is displayed in Fig. 1.

The dependence of the velocity of the electro-osmotic flow (v_{co}) on the applied electric field (E) is expressed by the Helmholtz–von Smoluchowski equation

$$v_{co} = -\frac{\varepsilon_0 \varepsilon_r \zeta}{\eta} E \tag{1}$$

where ζ is the zeta potential, ε_0 is the permittivity of vacuum, ε_r is the dielectric constant, and η is the viscosity of the electrolyte solution. This expression assumes that the dielectric constant and viscosity of the electrolyte solution are the same in the electric double layer as in the bulk solution. The term $-\varepsilon_0 \varepsilon_r \zeta/\eta$ is the defined electro-osmotic coefficient or, more properly, electro-osmotic mobility (μ_{co}) and expresses the velocity of the electro-osmotic flow per unit field. Accordingly, the Helmholtz–von Smoluchowski equation can be written

$$\mu_{co} = \frac{v_{co}}{E} \tag{2}$$

In a capillary tube, the applied electric field E is expressed by the ratio where V is the potential difference in volts across the capillary tube of length L_T (in meters). The velocity of the electro-osmotic flow, v_{co} (in meters per second), can be evaluated from the migration time t_{cot} (in seconds) of an electrically neutral marker substance and the distance L_D (in meters) from the end of the capillary where the samples are introduced to the detection windows (effective length of the capillary). This indicates that, experimentally, the electro-osmotic mobility can be easily calculated using the Helmholtz–von Smoluchowski equation in the following form:

$$\mu_{co} = \frac{L_T L_D}{V t_{co}} \, (\mathrm{m^2/V/s}) \tag{3}$$

which demonstrates that, by analogy to the electrophoretic mobility, the electro-osmotic mobility has the dimension of square meters per volt per second.

The electrically neutral marker substance employed to measure the velocity of the electro-osmotic flow has to fulfill the following requirements. The compound must be soluble in the electrolyte solution and neutral in a wide pH range and no interaction with the capillary wall must occur. In addition, the electrically neutral marker substance should be easily detectable in order to allow a small amount to be injected. If the electrically neutral marker interacts with the capillary wall or becomes partially charged by complexation with the components of the electrolyte solution, the measured electro-osmotic velocity

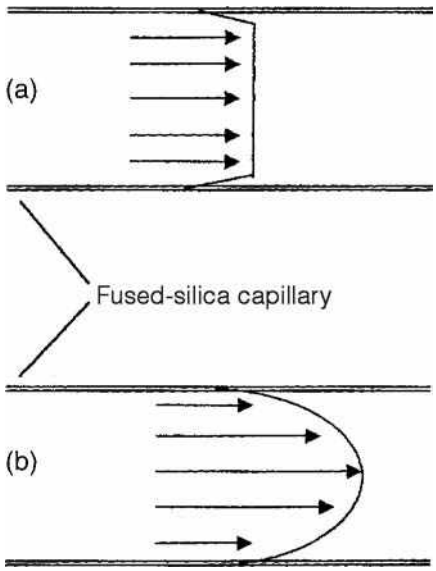

Fig. 1 Schematic representation of the flow profiles obtained with the same capillary column connected to an electric-driven system (a) and to a pressure-driven system (b). Arrows indicate flow velocity vectors.

may appear slower or faster than the real flow. Some compounds that adequately serve as electrically neutral markers include benzyl alcohol, riboflavin, acetone, dimethyl-formamide, dimethyl sulfoxide, and mesityl oxide.

Alternatively, the velocity of the electro-osmotic flow can be measured by weighing the volume of the electrolyte solution displayed by electro-osmosis from the anodic to the cathodic reservoir. When detection is performed by ultraviolet (UV) absorbance, a "solvent dip" equal to the electro-osmotic flow appears in the electropherogram after any sample injection. In most cases, the sample solvent has a lower UV absorbance than the electrolyte solution, resulting in a negative UV signal. On the other hand, if the UV absorbance of the sample solvent is higher than that of the electrolyte solution, a positive system peak can be observed at the time corresponding to the velocity of the electro-osmotic flow. The time at which the "solvent dip" appears in the electropherogram can be used to measure the velocity of the electro-osmotic flow in a very simple but less accurate way than those using an electrically neutral marker substance or the weight of the displaced liquid.

The Helmholtz–von Smoluchowski equation indicates that under constant composition of the electrolyte solution, the electro-osmotic flow depends on the magnitude of the zeta potential which is determined by many different factors, the most important being the dissociation of the silanol groups on the capillary wall, the charge density in the Stern layer, and the thickness of the diffuse layer. Each of these factors depends on several variables, such as pH, specific adsorption of ionic species in the compact region of the electric double layer, ionic strength, viscosity, and temperature.

Secondary equilibrium in solution, generation of Joule heat, and variation of protonic and hydroxylic concentration due to electrolysis may alter the hydrogen ion concentration in the capillary tube when electrolyte solutions having low buffering capacities are employed. A change in the protonic equilibrium directly influences the zeta potential through the variation of the charge density on the capillary wall resulting from the deprotonation of the surface silanol groups, which increases with increasing pH. The shape of a curve describing the dependence of the zeta potential on the electrolyte pH resembles a titration curve, the inflection point of which may be interpreted as the pK_a value of the surface silanol groups. At acidic pH, the ionization of the surface silanol groups is suppressed and the zeta potential approaches zero, determining the virtual annihilation of the electro-osmotic flow. Under alkaline conditions, the silanol groups are fully charged and the zeta potential reaches its maximum value, which corresponds to a plateau value of the electro-osmotic flow. Between these extreme conditions, the zeta potential rapidly increases with increasing pH up to the complete dissociation of the silanol groups, determining the well-known sigmoidal pH dependence of the electro-osmotic flow. The concentration and ionic strength of the electrolyte solution also have a strong impact on the electro-osmotic flow. The ionic strength influences the thickness of the diffuse part of the electric double layer to which the zeta potential is directly proportional. Because the thickness of the diffuse part of the electric double layer is inversely proportional to the square root of the ionic strength, the electro-osmotic flow decreases with the concentration of the electrolyte solution according to the following relationship:[3]

$$\mu_{co} \approx \frac{e}{3 \times 10^7 \mid z \mid \eta\sqrt{C}} \tag{4}$$

where, e, z, η, and C are the total charge per unit surface area, the electron valence of the electrolyte, the viscosity, and the concentration of the electrolyte in the bulk solution, respectively.

Another model that accounts for the decrease of the electro-osmotic flow with increasing the electrolyte concentration relates the electro-osmotic mobility to the concentration of a monovalent counterion, introduced with the buffer, according to the following relationship:[4]

$$\mu_{co} = \frac{Q_0}{\eta(1 + K_{wall}[M^+])}\left(d_0 + \frac{1}{K'\sqrt{[M^+]}}\right) \tag{5}$$

where η is the viscosity of the electrolyte solution and K' is a constant that, for a dilute aqueous solution at 25°C, is equal to 3×10^9/m $(\text{mol/L})^{-1/2}$. The first term on the right side of Eq. 5 is related to the dependence of the surface charge on the concentration of the monovalent cation in the

electrolyte solution. The model postulates that the initial charge per unit area at the surface of the silica capillary wall (Q_0) is reduced by the factor $1/1 + K_{wall}[M^+]$ upon incorporating a monovalent buffer of concentration $[M^+]$ into the electrolyte solution. This is a result of the neutralization of the free silanol groups on the capillary surface caused by the adsorption of the monovalent cations. The constant K_{wall} is defined as the equilibrium constant between the cations in the buffer solution and adsorption sites on the capillary wall. The second term describes the influence of the concentration of the monovalent cation on the thickness of the mobile region of the electric double layer. This is postulated to be composed of a fixed thickness (d_0) and the Debye–Hückel thickness $\delta = 1/K'[M^+]^{1/2}$, which is inversely proportional to the square root of the concentration of the monovalent ion. According to this model, increasing the concentration of the monovalent buffer cation in the bulk solution influences the electro-osmotic mobility by reducing the Debye–Hückel thickness of the diffuse double layer and by neutralizing the negative charges on the capillary wall resulting from the ionization of the silanol groups.

Certain counterions, such as polycationic species, cationic surfactants, and several amino compounds can be firmly held in the compact region of the electric double layer by forces additional to those of simple Coulombic origin. The specific adsorption of counterions at the interface between the capillary wall and the electrolyte solution results in a drastic variation of the positive charge density in the Stern layer, which reduces the zeta potential and, hence, the electro-osmotic flow. If the positive charge density of the adsorbed counterions exceeds the negative charge density on the capillary wall resulting from the ionization of silanol groups, the zeta potential becomes positive and the concomitant electro-osmotic flow is reversed from cathodic to anodic.

The dependence of the electro-osmotic flow on the specific adsorption of counterions in the electric double layer can be described by a model which correlates the electro-osmotic mobility to the charge density in the Stern part of the electric double layer (arising from the adsorption of counterions) and the charge density at the capillary wall (resulting from the ionization of silanol groups).[5] According to this model, the dependence of the electro-osmotic mobility on the concentration of the adsorbing ions (C) in the electrolyte solution is expressed as

$$\mu_{co} = \frac{\kappa^{-1}}{\eta}\left\{ze n_0 \frac{C}{V_m}\exp\left(\frac{ze\psi_d + \Phi}{kT}\right) \times\left[1 + \frac{C}{V_m}\exp\left(\frac{ze\psi_\delta + \Phi}{kT}\right)\right]^{-1} - \left(\frac{\gamma}{1 + [H^+]/K_a}\right)\right\} \quad (6)$$

where κ^{-1} is the Debye–Hückel thickness of the diffuse double layer, is the viscosity of the electrolyte solution, e is the elementary charge, z is the valence of the adsorbing ion, k is the Boltzman constant, T is the absolute temperature, is the number of accessible sites in the Stern layer, is the molar volume of the solvent, Φ is the specific adsorption potential of counterions, γ is the sum of the ionized and protonated surface silanol groups, $[H^+]$ is the bulk electrolyte hydrogen ion concentration, and is the silanol dissociation constant. According to this equation, at constant ionic strength, viscosity, and pH, the electro-osmotic mobility depends mainly on the surface density of the adsorbed counterions in the Stern region of the electric double layer, which follow a Langmuir-type adsorption model.

The reversal of the direction of the electro-osmotic flow by the adsorption onto the capillary wall of alkylammonium surfactants and polymeric ion-pair agents incorporated into the electrolyte solution is widely employedin capillary zone electrophoresis (CZE) of organic acids, amino acids, and metal ions. The dependence of the electro-osmotic mobility on the concentration of these additives has been interpreted on the basis of the model proposed by Fuerstenau[6] to explain the adsorption of alkylammonium salts on quartz. According to this model, the adsorption in the Stern layer as individual ions of surfactant molecules in dilute solution results from the electrostatic attraction between the head groups of the surfactant and the ionized silanol groups at the surface of the capillary wall. As the concentration of the surfactant in the solution is increased, the concentration of the adsorbed alkylammonium ions increases too and reaches a critical concentration at which the van der Waals attraction forces between the hydrocarbon chains of adsorbed and freesurfactant molecules in solution cause their association into hemimicelles (i.e., pairs of surfactant molecules with one cationic group directed toward the capillary wall and the other directed out into the solution).

Lowering the velocity or reversing the direction of the electro-osmotic flow may have a beneficial effect of on the resolution of two adjacent peaks, as evidenced by the following expression for resolution in electrophoresis elaborated by Giddings:[7]

$$R_s = \frac{\sqrt{N}}{4}\left(\frac{\Delta\mu}{\mu_{av} + \mu_{co}}\right) \quad (7)$$

where N is the number of theoretical plates, $\Delta\mu$ and μ_{av} are the difference and the average value of the electrophoretic mobilities of two adjacent peaks, respectively, and μ_{co} is the electro-osmotic mobility. According to this equation, the highest resolution is obtained when the electro-osmotic mobility has the same value but opposite direction of the average electrophoretic mobility of the two adjacent peaks.

Neutral polymeric molecules, such as polysaccharides and synthetic polymers, may also adsorb onto the Stern

layer, causing a variation of viscosity in the double layer with distance from the capillary wall, which affects the electro-osmotic mobility according to the following relationship:[2]

$$\mu_{co} = \frac{\varepsilon_r}{4\pi} \int_0^{\zeta} \frac{1}{\eta} d\psi \tag{8}$$

where ε_r is the dielectric constant, ζ is the zeta potential, η is the viscosity, and ψ is the electric potential. The value of the integral in this expression will approach zero when the viscosity in the double layer approaches infinity. Accordingly, the electro-osmotic flow is drastically reduced when the local viscosity of the double layer is increased as a result of the adsorption of a neutral polymer onto the Stern layer. It is worth noting that at constant value of the viscosity in the electric double layer, Eq. 8 is equivalent to the Helmholtz–von Smoluchowski expression for the electro-osmotic flow.

The incorporation of an organic solvent into the aqueous electrolyte solution also leads to a variation of the electro-osmotic flow.[8] The general trend is that the electro-osmotic flow decreases steadily with increasing concentration of the organic solvent in the hydro-organic electrolyte solution. This effect can be attributed, to some extent, to the increasing viscosity and decreasing dielectric constant of most hydro-organic electrolyte solutions with increasing concentration of organic solvent. However, in most cases, the decrease of the electro-osmotic flow is also observed at organic solvent concentrations greater than 50–60% (v/v), at which the ratio of the dielectric constant and the viscosity, ε_r/η is generally increasing. This indicates that the variation of the electro-osmotic flow caused by the incorporation of an organic solvent into the electrolyte solution cannot be solely related to the changes of the ratio ε_r/η.

Similar to the neutral polymers, organic solvents can adsorb at the interface between the capillary wall and the electrolyte solution, through hydrogen-bonding or dipole interaction, thus increasing the local viscosity within the electric double layer. Organic solvents may also influence the zeta potential by affecting the ionization of the silanol groups at the capillary surface, whose has been found to be shifted toward higher values with increasing the content of organic solvents in the electrolyte solution. The dependence of the zeta potential on the fraction of an organic solvent incorporated into the electrolyte solution may be also related to the variation of both the dielectric constant and the adsorption of counterions in the Stern layer. In practice, introducing a neutral polymer or an organic solvent into the electrolyte solution results in multiple changes, generally involving the viscosity and the dielectric constant of the bulk solution, the ionization of the silanol groups on the capillary wall, and the charge density in the Stern layer, as well as the local viscosity and the dielectric constant of the electric double layer.

Electro-Osmotic Flow Nonuniformity: Influence on Efficiency of CE

Victor P. Andreev
Institute for Analytical Instrumentation, Russian Academy of Sciences, St. Petersburg, Russia

INTRODUCTION

There are two types of nonuniformities of electro-osmotic flow (EOF) that can contribute significantly to the solute peak broadening and are important for capillary electrophoresis (CE). The first is the transversal nonuniformity of the usual EOF in the capillary with the zeta potential of the walls and longitudinal electric field strength constant and independent of coordinates. The second one is the nonuniformity of EOF caused by the dependence of the zeta potential of the walls or electric field strength on coordinates.

DISCUSSION

The first type of EOF nonuniformity was described in the classical article by Rice and Whitehead[1] written much earlier than the first works on CE. The equation for the EOF velocity profile in the infinitely long tube with radius a was given by

$$V(r) = \frac{\zeta \varepsilon \varepsilon_0 E}{\eta}\left(1 - \frac{I_0(\kappa r)}{I_0(\kappa a)}\right) \quad (1)$$

where ζ is the zeta potential of the wall, ε and η are the dielectric constant and viscosity of the buffer, respectively, ε_0 is the permitivity of the free space, $\kappa^{-1} = (\varepsilon\varepsilon_0\kappa_B T2ne^2)^{1/2}$ is the Debye layer thickness, κ_B is the Boltzmann constant, T is the temperature, n is the number of ions per unit volume (proportional to the concentration of buffer C_0), e is the proton charge, and $I_0(x)$ is the modified Bessel function. It is evident from Eq. 1 that the nonuniformity of the EOF profile can be substantial only if the capillary radius and Debye length are commensurate. In fact, for the case of $\kappa a \approx 1$, the profile of EOF according to Eq. 1 is very close to parabolic. Luckily, it is not the case of usual capillaries for CE with $a \geq 25$ μm because, even for distilled water, $\kappa^{-1} \approx 0.1$ μm. Another important result of Ref.,[1] is the prediction of the EOF profile in the long capillary with closed ends. In such a capillary, liquid moves in one direction in the vicinity of the walls and in the opposite direction near the axis of the capillary, thus making the total flow through the cross section equal to zero. With this result, it is quite evident that CE must be realized in a capillary with open ends; otherwise, nonuniformity of EOF would ruin the separation.

Results of Ref.,[1] were produced by employing a linear approximation of the exponential terms in the Poisson–Boltzmann equation for electrical potential and charge distribution. Strictly speaking, this linearization is valid only for $|\zeta| \ll kT/e \approx 0.03$ V, whereas the range of the values of the zeta potential is $|\zeta| \leq 0.1$ V. In Ref.,[2] the Poisson–Boltzmann equation and the Navier–Stokes equations for EOF velocity profile were solved numerically without linearization. The dependence of buffer viscosity on temperature and the existence of temperature gradients due to Joule heating were also taken into consideration. Calculated EOF profiles were compared with and predicted by Eq. 1, showing that the difference in flow profiles for $|\zeta| = 0.1$ V could be significant, especially for thin capillaries and low buffer concentrations ($ka \approx 10$). Calculated flow profiles were used to predict the stationary value of height equivalent to the theoretical plate (HETP) by using the results of generalized dispersion theory. It was shown that for low buffer concentrations ($C_0 \leq 10^{-4}$ M), the contribution of electro-osmotic flow nonuniformity to the HETP value could be larger than the contribution of the thermal effects and molecular diffusion.

A similar approach was used in Ref.,[3] where the contributions of EOF nonuniformity (H_{co}) and molecular diffusion (H_{diff}) to HETP were compared for different values of solute diffusion coefficients. It was shown[3] that for the typical CE velocities of EOF (1–2 mm/sec) and rather high buffer concentration ($C_0 = 10^{-2}$ M), $H_{co}H_{diff} \geq 1$ for $D \leq 2 \times 10^{-12}$/m^2/sec. For lower buffer concentrations, the influence of EOF nonuniformity is substantial for smaller molecules also ($H_{co} = 1.3 \times 10^{-8}$ m, $H_{diff} = 1.6 \times 10^{-8}$ m for $D = 2.4 \times 10^{-11}$ m^{2}sec, corresponding to α_2-macroglobulin).

The joint effect of EOF nonuniformity and particle–wall electrostatic interactions was studied in Ref.[4] Two types of solute particles were examined: one with the charge of the same sign as the zeta potential of the wall, and the other of the opposite sign. The particles of the first type are moving electrophoretically in the direction opposite to the direction of EOF and are electrostaticaly subtracted by the wall, whereas the particles of the second type are attracted by the wall and are moving

electrophoretically in the same direction as EOF. Particles of the second type spend a large portion of time in the vicinity of the capillary wall and, so, EOF nonuniformity contributes significantly to peak broadening, whereas for the particles subtracted by the wall, the influence of EOF nonuniformity is negligible because their residence time in the vicinity of the wall is close to zero. For example, for the particles with $D = 5 \times 10^{-11}$ m^{2}sec, in the capillary with $a = 10$ μm, $\zeta = -0.1$ V, and $E = 40$ kV/m, filled with diluted buffer ($C_0 = 10^{-5}$ M), one has HETP ≈ 10 μm for particles attracted by the wall, whereas for particles subtracted by the wall, HETP ≈ 0.1 μm. For neutral particles not interacting with the walls, HETP ≈ 0.2 μm was predicted. The difference was much less dramatic for the case of the higher buffer concentrations and the lower zeta potential. For example, for $\zeta = -0.02$ V, $C_0 = 10^{-3}$ M and the rest of parameters being the same as described earlier, HETP is determined mainly by molecular diffusion and is close to 0.1 μm.

The influence of EOF nonuniformity on efficiency of CE in the capillary with the zeta potential of the wall being the function $\zeta(x)$ of the longitudinal coordinate x was studied in Ref.[5] To calculate the EOF velocity profile, an important approximation was justified by the fact that usually $\kappa a \gg$ in CE. Thus, the doublelayer region was neglected and the following boundary condition was formulated:

$$V_x(x, a, t) = \frac{\varepsilon\varepsilon_0 E}{\eta}\zeta(x) \tag{2}$$

With this boundary condition, the Navier–Stokes equations for longitudinal V_x and radial V_r components of EOF velocity were solved numerically, and the calculated EOF profiles were used to simulate the solute peak shapes. The situation where the part of the capillary length was modified to the zero value of the zeta potential and the part of capillary was not modified ($\zeta \neq 0$) was studied. It was shown that the radial component of the velocity is non-zero only in the rather short transition region between the uncovered and covered parts of the capillary. At a distance of a few capillary diameters from the transient region, the radial flows are negligible and the axial component of the velocity in the covered section of the capillary has an almost parabolic profile. Peak shapes and peak variances were studied, and the general conclusion of Ref.,[5] was that the main contribution to the peak width was from the parabolic velocity profiles, the contribution of the radial flow in the transient regions being less significant. Based on this result, the mathematical model of CE in the capillary made of several sections with various non-equal values of the zeta potentials and radii was developed.[6] For each of the sections, the total flow was considered to be the sum of EOF caused by electrical potential differences along the section and the Poiseuille flow, caused by the pressure drop along the section. The values of the pressure drops and potentials differences were determined by the solution of the set of $2N$ algebraic equations, where N is the number of sections in the capillary. These equations reflect the fact that the total flow of liquid and total current are constant along the capillary, and the sums of pressure drops and potential differences at the sections are equal to the total pressure drop and total potential difference at the whole capillary, respectively. The lengths of the sections were considered to be much larger than the capillary radius, so the results of the model are valid everywhere except the immediate vicinity of the points where the radius of capillary or the zeta potential of the wall change their values. When calculating the values of HETP in such a capillary, particle–wall electrostatic interactions were taken into consideration, and it was shown that HETP values are considerably larger for particles attracted by the wall. It was also shown that differences in the values of the zeta potential contributes to HETP much more significantly than the differences in radii values. The situation that might happen in the case of a bubble-cell detector was modeled and considerable growth of HETP was predicted.

In Ref.,[7] the case was studied in which the zeta potential of the wall was the linear function of the longitudinal coordinate. This situation may happen when the value of the zeta potential is controlled by the external electrical potential applied to the wall. Electrical potential value inside the capillary is naturally a linear function of the longitudinal coordinate x; therefore, if the electrical potential applied to the outer boundary of the capillary wall is constant, then the potential difference across the wall is a linear function of x. The theoretical approach used in Ref.,[7] is similar to the one in Ref.[5] Secondary parabolic flow was shown to be generated, leading to the increase of HETP. It was predicted theoretically, and verified experimentally, that a pressure profile superimposed on the capillary can, in some cases, compensate for the disturbed profile and reduce the HETP value.

In Ref.,[8] the mathematical model of CE in rectangular channels with non-equal values of the zeta potentials of the walls was developed. This model may be of interest for the case of CE on a microchip, where the microgroves are produced by wet chemical etching and, so, the walls of the groove can have different values of zeta potential than the cover plate that is not etched. Flow profiles for the channels with different aspect ratios and different combinations of the zeta potential values were examined. It was shown, for example, that a 10% difference in the values of the zeta potentials of upper and lower walls can cause a sixfold growth of the HETP value.

The above-mentioned examples show that EOF nonuniformities may occur in different situations and must be given considerable attention, as they can reduce the CE efficiency dramatically.

Abstract
Almost 20 years after the first demonstration of electrophoresis on a microchip (μ-chip) substrate, advances in microfabrication techniques and electrophoretic separation methodologies have resulted in the development of integrated systems offering high-efficiency separations coupled to sophisticated sample handling and detection schemes. The miniaturization of chemical analysis systems employing electrokinetic phenomena is explored in this entry, with particular reference to applications involving three major classes of analytes: DNA, proteins, and cells.

INTRODUCTION

The transposition of capillary electrophoresis (CE) methods from conventional capillaries to channels on planar chip substrates is an emergent separation science that has attracted widespread attention from analysts in many fields. Owing to the miniaturization of the separation format, CE-like separations on a chip typically offer shorter analysis times and lower reagent consumption augmented by the potential for portability of analytical instrumentation. Microchip (μ-chip) electrophoresis substrates boast optically flat surfaces, short diffusion distances, low Reynolds numbers, and high surface (or interface)-to-volume ratios. By exploiting these physical advantages of the chip over conventional capillaries, efficient μ-chip electrophoresis systems can accomplish multiple complicated tasks that may not be realized by a conventional CE system alone.

The first published demonstration of electrophoresis on a chip appeared almost 20 years ago and, although the separation efficiencies and analysis times in this pioneering work did not represent significant improvements over those achievable by way of conventional CE, this work demonstrated the feasibility of miniaturizing a chemical analysis system involving electrokinetic phenomena for sample injection, separation, and solvent pumping. Within 2 years of the first publication in this field, analysis times on the order of seconds and even milliseconds had been demonstrated with similar μ-chip systems, and efficiencies in excess of 100,000 theoretical plates were routinely obtained. Subsequently, the integration of other functionalities such as sample manipulations and chemical reactions, alongside electrophoretic separation, has vaulted μ-chip electrophoresis to new heights. In order to provide a rudimentary introduction to this important analytical technique, this entry will present the fundamentals of μ-chip fabrication methods and materials, sample introduction and detection methods, as well as selected recent *case studies* or notable applications of electrophoresis in microfabricated devices for various classes of analytes and various fields of study.

ADVANCES IN μ-CHIP FABRICATION AND DESIGN

The name "μ-chip" refers to the scale of the dimensions of the separation channels or other fluidic features as opposed to the dimensions of the substrate itself, which tend to be on the order of 1–2 mm in thickness and anywhere from 1 to 10 cm in length (or diameter for circular substrates). The evolution of μ-chip-based electrophoretic systems benefited initially from the tremendous advances in semiconductor microfabrication technologies witnessed over the past two decades. Although semiconducting substrates are not ideally suited to electrophoretic applications due to the high voltages applied for separation and fluid manipulation, many of the established semiconductor microfabrication techniques were modified for the insulating glass or quartz substrates that were most commonly encountered in early developments in the field of μ-chip electrophoresis. Micromachining of silicon and glass can involve wet and dry etching, photolithography, electron beam lithography, or a variety of other techniques, all of which require the use of clean-room facilities and equipment. Limitations posed by these high-cost and complicated (and potentially harmful) fabrication procedures have, in part, led to greater interest in polymer-based μ-chips. The trend toward the use of polymeric substrate materials, such as

polycarbonate, poly(dimethylsiloxane) PDMS, and poly(-methyl methacrylate) PMMA, has also been driven by the need for disposable μ-chips that are compatible with a wide variety of cellular, biological, and clinical samples (akin to the disposable plastic pipette tips, tubes, beads, plates, etc. commonly encountered in modern laboratories). Polymer μ-chip substrates are typically fabricated by a number of technologies, including in situ polymerization, replica molding, hot embossing, laser ablation, imprinting, and injection molding, the last of which is perhaps the best-known and the most frequently used technique in industrial settings. A thorough review of polymer microfabrication technologies is presented by Becker and Gärtner.[1] Even more recently, improvements in polymer μ-chip fabrication methods have been described, which involve a two-stage embossing technique and solvent welding on PMMA with water as a sacrificial layer.[2] With this technique, the tedious procedure of fabricating the primary mold can be avoided, and thus the overall time needed for fabrication is decreased considerably.

The concept of a *lab-on-a-chip* or a *micro-total-analysis-system* (μ-TAS) has pushed the development of even more advanced design features on chips. Sophisticated channel features such as weirs, pressure valves, and posts (columns) can be found with increasing frequency on chips. Weirs can be used to outline a specific area in the channel where beads or solgels with immobilized enzymes can be packed. Liquid can flow through these physical obstacles but the beads are held in place because of their larger size. Elastomeric materials that function as diaphragm pumps or valves can be manufactured from PDMS sandwiched between the channel and cover plate of the chip. This way, fluid movement in the chip can be manipulated by pressure as well as by electrokinetic means. Many other novel chip designs and features have been reported in the literature. For example, Inoue et al.[3] recently fabricated an I-shaped microchannel array (IMA) chip by integrating 12 independent microchannels, 2 electrodes, and 24 reservoirs onto a 3 × 2 cm area in a PDMS–glass hybrid μ-chip, complete with an integrated electrical wiring system to facilitate the autonomous regulation of sample plugs and high-throughput electrophoretic assays, as illustrated in Fig. 1. Also, Liu et al.[4] have developed 3-D microfluidic networks with an integrated combinatorial mixer for high-throughput combinatorial cell-based assays.

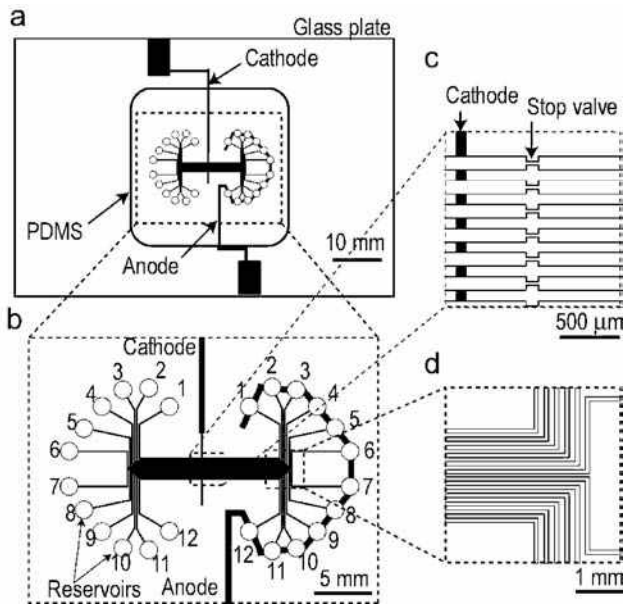

Fig. 1 Design of the IMA chip. a, Top view. The device consists of a 2 mm thick PDMS part with microchannels and a 1 mm thick glass plate with Au thin-film electrodes. b, Magnified view of the channel layout. The 12 I-shaped microchannels are arranged symmetrically with respect to both the horizontal and vertical axes. Each channel is 80 μm wide, 25 μm deep, and 28 mm long. The reservoirs with a diameter of 2 mm are punched in the PDMS part. The cathode is 80 μm wide and 200 nm thick. The anode is 400 μm wide and 200 nm thick. The distance between the cathode and the anode along the microchannels is 14.4 mm. c, Magnified view around the cathode. Each channel has a passive stop valve (8 μm wide and 80 μm long). The distance between adjacent channels (center to center) is 160 μm. The distance between the cathode and the passive stop valves is 0.4 mm. d, Magnified view around the corners of the microchannels.

SAMPLE INJECTION ON μ-CHIPS

Reproducible sample introduction is a crucial factor in μ-chip-based electrophoretic separations. Various μ-chip sample introduction schemes are illustrated in Fig. 2. Of the many proposed injection methods, electrokinetic injection based on electro-osmotic flow (EOF) is most commonly encountered on chips, because electrically driven fluid flow is easier to generate and control than pressure-driven flow. Electrokinetic sample injection is generally achieved through a simple cross, "T," or "double-T" arrangement of etched channels to form the injection structure. Each injector design has different injection modes depending on the applied electric field sequences. For example, the original T-geometry (which can suffer from sample leakage problems) can be operated in floating, pinched, reversed pinched, dynamic, gated, gated with diffusion, and double-L injection modes.

Research still continues into the development of enhanced electrokinetic injection techniques for μ-chips. Modifications made to the outlet end of the separation channel, such as its connection to a length of fused silica capillary to facilitate chip interfacing with off-chip detection systems for example, can be adopted equally well for chip inlets and sample introduction. The use of conventional capillary to interface between macroscale sample reservoirs and μ-chip platforms has been successfully

demonstrated[5] and has even been commercialized in the form of *sipper chips*, which are capable of sampling from up to 12 microtiter wells simultaneously via short lengths of conventional capillary interfaced to the bottom of the chip. In more recent work, Chang et al.[6] developed microfluidic electrophoresis devices with an enhanced injection scheme whereby a single- or a double-circular barrier is introduced in the intersection region of the microchannels in order to prevent sample leakage into the separation channel and to improve the sample plug definition.

Two of the main limitations of electrokinetic injection are its strong dependency on the surface properties of the channel walls and a bias toward different species depending upon their size and charge. Pressure-based injection techniques (such as pneumatic or hydrodynamic injection, based upon the hydrophobicity and wettability of channel surfaces) can solve the sampling bias problem, and so considerable effort has been devoted to the optimization of pressure injection. Karlinsey et al.[7] proposed a valved chip design that can perform both pressure and electrokinetic injections; Chen et al.[8] proposed a semihydrodynamic (SHD) injection coupled with a high-salt stacking method, which proved to be superior to regular hydrodynamic injection; Wang et al.[9] proposed an improved hydrostatic pressure sample injection method entailing nothing more than a simple tilt of the microchip, requiring no additional hardware and thus enabling this technology for disposable devices.

DETECTION ON μ-CHIPS

From the beginning, detection has been one of the main challenges for analytical microsystems, as very sensitive techniques are needed as a consequence of the ultrasmall sample volumes used in micrometer-sized environments. As μ-chip electrophoresis devices continue to advance, greater emphasis is being placed on detector design and configuration in order to achieve maximum sensitivity with low cost and ease of manufacture. The most common detection schemes employed in conjunction with μ-chip separations include optical [especially, laser-induced fluorescence (LIF) detection, chemiluminescence detection, and ultraviolet–visible (UV–Vis) absorbance], electrochemical, and mass spectrometric methods, although less commonly encountered chip detection methods such as refractive index, Raman, surface plasmon resonance, thermal lens, infrared, and nuclear magnetic resonance (NMR) have been used with success too.

LIF is the most widespread of all chip detection methods because of its high sensitivity despite small separation channel dimensions and the convenience of optically flat chip surfaces for detection purposes. However, since relatively few analytes are natively fluorescent, LIF detection often necessitates the development of selective and sensitive labeling strategies for each assay. Specialized on-chip LIF detection schemes such as the utilization of Hadamard transform CE with caged fluorescent labels have rendered detection limits down to as few as 18 molecules per injection event.[10]

Electrochemical detection (ECD) modes include amperometry, conductimetry, and potentiometry, with the first of these being employed most frequently. ECD is ideal for use with μ-chip electrophoresis systems because of the ease of miniaturization with no diminution in analytical performance and the ease of incorporating detection electrodes directly onto the chip by standard microfabrication procedures. Electroactive analytes can be easily detected using ECD methods, although non-electroactive compounds can also be detected by using derivatization agents, analogous to the use of derivatization in LIF detection schemes. Decoupling the electric field used to drive the electrophoretic separation from the ECD signal poses a

challenge on μ-chip electrophoresis substrates, just as it does with conventional CE capillaries. Recent fabrication developments involving gold nanoelectrode assemblies as working and decoupler electrodes in PMMA chips have enabled higher signal response (relative to a bulk gold working electrode) and reduced charging current and baseline drift (relative to a conventional palladium decoupler).[11] The development of a sheath flow ECD design,[12] which relies on gravity-driven flow of a sheath buffer to carry the electroactive analytes to the detection electrodes, is able to reduce the dependence of the ECD signal on electrode position, further improving the potential of ECD schemes for μ-chip-based electrophoretic analyses.

Mass spectrometry (MS) is a powerful alternative to ECD and optical detection schemes, especially for large biological molecules. The typical flow rates encountered in microfluidics (nanoliter to microliter per minute) are well suited to electrospray ionization mass spectrometry (ESI–MS). The integration of the ionization process onto microfluidic devices is challenging owing to the planar nature of microfabricated systems. Much work in this field deals with ways to create suitable tips for the generation of electrospray from the chip. One method for interfacing electrospray ionization with microfluidic devices involves gluing or bonding electrospray emitters, such as fused-silica capillaries or nanospray needles, to the end of the chip at the outlet of the microchannel. Another method is to integrate electrospray tips during the chip fabrication process. Advances in sheathless CE/ESI–MS interfaces have been reviewed by Zamfir.[13] Recognizing the potential for complementarity of microfabricated separation substrates and microfabricated detectors, Whitten, Reilly, and Ramsey have advanced a miniaturized ion-trap mass analyzer,[14] which shows spectral resolution comparable to conventional mass analyzers with slight compromises in sensitivity.

APPLICATIONS OF μ-CHIP ELECTROPHORESIS

One of the most impressive aspects of μ-chip electrophoresis is the diversity of analytes and the breadth of research fields that have been served by this technology. A comprehensive review of applications is not possible here, but instead, we will present a brief summary of interesting examples employing μ-chip electrophoresis for three major classes of analytes: DNA, proteins, and cells.

ELECTROPHORESIS OF DNA ON CHIPS

Since the first DNA separations on a single-lane μ-chip in the mid 1990s, improved fabrication and detection methods have allowed for a remarkable increase in the throughput and performance capabilities of these devices. Now, DNA analysis is one of the leading applications of μ-chip electrophoresis. Early DNA applications included the separation of oligonucleotides (10–25 bases) and sizing of longer DNA fragments. Sieving matrices such as linear poly(acrylamide) (LPA), hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), and hydroxypropylmethyl cellulose (HPMC) are often used for DNA fragment sizing. The formation of hydrogen bonds between polyhydroxy buffer additives and DNA analytes enhances the separation, as demonstrated by Xu, Jabasini, and Baba,[15] who separated DNA restriction fragments ranging in size from 72 to 1353 bp in a 3 cm long channel in 170 sec with HPMC. The application of μ-chip electrophoresis methods to more sophisticated DNA assays, including DNA sequencing, genotyping, and polymerase chain reaction (PCR) amplification, logically followed, and will be considered here.

Among the technologies being developed to reduce sequencing costs, μ-chip CE is most suitable for the de novo sequencing and assembly of large and complex genomes. DNA sequencing relies upon the Nobel Prize–winning Sanger dideoxy chain termination reaction, which is based on the controlled interruption of the enzymatic replication of an ssDNA template by a DNA polymerase. The Sanger reaction was used to produce a "ladder" of template-complementary DNA fragments that differ in length by one base and that bear unique fluorescent labels according to their terminal nitrogenous base, and so after separating these fragments (e.g., by μ-chip electrophoresis) and detecting the base-specific labels, the original sequence order of the fragments can be obtained by computational reassembly. Fredlake et al.[16] recently reported a microfluidic chip-based system that provides ultrafast DNA Sanger sequencing with read lengths up to 600 bases in 6.5 min.

Functional genomic studies focus on the analysis of gene variants in human populations for the purpose of disease diagnosis, prognosis, and management. Techniques such as single-nucleotide polymorphism (SNP) detection, single-stranded conformation polymorphism (SSCP) detection, heteroduplex analysis (HA), allele-specific PCR (ASPCR), and short tandem repeat (STR) analysis are commonly used for DNA mutation analysis. Single-nucleotide polymorphisms are single-base-pair changes or deletions in a natural DNA sequence, and there is an estimated number of 2–3 million SNPs that can differ between any two individuals' genomes. STRs are short stretches of repetitive DNA sequences that are distributed throughout the genome of every individual. Each genetic locus consists of 7–20 repeats of a specific 2- to 7-base sequence. By electrophoretic separation of these repeats, the DNA can be sequenced and genotyped. Because of the effectiveness of STR analysis, the Federal Bureau of Investigation (FBI) created a national criminal database—the Combined DNA Index System (CODIS)—in 1998. Owing to the rigorous demands of the database, analysis techniques need to possess high

reproducibility and throughput capability, and they should be fast, automated, and easily adaptable by instrument operators. To address these requirements, Goedecke et al. developed "GeneTrack," a multiplexed DNA analysis instrument.[17] It consisted of two units, the support and the top unit, with the former containing the necessary power supplies and the data acquisition system, and the latter containing the laser, optics, and the electrode board. The heart of the instrument, a microfabricated device, consisted of two glass plates thermally bonded together. Sixteen separation channels were wet-etched on one of the plates; sample injection was achieved using a classic double-T injector. The inner channel surfaces were silanized by following a modified Hjerten method and finally filled with LPA as the sieving media. Fluorescence detection was arranged with a multiline argon ion laser and four photomultiplier tubes (PMTs) that allowed for four-color detection when coupled with a system of dichroic mirrors. The developed system was validated by analyzing the DNA template 9947a with the PowerPlex® 16 PCR kit from Promega. All the 16 lanes on the microchip were used for the analysis, which was repeated 6 times over 4 days. It was reported that 92 out of the 96 total lanes performed successfully. Also, after statistical testing, the instrument was shown to have 0.4–0.9 bp absolute signal accuracy for the full 13-locus STR DNA determination as required by the CODIS. For the specific TH01 DNA locus it was shown that the required single-base-pair resolution was reliably achieved. The authors concluded by stating that "the system is optimized for the forensics 'casework' application and is expected to exceed current capillary systems in sample economy, critical temperature/environmental stability, and software features."

Improved throughput and reduced cost have governed genotyping assay development. A capillary array electrophoresis (CAE) bioanalyzer with 384 lanes etched radially around the center of a round, 200 mm diameter borosilicate glass wafer with a common central anode was developed.[18] The utility of this system was demonstrated for the simultaneous genotyping of the DNA from 384 individuals for a hereditary hemochromatosis (HHC)-related mutation in the human HFE gene. HHC is not only one of the most common autosomal recessive diseases in the United States, but its diagnosis also remains troublesome. The genotyping success rate for the 384-lane chip was found to be 98.7% with a relative mobility deviation of less than 2.2%. Electrophoresis of the samples was completed in 325 sec. It was concluded that the μ-chip device outperformed the best commercially available 96-capillary instruments by a factor of 20 and that it could be ideal for gene mapping, pharmacogenomic screening, forensics, and proteomics.

PCR is an enzyme-mediated process whereby, in response to temperature cycling, a single DNA molecule can be rapidly amplified into many billions of molecules. Scaling down PCR technology to allow its integration with microfluidic systems is essential to the analysis of DNA in this realm. For example, Prakash et al.[19] have used off-chip, real-time PCR to validate a recently developed chip technology that integrates PCR with CE to detect the respiratory pathogen *Bordetella pertussis*. This chip technology used less than 3 μl for PCR and only 0.3 μl for subsequent CE analysis to identify *B. pertussis* from the equivalent genetic content of two or fewer cells, as illustrated in Fig. 3. Another recent technology developed by Easley, Humphrey, and Landers[20] provides a non-contact, infrared-mediated system for μ-chip DNA amplification via PCR, which focuses on heat transfer modeling and subsequent fabrication of thermally isolated reaction chambers in glass devices. These devices are compatible with standard photolithography and wet-etching techniques and can realize rapid temperature control. Notably, this is the fastest static PCR in glass devices reported to date: 25 thermal cycles are completed in only 5 min in thermally isolated PCR chambers of 270 nl volume for DNA amplification. The recurring goals of low cost, low sample requirement, and high throughput for DNA analysis are clearly met by integrated μ-chip electrophoresis devices.[21]

ELECTROPHORESIS OF PROTEINS ON CHIPS

On-chip protein analysis encompasses a wide range of applications and technical developments. On-chip protein assays began with simple demonstrations of 1-D separations: sodium dodecyl sulfate (SDS) gel-based molecular sizing, isoelectric focusing (IEF), capillary electrochromatography (CEC), and micellar electrokinetic chromatography (MEKC). However, the sequential coupling of these methods in two orthogonal dimensions was subsequently demonstrated on a chip, to reproduce the more traditional 2-D separations fundamental to proteomic studies. A simultaneous 2-D microchip design consisting of an IEF microchannel orthogonal to an array of SDS-PEO [poly(ethylene oxide)] gel microchannels on a plastic substrate as small as 2 × 3 cm, as reported by Li et al.,[22] offered an alternative to the inherently serial nature of most 2-D microchip designs. This design permitted the focused and concentrated protein fractions from the IEF channel to be simultaneously injected and separated (on the basis of protein size) in the multiple, parallel SDS-gel channels in the orthogonal array, yielding a comprehensive protein separation in less than 10 min with a peak capacity of about 1700. Furthermore, it was proposed that the peak capacity could be increased by simply raising the density of microchannels in the second-dimension array, which would have the effect of increasing the number of fractions from the IEF dimension that could be simultaneously analyzed in the size-based SDS–PEO separation dimension.

However, fluorescent derivatization of proteins is not compatible with IEF (as the derivatization may alter the

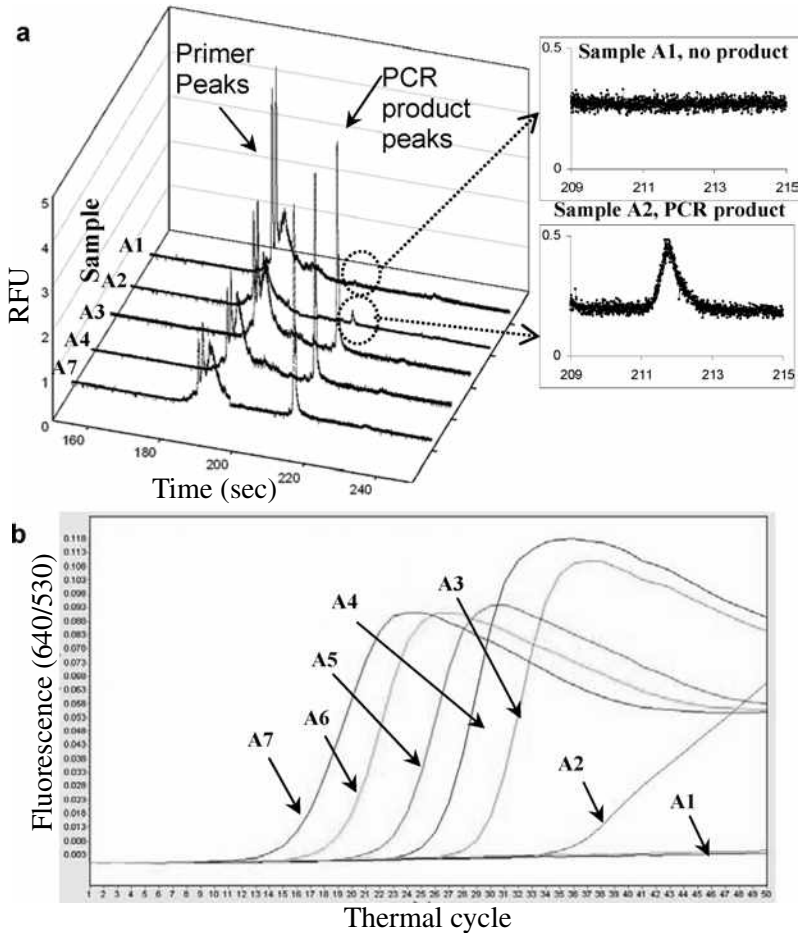

Fig. 3 Integration of PCR with CE to detect the respiratory pathogen *Bordetella pertussis*. a, The 3-D plot shows the CE analysis of different concentrations of *B. pertussis* samples run on the integrated chip. For clarity, the PCR product ''Time vs. RFU'' for samples A2 and A1 are shown in magnified inserts. b, Real-time PCR LightCycler® amplification profile of the IS481 hybridization probe assay with a dilution series of *B. pertussis*, for samples A7–A1. In CE the PCR amplification is analyzed based on the fluorescence intensity of the amplified DNA and time, while in real-time PCR it is analyzed at the amplification stage itself by the fluorescence of the hybridization probe at each thermal cycle.

isoelectric point of the labeled protein), and so Shadpour and Soper[23] recently described an alternative 2-D electrophoretic separation of derivatized proteins ranging in size from 38 to 110 kDa using an embossed PMMA microchip. In this work, separation in the first dimension (30 mm length) was based on size using SDS-microcapillary gel electrophoresis while separation in the second dimension (10 mm length) was based on pseudostationary phase partitioning using MEKC. LIF detection followed the MEKC dimension to provide for the sensitive determination of proteins conjugated with the Alexa Fluor® 633 label. Average plate numbers of 4.8×10^4 and 1.2×10^4 were obtained for the first and second dimensions, respectively, while the full 2-D separation was performed in about 12 min with a peak capacity of about 1000.

Covalent derivatization of proteins in this instance dictated the modes of separation and enhanced detection sensitivity. Non-covalent dye–protein interactions can alternatively be exploited to facilitate protein determination by μ-chip electrophoresis with LIF detection, thus offering greater selectivity and sensitivity than is possible with absorbance detection while entailing a simpler and faster labeling protocol than required by conventional covalent labels. Sloat et al.[24] recently employed the asymmetric squarylium dye Red-1c as a non-covalent label in both on-column and pre-column derivatization methods for protein determination by μ-chip electrophoresis with LIF detection. This was the first demonstration of Krylov's non-equilibrium CE of equilibrium mixtures (NECEEM) theory[25] to calculate binding constants for dye–protein complexes in microchip substrates based on areas beneath bound and free dye peaks in the resulting electropherograms (Fig. 4), with the aim of developing more selective and sensitive non-covalent chip-based labeling strategies for CE–LIF protein assays.

Beyond their rapidly developing role in 1-D and 2-D protein separations and protein-binding studies, μ-chip platforms also offer advantages in other aspects of protein assays, such as sample "prep" and direct transfer to MS detection systems. Whereas traditional protein assays may require spot excision and proteolytic digestion following 1-D or 2-D gel-based separations, concluding with

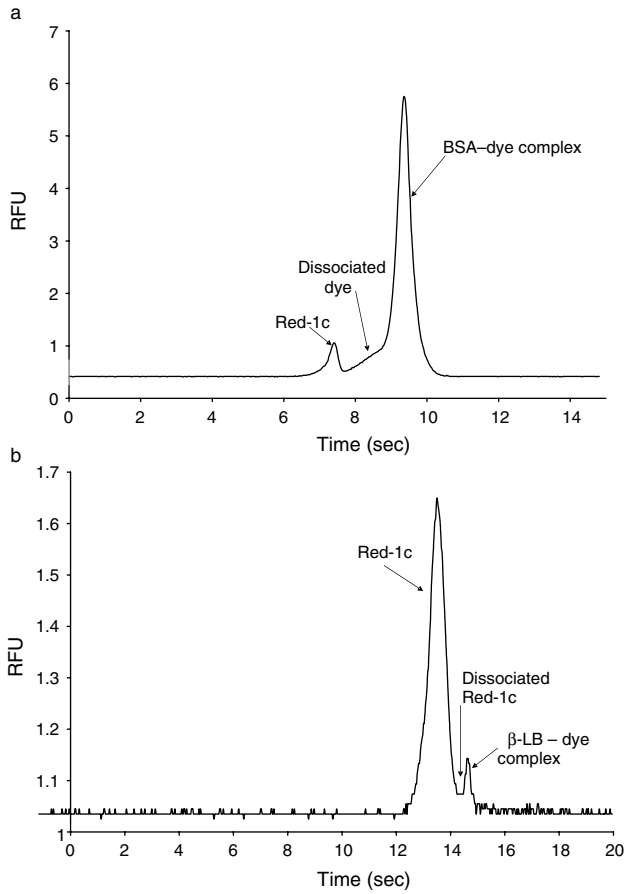

Fig. 4 The separation of free dye and protein–dye complex by micro-chip NECEEM. a, BSA–Red-1c complex. Sample and experimental details: Precolumn labeling of 0.50 μmol BSA with 5.0 μmol Red-1c; 60 sec injection; 2500 V separation voltage; 6 mm effective separation channel length; 800 V PMT voltage; b, β-lactoglobulin B–Red-1c complex. Sample and experimental details: Precolumn labeling of 75 μmol β-lactoglobulin B with 5.0 μmol Red-1c; 10 mm effective separation channel length; 100 mmol boric acid buffer (pH 9.5) with 100 mmol KCl.

detection of the resulting digestion fragments by mass spectrometry, μ-chip electrophoresis systems can integrate these many functionalities or can provide suitable alternatives to them. A microfabricated CE–MS device recently developed by Mellors et al.[26] performs electrospray ionization directly from the corner of the chip to a mass spectrometer to detect peptides and proteins with efficiencies in excess of 1 million plates per meter. A positively charged surface coating reversed the direction of EOF in the chip channels and prevented interactions between the analytes and channel surfaces. This work, which also identified 37 peptide fragments from the tryptic digest of bovine serum albumin (BSA), accounting for 58% coverage of the total sequence of BSA, offers much promise for future proteomic studies employing similar μ-chip technologies.

ELECTROPHORESIS OF CELLS ON CHIPS

Understanding biological chemistry from both structural and functional perspectives necessitates tools capable of analysis not only on the molecular level (e.g., of proteins and DNA) but also on the cellular level. Extending the realm of the so-called lab-on-a-chip to the lab-in-a-cell concept requires three particular areas to be addressed, including cell sorting or trapping, cell treatment, and cell analysis. Most cells have a net negative charge near physiological pH, and so an electric field can be used to transport them. Li and Harrison[27] first took advantage of this fact in their demonstration of electrophoretic and electro-osmotic pumping of three cell types—baker's yeast, *Escherichia coli*, and canine erythrocytes (red blood cells)—within a network of microfabricated capillary channels. EOF in their uncoated glass chips exceeded the electrophoretic mobility of the cells, and so the net transport of cells toward the cathode was observed at near physiological pH values. Cell velocities of up to 0.5 mm/sec in channels with 15 × 50 μm cross-sections were observed. Care was taken to avoid cell lysis caused by the application of the separation voltage (less than 600 V/cm and typically about 100 V/cm), although high electric fields (1–10 kV/cm) have been shown to cause cell membrane permeation. Cell adhesion to the channel walls was observed in the case of yeast and *E. coli*; however, reduction of cell counts significantly relieved this problem, as did wall treatment with a commercial trichlorohexadecylsilane agent, rendering the walls hydrophobic. This wall treatment, however, also substantially reduced the EOF, so that the electrophoretic mobility of the negatively charged canine erythrocytes in isotonic solution (toward the anode) exceeded the EOF toward the cathode. Furthermore, Li and Harrison were able to demonstrate the second component of cell analysis—namely, cell treatment—by successfully using electrokinetic effects to mix streams of canine erythrocytes and SDS directly on the chip and subsequently observing the resulting cell lysis. Thus, this successful demonstration of cell sorting or directed cell transport and cell lysing by an electrokinetic, valveless control scheme within a system of four intersecting channels clearly established the utility of electrophoresis on microfabricated devices for cellular analysis.

Single-cell analysis is essential to the growing pursuits of proteomics and systems biology. Thus, more and more sophisticated chip-based cellular assays have followed this pioneering work. For example, Huang et al.[28] recently developed a microfluidic device with a three-state valve to

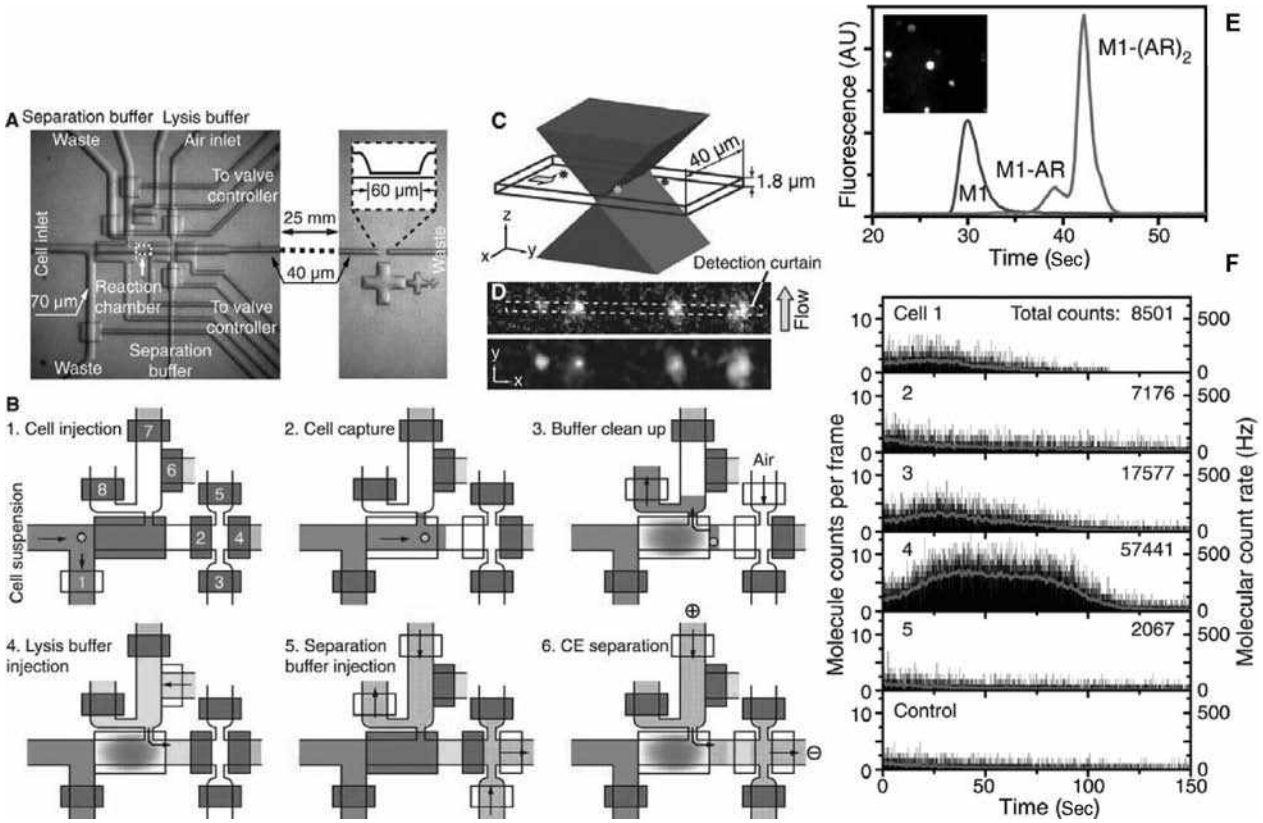

Fig. 5 The single-cell analysis chip and the analysis of β_2AR in Sf9 cells. integrate the isolation of an individual cell from a bulk suspension; the accurate metering and delivery of chemical reagents; the performance of cell lysis and chemical derivatization reactions; and the separation of derivatized cell contents by CE–LIF. Between the three-state valve and a conventional two-state valve in this system is the reaction chamber in which both cell capture and the labeling of proteins were achieved (see Fig. 5). The latter function involved fluorescent–antibody binding by injecting a lysing/labeling buffer into the reaction chamber to release the cell contents. In order to achieve high-efficiency counting of molecules in micrometer-sized channels, cylindrical optics were used to form a rectangular, curtain-shaped detection region across the channel. By combining this microfluidic device with single-molecule fluorescence counting, β_2 adrenergic receptors expressed in Sf9 cells were quantified and phycobiliprotein content in individual cyanobacterial cells (*Synechococcus* sp. PCC 7942) was also determined.

Greif et al.[29] reported on novel chip architectures for single-cell analysis based on full-body quartz glass (QG) μ-chips. The enhanced sensitivity of QG chips as compared to PDMS chips and PDMS quartz window (PQW) chips employing native UV laser-induced fluorescence (UV-LIF) detection was shown. The combination of a higher pH for the separation buffer and the use of dodecyl-β-D-maltoside (DDM) and methylcellulose (MC) as dynamic wall coatings resulted in higher detection sensitivities and separation efficiencies for single-cell electropherograms of *Spodoptera frugiperda* (Sf9) insect cells. This method offers promise for label-free protein fingerprinting of single cells.

CONCLUSIONS AND FUTURE PERSPECTIVES

The advantages typically associated with CE, such as reduced sample and reagent consumption, reduced analysis time, and increased separation efficiency, are augmented when the CE system is transposed to a μ-chip substrate. Beyond electrophoresis, however, μ-chip substrates offer the distinct advantage of functional process integration.

Analytical processes such as sample preparation, injection, reaction, and detection can be seamlessly tied to electrophoretically driven separations on microfabricated chips en route to the realization of a true lab-on-a-chip.

The very nature of μ-chip electrophoresis systems, characterized by their capacity for high-throughput, high-speed, high-sensitivity, and low-sample-consumption assays, makes them inherently well suited to the clinical setting, as documented in a recent review article by Dewald, Poe, and Landers.[30] Likewise, these same characteristics render μ-chip electrophoresis systems invaluable to numerous other realms, such as forensics, environmental analysis, oceanography, and homeland security. However, the full realization of portable, field-based, or point-of-care analysis systems still lags behind the promise of research-based systems, and this deficiency needs to be remedied through continued advances in interfacing, engineering, and commercialization. As the complexity of chip designs increases, and as we strive to fully realize the advantages offered by the microfluidics regime of the chip, we must continue to carefully manage methods of physically addressing their small structures and volumes, and of interfacing to the macroscale world beyond the chip. In this regard, passive approaches to controlling fluid flow through complex chip architectures without active valves will become key.[31]

Although chip fabrication techniques are quite well established and varied, they are still not accessible to the majority of analysts. Fabrication processes must continue to be refined to allow routine chip construction at the hands of analysts in regular research labs, or ideally, the chips themselves must be made more readily available at low cost and in a variety of application designs for all potential users. Miniaturization, or careful arrangement of the apparatus accompanying the electrophoresis chip, including power supplies, detection systems, computer controllers, and other components, into compact and robust systems, must be considered in order to take full advantage of the chip's small size. It is in this respect that novel, cost-effective approaches for rapid chip prototyping will be critical not only to application development, but possibly to mass fabrication of single-use, disposable microdevices.[32]

Despite these remaining challenges, which offer exciting opportunities for discovery in numerous fields of study, it should be noted that electrophoretic separations remain the cornerstone of μ-chip-based analysis systems, and so the fields of analytical chemistry and separation science must continue to take the lead in the development of these promising and important tools, techniques, and technologies.

Electrospray Ionization Interface for CE/MS

Joanne Severs
Bayer Pharmaceuticals, Berkeley, California, U.S.A.

INTRODUCTION

The development of the electrospray ionization (ESI) source for mass spectrometry (MS) provided an ideal means of detection for capillary electrophoretic (CE) separations. The ESI source is currently the preferred interface for CE/MS, due to the fact that it can produce ions directly from liquids at atmospheric pressure and with high sensitivity and selectivity for a wide range of analytes.

DISCUSSION

ESI is initiated by generating a high potential difference between the spray capillary tip and a counterelectrode.[1] This electric field leads to the production of micron-sized droplets with an uneven charge distribution, generally accepted to be due to an electrophoretic mechanism acting on electrolytes in the solvent.[2] This mechanism, combined with a shrinkage of the droplets due to solvent evaporation (aided by heat and an applied gas flow into the source), leads to electrostatic repulsion overcoming surface tension in the droplet. The "Rayleigh" limit is reached, a "Taylor cone" is formed, and smaller highly charged droplets are emitted, eventually leading to the production of gas-phase ions.[1–3] These ions are accelerated through a skimmer into successive vacuum stages of the mass analyzer. The ESI source has been demonstrated to act as an electrolytic cell, generating electrochemical oxidation and reduction.[2] The exact ionization mechanism will vary with experimental conditions and is still an area of continuing in-depth research and discussion.[3]

ESI is classified as a "soft" ionization technique. It produces molecular-weight information and very little, if any, fragmentation of the analyte ion, unless induced in the vacuum region of the mass analyzer. The number of charges accumulated by an analyte ion is proportional to its number of basic or acidic sites. The spray polarity and conditions, solution pH and nature, as well as solute concentration will all effect the charge state distribution observed in the mass spectrum. Multiple charging of an analyte ion encourages the release of very high-molecular-weight ions. It is mainly due to this fact that ESI has gained such enormous interest, especially among biochemists. Employing only small, relatively inexpensive mass analyzers, spectrometrists are able to obtain high-sensitivity information on analytes with molecular weights of up to 200 kDa. The multiple-charging phenomenon means that the mass-to-charge (m/z) range of the analyzer does not generally need to exceed 3000. A deconvolution algorithm,[4] generally built nowadays into the instrument software, can be applied to the series of multiple-charged, molecular-ion peaks, and a single peak, representing the molecular weight, is then displayed on a "true mass" scale. The m/z scale is calibrated with standards of known exact mass. Whereas ESI/MS has made the largest impact on large biomolecule analysis, CE/ESI/MS has also been applied with great success to the analysis of many small-molecule applications.

The development of the first CE/MS was prompted by the early reports on ESI/MS by Fenn and coworkers in the mid-1980s,[1] when it was recognized that CE would provide an optimal flow rate of polar and ionic species to the ESI source. In this initial CE/MS report, a metal coating on the tip of the CE capillary made contact with a metal sheath capillary to which the ESI voltage was applied.[5] In this way, the sheath capillary acted as both the CE cathode, closing the CE electrical circuit, and the ESI source (emitter). Ideally, the interface between CE and MS should maintain separation efficiency and resolution, be sensitive, precise, linear in response, maintain electrical continuity across the separation capillary so as to define the CE field gradient, be able to cope with all eluents presented by the CE separation step, and be able to provide efficient ionization from low flow rates for mass analysis.

Several research groups have presented work on the development of CE/ESI/MS interfaces. The interfaces developed can be categorized into three main groups: coaxial sheath flow, liquid junction, and sheathless interfaces. A schematic of the sheath-flow interface first developed for CE/ESI/MS by Smith et al.[6] is illustrated in Fig. 1a. A sheath liquid, with an electrolytic content, is infused into the ESI source at a constant rate, through the coaxial sheath capillary which surrounds the end of the separation capillary and terminates near the end of the separation capillary. This sheath liquid mixes with the separation buffer as it elutes from the tip of the CE, thus providing the necessary electrical contact between the ESI needle and the CE buffer, and closing the CE circuit. Because the CE terminus and ESI source are at the same voltage, if the ESI source requires a high voltage (2–5 kV) (rather than ground potential), then the ESI voltage chosen

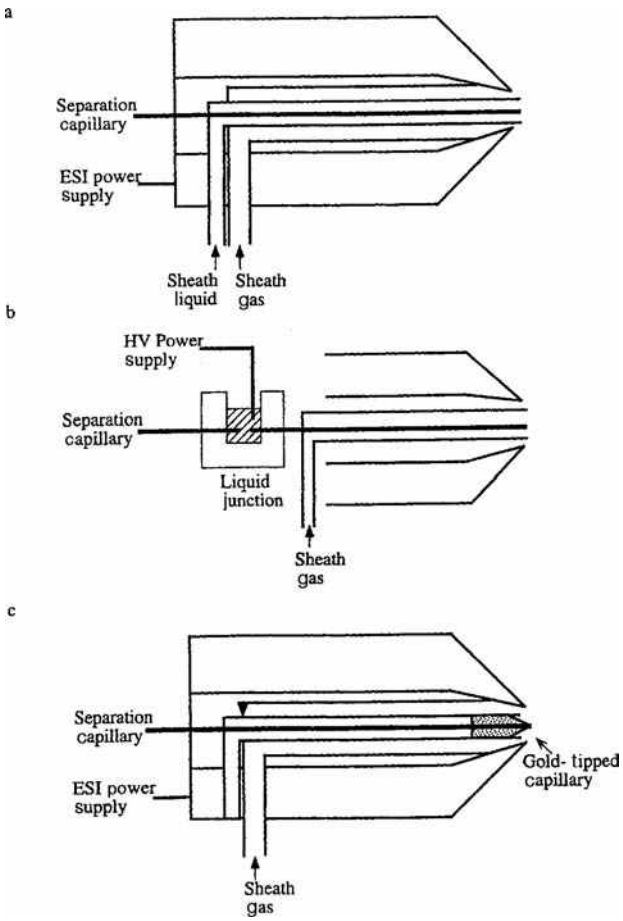

Fig. 1 Schematic illustration of CE/MS interfaces to an ESI. **Source:** a, a coaxial sheath-flow interface; b, a liquid-junction interface; c, a sheathless interface.

also directly affects the potential difference across the separation capillary. To date, the sheath–liquid interface has been the most widely used and accepted system, being the simplest to construct, with numerous results published employing sheath liquids typically containing 60–80% organic solvent, modified with 1–3% acid in water and typically introduced at flow rates of 1–4 μl/min. The composition of the sheath liquid should be optimized for the specific systems under investigation. Recent reports have confirmed that the relative dimensions and positioning of the separation and sheath capillaries also influence sensitivity and stability.

Although the additional flow of an organic-containing electrolyte into the ESI source moderately extends the range of CE buffer systems that can be used, the CE buffer composition still has a dramatic effect on the ESI signal, minimizing the buffer choice for best sensitivity to volatile solutions. Reports have also highlighted the need for a considered selection of sheath-liquid composition due to the possibility of formation of moving ionic boundaries inside the capillary.[7] The possibility of these effects occurring should be considered and minimized when transferring a CE method from an alternative detection system to MS. It should be noted, however, that these effects are minimized or eliminated when there is a sufficiently strong flow toward the CE terminus.

A "liquid-junction interface" has also been suggested and applied for CE/ESI/MS.[8] Electrical contact with this interface is established through the liquid reservoir which surrounds the junction of the separation capillary and a transfer capillary, as shown in Fig. 1b. The gap between the two capillaries is approximately 10–20 μm, allowing sufficient makeup liquid from the reservoir to be drawn into the transfer capillary while avoiding analyte loss. The flow of makeup liquid into the transfer capillary is induced by a combination of gravity and the Venturi effect of the nebulizing gas at the capillary tip.[8]

In comparisons of coaxial sheath-flow and liquid-junction interfaces, it has been noted that although both provide efficient coupling, the former is generally easier to operate. One of the major disadvantages in employing the liquid-junction interface is in establishing a reproducible connection inside the tee piece. Also, the use of a transfer capillary, which has no potential difference applied across it, can lead to peak broadening. Advantages of this interface, however, include the possibility of combining different outer-diameter capillaries through the junction and the extra mixing time provided for the makeup liquid and CE eluant.

The problem with both interfaces described so far is that they depend on the addition of excess electrolyte to the ESI source to maintain the circuit, generally leading to a decrease in analyte sensitivity. As previously mentioned, the first CE/MS interface reported made electrical connection between the separation buffer and the ESI needle via a metal coating on the tip of the CE capillary,[5] as represented in Fig. 1c. Although femtomole detection limits and separation efficiencies of up to half a million theoretical plates were achieved, problems included a high dependence on the buffer system used and the need to regularly replace the metal coating on the capillary tip.

The further development of interfaces which do not rely on an additional liquid flow are currently underway. Generally, they have employed metal deposition on the CE terminus that is tapered (by chemical etching or mechanical pulling) to provide an increased electric field at the capillary tip. These so-called "microspray" and "nanospray" approaches, with more effective ionization mechanisms, have been adopted recently by several groups for interfacing infusion systems, LC and CE to ESI/MS, and in all cases, significant gains in sensitivity and sample usage have been observed.[9,10] Attomole level detection limits from nanoliter sample volumes can now be attained, and the ability to form an electrospray from a purely aqueous solution is now possible. Alternative

sheathless interfaces have also been briefly investigated.[11] Stability problems still need consideration in most cases. An interface which does not use an additional makeup flow can, as well as aiding sensitivity, also avoid such problems as charge state distribution shifts in the mass spectrum. In addition, the ability to electrospray purely aqueous systems is often advantageous for looking at fragile biological and non-covalently bound analytes. In some cases, however, a makeup liquid may be found necessary. For example, for certain separations, the EOF may need to be minimized or eliminated in the CE capillary, and thus flow rates into the source will not be sufficiently high as to maintain a stable electrospray. If a capillary needs to be coated to avoid analyte interaction with the capillary wall, then a cationic coating, which reverses the electro-osmotic flow (EOF) rather than eliminating it, should preferably be chosen if a sheathless system is to be employed. Also, it may be found that a makeup liquid is necessary to increase the volatility of a specific CE electrolyte system.

Another disadvantage at present in using the sheathless interface is the time dispensed in preparing the tapered, coated tips. Although the coatings now employed are more stable than those initially used, the tips do not regularly survive more than a day or two of use. This can, however, be due to the tip "plugging" rather than the metal coating deteriorating. Filtering of electrolyte and analytes and rinsing of the capillary can, therefore, often prolong the capillary lifetime.

An instrumental attribute which aids the development and interfacing of CE to ESI/MS is the ability to pressurize the CE, at low pressure for sample injection and higher pressures for capillary content elution. Balancing of the heights of the capillary termini is also an important consideration in order to avoid syphoning effects. In all cases of CE/ESI/MS application, safety, with respect to the electrical circuits, should be considered. It should be verified that all circuits have a common ground, and the addition of a resistor in the ESI power supply line when interfaced to CE is a wise precaution.

An incompatability that does need to be considered in CE/MS method development is the use of certain CE buffer systems and additives which are detrimental to the ESI process. For example, although sample concentration can be increased by the use of more conductive buffers, this approach is not advantageous for ESI/MS detection. These characteristics result in a significant demand upon ESI interface efficiency.[12] Ideally, the chosen CE buffer should be volatile, such as ammonium acetate or formate. The use of pure acids or bases rather than a true buffer has also been shown to be advantageous for certain molecules. Non-aqueous buffer systems are also being employed more widely.

Capillary electrokinetic chromatography (CEKC) with ESI/MS requires either the use of additives that do not significantly impact the ESI process or a method for their removal prior to the electrospray. Although this problem has not yet been completely solved, recent reports have suggested that considered choices of surfactant type and reduction of EOF and surfactant in the capillary can decrease problems. Because most analytes that benefit from the CEKC mode of operation can be effectively addressed by the interface of other separations methods with MS, more emphasis has until now been placed upon interfacing with other CE modes. For "small-molecule" CE analysis, in which micellar and inclusion complex systems are commonly used, atmospheric pressure chemical ionization (APCI) may provide a useful alternative to ESI, as it is not as greatly affected by involatile salts and additives.

The efficiency of the ESI detection process for CE/MS can be considered in terms of the simple model of Kebarle and Tang[2] and has been discussed in great detail by Smith and coworkers.[12] These considerations indicate that analyte sensitivity in CE/ESI/MS may be increased by reducing the mass flow rate of the background components. This decrease in background flow rates can be experimentally accomplished by decreasing the electric field or employing smaller-diameter capillaries, and this predicted increase in analyte sensitivity is now well supported by experimental studies.[12]

To reduce the elution speed of the analyte ions into the source, the electrophoretic voltage can be decreased just prior to elution of the first analyte of interest, minimizing the experimental analysis time while allowing more scans to be recorded without a significant loss in ion intensity.[12] Alternatively, the use of smaller-diameter capillaries than conventionally used for CE also increases sensitivity.[12] A capillary diameter should, ideally, be commercially available, amenable to alternative detection methods, provide the necessary detector sensitivity, and be free from clogging. Capillary internal diameters of between 20 and 40 μm have been shown to be optimal and are compatible with "microspray" techniques.

The further development of microscale preconcentration and cleanup techniques and the resulting improvements in CE/MS concentration detection limits are likely to expand the use of this analytical technique. The more common use of small-diameter capillaries and even tiny etched microplate devices,[11] along with the improvements in ESI spray techniques are pushing research along. Further investigations into improving interface design, durability, reproducibility, and sensitivity are still necessary. The availability of improved, less expensive, and smaller mass spectrometers will almost certainly lead to increased use of CE/MS. However, the sensitivity and selectivity already demonstrated by CE/MS systems, in combination with the minute analyte volumes sampled, already make this a highly powerful technique.

Eluotropic Series of Solvents for TLC

Simion Gocan
Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania

INTRODUCTION

The easiest way to vary the relative adsorption of the sample (and its R_f value, migration rate, respectively) is to change the solvent: strong (polar) eluents decrease adsorption, and weak (no polar) eluents increase it. When benzene, for instance, is used as solvent on silica gels or alumina layers, the ethers and esters are found on top of the chromatogram (with high R_f values), ketones and aldehydes are approximately in the center (medium R_f values), and the alcohols are below them (low R_f values), whereas the acids remain at the starting point ($R_f = 0$). Thus the separation sequence follows the polarities of the compounds.

The dielectric constant may be taken as an indication of solvent polarity, but the interfacial tension between solvents and polar adsorbents, approximated by the interfacial tension between the solvent and water, has been suggested as a fundamental basis for correlating solvent strength.

The physical factors that determine solvent strength in a given adsorption system have long been understood in general terms. Solvent strength can be interpreted in terms of the following basic contributions: 1) interactions between solvent molecules and a sample molecule in solution; 2) interactions between solvent molecules and a sample molecule in the adsorbed phase; and 3) interactions between an adsorbed solvent molecule and the adsorbent.

ELUOTROPIC SERIES

Normal-Phase Thin-Layer Chromatography (NPTLC)

A series of authors has defined the solvent relative strength for polar adsorbents in the form of eluotropic series, grouping them in order of their chromatographic elution strength, with both pure solvents and mixtures of solvents included. The most familiar of these is, of course, the one set up by Trappe,[1] and variations of this have been published from time to time. Trappe gave the following series (listed in order of increasing elution power): light petroleum, cyclohexane, carbon tetrachloride, trichloroethylene, toluene, benzene, dichloromethane, chloroform, ether, ethyl acetate, acetone, *n*-propanol, ethanol, and methanol.

The eluotropic series of pure solvents is generally referred to a particular adsorbent. The magnitude of ε^o, the solvent strength parameter, can be defined as the adsorption energy of the solvent per unit of the standard activity surface. All these ε^o values are relative to the solvent pentane, for which ε^o is defined equal to zero. This parameter is defined as a measure of the degree of the adsorption interaction of the solvent with the stationary phase. As a function of this magnitude, the eluotropic series for various polar adsorbents is presented in Table 1.

It is well recognized that the eluotropic series of solvents, according to Snyder, is suited for monoactive site-type adsorbents, but in the case of multiactive site-type adsorbents (e.g., alumina), their imperfection becomes acute. Thus for multiactive-site-type adsorbents, the eluotropic series sequence and eluent strength values are highly dependent on the class of test solutes employed.[7]

A practical eluotropic series of solvents, based on the expended solubility parameter concept, was reported.[8] This series was defined based on partial specific solubility parameter (δ_s) that is equal to the sum of Keeson (δ_o) and acid–base ($2\delta_a\delta_b$), which represents the contribution to interaction forces introduced to characterize the solute, the mobile, and the stationary phase in liquid–solid chromatography. Exactly the same two interaction forces define ε^o and, consequently, there should exist a direct relation between ε^o and $\delta_s{}^2 = \delta_o{}^2 + 2\delta_a\delta_b$. Unfortunately, the general correlation for all the solvents on alumina is poor ($r^2 = 0.75$).

Snyder[2] has shown that there is a correlation between the ε^o values for a certain polar adsorbent (i.e., silica gel, Florisil, magnesia, and alumina). These values can be estimated from values for alumina using the following equations:

$$\varepsilon^o_{\text{silica gel}} = 0.77\varepsilon^o_{\text{alumina}}$$

$$\varepsilon^o_{\text{Florisil}} = 0.52\varepsilon^o_{\text{alumina}}$$

and

$$\varepsilon^o_{\text{magnesia}} = 0.58\varepsilon^o_{\text{alumina}}$$

I–VIII represent groups from Snyder's classification.
[a]Selectivity group irrelevant because of low P' values.
[b]Close to group and VIII.

The values calculated by means of these equations show the standard deviation of ε^o values $\pm$ 0.004 units with respect to the experimental values.

The relationships between eluent strength and composition for binary (one to two) and ternary (one to three) solvents have been derived:[2]

$$\varepsilon_1 - \varepsilon_2 = \varepsilon_1 + \frac{\log[X_2 10^{\alpha n_2(\varepsilon_2 - \varepsilon_1)} + 1 - X_2]}{\alpha n_2} \quad (1)$$

$$\varepsilon_1 \rightarrow \varepsilon_3 = \varepsilon_2 - \frac{\log[X_3 10^{\alpha n_3(\varepsilon_3 - \varepsilon_2)} + X_2]}{\alpha n_3} \quad (2)$$

Eluent strength is assumed to increase in the order $\varepsilon_1 < \varepsilon_2 < \varepsilon_3$ for solvents A, B, and C; n_2 and n_3 are the effective molecular areas of adsorbed solvent molecules B and C, respectively (with the exception of certain very strong solvents); X_2 and X_3 are the mole fractions of B and C in the solvent mixtures; and α represents the adsorbent's surface activity. To use Eqs. 1 and 2, we must know the activity degree of the adsorbent. Consequently, the α (adsorbent surface activity function) values for a few adsorbents with respect to water content are presented in Table 2. Based on the data in Tables 1 and 2, and by using Eq. 1, an infinite number of such series can be established.

The principle of the variation of solvent composition while holding solvent strength constant was first developed by Neher[9] for separation of steroids. Fig. 1 is a representation of the eluotropic series of Neher for application in this fashion. Six solvents, which will act as solvent S_1 (100% concentration, on the left), are arranged vertically, whereas the same solvents, acting as solvent S_2 (100% concentration, on the right of the horizontal lines) in a binary solvent eluotropic series, are arranged horizontally. We can obtain a very large number of binary systems, of the same or different strength, by means of this nomogram. The dashed line X determines 12 compositions of binary systems of the same average eluotropic properties. These

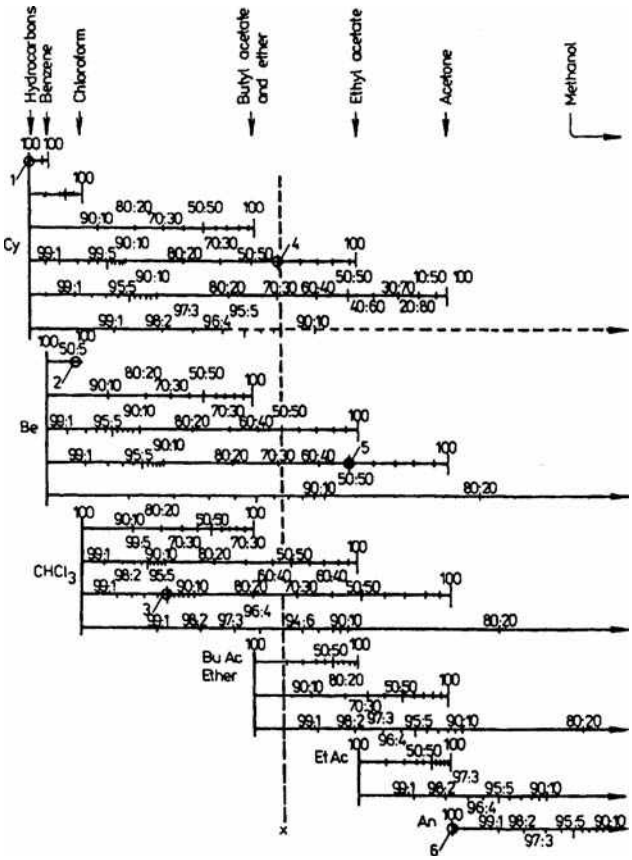

Fig. 1 Eluotropic series of Neher. Cy = cyclohexane; Be = benzene; BuAc = butyl acetate; EtAc = ethyl acetate; An = acetone.

systems are called equieluotropic systems. The nomogram in Fig. 1 corresponds to adsorption on silica gel.

Saunders[10] obtained another nomogram by using six very common solvents. With the help of the nomogram presented in Fig. 2, we can achieve binary solvent mixtures of certain strength in the interval 0.0–0.75. In this graph, ε^o is plotted across the top and in various binary solvent compositions in each of the horizontal lines below it. Each line corresponds to the range 0–100% by volume of binary solvent composition. Its manner of use is similar to that described for Neher's nomogram.

For NPTLC, the solvent strength weighting factor S_i is the same as the polarity index P' given in Table 1. The polarity index P' is given by the sum of the logarithms of the polar distribution constants for ethanol, dioxane, and nitromethane, and the selectivity parameters x_i is given as the ratio of polar distribution constant for solute I to the total solvent polarity (P'). The sum of the three values for x_i will be normalized up to 1.0. Snyder was able to show that the many solvents available could be grouped into eight classes with distinctly different selectivities. Solvents within the same selectivity group exhibit similar separation properties (Table 1).[3] The polarity index P' of a mixed

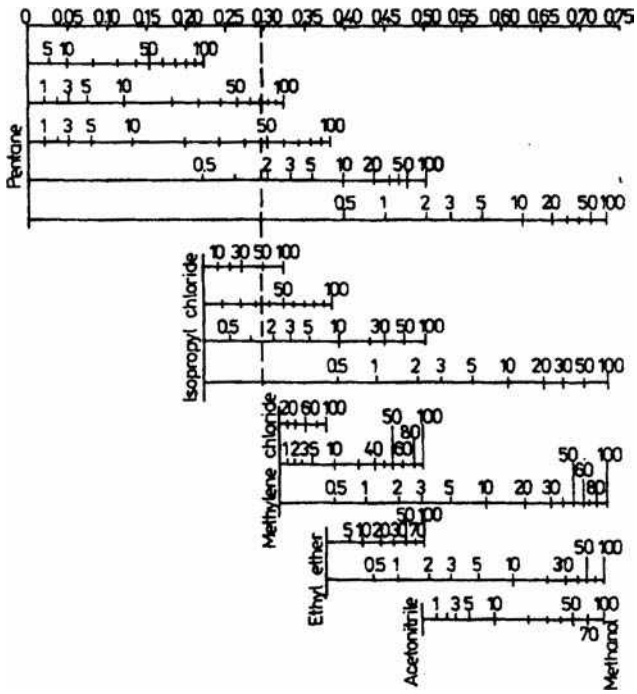

Fig. 2 Mixed solvent strengths on silica gel after Saunders.
Source: From Solvent selection in adsorption liquid chromatography, in Anal. Chem.[10]

mobile phase is the arithmetic average of the solvent polarity index weighting factor adjusted according to the volume fraction of each solvent as is given by:[11]

$$P' = \Sigma_i P_i' \phi_i \tag{3}$$

where P_i' is the polarity index weighting factor of solvent i (Table 1) and ϕ_i is the volume fraction of solvent i. For a binary solvent mixture containing 95% dichloromethane and 5% methanol, the polarity index of the mixed solvent is calculated as follows:

$$P' = (4.29)(0.95) + (5.10)(0.05) = 4.33$$

Reversed-Phase Thin-Layer Chromatography (RPTLC)

A general characteristic of RTLPC systems is that the stationary phase is non-polar vs. the mobile phase that is polar. Thus a decrease in polarity of the mobile phase leads to a decrease in retention. This situation is the reverse of the general trends observed in NPTLC. A decrease in polarity of the mobile phase can be realized by increasing the volume fraction of organic solvent in an aqueous organic mobile phase. The most common method for varying the chromatographic selectivity for neutral molecules is to change the type of organic modifier in the mobile phase. Eq. 4 can often be used as an acceptable approximation for the variation of the retention with the volume fraction of organic solvent in the mobile phase:[11]

$$\log k = \log k_w - S\phi \tag{4}$$

where k is the solute capacity factor, k_w is the solute capacity factor with pure water as the mobile phase, ϕ is the volume fraction of organic solvent, and S is a solute-dependent factor related to the solvent strength of the organic solvent.

The literature data suggest that RPTLC solvent strength varies as water (weakest) < methanol < acetonitrile < ethanol < tetrahydrofuran < propanol < (methylene chloride) (strongest). Thus solvent strength increases as solvent polarity decreases.

The eluotropic scale is a relative one; it is necessary to choose a reference. To obtain a positive value for solvent eluotropic strength, the reference solvent has to be water. The S values determined from the slope of Eq. 4 can be used as descriptor, in a semiquantitative way, of the solvent strength (S_i) of the organic solvent.[11] Some typical S_i values for common solvents are presented in Table 1. The solvent strength of a mixed mobile phase (S_T) is the arithmetic average of the solvent strength weighting factors adjusted according to the volume fraction ϕ of each solvent Eq. 5:

$$S_T = \Sigma_i S_i \phi_i \tag{5}$$

where S_i is the solvent strength weighting factor of solvent i and ϕ_i is the volume fraction of solvent i. If we want to change solvent selectivity to adjust resolution, then the volume fraction of the new solvent required to obtain an isoeluotropic mixture could be calculated from Eq. 5. For example, for methanol–water (60:40), $S_T = 1.56$; using acetonitrile as an example and the same value of $S_T = 1.56$, we obtain $1.56 = 3.2\phi_a + 0\phi_w = 0.49$. Thus a mixture of acetonitrile–water (49 : 51) is similar in solvent strength to a mixture of methanol–water (60:40). In a similar manner, it is possible to calculate several eluotropic eluents.

TLC APPLICATIONS

In adsorption TLC, there exists a competition between the sample and eluent molecules for a place on the adsorbent surface. If we assume that one molecule of sample (X) replaces m solvent molecules (S) on adsorption, we may represent the adsorption process as:

$$X_1 + mS_a \Leftrightarrow X_a + mS_1 \tag{6}$$

In this case, Snyder[2] found an important relationship for adsorption chromatography:

$$\log K^{o} = \log V_a + \alpha(S^{o} - A_s\varepsilon^{o}) \quad (7)$$

where the sample adsorption distribution coefficient K^{o} [ml/g] is defined as being equal to the ratio of sample concentrations in adsorbent and unadsorbed phases; V_a is adsorbent surface volume [ml]; S^{o} is dimensionless free energy of adsorption of a sample compound on adsorbent of standard activity ($\alpha = 0$) from pentane as solvent; and A_s is molecular area of adsorbed sample. For adsorbents of the same type, Eq. 7 expresses K^{o} as a function of some fundamental properties of the sample (S^{o}, A_s), adsorbent (V_a, α), and solvent (ε^{o}). The parameter ε^{o} defines the effect of the solvent on the adsorption of a given sample; therefore it may be equated with solvent strength. The larger is the solvent strength parameter ε^{o}, the smaller is the value of K^{o} for a given sample and adsorbent. Eq. 7 predicts that sample separation order can vary with solvent for sample components of different sizes (A_s). Let K^{o} and ε^{o} for solvent 1 be K_1 and ε_1, and K_2 and ε_2 for solvent 2. Thus from Eq. 4, the ratio of K values for a sample component adsorbent from two solvents is given as:

$$\log(K_1/K_2) = \alpha A_s(\varepsilon_2 - \varepsilon_1) \quad (8)$$

According to Eq. 8, the change in K on changing the solvent is predicted to be proportional to the difference in eluent strengths ($\varepsilon_2 - \varepsilon_1$) and to the sample molecule size A_s.

For the TLC or other bed, there were analogous relationships derived:[2]

$$R_{M'} = \log(V_a W/V^{o}) + \alpha(S^{o} - A_s\varepsilon^{o}) \quad (9)$$

where $R_{M'} = \log[(1/\xi R_f) - 1]$, W is total weight of adsorbent in the bed, V^{o} is bed void volume equal to the volume of solvent in a solvent wet bed, and $(R_f)_{true} = \xi(R_f)_{exp}$. Eq. 9 can be written for a given sample and adsorbent, for solvents 1 and 2, respectively. Then, subtracting the second equation from the first gives:

$$(R_{M'})_1 - (R_{M'})_2 = \alpha A_s(\varepsilon_2 - \varepsilon_1) \quad (10)$$

Eq. 10 can be useful in estimating the effect on sample R_f values of a change in solvent strength.

Eqs. 7 and 9 are a generally reliable relationship for adsorption systems with weak or moderately strong solvents. But, in their derivation, two major approximations were made:[2] 1) interactions between solvent and sample molecules are assumed unimportant; and 2) interactions between the adsorbent and various adsorbed molecules are assumed to be fundamentally similar in type. Both of these assumptions can be defended in the case of weak solvent systems, but they are poor approximations for strong solvents. These equations are concerned only with the primary effect of the solvent on sample adsorption. However, in the case of the majority of adsorption systems based on weak or moderately strong solvents, these approximate relationships are adequate for most purposes. For the strongest solvent systems (e.g., alcohols, acids, water, and their solutions), these equations can be corrected for secondary solvent effect by addition of a correction term Δ_{eas}:

$$R_{M'} = \log(V_a W/V^{o}) + \alpha(S^{o} - A_s\varepsilon^{o}) + \Delta_{eas} \quad (11)$$

where Δ_{eas} represents the secondary adsorption effect and is a complex function of solvent elution strength, adsorbent activity, solute structure, and various possible interactions between the solute adsorbent, and solvent and adsorbent. These aspects are largely discussed in Ref.[2] If $(\Delta_{eas})_1$ and $(\Delta_{eas})_2$ refer to the secondary solvent effects for a particular sample and solvents 1 and 2, respectively, then we can write:

$$(R_{M'})_1 - (R_{M'})_2 = \alpha A_s(\varepsilon_2 - \varepsilon_1) + (\Delta_{eas})_1 - (\Delta_{eas})_2 \quad (12)$$

Eq. 12 gives the difference in $\Delta R_{M'}$ values for a particular sample (A_s) in two solvents 1 and 2, with ε_1 and ε_2, respectively, as a function of adsorbent activity α, and the secondary solvent terms for the particular solvent contribution. The largest Δ_{eas} values were found for samples with free hydroxyl groups, and between these samples, two free hydroxyl groups in the sample molecule give a larger value of Δ_{eas} than does a single free hydroxyl. Sample molecules with intramolecularly bonded hydroxyl groups give much smaller values of Δ_{eas}, but limited hydrogen bonding of these groups with basic solvents is still possible. For the same sample molecule, the Δ_{eas} value will be a function of the eluent composition.

Now let us write Eq. 11 for a particular eluent and sample molecules 1 and 2, respectively:

$$(R_{M'})_1 - (R_{M'})_2 = \alpha(S_1^{o} - S_2^{o}) + \alpha\varepsilon(A_{s2} - A_{s1}) + (_{eas})_1 - (_{eas})_2 \quad (13)$$

In this equation, we find the different source and the selectivity between the two solutes, which can differ by the difference in energy of adsorption ($S_1{}^{o} - S_2{}^{o}$), molecular size ($A_{s2} - A_{s1}$), and secondary adsorption effect $(\Delta_{eas})_1 - (\Delta_{eas})_2$. These considerations are valuable for a large number of compounds, but in the case of some isomers, the second terms of Eq. 13 can be considered practically equal to zero and only difference sources for selectivity remain in the difference in energy of adsorption and the secondary adsorption effect. The secondary adsorption effect plays a major role in the separation of the isomers. For instance, in adsorption on silica gel with benzene–pyridine (90:10, vol/vol) as eluent, the following Δ_{eas} values: -0.90 ± 0.17 and $+0.05 \pm 0.11$ for *m*-hydroxybenzaldehyde and *O*-hydroxybenzaldehyde, respectively,

were obtained. These sample molecules can be very easily separated.

Adsorption TLC selection of the mobile phase is conditioned by sample and stationary-phase polarities. The following polarity scale is valid for various compound classes in NPTLC in decreasing order of K values: carboxylic acids > amides > amines > alcohols > aldehydes > ketones > esthers > nitro compounds > ethers > halogenated compounds > aromatics > olefins > saturated hydrocarbons > fluorocarbons. For example, retention on silica gel is controlled by the number and functional groups present in the sample and their spatial locations. Proton donor/acceptor functional groups show the greatest retention, followed by dipolar molecules, and, finally, non-polar groups.

The activity degree is another important characteristic for adsorbents. As is well known, the adsorbent is in contact with large amounts of water in the thin-layer preparation process water that has to be removed by drying at 100–120°C for approximately 30–60 min. This process is known as activation. The activity of the layer is directly correlated with the water content of the adsorbent. The silanol groups show a great affinity for water, which is bound by hydrogen bonds. Thus the activity degree can be controlled by the content of physisorbed water onto the adsorbent. Lower R_f values will be obtained on the adsorbent with a high degree of activity.

Generally speaking, the first problem with which the analyst is confronted concerns gathering information regarding the mixture to be separated, in terms of mixture polarity and the range of molecular masses. For example, if the mixtures that have to be separated are non-polar, then we can select an active stationary phase and non-polar mobile phase from the following scheme:

Sample to be separated:	non-polar → medium polar → polar
Stationary phase:	active → medium active → inactive
Mobile phase:	non-polar → medium polar → polar

Several mobile-phase optimization strategies in TLC are based on the use of isoeluotropic solvents (i.e., solvent mixtures of identical strengths but different selectivities). Selecting mobile phase will be achieved based on the eluotropic series (Figs. 1 and 2). These considerations are very general. The selection and optimization of one system of eluent is a more complex problem and must be discussed for each particular system. For example, the separation of 13 phenylurea and *s*-triazine herbicides was performed by overpressured layer chromatography (OPLC) with a binary mobile phase.[12] The optimization of the mobile-phase composition for the separation of these herbicides on silica gel was achieved by means of the "ELUO" method in which solvents are selected from an eluotropic series based on solvent power. The method is complementary to the "PRISMA" method for optimizing the compositions of binary, ternary, and quaternary mobile phase for OPLC and TLC.[13] The phenylurea herbicides could be separated with hexane–ethyl acetate (1:1, vol/vol), ethyl ether–benzene (9:1, vol/vol), or chloroform–ethyl acetate, and triazine herbicides could be separated with hexane–ethyl acetate (13:7, vol/vol), ethyl ether–benzene (9:1, vol/vol), or chloroform–ethyl acetate (3:1, vol/vol). The simultaneous separation of the herbicide classes could not be achieved and compounds that were chemically closely related were not well separated.

To maximize the differences in selectivity, solvents must be selected from different selectivity groups that are situated close to the Snyder's triangle apexes. For example, for NPTLC, a suitable selection could be solvents from several groups of Snyder's classifications (I, VII, and VIII), mixed with hexane to control solvent strength.[3]

Elution Chromatography

John C. Ford
Department of Chemistry, Indiana University of Pennsylvania, Indiana, Pennsylvania, U.S.A.

INTRODUCTION

By far the most common chromatographic mode of operation, elution chromatography is virtually the only mode used for analytical separations. Separation in elution chromatography occurs due to differences in migration velocities among the sample components. These differences are related to the affinities of the solutes for the mobile phase, of the solutes for the stationary phase, and of the mobile phase for the stationary phase, and to the properties of the stationary phase itself. Band broadening is typically caused by axial diffusion and mass transfer considerations. The plate number is a measure of the column efficiency, i.e., the ratio of separative to dispersive transport. The resolution is a measure of the overall quality of the separation of two solutes; resolution is a combination of the thermodynamic factors causing separative transport and the kinetic factors causing dispersive transport. Developing a useful elution separation requires more than obtaining the minimal resolution of the solutes of interest. A successful method should not only achieve the desired separation but should also do so in a cost-effective and robust manner. High-performance liquid chromatography (HPLC) method development has its own, extensive literature, reflecting the importance of HPLC as an analytical technique. Some considerations for practical separations are also discussed.

DEFINITION

Elution chromatography is one of the three basic modes of chromatographic operation, the other two being frontal analysis and displacement chromatography. All three modes were known to Tswett in the early 1900s, although a systematic definition was not made until 1943. Elution chromatography is by far the most common chromatographic mode and is virtually the only mode used for analytical separations. Most theoretical work has been directed at the elution mode, although frequently the results are applicable to other modes as well.

The current IUPAC nomenclature for chromatography defines elution chromatography as "a procedure in which the mobile phase is continuously passed through or along the chromatographic bed and the sample is introduced into the system as a finite slug."[1] Typically, the volume of the sample is small compared to the volume of the column. The individual components of the sample (the solutes) move through the column at different average velocities, each less than the velocity of the mobile phase. The differences in velocities are caused by differences in the interactions of the solutes with the stationary and mobile phases. Assuming essentially equivalent interactions with the mobile phase, solutes that interact strongly with the stationary phase spend less time on average in the mobile phase and consequently have a lower average velocity than components that interact weakly with the stationary phase. If the difference between the average velocities of two solutes is sufficiently large, if the dispersive transport within the column is sufficiently small, and if the column is sufficiently long, the solute bands are resolved from one another by the time they exit the column.

Elution chromatography can be performed with a constant mobile phase composition (isocratic elution) or with a mobile phase composition that changes during the elution process (gradient elution). The following discussion focuses on isocratic operation. Further, each of the mechanistic categories of chromatography (ion exchange, reversed-phase, normal phase, etc.) can be performed in the elution mode and additional information on elution chromatography can be obtained by reference to the appropriate sections of this encyclopedia.

Elution chromatography is categorized as being linear or non-linear, depending on the distribution isotherm, and as being ideal or non-ideal, with ideal behavior requiring both infinite mass transfer kinetics and negligible axial dispersion. Although truly linear distribution isotherms are rare, at low solute concentrations or over small ranges of solute concentration, sufficient linearity may exist to approximate linear elution. Linear, ideal elution would result in band profiles that are identical to the injection profiles—an unrealistic situation. Under linear, non-ideal elution conditions, thermodynamic factors control band retention and kinetic factors such as mass transfer resistances control the band shape. Guiochon, Shirazi, and Katti[2] have discussed the relationship between the isotherm and chromatographic behavior extensively.

The retention of a solute in elution chromatography is usually expressed as the retention factor, k (capacity factor or k'), given by $k = (t_R - t_M)/t_M$, where t_R is the retention time of the solute, and t_M is the hold up time (void time, dead time, or t_0). The hold up time is the time required to elute a component that is not retained at all by the stationary phase. One can relate k to the distribution coefficient, K, by $k = K\beta$, where φ is the phase ratio, the ratio of the stationary phase volume to the mobile phase volume. Rearranging

the definition of retention factor, we find that $t_R = t_M(1 + k) = t_M(1 + K\beta)$. Since it is usually reasonable to assume that t_M and β are the same for different solutes, the retention time differences are due to distribution coefficient differences. Under appropriate conditions, the distribution coefficient can be related to the thermodynamic distribution constant and elution chromatographic measurements can be used for physicochemical determinations of thermodynamic parameters.

Differences in solute retention are usually expressed as the separation factor (selectivity coefficient or α), given by $\alpha = k_b/k_a$, where k_a and k_b are the retention factors of the two solutes in question. By convention, k_b is the more retained solute and $\alpha > 1$, although this is not always followed. Since again it is reasonable to assume that φ is the same for different solutes, $\alpha = K_b/K_a$, where K_a and K_b are the distribution coefficients of the two solutes, and again, retention time differences are due to distribution coefficient differences. If two solutes have the same distribution coefficient (i.e., $\alpha = 1$) in a particular combination of mobile and stationary phases, they cannot be separated by elution chromatography in that system. However, $\alpha \neq 1$ is a necessary, but not sufficient, condition for a successful separation.

As a solute moves through the column, it undergoes dispersive transport as well as separative transport. Under typical elution chromatographic conditions, the dispersive transport is caused by axial diffusion and mass transfer considerations, such as slow adsorption–desorption kinetics. This dispersive transport results in band spreading lowering column efficiency, which can prevent adequate separation of different solutes. The plate number (plate count, number of theoretical plates, theoretical plate number, or N), defined as $N = t_R^2/\sigma_t^2$, where σ_t^2 is the variance of the band in time units, is a measure of the column efficiency, i.e., the ratio of separative to dispersive transport. Several alternate forms of this equation are commonly used, usually based on the assumption of Gaussian peak shape. The effective plate number, N_{eff}, is a combination of the plate number and the capacity factor, i.e., $N_{eff} = N[k/(1 + k)]^2$, and is generally more useful than N for comparing the resolving power of different columns.

Another common measure of column efficiency is the plate height [height equivalent to a theoretical plate (HETP), H], defined by $H = L/N$, where L is the length of the column, usually in centimeters. This is frequently presented as the reduced plate height, h, the ratio of the plate height to the diameter of the packing material. A "good" column has a high plate count (a low plate height; $2 < h < 5$).

The overall quality of the separation of two solutes is measured by their resolution (R_s), a combination of the thermodynamic factors causing separative transport and the kinetic factors causing dispersive transport, and is an index of the effectiveness of the separation. Defined by $R_s = (t_{r,b} - t_{r,a})/\frac{1}{2}[(w_{t,b} + w_{t,a})]$, where a and b refer to the two solutes, $t_{r,x}$ is the retention time of solute x, and $w_{t,x}$ is the peak width at the base of solute x in units of time, it is frequently estimated by use of the fundamental resolution equation

$$R_s = \left(\frac{\sqrt{N}}{4}\right)\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k_b}{1 + k_b}\right)$$

where k_b is the retention factor of the more retained solute, α is the separation factor of the solute pair under consideration, and N is the plate count. This equation assumes that the peak shapes are Gaussian and that the peak widths are equivalent.

Easy recognition of the two peaks over a wide range of relative concentrations is possible for $R_s = 1$, and this is essentially the practical minimum resolution desirable. It is usually stated that $R_s = 1$ corresponds to a peak purity of about 98%; however, this is correct only for equal concentrations of the two solutes. As the ratio of relative concentrations of the two solutes deviates from 1, the recovery of the lower concentration solute at a given level of purity becomes poorer.

Examination of the fundamental resolution equation shows that improvements in resolution can be obtained by: 1) increasing the column efficiency. The dependence of R_s on $\sqrt{N}$, rather than N, means that this method is most effective when the column efficiency is initially low. In other words, when using efficient columns to develop a separation, major improvements in R_s are not generally obtained by increasing N; 2) increasing α. If α is close to 1.0, the greatest increase in R_s can be obtained by changing those parameters that influence α, i.e., the mobile phase composition, the choice of stationary phase, the temperature, or, less frequently, the pressure. Increasing α from 1.1 to 1.2 increases R_s by more than 80%. However, as α increases, the amount of increase in R_s decreases, so that increasing α from 2.1 to 2.2 increases R_s by only about 4%; 3) increasing k. If k_b (and thus k_a) < 1, R_s can be significantly increased by changing the mobile phase composition to increase k_b. As for α, the amount of increase decreases as k_b increases, so that while changing k_b from 0.5 to 1.5 improves R_s by about 80%, increasing k_b from 1.5 to 2.5 increases R_s by about 20%. Moreover, increasing k_b increases the analysis time, so that this approach is also of limited practicality.

To summarize, the most successful approach to obtaining adequate R_s is usually to increase α by varying the mobile phase composition—e.g., choice of solvent(s), pH, or temperature—or by varying the stationary phase. Increasing R_s by increasing N or k_b works in selected instances, but is not as generally applicable.

Developing an elution separation method to be used for the analysis of numerous samples requires more than obtaining the minimal resolution of the solutes of interest.

A successful method should not only achieve the desired separation but should also do so in a cost-effective and robust manner. HPLC method development has its own, extensive literature, reflecting the importance of HPLC as an analytical technique.

Snyder, Kirkland, and Glajch state the goals of HPLC method development as: 1) precise and rugged quantitative analysis requires that R_s be greater than 1.5; 2) a separation time of <5–10 min; 3) ≤2% relative standard deviation (RSD) for quantitation in assays (≤5% for less-demanding analyses and ≤15% for trace analysis); 4) a pressure drop of <150 bar; 5) narrow peaks to give large signal/noise ratios; and 6) minimal mobile-phase consumption per run. Additionally, thorough testing of the robustness of proposed methods is recommended.

Elution Modes in FFF

Josef Chmelík
Institute of Analytical Chemistry, Academy of Sciences of the Czech Republic, Prague, Czech Republic

INTRODUCTION

Field-flow fractionation (FFF) is, in principle, based on the coupled action of a non-uniform flow velocity profile of a carrier liquid with a non-uniform transverse concentration profile of the analyte caused by an external field applied perpendicularly to the direction of the flow. Based on the magnitude of the acting field, on the properties of the analyte, and, in some cases, on the flow rate of the carrier liquid, different elution modes are observed. They basically differ in the type of the concentration profiles of the analyte. Three types of the concentration profile can be derived by the same procedure from the general transport equation. The differences among them arise from the course and magnitude of the resulting force acting on the analyte (in comparison to the effect of diffusion of the analyte). Based on these concentration profiles, three elution modes are described.

BACKGROUND INFORMATION

FFF represents a family of versatile elution techniques suited for the separation and characterization of macromolecules and particles. Separation results from the combination of a non-uniform flow velocity profile of a carrier liquid and a non-uniform transverse concentration profile of an analyte caused by the action of a force field. The field, oriented perpendicularly to the direction of the flow, forms a specific concentration distribution of the analyte inside the channel. Because of the flow velocity profile, different analytes are displaced along the channel with different mean velocities, and, thus, their separation is achieved.

According to the original concept,[1] the field drives the analytes to the accumulation wall of the channel. This concentrating effect is opposed by diffusion, driven by Brownian motion of the analytes, which causes a steady state when the convective flux is exactly balanced by the diffusive flux. The concentration profile is exponential and the corresponding elution mode is referred to as the normal mode. Recently, it has been called the Brownian elution mode.[2]

During last two decades, new elution modes were described[3–5] that were not suggested in the original concept.[1] Basically, they differ in the type of the analyte concentration profile.

In 1978, Giddings and Myers described another elution mode for large particles under conditions when diffusion effects can be neglected.[3] The particles form a layer on the channel wall and, under the influence of the carrier liquid flow, they roll on the channel bottom to the channel outlet. This elution mode is referred as the steric mode.[3]

The above-mentioned elution modes apply to the situation when the resulting force acting on the analytes does not change its orientation inside the channel. However, there exist conditions when the resulting force acting on analytes may change its orientation inside the channel [e.g., two counteracting forces, a gradient of a property (pH, density) of the carrier liquid, influence of hydrodynamic lift forces]. Under such conditions, the analytes form narrow zones at the positions where the resulting forces acting on them equal zero. The resulting force is changing its sign below and above this position in such a way that the analyte is focused into this equilibrium position. The concept of formation of narrow zones of analytes inside the FFF channel was first described in 1977 by Giddings.[6] In 1982, a technique utilizing sedimentation–flotation equilibrium and centrifugal field was suggested.[7] However, this technique has not been yet verified experimentally. Later, the general features of this elution mode were described and several techniques were implemented; for a review, see Ref.[8] The mode was called either the hyperlayer[4] or focusing[5] elution mode.

Some other elution modes have been described. They are induced by various factors—cyclical field, secondary chemical equilibria, adhesion chromatography, asymmetrical electro-osmotic flow; for a review, see Ref.[2] However, the number of their implementations is rather limited, and for this reason, these modes are not discussed here.

THEORY

FFF experiments are mainly performed in a thin ribbonlike channel with tapered inlet and outlet ends (Fig. 1). This simple geometry is advantageous for the exact and simple calculation of separation characteristics in FFF. Theories of infinite parallel plates are often used to describe the behavior of analytes because the cross-sectional aspect ratio of the channel is usually large and, thus, the end effects can be neglected. This means that the flow velocity

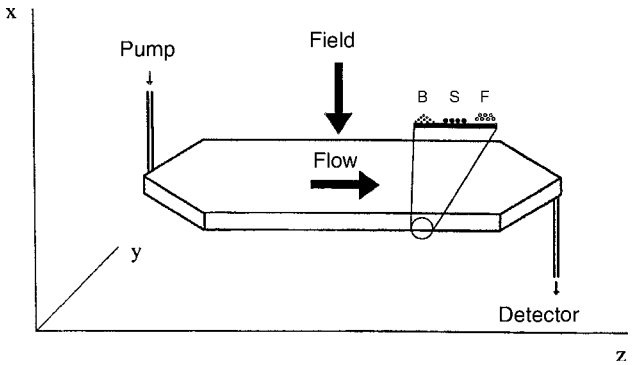

Fig. 1 The orientation of the field and flow in the given coordinate system. The zoomed inset shows the schematic representation of the zone shapes in particular elution modes (B for Brownian, S for steric, and F for focusing).

and concentration profiles are not dependent on the coordinate y. It has been shown that, under suitable conditions, the analytes move along the channel as steady-state zones. Then, equilibrium concentration profiles of analytes can be easily calculated.

Generally, the concentration profile of analytes in FFF can be obtained from the solution of the general transport equation. For the sake of simplicity, the concentration profile of the steady-state zone of the analyte along the axis of the applied field is calculated from the one-dimensional transport equation:

$$J_x = W_x c(x) - D\frac{\partial c}{\partial x} \tag{1}$$

where J_x and W_x are the components of the flux density of the analyte and of the transport velocity of the analyte along the axis of the applied field, $c(x)$ is the analyte concentration distribution along the direction of the applied field, and D is the total effective diffusion coefficient. The term $W_x c(x)$ corresponds to the x component of the convective flux of the analyte and the term $D(\partial c/\partial x)$ corresponds to the x component of the diffusive flux of the analyte. W_x equals the sum of the x components of the transport velocity of the analyte induced by the external field applied U_x and the transport velocity of the analyte induced by the carrier liquid flow $v_x (W_x = U_x + v_x)$. Because of the direction of the carrier liquid flow inside the FFF channel, the component v_x equals zero (the x axis is perpendicular to the direction of the flow) and, thus, W_x equals U_x.

Following the treatment given by Giddings,[9] imposing for the condition of the steady-state zone of the analyte, which is characterized by the null flux density, and applying the equation of continuity, the general solution of the analyte concentration profile can be expressed in the form

$$c(x) = c_0 \exp\left[\int_0^x \left(\frac{U_x}{D}\right) dx\right] \tag{2}$$

The integration limit $x = 0$ corresponds to the accumulation wall boundary. The particular solutions for the concentration profile are dependent on the course of the force field inducing the transport of the analyte, and the ratio of U_x and D.

The equation of the field-induced transport velocity was derived by Giddings:[10]

$$U_x = -ax^n \tag{3}$$

where a is constant and n equals 0 or 1. If $n = 0$, then U_x is constant; if $n = 1$, then U_x is dependent on the position inside the channel.

DISCUSSION

Brownian Elution Mode

The field-induced velocity of the analyte in the separation channel is constant and comparable with its diffusive motion (U_x = constant, $U_x t \approx \sqrt{2Dt}$, where t is time). The resulting concentration profile of the analyte is given by the exponential relationship[9]

$$c(x) = c_0 \exp\left(-\frac{|U_x|}{D}x\right) \tag{4}$$

where c_0 is the maximum concentration at the accumulation channel wall. The elution mode with the exponential concentration profile is called Brownian.[2]

It is known that there are two main factors influencing the behavior of analytes in this elution mode: the properties of the analytes (characterized by the so-called analyte–field interaction parameter[11] and the diffusion coefficient) and the strength of the field applied.

In Brownian elution mode, the retention ratio R is indirectly dependent on both the applied force F and the thickness of the channel w, and independent on the flow rate.[9] It can be expressed in an approximate form:

$$R = \frac{6kT}{Fw} \tag{5}$$

where k is the Boltzmann constant and T is the absolute temperature.

Steric Elution Mode

The velocity of transport induced by the force field in the separation channel is constant and much higher than the velocity caused by the diffusive motion of the analyte (U_x = constant, $U_x t \gg \sqrt{2Dt}$). In this case, the analyte forms a layer on the accumulation channel wall and its concentration in any other position inside the channel

equals zero. The particle radius r_p describes the distance of the particle center from the accumulation wall:

$$c(r_p) = c_0 \quad \text{and} \quad c(x \neq r_p) = 0 \tag{6}$$

The elution mode is called steric.[3] The retention ratio can be expressed in the form

$$R = \frac{6r_p}{w} \tag{7}$$

This shows that R is independent of both the field applied and the flow rate, and it is dependent only on the particle radius and the channel thickness. In fact, the retention ratio values corresponding to the pure steric elution mode have been seldom observed experimentally.[12] The observed values often correspond to the focusing elution mode as a result of the action of some additional forces influencing retention behavior of analytes.

Focusing Elution Mode

In this elution mode, the velocity of analyte transport induced by a force field in the separation channel is dependent on the position across the channel ($U_x \neq$ constant). Based on Eq. 3, the non-constant transport velocity can be, in the simplest case, described as

$$U_x = -a(x - s) \tag{8}$$

where s is the distance of the center of the focused zone from the channel wall (i.e., the position where the resulting force acting on the analyte equals zero). Combining this equation with Eq. 2, we obtain a relation for the resulting concentration profile of the analyte:

$$c(x) = c_0 \exp\left(-\frac{a}{2D}(x - s)^2\right) \tag{9}$$

where c_0 is the maximum concentration at the center of the focused zone at the position s. The concentration profile of the analyte across the channel thickness, in this simplest case, is Gaussian. In other cases, where other secondary effects act on the retention in the focusing elution mode, the observed concentration profile is more complex. However, even in these cases, the main feature remains the same; that is, the maximum concentration of the analyte is at the equilibrium position, where the resulting force acting on the analyte is zero, and not on the channel wall as in the case of the Brownian and steric elution modes. The elution mode is called focusing[5] or hyperlayer.[4] In the focusing elution mode, the retention ratio can be expressed in a form formally similar to the expression given for the steric elution mode (see Eq. 7):

$$R = \frac{6s}{w} \tag{10}$$

At least two counteracting forces are necessary for the formation of the focused zone of the analyte. The center of the zone is located at the position s where the resulting force is zero. Changing of both forces can control the resulting position of the particle zone.

CONCLUSIONS

In the majority of FFF techniques, the retention ratio is dependent on the analyte size. This dependence for Brownian and steric mode is described by Eq. 11, derived by Giddings:[13]

$$R = 6(\alpha - \alpha^2) + 6\lambda(1 - 2\alpha)\left[\coth\left(\frac{1 - 2\alpha}{2\lambda}\right) - \frac{2\lambda}{1 - 2\alpha}\right] \tag{11}$$

where $\alpha = d/2w$, $\lambda = kT/Fw$ and d is the analyte diameter. The curve describing this dependence is shown in Fig. 2. The values of R for the focusing mode lie above the curve. This complex situation shows that determination of the elution mode is very important for evaluation of the measured retention data because different elution modes can act on particular analytes in the same experiment.

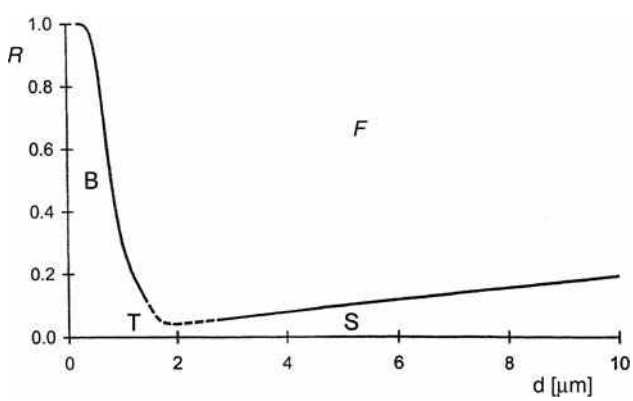

Fig. 2 Schematic representation of the dependence of the retention ratio R on the analyte size. Curve B corresponds to Brownian mode and the line S to the steric mode. The dashed part T denotes the transition between these two modes. The area F shows the range of applicability of the focusing mode.

INTRODUCTION

Size exclusion chromatography (SEC) elution behavior of different solvent/polymer/gel systems has been analyzed from chromatographic, thermodynamic, and hydrodynamic points of view, in two organic column packings, based on polystyrene/divinylbenzene (PS/DVB) copolymer, named: μ-Styragel and TSK Gel H_{HR}. Although both packings present similar chromatographic properties, some differences arise when eluting the same systems. The values of the adsorption distribution coefficients, K_p, have been correlated with the preferential solvation coefficient, λ, for both packings, showing that those systems with lower and negative λ values (denoting higher preferential solvation of the polymer by the gel packing) are those with $K_p > 1$. In addition, the main goal has been to make use of the λ values to adequately interpret the concentration effects (injected polymer concentration) on the elution volumes. In this regard, the experimental concentration effects have been completely explained taking into account not only the conventional hydrodynamic factors, but also thermodynamic aspects such as the preferential solvation phenomenon.

CONCENTRATION EFFECTS

SEC columns separate molecules according to their hydrodynamic volumes in solution. In an ideal experiment, only entropic effects play a role, and molecules are solely separated by size. However, in most cases, enthalpic processes owing to polymer gel–polymer solute interactions, in addition to solvent–polymer and solvent–gel matrix interactions, have to be taken into account, because they affect the values of the sample elution volumes.[1–7] When these non-exclusion secondary mechanisms are present, mainly as adsorption, the polymer–polymer interactions increase and shift the retention volumes of solute macromolecules to higher values. Both the exclusion of macromolecules and the interaction with the column packing are affected by the sample concentration or by the eluent applied, which is evidenced even for the inactive gel packing based on PS/DVB cross-linked materials.[2,8]

The concentration effect, i.e., the dependence of the elution volume on the injected polymer concentration, especially for good solvents, can be considered as a factor affecting the quantitative evaluation of polymer-packing interactions in SEC. This effect has been mainly interpreted on the basis of hydrodynamic factors.[9–19] Other authors have attempted to formulate theoretical models to account for concentration effects in SEC. Among them, the work carried out by Song and coworkers[15,19–22] deserves to be mentioned, on both narrow and polydisperse polymers. They successfully predicted the shifts of retention volumes, the axial spreading, and the skewing of chromatograms caused by the concentration effects. More recently, Lou et al.,[23] have performed simulations of SEC retention behavior of supramolecular complexes by including the concentration effects as a factor affecting the sample retention time. Skrinarova, Bleha, and Cifra[24] have studied the influence of the concentration effects on the partitioning of flexible polymers into pores with attractive walls by regarding the effect as a confined adsorption. Lastly, a simple analytical equation that is able to evaluate the distribution coefficients in SEC of polymers as a function of molar mass, injected sample concentration, and solvent quality has been presented.[25] The equation has been proven to be accurate, both in wide- and narrow-pore regimes, for a wide range of polymer concentrations, opening the possibility to analyze experimental data in concentrated solutions.

In the present work, the concentration effect has been correlated with the preferential solvation phenomenon. First, the observed non-exclusion mechanism has been quantified by means of the distribution coefficient, K_p, representing the concentration ratio of macromolecules inside the pores (i.e., in the quasistationary phase) to those in the mobile phase. Second, the shifts in the elution volume owing to either adsorption or, on the contrary, incompatibility of the solute with the gel packing, have been related to the preferential or selective sorption phenomenon. From a thermodynamic viewpoint, the

preferential adsorption coefficient, λ, is an equilibrium property that reflects the solvent–polymer–solute composition, both close to and far from the polymer gel. This magnitude is related to the chromatographic parameter K_p, to study the adsorption phenomena in the chromatographic systems, given that negative λ values will indicate preferential sorption of the solute polymer onto the gel packing, which occurs when $K_p > 1$. Conversely, positive λ values will denote incompatibility between both components, which accounts for $0 < K_p < 1$ values. The chromatographic data from previous work,[26–28] together with λ values, have successfully served to explain the observed concentration effect on the elution behavior of different solvent(1)/polymer(2)/gel(3) ternary systems in two commercial SEC packings, namely, μ-Styragel and TSK Gel H_{HR}.

EXPERIMENTAL TECHNIQUE

Chemicals

Polybutadiene (PBD) standards with a weight-average molar mass, in daltons, $\overline{M_w}$ = 5,900, 13,400, 18,100, 67,300, 90,000, 268,000, and 1,120,000 (polydispersity, I = 1.03–1.05) were purchased from Polymer Source, Inc. (Dorval, Canada); poly(dimethylsiloxane) (PDMS) standards with $\overline{M_w}$ = 8,100, 41,500, 76,035, 188,400, and 681,600 Da (I = 1.10–1.40) were supplied by Polymer Laboratories (Shropshire, U.K.).

Tetrahydrofuran (THF), benzene (Bz), toluene (Tol), 1–4 dioxane (Diox), and cyclohexane (CHX), of chromatographic grade, from Scharlau (Barcelona, Spain) were used as solvents or eluents.

Chromatography

Waters liquid chromatography equipment with a refractive index detector was used for SEC experiments and has been recently described.[26,27] Two sets of columns (7.8 mm I.D. × 300 mm length) based on a PS/DVB copolymer and with the following characteristics were compared: (i) three μ-Styragel columns from Waters (Milford, Massachusetts, U.S.A.) with nominal pore size of 10^3, 10^4, and 10^5 Å; 15 μm particle size; pore exclusion volume, V_p = 18.1 ml; total exclusion volume, V_0 = 17.7 ml; and (ii) three TSK Gel H_{HR} from Tosohaas, Tosoh Corp. (Tokyo, Japan) with pore sizes G2500, G4000, and G6000; 5 μm particle size; and V_p = 21.0 ml and V_0 = 16.4 ml. The volumes V_0 and V_p were determined with a PS standard of high-molar mass ($\overline{M_w}$ = 3,800,000) and with small molecules such as Tol or Bz in THF, respectively. All chromatographic experiments were performed at room temperature and the columns were equilibrated overnight prior to starting any experiment.

Chromatograms were obtained at a flow rate of 1.0 ml/min by injection of 100 μl of sample solution. The injected polymer concentration, c_2, ranged between 0.1 and 0.8 g/100 ml.

RESULTS AND DISCUSSION

Partitioning in SEC

Chromatographic separation of macromolecules by size depends on the strength and type of interactions in the chromatographic system and is characterized by being the retention or elution volume, V_e. For non-ideal SEC (when secondary mechanisms such as adsorption appear), V_e is given by:

$$V_e = V_0 + K_{SEC} K_p V_p \quad (1)$$

where V_0 is the interstitial or total exclusion volume of the column; V_p, the pore or packing volume; K_{SEC}, the distribution coefficient for ideal SEC based only on entropic effects; and K_p, the distribution coefficient accounting for interactions between the components of the system, such as solute–solvent, solvent–gel, or solute–gel (enthalpically driven) interactions. In the case of "ideal" SEC, separation is exclusively directed by conformational size changes of macromolecules; thus, the global distribution coefficient of the solute between the stationary and the mobile phases is $K_D = K_{SEC}$ and $K_p = 1$. However, if enthalpic effects, mainly owing to interactions between the polymeric solutes and the pore walls, take place, the retention volume is given by Eq. 1 with $K_p < 1$ when solute–gel interactions are repulsive or with $K_p > 1$ when attractive, such as the reversible adsorption of the polymer onto the matrix packing.

The primary elution data, in terms of the Universal Calibration plot, $\log(M[\eta])$ vs. elution volume for the systems: THF/PBD, Bz/PBD, Diox/PBD, Tol/PDMS, Bz/PDMS, and CHX/PDMS in both packings have been taken from the literature.[26,27] To better explain the elution trend, here, we have selected three values of the hydrodynamic volumes, ($M[\eta] = V_h = 10^6$, 10^7, and 10^8 ml/mol), which are representative of the most effective mass-separation range. According to Eq. 1, the obtained K_p values for the different assayed chromatographic systems are compiled in Table 1. In general, $K_p > 1$ and increases its value as V_h increases, leading to secondary mechanisms owing to the increasing polymer–gel matrix interactions. It is also observed that the lowest K_p values, and, therefore, the lowest adsorption effects occur in the TSK Gel H_{HR} columns, which could be attributed to their lower cross-linking degree with respect to μ-Styragel.[27]

Table 1 Experimental K_p values for different chromatographic systems eluted in two types of column packings at three hydrodynamic volumes (in ml/mol).

Packing	System	K_p[a]	K_p[b]	K_p[c]
μ-Styragel	THF/PBD	1.006	0.992	0.958
	Bz/PBD	1.293	1.298	1.325
	Diox/PBD	1.636	1.853	2.490
	Tol/PDMS	1.061	1.089	1.181
	Bz/PDMS	1.077	1.043	0.962
	CHX/PDMS	1.159	1.171	1.217
TSK Gel H_{HR}	THF/PBD	0.981	0.966	0.935
	Bz/PBD	1.205	1.160	1.038
	Diox/PBD	1.265	1.364	1.659
	Tol/PDMS	1.097	1.095	1.103
	Bz/PDMS	1.246	1.244	1.243
	CHX/PDMS	1.408	1.462	1.638

[a] $V_h = 10^6$.

[c] $V_h = 10^8$.

Quantitative Evaluation of the Enthalpic Polymer–Gel Interactions

The attractive interactions given by K_p have allowed quantification of the composition of each component of the ternary solvent (1)/polymer (2)/gel matrix (3) system in terms of volume fractions, ϕ_i ($i = 1$, 2, or 3), by means of a thermodynamic approach, and equations were recently derived.[26,27] Altogether, an increase of K_p as ϕ_3 increases was observed in most of the systems, evidencing more interactions between segments of the polymeric solute (2) and the gel matrix (3) (data not shown). The highest polymer–gel interaction was observed for the system Diox/PBD in both packings studied here, and is even more pronounced in the case of μ-Styragel in accordance with its higher cross-linking degree or chain density per volume unit.

Preferential Solvation

The preferential solvation phenomenon in a ternary polymer system indicates which component, (1) or (2), is preferentially adsorbed by component (3); it is quantified by means of the preferential solvation coefficient, λ. From a chromatographic point of view, adsorption or, conversely, incompatibility between solute (2) and gel matrix (3) can be detected through the coefficient K_p, as seen before. Therefore, both parameters, λ and K_p, have a similar physical meaning in the sense that an equilibrium between a binary and a ternary phase is established and, consequently, one could try to relate them. Accordingly, it is expected that when $K_p > 1$ [meaning compatibility between polymer (2) and gel matrix (3)], values of $\lambda < 0$ will be obtained, denoting a preferential solvation of component (2) toward the gel (3). On the contrary, because $\lambda > 0$ means preferential solvation of solvent (1) by the gel matrix (3), the polymer (2) would be eluted earlier, giving $K_p < 1$.

In fact, the preferential solvation coefficient, λ, represents the volume of solvent (1) or polymer (2) (in ml) adsorbed by the mass (in grams) of polymer (3), and can be calculated at finite polymer composition, ϕ_3, by

$$\lambda(u_1, \phi_3) = B_1(u_1)\bar{v}_3 + B_2(u_1)\bar{v}_3\phi_3 \tag{2}$$

where $\bar{v}_3$ is the partial specific volume of component (3), the polymer constitutive of the gel matrix, and B_1 and B_2 are obtained as follows.[26]

$$B_1 = -\frac{M_{13}}{M_{11}} \tag{3}$$

$$B_2 = -\frac{\left(\frac{M_{13}}{M_{11}}\right)^2 M_{111} - 2\frac{M_{13}}{M_{11}}M_{113} + M_{133}}{2M_{11}} \tag{4}$$

B_1 and B_2 are the corresponding M_{ij} and M_{ijk} functions dependent on the system composition and on the interaction functions, and have been recently given (see Eqs. 6–10) in Ref.[28] The calculation of the preferential solvation parameter has mainly served to be compared and related to the non-ideal chromatographic behavior expressed through K_p. In this regard, Figs. 1–3 show the theoretical variation of λ with ϕ_2 at different V_h (solid lines) together with single λ values, calculated with the real (ϕ_2, ϕ_3) composition data[28] for both packings (empty symbols for μ-Styragel and filled ones for TSK Gel H_{HR}). Concretely, Fig. 1 plots the above-mentioned dependence for PBD as polymeric solute in THF (part a) and in Bz (part b). As can be seen, in THF, the λ values are close to zero, in good accord with the K_p values close to unity obtained in this eluent, which is usually considered as non-interactive for "ideal" SEC. However, in Bz, the λ values are always negative, which means that the PS gel matrix is preferentially solvated by the PBD; in consequence, the solute will be eluted later, being in agreement with the $K_p > 1$ obtained in both packings.

In Fig. 2, the data for the Diox/PBD system have been plotted for μ-Styragel (part a) and for TSK Gel H_{HR} (part b) columns. Again, in this eluent, λ values are also negative, denoting values of $K_p > 1$, as experimentally observed in both packings.

In summary, the comparison of the PBD behavior, in the three eluents assayed, reveals that $\lambda^{\mu-\text{Styragel}}$ is always lower than $\lambda^{\text{TSK Gel H}_{HR}}$, i.e., the preferential solvation of PBD solute onto the PS gel is higher in the μ-Styragel columns, in accordance with the general trend $K_p^{\mu-\text{Styragel}} > K_p^{\text{TSK Gel H}_{HR}}$ pointed out in Table 1.

On the other hand, Fig. 3 compares the preferential solvation behavior of PDMS by PS gels in three solvents: Tol (part a), Bz (part b), and CHX (part c). As seen, in Tol,

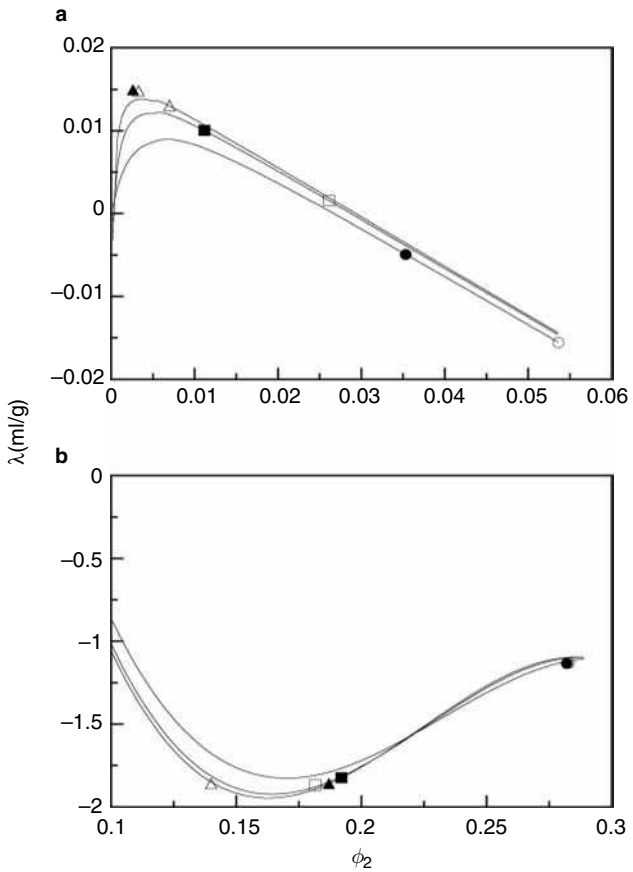

Fig. 1 Plot of the preferential solvation coefficient, λ, as a function of the volume fraction of polymer(2), ϕ_2, at three hydrodynamic volumes, $V_h = 10^6$ (○●); 10^7 (□■), and 10^8 (△▲) ml/mol for different systems: (a) THF/PBD/PS and (b) Bz/PBD/PS eluted in μ-Styragel (empty symbols) and TSK Gel H_{HR} (solid symbols) columns. as ϕ_2 increases, λ also does in positive value and reaches the highest values, denoting the poorest preferential solvation of the PDMS polymer on the matrix or, in other words, the best solvation of the solvent. Consequently, this tendency will be reflected by early solute elution and the lowest K_p values, in agreement with data compiled in Table 1. Also, the λ punctual values, in TSK Gel H_{HR}, are slightly higher than in μ-Styragel, as reflected in their respective K_p data. In Bz, λ values are close to zero, especially for the μ-Styragel columns, in which the K_p values approach unity, denoting no solute–gel attractive interactions, in accordance with the fact that $\lambda \approx 0$ means no preferential salvation, neither for the solute (2) nor for the solvent (1) by the gel (3). Finally, in CHX as eluent, no differences in both packings, among the punctual λ values, are noticed. However, only in CHX, λ tends to diminish as ϕ_2 increases indicating an increase in their K_p values, compared with those observed in Tol and in Bz, which is, again, in good agreement with the experimental chromatographic behavior noticed in both types of SEC columns.

Finally, further evidence on the correlation between the λ and K_p magnitudes is noticed independently of the column packing used. As a general trend, as the hydrodynamic volume increases (from 10^6 to 10^8 ml/mol), λ decreases and K_p data increase, which was also observed in previous studies.[26,27]

Concentration Effects on Elution Volumes

Another complicating factor in the quantitative evaluation of polymer-packing interactions by SEC is the concentration effect, i.e., the dependence of elution volumes, V_e, on the

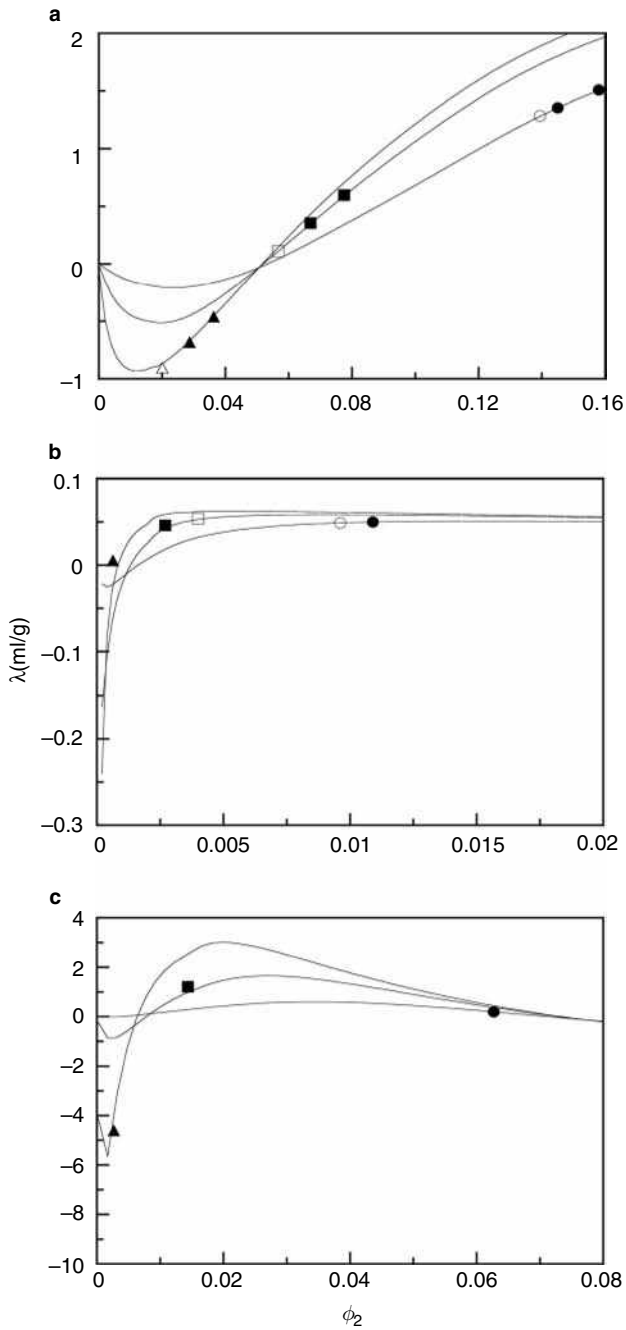

Fig. 3 Plot of the preferential solvation coefficient, λ, as a function of the volume fraction of polymer(2), ϕ_2, at three hydrodynamic volumes, $V_h = 10^6$ (○●); 10^7 (□■), and 10^8 (△▲) ml/mol for different systems: (a) Tol/PDMS/PS; (b) Bz/PDMS/PS; and (c) CHX/PDMS/PS eluted in μ-Styragel (empty symbols) and TSK Gel H_{HR} (solid symbols) columns. Solid line has been calculated with equations and ϕ_3 values given in Ref. 28. **Source:** From An analysis of the concentration effects on elution volumes through the preferential solvation parameter in two SEC packings, in Macromol. Chem. Phys.[28]

injected polymer concentration, c_2. As reported,[9] the slopes of linear plots, V_e vs. c_2, strongly depend on the thermodynamic quality of the eluent for the polymer, and become higher as the molar mass of the polymer increases, especially for good solvents. As usually found in the literature,[9–14,17,18] the hydrodynamic volume of the polymer decreases as the injected polymer concentration increases, making its V_e to be higher than the one obtained at zero concentration, especially for high-molar masses. Therefore, to avoid concentration effects on the elution volumes, all polymeric solute samples should be injected at different concentrations and then extrapolated to zero concentration.

Next, we need to clarify whether this hydrodynamic effect can be also influenced by the thermodynamic effect owing to the preferential solvation of the polymer (2) onto the gel (3) as the volume fraction of the polymer injected, ϕ_2, increases. For this purpose, Fig. 4 shows the dependence of the elution volumes on the solute concentration for different solvent/PBD systems in μ-Styragel (Fig. 4a) and in TSK Gel H_{HR} (Fig. 4b) columns; and Fig. 5 plots the same dependence for several solvent/PDMS systems in the

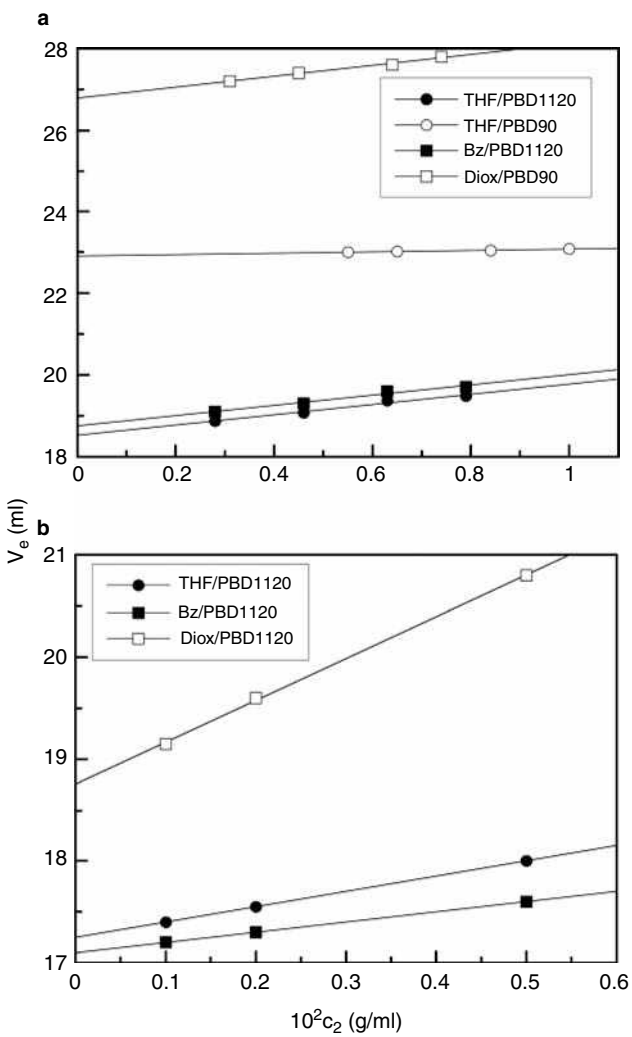

Fig. 4 Dependence of elution volumes, V_e, on the injected polymer concentration, c_2, for different solvent/PBD systems eluted in: (a) μ-Styragel and (b) TSK Gel H_{HR} column packings.

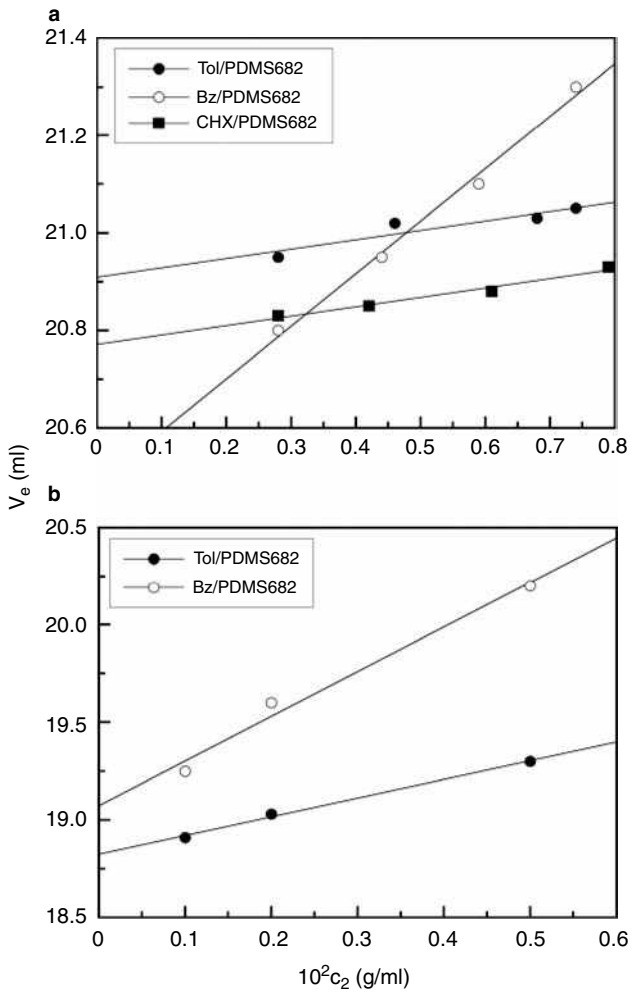

Fig. 5 Dependence of elution volumes, V_e, on the injected polymer concentration, c_2, for different solvent/PDMS systems eluted in: a, μ-Styragel and b, TSK Gel H_{HR} column packings.

same packings (parts a and b, respectively). As seen, the elution volumes always increase with increasing polymer concentration (positive slopes) owing to the decrease in the respective hydrodynamic volumes, as expected. A detailed analysis of this trend can be made, based not only on hydrodynamic, but also on thermodynamic considerations, because these slopes could also be a sensitive function of the polymer–gel and solvent–gel interactions.

Firstly, to discuss the thermodynamic quality of the solvents used, in Table 2, the values of the MHS exponent, a, for all the systems here studied, have been compiled. As known, a represents the thermodynamic affinity of the solvent by the polymer or, in other words, the magnitude representative of the solvent–polymer interactions. Hence, a value of $a = 0.50$ means a poor or "theta" solvent, i.e., a solvent in which the polymer has unperturbed dimensions; and, as a increases, the polymer coil becomes more expanded. Therefore, in the light of values in Table 2, at a given molar mass, for PBD, the solvent affinity will be

Table 2 Mark–Houwink–Sakurada (MHS) exponents for different solvent/polymer systems at 25°C.

System	a
THF/PBD	0.76
Bz/PBD	0.60
Diox/PBD	0.54
Tol/PDMS	0.60
Bz/PDMS	0.57
CHX/PDMS	0.53

THF > Bz > Diox, and for PDMS, the order is Tol > Bz > CHX. In this sense, the effect of the injected polymer concentration on the magnitude of the hydrodynamic volume should also follow the mentioned order, and it should be expected for the respective slopes of the V_e vs. c_2 plots. Consequently, and independently of the columns used, for PBD, it was expected that the concentration effect would be the most accentuated in THF and for PDMS in Tol. However, as can be seen in Figs. 4 and 5, this expected tendency is not accomplished in most systems.

For the sake of discussion, Table 3 contains the values of the slopes of Figs. 4 and 5. First, in the case of TSK Gel H_{HR}, when eluting PBD1120 (M = 1,120,000 g/mol), the slope values reveal that the concentration effect is more pronounced in Diox, contrary to the expected behavior based only in its a value (the lowest). Therefore, in addition to the hydrodynamic size of the macromolecules, other factors may be responsible for these deviations. In this sense, the reversible sorption of the polymeric solute onto the gel surface is likely playing a major role on increasing the elution volumes and, consequently, on enhancing the concentration effects. For this reason, it seems reliable to try to understand the observed concentration effects with the aid of the preferential solvation coefficient evaluated in the preceding section. In this regard, the comparison of λ values given in Figs. 1 and 2 show that the increase in negative value (meaning increasing polymer–gel adsorption) is more acute as PBD concentration (ϕ_2) increases, and in Diox as eluent. Both facts corroborate the major

Table 3 Slopes of the dependence of SEC elution volumes on the injected polymer concentration in the two gel packings.

System	$\Delta V_e/\Delta c_2$ (ml²/g) μ-Styragel	TSK Gel H_{HR}
THF/PBD (90)[a]	16.52	
THF/PBD (1120)	125.5	150.0
Bz/PBD (1120)	125.5	100.0
Diox/PBD (90)	133.0	
Diox/PBD (1120)		409.3
Tol/PDMS (682)	19.05	97.86
Bz/PDMS (682)	107.2	230.7
CHX/PDMS (682)	19.43	

[a]Figures in parenthesis refer to polymer molar mass in kD.

influence of λ on the concentration effect than the influence of the solvent affinity, because the elution volumes increase much more than if the preferential solvation phenomenon was not present.

Secondly, Fig. 4a shows the concentration effect obtained in the μ-Styragel packing for PBD1120 in THF and Bz as eluents. Taking into account only hydrodynamic considerations (see the a values), in THF, the slope should be a little higher than in Bz, but, as seen in Table 3, the same slopes are obtained. Again, this fact can be explained if the solvent hydrodynamic effect is compensated by the preferential solvation. Because λ values are more negative in Bz than in THF as ϕ_2 increases, this causes the PBD solute to be eluted similarly in both eluents, i.e., with an equal concentration effect, even though their solvation qualities were different. In addition, a similar behavior is observed for a polymer with low molar mass, such as PBD90 (M = 90,000 g/mol) in μ-Styragel columns eluted in THF and Diox (also plotted in Fig. 4a). From the respective a values, THF is a better solvent for PBD than Diox; thus, if only considering hydrodynamic factors, the concentration effect should be more important in THF as eluent. However, we find the opposite from their slope values (Table 3), which implies that the sorption of the PBD onto the gel matrix, when eluted in THF, is less significant than in Diox. This experimental trend is, again, clearly supported by the λ values depicted in Figs. 1a and 2a, which are much more negative in Diox than in THF, denoting a major solute–gel interaction in the former eluent, and, consequently, a higher influence of the preferential sorption.

Finally, Fig. 5 shows the behavior followed by the other polymer, PDMS682 (M = 6,82,000 g/mol), in both packings. In the case of μ-Styragel, Fig. 5a shows the behavior of PDMS682 in three solvents: Tol, Bz, and CHX. From the a data in Table 2, it is clearly seen that they are very similar; so it is expected that the hydrodynamic influence on the elution volumes should be nearly the same. Nevertheless, from the slope values in Table 3, the concentration effect is more acute in Bz than in Tol or in CHX. This behavior could again be understood through their respective thermodynamic λ data, which tend to give negative values when ϕ_2 increases (Fig. 3c), denoting more PDMS–gel attractive interactions in Bz than in the other two solvents assayed. With respect to the TSK Gel H_{HR} (part b), the concentration effect has been studied in two solvents with quite similar thermodynamic qualities: Tol and Bz. Therefore, a similar influence of the hydrodynamic factor on the concentration effect should be expected. However, the slope of the V_e vs. c_2 dependence in Bz is more than twice that in Tol. Again, this discrepancy can be properly attributed to the preferential sorption effect. In this sense, from the comparison of Figs. 3a and b, the Tol/PDMS system shows positive λ values as increasing ϕ_2 denote a lesser adsorption of the polymer onto the gel matrix, and lower elution volumes; the contrary is observed for Bz/PDMS system, supporting the experimental concentration effect depicted in Fig. 5a.

A final comparison of the concentration effects in both gel packings, for a given solvent/polymer system and a given molar mass, through their respective slope values reveals that, in general, the slopes in TSK gel H_{HR} are higher than those in μ-Styragel. In other words, the solute concentration influence is more accentuated in the gel that presents lower polymer–gel interactions and lower degree of cross-linking (or higher pore volume).[27] In consequence, for the same Δc_2, the hydrodynamic size of the polymer coil can decrease more in these columns, exhibiting, then, a higher change in the elution volumes.

In summary, as a main conclusion, there is a clear and quantitative influence of the preferential solvation effect on the polymer elution behavior in SEC. In the past,[10–12] the dependence of elution volumes on the sample concentration injected had been only attributed to conventional hydrodynamic aspects (solvent quality affecting the coil size), although never before the thermodynamic effects had been taken into account.

CONCLUSIONS

The comparison of the K_p data of different solvent–polymer systems in two column packings based on PS gels shows that adsorption of solutes onto the gel as secondary mechanism is more pronounced in μ-Styragel than in TSK Gel H_{HR}.

The observed solute–gel attractive interactions have been quantitatively analyzed through the values of the preferential solvation coefficient for all systems in both gels. The correlation between the thermodynamic parameter λ with the chromatographic distribution coefficient, K_p, has revealed that the lower the λ values, the higher the preferential solvation of the polymer by the gel and, consequently, the higher the K_p values. In general, the comparison in both packings yields that $\lambda^{\mu-\text{Styragel}} < \lambda^{\text{TSK Gel H}_{HR}}$, in agreement with the experimental chromatographic tendency $K_p^{\mu-\text{Styragel}} > K_p^{\text{TSK Gel H}_{HR}}$.

Finally, the most noticeable result has been the understanding of the usually observed concentration effects on the elution volumes based not only on hydrodynamic aspects, but also on the important influence of thermodynamic factors such as the preferential solvation. In this sense, it has been quantitatively shown that, for a given solvent/polymer system and a given molar mass, the concentration effect is more acute in the packing that presents lower polymer–gel sorption and lower degree of cross-linking.

Enantiomers: TLC Separation

Luciano Lepri
Alessandra Cincinelli
Department of Chemistry, University of Florence (UNIFI), Florence, Italy

Abstract
The most popular thin layer chromatography (TLC) techniques for separation of enantiomers are described here: 1) use of non-chiral phases for indirect resolution of optical isomers after derivatization to obtain the corresponding diastereoisomers; and 2) direct resolution of enantiomers using chiral stationary phases or chiral mobile phases. Advantages and limits of all reported techniques are discussed.

INTRODUCTION

Enantiomers are compounds that have the same chemical structure but different conformations, whose molecular structures are not superimposable on their mirror images, and, because of their molecular asymmetry, these compounds are optically active. The most common cause of optical activity is the presence of one or more chiral centers, which are usually related to tetrahedral structures formed by four different groups around carbon, silicon, tin, nitrogen, phosphorous, or sulfur.

Many molecules are chiral, even in the absence of stereogenic centers; that is, molecules containing adjacent π systems, which cannot adopt a coplanar conformation because of rotational restrictions due to steric hindrance, can exist in two mirror forms (atropisomers). This is the case for some dienes or olefins, for some non-planar amides, and for the biphenyl or binaphthyl types of compounds.

Optical isomers can be designated by the symbols D and L, which are used to indicate the relationship between configurations based on D(+)-glyceraldehyde as an arbitrary standard. If this relationship is unknown, the symbols (+) and (−) are used to indicate the direction of rotation of plane polarized light (i.e., dextrorotatory and levorotatory). In 1956, Cahn, Ingold, and Prelog[1] presented a new system, the *R* and *S* absolute configurations of compounds.

Many enantiomers show different physiological behaviors, and it is therefore desirable to have reliable methods for the resolution of racemates and the determination of enantiomeric purity. To this end, thin layer chromatography (TLC) is a simple, sensitive, economic, and fast method, which allows easy control of a synthetic process and can be used for preparative separations.

TLC SEPARATION OF ENANTIOMERS BY USE OF DIASTEREOMERIC DERIVATIVES

Because the stationary phases originally used in LC were achiral, much research was devoted to the separation of enantiomers as diastereomeric derivatives produced by reaction with an optically pure reagent (A_R). The resultant diastereomers could, because of their different physicochemical properties, then be separated on conventional stationary phases.

In addition, a significant increase in the sensitivity of detection and the location, on the layers, of some compounds that are not otherwise identifiable can be achieved by this method. There are, however, some disadvantages: 1) it is necessary to use derivatization reagents with 100% optical purity; 2) quantitation is founded on the assumption that the reaction is complete and not associated with racemization; and 3) the two chiral centers should be as close as possible to each other in order to maximize the difference in chromatographic properties.

Many chiral derivatization reactions have been used, and the compounds examined are mostly amphetamines, β-blocking agents, amino acids, and anti-inflammatory drugs. Silica gel and, to a lesser extent, silanized silica have been used as stationary phases. The ΔR_f values obtained for the diastereomeric pairs were usually not very high (0.04–0.07), with the exception of amino alcohol and amino acid diastereomers obtained with Marfey's reagent (0.06–0.22). Recently,[2] Marfey's reagent (1-fluoro-2,4-di-nitrophenyl-5-L-alaninnamide, FDNP-L-Ala-NH_2) and the two variants with phenylalaninamide (FDNP-L-Phe-NH_2) and valinamide (FDNP-L-Val-NH_2) were used to separate 17 DL-amino acids by normal- and reversed-phase TLC on SILG/UV_{254} and RP-18W/UV_{254} plates, respectively. In normal-phase chromatography ΔR_f values of diastereomeric pairs were included between 0.13

and 0.39 (FDNP-L-Ala-NH_2), 0.12 and 0.50 (FDNP-L-PHe-NH_2), and 0.21 and 0.55 (FDNP-L-Val-NH_2) by eluting with phenol–water 3 + 1 (v/v).

In reversed-phase chromatography ΔR_f for the three different derivatives were 0.02–0.09, 0.03–0.10, and 0.14–0.55, respectively, with acetonitrile (30–50%) in triethylamine phosphate buffer, pH = 5.5, as eluent. Resolution was always better for diastereosomers obtained with FDNP-L-Val-NH_2 under normal- and reversed-phase conditions. Derivatives appeared as bright yellow spots.

This procedure has become more and more important owing to the occurrence of D-enantiomers of amino acids in tissues of various organisms. In addition, amino acid residues in dietary proteins have been reported to have been significantly racemized.

TLC SEPARATIONS OF ENANTIOMERS BY CHIRAL CHROMATOGRAPHY

In chiral chromatography, the two diastereomeric adducts A_RE_R and A_RE_S are formed during elution, rather than synthetically, prior to chromatography. The adducts differ with respect to their stability in the use of chiral stationary phases (CSPs) or chiral-coated stationary phases (CCSPs) and/or in their interphase distribution ratio with the addition of a chiral selector to the mobile phase (CMP). The difference between the interactions of the chiral environment with the two enantiomers is called enantioselectivity.

According to Dalgliesh,[3] three active positions on the selector must interact simultaneously with the active positions of the enantiomer to reveal the differences between optical antipodes. This is a sufficient condition for resolution to occur, but it is not necessary. Chiral discrimination may happen as a result of hydrogen bonding and steric interactions, making only one attractive force necessary in this type of chromatography. Moreover, the formation of specific chiral cavities in a polymer network (as in the "Molecular Imprinting Techniques" section) could make it possible to base enantiomeric separations mainly on steric fit.

CHIRAL STATIONARY PHASES AND CHIRAL-COATED STATIONARY PHASES

Few chiral phases are used in TLC; one of the main reasons for this is that stationary phases with very high ultraviolet (UV) background can be used only with fluorescent or colored solutes. For example, amino-modified ready-to-use layers bonded or coated with Pirkle-type selectors, such as *N*-(3,5-dinitrobenzoyl)-L-leucine or *R*(–)-α-phenylglycine, are pale yellow and strongly absorb UV radiation.

Another reason is the high price of most CSPs. In spite of this, Pirkle-type CSPs, based on a combination of aromatic π–π bonding interactions, hydrogen bonding, and dipole interactions, allow the resolution of racemic mixtures of 2,2,2-trifluoro-1-(9-anthryl) ethanol, 1,1′-bi-2-naphthol, benzodiazepines, hexobarbital, and β-blocking agents derivatized with achiral 1-isocyanatonaphthalene. However, the most widely used CSPs or CCPs are polysaccharides and their derivatives (cellulose, cellulose triacetate, tribenzoate, and tricarbamate) and silanized silica gel impregnated with an optically active copper (II) complex of (2*S*,4*R*,2′*RS*)-*N*-(2′-hydroxydodecyl)-4-hydroxyproline (ChiralPlate, Macherey-Nagel, and high-performance thin layer chromatography [HPTLC] Chir, Merck, Germany) for chiral ligand exchange chromatography (CLEC). The chiral layer on the latter plates is combined with a so-called concentrating zone. β-Cyclodextrin bonded to silica gel H has also been used for the resolution of some racemic drugs and binaphthalenes.

CLEC is based on the copper (II) complex formation of a chiral selector and the respective optical antipodes. Differences in retention of the enantiomers are caused by dissimilar stabilities of their diastereomeric metal complexes. The requirement of sufficient stability of the ternary complex involves five-membered ring formation, and compounds such as α-amino and α-hydroxy acids are the most suitable.

The D-enantiomer of such bidentate compounds was generally retained more than L-enantiomer. Mixtures of methanol/acetonitrile/water or dichloromethane/methanol were often used as eluents. Chiral recognition based on CLEC was also involved in the enantiomer separation of amino acids and β-adrenergic blocking agents on silica gel plates coated with the copper(II) complex of enantiomeric amino acids (L-proline, L-arginine, and 1R,3R,5R-2-azobicyclo[3.3.0]octan-3-carboxylic acid).[4]

The resolution of optical antipodes on polysaccharides is mainly governed by the shape and size of the solutes (inclusion phenomena) and only to a minor extent by other interactions involving the functional groups of the molecules. The type and composition of the aqueous–organic eluents affect the separation because these result in different swelling of polysaccharides.

Commercially available silica gel plates coated with acid or basic chiral selectors [D-galacturonic acid, L-(+)-tartaric acid, L-lactic acid, (–)-brucine] were used for the separation of racemic ephedrine, atropine, neutral amino acids, and their 3-phenyl-2-thiohydantoins (PTH) derivatives. The use of amino acids as chiral selectors involved further possibilities of enantiomer separation owing to the simultaneous presence of basic and acidic groups. In fact, L-aspartic acid, L-lysine, L-histidine, L-arginine, and L-serine resolved racemic alkaloids, β-blockers, profens, some amino acids, and their Dns derivatives. Macrocyclic antibiotics [i.e., (–)-erythromycin and (–)-vancomycin] were also used as chiral agents for the separation of enantiomeric DNs amino acids. The mechanisms of chiral recognition was investigated by Aboul-Enein, El-Awady, and Heard;[5] they hypothesized that the formation of

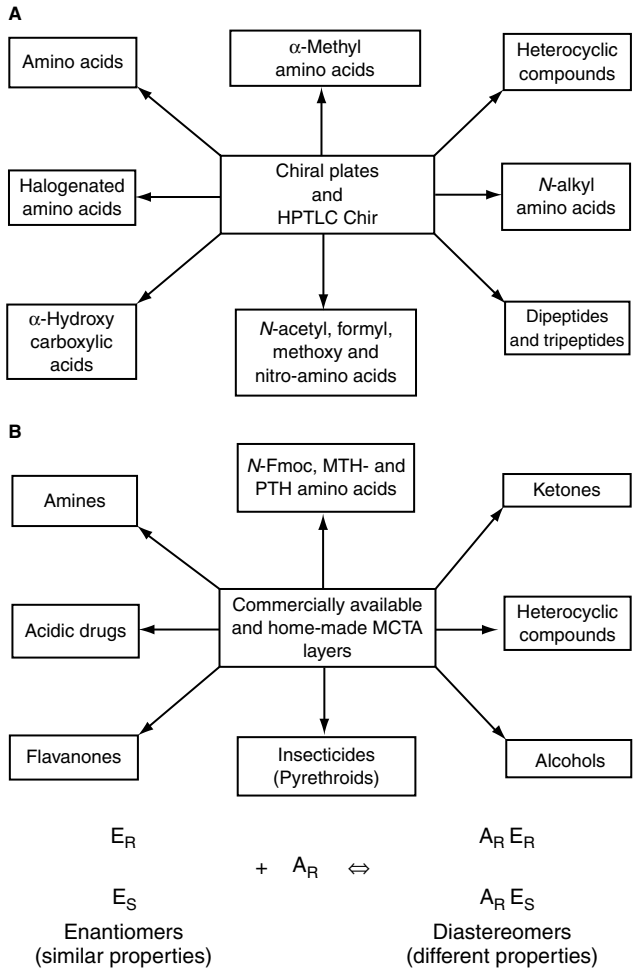

Fig. 1 Classes of chiral organic compounds resolved (A) by ligand exchange chromatography on Chiral plate and HPTLC Chir plates and (B) on MCTA layers.

diastereoisomers should occur within the pores of silica gel to obtain chiral discrimination.

A peculiar behavior of enantiomeric non-steroidal anti-inflammatory drugs (i.e., ibuprofen, naproxen, 2-phenylpropionic acid) was found by Sajewicz et al.[6] on 20 × 20 cm silica gel 60 F_{254} plates impregnated with L-arginine by using acetonitrile/methanol/water mixtures (5+1+0.75, 5+1+1, or 5+1+1.5 v/v/v) as eluents. The migration of the enantiomers of 2-arylpropionic acids deviates markedly from the strict vertical in the mutually opposite direction; the maximum sum of the left- and right-handed deviation was 4 ± 2 mm for ibuprofen, 6 ± 2 mm for nanoproxen, and 7 ± 2 for 2-phenylpropionic acid. Such deviations can improve resolution of racemic ibuprofen whose enantiomers are insufficiently separated by one-dimensional chromatography ($\Delta R_f = 0.03$). Better resolution is possible using a two-dimensional technique. As a consequence of these results, the application of densitometry to chiral separation of 2-arylpropionic acids must be used very cautiously.

In CSPs, owing to the nature of the polymer structure, the simultaneous participation of several chiral sites or several polymer chains is conceivable. In CCSPs, the chiral sites are distributed on the surface or in the network of the achiral matrix relatively far away from each other, and only bimolecular interaction is generally possible with the optical antipodes. A survey of the optically active substance classes separated with Chiral plate and HPTLC Chir layers and with microcrystalline cellulose triacetate (MCTA) plates is shown in Fig. 1. Cellulose tribenzoate and tricarbamate have recently been used for the separation of enantiomeric aromatic alcohols, Troger's base, and benzoin ethyl ether.

MOLECULAR IMPRINTING TECHNIQUES

This technique is based on the preparation of synthetic polymers with specific selectivity by using chiral imprinting molecules mixed with functional and cross-linking monomers (usually methacrylic acid and ethylene glycol dimethacrylate, respectively), capable of interacting with such molecules.

After polymerization, imprinting molecules (templates) are removed by extraction, leaving cavities that correspond to those of the template. The resulting product is called a molecular imprinting polymer (MIP).

MIPs containing L- or D-phenylalanine anilide, quinine, (+)-ephedrine, (+)-pseudoephedrine, (+)-norephedrine, R-(+)-propranolol, S-(+)-naproxen, and S-(–)-timolol were prepared and non-commercial microlayers (2.5 × 7 cm) were obtained by mixing the polymer (8100 mg) and gypsum (100 mg) as binders, with 1.9 ml water and 10 μl ethanol as wetting agent. Such polymers are easy to recognize and they usually separate enantiomers of molecules having structures similar to that of original template.[7]

CHIRAL MOBILE PHASES

Chiral mobile phases enable the use of conventional stationary phases and show only minor detection problems compared to CSPs or CCSPs. However, high-cost chiral selectors (e.g., γ-cyclodextrin) are certainly not advisable for TLC. Enantiomer separations can be achieved using chiral mobile phases in both normal- and reversed-phase chromatography. The first technique uses silica gel and, mostly, diol F_{254} HPTLC plates (Merck) and, as chiral selectors, D-galacturonic acid for ephedrine, *N*-carbobenzoxy (CBZ)-L-amino acids or peptides and 1*R*(–)-ammonium-10-camphorsulfonate for several drugs, and 2-*O*-[(*R*)-2-hydroxypropyl)]-β-cyclodextrin for underivatized amino acids. Extremely high ΔR_f values (0.05–0.25) were observed for the various pairs of enantiomers, proving the strong enantioselectivity of this system.

Most separations were effected by reversed-phase chromatography on hydrophobic silica gel (RP-18W/UV_{254} and

Sil C_{18}-50/UV_{254} from Macherey-Nagel, Germany; KC2F, KC18F, and chemically bonded diphenyl-F from Whatman, U.S.A.; and RP-18W/F_{254} from Merck, Germany) as stationary phase and β-cyclodextrin and its derivatives, bovine serum albumin (BSA), and the macrocyclic antibiotic vancomycin as chiral agents. Enantiomers that selectively interact with β-cyclodextrin cavities are generally *N*-derivatized amino acids, whereas the use of BSA as chiral selector is able to resolve many *N*-derivatized amino acids, tryptophan and its derivatives, derivatized lactic acid, and unusual optical antipodes such as binaphthols.

In particular, the resolution of dansyl-D- and L-amino acids by reversed-phase TLC using aqueous mobile phases containing methanol or acetonitrile and β-cyclodextrin as chiral selector is very useful for stereochemical analysis of amino acids from small peptides, since a significant number of naturally occurring peptides and peptide antibiotics isolated from plants and microorganisms contain at least one amino acid in D-configuration.[8]

QUANTITATIVE ANALYSIS OF TLC-SEPARATED ENANTIOMERS

Although TLC/mass spectrometry (MS) has been shown to be technically feasible and applicable to a variety of problems, TLC is generally coupled with spectrophotometric methods for quantitative analysis of enantiomers. Optical quantitation can be achieved by in situ densitometry by the measurement of UV/VIS absorption, fluorescence, or fluorescence quenching, or after extraction of solutes from the scraped layer. The evaluation of detection limits for separated enantiomers is essential because precise determination of trace levels of a D- or L-enantiomer in an excess of the other becomes more and more important. Detection limits as low as 0.1% of an enantiomer in the other were obtained.

Enantioseparation by CEC

Yulin Deng
Neuropsychiatry Research Unit, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

INTRODUCTION

Capillary electrochromatography (CEC) is considered to be a hybrid technique that combines the features of both capillary high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE). In CEC, a mobile phase is driven through a packed or an open tubular coating capillary column by electro-osmotic flow (EOF)[1,2] and/or pressurized flow.[3] The first electrochromatographic experiments were done in early 1974 by Pretorius et al.,[4] who applied an electric field across a packed column. This allows the analyte to partition between the mobile and stationary phases. As a high voltage is applied, electrophoretic mobility should also contribute to the chromatographic separation for charged analyses. The ability of CEC to combine electrophoretic mobility with partitioning mechanisms is one of its strongest advantages. For electro-osmotically driven-capillary electrochromatography (ED-CEC), the resulting flow profile is almost pluglike; thus, a high column efficiency, comparable to that in CE, can be obtained. For pressure-driven capillary electrochromatography (PD-CEC), although dispersion caused by flow velocity differences causes zone broadening, plate numbers are higher than in capillary HPLC due to the contribution of the electric field to total flow rate. Unlike ED-CEC, the use of an HPLC pump provides stable flow conditions and, thus, offers improvements in retention reproducibility, in sample introduction (e.g., split injection), in suppression of bubble formation, and in gradient elution. More importantly, because the solvent can be mainly driven by pressurized flow, the change of the direction of electric field is no longer limited, and the separation of mixtures of cationic, anionic and neutral compounds becomes possible in a single run. Additionally, neutral molecules can be separated without micelles or other organic additives; this makes CEC more amenable to coupling with mass spectrometry.

Chiral separation in CE is usually achieved by the addition of chiral complexing agents to form *in situ* diastereometric complexes between the enantiomers and the chiral complexing agent. Many of the chiral selectors successfully used in HPLC[5] can also be applied in CE, and thus the experience from both HPLC and CE can be transferred to CEC. During the last few years, interest in CEC has increased due to the improvement in the preparation of capillary columns[6,7] and in the stability and efficiency of separations.[6–9] A limited but dramatically increasing number of chiral separations in CEC have been reported so far. This review will be mainly devoted to recent developments and applications. We are also interested in exploring the potential advantages offered by CEC and, in particular, its practical utility for enantioseparation.

ENANTIOSELECTIVITY IN CEC

CEC is a more complicated system than CE and HPLC due to the combination of both electrophoretic and chromatographic transport mechanisms. It is difficult to define an effective selectivity (separation factor) as in the case of general chromatography or general electrophoresis. To better illustrate the interactions that control selectivity, we defined a relative selectivity and postulated a model that illustrates the effect of separation parameters on the enantioselectivity.[10]

For enantioseparation chiral stationary phases (CSPs), an expression of the relative selectivity is obtained:

$$\alpha_{\mathrm{r}} = \frac{\phi(K_{\mathrm{f2}} - K_{\mathrm{f1}})}{1 + \phi K_2 + \phi K_{\mathrm{f2}}} \tag{1}$$

Interestingly, this equation indicates that the electrophoresis mechanism does not influence the enantioselectivity and the electric field only plays a role in driving the mobile phase.

For enantioseparation with chiral additives in CEC, we derived another expression:

$$\alpha_r = \frac{(K_{\mathrm{f1}} - K_{\mathrm{f2}})[\phi K v_{\mathrm{c}} + (\mu_{\mathrm{c}} - \mu_{\mathrm{f}})E][\mathrm{C}]_{\mathrm{m}}}{(1 + \phi K + K_{\mathrm{f2}}[\mathrm{C}]_{\mathrm{m}})(v_{\mathrm{f}} + v_{\mathrm{c}} K_{\mathrm{f1}}[\mathrm{C}]_{\mathrm{m}})} \tag{2}$$

where v_f and v_c are the apparent flow velocity of the free analyte and the complexed analyte, respectively. Both Eqs. 1 and 2 show that the enantioselectivity is not only dependent on the difference in formation constants (K_{f}) between a pair of enantiomers with the chiral agents but also is influenced by some experimental factors. Substantially, chiral recognition of enantiomers is the direct result of the transient formation of diastereomeric complex between enantiomeric analytes and the chiral complexing agent (i.e., the difference in formation constants). However, the importance of experimental factors lies in the fact that they can convert the intrinsic difference into the apparent difference in migration velocity along the column. Therefore, the overall selectivity in chiral separation

can be considered to be made up of two contributing factors: the intrinsic difference (intrinsic selectivity) in formation constants of a pair of enantiomers, and the conversion efficiency (exogenous selectivity) of the intrinsic difference into the apparent difference in the migration velocity. According to Eq. 2, these experimental factors may include the equilibrium concentration of a chiral selector, the electric field strength, and the properties of the stationary phase.

In CEC with chiral additives, Eq. 2 shows that there exists a maximum selectivity at the optimal concentration of chiral selector. The optimal concentration is not nly dependent on the formation constants (K_{f1}, K_{f2}) butalso on properties of the column (ϕ and K) {i.e., $[C]_{opt} = \sqrt{(1+\phi K)/K_{f1}K_{f2}}$}.

Unlike in the case of a chiral column, the selectivity in CEC with chiral additives is determined by both partition and electrophoresis, and the electric field either increases or decreases the selectivity. Table 1 summarizes the relationship between the direction of field strength and the electrophoretic mobility of the free and complexed analytes. For PD-CEC, the solvent is mainly driven by pressurized flow; thus, there is no limitation to change the direction of electric field.

For enantioseparation on CSPs in CEC, non-stereospecific interactions, expressed as ϕK, contribute only to the denominator as shown in Eq. 1, indicating that any non-stereospecific interaction with the stationary phase is detrimental to the chiral separation. This conclusion is identical to that obtained from most theoretical models in HPLC. However, for separation with a chiral mobile phase, ϕK appears in both the numerator and denominator Eq. 2. A suitable ϕK is advantageous to the improvement of enantioselectivity in this separation mode. It is interesting to compare the enantioselectivity in conventional CE with that in CEC. For the chiral separation of salsolinols using β-CyD as a chiral selector in conventional CE, a plate number of 178,464 is required for a resolution of 1.5. With CEC (i.e., $\phi K = 10$), the required plate number is only 5976 for the same resolution.[10] For PD-CEC, the column plate number is sacrificed due to the introduction of hydrodynamic flow, but the increased selectivity markedly reduces the requirement for the column efficiency.

Table 1 Relationship between the field strength and the electrophoretic mobility for getting high enantioselectivity in CEC.

Direction of μ_{ep}		Size relationship	
μ_f	μ_c	(absolute value)	Direction of E
+	+	$\mu_f < \mu_c$	+
+	+	$\mu_f > \mu_c$	−
+	−	[a]	−
−	−	$\mu_f < \mu_c$	−
−	−	$\mu_f > \mu_c$	+
−	+	[a]	+

[a]The selection of direction of electric field is not influenced by size relationship in absolute values between the electrophoretic mobility of the free and complexed analytes.

CHIRAL SEPARATION IN CEC

There are different ways of performing chiral separation by CEC. Mayer and Schurig immobilized the chiral selectors by coating or chemically binding them to the wall of the capillary.[11,12] Permethylated β- or γ-CyD was attached via an octamethylene spacer to dimethylpolysiloxane (Chirasil-Dex) as the stationary phase. A high efficiency (~250,000/M) was obtained for the separation of 1,1′-dinaphthyl-2,2′-diyl hydrogenphosphate. An alternative coating approach was developed by Sezeman and Ganzler. Linear acrylamide was coated on the capillary wall, and after polymerization, CyD derivatives were bound to the polymer.[13]

Chiral separation can also be performed with packed capillaries. β-CyD-bonded CSPs that are most frequently used in HPLC and CE were successfully applied in CEC. The separation of a variety of chiral compounds, such as some amino acid derivatives benzoin and hexobarbital was achieved by using CSPs bonded with different CyD derivatives.[14,15] Proteins are not ideal for use as buffer additives in CE because of their large detector response; however, CEC may be a good way to use this type of chiral selectors. Lloyd et al. have performed CEC enantioseparation by using commercially available protein CSPs, such as AGP and HAS.[16,17] The resolution obtained on protein CSPs was good; the efficiency, however, was rather poor. Another HPLC–CSP based on cellulose derivatives has been also reported for enantioseparation by CEC.[18] CSPs modified by covalent attachment of poly-*N*-acryloyl-L-phenylalanineethylester or by coating with cellulose tris(3,5-dimethylphenylcarbamate) can be performed in the reversed-phase mode. Acetonitrile as organic modifier was found to be advantageous for this type of CSP. An anion-exchange-type CSP was recently developed for the separation of N-derivatized amino acids.[19] The new chiral sorbent was modified with a basic *tert*-butyl carbamoyl quinine. Enantioselectivity obtained in CEC was as high as in HPLC and efficiency was typically a factor of 2–3 higher than in HPLC. A recent innovative approach is the use of imprinted polymers as CSPs in CEC.[20,21] Imprinted polymers possess a permanent memory for the imprinted species, and, thus, their enantioselectivity is predetermined by the enantiomeric form of the templating ligand. The use of imprint-based CSPs in HPLC is hampered by their poor chromatographic performance. CEC, however, was found to greatly improve the efficiency of the imprint-based separation. The most successful approach is the use of capillary columns filled with a monolithic, superporous imprinted polymer obtained by

an *in situ* photo-initiated polymerization process. This technique enables imprint-based column to be operational within 3 hr from the start of preparation. Generally, the imprint-based CSPs show high enantioselectivity but somewhat low efficiency and are limited to the separation of very closely related compounds.

Enantioseparation can be achieved on a conventional achiral stationary phase by the inclusion of an appropriate chiral additive into the mobile phase. It is theoretically predicted that the enantioselectivity in CEC with a chiral additive may be higher than that using a chiral column with the same chiral selector.[10] Lelievre et al. compared an HP-β-CyD column and HP-β-CyD as an additive in the mobile phase with an achiral phase (ODS) to resolve chlortalidone by CEC.[22] It was demonstrated that resolution on ODS with the chiral additive was superior on the CSP; however, efficiency was low. With an increasing amount of acetonitrile, the peak shape was improved and the migration time was decreased. We achieved the separation of salsolinol by the use of CEC with β-CyD as a chiral additive in the mobile phase containing sodium 1-heptanesulfonate, as shown in Fig. 1. Salsolinol is a hydrophilic amine and is difficult to enantioseparate due to the small k' values on the reversed stationary phases. Sodium 1-heptanesulfonate was used as a counterion to improve the retention.

In conclusion, CEC has great potential in separation technology. Our theoretical model as well as many published practices in CEC show clearly that the benefit of combining electrophoresis and partitioning mechanisms in CEC is the increase in selectivity for the separation. The intrinsic difference in formation constants is critical, but the experimental factors, such as electric field or the stationary and mobile phases, can also contribute to the improvement of the overall enantioselectivity via increasing the conversion efficiency. However, only when both electrophoretic and partitioning mechanisms act in the positive effects, can high overall enantioselectivity in CEC be obtained.

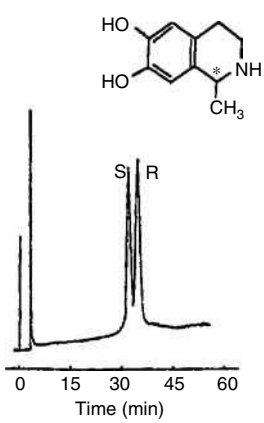

Fig. 1 Electrochromatogram of salsolinol enantiomers on a packed capillary column. Column: ODS-C18, 29 cm (23 cm effective length) × 75 μm I.D.; applied electric field strength: ~250 V/cm; mobile phase: 20 m*M* sodium phosphate buffer (pH 3.0) containing 12 m*M* β-cyclodextrin and 5 m*M* sodium 1-heptanesulfonate. The pump was set at the constant pressure of 100 kg/cm^2.

Enantioseparation in HPLC: Thermodynamic Studies

Damián Mericko
Jozef Lehotay
Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia

INTRODUCTION

Systematic thermodynamic studies with a large set of structurally related compounds can be useful to acquire insight into the separation and retention mechanism using a chiral stationary phase (CSP), or stationary phases in general. In addition, such studies can serve as predictors of expected separation for the enantiomers of analytes based on their structures.

The effect of temperature on the distribution of analytes at infinite dilution between the stationary and the liquid phases is well known. With the respect to all knowledge, it is still interesting to observe how the temperature of a chromatographic column influences the separation. In chromatographic separations, the temperature of the column plays an important role. Hence, the temperature is a critical parameter in chromatography; studying its effect on a separation and retention is the key to understanding the mechanism governing the chromatographic process.

The understanding of mechanistic aspects of chiral recognition in chromatography is important because it allows one to design improved chromatographic systems and it addresses fundamental concepts in chiral recognition also for disciplines outside of separation science.[1]

Temperature has a major impact on retention selectivity (enantioselectivity), resolution, and column efficiency for chromatographic enantiomer separations and can provide valuable information about solute conformational changes, the stationary phase transitions, as well as the chromatographic retention.[2,3]

Earlier results suggest that there are at least two completely different effects of temperature in reversed-phase high-performance liquid chromatography (RP-HPLC) which can affect resolution. One effect changes the separation factor (α), the peak-to-peak separation distance. A decrease in analysis temperature usually results in larger α-values for enantiomeric pairs. This fact is also well known from the general practice of chromatography. This occurs because the partition coefficients and, therefore, the free energy change ΔG of transfer of the analyte between the stationary phase and the mobile phase vary with temperature. This is the *thermodynamic effect*.[4]

In the case of multicomponent or ionisable mobile phases or an ionisable solute, both the distribution of the solvent components and the pK_a of the ionisable compound can also vary with temperature.

Another completely different effect of temperature is the influence on viscosity and on diffusion coefficients. This is largely a kinetic effect, which improves efficiency (i.e., peak width). There are two different mass transfer effects here. One is mobile mass transfer. An increase of temperature reduces the viscosity of the mobile phase. However, an increase of the temperature also increases the diffusion coefficients of the solute in both the mobile phase and the stationary phase (enhancing stationary phase mass transfer).[4]

In many cases, a temperature increase often produces a trade-off for resolution. The increased efficiency is good for resolution, while the lessening of the peak-to-peak separation is bad for resolution.

The temperature can also have the following additional effects that can influence separations:[5]

- Changes in the population of vibrational and rotational energy levels of the chiral solute
- Displacement of solute–solvent equlibria
- Displacement of conformational equlibria, and
- Aggregation and microcrystallization of the chiral solute.

In the case of chiral compounds, especially racemic mixtures, there are also some well-known effects of temperature, such as changing of elution order or coelution of enantiomers due to change of the temperature during the separation.

Moreover, there are many examples of enantiomerization processes which are accelerated by changing the temperature, which are not discussed in this text.

THEORETICAL ASPECTS OF THERMODYNAMIC STUDY

The retention of a solute in a chromatographic system is determined, first, by the magnitude of the distribution coefficient of the solute between the two phases and, second, by the amount of stationary phase available to the solute for interaction. The distribution coefficient in

chromatography is the equilibrium constant and, consequently, it can be treated rationally by conventional thermodynamics.

It follows that the distribution coefficient can be expressed in terms of the *standard energy* of solute exchange between the phases employing the traditional and well-established Arrhenious relationship (Eq. 1).

$$RT \ln K = -\Delta G \quad (1)$$

Now, classical thermodynamics gives another expression for the *free change of energy* (Eq. 2), which separates it into two parts, the *free change of enthalpy* and the *free change of entropy*.

$$\Delta G = \Delta H - T\Delta S \quad (2)$$

The change of enthalpy and change of entropy represent two distinctly different portions of the energy associated with distribution and are related to quite different parts of the distribution processes. The enthalpy term represents the energy involved when the solute molecules break their interactions with the mobile phase and interact with, and enter, the stationary phase. These interactions result from intermolecular forces that are electrical in nature and are accompanied by the absorption or evolution of heat. However, when the solute interacts with the stationary phase, because the interactive forces between the solute and the stationary phase molecules are stronger than those between the solute molecules and the mobile phase, the solute molecules are held more tightly and, consequently, are more restricted. This motion restriction, reduced freedom of movement or loss of randomness is measured as the entropy change. Thus, the free energy change is made up of an actual energy or free enthalpy change resulting from the intermolecular forces between solute and stationary phase and free entropy change that reflects the resulting restricted movement, or loss of randomness, of the solute while preferentially interacting with the stationary phase.

Direct enantiomeric separations are based on the formation of reversible diastereomeric associates or complexes that are created by intermolecular interactions of individual enantiomers with a chiral selector.[6] Diastereomeric association complexes can be depicted as follows (Fig. 1):

A_R and A_S are analytes in R and S configurations. If enantiomeric resolution is observed, the equilibrium

$$CSP + A_R \overset{K_R}{\Leftrightarrow} CSP\text{-}A_R$$

$$CSP + A_S \overset{K_S}{\Leftrightarrow} CSP\text{-}A_S$$

Fig. 1 Formation of diastereomeric association complexes.

(association) constants K_R and K_S have different values. Chromatographic retention depends upon the free energy of the partitioning process of the analyte between the mobile phase and the stationary phase. If the equilibrium constants are denoted by K_R and K_S, respectively, the expression for the change in free energy is as follows:

$\Delta G = -RT \ln K$, Will give the free energy difference :
$\Delta(\Delta G) = \Delta G_R - \Delta G_S$.

The free energy difference, $\Delta(\Delta G)$, can be calculated according Eq. 3 follows (if A_S is less retained analyte, $K_R > K_S$):

$$-\Delta(\Delta G) = RT \ln \frac{K_R}{K_S} \quad (3)$$

where R represents gas constant and T is temperature in Kelvin. Unfortunately, measuring K_R and K_S is not feasible in most cases. To a first approximation, $\Delta(\Delta G)$ can be calculated from the separation factor (α) as follows in Eq. 4:

$$-\Delta(\Delta G) = RT \ln \alpha \quad (4)$$

In the separations of the enantiomers by chromatography, the separation factor (α) is determined by the difference between the free energy of sorption (association) of each enantiomer. From the definition of k' (capacity factor) is clear that $k' = KV_s/V_m$ ($V_s/V_m = \phi$, ϕ is phase ratio of the chromatographic column) and the α value can be given as $\alpha = k'_R/k'_S$, thus, the free energy difference associated with a given α value can be easily computed from chromatographic data.

In certain cases, α values of 30 or more have been found, which then correspond to $\Delta(\Delta G)$ values in the range of 2 kcal/mol (8.4 kJ/mol). Generally, such values are obtained owing to very low retention of the first enantiomer eluted. This means that a very enantioselective sorption process is operating in the column, i.e., one of the enantiomers is virtually unbound by the CSP for steric reasons. Such phenomena are not easily explained by the three-point interaction model, but rather indicate the operation of a sort of "chiral steric exclusion" mechanism, more in line with a "steric fit" concept involving only one binding interaction.[7]

To calculate the thermodynamic parameters and acquire some information for an understanding of enantiomeric retention, selectivity and/or mechanism for the CSP, we need to involve the enthalpy and entropy terms (by an application of the Gibbs–Helmholtz equation: $G = H–TS$) as it is in Eq. 5:

$$\ln \alpha = -\frac{\Delta(\Delta H)}{RT} + \frac{\Delta(\Delta S)}{R} \quad (5)$$

Thus, from a study of the dependence of α on temperature, $\ln \alpha$ may be plotted as a function of $1/T$. This expression of

ln α as a function of $1/T$ is one form of the van't Hoff equation. Using a linear regression model on this kind of dependence, $\Delta(\Delta H)$, from the slope of the line, and $\Delta(\Delta S)$, from the intercept, can be determined. The value of $\Delta(\Delta H)$ represents the difference in change of enthalpy between the couple of enantiomers and $\Delta(\Delta S)$, in turn, difference in change of entropy for a couple of enantiomers, for more and less retained one.

In general, the corresponding $\Delta(\Delta H)$ and $\Delta(\Delta S)$ values can be obtained as the differences $\Delta H_R - \Delta H_S$ and $\Delta S_R - \Delta S_S$, or can be estimated from the selectivity factor (α), which is related to the difference in Gibbs energy of association $\Delta(\Delta G)$ for an enantiomeric pair as was already mentioned. The values of $\Delta(\Delta H)$ and $\Delta(\Delta S)$ obtained by the two methods should be identical within experimental error.[4]

According to this, the van't Hoff plot is usually a plot of either the logarithm of the retention factors (ln k_i') of an analyte or the selectivity factors (ln α) for two analytes vs. the inverse of absolute temperature ($1/T$).

Chromatographic retention is often used to calculate the partial molar enthalpy (ΔH_i) of transfer of solute from the mobile phase to the stationary phase. The transfer enthalpy can be used to characterize or compare various stationary phases using a particular mobile phase. Typically, the transfer enthalpy (ΔS_i) is obtained by invoking a form of the van't Hoff Eq. 6:

$$\ln\ k_i\ =\ \frac{-\Delta H_i}{RT} + \frac{\Delta S_i}{R} + \ln\ \phi \tag{6}$$

where k, ΔH_i, ΔS_i, R, T, and ϕ are the retention factor for the solute, partial molar enthalpy of transfer, partial molar entropy of transfer, the gas constant, the absolute temperature, and the phase ratio (that, is the volume of the stationary phase) (V_s), divided by the volume of the mobile phase (V_m), respectively. The procedure involves plotting ln k' against $1/T$, then setting the slope equal to $-\Delta H_i/R$ and solving for ΔH_i, and enable to determine ΔS_i, from the intercept ($\Delta S_i + \ln \phi$) of the plot. The limitation of this determination relates to the calculation of ΔS_i from the intercept, because it requires the knowledge of the phase ratio ϕ. When the dead volume of the column and the technical data are known, the phase ratio (ϕ) can be calculated.

The problem may often occur in the case of a commercial stationary phase. For example, in the case of RP-HPLC, if the information about bonding chemistry, starting silica, and surface coverage for commercial stationary phases is not available, it is typically not possible to calculate the phase ratio. In addition, since the bonding density of commercial columns is usually not accurately known, it is virtually impossible to assess the role of surface coverage, and more broadly, the stationary phase, on the retention mechanism.[8,9]

Dorsey and Cole[10] have published the way of calculation of phase ratio in RP-HPLC. They used monomeric (self prepared and packed) C_{18}, stationary phases. The volume of the stationary phase (V_s) was determined using the following Eq. 7:

$$V_s = \frac{(\%C)(M)(W_p)}{(100)(12.011)(n_C)(\rho)} \tag{7}$$

where %C is the carbon loading as determined from elemental analysis, M is the molecular weight of the bonded alkyl ligand (g/mol), W_p is the weight of the bonded packing contained in the chromatographic column, n_C is the number of the carbons in the alkyl ligand, and ρ is the density (g/cm^3). V_m was determined by using the gravimetric method with methylene chloride and methanol as the two pure liquids. They assumed that V_m for these columns would be essentially constant (within experimental error), since they were all prepared using the same starting silica.

The advantage of using van't Hoff plot of the logarithm of the enantioselectivity factor (ln α) vs. reciprocal absolute temperature ($1/T$) is that it does not require the knowledge of phase ratio for determination $\Delta(\Delta H)$ and $\Delta(\Delta S)$ values. In turn, it does not bring a solution of determination of the entropy of the solute transfer from the mobile phase to stationary phase (ΔS_i).

LINEAR VAN'T HOFF BEHAVIOR

In general, van't Hoff equation assumes that there is a single adsorption mechanism (hence, that the surface is homogeneous). The plot of ln k vs. $1/T$ is linear only if the associated thermodynamic parameters, ΔH and ΔS, are invariant with temperature changes. According to Gritti and Guiochon,[11] these assumptions are not likely to be fulfilled in reversed phase liquid chromatography (RPLC). First, they showed that RP-HPLC stationary phases are heterogeneous. Secondly, it is known that the structure of the alkyl bonded chains changes somewhat with temperature. Despite this, a majority of the plots of ln k' vs. $1/T$ found in the literature are mainly linear, or nearly so. Finally, the issue of linearity or non-linearity of van't Hoff plots is often matter of temperature range of thermodynamic study. According to previous considerations, there are two basic forms (of decrease of analyte retention with increasing temperature) that the linear van't Hoff curve can take. These two types of curves relate to the two basic types of chromatography.

The first is *interactive* (system A) chromatography where the major retentive mechanism results from solute phase interactions and the second *exclusion* (system B) chromatography, where the major retention mechanism depends on the amount of stationary phase available to each solute.[12]

For system A, it is characteristic to have a relatively very large enthalpy contribution (the slope of the van't Hoff curve is steep) with, conversely, a very low entropy contribution (the intercept is relatively small). The large value of the slope means that molecular forces dominate the distribution in favor of the stationary phase. It can be said that molecules are retained in the stationary phase as a result of molecular interactions. Thus, the change in enthalpy is the major contribution to the change in free energy and it can be said, *in thermodynamic terms*, *the distribution is energy driven*.

System B, in turn, seems to be a completely different type in comparison with system A. In this distribution system, there is a very high entropy contribution in comparison with the entropy contribution in system A. On the other hand, this distribution system shows a relatively small enthalpy contribution; in comparison with system A. Molecular forces do not dominate this distribution system. The elatively large entropy change is a measure of the loss of randomness or freedom that happens when the solute molecule transfers from one phase to the other. The more random and "more free" the solute molecule is in a particular environment, the greater will be its entropy in that environment. The large entropy change shown in system B indicates that the solute molecules are more constrained in the stationary phase (i.e., confined in the pores of the exclusion medium) than they were in the mobile phase. This restriction is responsible for the greater distribution of the solute in the stationary phase and its greater retention. Because the change in entropy is the major contribution to the change in standard energy, *in thermodynamic terms*, *the distribution is entropically driven.*

It is important to understand that chromatographic separations cannot be exclusively *energetically driven* or *entropically driven*; both components will always be present to a greater or lesser extent. It is by the careful adjustment of both the *energetic* and *entropic* components of a distribution that very difficult and subtle separations can be accomplished.[12] For both systems, there is characteristic plus value of the slope, which means that the process of molecule transfer between the stationary and mobile phase has negative value of change of enthalpy and the heat energy is released. Then it is clear that, in this case, the increase of the temperature is responsible for a decrease in retention and usually in enantioselectivity as well.

However, if the van't Hoff plots are linear, it indicates that the retention and/or selective processes governing the separation are unchanged over the temperature range studied. Furthermore, it can be assumed that a separation is a) thermodynamically reversible, b) (ΔH) and (ΔS) values are temperature independent, c) the enantiomers are retained in single associative mechanism, and d) a solvation–desolvation equilibrium does not obscure the association process of the enantiomers with the CSP.[13]

Enantioselective retention mechanisms are sometimes influenced by temperature to a greater extent than ordinary reversed-phase separations. Péter et al.[4] show some examples of how strongly can chiral recognition be dependent upon the temperature. It is must not be just in the case of separation of amino acid enantiomers by a chiral ether stationary phase, but it can be observed also on other CSPs, such as cyclodextrins, α_1-glycoprotein, and chiral macrocyclic antibiotics. Peter et al. explored the effect of the temperature on retention of β-methyl amino acids using teicoplanin CSP. They observed linear van't Hoff plots in the studied temperature range, 1.5–50°C. They suggested that the values of the thermodynamic parameters depend upon the structures of the compounds. They found that chiral recognition and enantioselective retention results from the distinct hydrogen-bonding, steric, and hydrophobic interactions that occur when two amino acid enantiomers are retained at the same CSP site. From the structure of the teicoplanin CSP, it is clear that the main contributor leading to the retention of both enantiomers on this CSP is the charge–charge interaction between the carboxylate group of the amino acid and the ammonium group of the teicoplanin molecule. Sun et al.[14] showed how chiral selectivity can be improved when simultaneously vancomycin as CSP and vancomycin as chiral mobile phase additive are used. They summarized that, with increasing concentration (up to 2 mmol/L) of vancomycin, a favorable effect on selectivity and an increase in enantiomeric resolution of warfarin, fluorbiprofen, and ketoprofen is observed. They observed a significant increase in the enthalpy and entropy differences between the two enantiomers for some very polar compounds, which indicates a change of the retention mechanism for the CSP-analyte.

In general, it is widely known that decreasing the temperature improves the separation, except for some anomalous behaviors. Takagi et al.[15] explored the effect of the temperature on chiral and achiral separations of diacylglycerol derivatives by HPLC using a commercial sumichiral OA-4100 chiral column. They observed a linear relationship between the logarithm of the enantioselectivity factor and the reciprocal of the absolute temperature. They assumed that, in a case of the use of hexane-1,2-dichloroethane as a mobile phase, the separation by carbon number is controlled by entropy differences, whereas separation by double bond number is based on the enthalpy contributions. In addition, they assumed that separation according to carbon number is nearly independent of the temperature, whereas that according to the number of the double bonds is dependent upon the temperature.

The isocratic retention of enantiomers of chiral analytes, e.g., tryptophan, 1,2,3,4-tetrahydroisoquinoline and γ-butyrolactone analogs, was studied on ristocetin A CSP at different temperatures and with various mobile phases. A linear dependence of van't Hoff plots was

observed. According to negative ΔH_i values for all enantiomers, Peter et al.[16] assumed that the transfer of the enantiomers from the mobile to the stationary phase is enthalpically favored. For all studied compounds in reversed phase mode (four different RP mobile phase of 0.1% TEAA–MeOH were used; 80:20, 60:40, 40:60, and 20:80), the change of enthalpy for the second-eluted isomer was always greater (i.e., more negative) than that for the first-eluted isomer. Probably, this means that the association between the second-eluted enantiomer and the CSP is more favorable than for the first enantiomer. In the case of $\Delta(\Delta H_i)$, the more negative value means that the interactions for these analytes are enthalpically favored. On the other hand, the more negative difference in entropy change can be explained by the fact that the difference in degrees of freedom of these enantiomers on the CSP is larger.

The influence of temperature on the performance of an enantioselective anion-exchange type chiral selector was investigated.[2] The resolution of 23 *N*-acylated amino acid Selectands (SAs) enantiomers was studied under linear chromatographic conditions over temperature range of 0–85°C with hydro-organic buffers (pH 6) as mobile phases on a covalently immobilized quinine *tert*-butylcarbamate chiral stationary phase. Using the quinine *tert*-butylcarbamate derived chiral stationary phase, the enantioselective interaction of *N*-acylated amino acids is strongly enthalpy-driven. The thermodynamics of enantioselective adsorption is correlated to structural and electronic properties of the *N*-acyl group and the side chain of the SAs.

Armstrong et al.[17] have studied the effect of temperature (carried out from 0°C to 45°C) on resolution behavior of proglumide, 5-methyl-5-phenylhydantoin, and *N*-carbamyl-D-phenyl-alanine on a vancomycin column. It has been observed that values of k, α, and resolution factor for all the three studied molecules have decreased with the increase in temperature, indicating the enhancement of chiral resolution at low temperature.

By varying the column temperature, linear van't Hoff for D,L-dansyl amino acids retention and enantioselectivity using immobilized human serum albumin as CSP were acquired and thermodynamic parameters were calculated. These linear behaviors were thermodynamically what was expected when there was no change in retention and enantioselective interactions over the temperature range (20–40°C) studied.[18]

Ding et al.[19] described the chiral separation of enantiomers of several dansyl-amino acids by HPLC in the reversed-phase mode. The natural logarithms of selectivity factors ($\ln \alpha$) of all the investigated compounds depended linearly upon the reciprocal of temperature ($1/T$). For most processes of enantioseparation, enantioselectivity, α, decreased with increasing of temperature, and the processes of chiral recognition were enthalpy-controlled. It is very interesting that enantioselectivity, α, increased with increasing temperature for dansyl-threonine (Dns-Thr) at a pH of 7.0; the enthalpy and entropy differences were all positive, indicating that the process of chiral recognition was controlled entropically. It can be concluded that the chiral recognition mechanisms are different for Dns-Thr at different pH's.

Usually, as most HPLC separations are enthalpy controlled, with prominal, a special case was found where the temperature dependence of the separation is entropy controlled. Thermodynamic data for chiral separation of prominal showed a straight line with a negative slope of $\ln \alpha$ vs. $1/T$.[20]

There have also been published other cases of inverse dependencies, with negative slope and with positive value of ΔH_i (so called anomalous behavior). They may occur, for example, in a case of separation of some bases in RP-HPLC. Their retentions increase with increasing the temperature. This may be due to a decrease in the pK_a's of the bases with temperature and, so, the change in protonization with the temperature may contribute to anomalous retention effects.[21]

Yan Lu et al.[22] observed another dramatic example. They used molecularly imprinted polymers (MIPs) as stationary phases for the study of chiral recognition in an aqueous environment. Thermodynamic studies at different pH (pH_{app} 6.4 and pH_{app} 4) revealed that the interaction between the pyridyl group of 4-L-phenylalanylamino-pyridine (4-L-PheNHPy) and the carboxylic acid group on the MIPs is also strong, implying that it also plays a profound role in determining the highly chiral selectivity of MIPs. In addition, it confirmed a different retention mechanism of 4-L-PheNHPy at different pH's of the mobile phases. Whereas, at pH_{app} 6.4, a linear van't Hoff plot showed an increase of $\ln k'$ with increasing temperature, in the case of pH_{app} 4, there was observed a completely inverse dependence. The decrease of $\ln k'$ with increasing temperature at pH_{app} 4 is attributed to enthalpy gained from the binding that is less than the enthalpy lost during the desolvation, which resulted in an endothermic process.

CHANGES IN ELUTION ORDER

In the case of enantioseparation, the slope of the straight van't Hoff line will then be proportional to the enthalpy difference, and $\ln \alpha = 0$ (the individual enantiomers will coelute) will give the temperature at which the enthalpy and entropy contributions cancel each other.[23] This temperature is known as the enantioselective temperature (T_{iso}) and can be defined as in Eq. 8. At this temperature, $\Delta(\Delta G) = 0$ and the enantiomers are not separated. Above T_{iso}, an inversion in the elution order of the enantiomers is expected. Knowing the T_{iso} of certain analytes under given experimental conditions might be helpful for

the determination of optical purities, as the elution order will be reversed.[13]

$$T_{iso} = \frac{\Delta(\Delta H)}{\Delta(\Delta S)} \quad (8)$$

This phenomenon has been mostly observed in gas chromatography (GC) at relatively high temperature (in comparison with HPLC, which is usually performed at relatively low temperatures), because solvation effects are essentially absent. Despite this, also in HPLC, some cases of change in elution order of the enantiomers have been achieved.[24]

Hermansson and Schill,[25] in 1988, first reported the inversion of the enantiomeric elution order for pseudoephedrine occurring on an α_1-acid glycoprotein-based (AGP) column with the addition of octanoic acid to the eluent. These effects might be due to a blocking of one or more of several chiral binding sites and conformational change of the protein as a consequence of variation of the properties of the mobile phase.

Later, in 1990, Haginaka[26] observed the inversion of the elution order of propanolol (PP) and its ester derivates (*O*-acetyl, -propyl, -butyl, and valeryl PP) on an ovomucoid-bonded column.

Pirkle and Murray[27] first reported the temperature-dependent elution order reversal in PI-basic proline-derivatized CSPs in 1993. They used (*RS*)-*N*-(3,5-dinitrobenzoyl)-α-phenylethylamine as the solute to investigate the response of the chromatographic behavior by changing the temperature on the CSP.

The reversal of enantiomeric elution order for the polysaccharide CSP was first reported by Okamoto et al. in 1991.[28] They found that the reversal of the elution order of the enantiomers on a modified cellulose column was associated with changes in the mobile phase modifiers during the investigation of the direct chromatographic enantioseparation of pyriproxyfen, an insect growth regulator. If one can find such phenomena, although very rare in HPLC, it will be important to understand the reasons for this behavior and to anticipate when such inversions of elution order are likely to occur.

The temperature is the determining factor for the discrimination process of (*R*)-(−) and (*S*)-(+)-sotalol by immobilized cellobiohydrolase 1 (CBH 1), as it influences, not only the extent, but also the sign of enantioselectivity. An inversion of the enantiomeric elution order was also induced by changes in the organic modifier added to the buffer solution.[29]

The presented examples emphasize the importance of careful temperature control in order to achieve reproducible separations in chiral chromatography. Although reversals in enantioselectivity are rare in HPLC, general predictions of the enantiomeric elution order on CSPs should be critically considered, especially if the extent of chiral recognition is marginal.

NON-LINEAR VAN'T HOFF BEHAVIOR

Since many of the studies showing linear van't Hoff behavior were conducted over a narrow temperature range (typically 20–50°C), it is possible that the deviation from linearity usually observed at about 20–25°C might have been missed.[8,9] On the other hand, if the stationary phase in HPLC undergoes a change in conformation at a certain temperature (transition temperature), the enthalpy and entropy of retention process will change, and non-linear van't Hoff plots will be obtained. Since both enthalpy and entropy of adsorption are influenced by any changes in solvation, which accompany analyte adsorption, it is conceivable that mobile phase composition might influence not only the magnitude, but also the sign of $\Delta(\Delta G)$. This implies that the elution order of a particular pair of enantiomers from a given CSP in HPLC could be mobile phase dependent.[13]

Despite the fact that van't Hoff plots are usually linear, Pirkle[30] showed that van't Hoff plots data obtained by temperature study of conformationally rigid spirolactam 1 are non-linear. The combination of using mobile phases of hexane containing 20, 10, or 5% (v/v) 2-propanol and use of CSP derived from (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine for separation of spirolactam is responsible for the curvature of van't Hoff lines. At low temperatures, residual silanol groups and strands of bonded phase adsorb the 2-propanol. The lack of strong dependence of ΔH on 2-propanol concentration suggests that the stationary phase and analytes are saturated with 2-propanol below 25°C, even when 2.5% 2-propanol is present. As the temperature increases, thermal desorption of 2-propanol leads to the formation of sites at which analyte adsorption is more exergonic, owing to the reduced need to displace 2-propanol. This can increase retention of the analyte provided the magnitude of the effect is sufficiently great.

In general, non-linear van't Hoff behavior may be indicative of a change in the mechanism of retention. Basically, any reversible process which alters the enthalpy and entropy of adsorption can, in principle, give rise to non-linear van't Hoff plots. Dissociative processes, such as ionisation, change in conformation, or changes in the extent to which the mobile phase interacts with either the analyte or stationary phase are examples of such reversible processes. In addition, the presence of multiple types of retention mechanisms or multiple types of binding sites may also lead to non-linear van't Hoff plots.[30]

Another example of curvature of van't Hoff plots relates to irreversible changes in the conformation of carbamate-derivatized amylose and cellulose CSP, which was observed for the normal-phase separation of the enantiomers of a dihydropyrimidinone acid and methyl ester. The apparent conformational change was thermally induced and depended upon the polar component of the mobile phase. The irreversible change in the conformation of

these CSPs, caused by modifiers and temperature, can also play an important role in projecting large-scale enantioseparation, such as simulated moving bed (SMB) chromatography.[31]

If the van't Hoff plot ($\ln k_i'$ vs. $1/T$) is not a straight line, it is often presumed that ΔH_i varies with temperature; ΔH_i is then evaluated from the slope at any particular $1/T$ value. This is valid if the phase ratio (ϕ) is constant with respect to temperature. Chester and Coym[32] have considered two questions regarding the interpretation of van't Hoff plots: if linearity is observed, does it imply that ΔH_i is constant with temperature (or does curvature imply that ΔH_i changes with temperature)? Is the phase ratio constant and does it have any influence on the curvature or slope of a van't Hoff plot?

They showed that, when the possibility of change in the phase ratio is considered, it becomes apparent that, nonlinear van't Hoff behavior may, or may not, be due to changes in enthalpy or entropy. Considering the molecular difference between two solutes instead of the solutes themselves can eliminate the phase ratio influence. Some cases show that in the resulting selectivity, van't Hoff plots may be linear, even when the van't Hoff plots of solutes are nonlinear. In such cases, temperature-dependent phase ratio changes, and not necessarily changes in the transfer enthalpy, may be responsible for the curved van't Hoff plots of individual solutes. In addition, the different solutes in RP-HPLC may also be responsible for different thermodynamic phase ratios.

ENTHALPY–ENTROPY COMPENSATION

Despite the fact that, in some cases, small differences in ΔH and ΔS can be observed (for various solutes, but on the same column with the same mobile phase), these differences could be found to be essentially insignificant when compared to a change in stationary-phase bonding density using enthalpy–entropy compensation. Enthalpy–entropy compensation is a term used to describe a compensation temperature, which is system independent for a class of similar experimental systems.[10,33] Melander et al.[34] have used the enthalpy–entropy compensation method in studies of hydrophobic interactions and separation mechanisms in reversed phase HPLC. Mathematically, enthalpy–entropy compensation can be expressed by the formula 9:

$$\Delta H_i = \beta \Delta S_i + \Delta G_\beta \tag{9}$$

where ΔG_β is the Gibbs free energy of the enantiomeric interactions (physicochemical interaction) in the chromatographic system at the compensation temperature (β), (β and ΔG_β are constants). The values of ΔH and ΔS are the corresponding changes in enthalpy and entropy, respectively. According to Eq. 7, when enthalpy–entropy compensation is observed with a group of compounds in a particular chemical transformation (or interaction in the case of chromatographic retention), all of the compounds have the same ΔG_β at the compensation temperature β. For example, if enthalpy–entropy compensation is observed in liquid chromatography (LC) or GC for a group of compounds, all the compounds will have the same net retention at the compensation temperature β, although their temperature dependencies may differ.[17] In order to express the free energy change ΔG_T measured at a given temperature T, the Gibbs–Helmholtz relationship can be rewritten using Eq. 10.

$$\Delta G_T = \Delta H\left(1 - \frac{T}{\beta}\right) + \frac{(T\Delta G_\beta)}{\beta} \tag{10}$$

Eq. 8 shows that a plot of ΔG_T for different compounds at a constant temperature T vs. the corresponding ΔH_i produces a straight line, and the compensation temperature β can be evaluated from the slope. Combination of Eqs. 6 and 9 leads to Eq. 11, which shows that plots of $\ln k_i'$ on $-\Delta H_i$ can be used to determine the compensation temperature β.

$$\ln k_i = \frac{-\Delta H_i}{R}\left(\frac{1}{T} - \frac{1}{\beta}\right) - \frac{\Delta G_\beta}{R_\beta} + \ln \phi \tag{11}$$

A similarity in values for the compensation temperature suggests that the solutes are retained by essentially identical interaction mechanisms and, thus, the compensation study is a useful tool for comparing retention mechanisms in different chromatographic systems.[35,36]

In addition, calculation of compensation temperature can be also used in order to compare GC and LC retention processes and, therefore, enthalpy–entropy compensation theory is often applied.[37]

CONCLUSION

There are many parameters which control the enantiomeric resolution by HPLC. The most important of them include parameters of the stationary phase, such as particle size of CSP, pore size of column, and kind of chiral selector, composition, and pH of the mobile phase, flow rate of mobile phase, and temperature. Systematic variation of column temperature should be considered as one way to improve chiral separations in HPLC. From the practical point of view, it is easier to vary column temperatures than mobile phase composition. In addition, variable temperature runs can provide useful information concerning the thermodynamic parameters for the CSP–analyte interactions. The effect of temperature on the resolution

and selectivity factors for a set of structurally related chiral compounds is often interpreted using van't Hoff plots generated from the chromatographic data. The study of temperature effects helps to estimate the interaction/separation behavior on the CSP and is the key to understanding the mechanism governing the chromatographic process.

INTRODUCTION

A typical stationary phase for chromatography, especially liquid chromatography (LC), is a chemically alkyl (C_{18})-bonded phase on silica gel particles. For the preparation of this type of bonded phase, alkylsilane is used to react with the silica gel surface by a silane-coupling reaction. In order to perform this synthesis, the silica gel to be bonded is treated to remove heavy metals and to prepare the surface for better bonding. Generally, only one of the functional groups bonds to form a Si–O–Si bond. Less often, two of the functional groups react to form adjacent Si–O–Si bonds. The remaining functional groups on each reagent molecule hydrolyze to form Si–O–H groups during workup, following the initial reaction. These groups, however, which form with the di- and tri- functional reagents, can cross-link with one another near the surface of the silica gel support. Thus, bonded phases made with any di- or tri- functional reagents are termed "polymeric" phases. A monofunctional silane reagent can only bond to the silanols and any excess is washed free as the ether resulting from hydrolysis of the reagent. Any packing made with a monofunctional silane reagent is referred to as a "monomeric" bonded phase. These schemes are summarized in Fig. 1a(i) and (ii). Other chemically bonded phases, such as cyano-, amino-, and shorter or longer alkyl phases are synthesized by similar bonding chemistries.

DISCUSSION

The products made by the above synthetic processes still have large numbers of residual silanols, which lead to poor peak shapes or irreversible adsorption, because chemically bonded groups on the silica gel surface have large, bulky molecular sizes and, after the bonding, the functionalized silane cannot react with the silanols around the bonded ligands. Because such alkyl-bonded phases are used for reversed-phase (RP) separations, especially for chromatography of polar molecules, any silanol groups that remain accessible to solutes after the bonding are likely to make an important contribution to the chromatography of such solutes; this is generally detrimental to the typical RP LC separations. It is a common fact that the residual silanols produce peak tailing for highly polar compounds which will interact with these silanol groups with deleterious effects. Therefore, the attempt to reduce the number of residual silanols on the silica gel is a common procedure in the preparation of chemically bonded stationary phases, where the surface of a RP material is ensured to be uniformly hydrophobic, for example, by blocking residual silanol groups with some functional groups. This process is the so-called "end capping." The end-capping process is possible with a smaller molecule than alkylchlorosilanes, such as a trimethyl-substituted silane (from trimethylchlorosilane or hexamethyldisilazane) as seen in Fig. 1a(iii). Because the molecular weights of these reagents are small, they do not add much to the total percent carbon, compared with the initial-bonded phase. It must be known that all chemically bonded phases on silica gel cannot be end-capped by this process, because the above reagents can react with diol and amino phases, and not only with silanol groups on the surface. To block, end cap, and then unblock these phases would be very time-consuming and too expensive to be practical. If the final-bonded phase is, in fact, a diol, this silane-bonding reagent is made from glycerol and has the structure Si–O–CHOH–CH_2OH. The cyano or amino phases are most often attached with a propyl group between the silicon atom and the CN or NH_2 group.

Often, when various bonded phases are studied for suitability for a particular separation, the question arises as to which is bonded most completely. This is a common question, because all phases, no matter how they are bonded, will have some residual silanols, even after an end-capping process. It is impossible for the bulkier bonding reagents to reach any but the most sterically accessible silanols. It is much easier for the smaller solutes to reach the silanols, however, and be affected by them. The final surface of the silica gel has three different structures, as demonstrated in Fig. 1b(i), (ii), and (iii), for a monomeric C_{18}, end capped by trimethylchlorosilane and residual silanols, respectively.

The presence of residual silanol groups can be detected most readily by using Methyl Red indicator,[1] which turns red in the presence of acidic silanol groups, but a more sensitive test is to chromatograph a polar solute on the RP material.

To test, chromatographically, any phase for residual silanols, the column has to be conditioned with heptane or hexane (which has been dried overnight with spherical 4A molecular sieves). The series of solvents to use if the column has been used with water or a water-organic-mobile phase, such as water → ethanol → acetone → ethyl acetate → chloroform

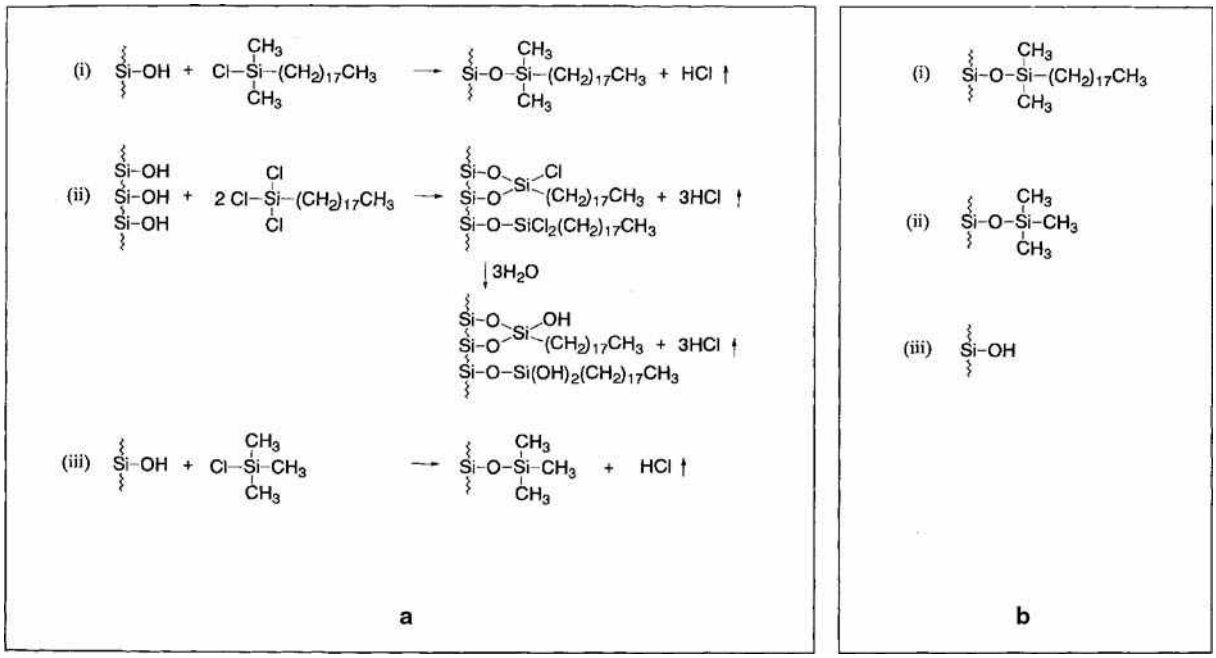

Fig. 1 a, Scheme of bonding chemistry for chemically bonded C_{18} silica phase: (i) synthesis of monomeric C_{18}; (ii) synthesis of polymeric C_{18}; (iii) end-capping process. b, Surface structure of a monomeric C_{18} phase: (i) monomeric C_{18} ligand; (ii) end-capped trimethyl ligand; (iii) residual silanol.

→ heptane. Once activated, a sample of nitrobenzene or nitrotoluene is injected, eluted with heptane or hexane, and detected at 254 nm. The degree of retention is then a sensitive guide to the presence or absence of residual silanols; if the solute is essentially unretained, the absence of silanols may be assumed. The better the bonding, the faster the polar compound will be eluted from the column. A well-bonded and end-capped phase will have a retention factor of between 0 and 1. Less well-covered silicas can have retention factors greater than 10. This is a comparative test, but it can also be useful for examining a phase to see if the end-capping reagent or primary phase has been cleaved by the mobile phase used over a period of time. Other methods to measure the silanol content of silica and bonded silica have been discussed by Unger.[2] Solid-state nuclear magnetic resonance spectrometry is the most powerful method to identify the species of residual silanol groups on the silica gel surface.[3]

In order to avoid the contribution of the residual silanols to solute retention, many packing materials that should not have silanols have been developed.[4] They are polymer-based materials and also polymer-coated silica phases. These polymer-based or polymer-coated phases can be recommended as very useful and stable stationary phases in LC separations of polar compounds; they also offer much better stability for use at higher pH alkaline conditions.

INTRODUCTION

Enoxacin, 1-ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-1,8-naphthyridine-3-carboxylic acid (ENX; Fig. 1), is a new broad spectrum fluorinated 4-quinolone antibacterial agent.[1] It has a broad spectrum of antibacterial activity and is particularly potent against Gram-negative organisms and staphylococci.[2] The 4-quinolone antibiotics have been used in the treatment of many soft tissue infections including bacterial prostatitis.[3] ENX is excreted, mainly, in urine as the unchanged drug. It is metabolized by oxidation (to oxo-enoxacin), by conjugation with formic and acetic acid (ring opening), and by deamination of the piperazinyl ring. Its major metabolite, oxo-enoxacin, accounts for 10–15% of the administered dose and each of the other metabolites constitutes less than 1% of the dose.[2] It has also been reported that ENX has potent competitive inhibitory effects on theophylline metabolism, causing elevated plasma theophylline concentration and potential toxicity.[4] Because of these properties of ENX, it is very important to develop suitable analytical methods for this substance. High-performance liquid chromatography (HPLC) is the most commonly employed method for the determination of ENX and its metabolites in plasma, urine, and tissues.[5–12] Capillary electrophoresis (CE) is becoming a reliable, preferable, and alternative method, especially for the analysis of drugs in biological matrices.[13,14] CE offers some advantages such as rapidity, short analysis time, and low cost.[15–17] Only one report on the analysis of ENX by CE is presented by Tuncel et al.[18] Further, the authors have also carried out the analysis of ENX by HPLC and compared this method with the CE method in pharmaceutical dosage forms and in biological fluids.

DETERMINATION OF ENX BY CE

Instruments

The experiments were conducted using a Spectrophoresis 100 system equipped with a modular injector and high-voltage power supply, and a model Spectra FOCUS scanning CE detector (Thermo Separation Products, California, U.S.A.) connected to a Model Etacomp 486 DX 4-100 computer which processed the data using PC 1000 (Version 2.6) running under the OS/2 Warp program (Version 3.0). The analysis was performed in a fused silica capillary which has a total length of 88 cm, an effective length of 58 cm, and an I.D. of 75 μm (Phenomenex, California, U.S.A.). The pHs of the solutions were measured with a Multiline P4 pH meter with SenTix glass electrode (WTW, Weilheim, Germany). All the solutions were filtered using a Phenex microfilter (25 mm, 0.45 μm) (Phenomenex) and were degassed using a model B-220 ultrasonic bath (Branson, Connecticut, U.S.A.).

Chemicals

Acetonitrile, methanol (HPLC grade), ethanol, propanol, hydrochloric acid, sodium hydroxide, borax, acetylpipemidic acid (internal standard (IS) for CE), and 3,4-dihydroxybenzylamine HBr (IS for HPLC) were from Merck (Darmstadt, Germany). Enoxacin was generously provided by Eczacibasi Ilac Sanayi ve Ticaret A.S. (Istanbul, Turkey). Blood samples were withdrawn from healthy volunteers after obtaining their consent. The serum samples were separated by centrifuging for 10 min at 5000 × *g*. Double-distilled water was used to prepare all the solutions. A stock solution of ENX (10 mg/25 ml of methanol) was prepared. Dilutions were made in the range of 2.5×10^{-5} to 1.2×10^{-4} *M*, each containing 0.25 μmol IS (acetylpipemidic acid) for CE and 0.11 μmol IS (3,4-dihydroxybenzylamine HBr) for HPLC. All the dilutions for CE were prepared in a background electrolyte. The background electrolyte was a 20 m*M* borate buffer at pH 8.6 for the CE experiments. The dilutions were analyzed by applying a +30 kV potential, injecting the sample 1sec and detecting at 265 nm where ENX and acetylpipemidic acid (IS) absorb the monochromatic light equivalently.

Procedure for CE Analysis

The fused silica capillary tubing was filled with the background electrolyte (pH 8.6; 20 m*M* borate). Both ends of the tube were dipped into a reservoir (8 ml) and a vial (1.1 ml) filled with the background buffer. The end part

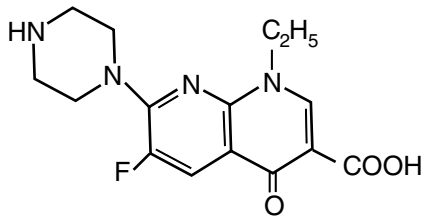

Fig. 1 The chemical structure of ENX.

where the sample (side of vial) was introduced was connected with a platinum electrode to the positive high-voltage side of the power supply. The reservoir side at the detector end was connected with a platinum electrode to the ground. Samples at a concentration of 7.7×10^{-5} *M* for the optimization of CE parameters were introduced by 1sec of vacuum injection corresponding to almost 65 nl. Before each run, the capillary was purged for 2 min with 0.1 *M* sodium hydroxide solution, then for another 2 min with double-distilled water. It was then equilibrated by passing the background electrolyte for 5 min prior to operation.

A background electrolyte consisting of borax was preferred for conducting the initial CE experiments because ENX has a carboxylic group on its structure. Several pH values were tested in the range from 8.45 to 9.95 using the concentration of 20 m*M* borax buffer. It was observed that the ENX (1.26×10^{-4} *M*) peak appeared in all the studied pH values, but the migration time of ENX, as expected, increased with increasing pH. Phosphate and citrate buffers of the same pH and concentration (8.6, 20 m*M*) were used to compare the effect of the nature of the buffer components. The migration time (t_M) of ENX was not affected by the buffer components, but the repeatability of the peak areas decreased with the use of citrate and phosphate buffers. It is concluded that some optimization studies are required if these buffer systems are to be used.

The influence of borax buffer concentration was investigated in the range from 10 to 100 m*M*. The sharpest peaks were obtained in the use of 10–30 m*M* concentrations and the t_M of ENX was almost constant, and an increase was observed in the use of borax concentration above 30 m*M*, but peak deformation also occurred due to the heat production by the Joule effect. In order to achieve optimization of the proposed analytical procedure, low buffer concentration was considered to decrease the electrophoretic mobility that corresponds to short analysis time. Based on the above results, the most convenient buffer system was 20 m*M* borate buffer at pH 8.6. Since the separation depends on the conditioning of the capillary inner surface in the CE analysis, the t_M and peak integration values might be very similar to the HPLC techniques.

The electropherogram of ENX and acetylpipemidic acid (IS) in the background electrolyte is shown in Fig. 2. The signal of electroosmosis and the migration time of the peaks of ENX and IS appeared at 3.8, 4.8, and 5.5 min, respectively. From the integration data, the net mobility toward the cathode (electroosmosis) and the ENX and IS toward the anode (electrophoretic) were 7.56×10^{-4}, 5.96×10^{-4}, and 4.6×10^{-4} $cm^2/V/sec$, respectively. The capacity factors were 3.82 (ENX) and 4.53 (IS).

Certain evaluation methods were examined based on the quantification processes. These can be divided into three

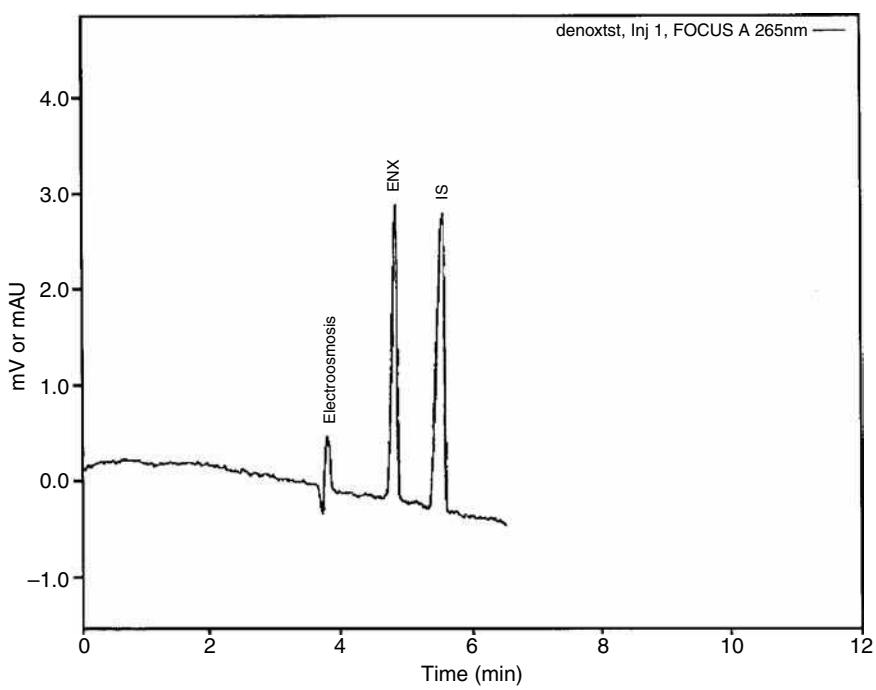

Fig. 2 Typical electropherogram of standard ENX (7.7×10^{-5} *M*) and IS (acetylpipemidic acid, 5.18×10^{-5} *M*). Conditions: 20 n*M* boratem pH 8.6; injection, hydrodynamically 1 sec; applied voltage, +30 kV; capillary, uncoated fused silica, 75 μm I.D., 88 cm total, and 58 cm effective length; detection at 265 nm.

Table 1 Precision of peak areas (days = 3; $n = 6$).

Precision of peak areas (RSD%)	PN no. IS	IS no. PN	IS and PN
Repeatability	2.80	0.99	0.99
Intermediate precision	3.24	2.86	1.36

groups, employing only the values of peak normalization (PN). The effect of the use of IS and certain evaluation methods, such as correction of peak area (normalization), was calculated by dividing the related peak area into t_M on which the precision was examined. These can be divided into three groups: a) employing only the area values of PN (PN no IS); b) computing the ratio values (IS no PN); and c) using the area values of peak normalized IS and ENX (IS and PN). The precision of the peak areas was calculated as shown in Table 1.

The success of the CE experiments from an analytical point of view depends on the conditioning of the capillary surface. Therefore, cleaning and conditioning processes, as explained in the experimental part, must be repeated after each injection to provide optimum resolution and reproducibility. The precision of the peak area was also assessed by considering certain evaluations, such as the effects of correction of peak area (normalization), which were found by the division of the related peaks into the corresponding migration times; the use of an internal standard was studied.

As seen from Table 1, the lowest RSD% values were obtained from those of IS and PN. Thus, such evaluation was considered throughout the rest of the study. A series of standard ENX solutions in the concentration range of 2.5×10^{-5} through 1.2×10^{-4} M, with each solution containing 0.25 μmol at a fix concentration of IS, were prepared and injected ($n = 3$). Linear regression lines were obtained by plotting the ratios of normalized peak areas to those of the internal standard vs. the analyte concentration. The calibration equation was computed using a regression analysis program, considering the ratio values vs. the related concentrations. The results are presented in Table 2.

Method Validation and Accuracy

From the electropherogram in Fig. 2, no interference from the formulation excipients could be observed at the migration times of ENX and IS. The limit of the detection (LOD) was 3.85×10^{-7} M, while the limit of quantification (LOQ) was 1.16×10^{-6} M. The results indicate good precision. Method accuracy was determined by analyzing a placebo (mixture of excipients) spiked with ENX at three concentration levels ($n = 6$) covering the same range as that used for linearity. Mean recoveries with 95% confidence intervals are given in Table 3.

Table 3 Precision of the method (spiked placebos).

Concentration levels (%)	50	100	150
Repeatability (days = 3; $n = 6$, RSD%)	2.0	2.5	2.1
Intermediate precision (days = 3; $n = 6$, RSD%)	3.3	3.0	3.1

Determination of ENX by HPLC

HPLC experiments were carried out using a Model 510 Liquid Chromatograph equipped with a Model 481 UV detector (Waters Associates, Milford, Massachusetts, U.S.A.). The chromatograms were processed by means of a chromatographic workstation (Baseline 810). Separation was performed on a reversed-phase Supelcosil LC-18 column (250 × 4.6 mm I.D., 5 μm particle size) (Supelco, St. Louis, Missouri, U.S.A.). The samples were injected into a 50 μl loop using a Rheodyne 7125 valve (Rheodyne, Cotati, California, U.S.A.).

Procedure for HPLC Analysis

The HPLC conditions were optimized by using different mobile and stationary phases. During HPLC experiments, a 10 mM phosphate buffer (pH 4.0)/acetonitrile (85:15, v/v) was used as a mobile phase. 3,4-Dihydroxybenzylamine-HBr (IS) was found to be a suitable internal standard for the HPLC experiments. The flow rate was 1.5 ml/min and detection was carried out at 260 nm. The ENX in tablet and the serum were identified by comparing the retention times of the pure ENX under the identical chromatographic conditions.

RESULTS AND DISCUSSION

Under the described chromatographic conditions, ENX has a retention time of 10.03 min, whereas IS eluted at 2 min.

Table 2 Linearity and accuracy of the method (spiked placebos).

Regression parameters			
Linearity	$r^2 = 0.9998$	intercept (mean ± SD) = $-0.02342 \pm 7.32 \times 10^{-3}$	slope (mean ± SD) = 9813.18 ± 102.31
Accuracy	50%	100%	150%
Mean recovery ±CI%	101.4 ± 2.12	101.1 ± 2.63	100.4 ± 2.25

Peak area ratios were linearly proportional to ENX concentrations in the range 3.12×10^{-6} through 3.12×10^{-4} *M*, with a detection limit of 1.56×10^{-6} *M*. The calibration equation was found to be [$R = -0.51 + 2.1 \times 10^5$ *C* (M); $r = 0.9992$], where *C* (M) is the molar concentration of ENX. The results of the HPLC experiments were compared with those obtained by the CE experiments. As described earlier, various reports on enoxacin analysis by HPLC are available. The different stationary phases used are μ-Bondapak C_{18}, Spherisorb S5 ODS2, Nucleosil C_{18}, Hypersil ODS, etc. The mobile phases used for the analysis of ENX are different ratios of water–acetonitrile, buffers–acetonitrile, acetonitrile–salt solutions, methanol–salt solutions, etc.[5–12]

Analysis of ENX in Tablets by CE and HPLC Methods

Enoxacin tablets (containing 400 mg active material) were obtained from the local market. Ten ENX tablets were accurately weighed. The average weight of one tablet was calculated, and then the tablets were finely powdered in a mortar. A sufficient amount of tablet powder, equivalent to 10 mg of ENX, was accurately weighed, then transferred to a 25 ml volumetric flask, and methanol was added to dissolve the active material. It was magnetically stirred for 10 min and made up to the final volume with the related solvent. The solution was then centrifuged at 5000 × *g* for 10 min. The supernatant and a fixed amount of IS solution were diluted with a background electrolyte or mobile phase to carry out either the CE or the HPLC assay. The electropherograms of ENX in tablets with IS are shown in Fig. 3.

Analysis of ENX in Serum by CE and HPLC Methods

For the CE analysis, 0.25 μmol of ENX (in 1 ml) was added to 1 ml of serum and was vigorously shaken. Then 3 ml of ethanol was added and mixed well using a shaker. The precipitated proteins were separated by centrifuging for 10 min at 5000 × *g*. A specific amount of clear supernatant was transferred to a tube, IS solution was added, and the final solution was directly injected to the CE instrument under the same conditions. It was reported that some determinations have been carried out by directly injecting the supernatant of the homogenates and urine into the CE.[16] This kind of application shortens the total analysis time. For HPLC, the precipitation of proteins of 1 ml serum was achieved according to the methods described by Nangia et al.,[7] i.e., by adding 50 μl $HClO_4$ (60% w/v), centrifuging for 10 min at 5000 × *g*, and directly injecting the supernatant into the column of the HPLC system under the conditions

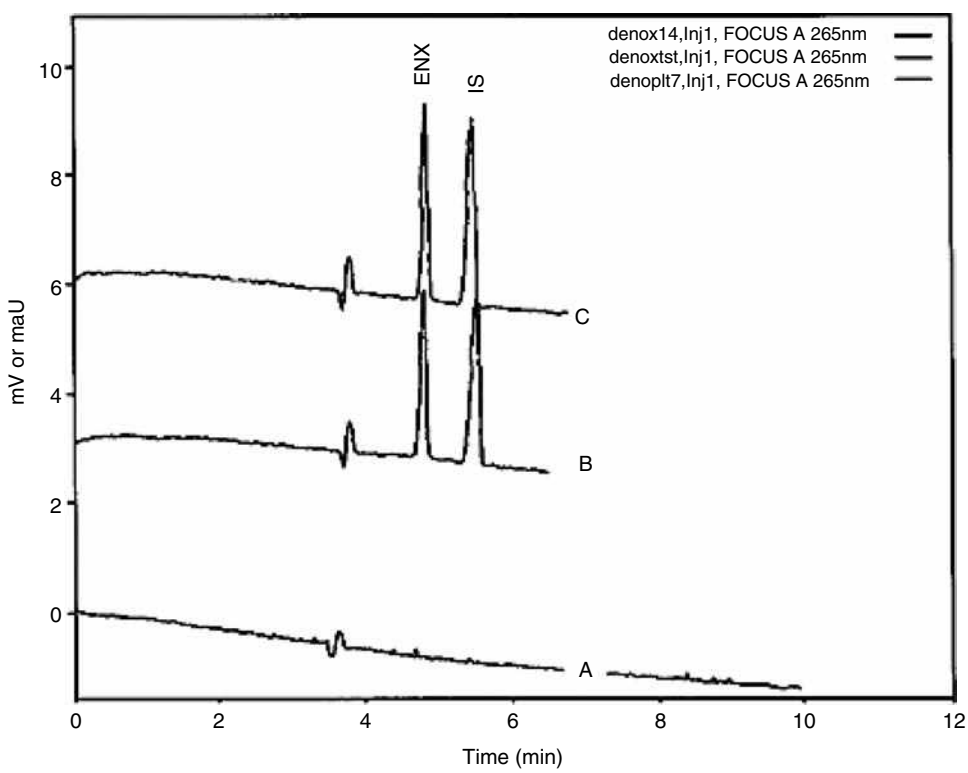

Fig. 3 Electropherograms of (a) inactive ingredients of a tablet solution of ENX; (b) standard ENX (7.7×10^{-5} *M*) and IS (acetylpipemidic acid, 5.18×10^{-5} *M*); and (c) enoxacin tablet solution containing IS. Conditions are the same as in Fig. 2.

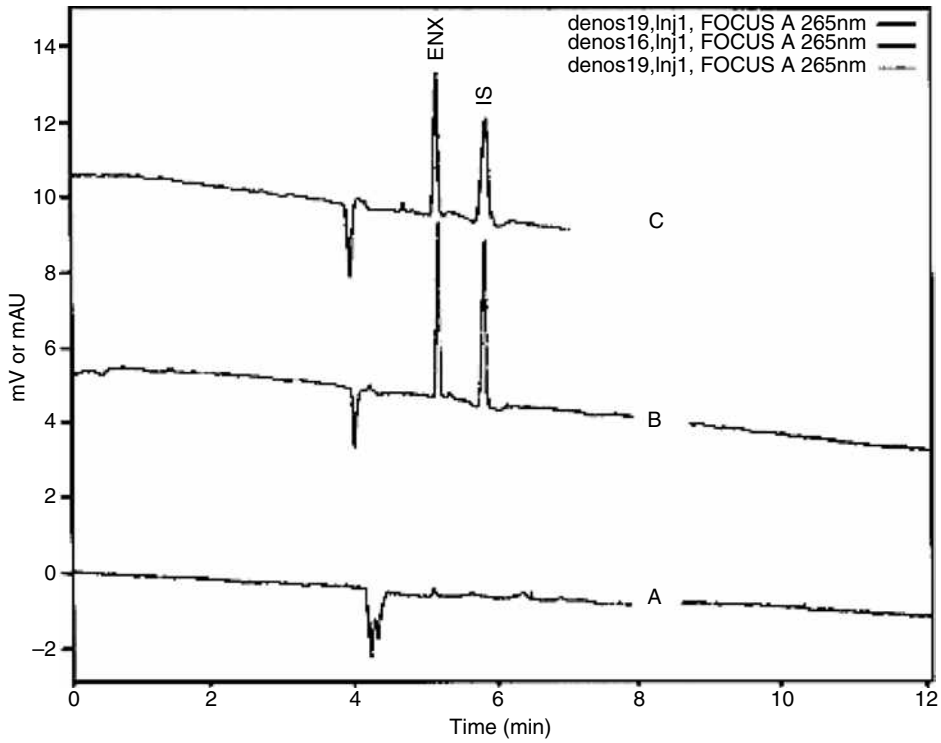

Fig. 4 Electropherogram of (a) blank serum deproteinized with ethanol; (b) serum spiked with the standard ENX solution (0.25 μmol) and IS (0.15 μmol); and (c) water spiked with the standard ENX solution (0.25 μmol). Conditions are the same as in Fig. 2.

mentioned above. The electropherograms of ENX with IS in the serum are given in Fig. 4.

CONCLUSIONS

A typical electropherogram is shown in Fig. 2, which indicates no interferences from the tablet excipients. In order to examine the applicability and validity of the CE method, ENX pharmaceutical tablets were analyzed by CE and HPLC methods. Results of the comparative studies are shown in Table 4. The results indicate that both methods, i.e., by CE and HPLC, show insignificant differences at the 95% probability level and the ENX tablet formulations satisfy the official requirements.[19] Certain experiments were conducted to elucidate the recovery of ENX and to validate the CE studies. Three sets of experiments with definite amounts of ENX were added to the serum and to the double-distilled water, and were analyzed. The same experiment was also performed without any ENX. The recovery was found to be 89.7 ± 0.63 (RSD%). The recovery experiments were also tested by HPLC and were found to be 78.8 ± 4.94 (RSD%). The difference between the methods could be due to the different precipitation procedures applied.

These results show that the proposed CE method is simple, rapid, and low cost, as compared to HPLC, especially for the quality-control analysis of ENX. It has also been observed that the amount of ENX found (Table 4) was always greater with CE than with HPLC. The presented CE method can be used for the analysis of ENX at trace levels in unknown matrices and also for routine quality control of ENX.

Table 4 Comparative studies for the determination of ENX tablet.

No. of experiment	Amount found (mg) using CE	Amount found (mg) using HPLC
1	419.7	410.1
2	428.5	417.4
3	422.3	414.9
4	417.1	419.9

Environmental Applications of Reversed-Flow GC

John Kapolos
Department of Agricultural Products Technology, Technological Educational Institute of Kalamata, Kalamata, Greece

INTRODUCTION

The reversed-flow gas chromatography (RFGC) technique, a subtechnique of the inverse gas chromatography (IGC), can be used for the determination of physicochemical quantities pertaining to environment and pollutants. Experimental setup and appropriate mathematical analysis for the calculation of physicochemical parameters are reviewed, taking into account: i) the interaction between air pollutant(s) and a solid surface in the absence, or in the presence, of a chemical reaction between two pollutants in the gas phase over the solid material (synergistic effects) and ii) exchange of gas pollutant(s) between atmospheric and water environment.

REVERSED-FLOW GAS CHROMATOGRAPHY

Interaction Between Air Pollutant(s) and a Solid Surface

One of the most important effects of atmospheric pollution is the damage to historic monuments and buildings and, generally, to cultural heritage. Volatile hydrocarbons, nitric oxide, nitrogen dioxide, sulfur dioxide, aromatic hydrocarbons, and suspended particulate matter are emitted by a number of processes, either anthropogenic or not. In addition, ozone plays a significant role in atmospheric pollution because of its relationship with chemical and photochemical changes. All these effects start with the deposition of air pollutants onto solid surfaces and lead to permanent corrosion and damage. The exterior surfaces of monuments have been attacked by more than one pollutant and, in addition, by secondary pollutants that are produced by chemical reactions in the gas phase, and have led to deterioration of the buildings and monuments.

The RFGC technique, a flow perturbation method developed in 1980,[1] is used to measure the following directly from experimental data: rate constants for adsorption, desorption, and chemical reaction of gaseous pollutants with the solid surface of the objects, diffusion coefficients of the pollutants which are diffused into the pores of the solid, deposition velocities and reaction probabilities for the action of air pollutants on the same surfaces, adsorption energies, local monolayer capacities, local adsorption isotherms, and probability density functions for the deposition of the pollutants onto the surface of the cultural heritage objects.[2,3] All the above quantities can be calculated, including, or not, apparent first-order rate constants for the chemical reaction of two pollutants in the gaseous phase above the solid surface (synergistic effects).[2,4]

A commercial gas chromatograph, equipped with an appropriate detector (depending on the kind of pollutant under study), is required to apply the RFGC technique.[5,6] The experimental arrangement is very simple and the traditional gas chromatograph is slightly modified to include a T-shape cell constructed from glass or stainless steel chromatographic tube inside the chromatographic oven, and a four- or six-port gas valve inside or outside the oven. The diffusion column (20–80 cm × 3–5 mm I.D.), connected perpendicularly to the sampling column (0.6–2.0 m × 3–5 mm I.D.) at its midpoint, contains only stagnant carrier gas (nitrogen or air), which also flows through the empty sampling column, either from D_1 to D_2 or vice versa. Near the closed end of the diffusion column, a small length (4–9 cm) is filled with particles of the solid under study. The sampling column is devoid of any solid or liquid material, and, for separation purposes, an additional separation column is placed before the detector.

After the solid bed is conditioned by heating it in situ, under a continuous carrier gas flow, the bed is cooled to the working temperature and a small volume of gas (0.5–1.0 cm^3 at atmospheric pressure) or liquid (1–5 μl) pollutant is introduced through the injector into the solid bed. When studying synergistic effects, two pollutants are introduced simultaneously or within a short interval of no more than a few seconds to the system.

After the appearance of the continuously rising concentration–time curve, the reversing procedure for the carrier gas flow by means of the four- or six-port valve is initiated. This reversal procedure, for a period shorter than the gas hold-up time in the sampling column, creates narrow and fairly symmetrical chromatographic peaks over the continuous elution curve.[7,8,9] These extra chromatographic peaks, called "sample peaks," and their heights H are measured as a function of the time t during the reversal procedure. The height is proportional to the concentration c, of the injected pollutant, at the junction point $z = 0$ and $x = l'$ of the sampling column (Fig. 1), at time t. The

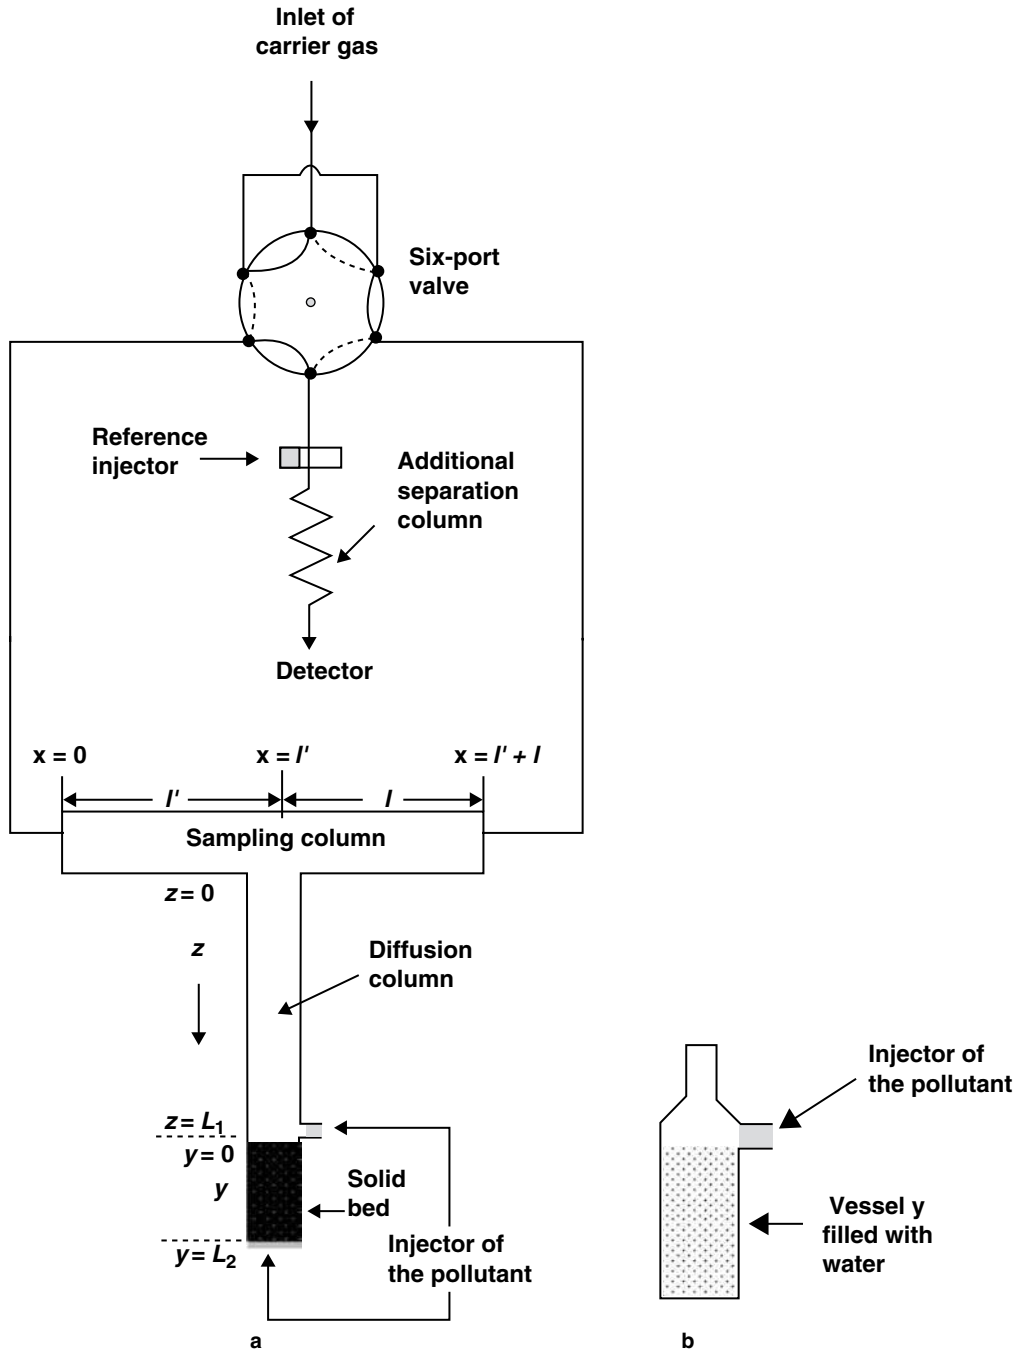

Fig. 1 Schematic representation of columns and gas connections for studying (a) the interaction between air pollutant(s) and a solid surface and (b) exchange of gas pollutant(s) between atmospheric and water environments.

mathematical expression of the above has been derived theoretically:[7,10]

$$H^{\frac{1}{M}} = gc(l', t) \tag{1}$$

where M (dimensionless) is the response factor for the detector ($M = 1$ for the linear FID and g is the proportionality constant (cm per mol/cm^3).

Now a question arises; is there any relationship between the measured concentration $c(l', t)$ and the physicochemical quantities pertaining to the various phenomena occurring in the solid bed region? For an answer, one must solve the mathematical equations describing all the physicochemical actions taking place in such systems.

First, the local (with respect to time) adsorption isotherm of the pollutant

$$c_s^* = \frac{a_y}{a_s} k_1 \int_0^t c_y(\tau) d\tau \tag{2}$$

Second, the mass balance equation for the pollutant in the region z (diffusion column)

$$\frac{\partial c_z}{\partial t} = D_z \frac{\partial^2 c_z}{\partial z^2} \tag{3}$$

Next, the mass balance equation for the same pollutant in region y, filled with the solid material under study

$$\frac{\partial c_y}{\partial t} = D_y \frac{\partial^2 c_y}{\partial y^2} - k_R \frac{a_s}{a_y} (c_s^* - c_s) \tag{4}$$

Finally, the rate of change of the adsorbed concentration:

$$\frac{\partial c_s}{\partial t} = k_R (c_s^* - c_s) - k_2\ c_s \tag{5}$$

where c_s^* is the local adsorbed concentration of the pollutant in equilibrium with that in the gaseous state (mol/g), n_s the initially adsorbed equilibrium amount of the pollutant (mol), a_s the amount of the solid material per unit length of column bed (g/cm), y the length coordinate along section L_2 (cm), a_y the cross-sectional area of the void space in region y (cm^2), k_1 the local adsorption parameter describing the local experimental isotherm of the pollutant on the solid surface, which varies with time (1/sec), c_y the gaseous concentration of the pollutant in the gas phase above the solid (mol/cm^3), τ the dummy variable for time (sec), c_z the gaseous concentration of the pollutant as a function of time t and length coordinate z along the column (mol/cm^3), D_z the diffusion coefficient of the pollutant in the carrier gas (cm^2/sec), D_y the effective diffusion coefficient of the pollutant in the region of the solid bed (cm^2/sec), k_R the rate constant for adsorption/desorption of the pollutant on the bulk solid (1/sec), c_s the concentration of the pollutant adsorbed on the solid (mol/g), and k_2 the rate constant of a possible first-order or pseudo-first-order surface reaction of the adsorbed pollutant (1/sec).

By taking the following initial conditions into consideration, $c_z(0,\ z) = 0$, $c_y(0,\ y) = (n_A/a_y)\ \delta(y - L_2)$, and $c_s(0,y) = 0$, where n_A is the amount (mol) of the pollutant introduced as a pulse at $y = L_2$, the system of the above partial differential (Eqs. 2–5) is solved by using double Laplace transformation of all terms with respect to time and length coordinates. By means of certain approximations and algebraic manipulations,[3] the t Laplace transform of the measurable concentration $c(l',\ t)$ of the pollutant in the sampling column at time t is given by the equation:

$$C(l',\ p) = G \frac{p^2 + kp}{(p - B_1)(p - B_2)(p - B_3)} \tag{6}$$

where

$$G = \frac{n_A a_1 a_2}{\dot{V}(a_1 + a_2 + a_2 Q)} \tag{7}$$

$$a_1 = \frac{2D_z}{L_1^2};\quad a_2 = \frac{2D_y}{L_2^2};\quad Q = \frac{2a_y L_2}{a_z L_1} \tag{8}$$

$$k = k_2 + k_R \tag{9}$$

L_1 and L_2 are the lengths of the sections z and y, respectively, α_z is the cross-sectional area of the region z (cm^2), $\dot{V}$ is the volumetric flow rate of the carrier gas, and B_1, B_2, and B_3 are the roots of the third degree polynomial of the denominator in Eq. 6.

The inverse Laplace transformation with respect to p of Eq. 6 leads to the equation:

$$c(l', t) = G\Big[A_1^0 \exp(B_1 t) + A_2^0 \exp(B_2 t) + A_3^0 \exp(B_3 t)\Big] \tag{10}$$

where

$$A_1^0 = \frac{B_1^2 + kB_1}{(B_1 - B_2)(B_1 - B_3)} \tag{11}$$

$$A_2^0 = \frac{B_2^2 + kB_2}{(B_2 - B_1)(B_2 - B_3)} \tag{12}$$

$$A_3^0 = \frac{B_3^2 + kB_3}{(B_3 - B_1)(B_3 - B_2)} \tag{13}$$

and the relationships between the physicochemical parameters previously defined, k_1, k_R, k_2, and D_y, and the exponential coefficients of time are as follows:

$$X = \frac{a_1 a_2}{a_1 + a_2 + a_2 Q} + k = -(B_1 + B_2 + B_3) \tag{14}$$

$$Y = \frac{a_1 a_2 k + (a_1 + a_2 Q) k_1 k_R}{a_1 + a_2 + a_2 Q} = B_1 B_2 + B_1 B_3 + B_2 B_3 \tag{15}$$

$$Z = \frac{a_1 + a_2 Q}{a_1 + a_2 + a_2 Q} k_1 k_2 k_R = -B_1 B_2 B_3 \tag{16}$$

where X, Y, and Z are auxiliary parameters.

As the height H of the extra chromatographic peaks, obtained by the repeated flow reversals, is proportional to

the gaseous concentration (Eq. 1) with a proportionality constant g (cm per mol/cm^3), we can write Eq. 10 as:

$$H^{\frac{1}{M}} = gG\sum_{i=1}^{3} A_i^0 \exp(B_i t) = \sum_{i=1}^{3} A_i \exp(B_i t) \tag{17}$$

where $A_i = gGA_i^0$ in cm.

Using a non-linear regression analysis PC program in GW-BASIC,[10] one can calculate the exponential and preexponential coefficients from the measured pairs H, t. From these, in turn, the calculation of the physicochemical quantities mentioned above is carried out as follows:

First, the value of k of Eq. 9 is calculated by dividing Eqs. 11 and 12 by Eq. 13. The results are

$$\frac{A_2^0(B_2 - B_1)(B_2 - B_3)}{A_1^0(B_1 - B_2)(B_1 - B_3)} = \frac{B_2^2 + kB_2}{B_1^2 + kB_1} = A_{21};$$

$$\frac{A_3^0(B_3 - B_1)(B_3 - B_2)}{A_1^0(B_1 - B_2)(B_1 - B_3)} = \frac{B_3^2 + kB_3}{B_1^2 + kB_1} = A_{31} \tag{18}$$

The mean value of k's, found from the above two relationships, is further used. The a_2 by Eq. 14 and then D_y by Eq. 8 are easily calculated, while the value of D_z is obtained from the literature or calculated by well-known equations.[11,12]

The values of k_1, k_R, and k_2 are computed by using, after rearrangement, Eqs. 15, 16, and 9. First, by dividing Eq. 16 by Eq. 15, one obtains the value of k_2; then, subtracting that from k yields k_R and, finally, by dividing Eq. 15 by k_R, we find k_1.

From the above-calculated parameters, through the following Eqs. 19 and 20, the overall deposition velocity (V_d), which is equivalent to an overall mass transfer coefficient of the gaseous pollutant to the solid surface, corrected for the activated adsorption/desorption and surface reaction, and the reaction probability γ of the pollutant with the surface under study are found:

$$V_d = \frac{k_1 V'_G(\text{empty})\varepsilon}{A_S} \cdot \frac{k_2}{k_R + k_2} \tag{19}$$

$$\frac{1}{\gamma} = \left(\frac{R_g T}{2\pi M_B}\right)^{\frac{1}{2}} \cdot \frac{1}{V_d} + \frac{1}{2} \tag{20}$$

where A_S is the total surface area of solid (cm^2) V'_G the gaseous volume of the section y of the experimental cell (Fig. 1a) (cm^3), R_g the ideal gas constant (J/K/mol), M_B the molar mass of pollutant, (kg/mol), and T the absolute temperature (K).

For calculating adsorption energies, local monolayer capacities, local adsorption isotherms, and probability density functions for the deposition of the pollutants onto the surface of the objects, the height H of the reversed-flow peaks and the physicochemical parameters B_i and A_i are used. The necessary relationships are as follows:

First, Eq. 10 of Ref.[13], which describes the local adsorption isotherm θ_t on the solid surface

$$\theta_t = \frac{c_s^*}{c_{\max}^*} = 1 - \exp(-KR_g T c_y) \tag{21}$$

where c_s^* and c_y have been defined after Eq. 5, $c_{\max}^*$ is the local monolayer capacity, with respect to time, ε is the adsorption energy, and K is the Langmuir constant[14] given by the relationship:

$$K = K^0(T)\exp\left(\frac{\varepsilon}{RT}\right) \tag{22}$$

where $K^0(T)$ is described by statistical mechanics[15] as

$$K^0 = \frac{h^3}{(2\pi m)^{\frac{3}{2}}(kT)} \cdot \frac{v_s(T)}{b_g(T)} \tag{23}$$

where k is the Boltzmann constant, m the molecular mass of the pollutant, h the Plank constant, and the ratio $v_s(T)/b_g(T)$ of two partition functions, namely that of the adsorbed molecule, $v_s(T)$, and that for rotations–vibrations in the gas phase $b_g(T)$. This ratio is taken approximately as unity.[14]

Second the gaseous concentration c_y (mol/cm^3) in the solid bed space is given by the equation:

$$c_y = \frac{uL_1}{gD_z}\sum_{i=1}^{3} A_i \exp(B_i t) \tag{24}$$

while the equilibrium adsorbed concentration c_s^* (mol/g) is obtained as

$$c_s^* = \frac{a_y}{a_s} k_1 \frac{uL_1}{gD_z}\sum_{i=1}^{3} \frac{A_i}{B_i}[\exp(B_i t) - 1] \tag{25}$$

where g, D_z, and L_1 have been defined above, u (cm/sec) is the corrected linear velocity of the carrier gas, and A_i and B_i are the parameters of Eq. 17.

Finally, the probability density function for the adsorption energy ε as the random variable and the time t as a structural parameter, $f(\varepsilon,t)$ can be based on the relationship:[16]

$$f(\varepsilon, t) = \frac{\partial c_{\max}^*}{\partial \varepsilon} = \frac{\partial c_{\max}^*/\partial t}{\partial \varepsilon/\partial t} \tag{26}$$

From the above Eqs. 21–26, the time distribution physicochemical parameters for the adsorption of the pollutants on the surface of the monuments can be calculated.

The adsorption energy ε is expressed by the next relationship, which is derived from Eq. 22:

$$\varepsilon = RT \ln\left(\frac{K}{K^0}\right) \tag{27}$$

The local isotherm θ_t is calculated with Eq. 21, where c_y is given by Eq. 24 and KR_gT by Eq. 12 of Ref.[17]

The local monolayer capacity $c^*_{\max}$ is obtained as a combination of Eqs. 21 and 25, and the calculated value of θ_t according to the relationship:

$$c^*_{\max} = \frac{c^*_s}{\theta_t} \tag{28}$$

Finally, the probability density function over time for the adsorption energy is given as follows:

$$f(\varepsilon, t) = \frac{1}{RT}\left[\frac{KRT(\partial c^*_s/\partial t) + (\partial^2 c^*_s/\partial c_y \partial t)}{\partial(KR_gT)/\partial t} - \frac{\partial c^*_s/\partial c_y}{KR_gT}\right] \tag{29}$$

The expressions for all derivatives with respect to time in the above relationship have been given in detail elsewhere.[16,18]

From the above mathematical analysis, the answer to the question (Is there any relationship between the measured concentration $c(l', t)$ and the physicochemical quantities pertaining to the various phenomena occurring in the solid bed region?) is obtained. Using only measurable experimental quantities, such as the height H of the extra chromatographic peaks and the time t when those peaks occur, RFGC was used to study the action of air pollutants, such as SO_2, NO_2, $(CH_3)_2S$, O_3, and volatile hydrocarbons on pure $CaCO_3$, Penteli marbles, inorganic pigments as well as surfaces of cultural and artistic value inside museums.[2–6,8,9] Synergistic effects of two gaseous substances,[4] effects of airborne particles deposited on solid surfaces, and characterization and comparison of the behavior of coverage which protects materials against air pollutants can also be carried out.

Finally, from the above-calculated physicochemical quantities, a mechanism for the interaction of air pollutant and a solid surface can be proposed.[8]

Exchange of Gaseous Pollutant(s) Between Atmospheric and Water Environments

Aside from the above interactions between air pollutants and solid surfaces, the RFGC was recently applied to describe and quantify the physical and chemical phenomena controlling the exchange of gas pollutants between the atmospheric and water environments and vice versa. These phenomena are of great significance in environmental chemistry,[19] either owing to the solubilities of air pollutants in water or owing to their ability to migrate from water to the atmosphere. A good example is dimethyl sulfide, which is emitted by oceanic phytoplankton and constitutes the major natural source of sulfur in the troposphere.

For a description of the mechanism involving the above phenomena, the following physicochemical quantities should be calculated:

i. Diffusion coefficient of the pollutant in the carrier gas (D_z, cm^2/sec).
ii. Diffusion coefficient of the pollutant in the water (D_L, cm^2/sec).
iii. Partition coefficient of the pollutant between the water at the interface and the carrier gas (K, dimensionless).
iv. Partition coefficient of the pollutant between the bulk water and the carrier gas (K', dimensionless).
v. Partition coefficient of the pollutant between the water at the interface and the bulk (K'', dimensionless).
vi. Henry's law constant for the dissolution of the pollutant in the water (H^+, atm).
vii. Overall mass transfer coefficients of the gas in the carrier gas (K_G, cm/sec) and in the liquid water (K_L, cm/sec).
viii. Gas (k_G, cm/sec) and liquid (k_L, cm/sec) film transfer coefficients.
ix. Gas (r_G, sec/cm) and liquid (r_L, sec/cm) phase resistances for the transfer of the pollutant to the water.
x. Thickness of the stagnant film in the liquid phase (z_L, cm).

The experimental setup which is used for the calculation of the above-mentioned parameters is described above. The only difference is an additional vessel at the end of the diffusion column where liquid water is placed instead of the solid bed (Fig. 1b). The experimental procedure is identical to the previously described one (except, of course, for the condition of the solid bed).

The height of the extra chromatographic peaks is again proportional to the measurable concentration $c(l', t)$ of the pollutant and is given by an equation analogous to Eq. 17, which is reproduced in detail elsewhere.[20]

$$\frac{H}{2} = c(l', t) = A_1 \exp(B_1 t) + A_2 \exp(B_2 t) + A_3 \exp(B_3 t) \tag{30}$$

where the pre-exponential coefficients A_1, A_2, and A_3 can be written as explicit functions of B_1, B_2, and B_3, the geometrical characteristics of the cell and other experimental quantities, but this is not needed for the calculation

of the above-mentioned physicochemical quantities. The exponential coefficients of time B_1, B_2, and B_3 are used first for the calculation of D_L, K, and H^+ according to the following equations:[20]

$$X = \frac{9AD_z}{KL_1L_2} + \frac{6D_z}{L_1^2} + \frac{6D_L}{L_2^2} = -(B_1 + B_2 + B_3) \quad (31)$$

$$Y = \frac{18AD_z^2}{KL_1^3L_2} + \frac{18AD_zD_L}{KL_1L_2^3} + \frac{36D_zD_L}{L_1^2L_2^2} = B_1B_2 + B_1B_3 + B_2B_3 \quad (32)$$

$$Z = \frac{36AD_z^2D_L}{KL_1^2L_2^3} = -B_1B_2B_3 \quad (33)$$

$$H^+ = \frac{R_gTd}{KM_L} \quad (34)$$

where X, Y, and Z are auxiliary parameters, A is the ratio of cross-sectional areas in z and y regions, α_z and α_L, respectively (cm^2), L_1 and L_2 are lengths in z and y regions, respectively (cm), d is the density of the liquid, M_L is the molar mass of the liquid, and D_z is the diffusion coefficient of the pollutant in carrier gas, which can be determined when the vessel y is empty.

For the calculation of the other parameters K_G and K_L, and, from them, k_G, k_L, r_G, r_L, z_L, K, K' and K'', the following equations are adopted:[20]

$$X_1 = \frac{12D_z/L^2 + 4k/L + k'}{1 + kL/5D_z} = (-B_1 + B_2 + B_3) \quad (35)$$

$$Y_1 = \frac{24D_z^2/L^4 + 24kD_z/L^3 + 12k'D_z/L^2}{1 + kL/5D_z} = B_1B_2 + B_1B_3 + B_2B_3 \quad (36)$$

$$Z_1 = \frac{24k'D_z^2/L^4}{1 + k_L/5D_z} = -B_1B_2B_3 \quad (37)$$

$$K_L = \frac{k'V_L}{a_L}; \quad K_G = \frac{ka_z}{a_L}; \quad \frac{1}{K_L} = \frac{1}{k_L} + \frac{K'}{k_G}; \quad z_L = \frac{D_L}{k_L}; \quad K'' = \frac{K}{K'} \quad (38)$$

where X_1, Y_1, and Z_1 have different physicochemical meaning than the above X, Y, and Z, $L = L_1$ (gas phase), $k = K_Ga_L/a_z$, and $k' = K_La_L/V_L$ (liquid volume).

From the above equations, it is clearly defined that only the measurable height H of the extra chromatographic peaks and the time t when these peaks are produced are needed for the calculation of all the physicochemical quantities which are necessary for the description of the flux of gaseous pollutants across the air–water interface.

Until now, RFGC was used for studying the system vinyl chloride/water,[20] SO_2/water, and the effects of surfactants in reducing air–water exchange rates.[21]

CONCLUSIONS

Reversed-flow gas chromatography, which is a subtechnique of inverse gas chromatography, can be applied to determination of necessary physicochemical quantities for the interaction between air pollutants and cultural objects and exchange of air pollutants between atmospheric and water environments.

Environmental Applications of SFC

Yu Yang
Department of Chemistry, East Carolina University, Greenville, North Carolina, U.S.A.

INTRODUCTION

Because supercritical fluids have liquid like solvating power and gaslike mass-transfer properties, supercritical fluid chromatography (SFC) is considered to be the bridge between gas chromatography (GC) and liquid chromatography (LC) and possesses several advantages over GC and LC, as summarized in Table 1. For example, SFC can separate non-volatile, thermally labile, and high-molecular-weight compounds in short analysis times. Another advantage of SFC is its compatibility with both GC and high-performance liquid chromatography (HPLC) detectors. Because of these advantages of SFC, there is a large number of SFC applications in environmental analysis. However, only selected recent works are reviewed here. Although sample preparation is often required before SFC analysis to remove the analytes from environmental matrices and to enrich them, sample preparation is not intensively discussed in this review. To facilitate the discussion, the environmental pollutants are classified and reviewed separately in this entry.

PESTICIDES AND HERBICIDES

The analysis of pesticides and herbicides has mainly been done either by GC with selective detectors or by HPLC with ultraviolet (UV) detection. As summarized in Table 1, GC is limited to thermally stable volatile compounds, whereas the HPLC with UV can only detect compounds with chromophores. These limitations of GC and HPLC led to the use of SFC in the analysis of pesticides and herbicides. Among the SFC works in environmental analysis, one-third of the works concerns the analysis of pesticides and herbicides.

Many detectors have been used to detect pesticides and herbicides in SFC. Among these detectors, the flame ionization detector (FID) is most commonly used for detection of a wide range of pesticides and herbicides, with a detection limit ranging from 1 ppm (for carbonfuran) to 80 ppm (for Karmex, Harmony, Glean, and Oust herbicides). The UV detector has frequently been used for the detection of compounds with chromophores. The detection limit was as low as 10 ppt when solid-phase extraction (SPE) was online coupled to SFC. The mass spectrometric detector (MSD) has also been used in many applications as a universal detector. The MSD detection limit reached 10 ppb with online SFE (supercritical fluid extraction)–SFC. Selective detection of chlorinated pesticides and herbicides has been achieved by an electron-capture detector (ECD). The limit of detection for triazole fungicide metabolite was reported to be 35 ppb. Other detectors used for detection of pesticides and herbicides include thermoionic, infrared, photometric, and atomic emission detectors.

A variety of both packed and open tubular columns have been used for separation of pesticides and herbicides. The columns were either used separately or coupled in series to achieve better separations. Although environmental water samples were mostly analyzed by SFC, analyses of pesticides and herbicides from soil, foods, and other samples were also reported.

POLYCHLORINATED BIPHENYLS

Since 1929, polychlorinated biphenyls (PCBs) have been produced and used as heat-transfer, hydraulic, and dielectric fluids. Because of their chemical and physical stability, PCBs have been found in many environmental samples. Generally, PCBs have been analyzed by GC with electron-capture detection. There are many reports on subcritical and supercritical fluid extraction of PCBs, but only a few on supercritical fluid separation of PCBs.

Among the works of supercritical fluid separations of PCBs, UV has been the most popular detector. A Microbore C_{18} column was used to separate individual PCB congeners in Aroclor mixtures. Density and temperature programming was also utilized for separation of PCBs. Both packed (with phenyl and C_{18}) and capillary (Sphery-5 cyanopropyl) columns were used in this work. Carbon dioxide, nitrous oxide, and sulfur hexafluoride were tested as mobile phases for the separation of PCBs.

A HD and MSD were also used for detection of PCBs in SFC. Capillary columns packed with aminosilane-bonded silica and open-tubular columns coated with polysiloxane were employed for PCB separation in these works.

POLYCYCLIC AROMATIC HYDROCARBONS

Polycyclic aromatic hydrocarbons (PAHs) have routinely been analyzed by GC and LC. However, both techniques have limitations in terms of analyte molecular weight and analysis time. The greater molecular weight range of SFC

Table 1 Comparison of characteristics of GC, SFC, and LC.

	GCX[a]	SFC	LC[b]
Suitability for polar and thermolabile compounds	Low	High	High
Size of analyte molecule	Small-Medium	Small-Large	Small-Large
Sample capacity	Low	High (packed column)	High
Possibility of introducing selectivity in the mobile phase	Low	High	Medium
Toxicity and disposal cost of the mobile phase	No	No (with pure CO_2) Low (with modifier)	High
Efficiency	High	Medium-High	Low
Use of gas-phase detectors	Yes	Yes	No
Analysis time	Medium	Medium	Long

[a]Only capillary GC is used for these evaluations. Fast GC and packed column GC are not included here.
[b]Capillary HPLC is not included.

with respect to GC makes it better suited for determining a wide range of PAHs. SFC also has advantages over HPLC for the analysis of PAHs when the same kind of columns is used. Supercritical fluid has similar solvating power as a liquid does, and the solute diffusion coefficients are much greater than those found in liquids. Therefore, comparable efficiencies to HPLC can be obtained by SFC in shorter analysis time. Because of these characteristics of SFC, the separation of PAHs by SFC with different kinds of packed and capillary columns is a well-investigated and established method.

The most popular detector for PAHs is the UV detector. The detection limit was 0.2–2.5 ppb for 16 PAHs. A diode-array detector was also used for PAHs in SFC, and the detection limit was reported to be as low as 0.4 ppb. Other detections used for PAHs include mass spetrometric, thermoionic, infrared, photoionization, sulfur chemiluminescence, and fluorescence detectors.

Although has mainly been used as the mobile phase in SFC, modifiers have often been added to to increase the solvating power of the mobile phase. Although the most frequently used modifier has been methanol, many other modifiers were also tested. The modifier effect on retention is discussed separately in this encyclopedia. Because organic modifiers are incompatible with FID, FID was rarely used for PAHs in SFC.

Fast separations of 16 PAHs were achieved within 6–7 min using packed columns. A comparison study of the PAH molecular shape recognition properties of liquid-crystal-bonded phases in packed-column SFC and HPLC found that the selectivity was enhanced in SFC. The result of an interlaborotory round-robin evaluation of SFC for the determination of PAHs also shows that SFC possesses distinct advantages over GC/MS and nuclear magnetic resonance (NMR) including speed, cost, and applicability.

POLAR POLLUTANTS

Because carbon dioxide is non-polar, the separation of polar compounds by supercritical carbon dioxide is difficult. Thus, polar modifiers are often used for the separation of phenols and amines. Derivatization has also been employed to obtain non-polar analytes in some applications. The UV detector has mainly been used for the detection of polar compounds. Oxidative and reductive amperometric detection was also utilized with a detection limit of 250 pg for oxidative detection of 2,6-dimethylphenol. The detection of amines has generally been achieved by FID. Other detectors used for the detection of polar analytes include Fourier transform infrared (FTIR), photodiode array, and flame photometry.

It should be pointed out that separation of more than one class of organic compounds can be achieved by SFC. For example, Fig. 1 shows the chromatogram of 35 PAHs, herbicides, and phenols from a contaminated water sample. Solid-phase extraction was used for sample preparation. Five Hypersil silica columns were coupled in series for separation of these contaminants. The percentage of methanol (as modifier) was varied from 2% (5 min) to 10% (29 min) at 0.5%/min. A pressure program was also applied. A diode-array detector was used in this work.

ORGANOTIN, MERCURY, AND OTHER INORGANIC POLLUTANTS

Organotin compounds are used extensively as biocides and in marine antifouling paints. These compounds accumulate in sediments, marine organisms, and water, as they are continuously released into the marine environment. Many of these organotin compounds are toxic to aquatic life. Most organotin separation techniques have been based on the GC resolution of volatile derivatives and coupled to elemental detection techniques that are often not sensitive enough to detect trace organotin compounds. However, the separation of organotin compounds was achieved by capillary columns (SB-Biphenyl-30 or SE-52) with pure CO_2 as the mobile phase. Inductively coupled plasma–mass spectrometry (ICP–MS) was used in most of the applications to improve the sensitivity for detecting trace organotin species. The reported detection limits range from 0.2 to 0.8 pg for tetrabultin chloride, tributyltin chloride, triphenyltin chloride, and tetraphenyltin. However, the detection limits obtained by FID are 15- to 45-fold higher than those obtained by ICP–MS for the above-mentioned organotin compounds. Flame photometric detector was also used to detect organotin species with a detection limit of 40 pg for tribultin chloride.

The separation of organomercury was conducted by using a SB-methyl-100 capillary column and pure CO_2 as the mobile phase. FID and atomic fluorescence were used for detection. The same column was also used for separation of mercury, arsenic, and antimony species using carbon dioxide as the mobile phase. A chelating reagent, bis(trifluoroethyl)dithiocarbamate, was used in this case to convert the metal ions to organometallic compounds before the separation. The detection limit of FID was 7 and 11 pg for arsenic and antimony, respectively.

Fig. 2 shows an example of separating organomercury using supercritical A 10 m 50 mm-inner CO_2. A 10 m × 50 μm inner diameter SB-Methyl 100 column was used for the separation. Due to their poor solubility in supercritical carbon dioxide, monoorganomercury compounds were derivatized by diethyldithiocarbamate. An interface for a system consisting of SFC and atomic fluorescence spectrometry was developed for the detection of organomercurials.

In closing, supercritical fluid chromatography is a promising technique for the analysis of environmental pollutants. The analytes range from inorganic species to polar and non-polar organic compounds. The sample matrices cover water, soil, sediments, sludge, and air particulate matters. The sample preparation has been done by solid-phase extraction, supercritical fluid extraction, or traditional solvent extraction. Modifiers are often used to enhance the solubility of analytes and to yield a better separation for polar and high-molecular-weight analytes. Packed columns are preferred for trace analysis because of their high sample capacity. Both gas-phase and liquid-phase detectors have been used in SFC to detect a wide range of environmental pollutants.

Environmental Materials: Supercritical Fluid Extraction of Polynuclear Aromatic Hydrocarbons

Maria de Fatima Alpendurada
Faculty of Pharmacy, University of Porto, Porto, Portugal

INTRODUCTION

Supercritical fluid extraction (SFE), usually with carbon dioxide and, often, with a modifier, has become of increasing interest in the last few years because of its selectivity, preconcentration effect, efficiency, simplicity, rapidity, cleanness, and safety, mainly concerning the extraction of organic compounds prior to separation and detection by chromatographic techniques. It has several advantages over classical solvent extractions, in comparison with recent extraction techniques. Approaches to obtain quantitative extractions, including fluid choice, extraction flow rate, modifiers, pressure, and temperature, are presented, as well as the potential for SFE to extract polynuclear aromatic hydrocarbons (PAHs) from soils, sediments, and biota. Improvements and new environmental applications are also reported.

PARAMETERS INFLUENCING THE SUPERCRITICAL FLUID EXTRACTION PROCESS AND APPLICATIONS

Since the first applications of SFE were published by Zosel in 1978, this extraction technique has developed into a key method for the separation of the contaminants from both sediment and biological matrices. SFE has a number of advantages over classical solvent extraction methods: It is faster, more selective, and less toxic, particularly when compared with techniques using solvents such as dichloromethane, thus reducing safety hazards. It has received the attention of some researchers who have reviewed and developed this technique and its suitability to the analysis of environmental matrices.[1–3] The application of SFE to PAHs was reviewed, and new analytical strategies involving the need for modified supercritical fluids to improve extraction efficiency, restrictor prevention from blocking, collection form of the eluant, and general operation conditions, has been demonstrated. This technique is radically different from liquid–solid extraction (LSE), subcritical water extraction, microwave-assisted extraction (MAE), and accelerated solvent extraction (ASE)—also known as pressurized liquid extraction or pressurized fluid extraction—because the main constituent of the solvent system, CO_2, separates from the extracts upon venting to the atmosphere, leaving the analytes that are trapped either on a solid phase, such as C_{18}, or in an organic solvent. The influence in the extraction process of various parameters will depend on a number of steps controlling the transport of analytes from the matrix to the bulk fluid, e.g., temperature, pressure, solvent type, and extraction time. Interested readers should consult an excellent review regarding the mechanisms controlling the binding, release, and transport in environmental materials.[4] Supercritical fluid extraction, at low (50°C) and high (200°C) temperatures, and an 18 hr Soxhlet extraction with dichloromethane for railway soil and diesel soot samples were compared for the PAHs extraction.[5] The samples were mixed with anhydrous Na_2SO_4. The mean recoveries for the 17 PAHs examined in the railway soil was 50% at 50°C, 81% at 200°C, and 90% at 350°C. For the diesel soot, the recovery for 13 PAHs was 51% at 50°C, 71% at 200°C, and 118% at 350°C. Although higher temperatures favored better recoveries for the higher-molecular-weight PAHs, it was also suspected that the two- to three-ring PAHs were actually generated at these elevated temperatures. So a 30 min extraction at 200°C was selected as the optimum. Temperature and organic modifiers—10% MeOH, diethylamine, and/or toluene—using a marine sediment (SRM 1941) diesel soot and air particulate matter (SRM 1649) were also examined. The best recoveries were obtained with CO_2–diethylamine at 200°C with a 15 min-static and 15 min-dynamic extraction time. Also, supercritical water at 250°C, CO_2 at 200°C, and CO_2 with 19% toluene at 80°C were compared for the extraction of PAHs from urban air. Surprisingly, the water was generally as effective as the other solvents under these conditions.[2] However, unlike CO_2, the water had to be subsequently removed from the extract. After optimization of the SFE-CO_2 extraction method for PAHs, similar results were obtained by using the acetone with MAE, ASE with acetone/dichloromethane, or Soxhlet with dichloromethane.

The use of a binary modifier, which is added to the extraction cell at the time of the extraction, rather than continuously, in the CO_2 stream showed an almost matrix-independent SFE method for the PAHs.[6] The modifiers, diethylamine, trifluoroacetic acid, citric acid, isopropylamine, and tetrabuthyl ammonium hydroxide, all individually at a 1% level in toluene, were tested for the extraction of CRM 392, sewage sludge, and marine sediment. The extractions were reproducible and

comparatively complete and, with the correct binary modifier, did not require any prior matrix treatment, e.g., with HCl. Diethylamine at 200°C gave the highest recoveries to examine the effect on the SFE of PAHs from marine sediment, diesel soot, and air particulates. Online coupling of an SFE system with a GC/MS instrument was performed by a homemade, suitably shaped accumulation cell,[7] eliminating the effect of CO_2 flow on the MS detector. Moreover, it enables multistep extraction based on the direct addition of a modifier into the extraction cell. The quantitative determination of PAHs and other organic pollutants in sewage sludge was performed by using SFE as a fast extraction method, followed by a short cleanup step. The extraction step was validated with CRMs.[8] Improving the extraction capacity of the supercritical fluid—higher temperature, higher pressure, stronger modifier effect—by using a ternary mixture of CO_2 modified with methanol/dichloromethane, 5:1, a more robust and applicable method to a larger range of matrices was obtained.[9] Fernández[10] used an experimental design to optimize the SFE of PAHs from sediment. Under the optimum conditions, the recovery of total PAHs was ~15% higher with SFE than with the comparative Soxhlet extraction. A five-level factorial experimental design was used to examine the optimum conditions for the extraction of two- to six-ring PAHs from sediment with pressure, temperature, and organic modifier. Depending on the nature of the matrix and the concentration of the compounds to be determined, the SFE system can be directly connected to the detector. All of the different extraction techniques mentioned above can be used for the extraction of PAHs in very complex environmental materials. A very recently developed work reported an extraction/cleanup procedure by SFE for biological samples (liver) and subsequent high-performance liquid chromatography HPLC-FL determination of those compounds in the enriched extract.[11]

COMMENTS ON THE EXTRACTION TECHNIQUES

Most recent studies on the previously discussed extraction techniques have made a direct comparison with the efficiency of Soxhlet extraction to validate the system used, effectively resulting in a benchmark method. Regarding these studies of extraction of PAHs from solid environmental samples, some overall observations can be made. With the exception of a few reports, the modern methods of extraction offer no greater efficiency than the centenary Soxhlet extraction method. Also, in terms of extraction, the extent of good agreement between data obtained by a wide range of extraction methods should suggest that there may not be any significant advantage with any particular method. Because one of the advantages of using MAE, ASE, and SFE is the use of small volumes of toxic organic solvents, in a number of cases the use of multiple extractions with a fresh change of solvent will approach the volume to the classical extraction method. Another apparent advantage of MAE, ASE, subcritical water extraction, and SFE is that the extractions are faster and, therefore, labor saving. The actual extraction cycle is short for MAE and ASE, ~5–10 min. However, for multiple extractions, there is little time between cycles for the analyst to undertake other tasks and also to attend the system while it is in use. The main advantage of Soxhlet extraction is that, once it has been set up, it can be left unattended for the full duration of the extraction, ~8–24 r. In many cases, the extent of the labor saved associated with MAE, ASE, and SFE is considerably exaggerated. Table 1 shows the conditions used to compare Soxhlet, ASE, SFE, and subcritical water extractions of PAHs. Also, the extraction quality greatly differed. In the case of Soxhlet and ASE, they were much darker, while extracts from subcritical water were orange, and the extracts from SFE (with CH_2Cl_2) were light yellow.[12] The organic solvent extracts also yielded more artifact peaks in the GC/MS and GC-flame ionization detection chromatograms, especially when compared to supercritical CO_2 (Figs. 1 and 2). Based on elemental analysis (carbon and nitrogen) of the solid residues after each extraction, subcritical water, ASE, and Soxhlet extraction had poor selectivity for PAHs vs. soil organic matter (~25–33% of the bulk solid organic matter was extracted along with PAHs), while SFE with pure CO_2 removed only 8% of the bulk organic matrix.

Table 1 Conditions used to compare soxhlet, ASE, SFE, and subcritical water extractions of PAHs.

Conditions	Soxhlet	ASE	SFE	Subcritical water
Sample size (g)	2	2	2	2
Extraction solvent	DCM–acetone	DCM–acetone	pure CO_2	water
Collection solvent	—	—	DCM	toluene
Pressure (bar)	ambient	70	400	50
Temperature (°C)	b.p. of solvent	100	150	300, 250
Flow rate	15 min/cycle	1 ml/min	1 ml/min	1 ml/min
Time	18 hr	50 min	60 min	30, 60 min
Solvent volume (ml)	150	15	15	10, 20

These conditions were used for determination of PAHs in soil samples collected from an abandoned gas-manufacturing plant.

Neither MAE nor ASE is currently in a configuration that would readily lead to the automation of sample preparation. Supercritical fluid extraction can be used as online system that can then be connected to the chromatographic and detection systems. Connected online with the GC/MS, SFE was successfully used for the determination of PAHs in marine sediments. Using either CO_2 alone or modified with toluene or MeOH in the extraction, the PAHs were cryofocused in the accumulation cell of the GC and then directly chromatographed.[7] For the study of PAHs in marine sediments, a new extraction technique, which consists of the combination of ASE (dynamic and static mode) and SFE (dynamic mode), was developed, with an extraction time longer than in ASE but shorter than in SFE, and better recoveries for five- to six-ring PAHs than in the conventional ASE and SFE.[13] Polynuclear aromatic hydrocarbons in tap and river water were extracted by SFE, online, with solid-phase extraction disks.[14] Table 2 presents the extraction conditions for SFE of PAHs from different environmental materials, as reported in the literature.

FUTURE TRENDS IN SFE

SFE with CO_2, whose most important benefits have already been mentioned, also shows significant limitations that are worth studying to understand the field of

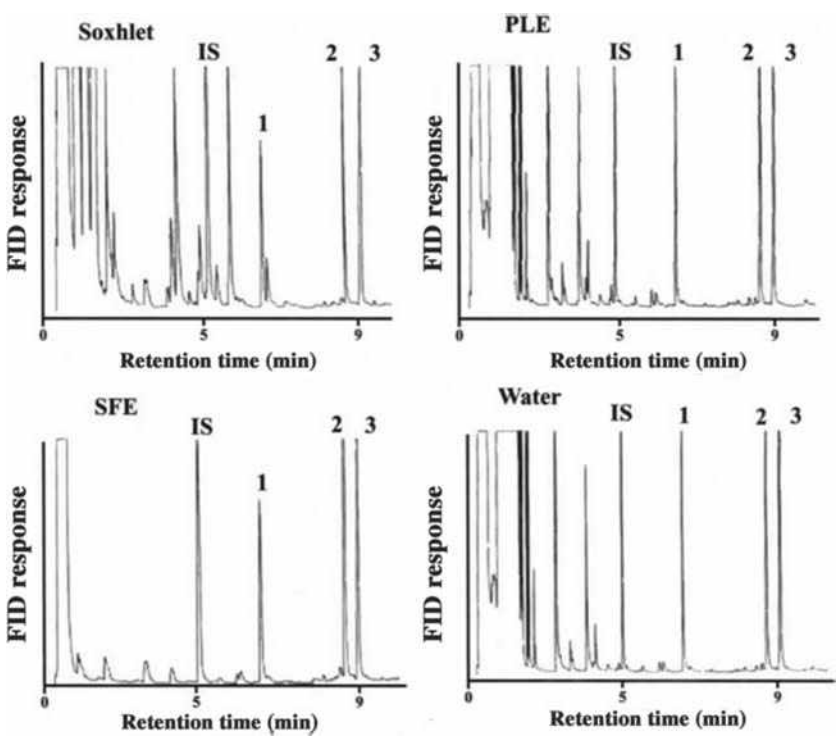

Fig. 2 GC-flame ionization detection chromatograms containing early artifact peaks from different solvent extraction methods: Soxhlet, ASE (PLE), SFE, and subcritical water extraction of a soil sample collected from a manufacturing gas plant site. Table 2 Extraction conditions for SFE of PAHs from different environmental materials.

Matrix	Reference material	Extractant	Temp. (°C)	Pressure (bar)	Extraction time (min)	Mode	Solvent collection	Recovery (%)	Refs.
Marine sediment	NIST 1649	CO_2 100%	200	450	15 + 30	static + dynamic	DCM	—	[5]
Sediment	NRCC HS-6	CO_2 100% or + 3 × 20 ul MeOH	70	200	15	dynamic	MeOH	80–100	[7]
Sewage sludge	CRM 088	CO_2 100% (step 1)	80	121	10 + 10	static + dynamic	toluene		[8]
		CO_2 + 1% MeOH and 4% DCM (step 2)	120	335	10 + 30	static + dynamic	toluene		[8]
		CO_2 100% (step 3)	120	335	5 + 10	static + dynamic	toluene	104–122	[8]
Soil	—	CO_2 + MeOH + DCM 5 : 1	95	450	15	dynamic	MeOH	90	[9]
Sediment	—	CO_2 100% or CO_2 + 2 to 10% methanol	140	340	15	dynamic	hexane	—	[10]
Soil	—	CO_2 100%	150	400	60	dynamic	DCM	>90%	[12]

The following abbreviations are used for organic solvents used: MeOH = methanol; DCM = dichloromethane.

application of the technique and to help in seeking alternatives in this context. The main drawbacks that SFE has to cope with are the difficulties in extracting polar analytes, the different efficiencies obtained from spiked and natural samples, and sometimes the need for a cleanup step before the analysis.[12] To point out the future trends in this extraction technique, it is mandatory to consider the latest contributions in this area. The coupling of supercritical CO_2 with subcritical water is a very recent and promising alternative that has proven to successfully extract nonpolar analytes.[14] The development of new analyte collection methods, with reduced solvent consumption resulting in more concentrated extracts, is also a target of current research. Another important future trend in SFE is the possibility of performing fieldwork.[15] In this context, a single SFE method for field extraction of PAHs in soil has been developed for the U.S. Department of Defense and it is currently being tested. The approach uses dry ice (thus avoiding compressed CO_2 tanks), and works well for nonpolar analytes, but requires the use of modifiers for the extraction of polar analytes. Increased energy costs and regulatory requirements for waste reduction and site remediation have created increased interest in the benefits and application of SFE. Current research is being conducted to develop methods for application to large-scale soil remediation. Such applications will occur as the SFE knowledge base expands.[16] Taking into account the breakthroughs in other alternatives, such as ASE, MAE, and Soxhlet, before selecting SFE as a primary extraction method, its main benefits and limitations should be weighted. Thus considering the characteristics of the matrix and the analytes involved, the analyst must select the most appropriate alternative.

CONCLUSIONS

It has become clear that the environmental chemist should be more diligent in developing methods that are more environmentally friendly and provide a safer work environment. Following the Montreal Protocol, there is a gradual phasing out of the use of chlorinated solvents. While it has the major environmental impact in the dry cleaning and bulk chemical industry, it seems inappropriate to continue developing methods that require chlorinated solvents when, with a review of literature and some practice, suitable alternatives can be found. The accreditation bodies could play an important role to clearly move the existence of methodologies that use organic solvents.

In this context, SFE has a great potential for replacing older extraction methods, e.g., Soxhlet extraction. Despite important limitations described elsewhere, with the help of special strategies for the extraction of moderately polar and highly polar analytes, the SFE range of applications will dramatically increase in the near future.

Environmental Pollutants: CE Analysis

Imran Ali

Hassan Y. Aboul-Enein
Pharmaceutical and Medicinal Chemistry Department, Pharmaceutical and Drug Industries Research Division, National Research Center, Dokki, Cairo, Egypt

INTRODUCTION

The quality of the environment is degrading continuously, due to the accumulation of various undesirable constituents. Water resources, the most important and useful components of the environment, are most affected by pollution. The ground and surface water at many places in the world are not suitable for drinking purposes, due to the presence of esthetic and toxic pollutants. Therefore, the importance of water quality preservation and improvement is essential and continuously increasing.[1,2] The most important toxic pollutants are inorganic and organic chemicals. Therefore, determination of these water pollutants at trace levels is essential in environmental hydrology.

PRINCIPLE OF CAPILLARY ELECTROPHORESIS (CE)

The schematic representation of a CE apparatus is shown in Fig. 1. The mechanism of separation of water pollutants in CE is based on the electro-osmotic flow (EOF) and electrophoretic mobilities of the pollutants. The EOF propels all pollutants (cationic, neutral, and anionic) toward the detector and, ultimately, separation occurs due to the differences in the electrophoretic migration of the individual pollutants. Under the CE conditions, the migration of the pollutant is controlled by the sum of the intrinsic electrophoretic mobility (μ_{ep}) and the electro-osmotic mobility (μ_{eo}), due to the action of EOF. The observed mobility (μ_{obs})of the pollutants is related to μ_{eo} and μ_{ep} by the following equation:

$$\mu_{obs} = \mu_{eo} + \mu_{ep} \tag{1}$$

The electrophoretic mobilities of cations (μ_{obs}) can be related to the limiting ionic equivalent conductivity, λ_{ekv}, by the following equation:

$$\mu_{obs} = \lambda_{ekv}/F = q_i/6\pi\eta r_i \tag{2}$$

where, F is the Faraday constant ($F = 9.6487 \times 10^4$ A sec/mol), λ_{ekv} (cm^2/mol/ohm) is related, by the Stokes law, to the charge of the hydrated cation q_i, to the dynamic viscosity of the electrolyte, η (g cm^2/sec), and to the radius of the hydrated cation r_i (cm). The μ_{ep} values can be calculated from the experimental data, the mobility of the cation (μ_{obs}), and the mobility of the EOF μ_{eo}, according to the following equation:

$$\begin{aligned}\mu_{ep} &= \mu_{obsp} - \mu_{eo} \\ &= [1/t_{m(ion)} - 1/t_{m(eo)}][l_T \cdot L_d/V]\end{aligned} \tag{3}$$

where, $t_{m(ion)}$, $t_{m(eo)}$, l_T and L_d are the migration time of the cation (sec), migration time of the EOF (sec), the overall capillary length, and the length of the capillary to the detector (cm), respectively. Thus, EOF plays an important role in the determination of metal ions by CE. The determination of water pollutants can be carried out by several modes of CE. The various modes of CE include capillary zone electrophoresis (CZE), micellar capillary electrokinetic chromatography (MECC), capillary isotachophoresis (CIEF), capillary gel electrophoresis (CGE), ion-exchange electrokinetic chromatography (IEEC), capillary isoelectric focusing (CIEF), affinity capillary electrophoresis (ACE), capillary electrochromatography (CEC), separation on microchips (MC), and non-aqueous capillary electrophoresis (NACE).[6] However, most of the water pollutant analyses have been carried out in the CZE mode.

SAMPLE PRETREATMENT

The treatment of the samples from environmental matrices is an important issue in CE. Little attention has been given for the water sample treatment in CE analysis of environmental pollutants. Soil samples have been extracted by the usual methods. Besides, the sediment samples were digested using strong acids. The samples containing a highly ionic matrix may cause problems in CE. EOF in the capillary can be altered by the influence of the sample matrix, resulting in poor resolution. Additionally, the

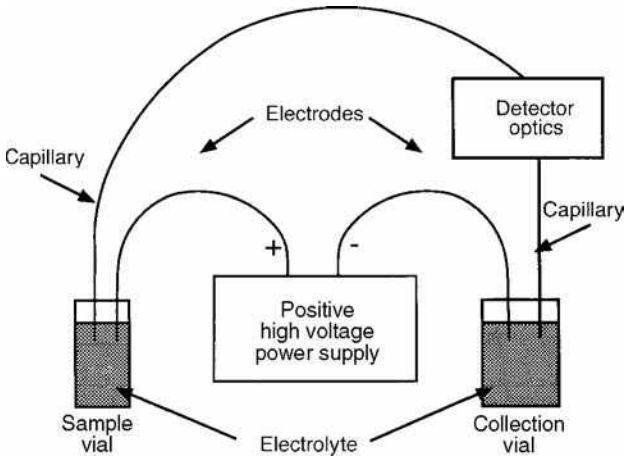

Fig. 1 Diagram of the CE system.

detector baseline is usually perturbed when the pH of the sample differs greatly from the pH of the background electrolyte (BGE). The samples containing UV absorbing materials are also problematic in the detection of the environmental pollutants. Due to all of these factors, some authors have suggested sample cleanup processes, solid/liquid phase extractions, and sample preparations prior to loading onto CE.[8–11] Real samples often require the application of simple procedures, such as filtration, extraction, dilution, etc. Electromigration of sample cleanup suffers severely from matrix dependence effects; even then, it has been used for preconcentration in inorganic analysis. The sample treatment methods have been discussed in several reviews.[5–7,10] The use of ion-exchange and chelating resins to preconcentrate the metal ion samples prior to CE application has been reported.[7,10] An online dialysis sample cleanup method for CE analysis has also been presented. Besides, several reports have been published on dialysis and electrodialysis for sample cleanup prior to CE injection.[5–7,10]

DETECTION

Generally, UV detection is used for the determination of most environmental pollutants. However, the use of UV detectors in CE for metal ion and anion analysis is not suitable due to the poor absorbance of UV radiation by metal ions and anions. The most common method to solve this problem is indirect UV detection. The main advantage of the indirect UV detection method is its universal applicability. The complexation of metal ions with ligands also increases the sensitivity of their detection. The complexing agent is either added to the electrolyte (in situ, online complexation) or to the sample before the introduction into the capillary column (off-line complexation). The most commonly used ligands are azo dyes, quinoline dyes, porphyrin, dithiocarbamate, aminopolycarboxylic acids, 4-(2-pyridylazo) resorcinol, 8-hydroxyquinoline-5-sulfonic acid, ethylenediaminetetraacetic acid, cyanides, various hydroxy carboxylic acids, crown ethers, and other organic chelating agents. Besides, UV visualizing agents (probe) have also been used to increase the sensitivity of detection in the UV mode. The important probes include, e.g., Cu(II) salts, chromate, aromatic amines, and cyclic compounds, e.g., benzylamine, 4-methylbenzylamine, dimethylbenzylamine, imidazole, *p*-toludine, pyridine, creatinine, ephedrine, and anionic chromophores (benzoate and anisates).[5–7,10,12] Care must be taken to avoid the interaction of the cations and visualizing agent with the capillary wall. Besides, the visualizing agents should exhibit a mobility close to that of the cations, its UV absorbance should be as high as possible, and the detector noise as low as possible. Furthermore, sensitivity of the UV detection has been increased by using a double beam laser as the light source.

To overcome the problem of detection in CE, many workers have used inductively coupled plasma-mass spectrometry (ICP-MS) as the method of detection.[5–7,10–12] Electrochemical detection in CE includes conductivity, amperometry, and potentiometry detection. The detection limit of amperometric detectors has been reported to be up to 10^{-7} *M*. A special design of the conductivity cell has been described by many workers. The pulsed-amperometric and cyclic voltametry waveforms, as well as multi step wave forms, have been used as detection systems for various pollutants. Potentiometric detection in CE was first introduced in 1991 and was further developed by various workers.[5–7,10,12] 8-Hydroxyquinoline-5-sulfonic acid and lumogallion exhibit fluorescent properties and, hence, have been used for metal ion detection in CE by fluorescence detectors.[5–7,10,12] Overall, fluorescence detectors have not yet received wide acceptance in CE for metal ions analysis, although their gains in sensitivity and selectivity over photometric detectors are significant. Moreover, these detectors are also commercially available. Some other devices, such as chemiluminescence, atomic emission spectrometry (AES), refractive index, radioactivity, and X-ray diffraction, have also been used as detectors in CE for metal ions analysis,[12] but their use is still limited.

SEPARATION EFFICIENCY IN CAPILLARY ELECTROHPORESIS

From the literature available and discussed herein, it may be assumed that the selectivity of various environmental pollutants by CE is quite good. However, the detection sensitivity for metal ions and anions is poor. Therefore,

Table 1 The applications of capillary electrophoresis for the determination of environmental pollutants.

Pollutants	Sample matrix	Electrolytes	Detection	Detection limit
Metal Ions in Water, Sediment, and Soil[5–7]				
Arsenic and selenium	Drinking water	20 m*M* KHP, 20 m*M* Boric acid (pH 9.03) hydrodynamically modified EOF	Hydride generation ICP-MS	6–58 ng/L
		75 m*M* Dihydrogen phosphate, 25 m*M* tetraborate (pH 7.65)	Direct UV 195	12 μg/L
		Chromate, 0.5 m*M* TTAOH (pH 10.5)	Indirect UV 254 nm	10 μg/L
Mg, Ca, Na, and K	Well water	5 m*M* Imidazole, 6.5 m*M* HIBA 2 m*M* 18-crown-6 (pH 4.1)	Indirect UV 214 nm	—
Alkali and alkaline Earth metals	Tap and mineral waters	10 m*M* Imidazole (pH 4.5)	Indirect UV 214 nm	0.05 mg/L
Uranyl cation (UrO_2^{2+})	River water	10 m*M* Perchloric acid, 1 m*M* phosphate, 0.6 m*M* borate, 0.01–0.1 m*M* arsenazo III 650 nm, 50–150 m*M* NaCl, 10% MeOH	Direct UV–VIS	10 μg/L
Zn and other transition metals	Tap water	10 m*M* Borate buffer, 0.1 m*M* HQS (pH 9.2)	Direct UV 254 nm	3–225 μg/L
Al	River, reservoir, and spring waters	40 m*M* AcOH, 10 m*M* NH_4Ac (pH 4.0)	Fluorescence 419 and 576 nm	19 μg/L
Ca, Mg, Ba, Na, K, and Li	Mineral water	3–5 m*M* Imidazole, pH 4.5	Indirect 214 nm	0.05 ppb
Cu, Ni, Co, Hg, Mn, Fe, Pb, Pd, Zn, Cd, Mg, Sr, Ca, and Ba	River water	2 m*M* $Na_2B_4O_7$, 2 m*M* EDTA pH 4.4	Direct UV 200 and 214 nm	10 μ*M*
Ca, Sr, Ba, Li, Na, K, Rb, Sc, and Mg	Tap, rain, and mineral waters	5 m*M* Benzimidazole, tartarate, pH 5.2, + 0.1% HEC or methy-HEC, + 40 m*M* 18C6	Indirect UV 254 nm	—

Chromate	Wastewater	0.02 m*M* Phosphate buffer (pH 7)	Direct UV	—
Fe, Ni, Pd, Pt, and Cu(I) cyano complexes	Leaching solutions of automobile catalytic converters	20 m*M* Phosphate buffer, 100 *M*m NaCl, 1.2 m*M* TBABr, 40 μ*M* TTABr (pH 11)	Direct UV 208 nm	20 μg/L
Speciation of Metal Ions[5–7]				
Arsenic species	Drinking water	0.025 m*M* Phosphate buffer, pH 6.8	Direct UV 190 nm	<2 mg/L
	Water	50 m*M* CHES, 20 m*M* LiOH	Conductivity	0.4 mg/L
	Tin mining	15 m*M* Phosphate buffer, 1 m*M* CTAB 50 m*M* CHES, 0.03% Triton X-100 20 m*M* LiOH, pH 9.4	Conductivity	0.4 mg/L
As(III), As(V), and dimethyl arsenic acid	Process water		ICP-MS	1 ppb
—	60 m*M* Calcium chloride (pH 6.7) cetyltrimethyl ammonium bromide, pH 10.0			
Arsenic and selenium species	Drinking water	20 m*M* KHP, 20 m*M* Boric acid (pH 9.03) hydrodynamiccally modified EOF	Hydride generation ICP-MS	6 ng/L
	Tap and drinking waters	75 m*M* Dihydrogen phosphate 25 m*M*, tetraborate (pH 7.65)	Direct UV 12 μg/L 195 nm	—
	—	20 m*M* Na_2HPO_4, 5 m*M* DTPA, pH 8.0 or 8.5	Indirect UV 214 nm	10^{-6} *M*
Cr(IV) and Cr(VI)	Rinse water from chromium platings	1 m*M* CDTA, 10 m*M* Formate buffer (pH 3.8)	Direct UV 214 and 254 nm	10 μg/L
	Chromium plating water	10 m*M* Formate buffer, 1 m*M* CDTA (pH 3.0)	Direct UV 214 nm	10 ppb
	Electroplating water	10 m*M* Formate buffer (pH 3.0)	Indirect UV 214 nm	50 ppb
	Wastewater	20 m*M* Na_2HPO_4, 0.05 m*M* TTAOH	Direct UV 214 and 254 nm	—
Fe(II) and Fe(III)	Electroplating waters	20 m*M* Phosphate buffer (pH 7.0)	Direct UV 214 nm	10^{-5} *M*

Pollutants	Sample matrix	Electrolytes	Detection	Detection limit
Hg(II), CH_3Hg^+, and $CH_3CH_2Hg^+$	—	25 m*M* $Na_2B_4O_7 \cdot 10\,H_2O$, pH 9.3	ICP-MS	81–275 ppb
Ir(II) and Ir(III)	4 m*M* H^+, 23 m*M* Cl^-, pH 2.4			Indirect UV 214 nm
—				
Pb(II), triethyl lead (IV), trimethyl lead (IV), and diphenyl lead (IV)	Na_2HPO_4–$Na_2B_4O_7$, 2.5 m*M* TTHA, 2.0 m*M* SDS, pH 7.5			Indirect UV 220 nm
ppb level				
Pt(II) and Pt(IV)	4 m*M* H^+, 23 m*M* Cl^-, pH 2.4		Indirect UV 214 nm	—
V(IV) and V(V)	Electroplating bath	20 m*M* Na_2HPO_4, 5 m*M* DTPA, pH 8.0 or 8.5	Indirect UV 214 nm	10^{-6} *M*
Anions Analysis[7,10]				
F^-	Rain water	1.13 m*M* PMA, 0.8 m*M* TEA, 2.13 m*M* HMOH, pH 7.7	Indirect UV 254 nm	0.6 μ*M*
F^-, Cl^-, Br^-, SO_4^{-2}, NO_3^-, NO_2^-, PO_4^{-3}, and thiosulphate	Tap water	2.25 m*M* PMA, 6.5 m*M* NaOH, 0.75 m*M* HMOH, 1.6 m*M* TEA, pH 7.7	Indirect UV 250 nm	1–3 mg/L
$HClO_4^-$, Br^-, F^-, NO_3^-, and NO_2^-	Tap water	20 m*M* Sodium sulfate, pH 2.5	Ionselective microelectrode	5 μg/L
Br^-, BrO_4^-, I^-, IO_4^-, NO_3^-, NO_2^-, and selenite organic and inorganic anions	River water Water from dumping area	Phosphate buffer, pH 2.9 9 m*M* PDCA, 0.05 m*M* TTABr, pH 7.8	Direct UV 200 nm Indirect UV 254 nm	— —
Br^-, NO_2^-, $S_2O_3^-$, NO_3^-, N_3^-, $Fe(CN)_6^{-4}$, MoO_4^{-2}, WO_4^{-2}, CrO_x^{-3}, and ReO_4^-	—	10 m*M* Borate, 220 m*M* NaCl, pH adjusted to 8.5 by sodium hydroxide	UV 214 nm	—
Phenols and its Derivatives[3,8]				
Alkyl phenols	1.25 m*M* $Na_2B_4O_7$, 15 m*M* NaH_2PO_4 pH 11.0 with 0.001% HDB		UV 254 nm	—
Chlorophenols	50 m*M* Na_2HPO_4/NaH_2PO_4, pH 6.9		UV 214 nm	0.06 mg/L

Miscellaneous derivatives of phenols	10 m*M* $Na_2B_4O_7/Na_3PO_4$, pH 9.8 20 m*M* CHES, pH 10.1 15 m*M* Na_3BO_3, pH 9.9	 Amperometric Indirect fluorimetry	UV 210 nm 0.03 mg/L 0.01 mg/L	0.3 mg/L
Pentachlorophenols	Drinking water	40 m*M* Sodium borate, pH 10	—	ng level
Chloro- and nitrophenols	Tap water	20 m*M* Sodium borate	—	μg level
Pesticides[9]				
Hexazinone and its metabolite	Ground water	50 m*M* SDS, 12 m*M* Sodium phosphate, 10 m*M* Sodium borate, and 15% MeOH, pH 9.0	UV 220–247 nm	—
Primisulfuron and triasulfuron	Water and soil	25 m*M* NaH_2PO_4 + 50 m*M* LiDS buffer	UV at 214 nm	—
Triazines and chlorotriazines	Tap and river Water	30 m*M* Sodium borate, 30 m*M* SDS, pH 9.3	UV at 210 nm	—
Chlorinated acid herbicides and related compounds	Water	5 m*M* Ammonium acetate in isopropanol-water (40 : 60, v/v), pH 10	MS	—
Chlorphyrifos	Air and soil	—	—	—
Triazine pesticides	50 m*M* Ammonium acetate, 0.7 m*M* CTAB, pH 4.5	MS and UV (230 nm)	—	
Polyaromatic Hydrocarbons[4]				
PAHs	Standard	8 m*M* $Na_2B_4O_7$, pH 9.0, 50 m*M* DOSS, 40% acetonitrile	UV 254 nm	—
	Standard	5 m*M* Resorcarene, pH 13.25, 6 *M* Urea, 50% acetonitrile	UV 260 nm	
Amines[4]				
Methyl, dimethyl trimethyl, and ethyl amines	Atmospheric aerosols	5 m*M* DHBP, 6 m*M* glycine, 2 m*M* 18-crown-6 ether, pH 6.5	Indirect UV 280 nm	—

(Continued)

Table 1 The applications of capillary electrophoresis for the determination of environmental pollutants. *(Continued)*

Pollutants	Sample matrix	Electrolytes	Detection	Detection limit
Substituted anilines	Tap and ground water, soil, and sediment	50 m*M* NaH_2PO_4, pH 2.35, 7 m*M* 1,3-diaminopropane	UV 280 nm	0.06 mg/L
Heterocyclic aromatic amines	Rain water	50 m*M* NaH_2PO_4–20 m*M* citric acid, 30 m*M* NaCl, 26% methanol	UV 190, 240, and 263 nm	0.05 mg/L
Carbonyls[4]				
Acetaldehyde, benzaldehyde, formaldehyde, and glyoxal	Rain water	5 m*M* Na_3PO_4–10 m*M* $Na_2B_4O_7$, pH 8.0, 20% acetonitrile	Laser-induced fluorescence 325 and 442 nm	—
Dyes[4,8]				
Synthetic cationic dyes	Standard	10 m*M* Citric acid, pH 3.0, 0.1% PVP	UV 214 nm	—
Anionic synthetic azo dyes	Standard	10 m*M* BTP-HCl, pH 6.5, 0.5% PEG, 0.05% PVP	UV 214 nm	—
Photoactive dyes	Coffee and beans	50 m*M* Boric acid/10 m*M* sodium borate, pH 8.5	—	0.08 μg/L
Chiral Separations[9,16]				
Fenoprop, mecoprop, and dichlorprop	20 m*M* Tributyl-β-CD in 50 m*M*, ammonium acetate, pH 4.6	MS	—	
2-Phenoxypropionic acid, dichloroprop, fenoprop, fluaziprop, haloxyfop, and diclofop enantiomers	—	10 – 4 *M* 75 m*M* Britton-Robinson buffer with 6 m*M* Vancomycin	—	—
Imazaquin isomer	—	50 m*M* Sodium acetate, 10 m*M* dimethyl-β-CD, pH 4.6	—	—
Phenoxy acid herbicides	—	200 m*M* Sodium phosphate, pH 6.5 with various concentrations of OG and NG	—	—
Diclofop		—	—

2-(2,4-dichlorophenoxy) propionic acid propionic acid, and	0.05 *M* Lithium acetate containing heptakis-(2,6-di-*O*-methyl)- β-cyclodextrin	UV 200 nm	—	
2-(2-methyl-4-chlorophenoxy) propionic acid	0.03 *M* Lithium acetate containing heptakis-(2,6-di-*O*-methyl)-β-cyclodextrin		UV 200 nm	—
1,1′-Binaphthyl-2-2′-dicarboxylic acid, 1,1′-binaphthyl-2,2′-dihydrogen phosphate, and 2,2′-dihydroxy-1-1′-binaphthyl-3,3′-dicarboxylic acid	—	0.04 *M* Carbonate, pH 9.0, with non-cyclooligosaccharides	UV 215–235 nm	—

AcOH, Acetic acid; BTP, Bis-trispropane; CD, Cyclodextrin; CDTA, Cyclohexane-1,2-diaminetetraacetic acid; CHES, 2-(*N*-Cyclohexylamino)-ethanesulphonic acid; CTAB, Cetyltrimethylammonium bromide; DHBP, 1,1′-Di-*n*-heptyl-4,4′-bipyridinium hydroxide; DOSS, Sodium dioctyl sulfosuccinate; DTPA, Diethylenetriaminepenta acetic acid; EDTA, Ethylenediaminetetraacetic acid; EOF, Electroosmotic flow; HDB, Hexadimethrine bromide; HEC, Hydroxyethyl cellulose; HIBA, α-Hydroxyisobutyric acid; HMOH, Hexamethonium hydroxide; HQS, 8-Hydroxyquinoline-5-sulfonic acid; ICP-MS, Inductively coupled plasma-mass spectrometer; KHP, Potassium hydrogenphthalate; LiOH, Lithium hydroxide; MeOH, Methanol; MES, Morpholinoethanesulfonic acid; NaAc, Sodium acetate; NaCl, Sodium chloride; NH_4Ac, Ammonium acetate; NaOH, Sodium hydroxide; NG, Nonyl-β-D-glucopyranoside; OG, Octyl-β-D-glucopyranoside; PAHs, Polyaromatic hydrocarbons; PDCA, Pyridine-2,6-dicarboxylic acid; PEG, Polyethylene glycol; PMA, Pyromellitic acid; PVP, Polyvinylpyrrolidine; RSD, Lower standard deviation; SDS, Sodium dodecyl sulfate; TBABr, Tetrabutylammonium bromide; TEA, Triethanolamine; TTABr, Tetradecyl-trimethylammonium bromide; TTAOH, Tetradecyl-trimethylammonium hydroxide; TTHA, Triethylenetetraminehexa acetic acid; and UV, Ultraviolet.

many attempts have been made to solve this problem. Organic solvents have been added to the BGE to improve the selectivities of many of the pollutants. It has also been reported that the organic solvents ameliorate the solubility of hydrophobic complexes, reduce the adsorption onto the capillary wall, regulate the distribution of complexes between aqueous phase and micellar phase, adjust the viscosity of the separation medium and, accordingly, accomplish an improvement in detection. The pH of the electrolyte solution is very important from the selectivity point of view. The pH controls the behavior of EOF, acid/base dissociation equilibria of complexes, and the state of existing complexes. Therefore, the selectivity can be improved by adjusting the pH of the BGE. Besides, ion pairing can be used to improve the separation in CE. Six types of ion pairing agents have been developed and used. Ion pairing has also been used in MECC for the improvement of the separation of hydrophobic or weakly hydrophobic metal complexes. In addition, the selectivity of the separation of environmental pollutants has also been increased by varying the partition and ion-association (micellar interactions) mechanisms.

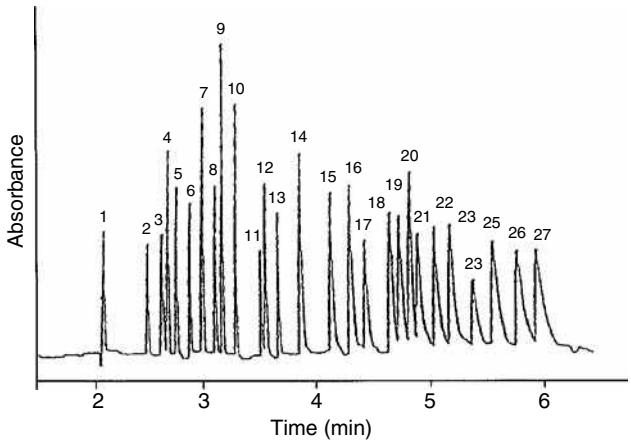

Fig. 2 The electropherogram of the separation of alkali, alkaline earth, transition metals, and lanthanoids on a fused silica capillary (60 cm × 75 μm) using 15 n*M* lactic acid, 8 m*M* 4-methylbenzylamine and 5% MeOH, pH 4.25, as running electrolyte with 30 kV as the separation voltage, 20°C temperature, and UV detection (214 nm).[5] Peaks: 1 = K; 2 = Ba; 3 = Sr; 4 = Na; 5 = Ca; 6 = Mg; 7 = Mn; 8 = Cd; 9 = Li; 10 = Co; 11 = Pb; 12 = Ni; 13 = Zn; 14 = La; 15 = Ce; 16 = Pr; 17 = Nd; 18 = Sm; 19 = Gd; 20 = Cu; 21 = Tb; 22 = Dy; 23 = Ho; 24 = Er; 25 = Tm; 26 = Yb; and 27 = Lu.

APPLICATIONS

During the last decade, CE has been increasingly used for the determination of environmental pollutants. Some of the methods of pre-treatment of waste environmental samples have been carried out prior to the injection into the CE system, as discussed above. CE has been applied for the determination of inorganic and organic pollutants. The major inorganic pollutants include metal ions and anions. On the other hand, the most common toxic organic environmental pollutants analyzed by CE are phenols, pesticides, polynuclear aromatic hydrocarbons, amines, carbonyl compounds, surfactants, dyes, and others. Recently, chiral separation of pollutants and xenobiotics has emerged as the most important issue for the environmental chemist. Therefore, CE has also been used for the analysis of the chiral pollutants. The application of CE for the determination of environmental pollutants is summarized in Table 1, which contains the type of pollutants, their sources, BGE used, detection method, and detection limit. As a specimen sample, a typical electropherogram of separated metal ions in a water sample by CE is shown in Fig. 2.[5]

Validation of Methods

There are only a few studies dealing with method validation of the determination of environmental pollutants by CE. However, some authors have demonstrated the application of their developed separation methods. The accuracy determination for Na, K, Ca, and Mg metal ions has been presented.[5–7] Similarly, the precision of migration times and peak areas for seven alkali and alkaline earth metals has been measured; RSD values were less than 0.4% for migration times and from 0.8% to 1.8% for peak areas.[5–7] In one of the experiments, the reported %RSD varied from 2.79 to 3.38 for Zn, Cu, and Fe metal ions.[13] Several other studies have shown reliable results with recoveries close to 100%, or good agreement with the results obtained by other methods.[13] In spite of this, the precision of linearity, sensitivity, and reproducibility of CE methods for metal ions and anions analysis are not better than ion chromatography.

CONCLUSIONS

The determination of environmental pollutants at trace level is currently a very important and challenging issue. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) have been used for the analysis of environmental pollutants but, in recent years, CE has also been used for the determination of environmental pollutants. A search of the literature indicates several reports of the analysis of environmental pollutants by CE, but CE could not have yet achieved a place in the routine analysis of these pollutants. The reason for this is the poor detection of metal ions and anions and the poor reproducibility of CE methods. Therefore, many workers have suggested various modifications and alternatives to make CE a

method of choice. To obtain good sensitivity and reproducibility, the selection of the capillary wall chemistry, pH and ionic strength of the BGE, complexing and visualizing agents, detectors, and optimization of BGE have been described and suggested.[5–7,12–15]

Apart from the points discussed for improvement of CE applications for the determination of environmental pollutants, some other aspects should also be addressed so that CE can be used as the routine method of choice in this field. The important points relating to this include the development and wide use of fluorescent and radioactive complexing agents, since detection by fluorescent and radioactive detectors is more sensitive and reproducible with low limits of detection. To make CE application more reproducible, the BGE should be developed in such a way to ensure its physical and chemical properties remain unchanged during the experimental run. The non-reproducibility of the methods may be due to the heating of BGE during a long analysis. Therefore, to keep the temperature constant throughout the experiments, a cooling device should be included in the instrument. Besides, especially for the determination of anions, the CE instrument should be designed with the facility to reverse the electrodes. There are only a few reports dealing with method validation. To make the developed method more applicable, the validation of the methodology should be performed. All the capabilities and possibilities of CE have not yet been explored but they are underway. However, eventually CE will be realized as a widely recognized method of choice for the determination of environmental pollutants.

In summary, there is much to be developed for the advancement of CE for the analysis of environmental pollutants. Definitely, CE will prove itself as the best technique for the determination of environmental pollutants within the next few years; it will achieve the status of the technique of routine analysis in most of the environmental laboratories.

Environmental Research: Ion Chromatography

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
Water, wastewater, and soil and air pollution analyses are the most important part of environmental analysis. Determination of common inorganic anions and cations is mandatory. Ion chromatography has almost replaced most of the wet chemical methods used in water analysis. This entry is a review of application of ion chromatography to environmental research.

INTRODUCTION

Environmental analysis is one of the most important fields of application for ion chromatography; it can be divided into water, soil, and air analysis. Ion chromatography has become an essential tool for the analytical chemist, especially in the area of anion analysis. In many cases, this method has replaced the conventional wet chemical methods, which are labor-intensive, time-consuming, and occasionally susceptible to interferences.

In addition to environmental applications, ion chromatography is now routinely being used for the analysis of ionic compounds in diverse areas such as power plant chemistry, semiconductor industry, food and beverages, household products and detergents, pharmaceuticals, biotechnology, and agriculture. In this entry, the application of ion chromatography in environmental research is described.

APPLICATION OF ION CHROMATOGRAPHY IN ENVIRONMENTAL ANALYTICAL CHEMISTRY

Environmental analytical chemistry can be regarded as the study of a series of factors that affect the distribution and interaction of elements and substances present in the environment, the ways they are transported and transferred, as well as their effects on biological systems.[1] An important job for analytical chemistry today is environmental analysis. This task can be performed using modern analytical techniques and methods. In the range of ionic compounds, the most important one is ion chromatography.

Modern ion chromatography was first reported in 1975 in a landmark paper by Small, Stevens, and Bauman.[2] At present, there are two main types of ion chromatography: suppressed ion chromatography and non-suppressed ion chromatography. Ion exchange remains the primary separation mode used in ion chromatography today, although the apparatus used for the separation of the ionic species includes ion pairing, ion exclusion, and chelation chromatography.

In recent years, the importance of monitoring and controlling environmental pollutants has become apparent in all parts of the world. As a result, analysts have increased their efforts to identify and determine toxic substances in air, water, wastewaters, food, and other sectors of our environment. Ion chromatography has been demonstrated to be a valuable tool for these analyses.

The primary concern when collecting environmental samples for analysis using any analytical technique (including ion chromatography) is that the sample must be a representative of the total sample matrix and that no contamination occurs during the sampling process. Moreover, appropriate methods for storage and preservation of the sample are definitely required.

In the range of environmental applications of ion chromatography, inorganic anions are, by far, the most important. The primary reason for this is the lack of alternative methods for anion analysis, which is not the case for cation analysis where many other instrumental techniques are readily available [e.g., atomic absorption spectrometry (AAS); inductively coupled plasma-atomic emission spectrometry (ICP-AES); and ICP-mass spectrometry (ICP-MS)].

However, ion chromatography has an advantage over spectroscopic techniques for cation analysis in the area of metal speciation. Moreover, ion chromatography is particularly beneficial for the simultaneous determination of cations and ammonia in wastewater containing amines. Examples of anion and cation chromatograms are given in Figs. 1 and 2, respectively.

During the development of ion chromatography, many comparisons between wet chemistry methods and ion chromatography were performed to validate the latter technique.[3] Recently, ion chromatography has become a well-established mature technique for the analysis of ionic species, and many standard organizations have regulatory methods of analysis based upon ion chromatography.[4]

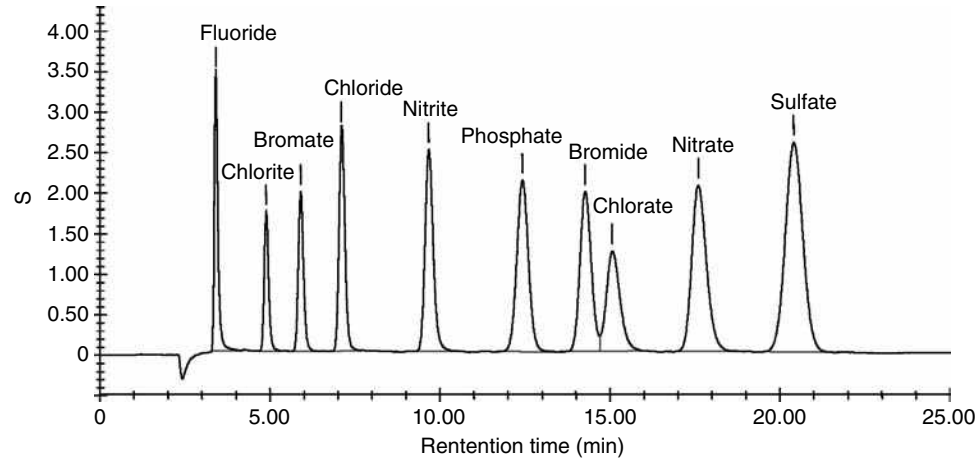

Fig. 1 Separation of inorganic anions standard.

Regulatory standards for water analysis require an analytical method with a detection limit of at least 25% of the parametric value. This method must be relatively simple, accurate, cheap, and adequate for routine laboratories. Ion chromatography meets these requirements. The separation and detection methods employed in ion chromatography as well as the selection of ionic species that may be analyzed with the ion chromatography method are summarized in Table 1 (inorganic anions), Table 2 (organic anions), and Table 3 (inorganic and organic cations). A survey of the detection methods used is given in Table 4.

WATER AND WASTEWATER ANALYSIS

Water in the environment occurs under various categories; it supports an incredible diversity of plant and animal life. It also plays an especially important role in human life and existence. It is also used by the industry and for agricultural purposes. For these and many more reasons, the knowledge of water quality is very meaningful and essential. Natural waters are dynamic systems that contain inert and living matter, organic and inorganic species, dissolved compounds, and insoluble substances. Moreover, the composition of water samples can change drastically during or after sampling.

One of the main environmental problems is the pollution of water by inorganic and organic compounds; they influence the quality of upgraded water and can cause health risks. Therefore, analysis of water is highly necessary, and it is critical to apply a method that enables the determination of more than one compound simultaneously.

Water-soluble inorganic ions can be determined by flow injection analysis, spectroscopic techniques, titration, and, most important of all, ion chromatography. The main focus of the application of ion chromatography in environmental

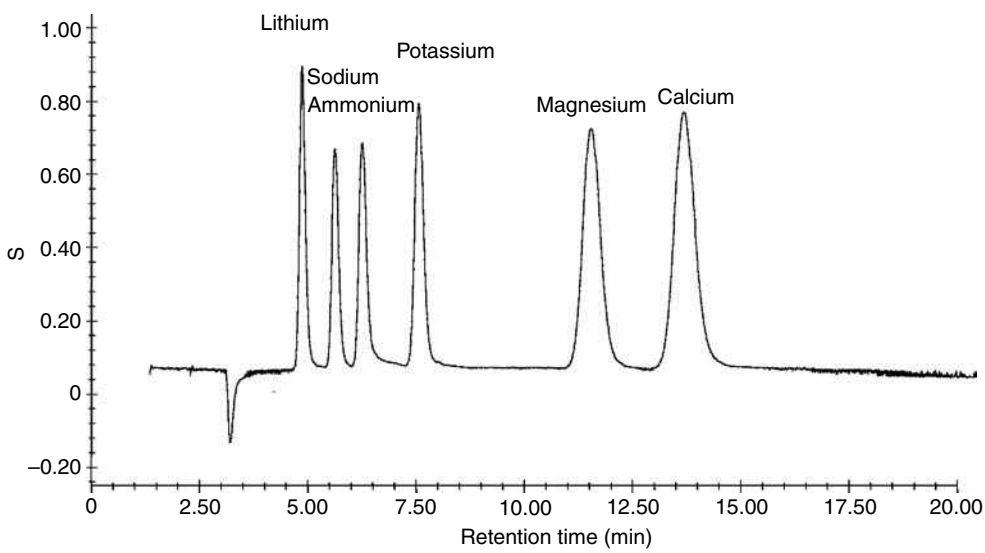

Fig. 2 Separation of alkali and alkaline earth metals.

Table 1 Inorganic anions determined by ion chromatography method.

Analyte groups		Analytes	Separation mechanism	Detection mode
Hydrophilic	Strong acids	F^-, Cl^-, Br^-, NO_2^-, NO_3^- PO_4^{3-}, SO_3^{2-}, SO_4^{2-}, ClO_2^-, ClO_3^-	Anion exchange	Conductivity, UV
		Arsenate, selenate, selenite	Anion exchange, ion exclusion	Conductivity
	Weak acids	$H_2BO_3^-$, CO_3^{2-}, SiO_3^{2-}	Ion exclusion, anion exchange	Conductivity, UV/Vis
Hydrophobic		CN^-, HS^-, I^-, BF_4^-, $S_2O_3^{2-}$, SCN^-, ClO_4^-	Ion exclusion, anion exchange	Amperometry, conductivity
Polyvalent chelating agents		EDTA, NTA	Anion exchange	UV/Vis
Polyvalent phosphates		$H_2PO_4^-$, HPO_3^-, HPO_4^{2-}, $P_2O_7^{4-}$, $P_3O_{10}^{5-}$	Anion exchange	Conductivity
Metal complexes		$Au(CN)_2^-$, $Au(CN)_4^-$, $Fe(CN)_6^{4-}$ $Fe(CN)_6^{3-}$, $Cu(EDTA)_2^-$, $Ni(EDTA)_2^-$	Ion pair, anion exchange	Conductivity

analytical chemistry is the qualitative and quantitative analysis of anions and cations in all kinds of waters.[5] These applications include the following:

- Determination of inorganic and organic anions and cations in all kinds of surface and groundwater (drinking water as well as sea, river, lake, streams, ground, and swimming pool water) and wastewater.[6–8]
- Determination of common anions and cations in rainwater.[9]
- Analysis of snow and ice samples.[10]

Natural waters encompass a wide variety of sample matrices including rainwater; mineral spring waters; groundwaters; surface waters (river, stream, lake, and pond waters); soil pore waters; runoff waters; snow, hail, and sleet; ice and ice cores; and well and bore waters.

In the past, drinking water disinfection was done through chlorination, until the 1970s when it was discovered that carcinogenic compounds such as trihalomethanes can be produced during this process.

In this connection, many drinking water utilities are changing their primary disinfectants from chlorine to alternative disinfectants, such as ozone, chlorine dioxide, and chloroamines, which reduce regulated trihalomethanes and some organochlorine compound levels but, at the same time, often increase levels of other potentially toxicologically important compounds, such as inorganic oxyhalide by-products (bromate, chlorite, and chlorate). Some of them have been classified as probable human carcinogens.

Bromate is a disinfection by-product that is produced from the ozonation of source water that contains naturally occurring bromide, whereas chlorite and chlorate are produced as a result of using chlorine dioxide as a disinfectant. Recently, bromate has become the most important inorganic oxyhalide by-product, and its concentration in drinking water has to be controlled. Another challenge is seawater, which represents a very difficult matrix for the analysis of trace ionic constituents, because chloride, sulfate, and sodium are the primary ions and they are present at extremely high concentrations.[11]

Determination of trace anions in water matrices containing high concentrations of salt can also be made by

Table 2 Organic anions determined by ion chromatography methods.

Analyte groups		Analytes	Separation mechanism	Detection mode
Carboxylic acids	Monovalent	Aliphatic, $C < 5$	Ion exclusion, anion exchange	Conductivity
		Aliphatic, $C > 5$, aromatic	Ion pair, anion exchange	Conductivity, UV
	Mono-, di-, and trivalent	Hydroxy carboxylic acids, di- and trivalent carboxylic acids	Ion exclusion	Conductivity
Sulfonic acids		Alkylsulfonates, $C < 8$, toluene, xylene, benzene sulfonates	Ion exclusion, anion exchange	Amperometry, conductivity
		Alkylsulfonates, $C > 8$, aromatic sulfonates	Ion pair, anion exchange + reversed phase	Conductivity
Alcohols and phenols		Phenols	Anion exchange	UV, amperometry
		Aliphatic alcohols	Ion exclusion, reversed phase, anion or cation exchange	Amperometry

Table 3 Cations determined by ion chromatography methods.

Analyte groups		Analytes	Separation mechanism	Detection mode
Inorganic	Group I and II metals	Li^+, Na^+, K^+,, Rb^+, Cs^+, g^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, amines, alkanolamines	Cation exchange	Conductivity
	Transition metals	Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Sn^{2+}, Sn^{4+}, Cr^{3+}, V^{4+}, V^{5+}	Ion exclusion, anion exchange	Conductivity, UV/Vis
	Lanthanide metals	La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, Yb^{3+}, Lu^{3+}	Anion exchange, cation exchange	UV/Vis
Organic	Low-molecular-weight amines, alkylamines, mono-, di-, tri-, tetramethylamine, alkanolamines, monoethanolamine, diethanolamine	CH_3NH_2, $C_2H_5NH_2$, $(CH_3)_2NH$, $(CH_3)_3N$, $C_6H_5NH_2$, $C_6H_{11}NH_2$, $C_{10}H_{21}NH_2$, $[R_1R_2R_3R_4]N^+$	Cation exchange, ion pair	Conductivity
	High-molecular-weight amines, alkylamines, aromatic amine, cyclohexamines, quaternary ammonium ions, polyamines		Cation exchange, ion pair	Conductivity, UV

multidimensional suppressed ion chromatography. In this method, trace concentrations of anions can be separated from the matrix anions (e.g., chloride, nitrate, and sulfate) by collecting a selected portion of the ion chromatogram on a concentrator column after suppression and reinjecting the concentrated amount of trace anions under the original chromatographic conditions.

The analysis of brines by ion chromatography is complicated by the high ionic strength and excess of NaCl in the sample. Ion chromatography can be used for

Table 4 Survey of the detection methods used in ion chromatography.

Detection mode	Principle	Applications
Conductivity	Electrical conductivity	Anions and cations with pK_a or $pK_b < 7$
Amperometry	Oxidation or reduction on Ag/Pt/Au/ glassy carbon and carbon paste electrodes	Anions and cations with pK_a or $pK_b > 7$
UV/Vis detection with or without postcolumn derivatization	UV/Vis light absorption	UV-active anions and cations, transition metals after reaction with 4-(2-pirydyloazo) rezorcinol (PAR), aluminum after reaction with tiron, lanthanides after reaction with arsenazo I, polyvalent anions after reaction with iron(III), silicate and orthophosphate after reaction with molybdate
Fluorescence in combination with postcolumn derivatization	Excitation and emission	Ammonium, amino acids, and primary amines after reaction with *O*-phenylamine (OPA)
Refractive index	Change in refractive index	Anions and cations at higher concentrations
Inductively coupled plasma-optical emission spectrometry (ICP-OES), inductively coupled plasma-mass spectrometry (ICP-MS)	Atomic emission	Hyphenation techniques for selective and sensitive transition metal analysis
MS	Electrospray ionization	Hyphenation technique for structural elucidation of organic anions and cations

the analysis of inorganic ions in natural waters brines, which include seawaters, subsurface brines, geothermal brines, and high-salinity groundwaters. A review of the application of ion chromatography for the analysis of high ionic strength waters and aqueous matrices has been described by Singh, Abbas, and Smesko.[12] The determination of cyanide in various samples is very important environmentally because of its large-scale industrial uses and its extreme toxicity. In all of the analytical methods developed so far, for cyanide and sulfide, removal of interferences is a necessary first step when analyzing most environmental samples. With the ion chromatography method cyanide and sulfide are separated and are thus determined simultaneously.[13]

Polyphosphates are widely used in industrial water treatment applications on account of their sequestering and dispersing properties.[14] Chelating agents such as nitriltriacetate acid (NTA) and ethylenediaminetetraacetic acid (EDTA) can also be determined rapidly by the same approach used for polyphosphonates.

The determination of various oxidation states of elements is of great interest as well. Until recently, analytical methods allowed analysts to determine only the total content of analytes, but it was soon realized that this analytical information was insufficient. Biochemical and toxicological investigation has shown that, for living organisms, the chemical form of a specific element or the oxidation state in which that element is introduced into the environment is as important as its quantity.[15] Ion chromatography plays an important role in hyphenated techniques used for species analysis, as an effective and reliable separation method.[16]

Besides the common inorganic anions (F^-, Cl^-, Br^-, NO_3^-, PO_4^{3-}, and SO_4^{2-}) and cations (Na^+, K^+, NH_4^+, Mg^{2+}, and Ca^{2+}), chromate and arsenite are of primary concern because of their greater toxicities as compared to chromium(III) and arsenate, respectively. Hexavalent chromium is a toxic form of chromium that must be monitored in manufacturing wastes. Ion chromatography with postcolumn addition of diphenylcarbazide is probably the most specific and sensitive method available for the determination of hexavalent chromium.

The simultaneous analysis of alkali and alkaline earth metals is another important ion chromatographic application in the field of drinking water and surface water analysis. Environmental samples with low levels of ammonium, in matrices with high concentration of sodium, are a typical case. Unfortunately, ammonium and sodium ions have similar selectivities for the common stationary phases. This problem can be solved by a column-switching technique[17] or by applying appropriate columns and eluents. Owing to the strong environmental impact, trace heavy metal ion determination and speciation have received particular attention in recent years.

There is a significant number of ion chromatography methods developed for the determination of metal pollutants in a wide variety of environmental samples. The review of the current state and progress of ion chromatography as an analytical tool for trace metal analysis in environmental samples is described by Shaw and Haddad.[18] Ion chromatographic separation by anion exchange of metal ions involves their presence as negatively charged complexes, which can be achieved off-line or online. In the off-line method, metal complexes are formed before the chromatographic separation, because complexes must be stable enough to avoid decomposition during separation or a ligand must be added to the eluent. In the online method, complexation is performed in the chromatographic column by adding the proper ligand to the eluent. Among the many ligands (mainly organic acids) used for simultaneous ion chromatography of metals, the most common additives are oxalic acid, pyridine-2,6-dicarboxylic acid (PDCA), and EDTA.

At an appropriate pH, EDTA forms negatively charged complexes with divalent or trivalent metal ions, and simultaneous separation of anions from metal ions is also feasible with this ligand.[19] Ion chromatography is increasingly being used for the separation of lanthanides. The separation of each rare earth element can be performed with either a cation- or an anion-exchange mechanism, depending on the eluent composition and the properties of the stationary phase.

SOIL ANALYSIS

Soil is one of the most complex environmental components; it is the vehicle by which pollutants generated by human action—particularly, agricultural and industrial activities—are driven from the ground surface to the underground waters.

Extension of ion chromatography to the analysis of soil has been hindered by the sample preparation problems associated with soil samples. Sample preparation includes crushing, homogenization, digestion, dissolution, stabilization, and filtration. Ion chromatographic procedures require that any sample that is to be analyzed be in a solution, most preferably in aqueous form. Dissolution of the sample in acids should be avoided when determining anions, unless a subsequent high dilution with water is possible, because the acid anions that are added could result in overloading of the analytical column. Analysis of the total nitrogen, phosphorous, and sulfur, and their corresponding oxidized anions, e.g., nitrite, nitrate, phosphate, and sulfate, is of importance when assessing soil conditions and fertility. Most, if not all, of the inorganic species important in agriculture exist as ions.[20]

The control of landfills, especially of hazardous waste landfills, is becoming increasingly important. For environmental control purposes, the leachates from hazardous waste landfills and leachability test samples have to be analyzed regularly.[21]

The quantitation of inorganic ions in sludge, leachates, and similar solid wastes by ion chromatography is similar, in practice, to the analysis of soil samples. Such samples are typically leached under aqueous conditions, then filtered and pretreated using solid-phase extraction (SPE), if necessary, before injection. Sludges and solid-waste samples can be prepared for analysis by ion chromatography using combustion methods.[22]

AIR POLLUTION

Atmospheric pollutants can occur in a variety of forms, namely, fumes, dust, gases and vapors, and mists and aerosols. The knowledge of the distribution of atmospheric pollutants between the gaseous and the particulate phase is very important for the environmental analytical chemist. Gases and particles, in fact, are very different in terms of their adverse effects on human health and on the ecosystem; they generally involve different formation pathways and removal processes.

The major areas where ion chromatography is used are for the analysis of atmospheric particulates, aerosols, acid rain, sulfur dioxide flue gas, and automobile exhaust.[23] Ion chromatographic applications in the area of air hygiene include the determination of:

- NO_2^-, NO_3^-, SO_3^{2-}, SO_4^{2-}, and NH_4^+ in ambient aerosols and in motor vehicle exhaust.
- Trace anions (F^-, Cl^-, NO_3^-, and SO_4^{2-}) and cations (Na^+, NH_4^+, and K^+) in precipitation samples.
- SO_2 and NO_x in the atmosphere and in combustion products.
- Heavy metals in flue dust.
- Common toxic substances, such as formaldehyde, in industrial environment.
- Specific toxic substances in industrial environments.

Measurements may be made directly with the extracts from filters, bulk collectors, particle collectors, solution bubblers, or diffusion tubes, or following concentration on solid cartridges or guard columns. Usually, air is first passed through the collected material and is then extracted into solutions for analysis.

Ammonia can be converted to the ammonium cation, sulfur dioxide to the more stable sulfate anion, and nitrogen dioxide to nitrite and nitrate ions. In addition, organic anions, which include carboxylic acids and amines, can be determined. Sulfur dioxide, which results primarily from the combustion of coal and petroleum, is one of the six major air pollutants; therefore, it is necessary to have a reliable analytical method for its determination. The United States Environmental Protection Agency (U.S. EPA) has been evaluating ion chromatography method for ambient SO_2 monitoring. It was noted that this method has no temperature stability problems and eliminates the use of the toxic chemical potassium tetrachloromercurate used in the previously recommended methods. The hydrogen peroxide-absorbing reagent is a very efficient collector of sulfur dioxide.

Coupling of the annular denuder sampling techniques with ion chromatography provides a valuable solution to the problem of precise and accurate measurement of atmospheric inorganic pollutants, with discrimination of the gaseous and the particulate phase.[24]

Heavy and transition metals, normally present in atmospheric particulates, can be separated and detected by isocratic ion chromatography with a postcolumn reaction and spectrophotometric detection.[25]

CONCLUSION

Since its introduction in 1975 ion chromatography has been used in most areas of analytical chemistry and has become a versatile and powerful technique for the analysis of a vast number of ions present in the environment. The most important aims in ion chromatography development are new stationary phases, miniaturized inductively coupled (IC) systems, enhanced peak capacity through the use of complex eluent profiles and the associated computer tools for simulation and prediction of retention, and hyphenated IC systems.

The development of ion chromatography allows the determination of ionic contaminants in environmental samples with very low detection limits and expands the range of determined analytes. Ion chromatography will continue to develop as more and more ionic contaminants become regulated at increasingly lower limits in the future.

Essential Oils: GC Analysis

M. Soledad Prats Moya
Alfonso Jiménez
Department of Analytical Chemistry, Nutrition and Food Sciences, University of Alicante, Alicante, Spain

Abstract
The use of essential oils is increasing because of the increase in the number of their applications and in the framework of natural and environmentally friendly materials. Many times the analysis of their components is quite complex due to the high number and the diversity of compounds in their composition. In this entry a general overview of the extraction methods is given by comparing conventional liquid–liquid and solid–liquid methods with new alternative ones, such as supercritical fluid extraction and microwave-assisted extraction. Gas chromatography methods and examples are treated and important issues such as detection systems, modern libraries for compounds identification, as well as multidimensional or hyphenated techniques are discussed. The use of these modern techniques and methods has improved resolution and sensitivity in essential oils determination and could open the possibility of future work in this area of chromatography.

INTRODUCTION

Natural products have served as an important source of drugs since ancient times. In recent years, a renewed interest in obtaining biologically active compounds from natural sources has been observed. Essential oils are highly concentrated substances present in aromatic plants that can be extracted from flowers, leaves, stems, roots, seeds, barks, resins, or fruit rinds. The levels of essential oils found in plants can be anywhere from 0.01 to 10 wt% of the total. This is why tons of plant materials are required for just a few hundred grams of oil. These oils are often used for their flavor and their therapeutic or odoriferous properties. They are used in a wide selection of products such as foods, medicines, and cosmetics.

Pure essential oils are complex mixtures of more than 200 components. They can be essentially classified into two groups: a volatile fraction constituting 90–95% of the oil in weight, containing the monoterpene and sesquiterpene hydrocarbons, as well as their oxygenated derivatives along with aliphatic aldehydes, alcohols, and esters; and a non-volatile residue that comprises 1 to 10 wt% of the oil, containing hydrocarbons, fatty acids, sterols, carotenoids, waxes, and flavonoids. Essential oils are characterized by two or three major components at fairly high concentrations (20–80%) while the rest of the components are present in trace amounts. Essential oils and their constituents are categorized as Generally Recognized As Safe (GRAS) by the U.S. Food and Drug Administration.[1]

OVERVIEW

Because of the enormous amount of raw material necessary to obtain a small amount of essential oil, many products on the market have been polluted with low-quality commercial oils to reduce their cost, a fact not always indicated on the label. Therefore it is important to study the chemical composition of the volatile fraction once the essential oil is extracted. This fraction is characterized by the complexity in the separation of its components, which belong to various classes of compounds and which are present in a wide range of concentrations. Therefore it is complicated to establish a composition profile of essential oils and to identify possible adulterations.

The gas chromatographic (GC) technique is almost exclusively used for the qualitative analysis of volatiles. The analysis of essential oils was developed in parallel with the technological developments in GC. Some of these developments were the application of more selective new column stationary phases and mass spectrometry (MS) detection devices which allow to identify the compounds. However, advances in instrumentation were not the only important factor in the development of analytical methods for essential oils in plants. Sample extraction and concentration techniques were also improved recently, in order to reduce the extraction time, to improve the extraction yield, and to enhance the quality of the extracts. The most outstanding improvements in the determination of the composition of essential oils came from the development of total analysis systems, i.e., systems where sample

preparation and analysis are integrated into a single online step. The great amount of information on the application of GC and hyphenated techniques to essential oils has led to much research in this field, and to the publication of recent reviews.[2–5]

EXTRACTION METHODS

Extraction of essential oils is one of the most time- and effort-consuming processes in the analysis of the constituents of plants. The extraction products can vary in quality, composition and quantity depending on the type of soil, weather, plant organs, and other factors.[6] Various extraction methods were traditionally employed, depending on the material or the available devices. The most common methods for essential oil isolation are steam distillation (SD) and hydro-distillation (HD). In the first method, water steam is passed through the raw material, which drives out most of its volatile fragrant compounds. SD is commonly used for fresh plant materials, such as flowers, leaves, and stems. In the HD method the plant is inserted into water in a Clevenger-type apparatus and subjected to heating; the vapor, which contains the volatile compounds, is passed through a cooler for condensation, with subsequent collection of the extract.[7]

An alternative method, useful for much smaller samples, involves extraction with organic solvents, such as dichloromethane or hexane, followed by evaporation of solvents from the extract.[8] However, this approach is not very popular when the extracts obtained are to be used in the cosmetic or food industry, because of the possible toxic organic solvent residue.

These conventional methods used to isolate valuable compounds from aromatic plants have important drawbacks, such as low yields, formation of by-products due to the degradation of thermally unstable and unsaturated compounds by temperature or hydrolytic effects, as well as large extraction times.[9] Therefore, some alternative extraction methods were proposed to overcome these drawbacks.

Supercritical fluid extraction (SFE) using CO_2 as extractant has shown good potential for the isolation of organic compounds from various samples, by minimizing sample handling, eliminating the use of residual solvents, and allowing the use of lower temperatures, which reduces the deterioration of heat-labile compounds.[10] As a consequence, a great number of applications using SFE were successfully developed in the last decade for different sorts of herbs.[11–13] By varying the temperature and pressure of the CO_2 during extraction, the flavor or odor components can be selectively extracted.[14] Nevertheless, there are two main limitations in the use of supercritical CO_2 extraction: the high costs and the lack of quantitative extraction of polar analytes from solid matrices, caused by the poor solvating power of this fluid.[15]

The use of superheated water extraction (SWE) is a good alternative to SFE since the pressure is not a critical factor due to the low compressibility of water over the typical temperature ranges.[16] The extract obtained using SWE is a relatively dilute aqueous solution, but some care must be taken with the solubility changes of the analytes on cooling the extract as precipitation problems can occur.

The use of high temperatures for rapid extraction has been extended to pressurized liquid extraction (PLE). This technique uses organic solvents at elevated temperature and pressure, improving the speed of the extraction process.[17] The extractor design, capable of withstanding high pressures, allows the extraction temperature to be raised above the boiling point of the solvent while the high pressure allows maintaining the solvent in a liquid state at a high temperature. Under these conditions, the extraction process is favored by the high solvent strength. Some authors have claimed that PLE is the most efficient sample preparation method in determining essential oils in some herbs.[18] However, coextraction of non-volatile ingredients is recognized as the main drawback of this method.

Another possibility for essential oils extraction is the use of microwave-assisted extraction (MAE). This methodology appeared to be quite attractive for the isolation of essential oils. The main advantage of using MAE for essential oils extraction is the effective heat transfer that allows quicker times of extraction as compared to classical methods. In the last few years, different applications using microwave energy have been developed.[19] A recent modification of this technique is solvent-free microwave extraction (SFME), where the sample is placed in the reactor inside the microwave oven without any solvent.[20–21] A cooling system outside the microwave oven cool the extract continuously. Finally, the mixture of water and essential oil is collected and separated in a vessel.

Even though SFE, SWE, PLE, and MAE give better yields for essential oils extraction, high sample temperatures with possible formation of undesirable by-compounds is a shortcoming. Therefore, extraction techniques with no sample heating have been recently applied to essential oils. Ultrasound-assisted extraction (USAE) is a low-cost technique that is carried out at ambient temperature. Moreover, USAE uses quite simple equipment.[18] The main shortcoming of USAE is the potential formation of free radicals during sonication of the solvent, which can lead to degradation of some labile compounds by oxidation.[22–23]

The use of these alternative extraction techniques has been generalized to many essential oils and different samples as previously mentioned. These techniques have improved recoveries in the determination of most organic additives, as well as permitted considerable reductions in solvent volume and extraction time. However, the comparison of extraction methods was usually reduced to relative

recoveries of target analytes, ignoring important analytical parameters of the method. Selectivity is one of these, as the coextraction of other organics from the matrix usually requires a postextraction cleanup step before chromatographic analysis. Therefore, there is still much effort to be carried out in this field in order to optimize the extraction of essential oils from different natural matrices. The selection of the best extraction method and the best conditions depends on the components to be extracted, and this is something to be carefully considered. The application of chemometrics based, for example, on the use of central composite designs (CCD) and multilinear regression analysis has recently been shown to be a good alternative for the optimization of extraction parameters, such as temperature, pressure, and static time.[24,25] In addition, several mathematical models have been presented in literature for essential oils extraction.[12,13,26]

CONCENTRATION OF ANALYTES

Another important aspect to be taken into account for a reproducible and accurate separation and determination of essential oils is the concentration of each component after extraction. In many cases, a preconcentration of the sample, prior to any other step in the analytical process, is necessary to assure a concentration range for an accurate determination. This is the way small amounts of each constituent in plants or complex matrices, such as pharmaceuticals, can be collected and concentrated using the headspace technique (HS-GC), which involves volatilization of the terpenoids and other substances in a closely confined space, followed with analysis of constituents in the gaseous phase.[27,28] HS sampling can be used when essential oils must be selectively introduced to a GC to avoid transfer of non-volatile constituents, which may increase running times or complicate separation. This process can be carried out as an equilibrium process (static headspace) or as a continuous one (dynamic headspace). In the last few years, different publications have appeared using HS associated to a concentration technique like solid-phase microextraction (SPME), sorptive extraction (SE), and single-drop microextraction (SDME). In particular, the coupling of HS to SPME has been reported as a powerful separation tool for essential oils analysis due to its simplicity.[29–32] Results were compared to those from steam-distilled samples and, in general, most of the monoterpene compounds were detected at higher levels by using HS-SPME with 30 sec extraction time. In addition, detailed information about terpenic compounds was obtained by using HS-SPME.[29]

Some authors have proposed the use of HS-sorptive extraction (HSSE) where the analytes are adsorbed onto a thick film of polydimethylsiloxane (PDMS) coating a glass-coated iron stir bar. This stir bar is suspended in the headspace volume from where the analytes are adsorbed by the PDMS coating. After sampling, the stir bar is placed in a glass tube and transferred to a thermodesorber from where the analytes are thermally recovered and further analyzed by GC. This concentration technique is very effective for trace analysis.[33]

GC ANALYSIS

The separation of essential oil components is usually carried out by GC with fused-silica capillary columns. The information obtained from high-resolution GC analysis of the volatile fraction of essential oils must be enough to determine any adulteration or loss of quality. Therefore a selective and accurate separation is absolutely necessary in the case of industrial analysis.

The properties and conditions of columns are variable, depending on the polarity of the components to be separated. The most commonly used columns include stationary phases, such as DB-1, Carbowax, OV-1, OV-101, PEG 20M, BP5, and DB-5, which cover a wide range of polarities. Column lengths normally range from 25 to 100 m, and stationary-phase film thickness ranges from 0.2 to 0.7 μm. Elution of components is usually performed with a temperature gradient ranging from 50°C to 280°C.

The developments in new stationary phases have led to the production of thermally and chemically stable phases, with greater selectivity and efficiency. It is advantageous to use a more selective phase for a given separation as the overlapping of peaks in the final chromatogram is often a significant drawback of chromatographic techniques in natural samples.[34] The discovery of chiral phases (mostly based on cyclodextrin derivatives) allows the resolution of enantiomers of volatile components. These phases can give different elution sequences for a range of polarities and provide a distinct advantage in identification because of large changes in solute relative retention times.[35]

An important drawback in the separation of essential oils is the time required for complete GC resolution of the components of interest, which can sometimes take hours. In fact, the analysis of essential oils is usually carried out with slow temperature programs, which take long times for the development of the whole chromatogram. There are several ways to reduce analysis time in GC. The most common approach is to use shorter capillary columns with reduced internal diameter (I.D.) and film thickness, i.e., narrow bore columns. When using these columns, the optimum carrier gas velocity is higher, and it is possible to work with higher average linear velocity without loss of efficiency. However, this increase in linear velocity must be linked with some specific conditions of measurement, such as fast oven heating, fast acquisition rate, high inlet pressures, and higher split ratios. In the last few years, several studies have been carried out in this area, using columns of 1, 2, 5 or 10 m length, 0.10 mm I.D., and

0.10 μm stationary-phase film thickness. These columns offer the most effective compromise between separation efficiency and analysis time. Time can decrease from tens of minutes to minutes or even seconds while keeping a resolution suitable for normal determinations.[35–38]

DETECTION AND CHARACTERIZATION OF CONSTITUENTS

The flame ionization detector (FID) is still widely applied for the detection and quantification of some of the essential oil components, such as terpenoids. As usual in GC–FID, the primary criterion for the identification of peaks is the comparison of the standard retention times with the retention times of peaks in the sample's chromatogram. However, this procedure is sometimes not useful as the identification is quite difficult and overlapping of peaks makes determination not possible.

The easiest and most frequently used way to identify essential oil components when using GC–FID is comparison with Kovats retention indices (RI). The use of this type of retention data, derived from two GC columns of different polarities, allows highly reliable identification of a large number of components in a particular sample.

By far, MS is the most popular detection technique for performing chromatographic studies of essential oils. The use of retention indices, in conjunction with GC–MS studies, is well established. Many laboratories use such procedures in their routine analyses to confirm the identities of unknown components. However, a feature of MS for essential oils is that mass spectra are not particularly unique in many cases because of the large number of isomers of the same molecular formula, but with different structures, that could exist. Therefore their mass spectra are similar and their identification is sometimes not easy. The most common approach to solve this problem, as well as the presence of unknowns on which very little other structural information is available, is the use of algorithms and powerful MS databases, as has been recently proposed.[37] Two different MS databases are commonly used as references: National Institute of Standards and Technology (NIST)/Environment Protection Agency (EPA)/National Institutes of Health (NIH)[38] and the Registry of Mass Spectral Data.[39] The first one contains more than 191,000 mass spectra of different chemicals. The largest database is the Registry of Mass Spectral Data, called the Wiley database, containing more than 400,000 different spectra, resulting from the work of many researchers in the field of MS. One of the commonly used algorithms was proposed by Oprean et al.[40] who consider two parameters as identification criteria for an unknown peak, i.e., the match index of the unknown mass spectrum with spectral libraries, and the relative retention indices computed from the retention times of the unknowns relative to a mixture of *n*-alkanes.

One of the most recently proposed methods to improve the analysis of complex mixtures, especially for deconvolution of overlapping mass spectra, is time-of-flight mass spectrometry (TOF-MS). This technique allows assignment of a spectrum to each individual solute in significantly overlapping elution profiles. This is an important advantage that can be exploited when fast GC methods are applied for complex samples because each overlapping peak may be deconvoluted and the individual spectrum of each overlapping solute may be obtained. Although great efforts have recently been carried out in this field, it remains to be determined if TOF-MS can be used on a routine basis even though a lot of works have been published using this detector in the last few years.[41–42]

The identification of compounds comprising more than 1 wt% in the oils can be also carried out by ^{13}C-NMR and computer-aided analysis.[43] The chemical shift of each carbon in the experimental spectrum can be compared with those of the spectra of pure compounds. These spectra are listed in the laboratory spectral database, which contains approximately 350 spectra of mono-, sesqui-, and diterpenes, as well as in the literature data. Each compound can be unambiguously identified, taking into account the number of identified carbons, the number of overlapped signals, as well as the difference between the chemical shift of each resonance in the mixture and in the reference.

The combination of GC with olfactometry is another possibility for detection that has been used in essential oils analysis.[41,44] Olfactometry adapters are commercially available and should include humidity of the GC effluent at the nose adapter and provide auxiliary gas flow. The correlation among eluted peaks with specific odors allows accurate retention indices or retention times to be established for the essential oil components. Some of them can be detected in this way after applying chemometric techniques, such as cluster analysis and principal component analysis, to the data from the sensors. A limitation of GC with olfactometry is that peak coelution in complex samples makes identification of the compound(s) responsible for an odor difficult, particularly where trace odorants coelute with larger odor-inactive peaks. One possible solution for identifying character-impact odorants where coelution occurs is to use comprehensive two-dimensional GC (GC × GC).[44]

HYPHENATED OR MULTIDIMENSIONAL ANALYSIS OF ESSENTIAL OILS

Hyphenated or multidimensional techniques have recently been introduced for the analysis of essential oils. Various approaches were recently proposed to obtain better results in the identification and quantification of essential oil components. Thus it is possible to use systems that incorporate separations prior to GC, multicolumn separations, and specific identification methods.

With respect to separations preceding GC analysis, some hyphenated techniques have been successfully used when there is a lack of resolution of the single-capillary GC method. One of these is the combination of high-performance liquid chromatography (HPLC) with GC. The prior HPLC step achieves the isolation of components of similar chemical composition, primarily based on polarity. Hence, this will separate saturated hydrocarbons from unsaturated or aromatic hydrocarbons, for example.[45] These systems are fully automated, but there is a problem with off-line sampling of HPLC fractions. The selection of the HPLC injection port will determine the particular method of separation. Therefore in this instrumental arrangement, each transferred fraction must be separately analyzed before the introduction of a subsequent fraction into the GC system. In general, the prior separation will be introduced to simplify the subsequent GC analysis, leading to improved resolution.

MULTIDIMENSIONAL GC

If highly complex samples, such as natural tissues, have to be studied, one way to improve the separation power is to couple, through an interface, two independent columns. The application of multidimensional GC (MDGC) to essential oils analysis was a great development in the determination of such complex samples.[46] This is an adequate approach when there are some zones on the chromatogram where peaks are not well resolved. The fractions corresponding to the zones with unresolved peaks are transferred to a second column containing a different stationary phase, where they are separated and completely resolved.

However, this evident improvement in instrumentation is only available to relatively few regions of the chromatographic analysis, as overlapping of peaks can be too complex for a complete resolution of each component, even after applying multiple-column couplings. The use of conventional MDGC technology is not possible for the entire analysis because this would involve transferring all the components to the second column, with the inherent technical problems of selectivity and sensitivity losses. This is why the MDGC analysis of essential oils is not focused on the increase of resolution for the whole sample, but only for specific components of interest in the quality control of the natural product.

Alternatively, when, across-the-board screening of an entire sample is required, MDGC is too time-consuming and complicated, and a comprehensive, i.e., a GC × GC, approach has to be used.[47] In this case, the entire first-column (first-dimension) eluate, cut into small adjacent fractions to maintain the first-dimension resolution, is subjected to further analysis on the second (second-dimension) column. GC × GC provide superior analyses compared to MDGC and single-column GC analysis, as can be seen in a recently published review.[48]

Finally, the most powerful option available for volatiles analysis is the introduction of a third mass spectrometric dimension in a comprehensive GC system.[49] MS techniques improve component identification and sensitivity, especially for the limited spectral fragmentation produced by soft ionization methods, such as chemical ionization (CI) and field ionization (FI). The use of MS to provide a unique identity for overlapping components in the chromatogram makes identification much easier. However, quadrupole conventional MS is unable to reach the resolution levels required for such separations. Only TOF-MS possesses the necessary speed of spectral acquisition to give more than 50 spectra per second.

CONCLUSIONS

The identification and determination of essential oils in many natural samples have improved greatly with the use of more powerful analytical techniques, such as fast extraction methods, better chromatographic detectors, and comprehensive GC. This improvement in analytical parameters opens a great future for the development of analytical methods for essential oils determinations, even at low limits of detection.

Evaporative Light Scattering Detection

Juan G. Alvarez
Department of Obstetrics and Gynecology, Beth Israel Deaconess Medical Center, Boston, Massachusetts, U.S.A.

INTRODUCTION

High-performance liquid chromatography (HPLC) is mainly carried out using light absorption detectors as ultraviolet (UV) photometers and spectrophotometers (UVD) and, to a lesser extent, refractive index detectors (RIDs). These detectors constitute the main workhorses in the field.[1] The sensitive detection of compounds having weak absorption bands in the range 200–400 nm, such as sugars and lipids is, however, very difficult with absorption detectors. The use of the more universal RID is also restricted in practice because of its poor detection limit and its high sensitivity to small fluctuations of chromatographic experimental conditions, such as flow rate, solvent composition, and temperature.[2] Moreover, if the separation of complex samples requires the use of gradient elution, the application of RID becomes almost impossible. Although for some solutes the use of either a reaction detector (RD) or a fluorescence detector (FD) is possible, this is not a general solution. In this regard, the analysis of complex mixtures of lipids or sugars by HPLC remains difficult owing to the lack of a suitable detector.

The miniaturization of detector cells is also extremely difficult and the technological problems have not yet been solved because the detection limit should also be decreased or, at least, kept constant.[2–6] Some progress in the design of very small cells for UVD and FD has been reported,[3–7] but the miniaturization of RD and RID seems much more difficult in spite of some suggestions.[8] Similarly, the development of open tubular columns is plagued by the lack of a suitable detector with a small contribution to band broadening. A non-selective detector more sensitive than the RID and easier to use with a small contribution to band broadening is thus desirable in HPLC. The mass spectrometer would be a good solution if it were not so complex[10] and expensive. The electron-capture detector (ECD)[11] and flame-based detectors have been suggested.[12] Both are very sensitive and could be made with very small volumes. Unfortunately, the ECD can be used only with volatile analytes and it is very selective. Both ECD and flame-based detectors are very sensitive to the solvent flow rate, and noisy signals are often produced. The adaptability of these detectors to packed columns is thus difficult. This probably explains why the ECD has been all but abandoned.

The evaporative light-scattering analyzer,[13,14] on the other hand, is an alternative solution which seems very attractive for a number of reasons. As most analytes in HPLC have a very low vapor pressure at room temperature and the solvents used as the mobile phase have a significant vapor pressure, some kind of phase separation is conceivable.

EVAPORATIVE LIGHT-SCATTERING DETECTOR

Principle of Operation

The unique detection principle of evaporative light-scattering detectors involves nebulization of the column effluent to form an aerosol, followed by solvent vaporization in the drift tube to produce a cloud of solute droplets (or particles), and then detection of the solute droplets (or particles) in the light-scattering cell.

Detector Components

Nebulizer: The nebulizer is connected directly to the analytical column outlet. In the nebulizer, the column effluent is mixed with a steady stream of nebulizing gas, usually nitrogen, to form an aerosol. The aerosol consists of a uniform dispersion of droplets. Two nebulization properties can be adjusted to regulate the droplet size of the analysis. These properties are gas and mobile-phase flow rates. The lower the mobile-phase flow rate, the less gas and heat are needed to nebulize and evaporate it. Reduction of flow rate by using a 2.1 mm I.D. column should be considered when sensitivity is important. The gas flow rate will also regulate the size of the droplets in the aerosol. Larger droplets will scatter more light and increase the sensitivity of the analysis. The lower the gas flow rate, the larger the droplets. It is also important to remember that the larger the droplet, the more difficult it will be to vaporize in the drift tube. An unvaporized mobile phase will increase the baseline noise. There will be an optimum gas flow rate for each method which will produce the highest signal-to-noise ratio.

Drift tube: In the drift tube, volatile components of the aerosol are evaporated. The non-volatile particles in the mobile phase are not evaporated and continue down the drift tube to the light-scattering cell to be detected. Non-volatile impurities in the mobile phase or nebulizing gas will produce noise. Using the highest-quality gas,

solvents, and volatile buffers, preferably a filter, will greatly reduce the baseline noise. Detector noise will also increase if the mobile phase is not completely evaporated. The sample may also be volatilized if the drift-tube temperature is too high or the sample is too volatile. The optimal temperature in the drift tube should be determined by observing the signal-to-noise ratio with respect to temperature.

Light-scattering cell: The nebulized column effluent enters the light-scattering cell. In the cell, the sample particles scatter the laser light, but the evaporated mobile phase does not. The scattered light is detected by a silicone photodiode located at a 90° from the laser. The photodiode produces a signal which is sent to the analog outputs for collection. A light trap is located 180° from the laser to collect any light not scattered by particles in the aerosol stream.

The signal is related to the solute concentration by the function $\Lambda = am^x$, where x is the slope of the response line, m is the mass of the solute injected in the column, and a is the response factor.

APPLICATIONS

Evaporative light-scattering detection finds wide applicability in the analysis of lipids and sugars. The analysis of lipids and sugars by HPLC has classicaly been hampered due to the lack of absorbing chromophores in these molecules. Accordingly, most analyses are carried out by GC, requiring derivatization in the case of the sugars or being especially difficult like the separation of the high-molecular-weight triglycerides, or even impossible for the important class of phospholipids, which cannot withstand high temperatures. Specific applications are as follows:

1. Use of evaporative light scattering detector in reversed-phase chromatography of oligomeric surfactants. Y. Mengerink, H. C. De Man, and S. J. Van Der Wal, J. Chromatogr. 552: 593 (1991).
2. A rapid method for phospholipid separation by HPLC using a light-scattering detector: W. S. Letter, J. Liq. Chromatogr. 15: 253 (1992).
3. Detection of HPLC separation of glycophospholipids: J. V. Amari, P. R. Brown, and J. G. Turcotte, Am. Lab. 23 (Feb. 1992).
4. Analysis of fatty acid methyl esters by using supercritical fluid chromatography with mass evaporative light-scattering detection: S. Cooks and R. Smith, Anal. Proc. 28, 11 (1991).
5. HPLC analysis of phospholipids by evaporative light-scattering detection: T. L. Mounts, S. L. Abidi, and K. A. Rennick, J. AOCS 69: 438 (1992).
6. Determination of cholesterol in milk fat by reversed-phase high-performance liquid chromatography and evaporative light-scattering detection: G. A. Spanos and S. J. Schwartz, LC–GC 10(10): 774 (1992).

Evaporative Light Scattering Detection for LC

Sarah S. Chen
Analytical Science, GlaxoSmithKline, King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

Evaporative light scattering detection (ELSD) is a powerful technique that can be applied in liquid chromatography (LC) to all solutes having lower volatility than the mobile phase. It consists of a nebulizer that transforms the eluent from the high-performance liquid chromatography (HPLC) into an aerosol, a drift tube to vaporize the solvent, and a light scattering cell (Fig. 1). When using ELSD in conjunction with LC, the eluent is nebulized immediately into a stream of warm gas. The solvent then vaporizes leaving a cloud of solute particles. The particles are subjected to a light source and scattering occurs in the scattering chamber. The amount of light scattered by the particles is proportional to the analyte concentration. These principles make ELSD a universal detector that can be used for analytes with low UV chromophores. Evaporative light scattering detection has been used for the detection of polymers in size-exclusion chromatography (SEC).[1] It has also been used in the detection of small molecules in reversed phase and normal phase LC.[2–4]

THEORY AND INSTRUMENTATION

Light scattering detection cannot be used if the analyte particles or solvent vapors absorb at the wavelength range of the light source. When particles are hit with a beam of light, the light may be absorbed, refracted, reflected, or scattered. Reflection and refraction always occur together and they prevail when the wavelength of light approaches the particle's size.[5] The sum of the reflection and refraction intensities equals the intensity of the incident light when there is no absorbance. Scattering occurs when the particle diameter is close to one-tenth of the wavelength. There are two types of scattering: Mie scattering and Rayleigh scattering. Mie scattering occurs when the ratio of particle diameter to the wavelength of light is greater than 0.1.[6] Rayleigh scattering occurs when the ratio is less than 0.1.[7] These numbers are approximate and a transition region does exist. The property of scattering has been used in the ELSD for LC. In ELSD, the eluent for LC is nebulized, and the amount of light scattered by the nebulized eluent particles is proportional to the analyte concentration.

Evaporative light scattering detection involves three successive and interrelated processes: nebulization of the chromatographic eluent, evaporation of the volatile solvent (mobile phase), and scattering of light by residual analyte particles. The three major parts of the system are the nebulizer, drift tube, and light-scattering cell.

Nebulizer

The nebulizer is normally interfaced directly to the LC column. It combines the eluent with a stream of gas to produce an aerosol. Much of the theoretical and practical basis of nebulization comes from atomic spectroscopy. The average droplet diameter and uniformity of the aerosol are the most important factors for ELSD sensitivity and reproducibility. As larger solute particles scatter light more intensely, an aerosol with large droplets and a narrow droplet size distribution leads to the most precise and sensitive detection. A good nebulizer should produce a uniform aerosol of large droplets with narrow droplet size distribution. The droplets cannot be too large, however; otherwise, the solvent in a droplet will not be completely vaporized and errors in detection will occur. The nebulizer properties that can be adjusted to obtain the desired droplet properties are, primarily, the gas flow rate and the LC mobile phase flow rate.[8]

Drift Tube

Volatile components of the aerosol produced by the nebulizer are evaporated in the drift tube to produce non-volatile particles in a dispersed mixture of carrier gas and solvent vapors. Ideally, the temperature in the drift tube should be high enough to ensure the complete evaporation of solvents, yet not so high as to be able to volatilize the analytes. If solvent removal is incomplete, detector noise will increase. When extremely large droplets reach the light scattering cell, they will be seen as spikes. If the drift tube temperature is too high, solute may be vaporized or partially vaporized, resulting in decreased sensitivity and accuracy. Droplet aggregation is another phenomenon that can occur in the drift tube. It can cause incomplete solvent removal and detector signal spiking. Overall, the drift tube should be wide enough, long enough, and hot enough to ensure complete and rapid solvent removal. Its outlet into the light-scattering cell should be shaped to send all of the particles past the detector window. There has been an increased need for a low temperature ELSD to address the detection of thermally labile compounds and volatile compounds. A low-temperature ELSD that can evaporate solvent at near-ambient temperature, 26–40°C, is now available from several vendors. These instruments are designed in a way that extremely large

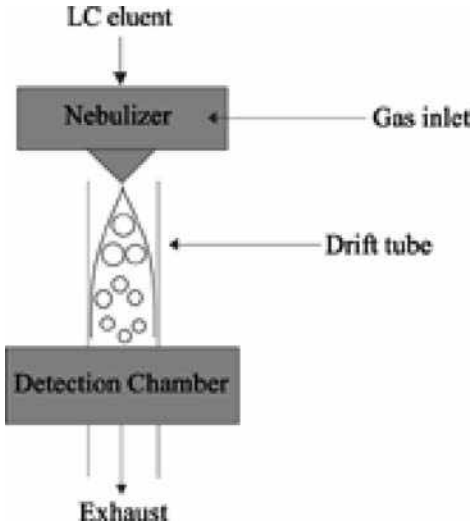

Fig. 1 Schematic diagram of evaporative light scattering detector.

droplets are expelled to waste. Only droplets of optimum size can survive and the surface area of these droplets will allow maximum vaporization of solvents at moderate drift tube temperatures.

Light Scattering Cell

The particle cloud leaves the drift tube and enters into a light scattering cell. Laser light is passed into the cell through a window, scattered by the analyte, and detected at an angle to the incident light. Single wavelength light at 632, 650, or 670 nm has been generally used in various instrument designs. Other instruments use a polychromatic light source. It is believed that a polychromatic light source emits a distribution of wavelengths where specific absorbance effects are minimized and mass sensitivity predominates over structural sensitivity. The response increases monotonically with analyte mass because of the averaging effects that occur when polychromatic scattered light is collected. Thus a polychromatic light source can be found more often than a single wavelength source in instruments. The detector is usually constructed in a way that material in the particle cloud will not stick to the window and fumes are properly vented. In addition, light traps are used to dissipate non-scattered light.

EXPERIMENTAL CONSIDERATIONS

The response factor of an ELSD largely depends on the size of analyte particles entering the detection chamber. After exiting from the HPLC column, the eluent stream is nebulized, and a scavenger gas stream carries the effluent cloud through a hot drift tube where the solvent vaporizes. The droplet shrinks to the volume of the non-volatile material contained in the eluent. The average particle size in the cloud at a given time and the particle size distribution can be derived from the elution profile of the analyte and the droplet size distribution given by the nebulizer. The average diameter, D_o, of the particles formed in a concentric nebulizer is given by the Atkinson equation:[9]

$$D_o = \frac{A\sigma_1^{1/2}}{u\rho_1^{1/2}} + B\left(\frac{\eta_1}{(\sigma_1\rho_1)^{1/2}}\right)^{0.45}\left(\frac{1000Q_1}{Q_g}\right)^{1.5} \quad (1)$$

where A and B are constants, σ_1 is the surface tension of the mobile phase, ρ_1 is the density of the mobile phase, η_1 is the viscosity of the mobile phase, u is the relative velocity of the gas and liquid streams in the nebulizer (i.e., the cross-section average velocity of the gas stream between the gas and the liquid nozzles, minus the cross-sectional average velocity of the solvent in the liquid tube), Q_1 is the volume flow rate of the mobile phase, and Q_g is the volume flow rate of the scavenger gas.

Eq. 1 predicts that the average droplet size depends on the gas and solvent flow rate. It also predicts that the average droplet size will depend on the nature of the solvent, because of the dependency on the density, surface tension, and viscosity of the nebulized liquid. The initial droplet size formed in the nebulizer has little to do with the property of the analyte as it predominantly contains mobile phase. The final droplet size in the scattering chamber is dependent on the analyte concentration. When optimizing detector conditions, the experimental parameters that can be adjusted are nebulizer gas flow rate, mobile phase flow rate, and drift tube temperature.

Effect of Scavenger Gas Flow Rate

While keeping mobile phase constant, a plot of the response for a constant sample amount vs. the scavenger gas flow rate exhibits a maximum at an intermediate flow rate, and so does the plot of the signal-to-noise ratio vs. flow rate. At large flow rates, the decrease in response is due to the fact that the average particle size of the solute cloud decreases with increasing gas flow rate according to Eq. 1. The response decreases accordingly with the particle size. At low flow rate, the response factor decreases rapidly with decreasing flow rate, while the noise increases and spikes appear. This is related to the fact that the flow velocity of the scavenger gas in the concentric nebulizer should be in the sonic range in order for the nebulizer to function properly. A low gas flow rate results in very large droplets that vaporize too slowly; hence a spike appears. Precipitation or aggregation can occur if the nebulizer gas pressure is too low. Precipitation in the drift tube can also cause a decrease in sensitivity.

Effect of Mobile Phase Flow Rate

An increase in eluent flow rate will result in increased droplet size and high response factor. However, a flow rate that is too high will result in the incomplete vaporization of the mobile phase and high background noise. When

ELSD is used in conjunction with LC, the effect of flow rate on the separation should also be considered.

Effect of Drift Tube Temperature

The solvent contained in the droplets formed in the nebulizer must be completely vaporized during the migration of these droplets down through the drift tube. Thus a compromise between the scavenger gas pressure, the mobile phase flow velocity, and drift tube temperature has to be chosen. The residence time of the droplets of solution in the drift tube should be large enough and the drift tube temperature should be high enough to ensure the complete vaporization of solvents. Meanwhile, the temperature must be low enough so that the analytes are not vaporized, as this would result either in a systematic error (small extent of analyte vaporization) or in a total loss of signal (total vaporization of analyte). Low temperatures avoid evaporation of semivolatile analytes and destruction of thermally labile compounds. Vaporization of the solvent is facile with organic mobile phases such as acetonitrile, hexane, or chloroform, but relatively difficult with aqueous mobile phases.

Other Considerations

The response of the evaporative light scattering detector is not linear. This is because the droplets scatter light with an intensity that increases much faster than the third power of their diameter.[10] The response of the detector is not linear but is given by

$$A = aC^b \tag{2}$$

where A is the response of the detector, a and b are numerical coefficients, C is the concentration of solute. The data can be plotted as log A vs. log C to obtain a graph that has a large linear region with a slope b and an ordinate a. This region can be used for quantitation. Slope b tends to be similar for similar compounds and falls between 1 and 2. A slope of 2 is the limiting value for Rayleigh scattering.[11]

One advantage of ELSD is that a wide range of solvents can be used, including acetone and chloroform which are not useful with UV detection. One drawback is that the solvent must be significantly more volatile than the analytes; thus the use of non-volatile buffers should be strictly avoided. Only high-quality HPLC solvents with minimum particulates should be used.

If the solvents remain clean and totally volatilized, baseline drift should not be observed during gradient elution. However, sensitivity may change in solvent gradients, mainly due to the change in droplet size as a result of the change in eluent properties such as surface tension, viscosity, and density. In general, shallow gradients are preferable.

Outlet waste gas stream from the ELSD may contain organic solvent vapors. For safety reasons, it is essential to ensure that the outlet of ELSD is properly directed to a safe vented outlet (e.g., a fume hood). Waste ventilation should occur at atmospheric pressure. A vacuum or restriction may result in pressure changes within the optical detection chamber and cause detector baseline instability.

CONCLUSIONS

Evaporative light scattering detection can be used as a universal detector for LC. Its operation includes the nebulization of the eluent in the nebulizer, solvent evaporation in the drift tube, and scattered light detection at the light scattering chamber. Experimental conditions which can be adjusted in most ELSD systems to optimize the detector sensitivity are the nebulizer gas flow rate, mobile phase flow rate, and drift tube temperature. The detector response is non-linear, but can be used in quantitative work if a calibration curve is obtained.

Evaporative Light Scattering Detection for SFC

Christine M. Aurigemma
William P. Farrell
Pfizer Global Research and Development, Pfizer Inc., La Jolla, California, U.S.A.

INTRODUCTION

The evaporative light-scattering detector (ELSD) was originally developed for use with high-performance liquid chromatography (HPLC) to detect nonvolatile compounds by mass rather than ultraviolet (UV) absorbance detection.[1] The response is dependent on the light scattered from particles of the solute remaining after the mobile phase has evaporated and is proportional to the total amount of the solute. Because no chromophore is necessary, a response can be measured for any solute less volatile than the mobile phase.

DISCUSSION

Although ELSD is considered a universal detector for HPLC,[2] there are additional advantages obtained from coupling ELSD to packed column supercritical fluid chromatography (SFC). SFC provides better selectivity and faster analysis times over HPLC as a result of the low-viscosity and high solute diffusion coefficients characteristic of supercritical fluids.[3] Detection limits for some solutes are improved using ELSD with SFC relative to HPLC.[4] In order to increase solvating power and improve peak shape, CO_2 is often modified with a polar organic solvent such as methanol.[5,6] Using this binary fluid allows for improved separation efficiency of compounds having a wide range of polarities that may otherwise require a buffer.

When compared to other mass-sensitive detectors such as flame ionization (FID), refractive index (RI), and mass spectrometry (MS), the ELSD can detect analytes without interference from organic modifiers and additives. The use of organic solvents in FID limits usefulness due to an increase in baseline noise, and FID cannot be used with HPLC. RI detectors, in general, are less sensitive than other detectors and are incompatible with gradient elution. Although the MS can be used with modifier gradients, ionization efficiencies can vary over orders of magnitude depending on the solute and mode of ionization. The ELSD is more practical than conventional UV detectors because solutes lacking in UV-absorbing chromophores can be directly detected without any sample derivatization or pretreatment. Baseline disturbances due to absorption of the mobile-phase solvents are not observed with ELSD. However, solvents containing trace levels of impurities and columns with low bleed characteristics must be employed for high-sensitivity work. The ELSD can be optimized to generate a narrow range of response factors to components within a structural class, and the use of appropriate standards would allow for quantitative analysis of these compounds.

Because organic solvent gradients do not interfere with ELSD, the detector is an ideal choice for coupling with SFC. A wide range of SFC–ELSD biomedical and pharmaceutical applications have demonstrated higher sensitivity, shorter analysis times, and better separation efficiencies with SFC than HPLC. Compounds without UV chromophores, such as carbohydrates and ginkgolide extracts, have been reported by Lafosse et al.,[3] Carraud et al.,[4] and Strode et al.,[7] using SFC modifier gradients. More efficient baseline separations of these compounds were achieved by SFC–ELSD than with HPLC, and no time-consuming derivatization steps were necessary. The analysis of triglycerides using SFC–ELSD, which required a polar organic modifier to elute, yielded a significant increase in sensitivity over HPLC–ELSD.[4] Underivatized amino acids were also effectively separated by SFC– ELSD.[3] A more complete review of the various SFC–ELSD interfaces and applications was recently published by Lafosse.[2]

Evaporative light-scattering detection response was found to have an exponential relationship to the mass of the solute by the equation:

$$A = am^b \tag{1}$$

where A is the peak area of the ELSD signal, m is the solute mass, and a and b are constants which depend on the nature of the mobile phase and of the solutes.[8] Because the peak area response is proportional to the amount of solute, a linear response would be more desirable if quantitation of sample components is required. Linearity can be achieved by plotting calibration curves on a log–log scale as in Eq. 2:

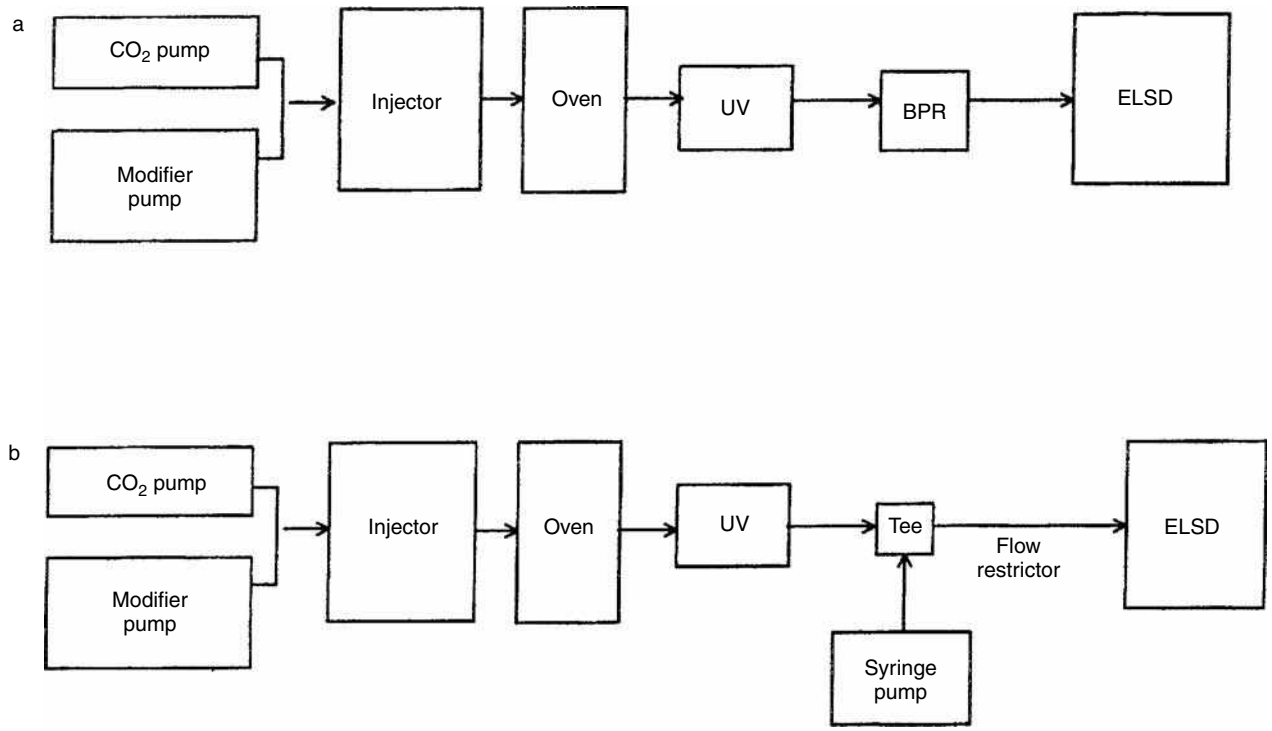

Fig. 1 Two common arrangements for SFC–ELSD coupling: (a) shows pressure control by a back-pressure regulator (BPR), and in (b), the pressure is regulated by a makeup fluid delivered by a pressure-controlled syringe pump.
Source: From Pressure-regulating fluid interface and phase behavior considerations in the coupling of packed-column supercritical fluid chromatography with low-pressure detectors, in J. Chromatogr. A.[12]

$$\log A = b \log m + \log a \quad (2)$$

The ELSD detector response is influenced by the functions of its three main units: the nebulizer, drift tube, and light-scattering cell. As the mobile phase passes through the nebulizer, it becomes dispersed by a flow of carrier gas such as nitrogen and forms an aerosol. The resultant droplets vary in size depending on factors including the flow rate of the nebulizer gas and the geometry of the nebulizer.[6] The droplets then travel through a heated drift tube where the mobile phase is evaporated, leaving behind only unsolvated particles. Upon exiting the drift tube, the solute particles enter a detection chamber and pass through a beam of light from either a polychromatic (tungsten lamp) or a monochromatic (laser) source. The light is scattered and a photomultiplier or photodiode detector, which measures the light intensity, produces a chromatographic signal. Refer to Ref.[1] for a more detailed discussion of the principles of light scattering.

When coupling a low-pressure detector such as the ELSD with SFC, detection takes place at atmospheric pressure, usually downstream of the back-pressure regulator.[2] Fig. 1a shows a common SFC–ELSD interface with downstream pressure control. Factors affecting ELSD response in this configuration include nebulizer design, evaporation conditions, carrier gas flow rate, and the use of makeup fluid.

Most commercial ELSDs employ a standard or modified HPLC nebulizer (Venturi flow type). It was believed that this nebulizer was not necessary for SFC because nebulization of the SFC mobile phase is accomplished by gas expansion in a restrictor which controls pressure and mobile-phase flow rates. To counter the cooling effects of CO_2 decompression in the linear fused-silica restrictor and improve heat transfer, Nizery et al., using a Cunow Clichy Model DDL 10 detector, placed the restrictor tip into a heated brass ring and applied heat to a small section of tubing between the restrictor and the drift tube.[9] They found that baseline noise resulting from the formation of ice crystals decreased and the performance of the ELSD was unaffected.

The droplet sizes formed and the flow rate of the particles in the drift tube are influenced by the design of the nebulizer. In order to maintain a constant nebulization, droplet sizes should not be too large making them difficult to evaporate or too small where solute vaporization could occur. This requires sufficient liquid and a carrier gas (usually nitrogen). Carraud et al., replaced a conventional ELSD nebulizer (Cunow Clichy Model DDL 10) with a short fused-silica restrictor and determined that the ELSD signal response was dependent on the CO_2 flow rate, although this was later disproved.[4]

Larger particle sizes produce higher intensities of scattered light. In order to obtain maximal ELSD sensitivity,

evaporator temperatures must be sufficient to allow for the formation of appropriately sized particles. A loss in sensitivity is observed if temperatures are too high because smaller particles may result from sublimation of some compounds. Upnmoor and Bruner[10] studied the effects of varying evaporator temperature on ELSD sensitivity and found that the optimal range of temperatures was between 40°C and 70°C. At lower temperatures, longer residence times required in the drift tube produced peak broadening as well as an increase in baseline noise.

The flow rate of the carrier gas (usually N_2) influences the residence time of the sample in the light-scattering chamber. Low gas flows may allow solute bands to broaden as they travel in the drift tube to the detector. Strode and Taylor[11] observed a decrease in ELSD signal with an increase in the carrier gas flow rate. However, the increase in gas flow improved peak width compared to that observed with the UV detector. It was later found that the total flow of gas (carrier gas plus the decompressed CO_2) through the detector influenced the signal response and the peak width.[11]

Most SFC–ELSD instruments employ a direct connection of the outlet of a back-pressure regulator to the detector inlet, as outlined in Fig. 1a. By operating in this manner, peak broadening in the transfer line between the back-pressure regulator and the detector may occur. Additionally, the pressure decrease in the transfer line may affect the strength of the mobile phase and, thus, the ability of the solutes to become completely solubilized. Pinkston bypassed the back-pressure regulator with a post-column tee that introduced a makeup fluid such as methanol from a high-pressure syringe pump under pressure control.[12] A fused-silica linear restrictor at the ELSD inlet maintained the pressure and was regulated by the flow of the makeup fluid, as shown in Fig. 1b. Pinkston theorized that this method of pressure control would prevent mass-transfer problems that diminish detector sensitivity and decrease the dependence of the ELSD response on mobile-phase composition.[12] The flow of makeup solvent enhanced the solubility of the analytes in the mobile phase. Additionally, the efficiency of forming appropriately sized particles in the ELSD was improved, generating better peak shapes and higher signal-to-noise ratios.

In conclusion, an ELSD with SFC provides a sensitive analytical tool for qualitative and quantitative analysis of solutes. Detection depends only on the solute being less volatile than the least volatile mobile-phase component. Detection is independent of the basicity or presence of a chromophore for a given solute. The detector response is a logarithmic function of the mass of the solute. The SFC–ELSD combination should be considered whenever a universal high-throughput analysis is needed.

Exclusion Limit in GPC/SEC

Iwao Teraoka
Department of Chemistry, Polytechnic University, Brooklyn, New York, U.S.A.

INTRODUCTION

A given gel permeation chromatography–size-exclusion chromatography (GPC–SEC) column can analyze the molecular weight (MW) of a polymer only over a limited range of MWs. Figure 1 illustrates a typical calibration curve for the column. The logarithm of the MW is plotted as a function of the retention time t_R. At low and high ends of MW, t_R barely depends on MW, effectively limiting the range of analysis to $M_1 < \text{MW} < M_2$. The exclusion limit refers to M_2.

DISCUSSION

The sharp slope of the calibration curve at the high-MW end of the calibration curve is caused by a drastic decline of the partition coefficient as the chain dimension increases beyond the accessible pore size of the column packing material. Polymer chains of MW $> M_2$ have a molecular size dimension which is much greater than the pore size. It is virtually impossible for these chains to enter the stationary-phase pores. Thus, at almost every plate in the column, they are partitioned to the mobile phase, thus eluting with little separation at around the dead time (volume) of the column. By contrast, polymer chains smaller or comparable to the available pore sizes can pentrate the pores to be partitioned to the stationary phase with a partition coefficient which depends on their chain dimensions. The dependence of the partition coefficient on the chain dimension allows polymer chains of different MWs to be separated and elute at different times. Columns packed with porous materials of a larger pore size have greater M_1 and M_2.

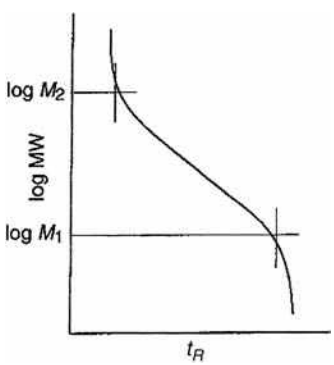

Fig. 1 Calibration curve of GPC–SEC column. Logarithm of the molecular weight, M, is plotted as a function of the retention time (volume) t_R (V_R).

For the high-MW chains that are excluded by the pores, there is a small dependence of t_R (V_R) on MW. The latter is mostly caused by the velocity gradient of the mobile phase and the population gradient of the polymer near the stationary-phase particles' surface. The mobile phase flows more slowly near the particles' surface because of the no-slip boundary condition of the fluid at the particles' surface. Among sufficiently long polymer chains to be excluded by the pore, those with a smaller dimension can more easily approach the particles' surface, compared with those of a greater dimension. Therefore, shorter chains flow more slowly. Longer chains stay away from the particles and flow along the fastest-flowing mobile phase, eluting earlier than other components. This mode of separation is called "hydrodynamic chromatography."

Extra-Column Dispersion

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

In addition to the dispersion that takes place during the normal function of the column, dispersion can also occur in connecting tubes, injection system, and detector sensing volume, and as a result of injecting a finite sample mass and sample volume onto the column.

DISCUSSION

The major sources of extra column dispersion are as follows:

1. Dispersion due to the sample volume (σ_S^2).
2. Dispersion occurring in valve-column and column-detector connecting tubes (σ_T^2).
3. Dispersion in the sensor volume from Newtonian flow (σ_{CF}^2).
4. Dispersion in the sensor volume from peak merging (σ_{CM}^2).
5. Dispersion from the sensor and electronics time constant (σ_t^2).

The sum of the variances will give the overall variance for the extra-column dispersion (σ_E^2). Thus,

$$\sigma_E^2 = \sigma_S^2 + \sigma_T^2 + \sigma_{CF}^2 + \sigma_{CM}^2 + \sigma_t^2 \quad (1)$$

Eq. 1 shows how the various contributions to extra-column dispersion can be combined. According to Klinkenberg,[1] the total extra-column dispersion must not exceed 10% of the column variance if the resolution of the column is not to be seriously denigrated; that is,

$$\sigma_E^2 = \sigma_S^2 + \sigma_T^2 + \sigma_{CF}^2 + \sigma_{CM}^2 + \sigma_t^2 = 0.1\sigma_c^2$$

In practice, σ_T^2, σ_{CF}^2, σ_{CM}^2, and σ_t^2 are all kept to a minimum to allow the largest contribution to extra-column dispersion to come from σ_S^2. This will allow the largest possible sample to be placed on the column, if so desired, to aid in trace analysis. Each extra-column dispersion process can be examined theoretically and two examples will be the evaluation of σ_S^2 and σ_T^2.

MAXIMUM SAMPLE VOLUME

Consider the injection of a sample volume (V_i) that forms a rectangular distribution of solute at the front of the column. The variance of the final peak will be the sum of the variance of the sample volume plus the normal variance from a peak for a small sample. Now, the variance of a rectangular distribution of sample volume (V_1) is $V_i^2/12$, and assuming the peak width is increased by 5% due to the dispersing effect of the sample volume (a 5% increase in standard deviation is approximately equivalent to a 10% increase in peak variance), then by summing the variances,

$$\frac{V_i^2}{12} + [\sqrt{n}(\nu_m + K\nu_s)]^2 = [1.05\sqrt{n}(\nu_m + K\nu_s)]^2$$

where the dispersion due to the column alone is $[\sqrt{n}(\nu_m + K\nu_s)]^2$ (see *Plate Theory*, p. 1829). Simplifying and rearranging,

$$V_i^2 = n(\nu_m + K\nu_s)^2(1.22)$$

Bearing in mind that

$$V_r = n(\nu_m + K\nu_s)$$

then

$$V_i = \frac{1.1V_r}{\sqrt{n}}$$

Thus, the maximum sample volume that can be tolerated can be calculated from the retention volume of the solute concerned and the efficiency of the column. A knowledge of the maximum sample volume can be important when the column efficiency available is only just adequate, and the compounds of interest are minor components that are only partly resolved.

DISPERSION IN CONNECTING TUBES

The column variance is given by V_r^2/n, and for a peak eluted at the dead volume, the variance will be V_0^2/n (see *Plate Theory*, p. 1829). Thus, for a connecting tube of radius r_t and length l_t, the dead volume (V_0) (i.e., the volume of the tube) is

$$V_0 = \pi r_t^2 l_t$$

Thus,

$$\sigma_E^2 = \frac{0.1(\pi r_t^2 l_t)^2}{n}$$

Now, for the dead volume peak from an open tube, $n = 1/0.6r_t$ (see *Open-Tubular Columns: Golay Dispersion Equation*, p. 1635). Thus,

$$\sigma_E^2 = 0.06\pi^2 r_t^5 l_t$$

However, when assessing the length of tube that can be tolerated, it must be remembered that the 10% increase in variance that can be tolerated before resolution is seriously denigrated involves *all* sources of extra-column dispersion, not just for a connecting tube. In practice, the connecting tube should be made as short as possible and the radius as small as possible commensurate with reasonable pressures and the possibility that if the radius is too small, the tube may become blocked. The different sources of extra-column dispersion have been examined in Refs.[2,3]

Extra-Column Volume

Kiyokatsu Jinno
Department of Materials Science, Toyohashi University, Toyohashi, Japan

INTRODUCTION

Three mechanisms produce dispersion of a band of solute in a chromatographic system as it passes through the separation column: 1) eddy diffusion; 2) longitudinal diffusion; and 3) mass transfer effects. These effects are discussed, in some detail, in this entry.

EXTRA-COLUMN BAND BROADENING

Three mechanisms produce dispersion of a band of solute in a chromatographic system as it passes through the separation column.

a. Eddy diffusion and flow dispersion, which is the term for the dispersion produced because of the existence of different flow paths through which solutes can progress through the column. These differences of traveling distance arise because the stationary phase particles have different sizes and shapes, and because the packing of the column is imperfect, causing gaps or voids in the column bed. To reduce dispersion due to the multiple path effect, we need to pack the column with small particles, with as narrow a size distribution as possible.
b. Longitudinal diffusion, which also arises because of diffusion of solute in the longitudinal (axial) direction in the column. This is an important source of dispersion in gas chromatography (GC), but less so in liquid chromatography (LC), because rates of diffusion are very much slower in liquids than they are in gases. This effect becomes more serious the longer the solute species spend in the column; so, unlike flow dispersion, using a rapid flow rate of mobile phase reduces this effect.
c. Mass transfer effects, which arise because the rate of the distribution process (sorption and desorption) of the solute species between mobile and stationary phases may be slow, compared to the rate at which the solute is moving in the mobile phase.

Except for the above general dispersions produced in the separation mechanisms, an unexpected, but important, dispersion can be produced outside the separation column by dead volumes in other parts of the chromatographic system, such as in the injector, the detector, the connecting tubing, and connectors. The combined effect of all of these parts is called "extra-column volume" and the dispersion produced by this volume is called "extra-column dispersion."[1–4] Fig. 1 demonstrates an example of this extra-column dispersion, in which different dead volumes are inserted between the column and the detector. One can see, from this figure, that the effect of extra-column volume can cause a serious loss in separation performance of the chromatographic system.

The variance (the square of the standard deviation) of the observed peak (σ^2) can be expressed as the sum of the peak variances caused only by the contribution of the column ($\sigma_p{}^2$) and all the contributions to the peak broadening due to the extra-column volume ($\sigma_{ex}{}^2$). This is expressed as

$$\sigma^2 = \sigma_p{}^2 + \sigma_{ex}{}^2 \tag{1}$$

Since the peak volume is four times the standard deviation (σ_s), Eq. 1 can be rewritten as

$$V_t{}^2 = V_p{}^2 + V_{ex}{}^2 \tag{2}$$

where V_p is the peak volume obtained only from column contribution and V_{ex} is the extra-column peak volume corresponding to the contributions of the injector, detector

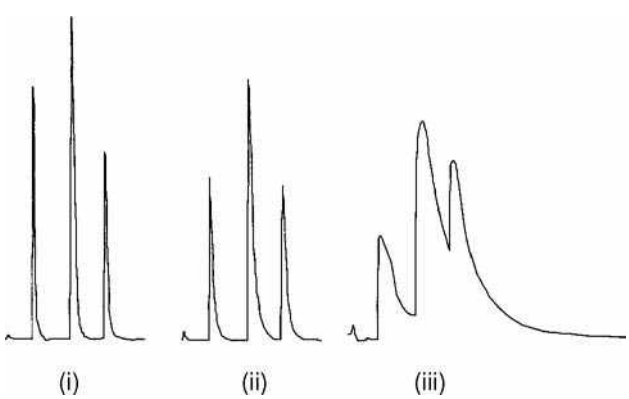

Fig. 1 Extra-column effects on the chromatogram. (i) Normal chromatogram for a test separation; (ii) chromatogram obtained by inserting 75 μl of extra volume between the column and the detector inlet tube; (iii) chromatogram obtained by inserting 2 ml of extra volume between the column and the detector inlet tube.

Table 1 Maximum extra-column peak volumes for peaks eluted by various columns.[a]

	Column type (length, mm; I.D., mm)		
	Conventional (250; 4.6)	**Semi-microcolumn (250; 1.5)**	**Microcolumn (250; 0.5)**
Maximum extra column			
Peak volume (V_{ex}, μl)	53	5.5	0.6
Peak volume (V_p, μl)	116	12	1.4

[a]The above numbers have been estimated by assuming as follows: Column porosity = 0.7; retention factor = 0; and theoretical plate number = 10,000.

cell, and connecting tubing. Dividing Eq. 2 by V_p^2 produces

$$(V_t/V_p)^2 = 1 + (V_{ex}/V_p)^2 \quad (3)$$

Therefore, if the observed peak is allowed to have a volume 10% greater than the column peak volume, the extra-column peak volume should be one-half (~46%) of the column peak volume. Table 1 lists column peak volumes and maximum extra-column peak volumes for various types of columns for LC; because the largest contribution from this extra-column volume should be considered in liquid phase separations, the diffusion coefficients in liquids are very small.

From Table 1, it is very clear that, as the absolute volume of a microcolumn is relatively small, the extra-column volume will contribute significantly to disturb the separation performance of the chromatography system. Because the small extra-column volume is still a large portion of the total system volume which, in turn, is much smaller than the conventional column system, and it is hard to eliminate such small extra-column volume, even if attempts to reduce are applied, a serious problem would be produced. Most typical discussions on the applicability of microcolumn separations in LC are concerned with how to reduce the extra-column volume; this makes microcolumn LC techniques still unpopular, although many advantages are proven and acknowledged. In conclusion, the minimum column volume one can use will depend on the amount of extra-column dispersion and on what we consider to be an acceptable increase in peak width that is produced by the extra-column effects. In practice, this acceptable increase is assumed to be 10%, based on an unretained solute and, if we take 50 μl as a typical value for extra-column dispersion, then the minimum column diameter in LC works out to about 4.6 mm for a column 25 cm long, which is the most popular conventional LC separation column configuration that is commercially available.

Fast GC

Richard C. Striebich
University of Dayton Research Institute, Dayton, Ohio, U.S.A.

INTRODUCTION

The examination of ways to conduct fast gas chromatography (GC) has been a popular research topic since the 1960s, and even more so in the past 10 years. The need to analyze complex mixtures by GC is often a balance between the ability to separate adjacent peaks in a chromatogram (resolution) and analysis time. Especially with complex mixtures, analysts can use longer columns and much slower programing rates to increase resolution; however, there is a penalty to be paid in analysis time. Because petroleum samples are arguably the most complex samples known, a good deal of work has been performed to provide the greatest possible resolution without regard for the consideration of time. Some GC petroleum analyses have been reported, which take 2–4 hr and longer.[1] However, there is a definite application for faster analyses with less resolution.

The history, methods, and applications for conducting fast analyses by GC are delineated in several excellent reviews.[2–6] In these works, the authors discuss several ways to shorten analysis time, such as the following:

1. Decrease the column length.
2. Increase the carrier gas flow rate.
3. Use multichannel columns.[6]
4. Provide rapid heating of the column with heating rates up to 1200°C/min and sometimes higher.[2]

Fast GC in these instances is best described as conducting analyses as fast as is possible to provide just enough separation of the compounds of interest. Oftentimes, in the search for maximum resolution, compounds can be overseparated, which usually lengthens the time of analysis.

OVERVIEW

In petroleum analyses, and specifically for aviation fuels, there are a good many separations where complete resolution is not needed. GC fingerprinting of different types of fuels (diesel, gasoline, aviation fuels, kerosene, etc.) can be performed quickly to characterize the mixtures in useful ways. Simulated distillation[1] is one good example of a chromatographic analysis that has low resolution, but can be conducted very quickly, (i.e., $\ll$ 5 min). Fortunately, excellent resolution is not usually necessary to obtain the critical information about distillation range,[7] and so this application is a good example of fast GC where limited resolution is acceptable. In this entry, we introduce simple fast GC concepts that can speed up the low-resolution analysis of petroleum products.

EXPERIMENTAL

Short (3–7 m) microbore gas chromatographic columns (0.10 mm internal diameter, 0.17 μm film thickness) can be used to provide much faster analyses with acceptable resolution for at least two different types of useful analyses: *fuel GC fingerprinting* and *simulated distillation analysis*. The detector for the instrument used for these analyses is a hydrogen flame ionization detector (FID) capable of very fast sampling rates (adjustable up to 200 Hz), which is necessary because of the narrow peaks that are generated. Carrier gas is one of the parameters investigated; both helium and hydrogen carrier gases were used, with high-pressure hydrogen routinely providing the best and fastest separations (in agreement with previous work and theory). In this work, the programing rates were limited to that which was available using an Agilent 6890 instrument with a fast heating option (i.e., input rates to 120°C/min with trackable rates to approximately 75°C/min). No attempts were made to increase programing rate by resistively heating the column.

RESULTS AND DISCUSSION

Analysis of aviation fuels by capillary GC can be performed using a variable level of resolution (peak separation) by changing the conditions of the GC. For the purposes of this work, the approximate resolution required was that obtained with conventional methods. That is, an experiment that is completed in 20–30 min is typical because it is fast enough to be productive with regard to research and testing, and provides enough resolution to obtain the needed useful information. In addition to this level of resolution, we briefly examined the output of a GC analysis conducted using a column of 50 μm internal diameter, half the diameter of typical fast GC columns. These conditions represent our laboratory's (present-day) limit of speed and resolving power (Fig. 1).

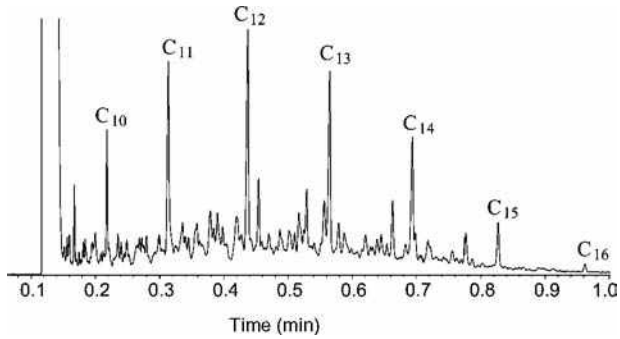

Fig. 1 Fast GC analysis of aviation turbine engine fuel using a typical laboratory GC instrument. Conditions: hydrogen carrier gas; temperature programming rate, 70–170°C at 120°C/min (actual 75°C/min); microbore column: 3 m × 0.10 mm I.D.

Effect of Column Dimensions

Table 1 shows a comparison of the general relationship that exists between GC efficiency as measured by the number of theoretical plates per meter and a particular column dimension. Because microbore columns (0.10 mm internal diameter) have more resolving power per meter, the length of these columns can be typically one third the length of standard bore columns (0.25 mm internal diameter) and still provide approximately the same resolution. Thus fast GC is really faster because of the use of shorter columns, which are more efficient because of their smaller inner diameter. Fig. 2a shows a typical high-resolution analysis using a conventional 30-m column (0.25 mm internal diameter) and a fast chromatogram with similar resolution, but with greatly reduced time. Changing column diameter and length is one of the easiest ways to decrease analysis times, but it is not without a price. Usually, this cost is in decreased column capacity (mass of solute chromatographed without overloading), or in the need to increase carrier head pressure.[4,6]

Effect of Carrier Gas

The widely accepted carrier gas for fast GC analyses is hydrogen, whereas in the United States, helium is the usual choice for conventional analyses. The use of hydrogen is typically better because faster optimal linear velocities are possible at the same generated resolution. Column efficiency is usually expressed in terms of *H* (i.e., the height equivalent of a theoretical plate, which, when minimized, expresses an optimal efficiency of separation between two components). By plotting the average velocity of the carrier gas vs. the *H* value, a van Deemter plot is generated. The optimal velocity of the carrier gas for the most efficient separation is higher for hydrogen carrier gas. Thus hydrogen can operate at higher carrier gas velocities without loss of resolution. Although helium carrier gas can be used above its optimal velocity, significant resolution decreases will occur at high flow rates.

Table 1 Chromatographic column diameter vs. efficiency.

Column internal diameter (I.D.) [mm]	Theoretical plates per meter
0.10	12,500
0.18	6,600
0.20	5,940
0.25[a]	4,750
0.32	3,710
0.45	2,640
0.53	2,240

[a]Most typically used in our laboratory.
Source: From *GC Reference Guide*.[8]

Because the van Deemter plot for hydrogen is flatter for higher velocities than it is for helium, less resolution is lost with higher velocities of hydrogen, compared to helium.

Effect of Temperature Programing

The ability to quickly ramp column temperature is an excellent way to increase analysis speed, given appropriate carrier gas flow rates and fast detector sampling rates. Along with column dimensions and operation above optimal velocities of hydrogen carrier gas, analyses can be performed extremely fast and with high resolution. Temperature programing for all of the experiments shown was at 70°C/min, which was approximately the fastest rate that the GC oven could reasonably track. Temperature programing rates of up to 120°C/min are possible to input into the GC, but the heaters cannot reliably heat the large oven at this rate. Clearly, faster temperature programs, using resistively heated columns and sheaths,[2] would lead to faster analyses. However,

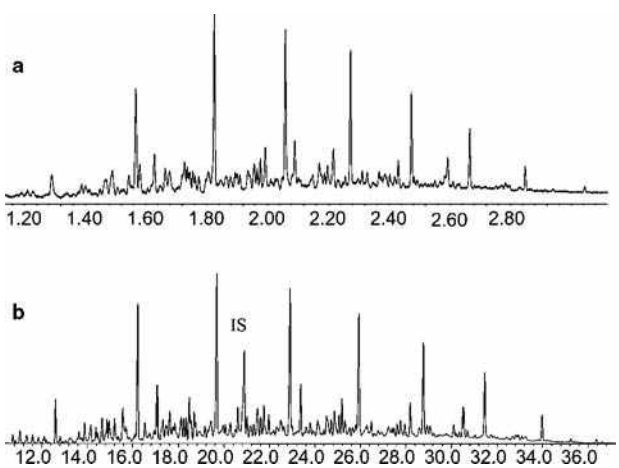

Fig. 2 Comparison of conventional 3 m × 0.25 mm I.D. (standard bore) column (b) with a 10 m × 0.10 mm I.D. column (a) with similar resolution.

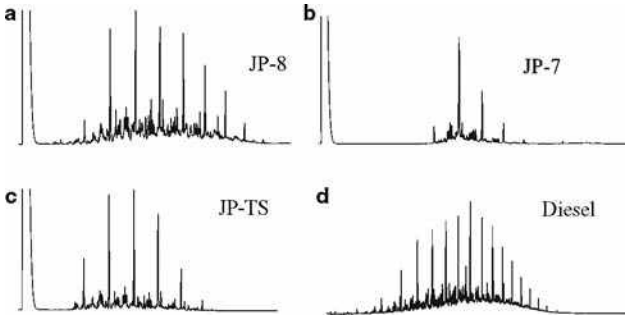

Fig. 3 Fast GC analysis of four fuels including (a) JP-8, (b) JP-7, (c) JP-TS, and (d) diesel fuel.

resolution is sacrificed if the column is heated so fast that large portions of the column act as a transfer line for GC solutes, whose boiling points have been exceeded too quickly. It is difficult to balance speed and accuracy with mixtures with wide boiling range.

APPLICATIONS

Fuel samples were examined using conditions similar to those used in this study, with 100 μm capillary columns and conventional GC instrumentation (Agilent 6890). Jet fuels are more of an analytical challenge because of their multicomponent nature; indeed, any analysis of jet fuel probably contains many unresolved solute zones. Enough chromatographic separation must be generated to conduct the particular task of the analysis, but must also be balanced with acceptable speed. The following applications show separations of various mixtures conducted with speed as the primary consideration.

Fuel GC Fingerprinting

Fig. 3 shows four examples of fuel "fingerprinting"; the normal alkane distribution helps to indicate the fuel type.

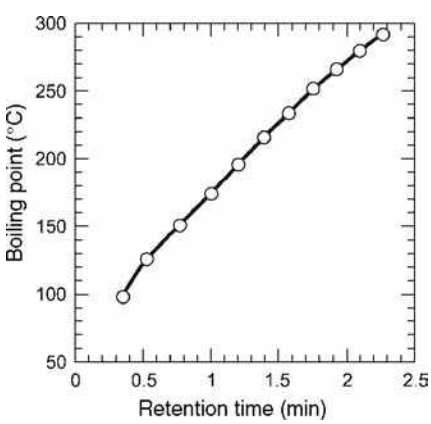

Fig. 4 Calibration curve for simulated distillation of JP-8, JP-TS, and JP-7.

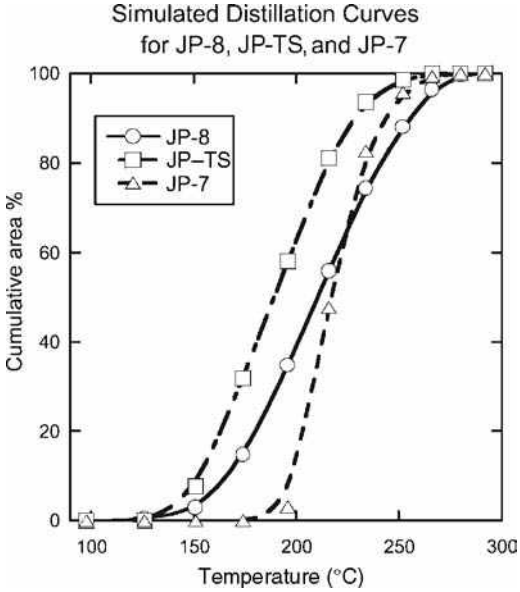

Fig. 5 Simulated distillation analysis of JP-8, JP-TS, and JP-7.

Because of the high resolution in this example, it is possible to obtain useful information from the chromatogram and to be able to compare this output tracing to those generated by other fuels. In many cases of fuel contamination, mixing of fuels, mislabeling of containers, and other commonly encountered problems, it is necessary to perform a "general pattern recognition" to identify or characterize the fuel.

Simulated Distillation

By conducting a calibration curve based on the boiling points of *n*-alkanes, it is possible to estimate the distillation temperatures according to the ASTM D2887 method.[9] Figs. 4 and 5 show the calibration and the simulated distillation curves, respectively, for JP-8, JP-TS, and JP-7, which were obtained from the fast GC analyses. These analyses are directly comparable to fuel specification tests for distillation range. Even analyses faster than these are possible because simulated distillation is a technique where very low resolution is required and generated. Relatively high resolution was maintained for these runs because the chromatographic data were correlated to other specification properties, such as freeze point and flash point.[7]

CONCLUSIONS

Fast GC has great potential as a highly productive investigative tool in today's analytical laboratory. It is becoming more widely used as more advanced GC systems are introduced. We have shown applications of GC analyses with acceptable resolution for aviation fuels, analyzed in fewer than 5 min. The speed of analysis may eventually improve

to the point where the GC could produce jet fuel analyses in much less than 1 min.

ACKNOWLEDGMENTS

This work was partially supported by the Fuels Branch of the Air Force Research Laboratory, Propulsion Sciences and Advanced Concepts Division, AFRL/PRSF under the program entitled "Advanced Integrated Fuel/Combustion System" (contract no. F33615-97-C-2719). Mr. Robert Morris was the technical monitor.

Fatty Acids: GC Analysis

Susana Casal
Beatriz Oliveira
Requimte, Bromatology Service, Faculty of Pharmacy, University of Porto, Porto, Portugal

Abstract
Fatty acids (FAs) are key molecules in living organisms. Gas chromatography (GC) is the most common analytical tool in fatty acid analysis, with broad applications in nutritional, biochemical, biomedical, microbiological, and agricultural fields. While the volatile short-chain FAs can be analyzed directly, for most samples the use of derivatives, mainly methyl esters (FAMEs), is mandatory. Several reagents can be used directly on the sample or, more commonly, on their lipid extracts. Depending on the type of the chromatographic column, different information can be retrieved. In medium polar columns (carbowax type) the FAs elute in a predictable order determined by their carbon chain length and the number of double bonds. The highly polar cyanosilicone phases allow the separation of polar compounds with close boiling points, like geometrical or positional isomers. Although flame ionization detection (FID) has proven to be a robust tool, it lacks selectivity, of special concern in misidentifications. Mass spectrometry (MS) is becoming increasingly popular, being essential in the recent two-dimensional gas chromatographic methods.

INTRODUCTION

Analysis of fatty acids (FAs) may be required for a variety of reasons. It may be important in food process control, quality assurance, detection of adulteration, or for regulatory reasons such as labeling. In the biological field, information on the FA composition in blood and tissues may be important for nutritional and health reasons—especially for FAs of functional significance (e.g., long-chain omega-3 acids)—or for the diagnosis of some metabolic diseases.

Depending on the situation, FA analysis might be used to generate a profile where all FAs are expressed as a weight percentage of the total FAs, as is usual in food characterization, or for the quantification of each FA in units of milligrams per gram. Food labeling requirements, for instance, can be limited to the saturated and *trans* FAs or can also include monounsaturated and polyunsaturated groups. This last fraction may be broken down further into total omega-6 and omega-3 with the latter detailed into individual FAs: docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA), and α-linolenic acid (ALA). Irrespective of the details, all these labels would require a FA profile to be obtained by a suitable chromatographic technique.

Capillary chromatography is by far the most common analytical tool in the analysis of FAs in food and other matrices, mainly as their methyl esters (FAMEs). The purpose of this entry is to provide some insights into this methodology, mainly for those initiating their work in this area. The reasons behind its popularity and the details involved in the process, as well as its main applications, will be discussed here. There is insufficient room in this entry to address all related details, but important reviews will be identified for those who might be interested.

FA CHEMISTRY

FAs constitute a wide range of molecules, ubiquitous in biological systems, occurring as components of virtually all lipids. They are found as esters of glycerol in triacylglycerides (>90%), diacylglycerides, and monoacylglycerides; as esters of other polar lipids such as lecithin; as sterol esters, esterified with natural aliphatic alcohols in waxes; and as free FAs (up to 1%). They are important sources of energy, as well as structural components of cell membranes, signaling molecules, and precursors of eicosanoids (EPA and arachidonic acid). Special attention is usually devoted to the essential FAs, linoleic and ALA, whose presence in food is of great importance.[1]

Chemically, FAs are aliphatic carboxylic acids, comprising an alkyl (hydrocarbon) chain with a methyl group at one end and a carboxylic group at the other. They can be grouped according to chain length, the number of double bonds (i.e., degree of unsaturation), its position and configuration, and the occurrence of additional functional groups along the chain. More than 400 FAs are known, occurring naturally or synthesized in the laboratory, but only a few of them are quantitatively important; they represent about 95% of the total FAs present in food lipids for human or animal consumption.[1] Indeed, most papers usually report only a dozen FAs, and less than 30 are present in most analytical standards. Recent gas chromatographic techniques, however, are able to identify more than 100 FAs in a single drop of blood.[2]

The major FAs comprise saturated, monounsaturated, and polyunsaturated ones, according to their chemical structures and properties. Most of them are unbranched and contain an even number of carbon atoms. Odd carbon number FAs are less common and are almost restricted to animal food of ruminant origin, namely milk, cheese, and meat, usually in trace amounts. Although rare in plant lipids, branched-chain acids are the major components of Gram-positive bacteria lipids. Small amounts of branched *iso* and *anteiso* FAs also occur in animal fats, waxes, and marine oils.

FA nomenclature is a complex issue. Their systematic names are rather extensive, and the trivial names, when existent, are often difficult to associate with the correspondent FA. In shorthand notations, the chain length (*c*) and the number of double bonds (*d*) is usually simplified to *c*:*d* but it does not specify the double-bond positions. The Greek letters Δ (delta) and ω (omega) are frequently used for this complementary purpose. Delta, followed by a numeral or numerals (Δ*x*,*y*), is used to allocate the position of one or more double bonds in the hydrocarbon chain, counting from the carboxyl group. Omega (ω) is used to indicate how far a double bond is from the terminal methyl group, irrespective of the chain length. The "*n*-*x*" system (*n*-minus) is analogous to the "ω" naming system. The omega terminology is usually used by biochemists/nutritionists, because it enhances the structural relationship between the different biosynthetic families and also because of the attention currently paid to the omega-3 fatty acids. This system is now superseding the classical one traditionally used by food chemists.

In nature, the monounsaturated (MUFA) and polyunsaturated FA (PUFA) double bonds are commonly in the *cis* (*c*-) or *E*-configuration, each being separated from the next by a methylene group (non-conjugated FAs). Therefore, unless otherwise indicated, the double bond is in the *cis* configuration. Whenever a *trans*-bond is present, it is indicated by an additional *trans*, "*t*-," or "*Z*-."

Detailed information regarding the formulas and molecular structures of different FAs is likely to be found in recent specialized chemical or biochemical books. Some of the more important FAs, their structures, systematic and trivial names, as well as their main sources, are summarized in Table 1.

GAS–LIQUID CHROMATOGRAPHY

Gas–liquid chromatography (GLC), or gas chromatography (GC), was first developed by lipid analysts. From its beginning more than 60 years ago, the instrumentation has become more sophisticated and accurate with the development of new detectors, capillary columns, temperature and pressure programming, etc. Many reviews and books detail these developments. Among the more comprehensive ones are the several books published by Dr. William W. Christie and his regularly updated website Lipid Library,[3] whose reading is recommended to all beginners in this field, as well as to those seeking answers to analysis problems.

Nowadays most gas chromatographs have similar configuration. In the injector category, the split–splitless is the most frequently used one with reproducible results, but particular attention should be paid when analyzing volatile FAs, because there is some discrimination in the usual split injectors. Hydrogen and helium are both efficient for FA separation but, while the former gives the best separation results and is less expensive, the latter is much safer and will resolve most situations. Detection in routine analysis is usually performed with a flame ionization detector (FID) that responds to non-oxidized carbon in a linear relationship. However, the carboxyl carbon is not appreciably ionized during combustion and, for maximum precision, the response factor must be known or calculated to correct the experimental data. These corrections are of particular importance for quantitative analysis. The correction factors are easily estimated from the ratio of known proportions of standards to the detected peak areas.

The analysis of FAs by GC in their free form is practically restricted to the volatile short chains (less than 10 carbons) present in lipid extracts, such as in milk fat, and cheese samples. For most FA mixtures, the use of ester derivatives, mainly methyl esters, is recommended. These esters are more volatile than the corresponding free FAs and, therefore, more suitable for analysis by GC in the gaseous form. They are also less polar, thereby reducing their adsorption onto the support and dimerization in the vapor phase with subsequent reduction in peak tailing and/or ghosting, improved peak shape, and resolution.

DERIVATIZATION OF FAs

Fatty acid methyl esters (FAMEs), esterified in the carboxylic group, are by far the most widely used derivatives. The boiling points of the methyl esters are markedly lower than those of the free FAs, being also more soluble in organic solvents. Several methods have been proposed for their preparation, based on the presence of free FAs, short-chain FAs, or highly PUFA.

During the transesterification process, the esterified FAs react with methanol, in the presence of a strong acidic or basic catalyst, producing a mixture of FAMEs and glycerol (Fig. 1). The reaction is reversible, but an excess of the alcohol is used to increase the yields of the methyl esters and to allow their phase separation from the released glycerol. Most FAs, including long-chain PUFA, can be treated with acidic or alkaline reagents with no adverse effects. However, some FAs, including conjugated linoleic acids (CLAs), form artifacts with acidic reagents. Also, for the derivatization of FAs containing epoxy, hydroperoxy, cycloprophenyl, and cyclopropyl groups, specific procedures have been developed.

Methylation is usually performed on lipids isolated from the matrix by several classical methodologies, but it

Table 1 Nomenclature of the most common fatty acids and their major sources.

can also be performed by a one-step procedure combining lipid extraction and transesterification directly on small amounts of dried sample.

Acid-Catalyzed Transesterification

Acidic reagents, including hydrochloric acid, sulfuric acid, boron trifluoride (Lewis acid), and acetyl chloride in methanol, catalyze the formation of methyl esters from both esterified FAs (the form in which FAs are normally found) and free FAs (normally present only in small amounts, but formed when samples are subjected to hydrolytic treatments) when heated with a large excess of anhydrous methanol.

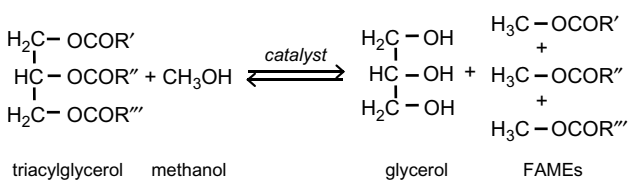

Fig. 1 Transesterification of triacylglycerols.

Acetyl chloride (5% in methanol) is often the preferred choice for samples containing sensitive FAs or when unknown substances are present in the samples. Usually, the lipids are dissolved in the reagent and heated overnight at 50°C, or for 2 hr at 80°C. Methyl esters are then extracted twice with an appropriate solvent, and the extract is further washed for removing acidity.

Boron trifluoride (12–14% in methanol) is probably the more frequently described derivatization agent in the literature for FAs methylation; it is recommended by several official institutions such as American Organization of

Analytical Chemists (AOAC) and by the ISO standards.[4,5] Special attention should be given to its toxicity. In the initial procedure, as described by Morrison and Smith,[6] the reagent is added directly to the lipid extract (about 10 mg) and heated for different periods depending on the FA's form (free or conjugated). Currently, this reagent is more frequently used after the saponification of glycerides and phospholipids with methanolic NaOH or KOH, as described in the official standards. Nevertheless, several authors have claimed the formation of artifacts and loss of PUFA with this reagent. It should be noted, for instance, that the use of old reagents or solutions that are too concentrated must be avoided.[3]

Base-Catalyzed Transesterification

Base-catalyzed transesterification proceeds faster than the acid-catalyzed reaction and requires lower temperatures. For this reason, combined with the fact that the alkaline catalysts are less corrosive than acidic compounds and lead to the formation of fewer artifacts, they are more frequently used. This type of catalysis is also recommended for samples containing short-chain FAs or labile FAs (polyunsaturated, conjugated unsaturations).

The first step is the reaction of the base with methanol, producing a methoxide and the protonated catalyst. The nucleophilic attack of the methoxide at the carbonyl group of the triglyceride liberates the methyl ester and the diglyceride, starting another cycle until all methyl esters are formed and glycerol released. Free FAs are not susceptible to nucleophilic attack by alcohols or bases and, thus, are not esterified under these conditions. Therefore, samples containing free FAs should be methylated by other methods. Absence of water must be guaranteed; otherwise, free FAs will be formed by hydrolysis.

Sodium methoxide (1–2 *M* in anhydrous methanol) is probably the most useful basic transesterifying agent. It can be prepared in the laboratory, with adequate precautions, simply by dissolving clean sodium in dry methanol, and it is stable for several months at 4°C. Glycerolipids are rapidly transesterified (2–5 min) at room temperature.

The simplest methylation method uses KOH (2 *M* in methanol). It is recommended, for instance, in the analysis of vegetable oils or virgin olive oil with reduced acidity (small amounts of free acids) by several European standards. The reaction is rapid and occurs at room temperature. It must be pointed out that sterol esters and waxes, as well as free FAs, do not react under these conditions, as mentioned earlier.

Other FA Derivatives

The *tert*-butyldimethylsilyl (tBDMSi) derivatives have high thermal and hydrolytic stability and improved sensitivity (two- to sixfold) when compared to the methyl esters, being adequate for samples with very small lipid amounts. Their stability, however, is limited to about three days.[7]

In cyanomethyl derivatization, particularly suited for use with the nitrogen–phosphorus detector, cyanomethyl esters are formed by alkylation of the carboxyl group ($R–COO–CH_2–CN$). The method is rapid, inexpensive, and is resistant to contaminants frequently found during the chromatographic separation of very-long-chain FAs.[8]

GC COLUMNS

The flexible fused silica columns have been commercially available for over three decades and allow substantial improvements in the separation of FAMEs, especially from oil samples rich in PUFAs, such as fish oil. Nevertheless, for some simple work, packed columns are still quite effective. The stationary phases for GC FAME analysis are almost exclusively polar polyesters. These are usually classified according to their degree of polarity, and usually only two main types are used: those with medium polarity such as the carbowax type [polyethylene glycol (PEG) under various trade names] and those with high polarity, with cyanopropil polysiloxane stationary phases, such as HP-88, CP-Sil88, BPX70, SP-2340, or SP-2560.[9]

To prevent misidentification of FAMEs, the GC column used should elute the compounds primarily by carbon chain length and next by the number of double bonds. There should be minimal overlap in the elution order among FAMEs having different chain lengths. This situation is fully accomplished by the PEG-phase capillary columns that are able to resolve these compounds with little or no overlap in the elution order of FAMEs of different carbon chain lengths. Complex FAME mixtures, with chain lengths up to 24 carbons and up to 6 double bonds, including all omega-3 and omega-6 fatty acids, can be separated on capillary columns of medium polarity and length.

Fig. 2 represents the chromatogram of a standard mixture of FAMEs eluted on a Carbowax-type column. For many samples, this type of column may be all that is required and should be the first column to buy for general FA analysis. Carbowax-type columns (Carbowax-20M, CP-Wax 52CB, DB-Wax, etc.) with dimensions of 25–30 m length and 0.25 mm I.D., and a film thickness of 0.2 μm, are preferred because of their stability and the predictable order in which all compounds elute. In fact, all FAMEs of a given chain length elute before those that are two carbons longer, the only exception being that 22:6 elutes between 24:0 and 24:1. Double-bond positional isomers are also separated, with the isomer with double bonds nearer to the ester group eluting first.

The high polarity of the cyanosilicone phases allows separation of polar compounds with close boiling points, like geometrical groups (*cis*, *trans*) or positional isomers, and complex samples such as polyunsaturated marine oils, being essential for the analysis of *trans* FAs and conjugated linoleic acid (CLA) isomers. As the separation on these phases is dependent on both polar interactions and boiling

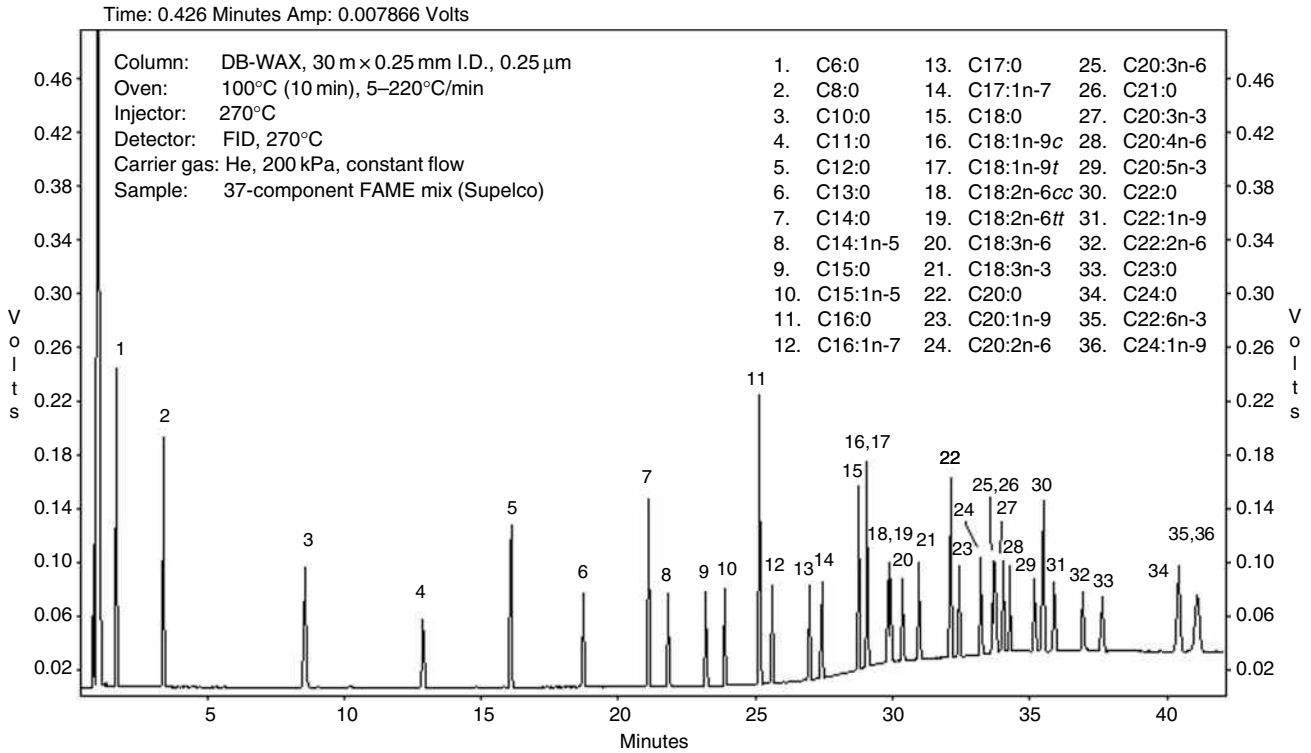

Fig. 2 Chromatogram of a standard mixture of fatty acid methyl esters (FAMEs) eluted on a 30 m DB-Wax column.

point, there is crossover in the elution sequence among FAMEs of different chain lengths and degrees of unsaturation. Also, a small alteration in the temperature program might induce alterations in the elution order, requiring special attention to avoid misidentifications. Fig. 3 represents the chromatogram of a standard mixture of 41 FAMEs

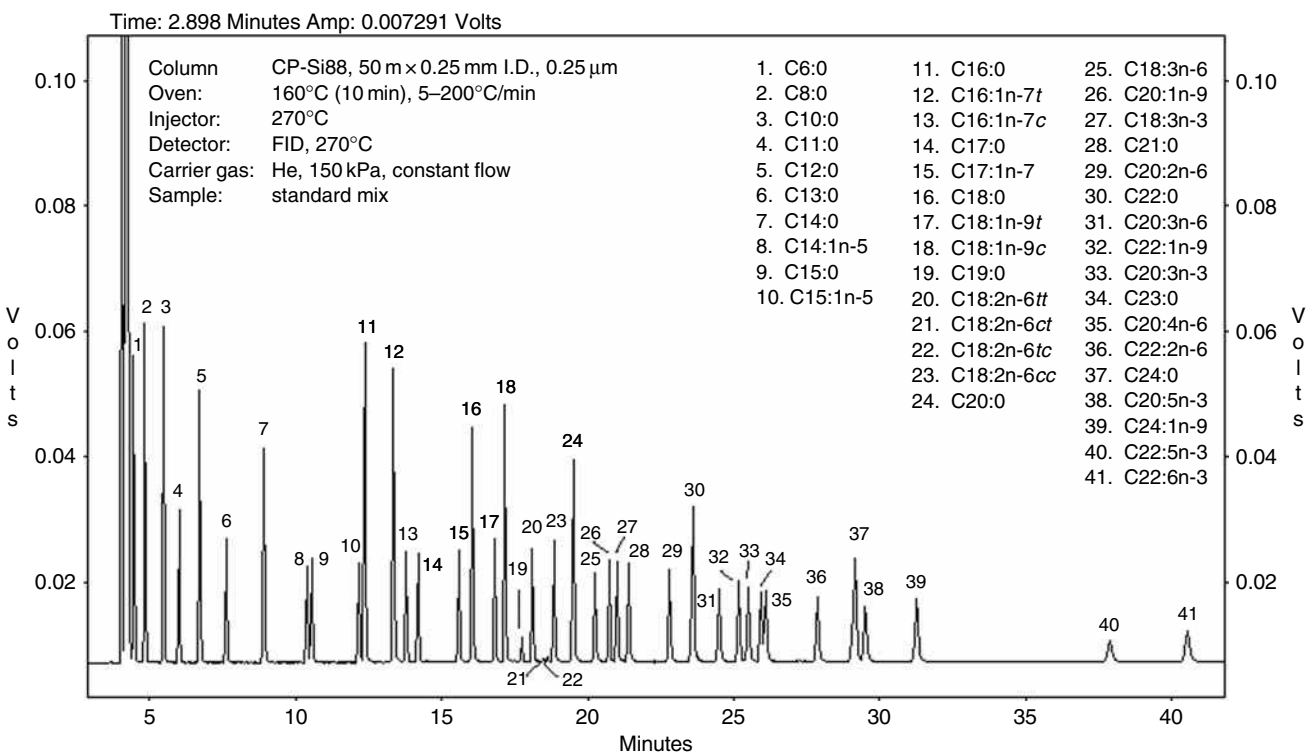

Fig. 3 Chromatogram of a standard mixture of fatty acid methyl esters (FAMEs) eluted on a 50 m CP-Sil88 column.

eluted on a 50 m CP-Sil88 column, where the separation of the *cis–trans* isomers is evident (see peaks 17 and 18, and 20–23). Nowadays, for most food FAs analyses, these polar columns are increasingly being selected because they provide simultaneous information on all the FA classes required for nutritional label, i.e., saturated, monounsaturated, polyunsaturated, together with *trans* fatty acids.

The non-polar phases, usually silicone liquid phases, are seldom used for FA analysis. Despite their high stability at high temperatures and low bleeding, separation occurs primarily on the basis of the boiling points of the FAMEs. For acids of each chain length, the unsaturated compounds elute before the saturated ones, but there is considerable overlap among unsaturated acids of the same chains length, with 18:1, 18:2, and 18:3 practically coeluting.

Irrespective of the column choice, bounded phases are recommended because they allow rinsing to remove contaminant material, besides presenting higher thermal stability and lower bleeding.

QUALITATIVE AND QUANTITATIVE ANALYSIS OF FAs

Qualitative Analysis

The number of individual FAs will vary greatly depending on sample complexity. Although less than 20 FAs are of importance in vegetable oils, the FA profile of a fish oil, for instance, is reasonably complex because of the range of chain lengths, degrees of unsaturation, and the presence of positional isomers. The additional presence of a partially hydrogenated vegetable oil (containing *trans* fatty acids), coconut or palm kernel oil (containing short-chain acids), or butterfat (containing *trans* fatty acids, short-chain acids, branched-chain FAs, and CLA), for instance, would complicate the mixture further. Indeed, in some cases, two different columns (varying in the type of chemical phase, length, internal diameter, and phase thickness) may be necessary to separate all the components in the sample.

Identification of the FAs can be achieved, more or less accurately, with conventional methods or, more acceptably, with mass spectrometry (MS). The conventional methods are based on comparison between the retention times of the components to be identified with those of known FAs in a synthetic or natural mixture. It is convenient to use commercially available standard mixtures of saturated, and mono- and polyunsaturated FAMEs (from Sigma, Matreya, Nu-Chek-Prep, Larodan, etc.). In their absence, natural lipid extracts are also useful. A good start can be made with the methylation of peanut oil, because it contains the most common FAs (16:0, 18:0, 18:1, 18:2) together with several long-chain saturated FAs (20:0, 22:0, 24:0) (Fig. 4). For the analysis of complex marine oils, the use of FAMEs, prepared from cod liver oil or salmon oil containing very different highly polyunsaturated *n*-3 fatty acids, is

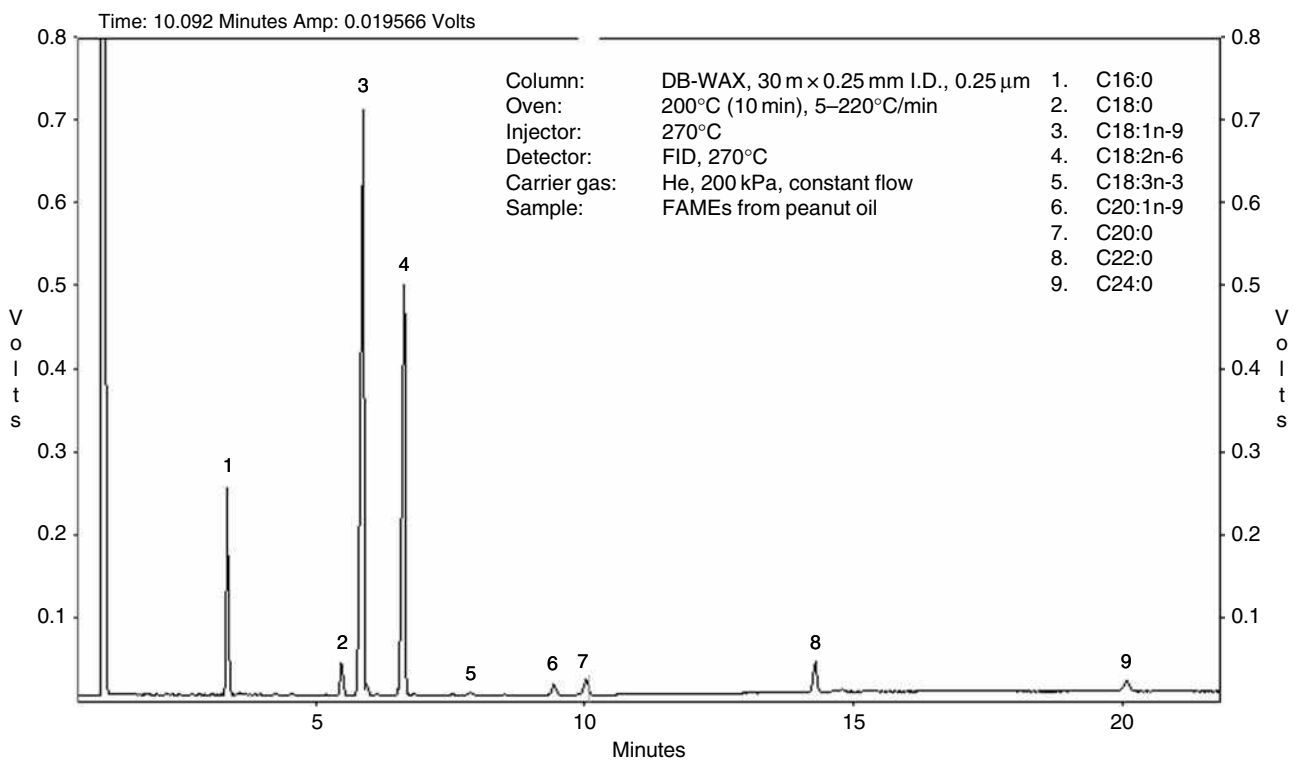

Fig. 4 Chromatogram of refined peanut oil fatty acid methyl esters (FAMEs) eluted on a 30 m DB-Wax column.

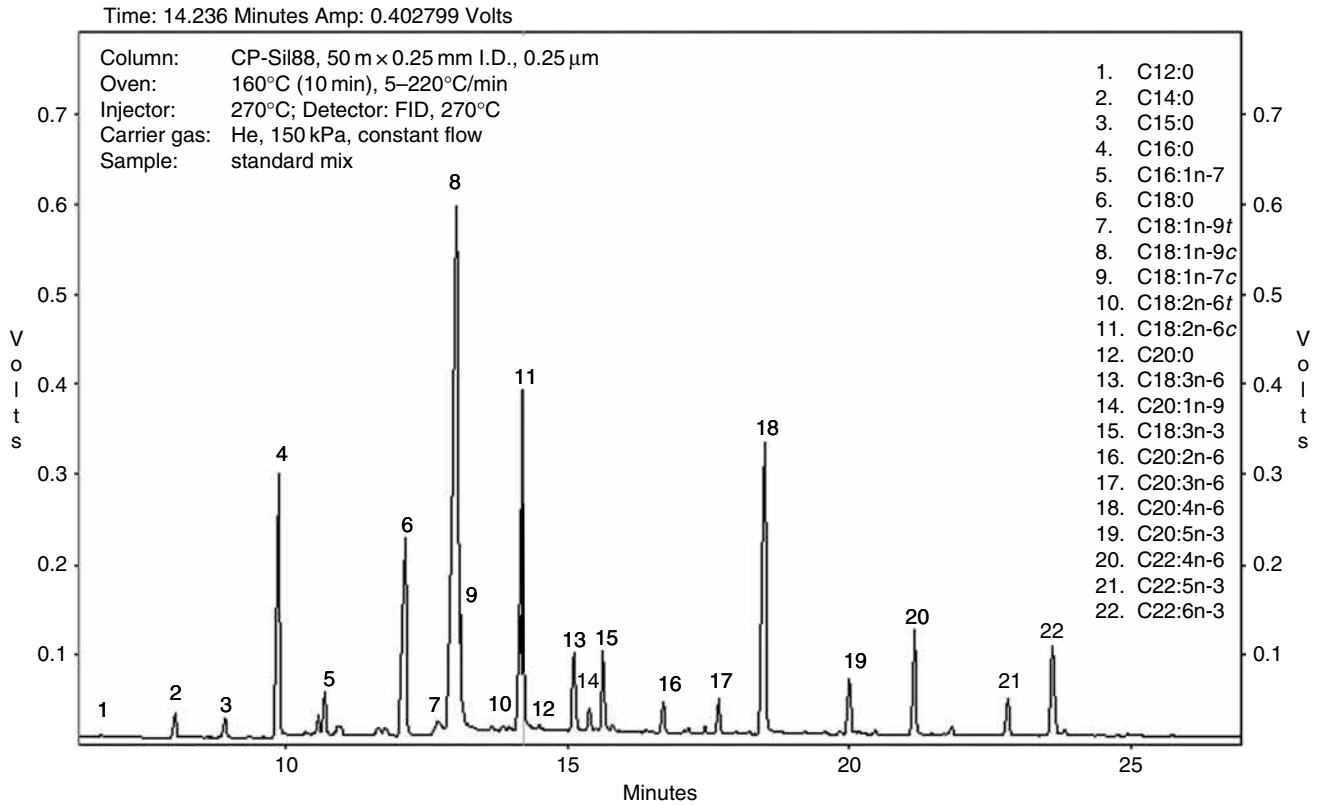

Fig. 5 Chromatogram of a commercial sample of animal origin (PUFA-2, from Supelco) eluted on a 50 m CP-Sil88 column.

recommended. Several natural mixtures from animal sources are also commercialized (Fig. 5). The qualitative composition of these samples has been well established, and they generally contain a wider range of FAs than do synthetic mixtures. Reference lipid samples of animal and vegetable origin may be procured from several official institutions.

In practice, it is convenient to base the identification not exclusively on retention time, which is temperature and gas flow rate dependent, but on relative retention times of FAs commonly occurring in nature, namely, palmitic acid (16:0) or stearic acid (18:0). The relative values can also be used to tentatively identify unknown acids if analysis is carried out under the same isothermal conditions.

Another means of identifying FAs of a homologous series is to use a well-known property of their elution under isothermal conditions: the linear relationship between the number of carbons in the aliphatic chain and the logarithms of the corrected retention times. The same linear relationship exists between a homologous series of *cis*-monoenes, dienes, trienes, etc. but attention must be paid to the fact that the retention times depends on the positions of the double bonds. This may be of some help in tentatively identifying unknown components. However, it does not offer any certainty and cannot be utilized in temperature-programmed analyses of mixtures comprising a wide range of FAs, differing both in chain length and in the degree of unsaturation.

Alternatively, the identification of FAMEs is possible using the concept of equivalent chain length (ECL), by expressing their elution positions relative to those of known straight-chain saturated FAMEs, under isothermal conditions. Details for the calculation of ECL and tables for a large number of FAMEs are available in specialized reports.[10] Recently a method was developed that allows this identification with temperature and pressure programming on a single capillary column.[11]

Quantitative Analysis

The quantification of FAs can be expressed in different forms, depending on the accuracy of the analysis in question.

Normalization

In most analyses, each FAME can be expressed as a weight percentage of the total FAMEs represented in the chromatogram. The areas under the GC peaks are approximately equivalent to the masses of the FAMEs they represent. Therefore, the area percentage of each peak (as a

percentage of the total areas of all FAME peaks) is approximately equal to the weight percentage of each FAME. This response represents a close approximation of weight percentage for simple vegetable oils, but is only an approximation.

In the simplest case, the percentage by weight of each component, expressed as methyl ester, is calculated by:

$$\%A = 100 \times \frac{\text{Area A}}{\text{Sum of all peaks' areas}} \quad (1)$$

However, with this approach, the longer- and the shorter-chain FAMEs are, respectively, overestimated and underestimated, because there is no exact linearity of the detector response to the FA mass. The response of the detector should be checked with a calibrated standard mixture. This correction is more important in studies concerning highly unsaturated FAs, high amounts of short-chain FAs, FAs with large differences in molecular weights, or even the presence of FAs with secondary groups. In these cases, correction factors must be used to convert peak areas into weight percentages. The area percentages are multiplied by a theoretical response correction factor (tables are published, e.g., Christie[9]), and are renormalized to give the true weight percentages. The corrections will only make small differences for chain lengths C_{14}–C_{24}, but will make significant differences for shorter chain lengths. These factors can easily be determined by analyzing known reference standard mixtures of methyl esters under chromatographic conditions identical to those of the sample.

One must also intend to express the results in FA percentages instead of FAME percentages. In such situations, the response factors should also consider the conversion of the methyl esters to the free acids based on their molecular weights. Furthermore, total fat is the sum of FAs from all sources, expressed as triglycerides. Thus, expressing the measured FAs as triglycerides requires the mathematical equivalent of condensing each of the three FAs with one glycerol.

It should also be noted that even these normalized peaks may still not be representative of the weight content of FAs in the sample. Some lipid samples can contain other forms of FAs that will not appear in the chromatographic run, such as polymerized FAs, making the FA proportions incorrect. Therefore, an internal standard should be used in critical cases, to give the sample content of a particular FA in absolute amounts (milligrams per gram of the sample). The use of suitable internal standards will also prevent one disadvantage of area normalization: error propagation (i.e., if one FA is wrongly estimated, or omitted when unknown, the results for the others are also affected).

In biochemical studies, however, the results should be expressed as a molar percentage, because it expresses the relative number of molecules of each type of acid, or glyceride component, present in a fat. The difference between the two modes of expression becomes especially

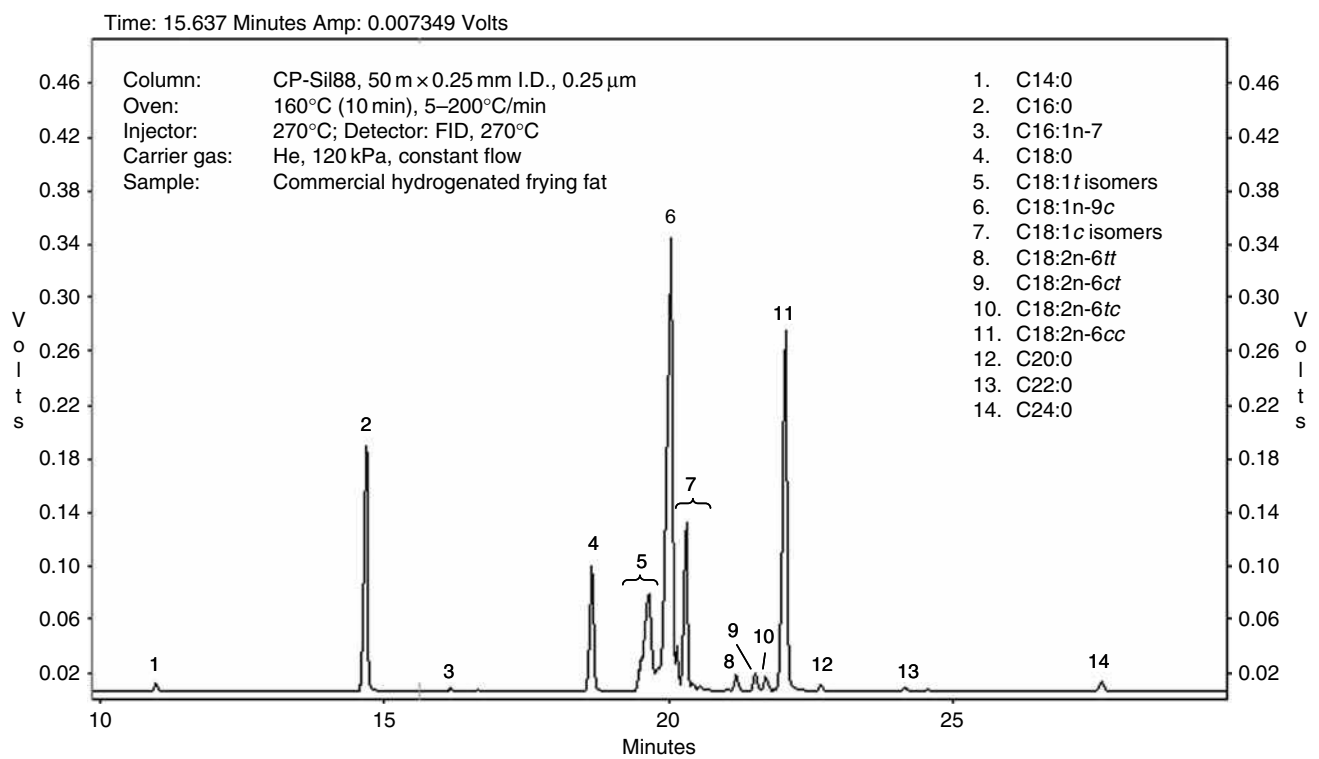

Fig. 6 Separation of *trans* isomers of a partially hydrogenated fat on a 50 m CP-Sil88 column.

significant when FAs of widely differing molecular weights are present in the same fat.

Absolute Amounts

In some cases, one has to measure the absolute amount of each FA, requiring the use of appropriate internal standards. This is best accomplished by adding a precise quantity of a FAME that is not present in the mixture—generally an odd-chain FA (11:0, 13:0, 15:0, 17:0, 23:0, or 29:0)—as an internal standard, but the analyst should be aware of the fact that odd-chain FAs are not always absent, and some can be significant components of dairy products. For a more complete and precise standardization, the internal standard should be added to the sample from which the lipids are to be extracted, in order to take the extraction yield into account.

The internal standard should, preferably, be in a form similar to that in which the bulk of FAs occur in the sample (often as triglycerides, although sometimes as phospholipids or cholesterol esters). Triundecanoin ($3 \times$ C11:0), for instance, is frequently used for milk fat; 23:0 is more suitable for determining EPA and DHA.

The response factor (F) for each FA in a calibrated standard is calculated as shown below:

$$F_{FA} = \frac{(\text{Area}_{FA} \times \text{Weight}_{IS})}{(\text{Area}_{IS} \times \text{Weight}_{FA})} \quad (2)$$

The FAME amount in a sample can be calculated from the following equation:

$$\text{FAME (mg/g)} = 1000 \times \frac{(\text{Area}_{FA} \times \text{Weight}_{IS} \times F_{FA})}{(\text{Area}_{IS} \times \text{Weight}_{sample})} \quad (3)$$

If the internal standard was added as a triacylglyceride, the concentrations obtained using the equation would also be of triacylglycerides.

SPECIAL APPLICATIONS

GC–MS Analysis

Mass spectrometry, coupled to GC (GC–MS), is probably the most powerful tool available for the identification of FAs separated by GC. Although generally used for structural analysis, the mass spectrometer also has a quantitative performance comparable to that of FID.[12]

Electron impact MS can be easily used for the identification of saturated FAs because their spectra are characterized by one prominent molecular ion and several ions with reduced mass (in steps of 14 amu, owing to the loss of successive methylene groups). Methyl esters, picolinylesters, pyrrolidines, and oxazolines are the derivatives used for this purpose.[3,13]

Mass spectrometry is particularly suitable for locating double bonds in PUFA, but this requires derivatives that fix the double-bond position. Good examples are those containing a nitrogen atom because these bonds have a pronounced tendency to ionize and migrate along the aliphatic chain, as in methyl esters or trimethylsilyl ethers. Picolinyl esters are the most widely used derivatives because they offer a specific mass fragmentation pattern with a particular value at the double-bond location. 4,4-Dimethyloxazoline (DMOX) derivatives are also becoming increasingly popular for this purpose. They have chromatographic properties similar to those of methyl esters, elute slightly later, and the peak resolution is usually retained. In the mass spectra, simple radical-induced cleavages occur at every carbon in the chain, resulting in gaps of 14 amu between adjacent methylene groups in a saturated chain and a gap of 12 amu when a double bond is present.[3,13]

GC–MS does not distinguish between geometrical isomers, but this can be achieved using the IR spectra obtained by GC-Fourier transform infrared (FTIR) spectrometry of the methyl esters.

Short-Chain FAs

When short-chain FAs are present in the lipid sample, the quantitative recovery of their methyl esters is questionable because of their volatility and partial solubility in water.

If short-chain acids are present (indicated by a series of peaks eluting just after the solvent front), then GC conditions should be adjusted to include a low-temperature step (often at 70°C) before the normal starting temperature. It is also extremely important to prevent the loss of the most volatile compounds during the injection procedure. Despite their suitability for most FAs, split injectors' tendency to lose short-chain FAs, especially those with lower molecular weights, is a reality.

The problem can be resolved partially by preparing derivatives with higher molecular weights, usually isopropyl or butyl esters in dairy products, where methanol is replaced by isopropanol or butanol with appropriate catalysts.[14]

trans Fatty Acids

There is a confirmed relationship between the consumption of foods containing *trans* fatty acids and high-low-density lipoprotein (LDL)-cholesterol levels associated with increased risk of coronary heart disease, a leading cause of death in the United States and a growing concern in Europe.

trans Fatty acids, also known as *trans* fat, are naturally present in dairy products, meats, and refined oils at levels of no concern. However, the actual main sources are the man-made partially hydrogenated fats, designed to

increase the shelf life and applicability of polyunsaturated oils. During the hydrogenation process, *cis*-fatty acids are partially converted to their *trans* isomers, which will be present in the final product if the hydrogenation process is incomplete. These edible fats are frequently used in fried or baked foods, cookies, snacks, salad dressings, and other processed foods.[15]

trans Fatty acids from dairy foods, mostly monoethylenic, have been known for decades and were traditionally determined by IR spectroscopy. Indeed, there was no exact knowledge of the man-made *trans* ethylenic bonds in hydrogenated PUFA until their discovery by capillary GLC, in the 1970s. Although in the beginning no special attention was devoted to their high levels, the *trans* fatty acids by virtue of their impact on blood lipid composition created a very strong demand for comprehensive analyses of edible fats. In fact, the U.S. Food and Drug Administration (FDA) has amended its regulation on nutritional labeling, requiring the inclusion of *trans* fatty acids in food nutritional information, with effect from January 2006. This necessitated reliable analytical methods for the determination of *trans* fatty acid levels.

The chromatographic technique of choice for this purpose is GC, but some adjustments have to be made to achieve an accurate separation of the *trans* isomers from the naturally present *cis*-isomers. Although for most analyses, namely for food labeling, only the total *trans* content is of interest, cases exist, in biological studies for instance, where a specific isomer needs to be quantified. Another factor to consider is the complexity of the *trans* fatty acids present in samples: it can be low, as in dairy products, or high, as in partially hydrogenated fats where the octadecenoic isomer group can constitute up to 26 *cis* and *trans* isomers with double-bond positions ranging from 4 to 16.

The chromatographic separation of *cis–trans* FAMEs requires specific columns. Preferably, a single capillary GLC method should yield detailed information on all types of FAs, allowing labeling of saturated, monounsaturated, polyunsaturated, and total *trans* levels, in a rapid analysis because more samples are continually analyzed on a day-to-day basis.

Long (50–100 m), highly polar (cyanopropyl) columns are used for separating *trans* polyenes[16] that elute earlier than the corresponding *cis*-isomers. The columns most suitable for isomer separation include the SP-2340, SP-2560, CP-Sil88; the last two, both 100 m long, are currently considered the most progressive for *cis–trans* isomer separation. Fig. 6 represents a chromatogram from a commercial hydrogenated frying fat, in which a huge amount of *trans* was detected (21%).

It should be noted that, with cyanopropyl columns (in contrast to the carbowax columns), even though retention time increases with chain length and degree of unsaturation, there is considerable chain length overlap. Furthermore, the resolution of isomeric FAs depends greatly on the column operating temperature. Varying the column temperature by 5–10°C affects the relative elution order of some 18:1 isomers, as well as of 11*c*-20:1 and geometric isomers of ALA. If the analyst is not aware of these variations, misidentification of FAs is possible, leading to inaccurate compositional reports.

When the *trans* fatty acids are difficult to separate by GC, silver-ion chromatography is a useful tool for simplifying any complex FAME sample into fractions according to the number, geometry (*cis* double bonds are held stronger than *trans* double bonds), and even positions of the double bonds. This separation principle can also be applied during sample preparation; special Ag-SPE phases are used for the separation of *trans* and *cis* isomers, the two fractions analyzed separately by GC.

Conjugated Linoleic Acids

These FAs, although chemically "*trans*," are regarded as a distinct class because of the claims on their beneficial health effects, intensively discussed nowadays.

Initial separation of commercial CLA can be achieved by GC but, depending on the sample's complexity, other chromatographic methodologies such as selected-ion recording (SIR) GC–MS with DMOX derivatives or silver-ion HPLC might be necessary to achieve full identification and quantification of the isomers.

It is recognized that long, polar cyanopropyl columns, such as CP-Sil88 or SP-2560, similar to those used for the separation of normal *trans* isomers, are required to achieve optimum separation of CLA isomers. If one is interested only in the two usually encountered major isomers—9*c*, 11*t* and 10*t*, 12*c*—most of the 50 m columns will be sufficient. For a better separation of minor or coeluting isomers a 100-m column is mandatory. Typical conditions might involve complex temperature programming and long running times, usually more than 80 min, and the elution of CLA isomers occur just after 18:3 *n*–3 and before 20:2 *n*–6. Quantification, in milligram of CLA per gram of the sample, would be carried out by adding an appropriate internal standard during extraction. Nevertheless, some isomers are accurately quantifiable by Ag-HPLC only.[17]

Special attention must also be devoted to the derivatization method, as isomerization and oxidation can occur under acidic conditions, thereby altering the original CLA content. Methylation procedures suitable for CLA have been the subject of extensive investigation. CLAs, if present entirely in an esterified form, can be converted to methyl esters with alkaline reagents such as sodium methoxide without causing any changes. However, commercial CLA mainly occur in free-acid form, which cannot be methylated under alkaline conditions. The usual approach is to use an alkaline method for esterified CLA, such as sodium methoxide, followed by

a mild acid method (hydrochloric acid, 80°C for 10 min) or trimethylsilyldiazomethane.

Fast GC in FAME Analysis

The traditional GC separation with a reduced run time, i.e., fast GC, is now the cutting edge and can be achieved by the use of shorter capillary columns, columns with reduced internal diameter, thinner stationary-phase films, H_2 as the carrier gas, higher carrier gas velocities, faster oven temperature programming rates, and combinations of these parameters. However, one must be careful to understand the impact of these changes on the chromatographic resolution. Despite the unavoidable decrease in efficiency, the overall analytical results are obtained with 95% reduction in analytical time, typically less than 2 min.[18]

Comprehensive Two-Dimensional Gas Chromatography

This chromatographic technique, known as GC × GC or 2-D-GC, has emerged in the past decade as a powerful separation technique, able to resolve coeluting peaks in complex samples. The separation can be performed, for instance, by boiling point in the first column and by polarity in the second, with columns usually coupled with a cryogenic modulator. The modulator repeatedly focuses a small portion of the first column eluate and injects it onto the second column. The second column, being very short and narrow, performs a flash (several seconds) separation for each modulation portion injected. Overall separation capacity of the system is greatly enhanced compared to the 1-D separation systems. Scan rate is a key to higher analytical resolution, and hence time-of-flight mass spectrometers (TOF-MS) are increasingly used.[19]

SOME RECOMMENDATIONS

- Lipid extraction, preceding FA analysis, is an important process and it should be performed correctly to achieve plausible results. Sometimes, incomplete lipid recovery may not be a problem if the material recovered is a representative sample; however, it can be misleading if FA compositional data are needed. If hydrolytic methods are used during extraction, or if the presence of free FAs is in order, an adequate derivatization method must be chosen to guarantee the methylation of both triacylglycerols and free FAs.
- Often for sample preservation before analysis, samples are freeze-dried. The possibility of oxidative damage is high in this situation, which can be reduced by following some guidelines. First, the lipids must be kept in the original matrix as long as possible and frozen at the lowest possible temperature, preferably −30°C or lower, to avoid enzymatic lipolysis. Autoxidation during storage can be reduced by flushing with nitrogen and adding a small amount of butylated hydroxyanisole (BHA) or butylated hydroxytoluene (BHT). Second, if extraction is mandatory, then total lipid extraction is done immediately, and the lipids are stored in solution or partially dried by solvent removal with nitrogen, at −30°C or lower, always in the presence of an appropriate antioxidant.
- Finally, it must be pointed out that, when interpreting the results of FA analyses, one should take into account the fact that FA composition is subject to considerable variations—depending on the breed and feed, in the case of animal fats, and on the plant variety, geographic location of the area of cultivation, and climate in the case of plant fat. Therefore, guideline values for individual oils and fats can differ from country to country.

Fatty Acids: Silver Ion TLC

Boryana Nikolova-Damyanova
Institute of Organic Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

INTRODUCTION

Fatty acids (FA) are basic structural elements of lipid molecules, determining many of their chemical and physical properties. Therefore determination of FA composition is mandatory for lipid analysis. For many years, silver ion thin-layer chromatography (Ag-TLC) has been one of the basic separation techniques employed in lipid analysis, the resolution of FA mixtures being one of the main tasks. FAs are separated according to the number, the configuration and, to some extent, the positions of the double bonds. While gas chromatography (GC) has always been the basic method in FA analysis, the specific separation features of Ag-TLC make this technique indispensable in performing certain analytical tasks. The complementary employment of GC or/and GC/MS together with Ag-TLC is probably the most powerful tool for elucidation of fatty acid composition in complex lipid samples.

SILVER ION COMPLEXATION WITH DOUBLE BONDS

The use of Ag-TLC in fatty acid analysis is based on the ability of Ag(I) to form weak, reversible charge-transfer complexes with olefinic double bonds. It is now considered that a σ-type bond is formed between the occupied $2p\pi$ orbitals of the olefinic bond, and the free 5s and 5p orbitals of Ag(I) and a weaker π-acceptor backbond is formed between the occupied 4d orbitals of Ag(I) and the free antibonding $2p\pi^*$ orbitals of the olefinic bond. Quantitative data on equilibrium constants exists for some short-chain mono- and diolefins only. The retention of longer-chain unsaturated compounds, such as FAs, is described on the basis of data collected by different silver ion separation techniques (mostly GC and Ag-TLC) and is supposed to depend on the strength of complexation with Ag(I). The latter, in turn, depends on the number, configuration, and the distance between double bonds. Thus the migration rules in Ag-TLC can be summarized as follows:

- The stronger FAs are held, the higher is the number of double bonds in the chain.
- FAs with *trans* double bonds are held less strongly than FA with *cis* double bonds.
- The retention of FAs with more than one double bond depends on the distance between the bonds, the order of decreasing retention being separated double bonds > methylene interrupted double bonds > conjugated double bonds.
- Longer-chain FAs are less strongly held than shorter-chain FA of the same unsaturation.
- FAs with an olefinic double bond are more strongly held than FAs with an acetylenic bond.
- Deuterated FAs are more strongly held than hydrogen analogs.

Although there is evidence that complexation with silver ions is the governing interaction in Ag-TLC, other factors should also be considered. Thus silica gel, which is the most widely used supporting material, possesses appreciable polarity and adsorption activity. Therefore, in many cases, an impact of mixed retention mechanism on migration, geometry of spots, and selectivity of resolution is to be expected. Also, the mobile-phase solvents are active elements of the chromatographic system and interactions both with the supporting material and FA is possible; this may also have a serious effect on the whole separation process.

SOME PRACTICAL CONSIDERATIONS

Both homemade and precoated glass plates are used in Ag-TLC. Silica gel G (with calcium sulfate as binder) is usually the supporting material. Layer thickness varied between 0.2–0.3 mm for analytical plates and 0.5–1.0 mm for preparative plates. Fully automated spreaders are now available, but simple spreaders are also effective. Some practice is needed to prepare the layer in the laboratory; thus precoated plates are often preferred.

The impregnation of the layer with silver ions is performed by either incorporating the silver salt into the silica gel slurry or by immersing or spraying the plate with water, ethanol, methanol, ammonia, or acetonitrile solutions of the salt. Silver nitrate is normally used. The only method that affords proper control of the Ag(I) content in the layer is to add silver nitrate to the slurry. However, this is inconvenient and messy and is less used now. Because it is evident from analytical practice that the content of silver ions in the layer is not critical over rather broad limits, immersion and spraying are considered equally good. Immersion procedures can be sufficiently well standardized to provide satisfactory results, and can be applied both to homemade and precoated plates. Spraying procedures are also often used in FA analysis, although they are less easily

standardized and are messier. Spraying may have to be repeated from two to six times until the layer is properly wetted. This is especially important for precoated plates.

The concentrations of impregnating solutions vary depending on the purpose. Immersion or dipping is carried out most often with 0.5–20% solutions of silver nitrate, while 10–40% solutions of silver nitrate are recommended for the spraying procedure.

After impregnation, the plates are air-dried, preserved in a dark place, and activated (between 5 and 30 min at 110–120°C in an oven) before sample application.

In spite of all precautions, humidity is not easy to control and is one of the main reasons for the relatively poor overall reproducibility of separations in Ag-TLC.

FAs are subjected to Ag-TLC usually in the form of methyl esters. The methods for methylation and transmethylation are simple, easy to perform, and with practically 100% yield. Methyl esters are particularly suitable when Ag-TLC is used as a complementary method with GC. Butyl and isopropyl esters were employed for the fractionation of butterfat FAs by Ag-TLC because these derivatives provided better resolution in GC. Conversion of positionally isomeric 18 : 1 and 20 : 1 FAs into phenacyl esters ensured complete resolution of the components by Ag-TLC; however, this is not possible when using methyl esters.

Mobile phases generally consist of two- and, rarely, three-component mixtures. Hexane or petroleum ether (BP 40–60°C), chloroform, benzene, and toluene are most often the major components, while smaller proportions of diethyl ether, acetone, methanol, ethanol, or acetic acid may be added.

The conventional approach is to perform the development in closed standard rectangular tanks lined with filter paper to saturate the atmosphere with the mobile-phase

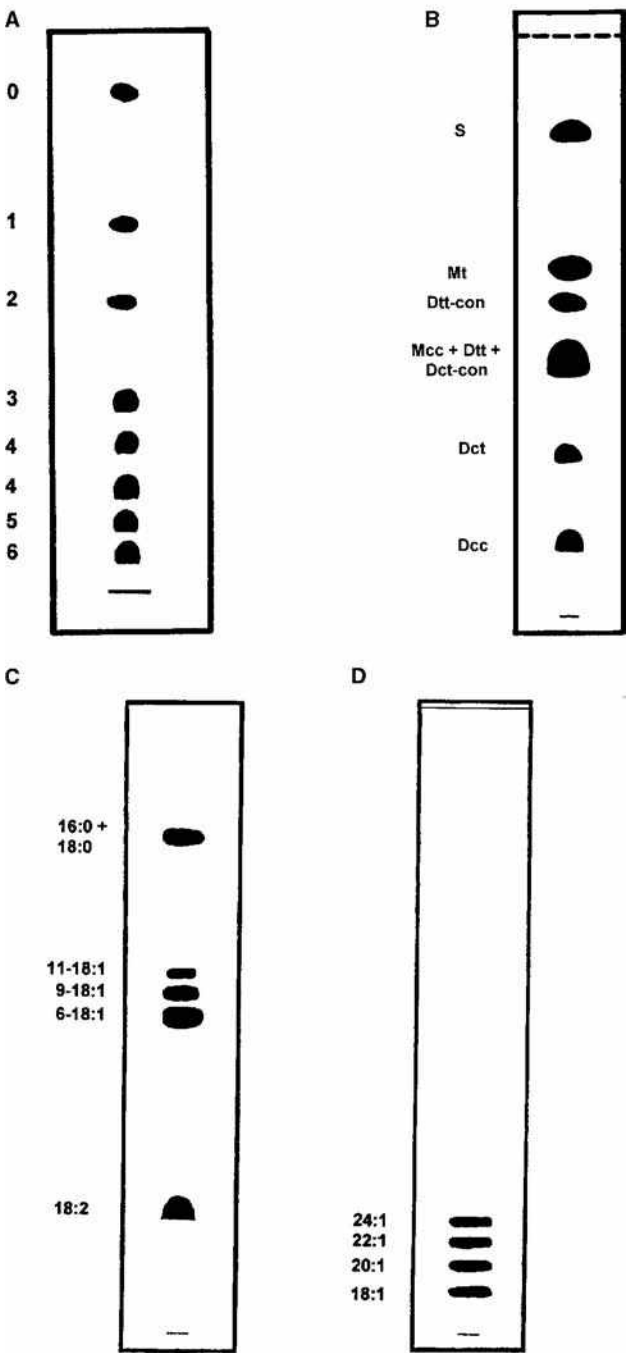

Fig. 1 A, Separation of a reference mixture of fatty acid methyl esters by Ag-TLC according to the number of double bonds. The plate was impregnated by dipping with 0.5% methanolic silver nitrate (w/v) and developed with 5 ml of light petroleum ether–acetone–formic acid, 97 : 2 : 1 (v/v/v); spots were detected by treating the plate in sequence with bromine and sulfuryl chloride vapors, followed by heating at 180–200°C. Numbers alongside denote the number of double bonds. B, Separation of reference mixture of fatty acid methyl esters by Ag-TLC according to the configuration of the double bond. The plate was impregnated with silver nitrate as in A, and developed with 2 ml of light petroleum–acetone, 100 : 2 (v/v) followed by 3 ml light petroleum–acetone, 100 : 7 (v/v). The spots are detected as in A. S, saturated; M, monoenoic; D, dienoic fatty acid methyl esters; c, *cis*; t, *trans*; con, conjugated double bonds. C, Separation of fatty acid phenacyl esters in *Pimpinella anisum* seed oil by Ag-TLC according to the position of the double bond in the chain. Plate was impregnated by dipping with 1% methanolic silver nitrate and was developed twice with mobile phase chloroform–acetone, 100 : 0.25 (v/v); *a* − *c*:*n* denotes the position of the double bond − the number of carbon atoms in the chain: the number of double bonds. (D) Separation of reference mixture of fatty acid methyl esters by Ag-TLC according to the chain length. The plate was sprayed with 20 ml acetonitrile containing 2 g silver nitrate until the layer was saturated. It was then activated for 30 min at 110°C and developed with toluene–hexane, 40 : 60 (v/v) in saturated closed standard tank. Spots were visualized by charring (the procedure was not specified).

vapors. Equal, and in many cases better, results are achieved by development in "open" cylindrical containers where a fixed volume of the mobile phase is added, passed through the plate, and permitted to evaporate from the upper edge of the plate.

Detection of separated zones depends on the analytical task. Destructive procedures are used for qualitative analysis and for quantification by photodensitometry. They consist in carbonization of the FAs by heating at 180–200°C after treating the plate with charring reagents. These can be introduced by spraying, by treatment with the respective vapors, or by incorporation of the reagent into the layer. Up to 50% ethanolic sulfuric or phosphomolybdic acids and copper acetate–phosphoric acid have been used as spraying reagents. Reliable results have been obtained by saturating the silica-gel layer with vapors of sulfuryl chloride. Non-destructive procedures are used in preparative Ag-TLC. It is performed by spraying the plate with a fluorescent indicator, mostly 2,7-dichlorofluorescein in ethanol, and viewing under UV light. The bands are then scraped from the plate and extracted with diethyl ether or hexane–methanol (in appropriate proportions). The excess silver ions and indicator are removed by passing the extract through a small silica column, or by washing with bicarbonate, ammonia, or sodium chloride solutions.

Examples of the separation of fatty acid derivatives by Ag-TLC are given in Fig. 1.

CONCLUSIONS

Silver ion TLC is a simple but reliable approach for separation, identification, quantification, and preparative isolation of fatty acids in lipid samples, depending on the number, configuration, position, and chain length (see Refs.[1–9] for additional information).

FFF Fundamentals

Josef Janca
Department of Chemistry, University of La Rochelle, La Rochelle, France

INTRODUCTION

Field-flow fractionation (FFF) is a separation method suitable for the analysis and characterization of macromolecules and particles. The separation is based on the interaction of the effective physical or chemical forces (e.g., temperature gradient; electric, magnetic, gravitational, or centrifugal forces; chemical potential gradient; etc.) with the separated species. The field, acting across a separation channel, concentrates them at a given position inside the channel. The formed concentration gradient induces an opposite diffusion flux. This leads to a steady-state distribution of the sample components across the channel. The velocity of the longitudinal flow of the carrier liquid also varies across the channel. A flow velocity profile is established inside the channel. As a result, the components of the separated sample are transported in the longitudinal direction at different velocities depending on their transversal positions within the flow of the carrier liquid. This general principle of FFF is demonstrated in Fig. 1.

DISCUSSION

One of three mechanisms, *polarization*,[1] *steric*,[2] and *focusing*,[3] can lead to the formation of different concentration distributions across the fractionation channel. The components of the fractionated sample are either concentrated in the direction of the accumulation wall (polarization FFF), totally compressed at the accumulation wall of the channel (steric FFF), or focused at different positions (focusing FFF), as shown in Fig. 1. Steady state inside the channel is reached in a short time due to the small channel thickness. The strength of the field can be controlled within a wide range in order to manipulate the retention conveniently. Many operational variables in FFF can be manipulated during the experiment by suitable programming.

The *polarization* and *steric* FFF methods are classified according to the nature of the applied field, whereas the *focusing* FFF methods are classified by considering the combination of various gradients and fields emphasizing the focusing processes. Polarization FFF methods make use of the formation of an exponential concentration distribution of each sample component across the channel with the maximum concentration at the accumulation wall, which is a consequence of the constant and position-independent velocity of transversal migration of the affected species due to the field forces. This concentration distribution is combined with the velocity profile formed in the flowing liquid. In steric FFF, the field strength is so high that all species interacting with the field are in contact with the accumulation wall. As a result, the proper size of the retained species determines their position in the flow velocity profile and, consequently, their elution velocity along the channel. Focusing FFF methods make use of transversal migration of each sample component under the effect of driving forces whose intensity varies across the channel. As a result, the sample components are focused at the positions where the intensity of the effective forces is zero and are transported longitudinally with different velocities according to the established flow velocity profile. The concentration distribution within a zone of a focused sample component can be described by Gaussian or similar distribution function.

PRINCIPLE AND THEORY

The carrier liquid flows in the direction of the channel's longitudinal axis, whereas the field forces act perpendicularly across the channel. The driving forces can be generated by a single field or by the coupled action of two or more different fields. Polarizing and focusing forces can operate simultaneously, resulting in a complex mechanism of separation. The field force F and, consequently, the velocity U are independent of position in the direction of the x-axis in polarization and steric FFF:

$$F \neq 0 \quad \text{and} \quad U \neq 0 \quad \text{for} \quad 0 < x < w \tag{1}$$

where w is the distance between the main channel walls in the direction of the x-axis, with $x = 0$ at the accumulation wall. On the other hand, the following hold for the x-axis-dependent direction of the field force in focusing FFF:

$$F = F(x) \quad \text{and} \quad U = U(x) \quad \text{within} \quad 0 < x < w \tag{2}$$

$$F(x) = 0 \quad \text{and} \quad U(x) = 0 \quad \text{for } x = x_{\max} \text{ with } 0 < x_{\max} < w \tag{3}$$

$$F(x) > 0 \quad \text{and} \quad U(x) > 0 \quad \text{for } x < x_{\max} \tag{4}$$

$$F(x) < 0 \quad \text{and} \quad U(x) < 0 \quad \text{for } x > x_{\max} \tag{5}$$

where the coordinate x_{max} corresponds to the position at which the concentration distribution of a sample component across the channel attains its maximal value.

POLARIZATION FFF

The equilibrium concentration distribution in the direction of the x-axis across the channel of a given component of the sample can be calculated from the continuity equation:

$$-D\frac{\partial c}{\partial x} - Uc = 0 \tag{6}$$

where D is the diffusion coefficient and c is the concentration. The solution of Eq. 6 gives the exponential concentration distribution of the sample component across the channel:[4]

$$c(x) = c(0)\exp(-xU/D) \tag{7}$$

By defining the mean layer thickness, $\ell = D/U$, Eq. 7 can be rewritten:

$$c(x) = c(0)\exp(-x/\ell) \tag{8}$$

The mean layer thickness is practically equal to the center of gravity of the concentration distribution.

STERIC FFF

The radius (or hydrodynamic equivalent of the radius) of the retained species determines the distance of the center of such a species from the accumulation wall. There is no distribution of concentration of the retained component across the channel. Consequently, the ratio α is a decisive parameter determining the retention in steric FFF:[2]

$$R = 6(\alpha - \alpha^2) \tag{9}$$

where $\alpha = r/w$, and r is the radius of the retained species.

FOCUSING FFF

It holds for a focused species at equilibrium that:

$$D\frac{\partial c}{\partial x} - U(x)c = 0 \tag{10}$$

The force $F(x)$, acting on one particle undergoing the focusing, can be written as:

$$F(x) = U(x)f \tag{11}$$

with the friction coefficient defined by:

$$f = kT/D \tag{12}$$

where k is the Boltzmann constant and T is the absolute temperature. Then the following holds:

$$\frac{\mathrm{d}c}{\mathrm{d}x} = \frac{F(x)c}{kT} \tag{13}$$

The focusing force can be approximated by:[5]

$$F(x) = -\left|\left(\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right)_{x\approx x_{max}}\right|(x - x_{max}) \tag{14}$$

where $[\mathrm{d}F(x)/\mathrm{d}x]_{x\approx x_{max}}$ is the gradient of the driving force. The solution is:

$$c(x) = c_{\max} \exp\left[-\frac{1}{2kT}\left|\left(\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right)_{x\approx x_{\max}}\right|(x - x_{\max})^2\right] \tag{15}$$

which is the Gaussian concentration profile of a single focused component. A more accurate approach[5] is based on the real gradient of the focusing forces and results in a concentration distribution of the focused species that is not Gaussian.

FLOW VELOCITY PROFILES

The separation is usually carried out in a belt-shaped narrow channel of constant thickness. The cross-section of the channel is rectangular. The 2D velocity distribution in a plane parallel to the sidewalls in such a channel (provided that the flow is isoviscous) is parabolic:

$$v(x) = \frac{Px(w - x)}{2L\mu} \tag{16}$$

where $v(x)$ is the longitudinal velocity at the x-co-ordinate, ΔP is the pressure drop along a channel of length L, and μ is the viscosity of the carrier liquid. The average velocity is:

$$\langle v(x)\rangle = \frac{\Delta P w^2}{12L\mu} \tag{17}$$

Other shapes of flow velocity profiles can be formed in channels whose cross-section is not rectangular but, for example, trapezoidal. The use of such non-parabolic flow velocity profiles can be advantageous, especially in focusing FFF.

SEPARATION

Separation is due to the coupled action of the concentration and flow velocity distributions. The concentration distribution across the channel of each sample component is established and the sample components are eluted along the channel with different velocities depending on the distance of their centers of gravity from the accumulation wall. The average velocity of the zone of a retained sample component is:

$$\langle v\rangle = \langle c(x)v(x)\rangle / \langle c(x)\rangle \tag{18}$$

The retention ratio R is defined as the average velocity of a retained sample component to the average velocity of the carrier liquid:

$$R = \frac{\int_0^w c(x)v(x)\mathrm{d}x \int_0^w \mathrm{d}x}{\int_0^w c(x)\mathrm{d}x \int_0^w v(x)\mathrm{d}x} \tag{19}$$

where $v(x)$ and $c(x)$ are the local velocity and concentration, respectively, of the retained species. From the practical point of view, the retention ratio R can be expressed as the ratio of the experimental retention time t_0 or the retention volume V_0 of an unretained sample component to the retention time t_r or the retention volume V_r of the retained sample component. Provided that a relationship exists between the position of the center of gravity of the zone and the molecular parameters of the sample component, these parameters can be calculated from the retention data without calibration.

The retention ratio in polarization FFF is thus given by:[6]

$$R = 6\lambda\left[\coth\left(\frac{1}{2\lambda}\right) - 2\lambda\right] \tag{20}$$

where $\lambda = l/w$. If λ is small, the following approximations hold:

$$\lim_{\lambda\to 0} R = 6(\lambda - 2\lambda^2) \quad \text{or} \quad \lim_{\lambda\to 0} R = 6\lambda \tag{21}$$

The retention parameter λ relates the dispersive effect of thermal energy to the structuring effect of the field on the retained species:

$$\lambda = \frac{kT}{Fw} \tag{22}$$

When the size of the separated species is commensurable with the thickness of the channel, the limit retention ratio in this mode of steric FFF is:[3]

$$\lim_{\alpha\to 0} R = 6\alpha \tag{23}$$

where $\alpha = r/w$; r is the particle radius.

The retention ratio in focusing FFF carried out in a channel of rectangular cross-section is given by the approximate relationship:[7]

$$R = 6\left(\Gamma_{\max} - {\Gamma_{\max}}^2\right) \tag{24}$$

where $\Gamma_{\max} = x_{\max}/w$ is the dimensionless co-ordinate of the maximal concentration of the focused zone.

METHODS AND APPLICATIONS

The retention is related to the size, charge, diffusion coefficient, thermal diffusion factor, and so forth of the separated species in polarization FFF, whereas it is exclusively

the size that determines the retention in steric FFF. As concerns focusing FFF, the retention is usually related to the intensive properties of the fractionated species. Consequently, FFF can be used to characterize the properties related to retention. Only the polarization and steric FFF methods are described here.

The particular methods of polarization and steric FFF are denominated by the nature of the applied field. The most important of them are described in the following subsections.

Sedimentation FFF

Sedimentation FFF is shown schematically in Fig. 2a. The separation channel is situated inside a centrifuge rotor and the centrifugal forces are applied radially.[8] The method can be used for the analysis and characterization of various latexes, inorganic particles, emulsions, biological cells, etc. The retention parameter λ depends on the effective mass of the particles:

$$\lambda = 6kT/(\pi d^3 g w \Delta\rho) \tag{25}$$

where g is the gravitational or centrifugal acceleration and $\Delta\rho$ is the density difference between the particles and the carrier liquid. The calculation of the particle size distribution is possible directly from the retention data.

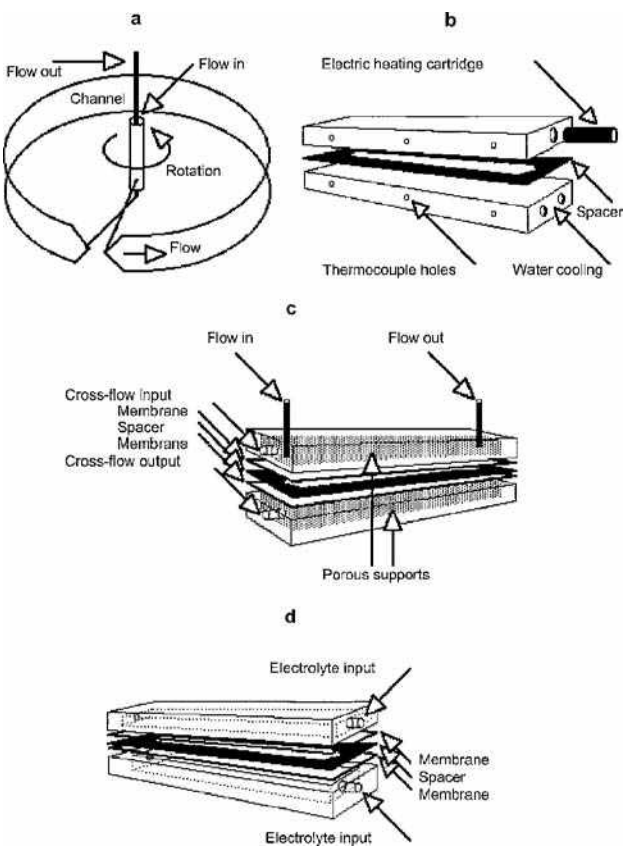

Fig. 2 Methods of polarization FFF. a, Sedimentation FFF; b, thermal FFF; c, flow FFF; and d, electric FFF.

Thermal FFF

Thermal FFF was the first experimentally implemented method.[9] It is used mostly for the fractionation of macromolecules. The temperature difference between two metallic bars, forming the channel walls with highly polished surfaces and separated by a spacer in which the channel proper is cut, produces the flux of the sample components, usually toward the cold wall. The channel for thermal FFF is shown in Fig. 2b. The relation between λ and the operational variables is given by:

$$\lambda = \frac{D}{wD_T(\mathrm{d}T/\mathrm{d}x)} \tag{26}$$

where D_T is the coefficient of the thermal diffusion, which depends on the chemical composition and structure of the fractionated species but not on their size. On the other hand, the diffusion coefficient D depends on the size. As a result, the differences in thermal diffusion coefficients allow fractionation according to differences in chemical composition and structure, whereas different diffusion coefficients allow fractionation based on the size differences. The performances favor thermal FFF over its competing methods.

Flow FFF

Flow FFF is a universal method because the cross-flow field acts on all fractionated species in the same manner and the separation is due to the differences in diffusion coefficients.[10] The channel, schematically demonstrated in Fig. 2c, is formed between two parallel semipermeable membranes. The carrier liquid can permeate through the membranes but not the separated species. The retention parameter λ is related to the diameter d_p of the separated species:

$$\lambda = kTV_0/\left(3\pi\mu V_c w^2 d_p\right) \tag{27}$$

where V_0 is the void volume of the channel, μ is the viscosity of the carrier liquid, and V_c is the volumetric velocity of the cross-flow. The separations of various kinds of particles such as proteins, biological cells, colloidal silica, polymer latexes, etc. as well as of soluble macromolecules have been described.

Electric FFF

Electric FFF uses the electric potential across the channel to generate the transversal flux of the charged species.[11] The walls of the channel can be formed by semipermeable

membranes that allow the passage of small ions but not of the separated species. The channel is shown in Fig. 2d. The dependence of the retention parameter λ on the electrophoretic mobility μ_e, and on the diffusion coefficient of the charged particles, is given by:

$$\lambda = D/(\mu_e E w) \tag{28}$$

where E is the electric field strength. As a result, the ratio of the diffusion coefficient to the electrophoretic mobility determines the retention. Species exhibiting only small differences in electrophoretic mobilities but significant differences in diffusion coefficients can be separated. Electric FFF is especially suited for the separations of biological cells as well as for charged polymer latexes and other colloidal particles and charged macromolecules.

Other Polarization FFF Methods

Other polarization FFF methods have recently been proposed theoretically and some of them implemented experimentally. Their use in current laboratory practice needs further development in methodology and instrumentation. One of the most recent review papers summarizes the state of the art of the polarization FFF methods.[12]

Steric FFF Methods

Any field force can be exploited to create conditions for effective action of the steric exclusion mechanism. The only condition is, as mentioned above, that the field strength be high enough to compress all retained species to the accumulation wall. In experimental practice, sedimentation FFF, flow FFF, and thermal FFF are the techniques actually applied in steric mode to separate effectively some particulate species.

FFF with Electro-Osmotic Flow

Victor P. Andreev
Institute for Analytical Instrumentation, Russian Academy of Sciences, St. Petersburg, Russia

INTRODUCTION

It is well known that the essence of field-flow fractionation (FFF) is in the interaction between the distribution of the sample particles in the transversal field and the non-uniformity of the longitudinal flow profile. The classical FFF is realized in the channel with the flow driven by the pressure drop. The flow, in this case, is called Poiseuille flow and its profile is parabolic.

DISCUSSION

Electro-osmotic flow (EOF) is widely used for the propulsion of liquid in modern chromatographic methods, so it was natural to study the possibility of FFF with EOF, generated by applying an electric field, E, along a channel or a tube with charged (having the non-zero zeta-potentials) walls. The usual EOF is very close to uniform. For the cylindrical tube of radius a, the EOF velocity profile is described by

$$V(r) = \frac{\zeta\varepsilon\varepsilon_0 E}{\eta}\left(1 - \frac{I_0(\kappa r)}{I_0(\kappa a)}\right) \tag{1}$$

where ζ is the zeta-potential of the wall, ε and η are the dielectric constant and viscosity of the buffer, respectively, ε_0 is the permitivity of the free space, $\kappa^{-1} = (\varepsilon\varepsilon_0 k_B T/2ne^2)^{1/2}$ is the Debye layer thickness [k_B is the Boltzman constant, T is the temperature, n is the number of ions per unit volume (proportional to the concentration of buffer C_0), e is the proton charge], and $I_0(x)$ is the modified Bessel function. As can be seen from Eq. 1, the velocity profile of the EOF in the tube is very close to uniform everywhere except the Debye layer vicinity of the wall. Thus, it is hard to exploit such a profile for FFF unless the concentration of buffer is very low.

That is why it was proposed[1,2] to realize the asymmetrical FFF in the flat channel by making its walls of different materials or chemically modifying them. If the channel walls have non-equal values of the zeta-potentials, then the shape of the EOF profile can be quite different from uniform. The flow profiles that can be generated in the FFF channel with the applied electric field E and pressure drop Δp are presented in Fig. 1. These profiles can be described by

$$V(r) = \frac{\zeta_2\varepsilon\varepsilon_0 E}{\eta}\cdot\left[(\zeta_R - 1)\frac{\sinh kY}{\sinh k} + (\zeta_R + 1)\right.$$
$$\left.\frac{\cosh kY}{\cosh k} + (1 - \zeta_R)Y - (1 + \zeta_R)\right] + V_0(1 - Y^2) \tag{2}$$

where $\zeta_R = \zeta_1/\zeta_2$ is the ratio of the zeta-potential of the accumulation wall to the zeta-potential of the depletion wall, $k = \kappa w/2$, w is the channel depth, $Y = 1 - 2y/w$, and $V_0 = \Delta p/2\eta L$.

For large values of k, the first two terms in the square brackets are substantially non-zero only in the Debye layer vicinity of the walls, whereas everywhere else the EOF profile is dominated by the last two linear terms in the square brackets. Therefore, the asymmetric EOF profile can be close to trapezoidal or close to triangular depending on the exact values of the zeta-potentials of the walls. If the signs of the zeta-potentials of the walls are different, then the liquid moves in one direction near one wall and in the opposite direction near another wall (this case can be interesting for the preseparation of the particles having different densities). The last term in Eq. 2 corresponds to the pressure-driven Poiseuille flow.

Having Eq. 2 for flow profile enables one to calculate the retention ratio R and χ coefficient describing the Taylor dispersion part of the theoretical plate height H for arbitrary flow profile, according to[3]

$$H = \frac{2D}{R\langle V\rangle} + \chi\frac{w^2\langle V\rangle}{D} \tag{3}$$

where $\langle V\rangle$ is the average velocity of the flow and D is the diffusion coefficient of sample molecules. Usually, in FFF, the second term of Eq. 3 is much larger than the first one.

Comparison of R and χ values for the flow profiles presented in Fig. 1 for the case of the FFF parameter $\lambda \ll 1$ gives $R = 6\lambda$ and $\chi = 24\lambda^3$ for classical FFF with Poiseuille flow and $R = 2\lambda$ and $\chi = 8\lambda^3$ for FFF with a triangular EOF ($\zeta_1 = 0$). The most interesting result corresponds to the case of FFF with a combined triangular EOF and counterdirected Poiseuille flow (with $V_0 = \zeta_2\varepsilon\varepsilon_0 E/4\eta$ leading to $dV/dY = 0$ for $Y = 0$). In this case, $R = 6\lambda^2$ and $\chi = 24\lambda^4$. Thus, the selectivity $S = d\ln R/d\ln\lambda = 2$ and is twice as large as in the case of classical FFF and FFF with a triangular EOF. The χ coefficient is very small for $\lambda \ll 1$, so that the Taylor dispersion is very low and efficiency is high. The function $F = S/\sqrt{\chi}$

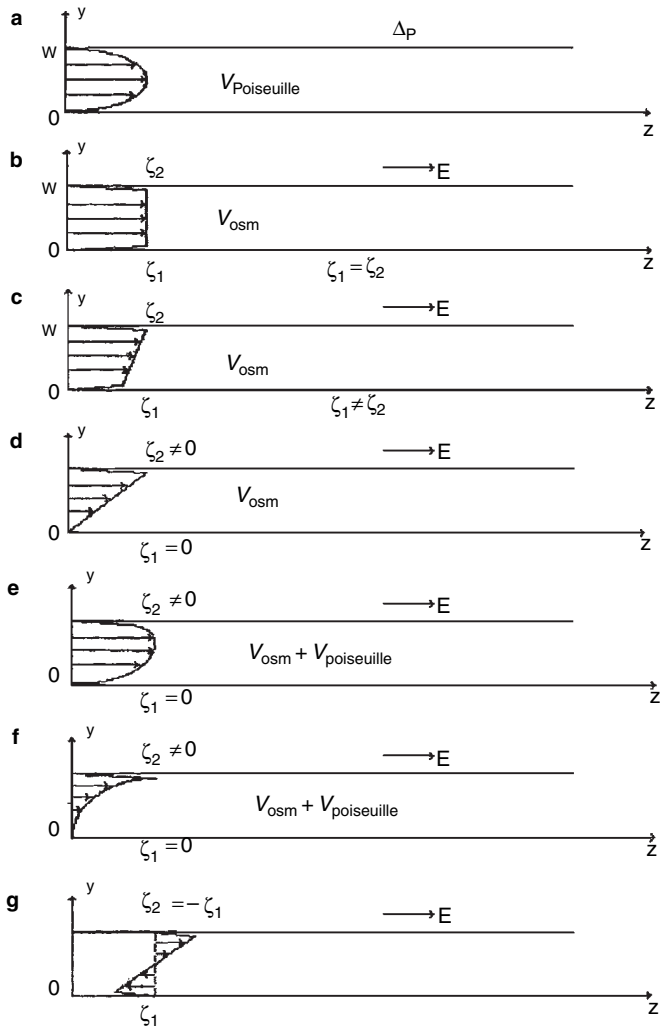

Fig. 1 Outline of the flow profiles in the FFF channels: a, Poiseuille flow; b, EOF (the equal zeta-potentials of the walls; c, trapezoidal EOF (the non-equal zeta-potentials of the walls); d, triangular EOF (the zero zeta-potential of the accumulating wall); e, codirected triangular EOF and Poiseuille flow; f, counterdirected triangular EOF and Poiseuille flow; and g, antisymmetric EOF (different signs of the zeta-potentials of the walls).

(fractionating power), characterizing the resolution for the given value of $\langle V \rangle$, is proportional to λ^{-2} in this case; in the rest of the cases, it is proportional to $\lambda^{-3/2}$. The situation with this kind of combined flow is very similar to the one described in Ref.[4] for the case of Poiseuille flow combined with the natural convection flow in the thermogravitational FFF channel.

High selectivity, efficiency, and fractionating power makes FFF with combined EOF and Poiseuille flows very interesting, as it can, at least theoretically, lead to finer separations for given values of λ. Experimental realization of FFF with asymmetrical EOF have not yet been reported due to some technical problems. However, considerable progress in this field is accomplished by a Finnish group (Riekkola, Vastamaki, and Jussila) working on the experimental realization of thermal FFF with asymmetrical EOF[5] and a Russian group (Andreev, Stepanov, and Tihomolov) working on gravitational FFF with asymmetrical EOF.[6]

The situation is more complicated, even theoretically, when the sample particles are charged. In this case, they are not only moving with the longitudinal flow (here, asymmetrical EOF) but are also forced by the longitudinal electric field to move along the channel electrophoretically. If the electrophoretic mobilities of the particles are different, then there are two types of separations combined: The FFF type due to the difference in λ values and the capillary zone electrophoresis (CZE) type due to the difference in electrophoretic mobilities. A great variety of variants of FFF and CZE combinations in the FFF channel with asymmetrical EOF could be imagined, depending on various factors such as the ratio of the zetapotentials of the channel walls, the sign and the value of the ratio of eletrophoretic and electro-osmotic velocities, and the type of the transversal field. Some of these combinations are examined in Ref.[6] They could lead both to the new possibilities of the method and to some new complications in the interpretation of the experimental results.

Another possibility for realizing FFF with EOF is to reduce the concentration of the buffer, thus making the Debye length commensurate, if not with the depth of the channel, then with the thickness $l = \lambda w$ of the layer of sample particles compressed to the accumulating wall of

FFF channel (for $C_0 = 10^{-5}M$ Debye length, $\kappa^{-1} = 0.1$ μm). In this case, EOF will be non-uniform enough to realize FFF in a channel with equal zeta-potentials of the walls.

In Ref.[7] the mathematical model of CZE, taking into consideration EOF non-uniformity and particle–wall electrostatic interactions, was developed. It was shown that for the particles electrostatically attracted by the wall of the capillary, two mechanisms of separation exist. The first is the usual CZE mechanism and it dominates for the case of high buffer concentrations; the second is the FFF accompanying the CZE mechanism and it dominates for low buffer concentrations. As is usual in CZE, the total velocity of the particle is the sum of its electrophoretic velocity and electro-osmotic velocity of the flow. The larger the electrical charge of sample particles, the stronger they are attracted to the wall and the higher is their concentration in the Debye layer vicinity of the wall, where the EOF is substantially non-uniform. Thus, for the particles with a higher charge, the mean velocity of movement with EOF will be lower than for the particles with the lower charge. Especially interesting with this type of FFF is for the particles with equal electrophoretic mobilities but different charges. Such types of particles (e.g., DNA fragments) cannot be fractionated by usual CZE, but can be fractionated by FFF accompanying CZE, where the separation is due to the difference of electrical charges, not the difference of mobilities. Note that for this type of FFF, there is no need for any external transversal field, because the particles are attracted to the walls by the field of the electrical double layer. As is usual in FFF, there is the transition point from normal diffusional FFF to steric FFF mode, taking place when the size of the particle is commensurable with λw. In Ref.,[8] it was theoretically predicted that steric FFF accompanying the CZE mode can be realized for the separation of DNA fragments in the range of 20–3000 bases with high resolution and speed. To realize this type of separation, one needs to develop a modified capillary with the positive value of the zeta-potential of the wall and without the irreversible sorption of DNA fragments on the walls. Such an attempt seems to be worthy because, unlike DNA separation by CZE in gel or polymer solution, in the case of FFF/CZE there is the possibility of online coupling with a mass spectrometer without the risk of gel particles going inside the spectrometer.

FFF: Data Treatment

Josef Janca
Department of Chemistry, University of La Rochelle, La Rochelle, France

INTRODUCTION

Field-flow fractionation (FFF) methods are classified into two main categories:[1–3] *polarization* FFF and *focusing* FFF. Their basic characterization is given in the entry *FFF Fundamentals*, p. 849. Whereas the polarization FFF methods allow to fractionate the samples on the basis of the differences in the extensive properties (such as the molar mass or particle size, etc.) of the individual species, the focusing FFF methods discriminate among the species, according to their intensive property differences (such as the charge or density, etc.). This entry deals with the data treatment of the experimental results from polarization FFF, thus with the quantitative characterization of the extensive properties. However, a principally identical approach can be applied to the intensive properties data treatment of the results obtained from the focusing FFF experiments.

In general, the methodology of the data treatment, concerning the separations of the macromolecular or particulate samples, does not depend on the particular separation method or technique. The basics of this methodology were elaborated in parallel with the development of size-exclusion chromatography (SEC)[4] and of the techniques of particle size analysis,[5] but they originate at the very beginning[6,7] of liquid chromatography (LC) of macromolecules and remain substantially unchanged until today.

Macromolecular or particulate samples fractionated by the FFF are usually not uniform but exhibit a distribution of the concerned extensive or intensive parameter[8] or, in other words, a polydispersity. Molar mass distribution (MMD), sometimes called molecular weight distribution (MWD), or particle size distribution (PSD) describes the relative proportion of each molar mass (molecular weight), M, or particle size (diameter), d_p, species composing the sample. This proportion can be expressed as a number of the macromolecules or particles of a given molar mass or diameter, respectively, relative to the number of all macro molecules or particles in the sample:

$$N(M) = \frac{n_i(M)}{\sum_{i=1}^{\infty} n_i} \qquad N(d_p) = \frac{n_i(d_p)}{\sum_{i=1}^{\infty} n_i} \tag{1}$$

or as a mass (weight) of the macromolecules or particles of a given molar mass or diameter relative to the total mass of the sample:

$$W(M) = \frac{m_i(M)}{\sum_{i=1}^{\infty} m_i} \qquad W(d_p) = \frac{m_i(d_p)}{\sum_{i=1}^{\infty} m_i} \tag{2}$$

Accordingly, the MMD (MWD) and PSD are called number or mass (weight) MMD or PSD, respectively. FFF provides a fractogram which has to be treated to obtain the required MMD or PSD. These distributions can be used to calculate various average molar masses or particle sizes and polydispersity indices.

AVERAGE MOLAR MASSES, PARTICLE SIZES, AND POLYDISPERSITIES

As mentioned, in addition to the MMD and PSD, various average molar masses, particle sizes, and polydispersity indexes can be calculated from the FFF fractograms. If the detector response, h, is proportional to the mass of the macromolecules or particles, the mass-average molar mass or mass average particle diameter can be calculated from

$$\overline{M_m} = \overline{M_w} = \frac{\sum_{i=1}^{\infty} M_i h_i}{\sum_{i=1}^{\infty} h_i} \qquad \overline{d_m} = \overline{d_w} = \frac{\sum_{i=1}^{\infty} d_i h_i}{\sum_{i=1}^{\infty} h_i} \tag{3}$$

and the corresponding number average values are calculated from

$$\overline{M_n} = \frac{\sum_{i=1}^{\infty} M_i n_i}{\sum_{i=1}^{\infty} n_i} = \frac{\sum_{i=1}^{\infty} h_i}{\sum_{i=1}^{\infty} (h_i/M_i)} \qquad \overline{d_n} = \frac{\sum_{i=1}^{\infty} d_i n_i}{\sum_{i=1}^{\infty} n_i} = \frac{\sum_{i=1}^{\infty} h_i}{\sum_{i=1}^{\infty} (h_i/d_i)} \tag{4}$$

The width of the MMD or PSD (polydispersity) can be characterized by the index of polydispersity:

$$I_{\mathrm{MMD}} = \frac{\overline{M_m}}{\overline{M_n}} \qquad I_{\mathrm{PSD}} = \frac{\overline{d_m}}{\overline{d_n}} \tag{5}$$

PRACTICAL DATA TREATMENT

Provided that the correction for the zone broadening should not be applied, the first step in the data treatment is to convert the retention volumes (or the retention ratios R) into the corresponding molecular or particulate parameter, characterizing the fractionated species. Whenever the zone broadening correction procedure has to be applied, the data treatment protocol is modified, as described in the entry *Zone Dispersion in FFF*, p. 2455.

The dependences of the retention ratio R on the size of the fractionated species (molar mass for the macromolecules or particle diameter for the particulate matter) are presented for various polarization FFF methods in the entry *FFF Fundamentals*, p. 849. The raw, digitized fractogram, which is a record of the detector response as a function of the retention volume, is represented by a differential distribution function $h(V)$. It can be processed to obtain a series of the height values h_i corresponding to the retention volumes V_i, as shown in Fig. 1. Subsequently, the retention volumes are converted into the retention ratios R_i:

$$R_i = \frac{V_0}{V_i} \tag{6}$$

The retention ratio R in polarization FFF is related to the retention parameter λ (see *FFF Fundamentals*, p. 849) by

$$R = 6\lambda\left[\coth\left(\frac{1}{2\lambda}\right) - 2\lambda\right] \tag{7}$$

or by an approximate relationship

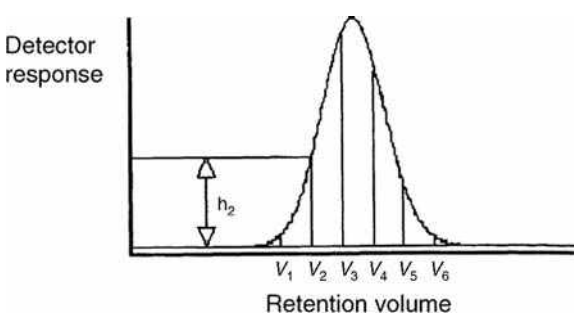

Fig. 1 Treatment of an experimental FFF fractogram of a polydisperse sample.

$$(\lim R)_{\lambda\to 0} = 6\lambda \tag{8}$$

and the parameter λ is directly related to the molecular or particulate parameters by the general relationships

$$\lambda = f(M^{-n}) \quad \text{or} \quad \lambda = f(d_p^{-n}) \tag{9}$$

where the exponent $n = 1$, 2, or 3. As concerns the focusing FFF methods, similar relationships exist between the retention ratio R and the intensive properties of the fractionated species.

Having the V_i values converted into the R_i values by using Eq. 6, the corresponding molar mass M_i or the particle diameter d_i values are calculated by applying Eqs. 7–9. The difficulty is that Eq. 7 is a transcendental function $R = f(\lambda)$ for which the inversion function $\lambda = f'(R)$ does not exist. As a result, Eq. 8 can be used as a first approximation to estimate the λ_i values from the experimental R_i data, and by applying a rapidly converging iteration procedure, the accurate λ_i values can be calculated. The subsequent attribution of the corresponding M_i or d_i values to the calculated λ_i values, by using the appropriate relationship, Eq. 9, is not mathematically complicated.

In order to obtain an accurate result, the regular segmentation ΔV_i of the raw fractogram must be converted into the ΔR_i and, thereafter, into the appropriate increment of the molar mass ΔM_i or of the particle diameter Δd_i. The corresponding conversions of the raw experimental fractograms into the MMD or PSD can be carried out according to the following protocol. Eqs. 3 and 4 can be rewritten in integral form:

$$\overline{M_m} = \frac{\int_0^\infty W(M)M\,dM}{\int_0^\infty W(M)\,dM} \qquad \overline{d_m} = \frac{\int_0^\infty d_p W(d_p)\,dd_p}{\int_0^\infty W(d_p)\,dd_p} \tag{10}$$

and

$$\overline{M_n} = \frac{\int_0^\infty N(M)M\,dM}{\int_0^\infty N(M)\,dM} \qquad \overline{d_n} = \frac{\int_0^\infty d_p N(d_p)\,dd_p}{\int_0^\infty N(d_p)\,dd_p} \tag{11}$$

where it holds for the normalized MMD or PSD:

$$\int_0^\infty W(M)\,dM = \int_0^\infty W(d_p)\,dd_p = \int_0^\infty N(M)\,dM = \int_0^\infty N(d_p)\,dd_p = 1 \tag{12}$$

By considering all of the above-mentioned transformations, Eqs. 10–12 give

$$\overline{M_m} = \int_0^\infty W(M)M\left(\frac{\partial M}{\partial \lambda}\right)\left(\frac{\partial \lambda}{\partial R}\right)\left(\frac{\partial R}{\partial V}\right)dV \left(\int_0^\infty W(M)dV\right)^{-1}$$

$$\overline{d_m} = \int_0^\infty W(d_p)d_p\left(\frac{\partial d_p}{\partial \lambda}\right)\left(\frac{\partial \lambda}{\partial R}\right)\left(\frac{\partial R}{\partial V}\right)dV \left(\int_0^\infty W(d_p)dV\right)^{-1}$$

$$\overline{M_n} = \int_0^\infty N(M)M\left(\frac{\partial M}{\partial \lambda}\right)\left(\frac{\partial \lambda}{\partial R}\right)\left(\frac{\partial R}{\partial V}\right)dV \left(\int_0^\infty N(M)dV\right)^{-1}$$

$$\overline{d_n} = \int_0^\infty N(d_p)d_p\left(\frac{\partial d_p}{\partial \lambda}\right)\left(\frac{\partial \lambda}{\partial R}\right)\left(\frac{\partial R}{\partial V}\right)dV \left(\int_0^\infty N(d_p)dV\right)^{-1} \quad (13)$$

Any of Eq. 13 can further be rewritten in a numerical form of Eqs. 3 and 4, which are convenient for the data treatment and calculations using the discrete M_i or d_i and h_i values. The acquisition of the experimental data and the treatment of the fractogram is easily performed by a computer connected online to the separation system.

FFF: Frit-Inlet Asymmetrical Flow

Myeong Hee Moon
Department of Chemistry, Kangnung National University, Kangnung, South Korea

INTRODUCTION

Frit-inlet asymmetrical flow field-flow fractionation (FIA-FlFFF)[1–3] utilizes the frit-inlet injection technique, with an asymmetrical flow FFF channel which has one porous wall at the bottom and an upper wall that is replaced by a glass plate. In an asymmetrical flow FFF channel, channel flow is divided into two parts: axial flow for driving sample components toward a detector, and the cross-flow, which penetrates through the bottom of the channel wall.[4,5] Thus, the field (driving force of separation) is created by the movement of cross-flow, which is constantly lost through the porous wall of the channel bottom. FIA-FlFFF has been developed to utilize the stopless sample injection technique with the conventional asymmetrical channel by implementing an inlet frit nearby the channel inlet end and to reduce possible flow imperfections caused by the porous walls.

DISCUSSION

The asymmetrical channel design in flow FFF has been shown to offer high-speed and more efficient separation for proteins and macromolecues than the conventional symmetrical channel. However, an asymmetrical channel requires a focusing-relaxation procedure for sample components to reach their equilibrium states before the separation begins. The focusing-relaxation procedure is achieved by two counterdirecting flow streams from both the channel inlet and outlet to a certain point slightly apart from the channel inlet end for a period of time. This is a necessary step equivalent to the stop-flow procedure as is normally used in a conventional symmetrical channel system. Although the stop-flow and the focusing-relaxation procedures are essential in each technique (symmetrical and asymmetrical channels, respectively), they are basically cumbersome in system operation due to the stoppage of flow with valve operations. In addition, they often cause baseline shifts during the conversion of flow. For these reasons, the frit-inlet injection technique, which can be an alternative to bypass those flow-halting processes, is adapted to an asymmetrical flow FFF channel in order to take advantage of hydrodynamic relaxation of sample components.

The frit-inlet injection device was originally applied to the conventional symmetrical channel in order to bypass the stop-flow procedure.[6] However, the lowest axial flow rate that can be manipulated in a frit-inlet symmetrical system is limited, because the total axial flow rate becomes the sum of the injection flow rate and frit flow rate, and the incoming cross-flow penetrates through the bottom wall at the same rate. The relatively high axial flow rate in a symmetrical system needs a very high cross-flow rate in order to separate relatively low-retaining materials, such as proteins or low-molecular-weight components.

Compared to the limited choice in the selection of flow rate conditions, application of the frit-inlet injection technique to an asymmetrical flow FFF channel can be more flexible in allowing the selection of a low axial flow rate condition which is suitable for low-retaining materials without the need of using a very high cross-flow rates and for the reduction of injection amount resulting from the concentration effect.

In FIA-FlFFF, sample materials entering the channel are quickly driven toward the accumulation wall and are transported to their equilibrium positions by the compressing action of a rapidly flowing frit flow entering through the inlet frit. The schematic view of an FIA-FlFFF channel is shown in Fig. 1. In the relaxation segment of a FIA-FlFFF channel, the frit flow stream and the sample stream of relatively low speed will merge smoothly. During this process, sample materials are expected to be pushed below the inlet splitting plane formed by the compressing effect of frit flow, as illustrated in Fig. 1b. Thus, sample relaxation is achieved hydrodynamically in the relaxation segment (under the inlet frit region), and the sample components are continuously carried to the separation segment where the separation of sample components takes place. System operation requires only a simple one-step injection procedure, with no need for valve switching or interruption of flow. This is far simpler and more convenient than the operation of the conventional relaxation techniques, such as stop-flow and focusing-relaxation procedures.

In the first experimental work on FIA-FlFF,[1] the system efficiency was studied by examining the effect of the ratio of injection flow rate to frit flow rate on hydrodynamic relaxation; the initial tests showed a possibility f using hydrodynamic relaxation in asymmetrical flow FFF with a number of polystyrene latex standards, in both normal and steric/hyperlayer modes of FFF. Normally, relaxational band broadening under hydrodynamic relaxation arises from a broadened starting band. The length of an

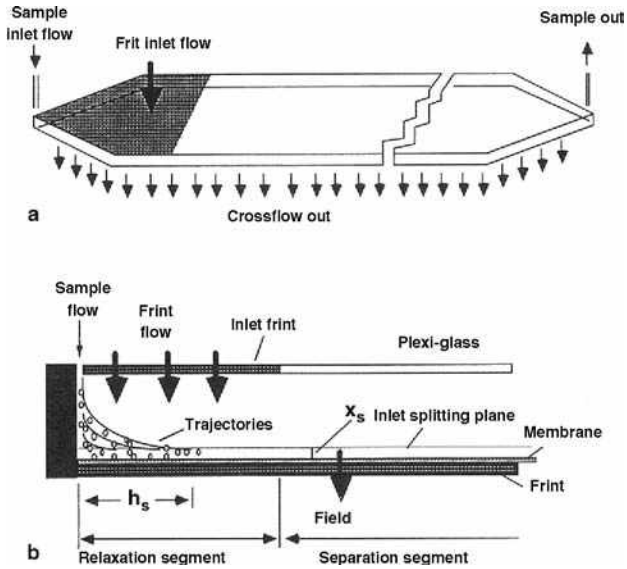

Fig. 1 Schematic view of an FIA-FIFFF channel.

initial sample band during hydrodynamic relaxation is dependent on flow rates as

$$h_s = \frac{\dot{V}_s}{\dot{V}_f}\frac{\dot{V}}{\dot{V}_c}L \tag{1}$$

where L is the channel length; $\dot{V}_s$, $\dot{V}_f$, $\dot{V}$, and $\dot{V}_c$ represent the flow rates of the sample stream, frit stream, effective channel flow, and cross-flow, respectively. Eq. 1 suggests that a small ratio of sample flow rate to frit flow rate, with a combined high cross-flow rate, is preferable in reducing h_s, leading to minimized relaxational band broadening.

Experimentally, the optimum ratio of V_s/V_f has been found to be about 0.03–0.05 for the separation of latex beads and for proteins.

Retention in the separation segment of the FIA-FlFFF channel is expected to be equivalent to that observed in a conventional asymmetrical channel system, if complete hydrodynamic relaxation can be obtained. It will follow basic principles, as shown by the retention ratio, R, given by

$$R = \frac{t^0}{t_r} = 6\lambda\left[\coth\left(\frac{1}{2\lambda} - 2\lambda\right)\right]\left(\text{where } \lambda = \frac{D}{w^2}\frac{V^0}{\dot{V}_c}\right) \tag{2}$$

where t^0 is the void time, t_r is the retention time, λ is the retention parameter, D is the diffusion coefficient, w is the channel thickness, and V^0 is the channel void volume. The void time in an FIA-FlFFF channel system is complicated to calculate, because sample flow and frit flow enter the channel simultaneously, and part of the merged flow exits through the accumulation wall. For this reason, channel flow velocity varies along the axial direction of channel. By considering these, the determination of void time can be represented as

$$t^0 = \frac{V^0 A_f/A_c}{\dot{V}_f - \dot{V}_c A_f/A_c}\ln\left(\frac{\dot{V}_s + \dot{V}_f - \dot{V}_c A_f/A_c}{\dot{V}_s}\right) + \frac{\dot{V}^0}{\dot{V}_c}\ln\left(\frac{\dot{V}_s + \dot{V}_f - \dot{V}_c A_f/A_c}{\dot{V}_{\text{out}}}\right) \tag{3}$$

where $\dot{V}_{\text{out}}$ is the channel outflow rate and A_f and A_c are the area of the inlet frit and the accumulation wall, respectively. Eq. 3 represents the void time calculation in terms of volumetric flow rate and channel dimensions only; it is valid for any channel geometry, such as rectangular, trapezoidal, and even exponential design. Retention in FIA-FlFFF has been shown to follow the general principles of FFF with the confirmation of experimental work. It has also been found that the trapezoidal channel design provides a better resolving power for the separation of protein mixtures than a rectangular channel in FIA-FlFFF.

INTRODUCTION

The present work consists of a comparative study of three different extraction techniques—specifically, liquid–liquid extraction (LLE), solid-phase extraction (SPE), and supercritical fluid extraction (SFE)—for the trace analysis of fipronil insecticide in water samples. The extracted fipronil was analyzed via high-resolution gas chromatography using electron capture detection (HRGC–ECD). The extraction methods presented linear calibration all over the investigated concentration range (0.1–1.0 μg/L). The limit of detection (LOD) was determined at 0.1 μg/L concentration level, and precision, measured by the relative standard deviations (RSD), was 7.7% for LLE, 7.8% for SPE, and 0.5% for SFE.

FIPRONIL RESIDUES IN WATER

The principal application of pesticides is related to food crops, but even given the extensive use of pesticides, about one-third of the world's total crops yield is destroyed by pests and weeds during growth, harvesting, and storage.[1] Although these pesticides are considered essential for agricultural development, some of them can cause serious ambient contamination.[2–4]

Fipronil is a highly effective, broad-spectrum insecticide with potential value for the control of a wide range of crop, public hygiene, amenity, and veterinary pests.[5] It belongs to a relatively new insecticide class, the phenylpirazoles. It was discovered in 1987 by Rhône-Poulenc researchers in Ongar, England,[6] and exhibits a mode of action that differs from traditional organophosphate, carbamate, and pyrethroid insecticides. Fipronil acts by blocking the GABA-gated chlorine channels of neurons in the central nervous system.

In recent years, there has been much discussion about the toxicity of fipronil. It is classified as a World Health Organization (WHO) class II moderately hazardous pesticide.[7] Fipronil is a relatively new insecticide that has not been used long enough to evaluate the risk; it may be dangerous to human health.[5]

Because of the rigorous limits for water purity, methods for extraction and preconcentration of pesticides present in water have become necessary. For these purposes, LLE, SPE, and SFE were used in this work.

Liquid–liquid extraction is a simple and convenient technique used to separate organic compounds from solutions or aqueous suspensions where they are present. Although LLE is often considered the conventional extraction method, it presents disadvantages because it consumes large volumes of organic solvents, which are expensive and represent a danger to health and the environment.[4]

Solid phase extraction is used in the analysis of both polar and non-polar analytes, where the matrix and the analyte of interest are usually dissolved in a liquid. It is applied to pesticide analysis in water samples because this is an easy and fast process.[8] According to Font et al.[9] the recovery of pesticides from water samples through SPE depends on the type of water, pH, and treatment of the sorbent.

Comparing LLE with SPE, Majors[10] concluded that SPE presents advantages because it reduces the consumption of solvents, has fewer steps, is less laborious and more efficient, and prevents emulsions.

Supercritical fluid extraction is a newer technique that is also used in the extraction of pesticide residues, presenting advantages in relation to other techniques, including economy of samples, solvents, reagents, and time. It also usually presents a larger recovery in the analysis of real samples.[11] Levy[12] claims that not much literature is available regarding organic pollutant supercritical fluid extraction in the aqueous matrix due to the mechanical difficulty of retaining the liquid and polar matrix in the extraction cell. Carbon dioxide has been the most widely used solvent due to its mild critical conditions, high volatility, low viscosity, high diffusivity, low cost,[13] and other favorable properties.

This entry describes the development and validation of analytical methodologies using LLE, SPE, and SFE,

followed by gas chromatography with electron capture detection analysis for the determination of fipronil residue in water.

EXPERIMENTAL

Chemicals

The fipronil standard, more than 99% pure, was obtained from Chem Service (West Chester, Pennsylvania, U.S.A.). The fipronil standard solution was prepared in ethyl acetate. Mallinckrodt (Phillipsburg, New Jersey, U.S.A.) supplied all the nanograde solvents for pesticide-residue analyses. Several adsorbents—such as octadecyl silane (35–75 mesh, Supelco), chromossorb (100–120 mesh, Johns Manville), florisil (100–200 mesh, Riedel), silica gel 60 (70–230 mesh, Merck), and XAD-7 (20–60 mesh, Rohm and Haas)—were tested as sorbents in the SPE cartridges. Different modifiers (hexane, acetone, methanol), various temperature (50, 60°C), and pressure conditions (120, 250, and 300 atm) were tested for supercritical fluid extraction. The water was purified with a Millipore Milli Q Plus System (Bedford, Massachusetts, U.S.A.).

Extraction

For all three extraction methods investigated—specifically, LLE, SPE, and SFE—100 ml of water purified in a Milli-Q system (Millipore, Eschborn, Germany) was enriched with the analytical standards mixture at 0.1 mg/L concentration level.

The best results obtained through each extraction method are described below. In LLE, 60 ml of dichlomethane was used to remove analytes from the aqueous matrix. In SPE, 1.0 g of C_{18} (octadecyl silane) sorbent was used as solid support, and ethyl acetate was used for both phase condition and compound elution. In SFE, the C_{18} phase was used as support for the sample and CO_2 in a supercritical state modified with acetone in the compound extraction at 60°C, while a pressure of 300 atm was used as the mobile phase.

GC–ECD ANALYSIS

The extracts analyses were performed using a HP 5890 series II gas chromatograph equipped with a Ni^{63} electron capture detector (Palo Alto, California, U.S.A.) and a Croma-5 coated with 0.25 mm film of cross-linked 5% phenyl methyl polysiloxane stationary phase, 30 m × 0.25 mm I.D. (Croma, São Carlos, São Paulo State, Brazil). A volume of 1 μl was injected under the following temperature conditions: injector at 250°C and detector 300°C. The initial oven temperature was settled at 140°C, programmed at 4°C/min to 270°C for 1 min. The split ratio was 1:20.

RESULTS AND DISCUSSION

Few analytical methods have been reported for the determination of fipronil residues.[6] Fig. 1 presents the fipronil insecticide chromatogram obtained by gas chromatography with electron capture detection, prepared in ethyl acetate at 0.1 mg/L concentration.

The three extraction techniques evaluated—LLE, SPE, and SFE—are appropriate for fipronil analysis in water samples. The recovery results obtained using LLE, SPE, and SFE were in the 98.0–102.8% range. Table 1 presents the recovery and RSD values obtained when LLE, SPE, and SFE were applied. These results are consistent with the acceptable range.[14,15] The extraction methods presented linear calibration at the investigated concentration range (0.1–1.0 μg/L) with correlation coefficient (r) higher than 0.99.

Due to the high amount of solvents used, LLE presents some drawbacks: costly solvent fees, environmental contamination, and work safety conditions due to

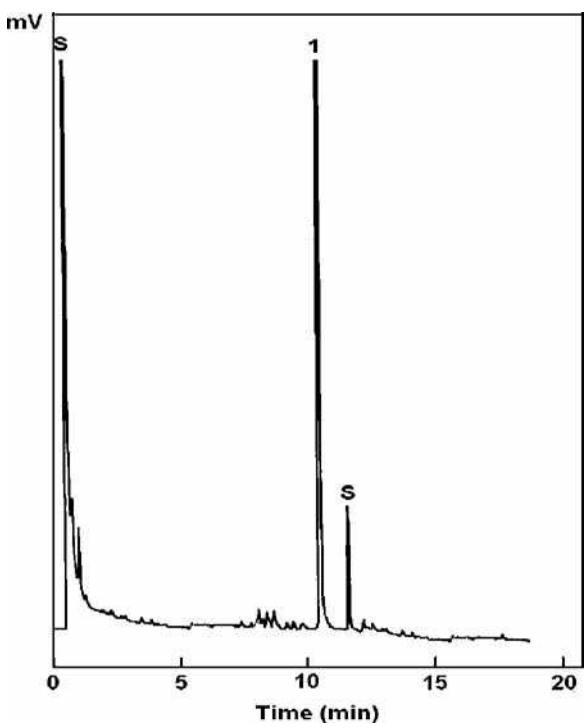

Fig. 1 Chromatogram of fipronil pesticide obtained by gas chromatography/electron capture detector at 0.1 mg/L concentration. S = ethyl acetate solvent; 1 = fipronil.

Table 1 Extraction recovery (%) and corresponding relative standard deviation (RSD) obtained through liquid–liquid extraction (LLE), solid phase extraction (SPE), and supercritical fluid extraction (SFE) in water samples enriched with 0.1 mg/L of fipronil pesticide.

	Recovery (%)±RSD (%)		
Pesticide	**LLE**	**SPE**	**SFE**
Fipronil	102.8 ± 7.7	102.1 ± 7.8	98.0 ± 0.5

the manipulation of organic solvents.[16,17] Solid phase extraction has some advantages over the conventional extraction techniques, such as LLE: simplicity, quick extraction, purer extracts, freedom from interference, lower operational cost, selective extraction, and small volume consumption of high-purity solvents. It also allows extraction and sampling in the field for later transport and storage.[10] The results obtained in our research group, which substituted SFE for other pesticide extractions in different matrices, presented excellent recovery results, besides sample, solvent, reagent, and time-saving advantages.[1,18]

Although the data showed that the three extraction methods were able to isolate the fipronil residue from water samples, the best results were obtained by using SPE and SFE, which are faster and cheaper, making them more useful techniques for the analysis of fipronil in drinking water.

The LOD was calculated by multiplying the average value of the noise sampled at the retention time of each analyte by 3,[19] and the limit of quantification was ten times the average value of the noise in this same region.[20] The detection limit found was 0.1 μg/L, and the quantification limit was 0.3 μg/L. It is possible to determine fipronil residues in water at a concentration similar to the European Union maximum admissible, 0.1 μg/L.[21]

CONCLUSION

The three extraction techniques evaluated—LLE, SPE, and SFE—are adequate for fipronil residue analysis in water samples, with good recovery results. Solid-phase extraction and SFE are the preferred techniques, as they are more sensitive and faster. Another advantage of these techniques is that they reduce the consumption of organic solvents associated with risks to health and the environment, as well as the high costs of their use and discard. However, as fipronil is a relatively new insecticide, it has not been in use long enough for researchers to evaluate the risk it may pose to human health.

Flame Ionization Detector for GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The flame ionization detector (FID) is, by far, the most commonly used detector in GC and is probably the most important. It is a little uncertain as to who was the first to invent the FID; some gave the credit to Harley, Nel, and Pretorius,[1] others to McWilliams and Dewer.[2] In any event, it would appear that both contenders developed the device at about the same time, and independently of one another; the controversy had more patent significance than historical interest. The FID is an extension of the flame thermocouple detector and is physically very similar, the fundamentally important difference being that the ions produced in the flame are measured, as opposed to the heat generated.

DISCUSSION

The principle of detection is as follows. Hydrogen is mixed with the column eluent and burned at a small jet. Surrounding the flame is a cylindrical electrode and a relatively high voltage is applied between the jet and the electrode to collect the ions that are formed in the flame. The resulting current is amplified by a high-impedance amplifier and the output fed to a data acquisition system or a potentiometric recorder.

A detailed diagram of the FID sensor is shown in Fig. 1. The body and the cylindrical electrode is usually made of stainless steel and stainless-steel fittings connect the detector to the appropriate gas supplies. The jet and the electrodes are insulated from the main body of the sensor with appropriate high-temperature insulators. Some care must be taken in selecting appropriate insulators as many glasses (with the exception of fused quartz) and some ceramic materials become conducting at high temperatures (200–300°C).[3]

As a result of the relatively high voltages used in conjunction with the very small ionic currents being measured, all connections to the jet or electrode must be well insulated and electrically screened. In addition, the screening and insulating materials must be stable at the elevated temperature of the detector oven. In order to accommodate the high temperatures that exist at the jet tip, the jet is usually constructed of a metal that is not easily oxidized, such as stainless steel, platinum, or platinum–rhodium. The detector electronics consist of a high-voltage power supply and a high-impedance amplifier. The jet and electrode can be connected to the power supply and amplifier in basically two configurations. The floating jet configuration is the most commonly used and in this arrangement, + 250 to + 400 V is applied to the cylindrical electrodes and the jet is connected to a ground by a very high resistance. The signal developed across the resistance is amplified, modified, and passed to a recorder of the data acquisition system. In the second alternative, the jet is grounded and the high-voltage power supply is electrically floated. Then, + 250 to + 400 V is applied to the cylindrical electrodes and the negative terminal of the power supply is connected to a ground by a very high resistance. The signal that is developed across the resistance is again amplified, modified, and passed to a recorder of the data acquisition system.

RESPONSE MECHANISM OF THE FID

The FID has a very wide dynamic range, has a high sensitivity, and, with the exception of about half a dozen low-molecular-weight compounds, will detect all substances that contain carbon. The response mechanism of the FID has been carefully investigated by a number workers. It was originally thought that the ionization mechanism in the FID flame is similar to the ionization process in a hydrocarbon flame, but it quickly became apparent that ionization in the hydrogen flame is many times higher than could be accounted for by thermal ionization alone. It would appear that the ionization potentials of organic materials become much lower when they enter the flame.

The generally accepted explanation of this effect is that the ions are not formed by thermal ionization but by thermal emission from small carbon particles that are formed during the combustion process. Consequently, the dominating factor in the ionization of organic material is not their ionization potential but the work function of the carbon that is transiently formed during their combustion. The flame plasma contains both positive ions and electrons which are collected on either the jet or the plate, depending on the polarity of the applied voltage. Initially, the current increases with applied voltage, the magnitude of which depend on the electrode spacing. The current continues to increase with the applied voltage and eventually reaches a plateau at which the current remains sensibly constant. The voltage at which this plateau is reached also depends on the electrode distances.

As soon as the electron–ion pair is produced, recombination starts to take place. The longer the ions take to reach the electrode and be collected, the more the recombination

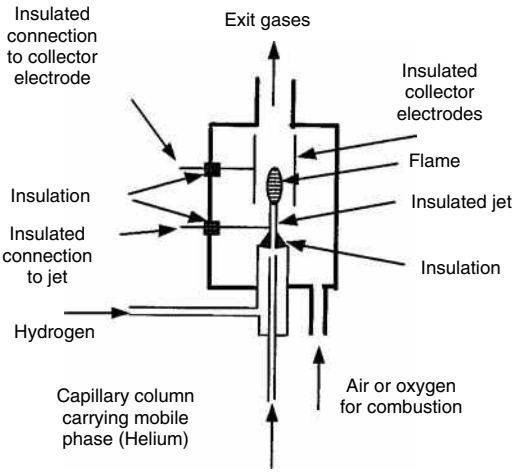

Fig. 1 The FID sensor.

takes place. Thus, the greater the distance between the electrodes and the lower the voltage, the greater the recombination. As a result, initially the current increases with the applied voltage and then eventually flattens out, and at this point, it would appear that all the ion–electron pairs were being collected. In practice, the applied voltage would be adjusted to suit the electrode geometry and ensure that the detector operates under conditions where all electrons and ions are collected.

It was also shown that the airflow should be at least six times that of the hydrogen flow for stable conditions and complete combustion. The base current from the hydrogen flow depends strongly on the purity of the hydrogen. Traces of hydrocarbons significantly increase the base current, as would be expected. Consequently, very pure hydrogen should be employed with the FID if maximum sensitivity is required. Employing purified hydrogen, Desty et al., reported a base current of 1.45×10^{-12} A for a hydrogen flow of 20 ml/min. This was equivalent to 1×10^{-7} C/mol. The sensitivity reported for *n*-heptane, assuming a noise level equivalent to the base current from hydrogen of $\sim 2 \times 10^{-14}$ A (a fairly generous assumption), was 5×10^{-12} g/ml at a flow rate of 20 ml/min. It follows that although the sensitivity is amazingly high, the ionization efficiency is still very small ($\sim$0.0015%). The general response of the FID to substances of different type varies very significantly from one to another. For a given homologous series, the response appears to increase linearly with carbon number, but there is a large difference in response between different homologous series (e.g., hydrocarbons and alcohols).

The linear dynamic range of the FID covers at least four to five orders of magnitude for $0.98 < r < 1.02$. This is a remarkably wide range that also helps explain the popularity of the detector. Examination of the different commercially available detectors shows considerable difference in electrode geometry and operating electrode voltages, yet they all have very similar performance specifications.

OPERATION OF THE FID

The FID is one of the simplest and most reliable detectors to operate. Generally, the appropriate flow rates for the different gases are given in the detector manual. The hydrogen flow usually ranges between 20 and 30 ml/min and the airflow is about six times that of the hydrogen flow (e.g., 120–200 ml/min. The column flow that can be tolerated is usually about 20–25 ml/min, depending on the chosen hydrogen flow. However, if a capillary column is used, the flow rate may be less than 1 ml/min for very small-diameter columns. The mobile phase can be any inert gas—helium, nitrogen, argon, and so forth. To some extent, the detector is self-cleaning and rarely becomes fouled. However, this depends a little on the substances being analyzed. If silane derivatives are continuously injected on the column, then silica is deposited both on the jet and on the electrodes and may need to be regularly cleaned. In a similar way, the regular analysis of phosphate-containing compounds may eventually contaminate the electrode system. Electrode cleaning is best carried out by the qualified instrument service engineer.

Apparently, the sole disadvantage of the FID as a general detector is that it normally requires three separate gas supplies, together with their precision flow regulators. The need for three gas supplies is a decided inconvenience but is readily tolerated in order to take advantage of the many other attributes of the FID. The detector is normally thermostatted in a separate oven; this is not because the response of the FID is particularly temperature sensitive but to ensure that no solutes condense in the connecting tubes.

The FID has an extremely wide field of application and is used in the analysis of hydrocarbons, solvents, essential oils, flavors, drugs, and their metabolites—in fact, any mixture of volatile substances that contain carbon.

Flash Chromatography

Mark Moskovitz
Gary Witman
Dynamic Adsorbents, Inc., Atlanta, Georgia, U.S.A.

Abstract
Flash chromatography offers an affordable, simple, fast, and convenient solution for the purification of synthetic and natural organic compounds from crude mixtures. It plays a critical role in the purification of natural plant alkaloids. Due to modularity of design and ease of use flash has become the scale-up process in the purification of products initially isolated using thin-layer chromatography (TLC) chemistry. Prepackaged flash columns are offered with more than 30 different phase chemistries having corresponding TLC plates. Using either isocratic or gradient elution techniques with flash chromatography it is possible to separate out a desired compound(s) on a single run.

INTRODUCTION

It has been 30 years since Still, Kahn, and Mitra published their seminal article.[1] This short, elegant paper established the separation technique that has eventually evolved into flash chromatography. In the subsequent three decades, dramatic advances in the life sciences have placed increasing demands on the separation sciences. These have been especially prominent in producing enhanced methods for the purification of synthetic and natural organic compounds. For many separation demands, there has been no advancement since this original paper.

Initially developed at Columbia University, flash chromatography is "an air pressure driven hybrid of medium pressure and short column chromatography which has been optimized for particularly rapid separations."[1] The resolution is measured in terms of the ratio of retention time (r) to peak width (w, $w/2$). It is measured by baseline resolution in the valley between the peaks and the distance from peak to peak. Sample size can be increased dramatically if less resolution is required. This innovative work by the Columbia University team demonstrated that column performance was quite sensitive to the rate of elution, and the best performance was accomplished with relatively high eluent flow rates.

Initially, flash chromatography was performed as a manual operation using self-packed glass columns. As the technology evolved, this chromatographic process became increasingly automated and simple in design. Self-packed glass columns have been replaced with disposable prepackaged cartridge columns that are modular in design and capable of withstanding high pressures and corrosive eluent agents. Furthermore, these prepackaged flash columns have translucent casings. The casings allow organic synthesis chemists to determine when the column is equilibrated, and when it has dried at the conclusion of the run.

Fig. 1 shows an example of commercially prepacked flash cartridges.

In addition, cartridge columns provide high-purity fractions, consistent flow rates from column to column, and reproducible results. They are simple to use and can be replaced in as little time as 20 min. Solvent waste is minimized as chemists are able to visually confirm when the equilibration occurs. Vendors now provide columns packed with 10–60 μm diameter irregular or spherical packings with more than 30 different phase chemistries that have corresponding thin-layer chromatographic (TLC) plates. This allows for method development and purity checks to be performed during flash chromatography experiments. Compressed air-driven pumps can now deliver solvent at flow rates of liters per minute with high-pressure capability. Furthermore, stationary-phase silica packing is now complemented and is increasingly being replaced by superior adsorbent materials such as alumina.

Flash chromatography can be employed to separate many crude mixtures, such as peptides and natural plant compounds, to high-purity levels. Subsequently, costly analytical high-performance liquid chromatography (HPLC) separation methods can easily be converted to flash purification methods. The selection of the proper flash system and cartridges can simplify the process, saving the chromatographer valuable time and significant amounts of money.

Fig. 2 shows an example of a flash chromatography system.

Eluents can be sampled using isocratic, step gradient, or linear gradient elution methods for up to dozens of segments. For complex mixtures of components that exhibit a broad range of retentivity, as in the isolation of natural product extracts, the use of gradient elution allows the separation of the whole sample in a single run.[2] When compounds are well resolved by TLC, isocratic separation

Fig. 1 Examples of typical flash chromatography cartridges.

is usually sufficient to achieve separation. More complex or poorly resolved samples may require gradient elution. In this situation, the stronger solvent concentration is increased during the sample purification. Elution mode can also effect separation.

THEORY/METHODOLOGY

In preparative chromatography, it is essential to remove the mobile phase from the collected fraction. Therefore, to simplify separations, all eluent components, including buffers, should be volatile. Best separations are achievable if one can inject a large amount of sample dissolved in a relatively small volume of mobile phase. The critical properties of the solvents are the viscosity of the concentration sample solution in the mobile phase and the elution strength of the sample solvent compared to the mobile phase.[3] Ultimately, the goal is to select a phase system having sufficient sample solubility. This will determine the possible column loading, the performance, the throughput of the system, and the concentration of the collected fractions.

Properties of the flash system that need to be addressed include selecting eluents allowing for high loading capacity, using air-driven pumps with enhanced performance, and selecting the right sorbent media to get the highest concentration of the selected fractions.

One fundamental principle in dealing with flash chromatography is to assure that separation purification is first achieved using TLC. By doing so, the mobile and separation media, as well as elution techniques desired for scale-up, are tested first on a smaller scale. Using similar materials, it is possible to then scale up from TLC to preparative or industrial scale purification. The same stationary-phase (sorbent) packing material, such as silica gel or alumina, can be provided by vendors, such as Dynamic Adsorbents, Inc., Georgia, United States, and is used for both TLC and flash chromatography. This consistency in sorbent packing media assures identical chromatographic selectivity. The scaling-up process is easier if the packing material is the same, or at least from the same batch or manufacturing process, as that used in the TLC analytical and preparative scales.[4] TLC retention factor (R_f) values correlate directly with the separation on a column. TLC R_f is inversely proportional to flash cartridge retention, which is also measured in column volumes.

Preparative flash chromatography methods can be achieved in as little time as 2–3 days. To optimize separation conditions, dozens of TLC evaluations can be simultaneously run in small beakers. This is achieved by having a different solvent system in each beaker. Each TLC

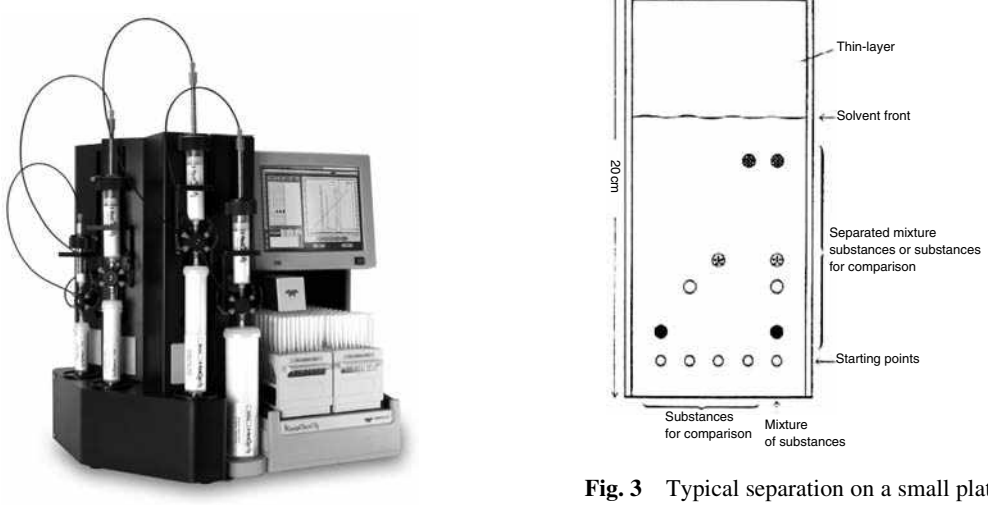

Fig. 2 Example of a flash chromatography system.

Fig. 3 Typical separation on a small plate.
Source: From Column Chromatography with Dynamic Adsorbents, Inc. 2nd Ed.[5]

system requires 10 min or less to run. Through this technique it is possible to optimize the developing solvent system. This can be accomplished by using a Vario chamber enabling simultaneous, side-by-side development, with six different solvents on the same TLC plate. Developing a pilot scale purification process requires 2–5 hr of TLC, and 2–4 hr of laboratory work to confirm a small-scale cartridge (Fig. 3).

Without TLC plates, method development for the separation and purification of compounds consists of running small-scale analytical or small-scale flash chromatography. Once mobile and stationary phases for optimal sample purification are identified, the full sample batch is purified by using preparative flash techniques. Prerequisites for a successful method transfer include the need for similar sorbents, identical composition of the mobile phase, and adherence to reproducible chromatographic conditions in TLC and preparative chromatography.[6] Manufacturers of media have addressed the demands of end users and have provided products with defined pore structure, chemical purity, as well as specific pore volume and surface characteristics. The contemporary selectivity of TLC media as flash grade alumina or silica gel media is basically identical. As resolution decreases with increasing particle size, there is a trend in flash chromatography toward using smaller particle size material and increasing pump pressure to quickly drive the eluent through the stationary phase.

Pilot scale manufacturing may require hundreds of grams of material. Flash chromatography provides the means to purify large volumes of material. Columns typically use 40–60 μm diameter silica or alumina particles. They permit high flow rates and effective separations with modest system pressures in the range of 40–100 psi. Through the use of these larger particles and radial compression technology, it is possible to achieve excellent separation at a fraction of the cost of HPLC systems.

The goals of preparative flash chromatography are to produce a highly concentrated fraction, to collect and transfer the fraction without contamination, and to perform the separation as quickly and cheaply as possible (Fig. 4).[7]

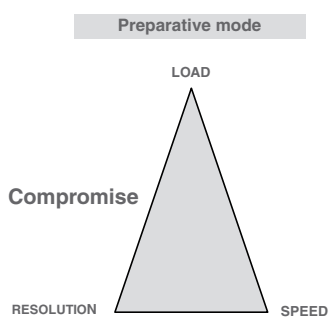

Fig. 4 Preparative mode compromise.

When the column dimensions are changed to optimize a separation, or to scale a separation to be preparative or narrow bore, the mobile-phase flow rate is adjusted in proportion to the cross sectional area of the column. This then maintains consistent linear velocity and retention times.

$$\text{Flow rate}_{\text{final}} = \frac{(D_{final})^2}{(D_{initial})^2} \quad (1)$$

When scaling up run times on a preparative column from small-scale analytic testing, a simple procedure is followed:

$$\text{Run time (prep)} = \text{Run time (analytical)} \times \frac{\text{Column length (analytical)}}{\text{Column length (preparative)}} \quad (2)$$

To retain the same end product resolution while increasing the column diameter, the gradient shape must be maintained by keeping constant the ratio of the gradient volume to the column volume.

SCALE-UP UTILITY OF FLASH CHROMATOGRAPHY

Among the factors affecting the purification efficiency of flash chromatography are sample homogeneity and sample concentration. When the compound and reaction by-products are highly diluted or dissolved in an overly polar solvent, the compound peak broadens, leading to loss of resolution. Simply put, volume overloading causes significant band broadening that degrades sample resolution.

Because small-diameter narrow particle range adsorbents are more expensive to manufacture, there is a cost advantage for using larger-diameter materials in preparative columns. There are also other advantages to using larger particle sizes. For example, when the column overload increases, the sample band widths start to increase and the column plate number becomes more a function of sample size than of the column conditions. As a result, it is often advantageous to use larger particles. Larger particles have higher loadability, cause lower back pressure, and therefore increase flow rate while decreasing elution time.[8]

Oftentimes, the objective of preparative flash separations may be different from the objective of analytical separations. Speed and sensitivity may be less important than product purity in preparative chromatography. Preparative columns may operate at flow rates lower than in analytic columns with gradient profiles altered in order to compensate for the less efficient mass transfer of larger adsorbent particles.

There is a major advantage in the use of alumina oxide (alumina) over silica gel ($SiO_2 \times H_2O$) for flash

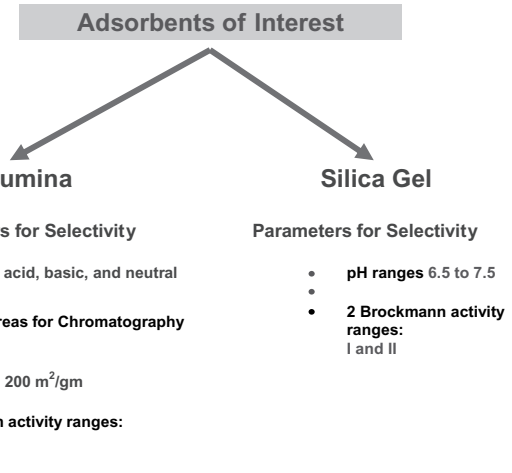

Fig. 5 Graph shows advantages of alumina over silica.

chromatography purification applications (Fig. 5). Owing to its amphoteric character, alumina oxides can be used in specifically defined pH ranges.

Using flash grade silica, or alumina with a high-purity clean particle size distribution, is essential. The particle size distribution of the silica or alumina flash product of 32–63 μm or 230–400 mesh is the favored industry average. This ensures a more uniform adsorbent-packed column or cartridge, providing superior resolution and separation.

The importance of the clean particle size distribution varies depending on the type of chromatography being performed. In medium pressure liquid chromatography (MPLC), it is very important that silica or alumina particles of a very clean particle distribution be used (no fines and no large particles). Separation chemists need to remember that not all 40–63 μm silica gels are the same. Additionally, it is also very important to use an alumina or silica gel containing as little metal contamination as possible as demonstrated by Dynamic Adsorbents, Inc., media.

In flash chromatography, one requires an adsorbent with a much higher percentage of particles between 32

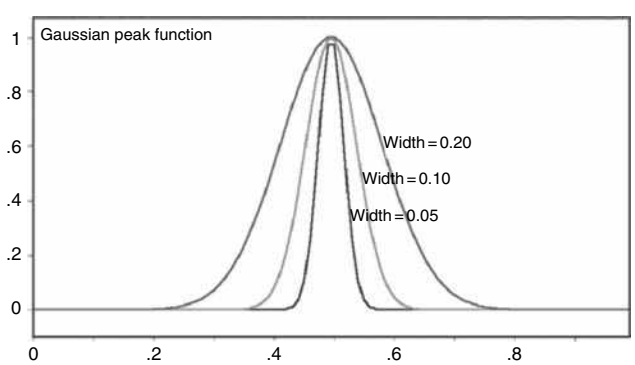

Fig. 6 An example of ideal Gaussian curves.

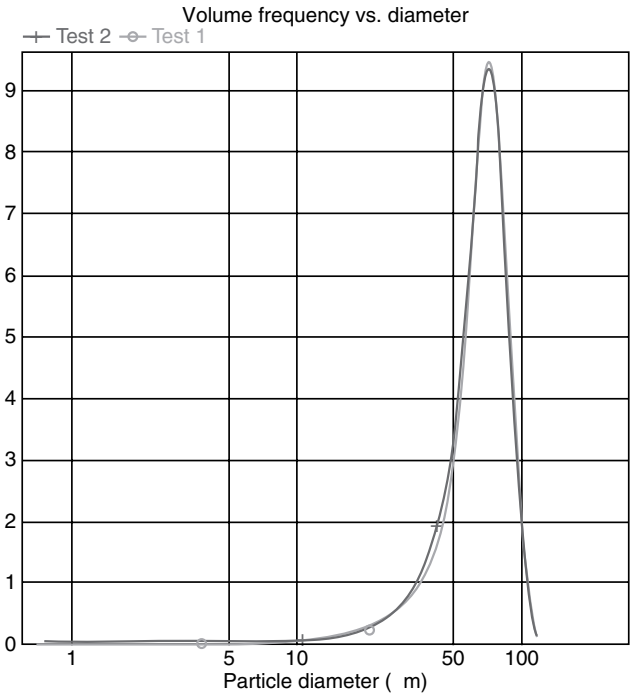

Fig. 7 Typical Micromeritics saturn instrument scan for illustrating and determining particle size distribution.

and 63 μm and a very low level of small particles, or fines, below 32 μm. Fines increase backpressure, which may result in clogging—a complication of the separation process that is particularly dangerous when using glass columns. Fines can also pass through filters and contaminate the final product, therefore rendering the final product useless. Using a sorbent containing fewer fines provides a more regular, stable, and reproducible chromatography bed. This achieves a faster, more even flow rate that yields superior separations.

An adsorbent having 90% particles on average would be the ideal range. The connection between particle size distribution and column performance is important. When the range in particle size is broad, column packing becomes uneven. Furthermore, some regions may be mainly composed of large particles where the solvent will flow quickly, meeting very little resistance. In a similar situation, there are other regions composed primarily of smaller particles causing uneven flow characteristics secondary to more solvent resistance. The solvent will take the path of least resistance through the column and flow around the pockets of small particles and not straight through the column. This uneven flow greatly affects the separation as the peaks will have different retention times depending on the flow path when the solvent emerges from the column. When the sample exits the column, compounds will give peaks that are broad and poorly separated (Fig. 6).

Table 1 Functionalized silica gel.

Functionalization	Suitable solvent
Amine (most organic compounds)	Hexane, ethyl acetate, methylene chloride, chloroform, methanol, ethanol, isopropranol, water, acetonitrile
Cyano (most organic compounds)	Hexanes, ethyl acetate, methylene chloride, chloroform, methanol, ethanol, isopropanol, water, acetonitrile
C-2, C-8, C-18	Methanol, ethanol, isopropanol, water, acetonitrile, etc.
Fluoro-tagged (separate organic compounds from fluorinated compounds and separation of fluorinated compounds by degrees). Fluorous silica gel may be used in the purification of peptides, oligonucleotides, and oligosaccharides. The orthogonal nature of this purification enables desired oligomers to separate from truncations and deletion sequences.	Methanol, water. This is a two-step separation. Fluorous molecules are selectively retained on the stationary phase while non-fluorous molecules are not. The fluorous component is eluted with a fluorophilic solvent, without the need for buffers or fluorinated solvents.

Uneven solvent flow will give broad peaks that are poorly separated from other components.

A more even particle distribution provides a narrower Gaussian peak and purer compounds (Fig. 7).

APPLICATION

Flash chromatography is playing a leading role in the purification of natural plant alkaloids. These are increasingly being looked upon as the major source for pharmaceutical agents. In areas such as antineoplastic and anti-infective agents, natural products are the dominant source of successful new bioactive compounds.[9,10] Among the estimated 420,000 plant species on Earth, less than 10% have been phytochemically investigated. Within each plant species lay multiple metabolites that still need to be screened as pharmaceutical agents.[11] The following are purified using alumina oxide as an adsorbent in flash chromatography processes:

Alkaloids—basic, medium activity isolation of ergo, opium, rauwolfia, and other alkaloids
Antibiotics—neutral isolation, purification
Essential oils—basic, neutral removal of terpenes
Plant extraction—basic, neutral, acid isolation of active substances
Degradation of organic solvents—basic, highly active
Enzymes—neutral purification
Glycosides—neutral isolation of digitalis, strophanthus glycosides
Lipids—non-polar lipids, glycolipids, and phospholipids
Removal of peroxides—basic, highly active from organic solvents
Hormones—neutral isolation and purification of ketosteroids from neutral materials
Purification of organic solvents—basic, highly active for technical purposes
Oils—basic clarification of fatty oils, separation of fatty acids

A cardinal reason for using alumina, rather than silica gel as the sorbent for purifying organic compounds, is that natural compounds contain amines or nitrogen-containing heterocyclic structures. The amphoteric property of alumina is the chemical mechanism for superior separation of natural products containing alkaloids. These are cyclic organic compounds in a negative oxidation state.

Silica gel can be used in either normal- or reversed-phase conditions. Normal-phase silica is slightly acidic and has some acid-sensitive compounds that will break down when using silica for separation/purification. Compounds that have an acidic or basic moiety may streak or tail with normal or reversed-phase silica. This may occur when interacting with residual surface silanol groups on normal-phase chromatographic support. This interaction between functional groups and the silanol groups causes peak streaking and tailing, which then leads to a deterioration in chromatographic purification. For acidic and basic organic compounds, it is recommended that alumina oxide be used as the adsorbent agent.

An option for using silica gel as the sorbent for purifying acidic or basic compounds would be to add a mobile-phase modifier. This process reduces peak tailing and sharpens peaks. However, when using modifiers (such as triethylamine or ammonium hydroxide for basic compound separations), the added modifier remains after evaporation of the volatile solvents such as dichloromethane and methanol. Removal of the modifier then requires the additional steps of extraction, or washing, with a suitable solvent. Additionally, this may also be achieved by concentrating the mixture down to an oil. In practice, using alumina as the sorbent provides a far simpler solution and a much cleaner product. Silica gel is commercially functionalized in C-2, C-8, C-18, amine, cyano, diol, fluoro-tagged products, and many others (Table 1).

When reusing a functionalized silica column, it is recommended to always flush the column with the highest polarity solvent that was used in the previous separation or purification. Subsequently, purge the column with air following flushing. Purging with air, and keeping the column in a desiccator when not in usage, increases the life expectancy of the column.

CONCLUSION

Advances in media, eluent materials, and air-driven pumps allow today's chromatographer to achieve the defined goals of preparative flash chromatography. Highly concentrated fractions are collected and transferred without contamination. Flash separations are performed quickly and as cheaply as possible. The need for more costly preparative HPLC has now been eliminated in many settings.

Flash Chromatography: TLC for Method Development and Purity Testing of Fractions

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Flash chromatography (FC) is a type of preparative column liquid chromatography (LC) that was first described in 1978. As traditionally performed in most laboratories today, and taught in college organic chemistry laboratory courses, sorbent (usually ~40–60 micron diameter silica gel, 60 Å pore size) is manually dry packed into a glass tube (e.g., 10–20 cm length and 10–50 mm I.D.) fitted with a stopcock at the bottom. Sample is applied (after filtration if necessary) on to the top of the column, a relatively non-polar eluent (mobile phase) is forced through using a vacuum manifold, air pressure, or a low-pressure (<100 psi) pump, and fractions of effluent are collected (~ every 0.5 column volume) and analyzed. The volume of eluent, flow rate, sample load, and fraction size are determined by the size of the column; in general, longer columns give better resolution and wider columns higher sample loading. Sample sizes separated by FC are typically at milligram to gram levels, but scale up to 10s or even 100s of grams is possible. FC is faster than traditional column purification using gravity flow and larger silica gel particles; it is less efficient and has lower separation power when compared with analytical column high-performance liquid chromatography (HPLC), but higher sample amounts can be purified.

Modern online FC systems have made the method faster, safer, and more flexible and reproducible by incorporating reusable plastic cartridges prepacked with the sorbent and other features such as eluent (isocratic or gradient) pumped at a high rate by a medium pressure pump, ultraviolet (UV) detection, computer software control, and automated fraction collection (Figs. 1 and 2 show typical modern FC systems). These systems are applied in sample cleanup, natural products purification, organic synthesis, combinatorial chemistry, drug discovery, pharmaceutical intermediate purification, and many other areas. Normal phase (NP) FC of polar compounds on silica gel columns is still the most widely used mode, but reversed phase (RP; e.g., C_{18} octadecyl silane), celite, ion exchange, and other types of sorbents are becoming used more frequently. This entry will focus only on NP-FC.

THIN-LAYER CHROMATOGRAPHY AS A PILOT METHOD FOR FC

Isocratic Elution FC

Thin-layer chromatography (TLC) of the sample mixture is most often used to predict the optimum isocratic eluent composition in traditional and modern FC. For rapid elution and separation, the TLC mobile phase should provide an R_f value of 0.15–0.35 for the component of interest, and the difference in R_f values (delta-R_f) should be 0.15 or greater between components to be separated. R_f is defined as the distance traveled by the compound zone divided by the distance traveled by the mobile phase front.

In terms of column volumes (CVs), the ideal FC mobile phase elutes the desired component in 3–6 CVs and will separate two components if their CVs differ by 1 or more. A CV is defined as the volume of solvent filling the sorbent pores and spaces between particles in a column of any dimensions, and it is related to R_f by the equation $CV = 1/R_f$. As examples, an R_f of 0.90 indicates that 1.1 CV will be required to elute the compound from the column, R_f 0.50 requires 2.0 CV, and R_f 0.10 requires 10 CV.

When adjusting mobile phases to meet the R_f and delta-R_f or CV and delta-CV requirements, it should be remembered that when using NP silica gel, mobile-phase strength and component mobility increase when the solvent composition becomes stronger (more polar) [e.g., hexane–ethyl acetate (9:1, v/v) replaced by (8:2, v/v)], and selectivity is changed by using a different solvent combination that maintains a similar, favorable retention [e.g., hexane–dichloromethane (1:2) instead of hexane–ethyl acetate (1:1)]. Table 1 gives solvent strength values that allow calculation of mobile phases with similar strengths but different selectivities that may improve resolution using the equation:

$$\begin{aligned}\text{Solvent strength} = {} & (\text{solvent A}\% \\ & \times \text{solvent A strength})/100 \\ & + (\text{solvent B}\% \\ & \times \text{solvent B strength})/100.\end{aligned}$$

Fig. 1 VersaFlash high throughput flash purification (HTFP) system shown with two stacked prepacked 40 × 75 mm (51 g) cartridges inserted in the support stand and 110 × 300 mm (1.35 kg), 80 × 150 mm (410 g), and 23 × 110 mm (23 g) cartridges on the right side of the eluent pump. The 3-way valve injector at the upper right allows direct application of sample onto cartridges using a syringe. The outlet tubing can be used for manual sample collection or connection to an automated fraction collector or UV detector.
Source: Photograph supplied by Supelco, Bellefonte, Pennsylvania.

Table 1 Solvent strength values of different solvents used to prepare TLC mobile phases and FC eluents.

Solvent	Strength
Methanol	0.95
Ethanol	0.88
2-Propanol	0.82
Acetonitrile	0.65
Ethyl acetate	0.58
Tetrahydrofuran	0.57
Acetone	0.56
Dichloromethane	0.42
Chloroform	0.40
Diethyl ether	0.38
Toluene	0.29
Hexane	0.01
Heptane	0.01
Iso-octane	0.01

With this equation, it is found that hexane–ethyl acetate (50:50) has a solvent strength of 0.30, hexane–ethyl acetate (60:40) is 0.24, and hexane–dichloromethane (30:70) is 0.30. A greater TLC separation will lead to a greater difference in CV values and allow more samples to be applied to the column. For example, if impurity A is separated from the compound of interest (target compound) B with respective R_f values of 0.55 (1.8 CV) and 0.40

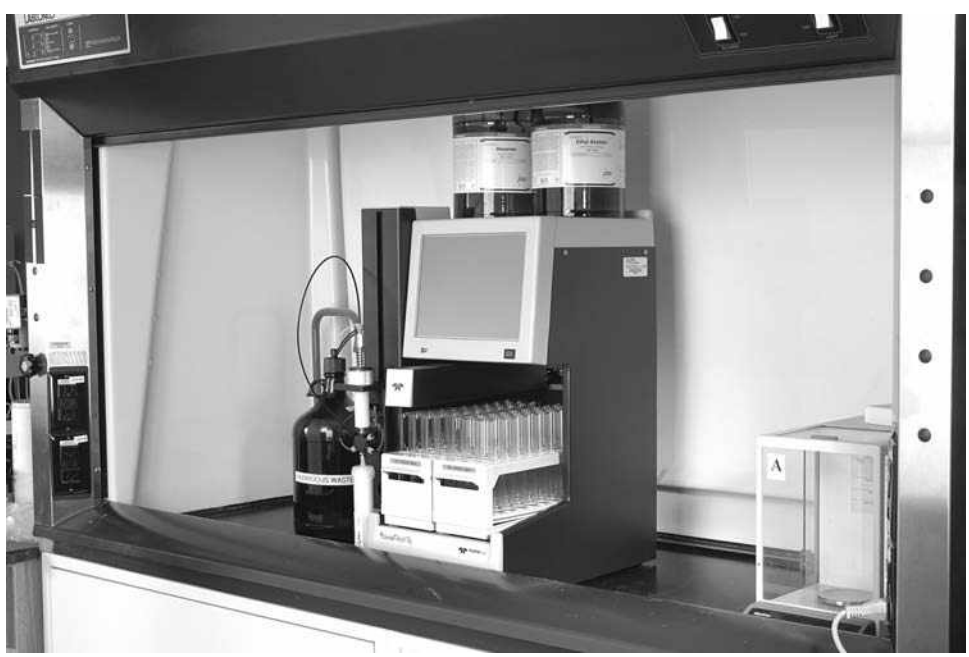

Fig. 2 CombiFlash R_f automated FC instrument, which features a PC touchscreen controller with PeakTrack software, linear and/or step gradients, 4–330 g column sizes, two fraction collection racks each holding seventy 18 × 150 mm tubes, six-position motor powered sample loading valve, and UV variable dual-wavelength detector.
Source: Photograph supplied by Teledyne Isco, Inc., Lincoln, Nebraska.

(2.5 CV), delta-CV is 0.7 and only a small amount of sample can be purified before overload and loss of resolution occurs. Both R_f values are outside the optimal 0.15–0.35 range. If a weaker mobile phase can be used giving separation within the optimal range with respective R_f values of 0.35 (2.9 CV) and 0.20 (5.0 CV), the delta-CV is 2.1 and a greater than five-fold sample load increase is potentially possible.

For the best transfer of TLC results to FC, the sorbents used in both methods should match as closely as possible (same manufacturer). Differences in the sorbents (e.g., moisture content, particle size, pore size, shape, TLC binding agents), as well as in the basic chromatographic processes (closed column compared with an open layer, mobile phase velocity, relative humidity) may cause the TLC conditions not to be directly transferable to FC and require application of a predetermined correction factor to the TLC results.

Traditional large volume glass TLC chambers (N-tanks) are usually used for development of 20×20 cm commercially precoated silica gel TLC plates with the mobile phase when scouting FC eluents. However, microscope slide size TLC plates (2.5×7.5 cm) developed in small-capped jars can be used if available with silica gel matching the FC column. For faster method development, the Uniflash (Hologent Technologies, Inc., Baldwin Park, California, U.S.A.) Planar Station horizontal chamber allows four different mobile phases to be evaluated simultaneously on two microscope slide plates precoated with Merck silica gel 60 or their own UniFlash silica; other manufacturers offer different microscope slide plates that may transfer more directly to the FC column to be used. The Planar Station has a base with four separate wells each holding up to 1 ml of mobile phase, Teflon plate holder supporting two microscope slide TLC plates, and 0.5 in. thick glass cover that achieves vapor saturation of the individual mobile phases with the plate surface. Mobile phase is added to each well, the plate holder is placed in the plate loading position over the base, the plates are spotted with sample at both ends, and they are placed face down on the plate holder such that they contact the top edges of the mobile phase wicks. The cover plate is placed on the plate holder over the TLC plates, creating four separate sealed chambers. The plate holder/cover assembly is shifted to the development position over the base, causing the bottom edge of each wick to contact the respective mobile phase in the wells of the base. Mobile phase is drawn up to the plates to produce a total of four unique chromatograms. In examples of possible patterns of usage, the wells can be filled with mobile phases consisting of four different solvent combinations, or a single solvent pair with four different percentage compositions.

Sample solutions are generally applied to the origin line of the TLC plate using a micropipette. Separated zones that are naturally colored are detected by viewing in daylight, naturally fluorescent zones are detected in a viewing box under 254 or 366 nm UV light, and compounds that absorb 254 nm UV light are detected as dark zones on a bright green background on plates containing a fluorescent phosphor by viewing under 254 nm UV light (fluorescence quenching detection).

Gradient Elution FC

Step or continuous (linear) gradients may be required for FC separation of complex mixtures. For predicting step gradients, TLC is used to choose different solvent mixtures that elute each component with R_f 0.15–0.35, and the calculated number of CVs of each required for component elution is used for FC starting with the weakest (least polar). For linear gradients, TLC is used to find weak (all R_f values are low) and strong (all high R_f values) solvents, and an FC gradient is run from pure weak solvent to pure strong solvent.

Teledyne Isco, Inc., offers PeakTrak 2.0 software featuring an R_f to gradient calculator for use with their CombiFlash automated FC purification systems (Fig. 2). Only two thin layer developments of the crude reaction mixture with different mobile phases providing R_f values within the range of 0.2–0.8 are needed. The mobile-phase composition and corresponding R_f values are entered into the calculator, and the software gives a gradient profile specific to the sample for separation between the target compound and the nearest impurity. The linear gradient suggested may include an isocratic hold to provide greater sharpening and separation of the FC peaks of the two compounds, compared with fully isocratic or linear gradient separation. An auto scale-up feature is also included in the software.

ANALYSIS OF FC FRACTIONS

Collected FC fractions are analyzed by TLC to determine if the compound of interest is present and to determine its purity. The mobile phase should be reoptimized, if necessary, for separation of the compounds most likely to be present in each fraction. R_f values and detection characteristics of the compound zones separated from fractions are compared with those of standards (if available) developed on the same plate to aid identification of the zones. The ability to apply multiple standards and samples onto

one plate is an advantage in terms of speed and cost of analysis.

CONCLUSION

TLC is the most widely used technique for method development and determining the purity of fractions in FC. In this entry, it is shown how both isocratic and gradient eluents can be easily and rapidly optimized by TLC on layers corresponding to FC columns.

Flavonoids: CCC Separation

L.M. Yuan
Department of Chemistry, Yunnan Normal University, Kunming, China

INTRODUCTION

Various countercurrent chromatography (CCC) methods employ two-phase solvent systems for separation of flavonoids. $CHCl_3$: CH_3OH : H_2O (4 : x : 2, for which x is between 2.5 and 4 for different samples) may be used for their prefractionation. Two-phase solvent systems can be divided into four types: $CHCl_3$: CH_3OH : H_2O, $CHCl_3$: CH_3OH : *n*-BuOH :H_2O, EtOAc : PrOH : H_2O or BuOH : HOAc : H_2O, and *n*-C_6H_{14} : EtOAc : CH_3OH : H_2O, respectively. CCC fractionation permits the use of either stepwise elution or gradient elution, and analytical-scale CCC can also be carried out for separation of flavonoids.

FLAVONOIDS

Flavonoids are polyphenolic compounds and have a wide polarity range. Successful CCC depends on the appropriate choice of a solvent system. The partition of solutes between two immiscible solvent phases is an ideal method for the separation of flavonoids because the phenomenon of irreversible adsorption, tailing, sample loss, and denaturation, which plague analysts using other forms of liquid chromatography (LC), are avoided.

SEPARATION OF FLAVONOIDS BY CCC

Flavonoids are a specific class of polyphenols. It is generally believed that flavonoids include a wide variety of phenolic compounds, such as flavones, flavonols, flavanones, flavanonols, anthocyanidins, flavan-3,4-diols, xanthones, flavan-3-ols, isoflavones, isoflavanones, chalcones, dihydrochalcones, aurones, and homoisoflavones. Their separation poses special problems because there is often irreversible adsorption and even hydrolysis on solid supports.

The development of CCC began in the mid-1960s. Among various types of CCC modes for the separation of flavonoids, the main techniques are droplet countercurrent chromatography (DCCC), rotary locular countercurrent chromatography (RLCCC), and centrifuge partition chromatography (CPC). Today, the cartridge and multilayer coil CPC methods are the leading techniques.

The selection of a solvent system is the most important step in performing CCC. Selecting a solvent system for CCC means *simultaneously* choosing the column and the eluent. The chromatographic literature contains numerous examples of solvent systems used in various CCC systems for separation of flavonoids,[1–6] and consultation of these references may give some leads as to possible systems that would be useful for a particular separation. The selection of appropriate biphasic solvent systems also may be aided by thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC) experiments.

One quite remarkable comparative separation of flavonoids by DCCC, RLCC, and cartridge and multilayer coil CPC methods, with the same solvent system (chloroform–methanol–water, 33 : 40 : 27), is shown in Fig. 1.[7,8]

Elutions of the three peaks were similar and according to the order of increasing polarity: hesperetin, kaempferol, quercetin. The above peak effect can be seen in the various CCC methods, which have similar two-phase solvent systems, for the separation of flavonoids, but DCCC and RLCC require much more time than CPC.

A versatile two-phase solvent system for flavonoid prefractionation by high-speed CCC was introduced.[9] The

flavonoid compounds encompass a wide polarity range and exhibit good solubility in methanol. The two-phase solvent system composed of $CHCl_3$:CH_3OH : H_2O = 4 : *x* : 2, in which *x* was between 2.5 and 4 for different samples, was selected for the separation of crude flavonoid extracts because this solvent system contains methanol and provides nearly equal volumes of the upper and lower phases with reasonably short settling times. Changing the ratio of methanol in the solvent system permitted changing, simultaneously, the selectivity of the upper and lower phases, as methanol can dissolve in chloroform and water and may change the polarity of the two phases.

The previous applications of CCC are summarized in Table 1. One may use this table to search for suitable solvent systems that have been previously used for similar compounds.

In Table 1, the various two-phase solvent systems are divided into four types. It has been shown that the solvent system chloroform–methanol–water has been used for the greatest number of applications. $CHCl_3$: CH_3OH : H_2O is a versatile CCC solvent system for flavonoid separations as well.

The second most used two-phase solvent system is $CHCl_3$: CH_3OH : *n*-BuOH (*i*-PrOH or PrOH) : H_2O. It is similar to $CHCl_3$: CH_3OH : H_2O, but CH_3OH is partially replaced by BuOH, *i*-PrOH, or PrOH. The desirable *K* value may be obtained by varying the ratios.

The third most used type of two-phase solvent system is EtOAc : PrOH (BuOH or EtOH) : H_2O or BuOH : HOAc (or PrOH) : H_2O. It is a more polar solvent system and is useful for the separation of flavonoid glycosides.

The final type of solvent system is *n*-C_6H_{14} : EtOAc : CH_3OH : H_2O. Sometimes CH_3OH also may be substituted by other solvents such as BuOH. It is a slightly more hydrophobic solvent system than $CHCl_3$: CH_3OH : H_2O.

Analogous to HPLC, CCC fractionation permits the use of either stepwise elution or gradient elution, provided that some precautions are taken. For example, in the isolation of extracts of *Ginkgo biloba*, one starts with water as a stationary phase, eluting with ethyl acetate with increasing amounts of *i*-butanol and finally reaching the 6 : 4 proportion of ethyl acetate : *i*-butanol at the end of the elution.[10]

Samples ranging in size from microgram to gram quantities can be separated with the range of available instruments. Analytical-scale CCC also was carried out for the separation of flavonoids.[11]

CONCLUSIONS

The application of CCC to the separation of flavonoids has been proven to be very successful. Chloroform–methanol–water can be chosen as starting point and, by modifying the relative proportions of methanol or by replacing methanol with other solvents, it is possible finally to obtain the required distribution of sample components between the two phases. EtOA : PrOH : H_2O and *n*-C_6H_{14} : EtOAc : CH_3OH : H_2O also are very useful solvent systems. The technique is versatile and can be employed for the initial fractionation of crude extracts for the separation of closely related flavonoids and/or the isolation of pure products.

INTRODUCTION

Flavonoids are widely spread plant secondary metabolites called C_6–C_3–C_6 phenolics, which are classified in three groups, depending on the nature of the C_3 fragment and the type of the heterocyclic ring, as follows: 1) chromone derivatives (flavones, flavonols, flavanones, and flavanonols); 2) chromane derivatives (catechines and antocyanidines); and 3) flavonoids with open propane chain (chalcones) and with a furane ring (aurones). From all of these, flavones, flavonols, and flavanones are the most abundant in the plant kingdom and their skeleton is given in Fig. 1. Substitution in the positions 3, 5, 6, 7, 8, 2′, 3′, 4′, 5′, and 6′ gives all the compounds from these groups, with hydroxylation, methoxylation, and glycosylation being the most common substitution. Thousands of various flavonoids with various substitution patterns are recognized today as *free* flavones, flavonols, and flavanones, i.e., *aglycones*, and as *flavonoid glycosides*, which consist of flavonoid, non-sugar component *aglycone*, connected to the *sugar moiety* (mostly monosaccharides and disaccharides). Bonding to sugars makes flavonoids soluble in water and enables their easy transport within plants.

Flavonoids are a well-defined group of compounds with established physical and chemical characteristics. This especially counts for their absorption of ultraviolet (UV) radiation, which makes their UV spectra very characteristic and UV spectroscopy a method of choice for their characterization.[1] Two main absorption bands are observed: 1) band I (300–380 nm) due to absorption of ring B; and 2) band II (240–280 nm) due to absorption of ring A. The position of these bands gives information about the kind of the flavonoid and its substitution pattern; thus UV spectroscopy is used as a main method for the identification and the quantification of flavonoids for decades.

There are several published information regarding the isolation and the identification of flavonoids in plant material using different methods, mainly chromatographic and spectroscopic. Today, high-performance liquid chromatography (HPLC) is established as the most convenient method which enables separation and identification of flavonoids using various detection systems.[2–4] As for the quantitative analysis, much data have been published in the last few years confirming the suitability of this technique for simultaneous determination of flavonoid compounds in various samples, which gives an insight into the distribution of flavonoids in the studied material. HPLC methods are developed for qualitative and quantitative analyses of flavonoids in fruits and beverages, wine, honey, propolis, and, especially, in various plant materials[5–14] using different detection systems, from which UV diode array detectors are settled as the most suitable for these compounds and the most accessible as well.

EXPERIMENTATION

Stationary Phases

HPLC is the method of choice for the separation of complex mixtures containing non-volatile compounds such as various flavonoids in extracts prepared from different samples. A survey of literatures revealed that most researchers have used C_{18}-reversed stationary phases, which proved to be superior to the normal phase technique. The reversed phases are suitable for separating flavonoids in a wide range of polarities, as Vande Casteele et al.[15] have demonstrated the separation of 141 flavonoids from polar triglycosides to relatively non-polar polymetoxylated aglycones belonging to the classes of flavones, flavonols, flavanones, dihydroflavonols, chalcones, and dihydrochalcones.

The use of normal phase silica columns was also described but after acetylation of the flavonoids and then isocratic elution on silica gel.[16] Polystyrene divinylbenzene as a stationary phase was also found to give satisfactory separation and good peak shapes without using acidic

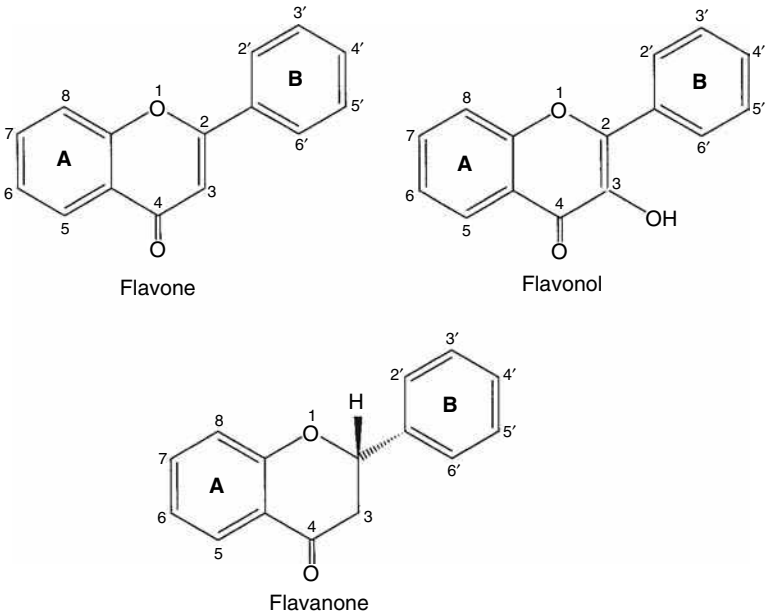

Fig. 1 Structure of flavone, flavonol, and flavanone.

mobile phases,[17] which are not so favorable for use with reversed phases.

The choice of a column involves matching the class of flavonoids to be separated to the characteristics of the stationary phase capable of providing satisfactory retention, selectivity, and peak shapes. As for the dimensions, the most popular are 150 and 250 mm long, with 5 μm particle size, although phases with 3 μm particles are becoming more popular because of better efficiency and less solvent consumption. The use of guard columns is recommended in order to extend their lifetime by protecting the analytical column from impurities in the samples prepared from various natural products.

Mobile Phases

The preferred solvent system used for the separation of flavonoids on reversed-phase stationary phases is methanol–water, followed closely by acetonitrile–water. Usually, acetic or formic acid is added (sometimes phosphoric acid, potassium dihydrogen phosphate, ammonium dihydrogen phosphate, and perchloric acid), which enables improved separation and prevention of peak tailing with respect to the phenolic character of the flavonoids. Ion pairing has also been used for improving the separation of neutral glycosides from flavonol sulfates.[4]

Often, gradient elution with a linear gradient, combined with isocratic steps, usually gives the best separation of flavonoids, differing in the degree of saturation, hydroxylation, methylation, and/or glycosylation. Optimization of the elution program is usually performed by changing the elution program until a satisfactory resolution and analysis time is achieved, depending on the analysis purpose, i.e., qualitative or quantitative analysis.

Detection Systems

Identification of flavonoids separated by HPLC is commonly performed by comparing the obtained retention times with the ones of authentic samples as well as by analysis of their characteristics collected by the detector.

Detection of flavonoids separated by HPLC can be performed using several detection systems. Photodiode array detectors (DADs) are the most convenient for use because of their availability and easy maintenance, and mainly because of the valuable information for the identification of flavonoids contained in their UV [or ultraviolet–visible (UV–Vis)] spectra. The sophisticated software packages enable storage of all the spectra obtained during the elution process, which can later be analyzed and compared to the spectra from a library previously prepared from authentic samples of flavonoids. An experienced analyst working on flavonoids can recognize the peaks from flavonoids in the chromatogram from the spectra, which are, as previously mentioned, very characteristic, although they are not enough for identification. As for the quantitative analysis, scanning over a wide wavelength range enables measuring all the components at wavelengths of their absorption maxima, which provides maximum sensitivity.

Fluorescence detectors have also been employed for flavonoid determination, offering higher sensitivity and selectivity, as suggested by the results in the analysis of

3′,4′,5′-trimethoxyflavone, which has been determined by excitation at 330 nm and by detection at 440 nm.[18]

Overcoming the difficulty in introducing the liquid sample into the mass spectrometer in the last decade enabled their use for HPLC detection, even in routine practical applications. The atmospheric pressure chemical ionization, thermospray, and electrospray ionization systems have proved to be most convenient for flavonoid analysis by HPLC/MS.[18,19] Mass spectrometry is a more specific and extremely selective detection technique, although it is not enough for structure elucidation (it reveals the structural fragments that are present, but not the exact substitution pattern). It offers the molecular weight of the molecular ion, which helps the tentative identification of the flavonoid. The use of HPLC/MS/MS gives additional information about the characteristic fragmentation pattern—"fingerprint" of the substance, which is very useful for qualitative and quantitative analyses in complex matrices. An excellent illustration of the use of HPLC/MS for the identification of flavonoids is presented in the work of Huck et al.,[19] who have isolated and characterized polymethoxylated flavones from *Primulae veris flos* using HPLC/ESI/MS. The six detected flavonoid compounds were found to be mono-, di-, tri-, and pentametoxyflavones, but their exact substitution pattern could not be revealed, except for 3′,4′,5′-trimetoxyflavone, for which ^{13}C NMR spectral data were available.

As regards the sensitivity of the MS detection in HPLC analysis of flavonoids, this technique has proved to be the most sensitive as compared to UV and fluorescence detection. A very comprehensive comparison of the four detection systems—UV, fluorescence, and two MS systems [atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI)]—for the determination of the previously identified 3′,4′,5′-trimethoxyflavone[18] is presented in Table 1. Fluorescence detection is 10 times more sensitive than UV detection, whereas MS detection is 50 times more sensitive than UV detection and 5 times more sensitive than fluorescence detection.

Similar assay of the detection systems is performed by Stecher et al.,[9] who analyzed flavonols and stilbenes in wine and biological products and found that ESI/MS detection gave two, three, and nine times lower limit of detection (LOD) for myricetin, quercetin, and kaempferol, respectively, as compared to UV absorbance detection at 377 nm (absorption maximum of flavonols).

A significant amount of literature regarding the antioxidant properties of flavonoids and other plant polyphenols is available. As the essence of redox chemistry involves electron transfer, it seems natural that electrochemical detection rivals spectrophotometric detection techniques for the compounds that are supposed to be antioxidants. With the improvements in electrochemical detector geometries and electronics over the last decade, coupled with a requirement for increased sensitivity, the use of electrochemical detectors offers significant additional advantages when combined with the traditional UV–VIS detection in the analysis of flavonoids and other plant polyphenols.[20]

APPLICATIONS

Several information regarding HPLC analysis of flavonoids, often together with other phenolic constituents, in various samples, such as fruits, vegetables, juices, wines, honey, propolis, and, especially, plant material, are published. The enormous interest in studying these compounds is a result of their potential importance to health and antioxidant defense mechanisms, which has imposed the need for developing methods for their identification and quantification in various natural products. Reversed-phase HPLC (RP HPLC) with combined isocratic and gradient elution with acidic mobile phases and UV diode array or mass spectrometer detector is the most often used system for flavonoid analysis. Depending on the nature of the sample, a variety of sample preparation techniques has been developed in order to achieve good recovery of the analyzed compounds in a simple sample preparation procedure. The procedure includes extraction of the flavonoids in a polar solvent; this extract is then used either for injection onto the column (after filtration) or for further fractionation and purification of the flavonoids to obtain a relatively "clean" sample for injection. The latter step can be carried out in

Table 1 Regression equations for the calibration curves (logarithmic), regression coefficients, and detection limits for the determination of 3′,4′,5′-trimethoxyflavone.

Detection method	Regression equation	Regression coefficient (R^2)	Detection limit
UV at 213 nm	$y = 0.990x + 13.158$	0.9986	0.244 ng
Fluorescence at 330/440 nm	$y = 0.879x + 12.926$	0.9946	24.4 pg
ESI–MS	$y = 0.692x + 17.349$	0.9956	5.00 pg
APCI–MS	$y = 0.899x + 15.798$	0.9997	5.00 pg

several ways: by liquid–liquid extraction in suitable solvents; by chromatographic techniques (thin layer or column chromatography) on various stationary phases (silica, reversed phases, Amberlite, and Sephadex); or by solid-phase extraction techniques using different adsorbents, which in the last decade has been found very convenient for the isolation of flavonoids from complex matrices.

Flavonoids in Fruits, Juices, and Wine

During the past decades, extensive analytical research has been performed on the separation of phenolic constituents in various fresh fruits and fruit products. A very thorough examination was performed by Barberán et al.,[11] on samples of several types of fresh nectarines, peaches, and plums using RP HPLC/DAD/ESI/MS and combined isocratic and gradient elution with a mobile phase of water–methanol with 5% formic acid. The samples were prepared by extraction of a homogenized frozen fruit material with water–methanol (2:8), by centrifugation, by filtration, and by injection into the column. This procedure recovers 85–92% of all phenolic compounds including hydroxycinnamates, procyanidins, flavonols, and anthocyanins. In the chromatograms obtained for nectarin and peach samples, three peaks from flavonols (quercetin 3-glucoside, quercetin 3-rutinoside, and, probably, quercetin 3-galactoside), several peaks from flavan-3-ols (catechin, epicatechin, and dimer procyanindines), and two anthocyanin pigments (cyanidine 3-glucoside and cyanidine 3-rutinoside) have been identified by comparing the retention data, the UV, and the mass spectra of the detected flavonoids with the ones obtained for authentic markers. Quantification was done using external standards: quercetin 3-rutinoside for flavonols at 340 nm, cyanidine 3-rutinoside for anthocyanins at 510 nm, and catechin for flavan-3-ols at 280 nm.

An HPLC/DAD method was developed for the separation and the determination of flavonoid and phenolic antioxidants in commercial and freshly prepared cranberry juice.[6] Two sample preparation procedures were used: with and without hydrolysis of the glycoside forms of flavonoids carried out by the addition of HCl in the step prior to solid-phase extraction (SPE). The flavonoid and phenolic compounds were then fractionated into neutral and acidic groups via a SPE method (Sep-Pak C_{18}), followed by a RP HPLC separation with gradient elution with water–methanol–acetic acid and a detection at 280 and 360 nm. A comparison of the chromatograms obtained for extracts prepared with and without hydrolysis showed that flavonoids and phenolic acids exist predominantly in combined forms such as glycosides and esters. In a freshly squeezed cranberry juice, for instance, 400 mg of total flavonoids and phenolics per liter of sample was found, 56% of which were flavonoids. Quercetin was the main flavonoid in the hydrolyzed products, where it accounted for about 75% of the total flavonoids, while it was absent in the unhydrolyzed products.

The flavonoid constituents of *Citrus* have attracted attention in the last decade because of their biological activities (anticarcinogenic, anti-inflammatory effects, etc.) together with the chemotaxonomic importance of the specific flavanone glycosides found in this species. The presence of 12 flavonoids (9 flavanone glycosides, 2 flavanone aglycones, and 1 flavone glycoside) was detected in samples from leaves and fruits of *Citrus aurantium*.[7] The use of different extraction solvents was studied (methanol, dioxane–methanol 1:1, 0.1% NaOH aq., 0.01% KOH methanolic, pyridin, dimethylformamide, and dimethylsulfoxide), with dimethylsulfoxide representing the best results. Also, an exhaustive description of the optimization process by studying the quantitative chromatographic parameters—k', w, α, N, height equivalent to a theoretical plate (HETP), and R—is given with the discussion of the effects of the variation of the methanol (acetonitrile) content in the mobile phase, the degree of mobile phase acidity, together with the influence of the structural

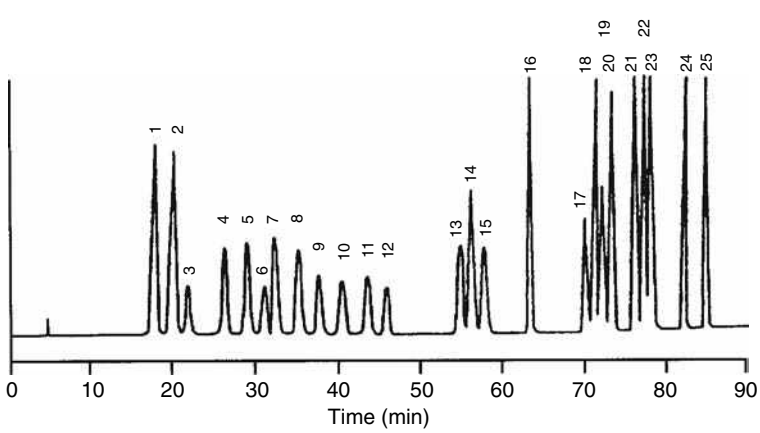

Fig. 2 Separation of 25 flavonoid standards (1—eriocitrin; 2—neoeriocitrin; 3—robinetin; 4—narirutin; 5—naringin; 6—rutin; 7—hesperidin; 8—neohesperidin; 9—isorhoifolin; 10—rhoifolin; 11—diosmin; 12—neodiosmin; 13—neoponcirin; 14—quercetin; 15—poncirin; 16—luteolin; 17—kaempferol; 18—apigenin; 19—isorhamnetin; 20—diosmetin; 21—rhamnetin; 22—isosakuranetin; 23—sinensetin; 24—acacetin; 25—tangeretin) using C_{18} Lichrospher 100, 250 × 4.0 mm, 5 μm, Merck; gradient elution with 0.01 *M* phosphoric acid–methanol with flow rate of 0.6 ml/min at 40°C and detection at 285 nm.

Source: From High—performance liquid chromatographic determination of naturally occurring flavonoids in *citrus* with a photodiode-array detector, in J. Chromatogr. A.[8]

characteristics of the studied flavonoids on their behavior in the reversed-phase chromatographic system.

Another thorough procedure for flavonoid analysis in *Citrus* samples is presented in the work of Nogata et al.[8] They developed a method for separation of 9 flavanones, 10 flavones, and 6 flavonols using a RP HPLC system with gradient elution with 0.01 *M* phosphoric acid–methanol and for detection at 285 nm, which is presented in Fig. 2. Identification was carried out by comparing the retention data and the spectra of the sample components with the ones of the standards. For quantitative analysis, all flavonoids exhibited good linearity ($r = 0.988$–1.00) between concentration and peak area in the investigated concentration range (10–200 ppm) with detection limits from 0.5 to 2.5 ppm.

To investigate the probable health benefits of flavonoids and stilbenes in red wine, a RP HPLC method with enhanced separation efficiency, selectivity, sensitivity, and speed has been established for the determination of the flavonols quercetin, myricetin, and kaempferol and the stilbenes *cis*- and *trans*-resveratrol in a single run.[9] The sample preparation step for wines and grape juices included only filtration prior to injection. Identification was carried out by the comparison of the retention data, the UV, and the mass spectra of the flavonoids and the stilbenes with the ones obtained for standards. Quantitative analysis using external standards showed good linearity ($R^2 > 0.999$ for UV and $R^2 > 0.9878$ for MS detection), recoveries between 95% and 105%, and limits of detection in the nanogram range, with MS being more sensitive.

An interesting improvement in the sample preparation step has been suggested[10] using only filtering of the sample prior to injection into the system composed of two columns: clean-up column (50×2.1 mm packed with C_{18} stationary phase, 5 μm) and analytical column (250×2.1 mm, C_{18}, 5 μm). A column-switching procedure enables the sample introduced in the first column to be cleaned from the disturbing matrix compounds for 2 min (elution phosphate buffer, pH = 7, with 10% acetonitrile), and then by a gradient of the mobile phase (phosphate buffer, pH = 2.5, with acetonitrile); the retained analytes—flavonoids—are eluted to the analytical column, where they are separated and detected at 365 nm. The method was used for the determination of flavonoid profiles of berry wines containing the flavonols quercetin, myricetin, kaempferol, rutin, and isoquercitrin.

Flavonoids of Honey and Propolis

A very interesting application of flavonoid analysis by HPLC has been carried out by Barberán et al.[11] on honey samples. They used RP HPLC/DAD for the analysis of 20 flavonoid aglycones, which could be considered as markers for the floral origin of honey. Different solvent systems were applied to the analysis of flavonoids from citrus and rosemary honeys. The sample preparation included dilution with water and HCl (pH = 2–3) for hydrolysis of glycosides, followed by purification using chromatography on Amberlite XAD-2 and Sephadex LH-20. The flavonoid markers of the botanical origin, hesperetin and apigenin, were detected using methanol–water and acetonitrile–water mixtures with formic acid. Quercetin and kaempferol were separated using Prizma-optimized conditions, whereas tectochrysin was eluted with methanol–water and acetonitrile–water mixtures by increasing the content of the organic solvent at the end of the elution programs. The use of diode array detection was found essential in studies of the floral origin of honey by flavonoid analysis.

Flavonoid analysis has also been carried out in propolis, another beehive product rich in flavonoids, which are partly responsible for its pharmacological activity.[12] Qualitative and quantitative analyses were performed by using a reversed-phase column and isocratic elution with water–methanol–acetic acid (60:75:5) and by monitoring at 275 and 320 nm. The propolis sample was cut into small pieces, extracted with boiling methanol, and the methanolic extract was then diluted with water and, subsequently, extracted with light petroleum and diethyl ether. The last extract contained the propolis flavonoids pinocembrin (21.4%), galangin (5%), chrysin (4.8%), quercetin (2.2%), and tectochrysin (1.1%).

Plant Material

Flavonoids play important roles in plant biochemistry and physiology; they are responsible for the biological effects of plants and their extracts as well as preparations on humans. HPLC is found very suitable for the detection and the determination of flavonoids present in various plants and plant products; the so-called HPLC fingerprint analysis is suggested for quality control and standardization because of the ability of good separation and resolution of complex mixtures as well as peak purity control. One of the limitations of the assays of flavonoids in plant material is the fact that many compounds, especially glycosides, are not commercially available. One of the possible solutions to this problem is the hydrolysis of flavonoid glycosides during the extraction procedure, which aids the identification on flavonoid aglycones. Such a procedure (the extraction in acetone with the addition of HCl for hydrolysis of glycosides) is proposed for the screening of flavonols and the determination of quercetin in medicinal plants using RP HPLC with gradient elution with water–acetonitrile–acetic acid and UV

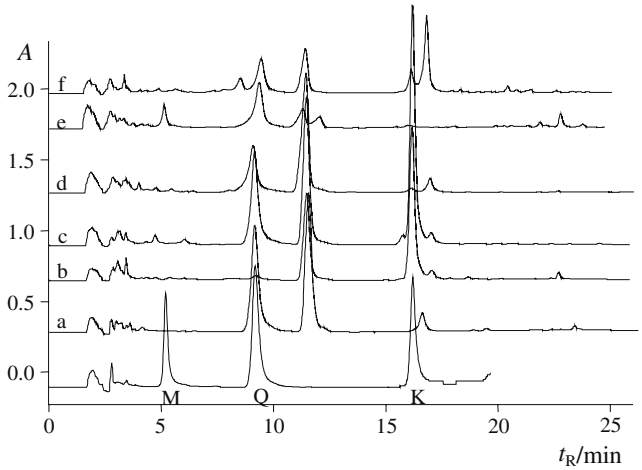

Fig. 3 Chromatograms obtained for extracts of the following: a) *H. herba*; b) *R. pseudoacaciae flos*; c) *P. spinosae flos*; d) *Sambuci flos*; e) *B. folium*; and f) *Primula flos*, and for mixture of authentic samples of myricetin (M), quercetin (Q), and kaempferol (K) using: C18 (250 × 4.6 mm, 5 μm, Varian); gradient elution with 5% acetic acid–acetonitrile with flow rate of 1.0 ml/min at 30°C and detection at 367 nm.

diode array detection.[13] Quercetin was found to be the most abundant, especially in *Hyperici herba* and *Pruni spinosae flos*, kaempferol in *Robiniae pseudoacaciae flos* and *P. spinosae flos*, whereas myricetin was detected only in *Betulae folium*, as can be seen in the chromatograms presented in Fig. 3. The content of quercetin ranged from 0.026% in *Bursae pastoris herba* to 0.552% in *Hyperici herba*.

Another quantitative RP HPLC method, based on the reduction of the complex flavonoid glycoside pattern by acid hydrolysis to one major aglycone (quercetin) and one C-glycoside (vitexin), was developed and employed for the characterization of Crataegus leaves and flowers.[14] A qualitative fingerprint method was also developed for the separation and the identification of all characteristic flavonoids (glycosides and aglycones). Samples for fingerprint analysis were prepared by extraction with 80% methanol and then filtered through Bond Elut C_{18} cartridge prior to injection. Elution was performed by a mobile phase composed of tetrahydrofuran–acetonitrile–methanol and 0.5% orthophosphoric acid and was monitored at 370, 336, and 260 nm. For quantitative analysis, extraction was carried out with methanol in a Soxhlet apparatus, HCl was added to the methanolic extracts for the hydrolysis of glycosides, and, finally, they were filtered through Bond Elut C_{18} before injection. Separation and quantification of vitexin and quercetin were performed for characterization and standardization of the plant material as well as its extracts and preparations.

Structure–RP HPLC Retention Relationships of Flavonoids

The ability to predict the chromatographic mobility of a compound under given conditions, based on its structure, offers many advantages in analysis. The elution sequence of individual flavonoids can be interpreted by assuming that the compounds are first adsorbed on the reversed stationary phase by "hydrophobic interaction," and then subsequently eluted with the mobile phase according to the extent of hydrogen bond formation. Therefore the hydrogen bond donating and/or accepting ability of a given substituent as well as its contribution to the hydrophobic interaction have to be considered. The retention data of 141 flavonoids[15] imply the balance between these two effects, resulting in almost identical retention of tricetin pentamethylether (pentamethoxy flavone) and unsubstituted flavone.

Hydroxylation in positions other than 3 and 5 decreases retention owing to increasing polarity (hydrogen bond formation ability). The presence of an OH group in positions 3 and 5 is specific because of the formation of an intramolecular hydrogen bond with the carbonyl group on C-4, which is the strongest hydrogen bond acceptor in flavones and isoflavones. This is the reason for the increase in retention, especially when OH is substituted in position 5, whereas another OH group in position C-3 only slightly lowers the retention. This produces poor separation of the so-called critical pairs

flavone–flavonol differing only in the OH group in position 3.

Methylation of the OH groups more or less prevents their effect, which means that flavonoids and their partial methyl ethers are easily separated. On the other hand, the introduction of additional methoxy groups has little or no effect on retention—introducing another type of critical pair differing only in one methoxy group.

Glycosylation of an OH group means introducing a hydrophilic moiety together with shielding (by hydrogen bonding or just by steric hindrance) some hydrophilic substituents already present in the vicinity. The shielding effect plays a role when an OH group located *ortho* to another OH group is glycosylated (e.g., glycosylation of 7- or 4′-OH without an adjacent *ortho*-OH decreases the t_R values by 4.26–3.83 min, whereas, in the presence of an *ortho*-OH, the decrease is only 2.28–1.55 min[15]). The fact that the t_R value of luteolin-5-β-D-glucopyranoside is only 0.37 min smaller than that of the corresponding 7-β-D-glucopyranoside can also be explained by the shielding effect of sugar on the carbonyl group. The contributions of various types of sugars to the hydrophilic interaction decrease from hexoses through pentoses to methylpentoses.

Saturation of the C_3 ring, which means transformation of flavones to flavanones and of flavonols to dihydroflavonols, affects the retention in a very complex way. The saturation itself has a small effect; however, in the presence of OH groups, the retention is always decreased. This is explained by the interruption of the conjugation in the system, affecting the acidity and therefore the hydrogen bond accepting and donating abilities of the OH groups, especially the 3-OH groups which are phenolic in flavones and alcoholic in flavanones.

CONCLUSIONS

RP HPLC has proved to be the method of choice for the separation of a variety of flavonoids in different samples. The phenolic nature of these compounds requires the use of acidic mobile phases for satisfactory separation and peak shapes, whereas the detection is usually carried out with photodiode array detectors which are also very helpful for their identification of the characteristic absorption spectra of the flavonoids. In the last decade, mass spectrometers connected to HPLC systems introduced a greater selectivity and sensitivity in flavonoid analysis. Improving the characteristics of the stationary phases and developing more sophisticated instruments as well as devices for more efficient and faster sample preparation are the challenges for all modern analysts. Discovering the beneficial health effects of flavonoids and the "going-back-to-nature" trend motivates the development of more efficient and fast procedures for their identification and quantification, with HPLC remaining the most powerful technique for their separation from the complex mixtures.

Flavonoids: SFC Analysis

Xia Yang
Huwei Liu
Institute of Analytical Chemistry, Peking University, Beijing, China

INTRODUCTION

Several kinds of flavonoids are efficiently separated and analyzed using packed or capillary column supercritical fluid chromatography (SFC). The composition of mobile phase, stationary phase, temperature, and pressure all affect the resolution. This entry mainly focuses on the separation of polymethoxylated flavones, polyhydroxyl flavonoids, and flavonol isomers.

FLAVONOIDS

As a result of the development of chromatography technology, supercritical fluid chromatography (SFC) has been used to separate more and more compounds, owing to the low viscosity and high diffusivity of its mobile phase compared to the liquid mobile phase in HPLC. Supercritical carbon dioxide is the most popular SFC mobile phase because it is non-toxic, non-flammable, and easy to obtain, and it has a near-ambient critical temperature (approximately 31°C at 74 bar). However, CO_2 has weak solvating power for polar compounds. Supercritical fluids that are substantially more polar than carbon dioxide generally tend to have extreme critical temperatures and pressures (e.g., water with a critical temperature near 400°C), which makes them difficult or dangerous to work with and raises questions about the effect of such conditions on labile solutes themselves.[1] So CO_2 is the best choice, but it is often modified by such polar organic solvents as methanol, ethanol, etc. However, this binary mobile phase cannot elute very polar compounds efficiently. To widen the applicability of SFC, a small amount ($< 1\%$) of additive is added to a modifier to form a ternary mixture with CO_2. Organic acids, such as trifluoroacetic acid and citric acid, were used as additives to cause polar solutes (e.g., hydroxybenzoic and polycarboxylic acids) to be eluted rapidly and efficiently from packed SFC columns.[2–4]

Flavonoids are a group of naturally occurring substances derived from flavone (phenyl-γ-benzopyrone) that are widely distributed in the plant kingdom and used in herbal medicines throughout the world. They are 15-carbon compounds consisting of two aromatic rings and, based on the oxidation level of another ring, are classified into several groups, i.e., chalcones, flavanones, flavones, isoflavones, and flavonols, which are collectively known as the "yellow pigments," and the colored "anthocyanin pigments." Flavonoid compounds may undergo further enzymatic hydroxylation, methylation, glycosylation, sulfonation, acylation, and/or prenylation reactions, resulting in the immense diversity of flavonoid structures. There are more than 5000 identified flavonoid compounds found in nature.

Traditionally, flavonoids have been separated and analyzed by high-performance liquid chromatography (HPLC)[5,6] and gas chromatography (GC).[7] However, recent developments of SFC may permit a more accurate and complete analysis of plant phenolic compounds. Supercritical fluid chromatography brings together the advantages of both HPLC and GC techniques because it may be readily employed in the analysis of non-volatile and thermolabile compounds and provides facile coupling to detector technologies such as mass spectrometry and Fourier transform infrared (FTIR) spectroscopy. In recent years, SFC has been used to separate flavonoid compounds, most of which are polymethoxylated flavones and polyhydroxylflavonoids.

SEPARATION OF FLAVONOIDS

Separation of Polyhydroxylflavonoids by Packed-Column SFC

Liu et al.[8] separated polyhydroxylflavonoids, quercetin, and risetin by packed-column SFC with a ternary mobile phase. They designed an SFC apparatus with two syringe pumps and a variable-wavelength UV detector. A manual back-pressure regulator was also used to control the flow rate. This experiment showed that there are several factors affecting the result.

Mobile Phase

Neither pure supercritical CO_2 nor ethanol-modified CO_2 eluted all the flavonoids tested in this experiment. But when phosphoric acid and ethanol modifiers were added to the mobile phase together, the separation on a silica-based column was significantly improved, and quercetin and risetin were eluted rapidly and efficiently. With an increase of phosphoric acid concentration, the peak shapes were also improved. Because the phosphoric acid molecules could be adsorbed onto the active sites of the

stationary phase, which could prevent solute molecules from being strongly adsorbed, the interaction between solutes and stationary phase was eliminated, making the solutes easily elute from the chromatographic system.

Stationary Phase

The polarity of the column packing is in the following order: cyanopropyl > phenyl > ODS C_{18}. It is understandable that the ODS column is not suitable for the separation because of its low polarity. Both the cyanoprophyl and phenyl columns could separate these solutes efficiently, but the latter exhibited shorter separation times.

Pressure and Temperature

The capacity factor for the separation of flavonoids is decreased with the increase of operating pressure, in addition to the effect of the decrease in modifier concentration, thus indicating that the pressure effect is a very important one.

The retention times of solutes slightly increased with increasing temperature in the range of 40.0–65.0°C. As the volatilities of the solutes were increased with an increase in the temperature (which is favorable to shorten the retention time), the density of the mobile phase decreases with the temperature, which is not favorable for eluting the solute. In the range of temperatures mentioned above, the second factor is dominant; thus a lower temperature is desirable for the separation of quercetin and risetin.

Separation of Polymethoxylated Flavones by Packed-Column SFC

Morin et al.[9] successfully separated polymethoxylated flavones (PMFs) by packed-column SFC, illustrating that the SFC procedure is considerably faster than HPLC, with good resolution and adequate accuracy for the quantitative analysis of the PMFs. The chromatographic system consisted of a bare silica column (250 × 4.6 mm I.D.) with a carbon dioxide–methanol mobile phase and UV detection (313 nm). The pressure was controlled by a manual back-pressure regulator connected in series after the detector and maintained at 40°C with a water bath. Six compounds, including tangeretin, heptamethoxyflavone, nobiletin, sinensetin, tetramethylisoscutellarein, and isosinensetin (Table 1), were separated in less than 12 min as shown in Fig. 1. The resolution between nobiletin and heptamethoxyflavone is greater than 1.5, whereas reversed-phase HPLC required the use of water–tetrahydrofuran solvent to resolve these two compounds satisfactorily. If the carbon dioxide and methanol flow rates are increased from 3 and 0.3 ml/min to 9 and 0.9 ml/min, respectively, the polymethoxylated flavones (tangeretin, nobiletin, sinensetin, and tetramethylisoscutellatrein) are separated in 2 min

Table 1 Structures of polymethoxylated flavones.

PMF	Systematic name
Heptamethoxyflavone	3,5,6,7,8,3′,4′-Heptamethoxyflavone
Hexamethoxyflaxone	3,5,6,7,3′,4′-Hexamethoxyflavone
Nobiletin	5,6,7,8,3′,4′-Hexamethoxyflavone
Sinensetin	5,6,7,3′,4′-Pentamethoxyflavone
Tangeretin	5,6,7,8,4′-Pentamethoxyflaxone
Isosinensetin	5,7,8,3′,4′-Pentamethoxyflavone
Tetramethylisoscutellarein	5,8,7,4′-Tetramethoxyflavone
Tetramethylscutellarein	5,6,7,4′-Tetramethoxyflavone

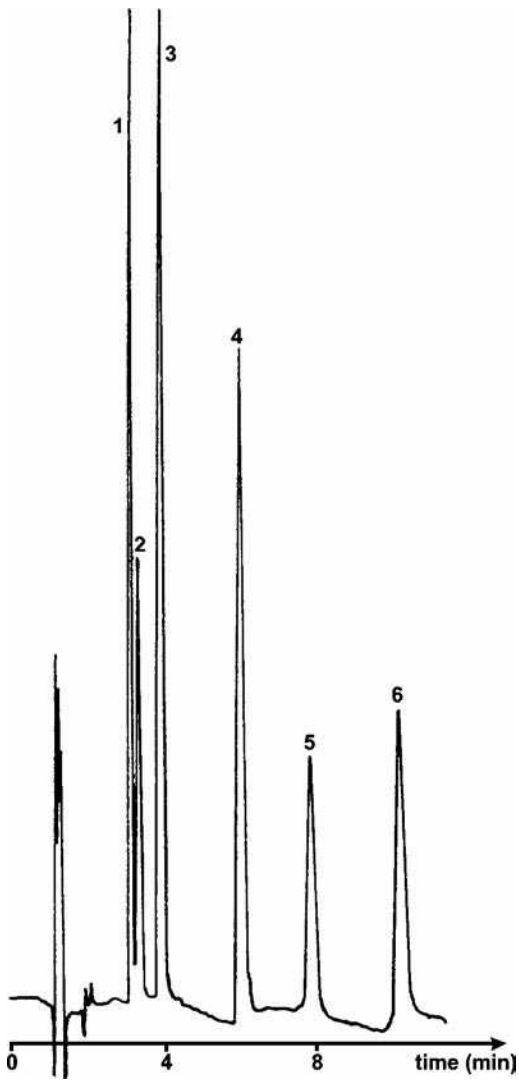

Fig. 1 SFC separation of synthetic mixture of polymethoxylated flavones. Column, 250 × 4.6 mm I.D.; stationary phase, Zorbax (5 μm) silica; mobile phase, carbon dioxide modified with 10% methanol; inlet pressure, 220 atm; outlet pressure, 200 atm; column temperature, 40°C; carbon dioxide flow-rate, 3 ml/min; methanol flow-rate, 0.3 ml/min; UV detection at 313 nm. Peaks: 1 = tangeretin; 2 = heptamethoxyflavone; 3 = nobiletin; 4 = sinensetin; 5 = tetramethylisoscutellarein; 6 = isosinensetin.

without any significant loss of efficiency and resolution. Thus packed-column SFC appears to be useful for rapid analyses of the main polymethoxylated flavonones.

Separation of Flavonol Isomers by Packed-Column SFC

Flavonol isomers, which differ only in the position of hydroxyl group on their chemical structures, showed different chromatographic behaviors. Liu et al.[10] separated three flavonol isomers (3-hydroxyflavone, 6-hydroxyflavone, and 7-hydroxyflavone) by a lab-constructed packed column SFC system with carbon dioxide modified with ethanol containing 0.5% (V/V) phosphoric acid as the mobile phase. The effects of temperature, pressure, composition of mobile phase, and packed-column type on the separation were studied. It was indicated that the addition of phosphoric acid to the mobile phase enabled flavonol isomers to be eluted from the column. It was also shown that a phenyl-bonded silica column was better and the ODS column was not as effective for the isomer separation. Increasing pressure shortened the retention time of each compound, with good resolution, and higher temperature led to longer retention times, and even the loss of the bioactivities of these components. Under selected conditions, the separation of these isomers was very satisfactory, as illustrated in Fig. 2.

Separation of Polymethoxylated and Polyhydroxylated Flavones by Open-Tubular Capillary SFC

Solvent modifiers and additives can be used to adjust the retention and selectivity of separation in packed-column SFC. Similar effects have been reported with open-tubular capillary SFC.[11] The advantage of capillary column over packed column arises from the differences in permeability. Pressure ramps are much easier to use in capillary columns to modify the solvent strength (via density modification) as compared to packed columns. Therefore it should be entirely feasible, with capillary SFC, to combine the benefit of solvent density (pressure) programming with simultaneous modification of the solvent strength.[12,13]

Hadj-Mahammed et al.[11] analyzed a mixture of flavone, 5-methoxyflavone, and tangeretin by supercritical CO_2 SFC on capillary columns with two types of detectors: flame ionization (FID) and FTIR. Peak identification was achieved with the help of the FTIR fingerprint of each compound. However, the separation was satisfactory only by the use of supercritical CO_2 density programs, without the use of a phase modifier. The separations were accomplished using a Carlo Erba SFC system equipped with a Model SFC 300 pump and a Model SFC 3000 oven. The fused silica capillary columns were BP1 (12 m × 0.1 mm I.D.; 0.1 μm film of dimethylpolysiloxane) and DB5 (15 m × 0.1 mm I.D.; 0.4 μm film of 94% dimethyl-, 5% diphenyl-, and 1% vinylpolysiloxane). The two supercritical CO_2 density programs used in this work were P1 [from 0.127 g/ml (at a pressure of 73.3 bars) to 0.689 g/ml (324.2 bars) isothermally at 100°C] and P2 [from 0.111 g/ml (at a pressure of 79.0 bars) to 0.511 g/ml (318.5 bars) isothermally at 150°C].

On the DB5 capillary column, satisfactory separation of hydroxyl- and methoxyflavones could be obtained using either of the two gradient systems, but the retention times of the analytes for P2 were shorter than those for P1. This is due to the variation in the solubilities of flavones in the supercritical mobile phase when the density gradient was employed. The polarity effect of the stationary phase (BP1 phase is less polar than the DB5) is illustrated in Table 2. It can be seen that, on BP1, the flavones are less retained and the analysis time is decreased by nearly half, while conserving a satisfactory separation.

In summary, the use of a polar capillary column and an appropriate gradient of supercritical CO_2 density at a temperature of about 150°C permits the flavonoids to be separated rapidly and effectively.

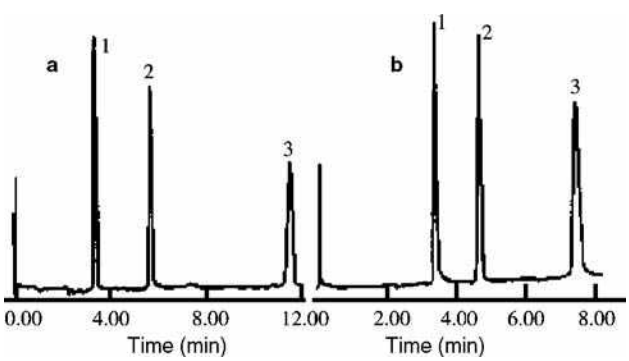

Fig. 2 Effect of stationary phase Pressure: 25 MPa, temperature: 50°C, mobile phase: carbon dioxide-ethanol with 0.5% phosphoric acid: 90 : 10, flowrate: 1.05 ml/min, stationary phase: a) cyano column, b) phenyl column.

Table 2 Comparison of retention times and capacity factors of flavones analyzed using capillary columns DB5 and BP1 with supercritical CO_2 density program P2.

	DB5		BP1	
Flavones	t_R (min)	k'	t_R (min)	k'
Flavone	17.93	2.40	9.52	1.36
5-Methoxyflavone	20.83	2.93	11.82	1.93
Tangeretin	25.84	3.90	16.53	3.10

CONCLUSIONS

Both packed-column and open-tubular capillary SFC can be used to separate flavonoids, and, in most cases, the separation is improved by changing the composition of mobile phase, stationary phase, temperature, and pressure.

Although HPLC has been used more often than SFC for the separation of flavonoids until now, SFC still has its particular merits and can be listed as the promising approach.

INTRODUCTION

Flow field-flow fractionation (flow FFF or FlFFF) is one of the FFF subtechniques in which particles and macromolecules are separated in a thin channel by aqueous flow under a field force generated by a secondary flow. As with other FFF techniques, separation in FlFFF is based on the applied force directed across the axis of separation flow. In FlFFF, this force is generated by cross-flow of liquid delivered across the channel walls. In order to maintain the uniformity of cross-flow moving in a typical rectangular channel, two ceramic permeable frits are used as channel walls and the flow stream enters and exits through these walls. The force applied in FlFFF is a Stokes force that depends only on the sizes of sample components.

PRINCIPLES

In FlFFF, particles or macromolecules entering the channel are driven toward an accumulation wall by the cross-flow. Normally, a sheet of semipermeable membrane is placed at the accumulation wall in order to keep sample materials from being lost by the wall. While sample components are being transported close to the accumulation wall, they are projected against the wall by Brownian diffusion. The diffusive transport against the wall leads the sample components to be differentially distributed against the wall, according to their sizes: The larger particles, having a small diffusion coefficient, are placed at an equilibrium position closer to the vicinity of accumulation wall than the smaller ones. Thus, small particles, which are located further from the wall, will be exposed to the fast streamline of a parabolic flow profile, and they will be eluted earlier than the larger ones. This is the typical elution profile that can be observed in the normal operating mode of FFF (denoted as Fl/Nl FFF). Retention time in Fl/Nl FFF is inversely proportional to the diffusion coefficient of the sample; it is represented as

$$t_r = \frac{w^2}{6D}\frac{\dot{V}_c}{\dot{V}}\left(\text{where } D = \frac{kT}{3\pi\eta d_s}\right) \tag{1}$$

where w is the channel thickness, D is the diffusion coefficient, $\dot{V}_c$ is the cross-flow rate, and $\dot{V}$ is the channel flow rate. Because the diffusion coefficient D is inversely proportional to the viscosity of carrier solution η and hydrodynamic radius d_s, the retention time can be simply predicted provided the particle diameter or the diffusion coefficient is known. Conversely, the particle diameter of an unknown sample can be calculated from experimental retention time by rearranging Eq. 1.

As the particle size becomes large at or above 1 μm, the diffusional process of particles becomes less dominant in FFF. In this regime, a particle's retention is largely governed by the particle size itself, in which the center of large particles is located at a higher position than small ones. Thus, large particles meet the faster streamlines and they elute earlier than the small ones; the elution order is reversed. However, it is known, from experimental results, that particles migrate at certain positions elevated from the wall due to the existence of hydrodynamic lift forces that act in the opposite direction to the field. This is described as the steric/hyperlayer operating mode of separation in flow FFF and is denoted by Fl/Hy FFF. Whereas the theoretical expectation of particle retention in Fl/Nl FFF is clearly understood, retention in Fl/Hy FFF is not predictable because the hydrodynamic lift forces are not yet completely understood. Therefore, the particle size calculation in Fl/Hy FFF relies on the calibration process in which a set of standard latex particles of known diameter is run beforehand as

$$\log t_r = -S_d \log d_s + \log t_{r1} \tag{2}$$

where S_d is the diameter-based selectivity and t_{r1} is the interpolated intercept representing the retention time of a unit diameter. The S_d values found experimentally are about 1.5 in Fl/Hy FFF. By using Eq. 2, the particle diameters of unknown samples can be calculated once the calibration parameters S_d and t_{r1} are provided.

TYPES OF CHANNEL IN FIFFF

There are two main categories of flow FFF channel systems, depending on the use of frit wall. The above-described flow FFF system has a frit on both walls; this is classified as a symmetrical channel, as shown in Fig. 1a. An asymmetrical channel system is being widely studied in which only one permeable frit wall is used, at the accumulation wall, and the depletion wall is replaced with a glass plate (Fig. 1b). In an asymmetrical channel, part of the flow entering the channel is lost by the accumulation wall and this acts as a field force to retain the sample components in the channel, as does the cross-flow in a symmetrical channel.

The separation efficiency of an asymmetrical flow FFF system has been known to be higher than that of a conventional symmetrical channel. Because an asymmetrical channel utilizes only one frit, non-uniformity of flow that could arise from the imperfection of frits can be reduced. In addition, the initial sample band can be kept narrower in an asymmetrical channel, due to the focusing–relaxation procedure, which is an essential process in an asymmetrical channel. The relaxation processes, which provide an equilibrium status for sample components, are necessary in both symmetrical and asymmetrical channels for a period of time prior to the separation. For a symmetrical channel, this is normally achieved by stopping channel flow immediately after sample injection, while the cross-flow is applied.

During the relaxation process, sample components seek their equilibrium positions where the drag of the cross-flow is counterbalanced with diffusive transports (or lift forces) against the walls. After relaxation, flow is resumed and separation begins. However, in an asymmetrical channel, the relaxation process is achieved by two convergent focusing flow streams originating at the channel inlet and outlet (focusing–relaxation). Thus, injected sample can be focused at a certain position near the inlet end and the broadening of the initial sample band can be better minimized. This will lead to a decrease in band broadening of an eluted peak in an asymmetrical channel.

In asymmetrical flow FFF, two channel designs are utilized: rectangular and trapezoidal. Because flow velocity decreases along the axis of migration, a trapezoidal channel in which the channel breadth decreases toward the outlet is known to be more efficient in eluting low-retaining materials such as high-molecular-weight proteins. Retention in an asymmetrical flow FFF system follows the basic FFF principle and the retention time is calculated as

$$t_r = \frac{w^2}{6D}\ln\left(1 + \frac{\dot{V}_c}{\dot{V}_{\text{out}}}\right) \tag{3}$$

where $\dot{V}_c$ is the cross-flow rate and $\dot{V}_{\text{out}}$ is the outlet flow rate.

In addition to the rectangular channels in FlFFF described thus far, a cylindrical channel system has been developed with the use of hollow fibers in which the fiber wall is made of a porous membrane, as shown in Fig. 1c. It also requires a focusing–relaxation process, as does an asymmetrical channel. Retention in hollow-fiber flow FFF (HF-FlFFF) is controlled by the radial flow, which effectively acts as the cross-flow of a conventional flow FFF system, and the retention in a hollow fiber resembles that of an asymmetrical channel system.

However, the retention ratio in HF-FlFFF is approximately 4λ for a sufficiently retained component, which is somewhat different from that of a conventional channel system ($R \cong 6\lambda$). The retention time in a hollow fiber is calculated as

$$t_r = \frac{r_f^2}{8D}\ln\left(1 + \frac{\dot{V}_{\text{rad}}}{\dot{V}_{\text{out}}}\right) \tag{4}$$

where r_f^2 is the radius of the fiber and $\dot{V}_{\text{rad}}$ is the radial flow rate. Although a number of experiments have indicated a

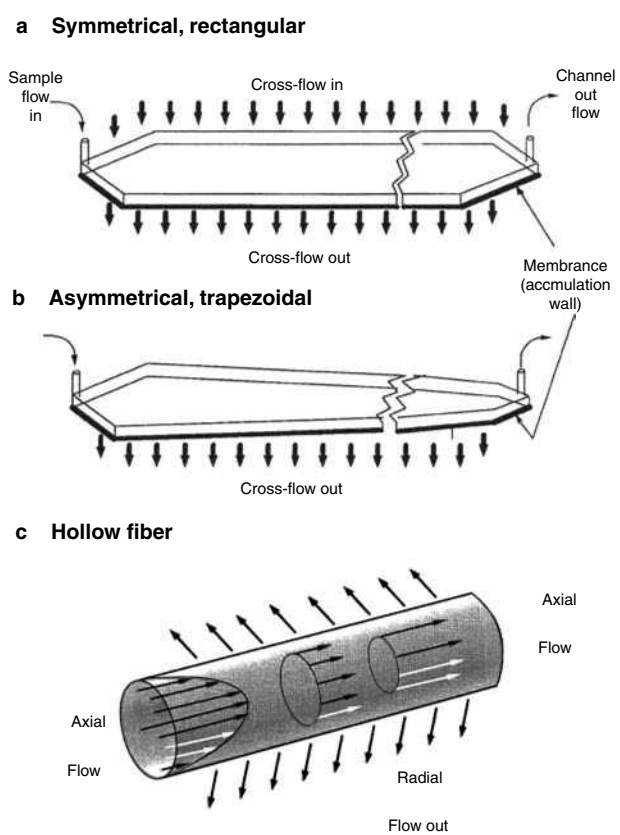

Fig. 1 Types of channel in FFF.

great potential of hollow fibers as an alternative for a flow FFF channel, a great deal of study related to their performance and optimization is needed.

Fluorescence Detection in CE

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

INTRODUCTION

One cannot overestimate the importance of fluorescence detection in high-performance-capillary electrophoresis (HPCE).[1] The success of the human genome project along with the forthcoming revolutions in forensic testing and genetic analysis might not have occurred without the sensitivity and selectivity of laser induced fluorescence (LIF) detection.

BASIC CONCEPTS

The stunning sensitivity of fluorescence detection arises from two areas: (a) detection is performed against a very dark background and (b) the use of the laser as an excitation source provides a high photon flux. The combination of the two can yield single-molecule detection in exceptional circumstances, although picomolar ($10^{-12}M$) is typically obtained. Under conditions that are easy to replicate, LIF detection is often times more sensitive compared to ultraviolet (UV) absorption detection.

Most molecules absorb light in the ultraviolet or visible portion of the spectrum, but only few produce significant fluorescence. This provides for the extreme selectivity of the technique. Molecular fluorescence is usually quenched through vibronic or collosional events resulting in a radiationless decay of excited singlet-state energy to the ground state. In aromatic structurally rigid molecules, quenching is less significant and the quantum yield increases.

The selectivity of fluorescence is to itself a problem because the technique is applicable to fewer separations. Sophisticated derivatization schemes have been developed for these applications to take advantage of the attributes contributed by fluorescence detection. Because there are two instrumental parameters to adjust, the excitation and emission wavelengths, the inherent selectivity of the method is further enhanced.

The fundamental equation governing fluorescence is

$$I_f = \Phi_f I_0 abc E_x E_c E_m E_{\text{pmt}}$$

where I_f is the measured fluorescence intensity, Φ_f is the quantum yield (photons emitted/photons absorbed), I_0 is the excitation power of the light source, a, b, and c are the Beer's Law terms, and the E terms are the efficiencies of the excitation monochromator or filter, the optical portion of the capillary, the emission monochromator or filter, and the detector (photomultiplier or charge-coupled device), respectively. It is no wonder why optimization of fluorescence detection is difficult for the uninitiated.

EXCITATION SOURCES

The optimal excitation wavelength is usually a combination of the power of the light source and the molar absorptivity of the solute at the selected wavelength. The argon-ion laser is used for most DNA applications since the primers, intercalators, and dye terminators have been optimized for 488 nm excitation. For other applications, particularly for small molecules, where native fluorescence is measured, a tunable light source is desirable. The deuterium lamp is useful for low-UV excitation and the xenon arc is superior in the near-UV to visible region. With a 75-W xenon arc, the limit of detection (LOD) is 2 ng/ml ($6 \times 10^{-9}M$) for fluorescein using fiber-optic collection of the fluorescence emission.[2] This is a 100-fold improvement compared to absorption detection. By using a microscope objective to focus the light along with a sheath-flow cuvette (to reduce scattering, see below) and lens to collect the light, the LOD is reduced to 8×10^{-11}.[3] Nevertheless, the LOD using conventional tunable sources will never be superior to that found with the laser.

It is possible to select lasers other than the argonion laser for LIF detection. A 625 nm diode laser is available on a commercial unit (Beckman P/ACE and MDQ). Tunable dye lasers would be desirable but cost and reliability has precluded widespread use. The KrF laser is particularly useful because it emits in the UV at 248 nm. If fiber optics are employed to direct the laser light, then a UV transparent fiber optic must be used. A table of lasers and their wavelengths of emission is given in Table 1.

Lower-power lasers are often used in HPCE. Because scattered light is the factor that often limits detectibility, raising the power levels is ineffective. At high laser power, photobleaching becomes more likely to occur as well.

Table 1 Laser light sources for LIF detection.

Laser	Available wavelengths
Ar ion (air-cooled)	457, 472, 476, 488, 496, 501, 514
Ar ion (full frame)	275, 300, 305, 333, 351, 364, 385, 457, 472, 476, 488, 496, 501, 514
Ar ion (full frame, frequency doubled)	229, 238, 244, 248, 257
ArKr	350–360, 457, 472, 476, 488, 496, 501, 514, 521, 514, 521, 531, 568, 647, 752
HeNe	543, 594, 604, 612, 633
Excimer	
XeCl (pulsed)	308
KrF (pulsed)	248
Nitrogen (pulsed)	337
Nitrogen-pumped dye (tunable)	360–950
Solid state	
YAG (frequency doubled)	532
YAG (frequency quadrupled)	266
Diode lasers	
Frequency doubled ($LiNbo_3$)	415
Frequency doubled (KTP)	424
Frequency tripled (Nd-doped YLiF)	349

METHODS FOR COLLECTING FLUORESCENT EMISSION

The goal here is to minimize the collection of scattered radiation and optimize the collection of emitted fluorescence. Scattered radiation comes from two sources: Rayleigh scattering and Raman scattering. Rayleigh scattering occurs at the wavelength of excitation. To optimize the LOD, virtually all of this radiation must be excluded from detection. Raman scattering is observed at longer wavelengths than Rayleigh scattering and it is times less intense. Despite the weakness of Raman scattering, this effect can significantly elevate the background if left unchecked. Bandpass and/or cutoff filters are often used to reduce the impact of scattering. It is important to ascertain that the selected filter does not fluoresce as well.

Fiber optics held at right angles to the capillary can be employed to route emitted light toward the photomultiplier tube (PMT).[2] The Beckman LIF detector employs a collecting mirror to increase the amount of collected emission. One problem with both of these approaches is the failure to prevent small amounts of scattered light from reaching the PMT. Cutoff and/or bandpass filters are not 100% efficient in this regard. This is particularly important when lasers are used because of the intense scattering of light.

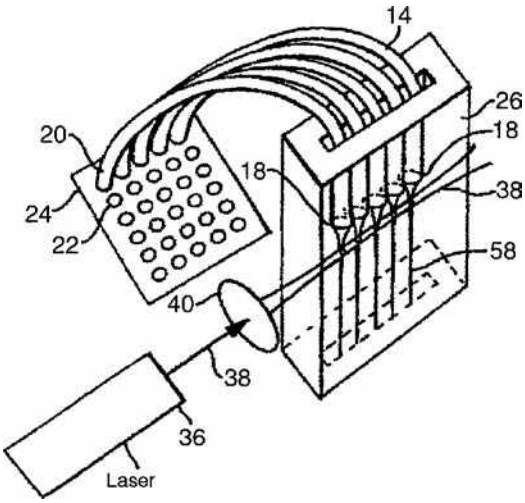

Fig. 1 Multiple-capillary instrument employing the sheath-flow technique. Key: 14, capillary; 18, capillary outlet; 20, capillary inlet; 22, buffer well; 24, microtiter plate; 26, quartz chamber; 36, laser; 38, laser beam; 40, lens; 58, fluidic stream. The electrodes are not shown nor is the device for delivering the sheath fluid.
Source: Reprinted in part from U.S. Patent No. 5,741,412.

The sheath-flow design is an important advance in reducing scattering because detection occurs after the solutes have exited the capillary.[4] Scattering occurs whenever a refractive index (RI) change occurs in the optical path.These RI changes include the air–capillary interface and the buffer–capillary interface. Eliminating the capillary from the optical path effectively removes four scattering surfaces. This becomes most important in multiple-capillary systems such as the DNA sequencer because many surfaces are now involved. The sheath-flow device patented in 1998[5] is illustrated in Fig. 1 for a five-capillary system. In actual practice, 96 capillaries are employed. The laser beam is sufficiently strong that attenuation is not significant or at least can be compensated for in the software. Fluorescence from each capillary is then imaged onto a charge-coupled device (CCD) camera.

For single-capillary systems, a conventional PMT is used for detection. Light is routed to that PMT either with fiber optics, a collecting mirror, epiillumination microscopy, or a microscope objective. For multiple-capillary systems, the system must be scanned[6] or the light imaged onto a CCD camera.

DERIVATIZATION

Derivatization is important in capillary electrophoresis to enhance the detectibility of solutes that are non-fluorescent.[7] The chemistry can occur precapillary, on capillary, postcapillary. Typically, the solutes are amino acids,

catecholamines, peptides, or proteins, all of which contain primary or secondary amine groups.

Reagents such as *ortho*-phthaldehyde (OPA), naphthalenedialdehyde (NDA), 3-(4-carboxy-benzoyl)-2-quinoline carboxaldehyde (CBQCA), fluorescein, and fluorenylmethyl chloroformate (FMOC) are all useful for precapillary derivatization, the most common of the three techniques. For carbohydrates, reagents such as aminopyrene naphthalene sulfonate (APTS) are used for precapillary derivatization. For chiral recognition, prederivatization with optically pure fluorenylethyl chloroformate (FLEC) provides for both enantioseparation by micellar electrokinetic capillary chromatography (MECC or MEKC) and a tag that absorbs at 260 nm and emits above 305 nm. Reagents for derivatizing carbonyl, hydroxyl, and other functional groups are also available.

For on-capillary and postcapillary derivatization, the reagent must not fluoresce until reacted with the solute. For these purposes, NDA and OPA are the best choices. With on-capillary derivatization, it is possible to use a reagent that fluoresces, but its removal prior to solute detection can be difficult.

The advantage of precapillary and on-capillary derivatization is the lack of the need for additional instrumentation beyond the basic HPCE instrumentation. The disadvantage of precapillary derivatization is the need for extra sample-handling steps. For postcapillary derivatization, the need for additional miniaturized instrumentation is the principle disadvantage. This problem may be overcome when dedicated microfabricated systems become available.

Important non-DNA application areas for precapillary derivatiation with LIF detection include the determination of amino acids and amines in cerebrospinal fluid to distinguish disease states such as Alzheimer's disease and leukemia from the normal population. In vivo monitoring of microdialysates from the brain of living animals has been employed for the determination neuropeptides, amphetamine, neurotransmitters, and amino acids. The contents of single neurons and red blood cells have been studied as well.

A variant of postcapillary derivatization is chemiluminescence (CL) detection.[8] In this case, the chemical reaction replaces the light source for excitation. The detector is a PMT run at high voltage. Solutes can be tagged with CL reagents such as luminol or directly excited via the peroxyoxalate reaction. The latter works best for aminoaromatic hydrocarbons such as dansylated amines. The LODs using CL detection approach laser levels because of the low background. However, the need for specialized apparatus has limited the applicability of CL detection.

FLUORESCENCE DETECTION FOR MICROFABRICATED SYSTEMS

The so-called micro-total analytical systems (mTAS) can integrate sample handling, separation, and detection on a single chip.[9] Postcapillary reaction detectors can be incorporated as well.[10] Fluorescence detection is the most common method employed for these chip-based systems. A commercial instrument (Agilent 2100 Bioanalyzer) is available for DNA and RNA separations on disposable chips using a diode laser for LIF detection. In research laboratories, polymerase chain reaction (PCR) has been integrated into a chip that provides size separation and LIF detection.[11]

INDIRECT FLUORESCENCE DETECTION

When detecting solutes that neither absorb nor fluoresce, indirect detection can be employed. With this technique, a reagent is added to the background electrolyte that absorbs or fluoresces and is of the same charge for the solute being separated. This reagent elevates the baseline. When solute ions are present, they displace the additive as required by the principle of electroneutrality. As the separated ions migrate past the detector window, they are measured as negative peaks relative to the high baseline. The advantage of indirect fluorescence compared to indirect absorption is an improved LOD.

The sensitivity of indirect detection is given by the following equation:[12]

$$C_{\mathrm{LOD}} = \frac{C_R}{(\mathrm{DR})(\mathrm{TR})}$$

where the CLOD is the concentration limit of detection, is the concentration of the reagent, D_R is the dynamic reserve, and TR is the transfer ratio. Thus, the lowest CLOD occurs when the reagent concentration is minimized.

With 100 μm fluorescein, a mass limit of detection of 20 μ*M* was measured for lactate and pyruvate in single red blood cells. Fluorescein is a good reagent because it absorbs at 488 nm and thus matches the argon-ion laser emission wavelength. In indirect absorption detection, the additive concentration is usually 5–10 m*M*. Band broadening due to electrodispersion is less unimportant in indirect fluorescence detection because the solute concentration is so low. At higher solute concentrations, the system will be less useful because of electrodispersion. The concentration of the indirect reagent could be increased, but then indirect absorption detection becomes applicable.

With the advent of microfabricated systems that employ LIF detection, it is expected that indirect fluorescence will gain importance as a general-purpose detection scheme.

Fluorescence Detection in HPLC

Ioannis N. Papadoyannis
Anastasia Zotou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Detection based on analyte fluorescence can be extremely sensitive and selective, making it ideal for trace analysis and complex matrices. Fluorescence has allowed liquid chromatography (LC) to expand into a high-performance technique. High-performance liquid chromatography (HPLC) procedures with fluorescence detection are used in routine analysis for assays in the low nanogram per milliliter range and concentrations as low as picogram per milliliter often can be measured. The linearity range for these detectors is similar to that of ultraviolet (UV) detectors (i.e., 10^3–10^4).

DISCUSSION

One major advantage of fluorescence detection is the possibility of obtaining three orders of magnitude increased sensitivity over absorbance detection and its ability to discriminate analyte from interference or background peaks. Contrary to absorbance, fluorescence is a "low-background" technique. In an absorbance detector, the signal measured is related to the difference in light intensity in the presence of the sample vs. the signal in the absence of the sample. For traces of analyte, this difference becomes extremely small and the noise level of the detector increases significantly. In a fluorescence detector, however, the light emitted from the analyte is measured against a very low-light (dark) background and, thus, against a very low noise level. The result is a much lower detection limit, which is limited by the electronic noise of the instrument and the dark current of the photomultiplier tube.

Another major advantage of fluorescence detection is selectivity. The increased selectivity of fluorescence vs. absorbance is mainly due to the following reasons: (a) Most organic molecules will absorb UV/visible light but not all will fluoresce. (b) Fluorescence makes use of two different wavelengths (excitation and emission) as opposed to one in absorbance, thus decreasing the chance of detecting interfering chromatographic peaks.

Quantitative analysis can be performed with fluorescence detection even when poor column resolution occurs, provided there is enough detection selectivity to resolve the peaks.

One of the weak points of fluorescence is that relatively few compounds fluoresce in a practical range of wavelengths. However, chemical derivatization allows many non-fluorescent molecules containing derivatizable functional groups to be detected, thus expanding the number of applications. Fluorescence derivatization can be accomplished either via precolumn or postcolumn methods.

THEORETICAL BACKGROUND OF FLUORESCENCE DETECTION

Fluorescence is a specific type of luminescence. When a molecule is excited by absorbing electromagnetic radiation (a photon) supplied by an external source (i.e., an incandescent lamp or a laser), an excited electronic singlet state is created. Eventually, the molecule will attempt to lower its energy state, either by reemitting energy (heat or light) by internal rearrangement or by transferring the energy to another molecule through a molecular collision. This process distinguishes fluorescence from chemiluminescence, in which the excited state is created by a chemical reaction. If the release of electromagnetic energy is immediate or stops upon the removal of the excitation source, the substance is said to be fluorescent.

In fluorescence, the excited state exists for a finite time (1–10 ns). If, however, the release of energy is delayed or persists after the removal of the exciting radiation, then the substance is said to be phosphorescent.

Once a photon of energy $h\nu_{ecx}$ excites an electron to a higher singlet (absorbance) state (1 fs), emission of the photon $h\nu_{em}$ occurs at longer wavelengths. This is due to the competing non-radiative processes (such as heat or bond breakage) occurring during energy deactivation. The difference in energy or wavelength represented by $h\nu_{em} - h\nu_{exc}$ is called the *Stokes shift*.

The fluorescence signal, I_f, is given by

$$I_f = \varphi I_0\left(1 - e^{-kcl}\right)$$

where φ is the quantum yield (the ratio of the number of photons emitted to the number of photons absorbed), I_0 is the intensity of the incident light, c is the concentration of the analyte, k is the molar absorbance, and l is the path length of the cell.

With few exceptions, the *fluorescence excitation spectrum* of a single fluorophore in dilute solution *is identical to its absorption spectrum*. Under the same conditions, the *fluorescence emission spectrum is independent of the excitation wavelength*, due to the partial dissipation of the excitation energy during the excited lifetime. The emission intensity is proportional to the amplitude of the fluorescence excitation spectrum at the excitation wavelength.

DEACTIVATION PATHWAYS IN FLUORESCENCE

The excited state exists for a finite time (1–10 ns) during which the fluorophore undergoes conformational changes and is also subject to several interactions with its molecular environment. The processes which deactivate the excited state may be radiational or non-radiational (see Fig. 1) and are the following.

Internal Conversion

A transition from a higher (S_3, S_2) to the first singlet excited energy state occurs (S_1) through an internal conversion (in 1 ps). Internal conversion is increased with increasing solvent polarity.

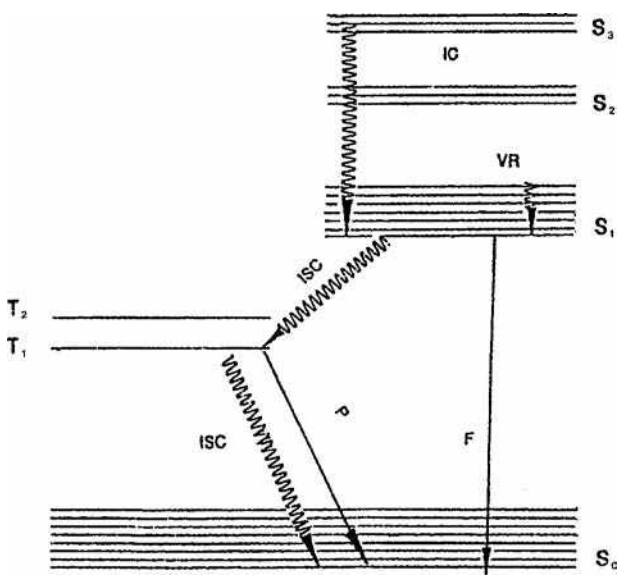

Fig. 1 Deactivation pathways in fluorescence; S_1, S_2, and S_3 are singlet excited states; S_0 is the ground state; T_1 and T_2 are triplet excited states; VR is vibrational relaxation, IC is internal conversion, ISC is intersystem crossing, P is phosphorescence, and F is fluorescence.

External Conversion (Quenching)

This is a chemical or matrix effect and can be defined as a bimolecular process that reduce the fluorescence quantum yield without changing the emission spectrum. Fluorescence radiation is transferred to foreign molecules after collisions.

Vibrational Relaxation

The energy of the first excited singlet state is partially dissipated through vibrations, yielding a relaxed singlet excited state. *Increased vibrations lower the fluorescence intensity*, due to the fact that they occur much faster (1 ps) than the fluorescence event. The molecular structure itself will determine the amount of vibrations. Rigid and planar molecules usually do not favor vibrations and they are prone to fluoresce.

Intersystem Crossing (Photobleaching)

This is a non-radiational process under high-intensity illumination conditions and in the same timescale as fluorescence (1–10 ns). It is defined as a transition from the first excited singlet (S_1) to the excited triplet (T_1) state. This is a "forbidden" transfer and necessitates the change of electron spin. *The quantum yield of fluorescence is reduced and phosphorescence also occurs*.

Phosphorescence

This event occurs due to a radiational relaxation to the ground singlet (S_1) state and in the 0.1 ms to 10 sec time frame. Therefore, the emission is at even longer wavelengths than in fluorescence. Energy addition to the molecule in the form of heat or collisions of two triplet-state molecules can cause delayed fluorescence.

FACTORS AFFECTING FLUORESCENCE

Molecular structure and environmental factors such as acidity, solvent polarity, and temperature variations exert significant influence on fluorescence intensity. Also, variations in mobile-phase composition will cause excitation and emission-wavelength changes in the fluorophore.

Molecular Structure

Common fluorophores possess aromaticity and electron-donating substituents on the ring. Only compounds with a high degree of conjugation will fluoresce. The possible molecular transitions resulting in fluorescence are $\sigma \rightarrow \sigma^*$, occurring only on alkanes in the vacuum UV region, and $\pi \rightarrow \pi^*$ with very high extinction coefficients, occurring in alkenes, carbonyls, alkynes, and azo

compounds. The majority of strong fluorophores undergo this transition and the excited state is more polar than the ground state.

Solvent Polarity

Polar solvents affect the excited state differently in $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions. The excited state in $\pi \rightarrow \pi^*$ transition is stabilized. A reduction in the energy gap will occur and the emission will be shifted to a longer wavelength (red shift). Therefore, the difference between excitation and emission wavelengths will be greater in polar solvents.

Temperature

A rise in temperature increases the rate of vibrations and collisions, resulting in increased intersystem crossing, internal and external conversion. Consequently, the fluorescence intensity is inversely proportional to the temperature increase. Additionally, an increased temperature causes a red shift of the emission wavelength.

Acidity

Acidity can drastically affect the fluorescence intensity. The pK_a of concern is the pK_a of the excited state. Because protonation is faster than fluorescence, the pK_a can be quite different than it is for the molecule in the ground state. Therefore, a pH optimization vs. fluorescence intensity is needed for molecules that are particularly prone to pH changes.

FLUORESCENCE DETECTOR INSTRUMENTATION

Fluorescence detectors for HPLC use come in many designs from the manufacturer. Differences in detector design can lead to markedly different results during interlaboratory comparisons.

Fluorescence detectors are based either on the straight-path design (similar to UV photometers) or on the more often encountered right-angle design. The common excitation source lamps used are continuous deuterium, xenon, xenon–mercury, and pulsed xenon. Recently, the use of high-power light sources for excitation, such as laser sources, allows the development of much smaller volume flow cells with less scatter (noise), resulting in improved efficiency. Photomultiplier tubes are commonly used as the photodetectors (photocells) vs. photodiodes in UV detectors. They convert a light signal to an electronic signal.

Detector flow cells are the link between the chromatographic system and the detector system. The cell cuvettes are made of quartz, with either cylindrical or square shapes and volumes between 5 and 20 μl. The sensitivity is directly proportional to the volume. However, resolution decreases with increasing volume. Fluorescence is normally measured at an angle perpendicular to the incident light. An angle of 90° has the lowest scatter of incident light. However, fluorescence from the flow cell is isotropic and can be collected from the entire 360°.

With the straight-path design, a standard UV cell can be used, but the filters must be selected so as to prevent stray light from reaching the photodetector. The right-angle design often uses a cylindrical cell. This design is less efficient than the straight-path cell because light-scattering problems result in a lower light intensity reaching the photodetector. However, this design is less susceptible to interference from stray light from the lamp, because the photodetector is not in line with the lamp.

With respect to monochromator type, three general detector designs are available: filter–filter, grating–filter, and grating–grating, where either a filter or monochromator grating is used to select the correct excitation and emission wavelengths. Gratings allow a choice of any desired wavelength, whereas filters are limited to a single wavelength.

Fluorescence detectors that use *filters* to select excitation and emission wavelengths are called *filter fluorometers*. This type of detector is the most sensitive, yet the simplest and least expensive. A diagram of this simple form of fluorescence detector is shown in Fig. 2. Usually, in order to enhance the fluorescence collected from the flow cell, lenses are employed along with filters. The lenses are positioned before the excitation filter and after the flow cell to focus and collect the light.

The ultimate in fluorescence detection is a detector that uses a diffraction grating to select the excitation wavelength

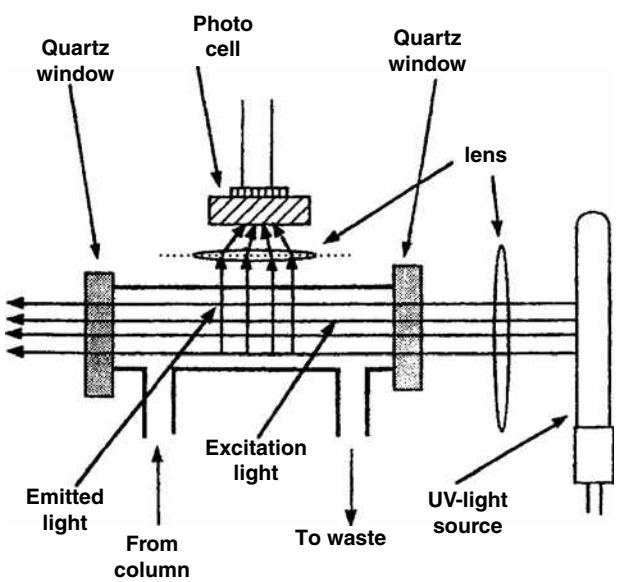

Fig. 2 Schematic of a single-wavelength fluorescence detector.

and a second grating to select the wavelength of the fluorescent light. These dual monochromatic *grating–grating* fluorescence detectors are called *spectrofluorometers*. If the gratings are used in the scanning mode, the detector is a *scanning spectrofluorometer*. A fluorescence or excitation spectrum can be provided by arresting the flow (stop-flow technique) of the mobile phase when the solute resides in the detecting cell or by scanning the excitation or fluorescent light, respectively. In this way, it is possible to obtain excitation spectra at any chosen fluorescent wavelength or fluorescence spectra at any chosen excitation wavelength.

The *grating–filter* detector is a hybrid between the filter–filter and the grating–grating types. Both high sensitivity and intermediate selectivity are achieved. The use of a filter in combination with gratings is ideal for lowering the background.

Grating–grating fluorometers are convenient for method development, because they permit selection of any excitation or emission wavelength. Filter–filter instruments, on the other hand, are simpler, easier in use, less expensive, more sensitive, and better suited for transferring an HPLC method between laboratories.

With the vast development of technology, fluorescence detectors have become programable. Optimization of wavelength-pair maxima for each analyte can be time programmed during the chromatographic run.

The proper use of fluorescence detectors necessitates knowledge and understanding of noise sources. Dual monochromatic detectors have stray light leakage. When the wavelength pair is close, the background noise can significantly limit the detection limit. The *stray light*, along with *reflection* and *scattering*, increases the blank signal, resulting in reduced signal-to-noise ratio. Reflection occurs at interfaces that have a difference in the refractive index. Scattering can be of *Rayleigh* or *Raman* type.

In Rayleigh scatter, the wavelength of the absorbed and emitted photons are the same. Ultraviolet wavelengths scatter more than visible. Rayleigh scatter can be a significant problem when the wavelength pair overlaps (less than 50 nm) and instruments do not have filter accommodations and adjustable slits.

Raman scatter can also be troublesome. Depending on the wavelength pair of the sample, Raman scatter from the mobile phase can overlap the fluorescence signal and, thus, can be misdiagnosed as the fluorescence signal itself. This problem arises during increasing instrument sensitivity. However, satisfactory separation can be achieved by changing the excitation wavelength because emission is independent of the excitation wavelength.

To summarize, in terms of instrumental operation, the following practices should be followed: proper zeroing of the blank and non-tampering with the gain during serial dilutions. Increased sensitivity should be accomplished by varying the full-scale range.

The basic sequence in instrumental adjustments is to select the minimum gain necessary to allow a full-scale deflection, at the least sensitive scale. When linear curves are prepared, the gain need not be adjusted. Amplification should always be done using the range control. Any small changes in the gain during calibration will cause non-linearity. Once the gain has been set, the zero can be set. To ensure reproducibility, zeroing the detector from time to time during the day is recommended, because the dark current can change during the day.

Foam CCC

Hisao Oka
Food-Related Chemistry, Laboratory of Chemistry, Aichi Prefectural Institute of Public Health, Nagoya, Japan

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

When a foam moves through a liquid, it carries particles caught at its interface, resulting in accumulation of these particles at the surface. For many years, this phenomenon has been utilized for the separation of minerals and metal ions. Since the method only employs inert gas and aqueous solution, it should have great potential for the separation of biological samples. This idea has been materialized using the high-speed countercurrent chromatographic (HSCCC) system. In this foam CCC method, foam and liquid undergo rapid countercurrent movement through a long, fine Teflon tube (2.6 mm I.D. × 10 m) under a centrifugal force field. This foam CCC technology has been applied to the separation of a variety of samples.

APPARATUS OF FOAM CCC

Fig. 1a illustrates a cross-sectional view of the foam CCC apparatus. The rotary frame holds a coiled separation column and a counterweight symmetrically at a distance of 20 cm from the central axis of the centrifuge. When the motor drives the rotary frame, a set of gears and pulleys produces synchronous planetary motion of the coiled column in such a manner that the column revolves around the central axis of the centrifuge while it rotates about its own axis at the same angular velocity in the same direction. The rotating force field resulted from this planetary motion induces countercurrent movement between the foam and its mother liquid through a long, narrow, coiled tube. Introduction of a sample mixture into the coil results in the separation of sample components. The foam active components are quickly carried with the foaming stream and are collected from one end of the coil, while the rest moves with the liquid stream in the opposite direction and is collected from the other end of the coil.

Fig. 1b illustrates the column design for foam CCC. The coiled column consists of a 10 m long, 2.6 mm I.D. Teflon tube of 50 ml capacity. The column is equipped with five flow channels. The liquid is fed from the liquid feed line at the tail and collected from the liquid collection line at the head. Nitrogen gas is fed from the gas feed line at the head and discharged through the foam collection line at the tail, while the sample solution is introduced through the sample feed line in the middle portion of the coil. The head–tail relationship of the rotating coil is conventionally defined by an Archimedean screw force, where all objects of different density are driven toward the head. Liquid feed rate and sample injection rate are each separately regulated with a needle valve, while the foam collection line is left open to the air.

APPLICATION

Foam CCC can be applied to two types of samples with: 1) affinity to the foam producing carrier; and 2) direct affinity to the gas–liquid interface.

Foam Separation Using Surfactants

This technique was demonstrated for the separation of methylene blue and dinitrophenyl (DNP)-leucine having affinity to the foam producing carrier. Sodium dodecyl sulfate (SDS) and cetyl pyridinium chloride (CPC) were used as carriers to study the effects of their electric charges on the foam affinity of various compounds. When the sample mixture was introduced with the anionic SDS surfactant, the positively charged methylene blue was adsorbed onto the foam and quickly eluted through the foam collection line while the negatively charged DNP-leucine was carried with the liquid stream in the opposite direction and eluted through the liquid collection line. Similarly, when the same sample mixture was introduced with the cationic CPC surfactant, the negatively charged DNP-leucine was totally eluted through the foam collection line and the positively charged methylene blue through the liquid collection line.

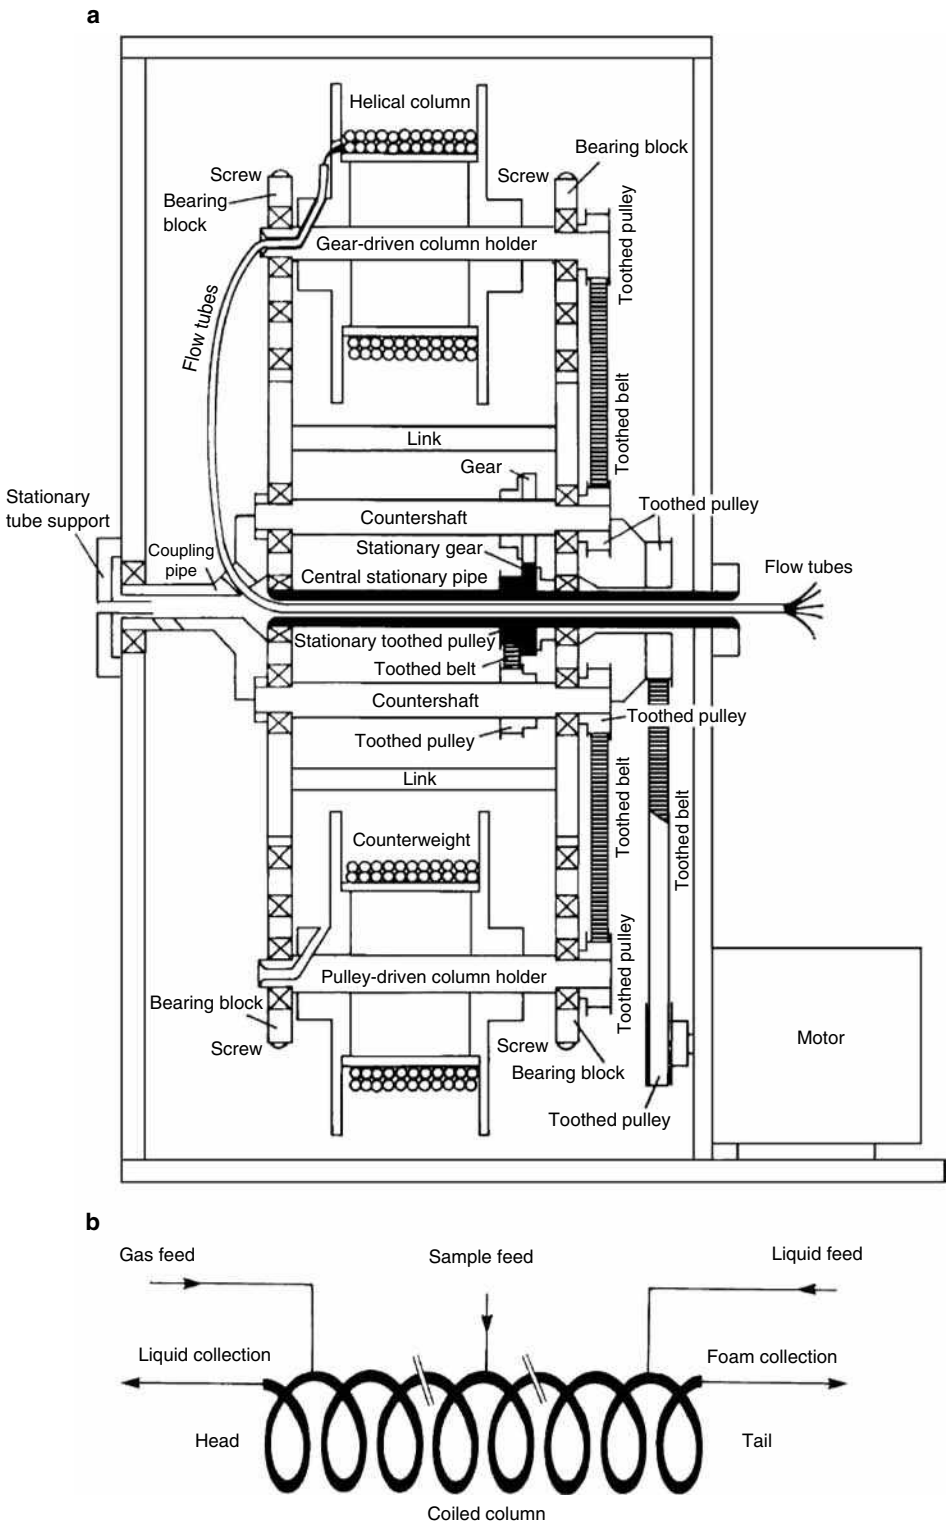

Fig. 1 a) Foam CCC apparatus; and b) column design for foam CCC.

Foam Separation Without Surfactant

Many natural products have foaming capacity so that foam CCC may be performed without surfactant. This possibility was demonstrated using bacitracin complex (BC) as a test sample because of its strong foaming capacity. Bacitracin complex is a basic cyclic peptide antibiotic consisting of more than 20 components, but except for the major components BCs-A and -F, the chemical structures of the other components are still unknown.

The foam CCC experiment for the separation and enrichment of BC components was conducted using nitrogen gas and distilled water entirely free of surfactant or other additives.

Batch sample loading

Foam CCC of BC components was initiated by simultaneously introducing distilled water through the liquid feed line at the tail and nitrogen gas through the gas feed line at the head into the rotating column, while the needle valve in the liquid collection line was fully open. After steady state hydrodynamic equilibrium was reached, the pump was stopped and the sample solution was injected into the sample feed line at the middle of the column. After the lapse of a predetermined standing time, the needle valve opening was adjusted to the desired level and pumping was resumed. Effluents were collected at 15 sec intervals. The bacitracin components were separated in the order of hydrophobicity of the molecule in the foam fractions, with the most hydrophobic compounds being eluted first. This method can also be applied to continuous sample feeding as described below.

Continuous sample feeding

The experiment was initiated by introducing nitrogen gas into the gas feed line at the head of the rotating column. Then, a 2.5 L volume of the BC solution was continuously introduced into the coil through the sample feed line at 1.5 ml/min. The hydrophobic components produced a thick foam that was carried with the gas stream and collected from the foam collection line at the tail, while the other components stayed in the liquid stream and eluted from the liquid collection line at the head. High-performance liquid chromatography (HPLC) analysis of the foam fraction revealed that the degree of enrichment increased with the hydrophobicity of the components. These results clearly indicate that the present method is quite effective for the detection and isolation of small amounts of natural products present in a large volume of aqueous solution.

Recycling sample injection

In this system, the effluent from the liquid outlet is directly returned into the column through the sample feed line so that the sample solution is continuously recycled for repetitive foam fractionation (Fig. 2). The utility of this system was demonstrated in the separations of microcystin extract and bacitracin complex from large volumes of sample solution. Microcystins were separated and enriched in decreasing order of hydrophobicity. Bacitracin A, a hydrophobic major component, in the bacitracin complex was highly enriched in the foam fraction and almost completely isolated from other components. This recycling foam CCC method may be effectively applied for the separation and enrichment of various foam-active components from crude natural products.

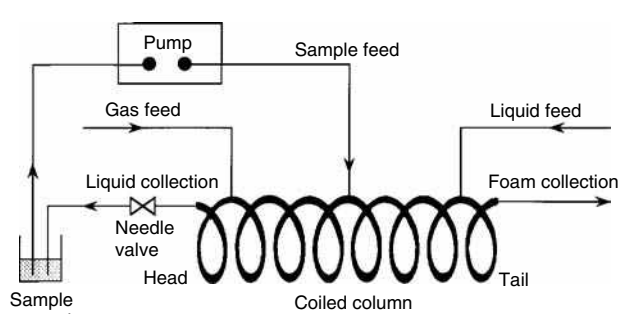

Fig. 2 Foam CCC system with recycle sample injection.

The general procedure for foam CCC using this recycling sample injection is as follows: 1) Clamp the liquid feed inlet (no liquid feed is employed); 2) rotate the column at 500 rpm; 3) fully open the needle valve; 4) introduce nitrogen gas at 80 psi through the gas feed line; 5) introduce the sample at a flow rate of 9.0 ml/min through the sample feed line for 20 min; 6) stop the pumping; 7) close the needle valve; 8) resume the pumping at a flow rate of 1.0 ml/min; 9a) when foam emerges, fractionate effluents from foam outlet at 2.5 min intervals; 10) increase the flow rate to 1.5 ml/min; 9b) when failing to elute at step 8, increase the flow rate to 1.5 ml/min or until the foam is eluted.

Foaming parameters

For application of foam CCC to various natural products, it is desirable to establish a set of physicochemical parameters that reliably indicate their applicability to foam CCC. Two parameters were selected for this purpose, i.e., "foaming power" and "foam stability," which can be simultaneously determined by the following simple procedure. In each test, the sample solution (20 ml) is delivered into a 100 ml graduated cylinder with a ground stopper and the cylinder vigorously shaken for 10 sec. The foaming power is expressed as the volume ratio of the resulting foam to the remaining solution, and the foam stability by the duration of the foam.

In order to correlate the foaming parameters to the foam productivity in foam CCC, the following five samples were selected because of their strong foaming capacities: bacitracin, gardenia yellow, rose bengal, phloxine B, and senega methanol extract. The results of our studies indicated that a sample having foaming power greater than 1.0 and foam stability of over 250 min could be effectively enriched by foam CCC. These minimum requirements of foaming parameters derived from the bacitracin experiment were found to be well applicable to four other samples.

CONCLUSIONS

Foam CCC can be successfully applied to a variety of samples having foam affinity with or without surfactants.

The method offers significant advantages over conventional foam separation methods by allowing the efficient chromatographic separation of sample in both batch loading and continuous feeding. We believe that the foam CCC technique has great potential in the enrichment, stripping, and isolation of foam active components from various natural and synthetic products in both research laboratories and industrial plants.

Food Analysis: Ion Chromatography

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
Ion chromatography (IC) plays an important role not only in the determination of anions and cations in water and wastewater but also in analysis of different kinds of samples such as food and beverages. The entry is a short review of food sample pretreatment and application of IC for the analysis of inorganic and organic ions.

INTRODUCTION

Ion chromatography (IC) has become a useful tool for the analytical chemist especially in the area of inorganic and organic anions and cations analysis.

Originally, IC was developed as a chromatographic method for inorganic anions, using ion-exchange stationary phases and conductivity detection. Recently, the definition of IC has been broadened to include other separation modes such as ion pair chromatography and ion exclusion chromatography, which are based on different separation mechanisms than simply ion exchange.

Ions that are most commonly determined in food samples are: inorganic anions, carboxylic acids, metal ions, and organic cations. Some anion-exchange stationary phases do not always allow a baseline-resolved separation of all inorganic and organic ions under isocratic conditions.

The introduction of gradient elution greatly improved these analyses. The reason IC easily deals with complex matrices lies not only in the stability and resistance to contamination of the stationary phases used, but also in the sensitivity and specificity of the detection methods employed.

IC is increasingly being adopted by many test and research laboratories in food and beverage industry.[1,2] A survey of the application of IC in food and beverage industry is given in Table 1.[3]

SAMPLE PREPARATION FOR FOOD ANALYSIS

Regarding the application of IC for foodstuff analysis, the crucial step is sample preparation. Adequate sample preparation has growing importance because it allows full exploitation of the potential of IC. Thus, it is essential to modernize traditional sample preparation techniques in food analysis, which very often result in solutions that are easily contaminated by high quality of reagents involved or prone to causing IC column contamination.

Sometimes, sample extraction with deionized water and membrane filtration is completely sufficient. In case of a complex sample matrix, more sophisticated sample preparation procedures are required.

The most often used and promising techniques for obtaining solutions for direct IC injection of food samples are: accelerated solvent extraction (ASE), supercritical fluid extraction (SFE), solid-phase extraction (SPE), and UV photolysis and pyrolysis.[4] The ASE technique basically employs the principles of traditional solvent extraction but at higher temperature and pressure, in which conditions solvents show better extraction properties.

SFE uses the principles of traditional liquid–solid extraction. It is extensively used for the separation of organic compounds from food as well as for the separation of inorganic compounds.

SPE offers many advantages over liquid–liquid extraction and permits removal of interferents and analyte concentration at the same time. The extraction conditions are mainly affected by pH, matrix ionic strength of the elution solvent, flow rate, and physicochemical characteristic of the sorbent bed.

The UV digestion of any sample is directly proportional to the UV intensity and irradiation time, and is inversely proportional to the concentration of organic substance.

Microwave-oven digestion involves heating the samples with acids in a polytetrafluoroethylene (PTFE) vessel using microwave radiation. The PTFE vessels are transparent to microwaves and the sample directly absorbs electromagnetic energy that is transmitted to the polar molecules present in the sample, forcing them to vibrate at high frequency. This results in high sample temperatures without the vessel being heated.

Pyrohydrolysis is a technique that uses decomposition of the matrix by superheated water vapors. This technique can be used for the determination of halogens, borates, nitrates, sulfates, etc. in various food matrices.

Table 1 Areas and typical examples of ion chromatography application in the food and beverage analysis.

Application area	Analytical examples
Baby food	Determination of iodide, amines, and transition metals
Beverages	Determination of inorganic anions and cations in the water being used; in sweeteners and flavors and in the finished products; organic acids and carbohydrates in beer, wine, and juice
Canned food	Determination of chloride, nitrite, nitrate, sodium, potassium, organic acids, and transition metals in canned fruit and canned vegetables, species, vinegar, and fish
Cereal products	Determination of bromate and propionate in bakery products
Fats, oils, carbohydrates, and flavors	Determination of fatty acids and carbohydrates in corn syrup
Meat processing	Determination of nitrite/nitrate ratio in meat products; nitrate in the water being used
Milk production	Determination of iodide in whole milk; chloride and/or sodium in butter; lactate, pyruvate, and citrate in cheese

APPLICATION OF IC IN BEVERAGE AND FOOD ANALYSIS

The methods used to evaluate foodstuff quality are commonly required to be reliable, rapid, and convenient. IC meets these requirements, although simply suppressed conductivity detection is sufficient only for the detection of selected ions such as chloride, sulfate, sodium, potassium, magnesium, and calcium. Its application strongly depends on sample matrix. Sometimes an alternative detection mode should be used.

Generally speaking, most inorganic anions and cations have weak absorption in UV–Visible spectral region. Thus, only selected ions can be determined by UV detection.[5] Therefore other detection techniques such as amperometry, spectrometry, and refractive index are used for food analysis. The best detection limit is offered by mass spectrometry because of the reduction of chemical noise especially in complex matrices.[6]

The determination of anions and cations in alcoholic and non-alcoholic beverages is of importance from both health-related and manufacturing perspectives. It concerns the determination of inorganic and organic anions and cations,[7,8] and carbohydrates[9,10] in beverages of all kinds (e.g., beer, wine, fruit juices, refreshers, coffee, and tea).

The analysis of organic acids, carbohydrates, sulfites, ascorbic acid, and ethanol is of primary interest for characterizing beer and monitoring of brewing process. For monitoring the brewing process in terms of carbohydrates, anion-exchange chromatography with pulsed amperometric detection is the method of choice.

The spectrum of organic acids in wine is extremely complex and represents a challenge for IC analysis due, in part, to large concentration differences.[11] In many cases, a number of organic additives are added to refreshing drinks. These additives include sweeteners such as saccharin or aspartame, preservatives such as benzoic acid, and flavors such as citric acid and caffeine. They can be simultaneously analyzed using a multimode phase with anion-exchange and reversed-phase, and simultaneous conductive and UV detection.

Sweeteners such as saccharine, sodium cyclamate, and acesulfam-K are more and more frequently used in food industry instead of sugar or glucose syrup. These compounds in alkaline medium exist as anions, thus anion-exchange chromatography with conductivity detection provides an alternative to reversed-phase liquid chromatography (RPLC) with UV/Vis detection.[12]

A serious analytical problem is the analysis of preservatives used in food preparation. Usually, separation is carried out on chemically modified silica, utilizing suppressed conductivity detection and UV/Vis detection for preservatives containing chromophores.[13]

As in the case of inorganic anions (Cl^-, NO_2^-, NO_3^-, PO_4^{3-}, SO_4^{2-}), many inorganic cations (e.g., Na^+, K^+, NH_4^+, Mg^{2+}, and Ca^{2+}) are introduced into beverages with water. Others are introduced as counterions to added ingredients. These ions are monitored due to restrictions imposed by different countries and for purposes of mass balance. Thus, the content of these ions needs to be monitored by the manufacturer to maintain high quality of the product. The quality of beverages, in a sense, is based on ion controlling, because some ions such as K^+ and Na^+ are beneficial to human health; some of them are not.

Some organic acids such as citrate and malate, and inorganic anions such as phosphate are monitored due to their function as acidifiers or flavor enhancers. In addition, the presence of some organic acids can be used to reveal potential food adulteration.[14] As an alternative to ion-exchange chromatography, ion-exclusion chromatography is also used for determining organic acids especially in milk products and fruit juices.[15]

Ions determined in food samples can be divided into: nitrogen, sulfur and phosphorus compounds, halides, and inorganic and organic cations. For health purposes, the determination of nitrogen compounds such as nitrite, nitrate, ammonium, and biogenic amines is of great importance. Nitrates are naturally present in many foodstuffs, noticeably

vegetables, where their content varies to a great extent because of the widespread nitrogenous fertilizers in use.

Vegetables are not the only source of nitrate intake. Potassium and sodium salts of both nitrate and nitrite are commonly used in food industry, in curing meat, for fixing the color, for inhibiting the microbial growth, and for obtaining the characteristic flavor.[16]

The determination of nitrite and nitrate in meat and sausage products is an important problem, because their tolerated concentrations are strictly limited. Sample preparation includes homogenization of the sample, its extraction with a 5% borax buffer in a hot water bath, and subsequent Carrez precipitation with 15% potassium hexacyanoferrate(II) and 30% zinc sulfate solution.

The nitrate content is also important for monitoring the food adulteration in dairy industry.

The determination of nitrite and nitrate is usually performed simultaneously by using a bicarbonate/carbonate or hydroxide eluent and suppressed conductivity detection, alone or coupled with UV/Vis detection in the case of complex matrices.

Sulfur species commonly used in the food industry as preventing agents are sulfites. Moreover, sulfate concentration can be affected by technological use of sulfites.

Sulfate can be determined simultaneously with other inorganic species of sulfur such as thiosulfate and dithionate, using conductivity, UV/Vis or amperometric detectors.

Total phosphorus content is one of the parameters used to define product quality and originality. Phosphorus compounds are present in most vegetables and foods. Some of them such as proteins and phospholipids are important indicators of metabolic activity. Inorganic phosphates are extensively used as fertilizers, so the same considerations that apply for nitrogen species are also valid for phosphorus content in food samples.

Phosphorus concentration in milk affects almost all aspects of cheese manufacturing, and in soft drinks production, where it acts as acidifier and flavor.[17] Polyphosphates are widely used as additives: in meat-based products for reducing water loss, to increase the uptake of water for economic purposes, in fruit juices as flavor and color preservatives, in diary industry as additive for cheese, etc.

The most common way of phosphate determination is its separation with bicarbonate/carbonate or hydroxide eluent followed by suppressed conductivity detection. Yet this does not suffice for polyphosphates determination in food samples that have to be determined by means of gradient IC. When determining orthophosphate content, it should be noted that only free PO_4^{3-} ions, and not the total phosphate, are detected by IC. The reason is that some phosphate is bound by calcium especially in fruit juices.[18]

Next group of anions determined in food samples are halides. The principal source of fluoride intake is water, however, other foods such as tea[19] and fish can be a source of fluoride as well. In dairy products such as cream and cheese, fluoride content is very high and can exceed by threefold the original fluoride concentration in milk.

Chloride is one of the most common inorganic anions in food. Its content is usually related to presence of sodium. In food industry, it is commonly added in the form of NaCl as a preservative or to enhance sapidity of the final products.

The bromide content in food is mainly related to disinfecting with methyl bromide. Some plants such as carrot, celery, and tomato accumulate bromide and its determination can be used as a marker of methyl bromide treatment. High bromide concentration in soft drinks can derive from the addition of brominated vegetable oils.

Bromate is a potential carcinogenic agent; thus its determination even at trace levels is important in drinking water. There is some health risks concerning with residual bromate in bakery products, because bromate salts are used as dough conditioners in baking industry. The majority of bromate is reduced to bromide during baking processes, however residual bromate has still been found in some baked goods.[20]

Common sources of iodide include not only iodized table salt and seafood, but also other foods such as eggs and milk. In standard analytical conditions, IC allows simultaneous determination of fluoride, chloride, and bromide with suppressed conductivity detection, while iodide is usually determined separately with amperometric detection.

Among many other anionic species determined in foodstuff, the most important are: cyanide, carbonate, and certain anionic metal complexes. Cyanides are very toxic compounds; concentrations as low as a few ppm are dangerous for human health. Cyanide is naturally present in some vegetables, such as cassava, sorghum, and fruit seeds. Amperometric detection provides high sensitivity for cyanide.

Carbonate is naturally present in fermented beverages or added to soft drinks. Taking into consideration of its weak acidity, the separation technique of choice is ion exclusion chromatography coupled with conductivity detection.

Selected metal anionic forms such as arsenic species are toxic compounds and their presence must be detected at very low levels. Similar to inorganic arsenic species, simultaneous determination of selenite and selenate, as well as Cr(III)/Cr(VI), provides important information about oxidation states and their influence on food quality and human health.

These species can be determined by UV/Vis or amperometric detection, coupled with suppressed conductivity, or by hyphenated techniques such as ion chromatography–mass spectrometry (IC–MS) or ion chromatography-inductively coupled plasma–mass spectrometry (IC-ICP–MS).[21]

Inorganic cations such as sodium, potassium, ammonium, calcium, magnesium, heavy and transition metals, and organic amines are present in foods and their concentrations can significantly vary.

IC allows simultaneous determination of alkaline and alkaline earth metals, as well as ammonium and biogenic

amines with conductivity detection, while heavy and transition metals are more commonly determined by post-column derivatization technique by absorbance detection.[22] The main advantage of post-column derivatization technique by UV detection is the simultaneity of the procedure and the ability to distinguish between different oxidation states.[23]

Another important application of IC in food industry is determination of biogenic amines. Usually, they are separated by ion-pair chromatography on a chemically bonded reversed phase, using UV detection, amperometry[24], or MS detection.[25]

CONCLUSION

IC has been applied successfully to analysis of inorganic and organic ions in foodstuffs. Its reliability and versatility in analyzing complex matrices typical of food samples with high selectivity, sensitivity, and reproducibility provides a rapid and convenient means to obtain complex profiles of ionic components.

New developments in sample preparation, higher capacity of ion-exchange stationary phases coupled with high efficiency, different selectivity, solvent compatibility, and major diffusion of IC detection techniques other than conductivity cause more widespread usability of IC in food industry.

INTRODUCTION

Many synthetic and natural colors are used in foods all over the world. In Japan, 12 synthetic and 66 natural colors are generally permitted for use in foods. The Japanese government requires labeling on the package concerning kinds of colors that have been used in the contained foods. However, non-permitted colors are also frequently detected in food, and also unlabeled foods are found in the market. Thus, the inspection of colors in foods has been performed by a public health agency.

The analyses of colors in foods have been mainly achieved by thin-layer chromatography (TLC), because TLC is a simple and effective technique for the separation of components in a mixture. However, the only useful information obtained from a TLC plate to identify a component is the R_f value; the identification of the separated components is difficult unless an appropriate spectrometric method, such as ultraviolet-visible absorption spectrometry, is used. A stepwise operation, including individual component separation by TLC and measurement of the spectrum, is laborious and time-consuming, because it requires extra steps such as extraction of the desired compound from the TLC plate and elimination of adsorbents.

TLC/scanning densitometry is a useful tool for the identification of the target compounds on a TLC plate, because the combined methods can separate and then directly measure ultraviolet-visible absorption spectra of the compounds without the laborious and time-consuming procedures described above. In this entry, we deal with the identification of synthetic and natural colors in foods using TLC/scanning densitometry.

SYNTHETIC COLORS

A simple and rapid identification method for synthetic colors in foods has been established, using TLC/scanning densitometry.[1] Forty-five synthetic colors were able to be completely separated on a C18 TLC plate by complementary use of the following four solvent systems: 1) acetonitrile–methanol–5% sodium sulfate (3:3:10); 2) methyl ethyl ketone–methanol–5% sodium sulfate (1:1:1); 3) acetonitrile–methanol–5% sodium sulfate (1:1:1); and 4) acetonitrile–dichloromethane–5% sodium sulfate (10:1:5). We measured the visible absorption spectra of the synthetic colors on the developed C18 TLC plates by scanning densitometry to identify them. The spectra of the colors purified from foods were in close agreement with those of the standard colors, and the reliability of identification was established.

Next, we successfully applied this technique to the identification of an unknown synthetic color in a pickled vegetable.[2] This color was suspected to be orange II (Or-II), which is not permitted for use in foods in Japan. It was difficult to identify Or-II by conventional analytical methods for food colors, including TLC and high-performance liquid chromatography (HPLC), because there are actually three isomers in total: orange I (Or-I), orange RN (Or-RN), and Or-II, due to differences in the positions of hydroxyl groups in the molecules. Under conventional TLC or HPLC conditions, it is hard to separate these isomers from each other. As shown in Fig. 1 (left), the unknown color showed the same R_f value as those of Or-II and Or-RN, although it showed a different R_f value from Or-I. In order to identify the unknown color, we measured the visible absorption spectrum of the color using TLC/scanning densitometry and compared it with those of Or-II and Or-RN. Both spectra of the unknown color and Or-II gave maximum absorption at only 485 nm; however, that of Or-RN showed maximum absorption at 485 and 400 nm. Therefore, we identified the unknown color in the pickled vegetable to be Or-II.

Thus, TLC/scanning densitometry is shown to be effective for the identification of an unknown synthetic color in foods.

NATURAL COLORS

Lac Color and Cochineal Color

Lac color is a natural food additive extracted from a stick lac, which is a secretion of the insect *Coccus laccae*

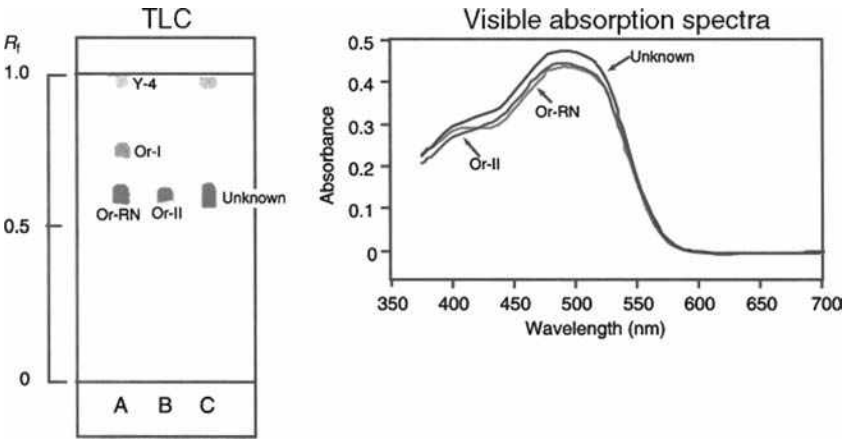

Fig. 1 TLC and visible absorption spectra of synthetic colors extracted from a pickled vegetable under TLC/scanning densitometry. (A) Standards of tartrazine (Y-4), orange I (Or-I), and orange RN (Or-RN). (B) Standard of orange II (Or-II). (C) Extract of the sample. TLC/scanning densitometric conditions. Plate: RP-18 (E. Merck). Solvent system: methyl ethyl ketone-methanol-5% sodium sulfate (1:1:1). Apparatus: Shimadzu CS-9000. Wavelength scanning range: 370–700 nm. Slit size: 0.4 × 0.4 mm. Measuring mode: reflecting absorption.

(*Laccifer lacca* Kerr), and is widely used for coloring food. It is known that the red color is derived from a water-soluble pigment including laccaic acids A, B, C, and E. Cochineal color extracted from the dried female bodies of the scale insect (*Coccus cacti* L.) is water-soluble and has a reddish color. The main coloring component is carmic acid.

Because these colors are frequently used in juice, jam, candy, jelly, etc. it is required to establish a simple and rapid analysis method using TLC. However, as described in the "Introduction," the only useful information obtained from a TLC plate to identify a component is the R_f value. Therefore, we applied TLC/scanning densitometry to the identification of lac and cochineal colors in foods.[3]

TLC conditions

After various experiments, the best results were obtained using methanol–0.5 mol/L oxalic acid (5:4.5) as the solvent system, with a C18 TLC plate. As shown in Fig. 2 (left), the lac color standard was separated into two spots at R_f values of 0.60 and 0.29, and cochineal color standard gave a spot at R_f value of 0.52. Anthraquinone compounds, such as lac and cochineal colors, showed extreme tailing on the C18 TLC plate using conventional TLC conditions. We have previously found that the use of a solvent system containing oxalic acid is effective for controlling the tailing of anthraquinone compounds. Therefore, we decided to use a solvent system containing oxalic acid and tried various TLC conditions. Finally, we found the best conditions described above.

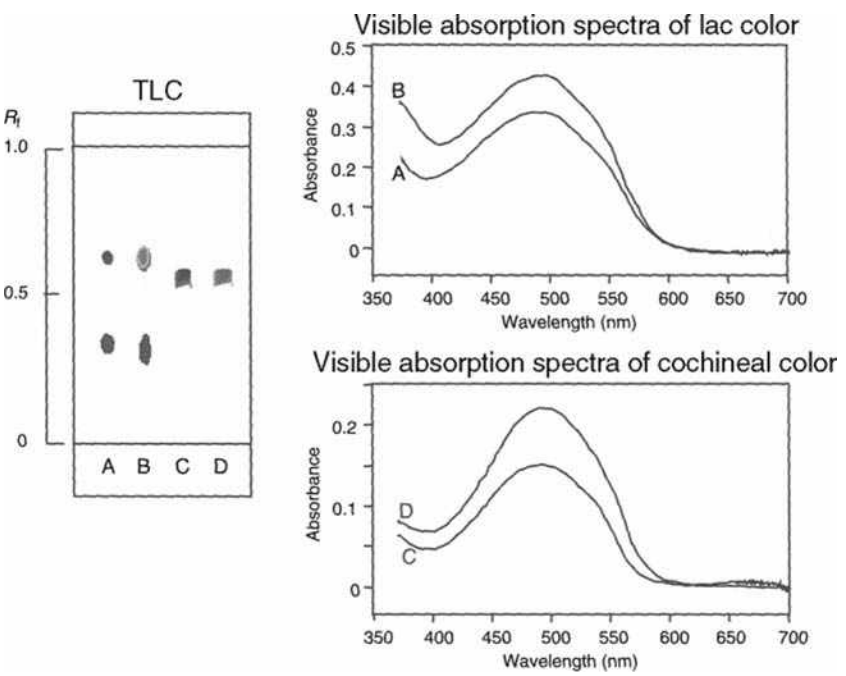

Fig. 2 TLC and visible absorption spectra of lac color and cochineal color extracted from commercial foods under TLC/scanning densitometric conditions. (A) Lac color standard. (B) Extract of jelly. (C) Cochineal color standard. (D) Extract of spagetti sauce. Plate: RP-18 (E. Merck). Solvent system: methanol-0.5 mol/L oxalic acid (5.5:4.5). Other conditions: see Fig. 1.

Measurement of visible absorption spectrum by scanning densitometry

Reflection spectra of the spots of lac color standard at R_f values of 0.60 and 0.29 and cochineal color standard at R_f value of 0.52 on the TLC plate were taken under the conditions described above. The obtained spectra showed good agreement with the spectra obtained from methanol solutions. Therefore, we considered that TLC/scanning densitometry is effective for the identification of these natural colors.

Application to commercial food

Reproducibility of the R_f value by reversed-phase TLC (RP-TLC). In order to examine the effects of the contaminants contained in the sample on the R_f value, 122 commercial foods (41 foods for lac color and 81 foods for cochineal color) were analyzed by C18 TLC as described above. The obtained R_f values of the spots were then compared. The difference between the R_f value of the standard color and the R_f value of the color in the sample was expressed as the ratio between the R_f value of the color in the sample (Ra) and the R_f value of the standard color (Rs); the reproducibility was evaluated according to the coefficient of variation of this ratio.[4] With respect to lac color, the average Ra/Rs values were 0.99 with a coefficient of variation of 8.1% and 1.00 with 4.6% for spots at R_f values of 0.29 and 0.60, respectively. Cochineal color gave an average Ra/Rs value of 0.99 with a coefficient of variation of 5.9%. These results suggest that the spots extracted from the samples appear nearly at the same positions as those of the lac color and the cochineal color standard without being affected by contaminants in the sample, and that the identification of the color is reliable and reproducible.

Identification by TLC/scanning densitometry. The visible absorption spectra of the spots of the lac and cochineal colors on the C18 TLC plates, for which the reproducibility of the R_f value had been evaluated, were measured using a scanning densitometer. Fig. 2 shows the typically obtained TLC chromatograms and spectra obtained from the spots. The spectra of the colors purified from foods were in good agreement with those of the standard colors; thus, the reliability of identification was then established.

Paprika Color

Paprika color is obtained by extraction from the fruit of red peppers (*Capsicum annuum*) and contains capsanthin and its esters, formed from acids, such as lauric acid, myristic acid, and palmitic acid, in large amounts as its color components. Commercially available paprika colors are known to have different compositions of these color components, depending on the material from which the paprika color is extracted; this makes the identification of paprika color, based on the analysis of the color components, impossible, causing difficulty in developing a simple, rapid, and reliable identification method for the paprika color in foods. Therefore, we investigated a TLC/scanning densitometric method for the identification of paprika color using capsanthin, which is a main product of saponification, as an indicator.[5]

TLC conditions

When a paprika color standard, before saponification, was subjected to C18 TLC, a number of overlapping spots were observed, and a satisfactory separation could not be obtained. This was probably due to the paprika color containing a large number of esters. Paprika color is known to be hydrolyzed into a carotenoid and a fatty acid when saponified under mild conditions. Thus, a paprika color standard, after saponification, was subjected to TLC using a solvent system of acetonitrile–acetone–*n*-hexane (11:7:2) on a C18 plate. It was found that the paprika color standard, after saponification, was satisfactorily separated into a main spot having an R_f value of 0.50 and two subspots having R_f values of 0.60 and 0.75 (Fig. 3A). The main

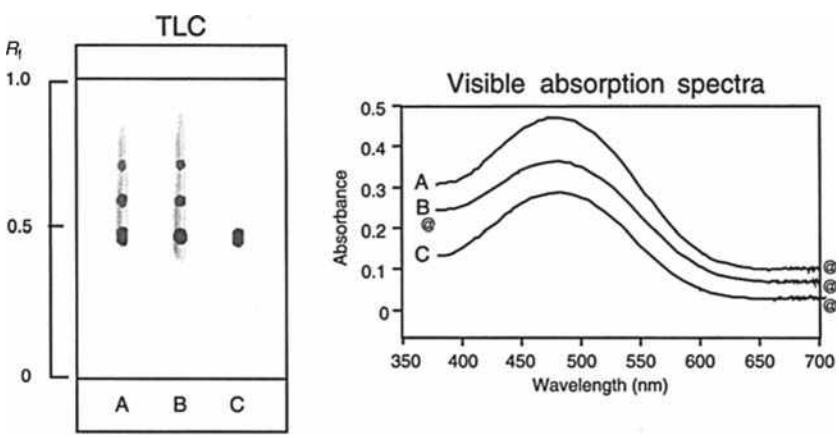

Fig. 3 TLC and visible absorption spectra of hydrolyzed paprika colors extracted from commercial foods under TLC/scanning densitometric conditions. (A) Hydrolyzed paprika color standard. (B) Hydrolyzed extract of rice-cracker. (C) Capsanthin. Plate: RP-18 (E. Merck). Solvent system: acetonitrile–acetone–*n*-hexane (11:7:2). Other conditions: see Fig. 1.

spot was identical with the spot of the capsanthin standard in terms of its R_f value, color, and shape (Fig. 3C).

As described above, it was suggested that the paprika color is hydrolyzed into a carotenoid and a fatty acid by saponification under mild conditions. Next, the saponification conditions were investigated; based on various experimental results, the following saponification conditions were selected: reaction time, 24 hr; amount of 5% sodium hydroxide–methanol solution, 2 ml.

Measurement of visible absorption spectrum by scanning densitometry

The separated spots, obtained by subjecting a paprika color standard, after saponification, to C18 TLC under the conditions described above, were then subjected to scanning densitometry. The visible absorption spectra were scanned in the wavelength range of 370–700 nm, and excellent visible absorption spectra were obtained (Fig. 3A). The spectrum of the main spot ($R_f = 0.50$) of the paprika color, after saponification, showed its maximum absorption wavelength at 480 nm, which identically matches the spectrum of the capsanthin standard (Fig. 3C).

Application to commercial foods

Reproducibility of the Rf value by RP-TLC. The paprika color in 42 samples from commercially available foods, that had a label stating the use of paprika color, were analyzed by C18 TLC to examine the influence of the coexisting substances from the sample on the R_f value. The obtained R_f values of the main spot ($R_f = 0.50$) of saponified paprika color were then compared, and Ra/Rs value was computed. The average Ra/Rs value was 1.01 with a coefficient of variation of 2.6%, suggesting that the spot extracted from the samples appear nearly at the same position as that of the paprika color standard without being affected by contaminants in the sample and that the identification of the color is reliable and reproducible.

Identification by RP-TLC/scanning densitometry. The visible absorption spectra of the main spot of the saponified paprika color on the C18 TLC plates, for which the reproducibility of the R_f value had been evaluated, were measured using a scanning densitometer. Fig. 3 shows the typically obtained TLC chromatograms and spectra obtained from the spots. The spectra of the colors purified from foods were in good agreement with those of the standard colors, and the identification reliability was then destablished.

Gardenia Yellow

Gardenia yellow is a yellow color obtained by extracting or hydrolyzing the fruit of the *Gardenia augusta* MERR. var. *gardiflora* HORT. with water or ethanol and is widely used for the coloring of noodles, candies, and candied chestnuts. The yellow color is derived from the carotinoids crocin and crocetin. Crocetin is the hydrolysis product of crocin. Gardenia yellow has been conventionally analyzed by a method based on reversed-phase chromatography/scanning densitometry using crocin as the indicator. However, when this method was applied to samples containing caramel or anthocyanins, their spots overlapped with that of crocin, which made it difficult to identify the gardenia yellow. Therefore, we evaluated an analytical method for gardenia yellow based on C18 TLC/scanning densitometry using crocetin as the indicator by hydrolyzing crocin, extracted from food samples, into crocetin.[6]

Hydrolysis and TLC conditions

In order to examine the optimal hydrolysis conditions of crocin, a standard crocin solution was hydrolyzed by varying the pH of the solution, temperature, and incubation time; the degree of hydrolysis was followed by C18 TLC as described below. Samples of crocin were completely hydrolyzed to crocetin by adjusting the pH to 11 or above with 0.1 mol/L sodium hydroxide and incubating them at 50°C for 30 min. Therefore, we applied these conditions to hydrolyze crocin to crocetin in the subsequent work.

Next, we investigated the optimal TLC conditions for the separation of crocin and crocetin and found that the combined use of a C18 TLC plate and solvent system of acetonitrile–tetrahydrofuran–0.1 mol/L oxalic acid (7:8:7) gave a satisfactory separation. Under these TLC conditions, crocin gives three spots at R_f values of 0.74, 0.79, and 0.83, and crocetin gives one spot at an R_f value of 0.51 (Fig. 4, left).

Measurement of visible absorption spectrum by scanning densitometry

Reflection spectra of the spots on the TLC plates separated under the conditions described above were measured at scanning wavelengths of 370–700 nm. Fig. 4 (right) shows the visible absorption spectra obtained; the maximum absorption wavelengths were 435 and 460 nm, being in complete agreement with the visible absorption spectrum for the standard preparation of crocetin.

Application to commercial foods

As described above, foods that contained caramel or anthocyanins, for which the identification of gardenia yellow was impossible by the analytical method using crocin as an indicator due to the appearance of interfering spots at the same positions as the spots of crocin on the C18 TLC plates, were analyzed by the present method. As shown in Fig. 4 (left), crocetin appeared as a clear spot on the plate, and the shape and R_f value of the spot were in close agreement with those of the standard preparation. Hence, gardenia yellow can be identified using crocetin as the indicator.

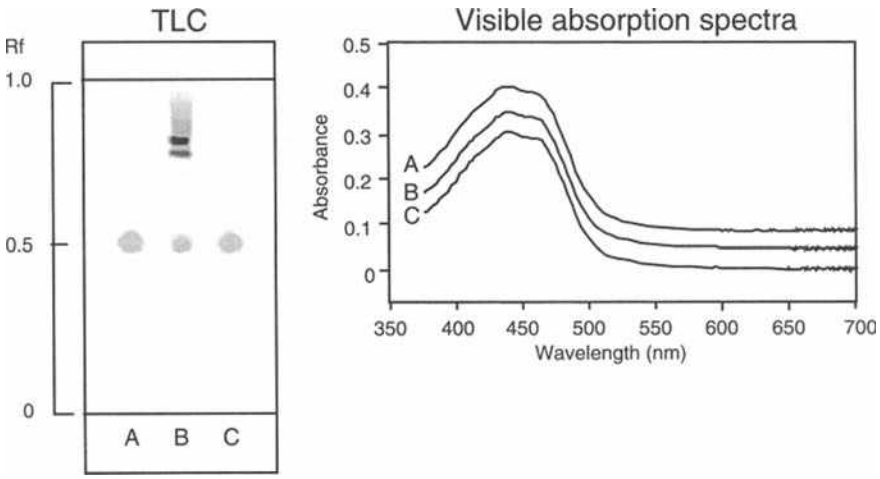

Fig. 4 TLC and visible absorption spectra of the hydrolyzed gardenia yellow extracted from commercial foods under TLC/scanning densitometry. (A) Hydrolyzed gardenia yellow standard. (B) Candy containing gardenia yellow and anthocyanin. (C) Crocetin. Plate: RP-18 (E. Merck). Solvent system: acetonitrile-tetrahydrofuran-0.1 mol/L oxalic acid (7:8:7). Other conditions: see Fig. 1.

Reproducibility of the R_f value by RP-TLC. To examine the influence of the contaminants contained in the sample on the R_f value, 37 commercial foods were analyzed by C18 TLC. The obtained R_f values of the spots were then compared. The mean value of Ra/Rs was 0.99, and the coefficient of variation was 2.5%. These results suggest that the spots of crocetin generated by hydrolysis appear nearly at the same positions as those of the standard color, without being affected by contaminants in the sample, and that the identification of the color is reliable and reproducible.

Identification by RP-TLC/scanning densitometry. The visible absorption spectra of the crocetin spots on the reversed-phase TLC plates, for which the reproducibility of the R_f value had been evaluated, were measured using a scanning densitometer. Fig. 4 shows the typically obtained TLC chromatograms and spectra obtained. The spectra of the colors purified from foods were in close agreement with that of the standard dye, and the identification reliability was then established.

CONCLUSIONS

We introduced the identification of food colors in foods using TLC/scanning densitometry and consider the method to be sufficiently applicable to routine analyses at facilities such as the Centers of Public Health and the Food Inspection Office. Also, we consider that TLC/scanning densitometry is applicable to the identification of various food additives, drugs, and pesticides in foods. However, TLC/scanning densitometry has a limitation: It can be applied only to samples which have chromophores in the molecules. Recently, applications of the TLC/matrix-assisted laser desorption ionization time-of-flight mass spectrometry (TOF-MS),[7] TLC/fast atom bombardment MS,[7] and TLC/multiphoton ionization TOF-MS[8] have been reported. Combined uses of these techniques and TLC/scanning densitometry can develop further applications of TLC.

Food: Drug Residue Analysis by LC/MS

Nikolas A. Botsoglou
Laboratories of Nutrition, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract
Analyzing drug residues in animal-derived food is complicated as it is not known whether residues exist, and if they exist, the type and quantity are not known. The possibility for unambiguous identification of illegal drug residues is offered by coupling liquid chromatography (LC) with mass spectrometry (MS). The major problems that frequently appear when LC is coupled with MS and their elimination are discussed in this entry.

INTRODUCTION

Numerous detection systems that are based on almost all kinds of known analytical techniques have been developed for screening, identifying, and quantifying drug residues in food. Each detection system has its own advantages and drawbacks, which must be carefully considered before selecting the most convenient system for a particular analyte in a particular matrix. Screening assays based on microbiological or immunochemical detection offer the advantage to screen rapidly and at low cost a large number of food samples for potential residues but cannot provide definitive information on the identity of violative residues found in suspected samples. Analyzing drug residues in food is complicated as it is not known whether residues exist, and if they exist, the type and quantity are not known. For samples found positive by the screening assays, residues can be tentatively identified and quantified by combining an efficient liquid chromatographic (LC) separation and a selective physicochemical detection system such as UV, fluorescence, or electrochemical. The potential of pre- or postcolumn derivatization can further enhance the selectivity and sensitivity of LC analysis. Nevertheless, unequivocal identification is not possible unless a more efficient detection system is employed. The possibility for unambiguous identification of the analytes is offered by coupling LC with mass spectrometers (LC–MS). MS detection systems use the difference in mass-to-charge ratio (m/z) of ionized atoms or molecules to separate them from each other. Molecules have distinctive fragmentation patterns that provide structural information to identify structural components.

LC–MS COUPLING

When LC is coupled with MS, three major problems generally appear. The first concerns the ionization of non-volatile and/or thermolabile analytes. Since MS operation is based on magnetic and electric fields that exert forces on charged ions in a vacuum, a compound must be charged or ionized in the source to be introduced in the gas phase into the vacuum system of the MS. This is easily attainable for heat-volatile samples, but thermally labile analytes may decompose upon heating. The second is due to the mobile-phase incompatibility as a result of the frequent use of non-volatile mobile-phase buffers and additives in LC. This is why routine or long-term use of non-volatile mobile-phase constituents such as phosphate buffers and ion-pairing agents is prohibited by all current LC–MS methods. As far as the third problem is concerned, this is related to the apparent flow rate incompatibility as expressed in the need to introduce a mobile phase eluting from the column at a flow rate of around 1 ml/min into the high vacuum of the MS. To eliminate these problems, several different interfaces that provide broad analytical coverage have been developed. The main limitation of the LC–MS interfaces is the lack of fragmentation data provided for structure determination because most interfaces operate in a basically chemical ionization (CI) mode, providing mild ionization and making identification of unknowns difficult or impossible. Hence, the choice of a suitable interface for a particular application has always to be related to the analytes considered, especially their polarity and molecular mass, and the specific analytical problem as well.[1]

Among the currently available interfaces for drug residue analysis, more interesting appear the particle-beam (PB) interface, the thermospray (TSP) interface that works well with substances of medium polarity, and the atmospheric pressure ionization (API) interfaces that have opened up powerful application areas to LC–MS for ionizable compounds. Among API interfaces, most versatile appear to be the electrospray (ESP) interface and its variants including the ion spray

(ISP), the turbo ISP and the Z-spray interfaces, which are suitable for substances ranging from polar to ionic and from low to high molecular mass. The ISP and turbo ISP, in particular, are compatible with flow rates commonly used with conventional LC columns, whereas both ESP and ISP appear to be valuable in terms of analyte detectability. Complementary to ESP and ISP interfaces with respect to the analyte polarity is the atmospheric pressure chemical ionization (APCI) interface that is equipped with a heated nebulizer. This is a powerful interface for both structural confirmation and quantitative analysis. API interfaces coupled to LC and tandem mass spectrometry (LC–MS–MS) have opened a new era in qualitative and quantitative analysis of veterinary drug residues. Depending on the quantitative or confirmatory nature of analysis, two types of mass spectrometers can be employed. The triple quadrupole instruments will produce ions with collision-induced fragmentation such as daughter ions for multiple reaction monitoring, while the ion trap spectrometers can produce MS^n fragment ions such as granddaughter ions. The advantages and disadvantages of these two types of instruments have been investigated in literature.[2]

PB INTERFACE

PB interface is an analyte enrichment interface in which the column effluent is pneumatically nebulized into a near atmospheric pressure desolvation chamber connected to a momentum separator, where the high-mass analytes are preferentially directed to the MS ion source, while the low-mass solvent molecules are efficiently pumped away. With this interface mobile phase, flow rates within the range 0.1–1.0 ml/min can be applied. PB–MS appears to have high potential as an identification method for residues of some antibiotics in foods as it generates library-searchable EI spectra and CI solvent-independent spectra. Limitations of the PB–MS interface, as compared with other LC–MS interfaces, include lower sensitivity, difficulty in quantification, and lower response with highly aqueous mobile phases. The low sensitivity can be attributed in part to chromatographic band broadening during the transmission of the sample through the interface and in part to non-linearity effects that appear at low analyte concentrations.[3]

LC–PB–MS has been investigated as a potential confirmatory method for the determination of malachite green in incurred catfish tissue,[4] and cephapirin, furosemide, and methylene blue in milk, kidney, and muscle tissue, respectively.[5] LC–PB–MS has also been investigated for the analysis of ivermectin residues in bovine liver and milk.[6] The specificity required for regulatory confirmation was obtained by monitoring the molecular ion and characteristic fragment ions of the drug under negative-ion chemical ionization (NCI) and selective ion monitoring (SIM) conditions. Quantification and confirmation of tetracycline, oxytetracycline, and chlortetracycline residues in milk[7] and chloramphenicol residues in calf muscle[8] have been also carried out using LC–PB–NCI–MS.

THERMOSPRAY INTERFACE

TSP interface is widely used for the determination of drug residues in foods.[1] TSP is typically used with reversed-phase columns and volatile buffers. Aqueous mobile phases containing an electrolyte such as ammonium acetate are passed through a heated capillary prior to entering a heated ion source. Since the end of the capillary lies opposite a vacuum line, nebulization takes place and a jet of vapor containing a mist of electrically charged droplets is formed. As the droplets move through the hot source area, they continue to vaporize, and ions present in the eluent are ejected from the droplet and sampled through a conical exit aperture in the mass analyzer. The ionization of the analytes takes place by means of direct ion evaporization of the sample ion or by solvent-mediated CI reactions. With ionic analytes, the mechanism of ion evaporation is supposed to be primarily operative as ions are produced spontaneously from the mobile phase. Drawbacks of LC–TSP–MS are the requirements for volatile modifiers and the control of temperature, particularly for thermolabile compounds.[9] Also, ion evaporation often yields mass spectra with little structural information. Lack of structural information from LC–TSP–MS applications can be overcome by the use of LC–TSP–MS–MS. Use of this tandem MS approach provides enhanced selectivity, generally at the cost of a loss of sensitivity as a consequence of decreased ion transmission.

LC–TSP–MS has been successfully applied for detection/confirmation of nicarbazin residues in chicken tissues using negative-ion detection in the SIM mode.[10] LC–TSP–MS in the SIM mode has also been used for quantification of residues of moxidectin in cattle tissues and fat,[11] and nitroxynil, rafoxanide, and levamisole in muscle.[12] Confirmatory methods based on LC–TSP–MS have further been reported for determination of penicillin G,[13] cephapirin,[14] and various penicillin derivatives[15] in milk. Comparative evaluation of the confirmatory efficiency of LC–TSP–MS and LC–TSP–MS–MS in the assay of maduramycin in chicken fat showed the former approach to be marginally appropriate whereas the latter highly efficient.[16] Tandem LC–MS–MS has also been successfully applied for analyzing residues of chloramphenicol in milk and fish.[17]

ESP AND ITS VARIANTS ION SPRAY, TURBO ION SPRAY, AND Z-SPRAY INTERFACES

The ESP interface, a widely applicable soft ionization technique, operates at the low microliter/minute flow rate, necessitating use of either capillary columns or post-column splitting of the mobile phase. For ESP ionization, the analytes must be ionic or have an ionizable functional group or be able to form an ionic adduct in solution. The analytes are commonly detected as deprotonated species or as cation adducts of a proton or an alkali metal ion. The first step in the ESP is the nebulization of the liquid into small droplets. This process is supported by the introduction of a drying gas as well as a nebulizer gas such as nitrogen, by different techniques. In the most commonly used approach, a coaxial nebulizing gas of nitrogen or air is used for evaporation of the aqueous eluents at higher LC flow rates.[18] The influence of the LC mobile phase on the ESP process has been studied by several workers.[19,20] When using positive-ion ESP ionization, use of ammonium acetate as a mobile-phase modifier is generally unsuitable. Instead, organic modifiers, such as heptafluorobutyric or trifluoroacetic acid, usually at a concentration of 0.1% are strongly recommended. For negative-ion applications, the choice of the modifier is even more limited, triethylamine being the only suitable compound.

ISP interface is a pneumatically assisted ESP. However, unlike the ESP interface, ISP allows higher flow rates (0.05–0.20 ml/min) by virtue of pneumatically assisted vaporization. A capillary is housed inside an external tube through which the nebulizing gas is coaxially directed. To avoid source contamination by non-volatile compounds such as salts, off-axis ESP nebulization instead of on-axis with the sampling orifice has been developed by several manufacturers. ISP and turbo ISP interfaces are generally used off-axis positioned at 30–45° relative to the axis or in the case of the Z-spray source the ESP nebulization is performed orthogonally to the sampling cone. Since both ESP and ISP produce quasi-molecular ions, more sophisticated techniques such as LC–MS–MS are required to obtain diagnostic fragment ions and, thus, analyte structure elucidation. Identification can often be achieved by using daughter ion MS–MS scans and collisionally induced dissociation (CID), most commonly on a triple quadrupole MS; in this way, dissociation of the quasi-molecular ion occurs and diagnostic structural information can be obtained.

The turbo ISP interface has been developed for conventional LC systems with high flow rates. Relatively high gas temperatures must be applied to achieve sufficient heat transfer to the evaporating droplets. The Z-spray interface is another variant where the ESP nebulization is performed with concurrent desolvation gas. Ions are extracted orthogonally from the spray into the sampling cone, while large droplets and non-volatile material are collected onto a baffle plate. From the expansion area behind the sampling cone the ions are again extracted orthogonally into the high-vacuum region of the spectrometer.[18]

LC–ESP–MS has been successfully used for multiresidue assay of penicillins in milk ultrafiltrate at the 100 ppb level after postcolumn splitting of the eluent and recording under SIM conditions in the positive-ion mode.[21] Significantly lower detection limits have been reported by other workers who described an LC–ESP–MS confirmatory procedure for the simultaneous determination of five penicillins in milk and meat under SIM conditions in the negative-ion mode.[22] Further, ESP has been shown to be useful in the analysis of several classes of veterinary drugs including sulfonamides and tetracyclines, which exhibit spectra with four common ions; however, this was not possible for the group of β-agonists because of their more diverse chemical structure.[23] Negative-ion ESP–MS has also been used for the detection/identification of a number of non-steroidal anti-inflammatory drugs, including phenylbutazone, flunixin, oxyphenbutazone, and diclofenac.[24] LC–ESP–MS has been found suitable for the determination of four coccidiostats in poultry products.[25] In addition, LC–ESP–MS–MS has been proposed for quantification/confirmation of 10 sulfonamides in liver and kidney tissues of bovine, swine, and chicken.[26] LC–ESP triple quadrupole MS–MS has also been applied for the assay of five macrolides in bovine, swine, and poultry tissues, bovine milk, and eggs,[27] 11 fluoroquinolones in porcine kidney,[28] mebendazole, and its metabolites in sheep liver and muscle,[29] and multiclass veterinary drugs in animal muscles,[30,31] eggs,[32] and shrimps.[33]

LC–ISP–MS has also been shown to be an attractive approach for the determination of semduramicin in chicken liver.[34] Tandem MS using CID of the molecular ions further enhanced the specificity, providing structure elucidation and selective detection down to 30 ppb. LC–ISP–MS has also been successfully applied for the assay of 21 sulfonamides in salmon flesh.[35] Coupling of LC with either ISP–MS or ISP–MS–MS has also been investigated as an attractive alternative for the determination of erythromycin A and its metabolites in salmon tissue.[36] The combination of these methods permitted identification of a number of degradation products and metabolites of erythromycin at the 10–50 ppb level. Tandem MS with CID has also been applied for the specific monitoring of danofloxacin and its metabolites in chicken and cattle tissues at levels down to 50 ppb.[37] LC–ISP triple quadrupole MS–MS has also been proposed for confirmation of aminoglycoside residues in bovine kidney.[38]

ATMOSPHERIC PRESSURE CHEMICAL IONIZATION INTERFACE

Complementary to ESP and its variants with respect to analyte polarity is the APCI interface. This is equipped with a heated nebulizer that can be used for LC flow rates

of 0.5–1.5 ml/min. The nebulized liquid effluent is swept through the heated tube by a coaxial nitrogen stream at high temperature. The heated mixture of solvent and vapor is then introduced in the ionization source where a corona discharge electrode initiates APCI. Ionization in APCI is primarily based on gas-phase chemical reactions and contains charge transfer from solvent-based reagent gas to the analyte molecules. The reagent gas is generated by a series of ion–molecule reactions initiated by the corona discharge electrode.[39] The spectra and chromatograms from APCI are somewhat similar to those from TSP, but the technique is more robust, especially with gradient LC and often more sensitive. APCI is particularly useful for heat-labile and low-mass or high-mass compounds. In contrast to TSP interface, no extensive temperature optimization is needed with APCI. The applicability of the APCI interface is restricted to the analysis of compounds with lower polarity and lower molecular mass compared with ESP and ISP.

Applications include the LC–APCI–MS multiresidue determination of quinolone antibiotics,[40] the determination of tetracyclines in muscle at the 100 ppb level,[41] and the determination of fenbendazole, oxfendazole, and the sulfone metabolite in muscle at the 10 ppb level.[42] In addition, LC–APCI–MS–MS has been proposed for the determination of the coccidiostats dimetridazole and ronidazole residues and their common metabolites in poultry muscle and eggs,[43] for the determination of residues of five coccidiostats in both positive and negative modes,[44] and for the quantification of tranquillizers and β-blockers in muscle and liver tissues of food-producing animals.[45]

Although the detection capability of LC–MS–MS is very powerful, the cleanup process of the sample prior to instrumental analysis must always be kept in mind because the better the cleanup the better the results of the hyphenated technique used. Investigation of sample matrix effects, ion suppression, and "cross talk" effects that can reduce the ion intensity of the analytes and lead to poor reproducibility and accuracy should always be part of the validation of LC–MS–MS assays in residue analysis.

CONCLUSION

The need to use veterinary drugs in animal husbandry will continue well into the future, and therefore monitoring of edible animal products for violative residues will remain an area of increasing concern and importance, due to the potential impact on human health. The successful hyphenation of LC with MS has led to development of highly flexible, computer-aided analytical methods that offer the required possibility for unambiguous identification of drug residues in food. LC–MS is now in a mature state, but it still cannot be considered routine in the field of drug residue analysis. Possible reasons are the high initial cost, which is 2–4 times higher than that of gas chromatography (GC)–MS, and the poor detection limits, which are approximately 100 times higher than in GC–MS. Coupling of LC with tandem MS is a solution for improving detection limits by reducing the background noise, but this combination is 2 or 3 times more expensive than its LC–MS analogue. However, there are also disadvantages to the LC–MS–MS technique as high background noise can be observed due to solvent/salt concentrations. In addition, screening by multiresidue analysis in the scan mode is normally not possible due to the low sensitivity. Moreover, the search and identification of unknowns is difficult since spectrum libraries are not available due to influence of the experimental conditions and variation of spectra and MS–MS data between instruments supplied by different manufacturers.

INTRODUCTION

Penicillin antibiotics are part of a wide variety of antimicrobial agents that are used as veterinary drugs to prevent and treat infectious diseases. Such use may lead to problems with residues in the livestock products. To provide safe products for consumers, the quantification of these residues in foods is required.

As most of the penicillins dissolve easily in water, high-performance liquid chromatography (HPLC) appears to be the best-suited approach for the analysis of residual penicillins in food. However, many HPLC methods require derivatization or special instrumentation because penicillins do not have any specific, strong ultraviolet (UV) absorption. Above all, the derivatization technique using mercury (II) chloride and 1,2,4-triazole or imidazole was applied to many analyses of penicillins. On the other hand, because it is not desirable to use toxic reagents such as mercury (II) chloride, there is a great need for a simpler, safer analytical method. To analyze the penicillins in food using a UV detector, a device is needed for sample preparation and chromatographic separation to remove interfering compounds which originate from the sample matrix. Because animal tissues (primarily muscle, kidney, and liver) include large amounts of sample matrix in comparison with milk, this causes difficulties for the development of simultaneous analysis of penicillins in these tissues. However, using an ion-exchange cartridge, in combination with ion-pair HPLC, has been reported to be very effective for simultaneous determination of the penicillins in the tissues. On the other hand, liquid chromatography/mass spectrometry (LC/MS) methods have also been published for the analysis of residual penicillins in food because mass spectrometric techniques can confirm and determine them, with high sensitivity and selectivity.

In this entry, we deal with the simultaneous determination of penicillins in animal muscle, liver, and kidney using ultraviolet (UV)–HPLC and LC/MS.

UV–HPLC METHOD

Benzylpenicillin (PCG), phenoxymethylpenicillin (PCV), oxacillin (MPIPC), cloxacillin (MCIPC), nafcillin (NFPC), and dicloxacillin (MDIPC), all of which are representative weakly acidic penicillins, are widely used as veterinary drugs for livestock. We have reported, in our previous studies,[1,2] the applicability of sample cleanup with an ion-exchange cartridge, in combination with ion-pair HPLC, for the analysis of ionizable compounds. We therefore applied the same technique to develop an analytical method for the quantitative determination of these residual penicillins in bovine muscle, kidney, and liver.[3,4]

HPLC Conditions

After examination of several ion-pair reagents for acidic compounds, 12 m*M* of cetyltrimethylammonium chloride was chosen because it gave the best result in the separation of penicillins. When the pH of the mobile phase was adjusted to 6.2, the six penicillins exhibited good separations from each other, with adequate capacity factors.

Thus a satisfactory separation of the penicillins was obtained using TSKgel ODS-80Ts (5 μm, 150 × 4.6, I.D.) column and acetonitrile-0.02 *M* phosphate buffer, pH 6.2, (4.3 : 5.7, v/v) containing 12 m*M* of cetyltrimethylammonium chloride, as the mobile phase (Fig. 1a).

Sample Extraction

Although the repeated (three times) extraction of the penicillins with 2% NaCl aqueous solution (60, 40, 40 ml) from bovine muscle was very simple and gave satisfactory extraction efficiency, the same extraction procedure could not be applied to bovine kidney and liver. Because the resultant extracts were foamy and viscous, it caused the serious problems in the sample cleanup procedure. To avoid these problems, the addition of aqueous solutions of sodium tungstate and sulfuric acid to the extraction solution (2% NaCl), as deproteinization reagents, yielded satisfactory results. After a series of preliminary experiments, we decided to use 55 or 50 ml of 2% NaCl aqueous solution and 5 or 10 ml of the deproteinization reagent (5% sodium tungstate aqueous solution-0.17 *M* sulfuric acid solution, 1 : 1) as the first extraction solution for bovine kidney and liver. For the remaining two extractions, for each, 40 ml of 2% NaCl

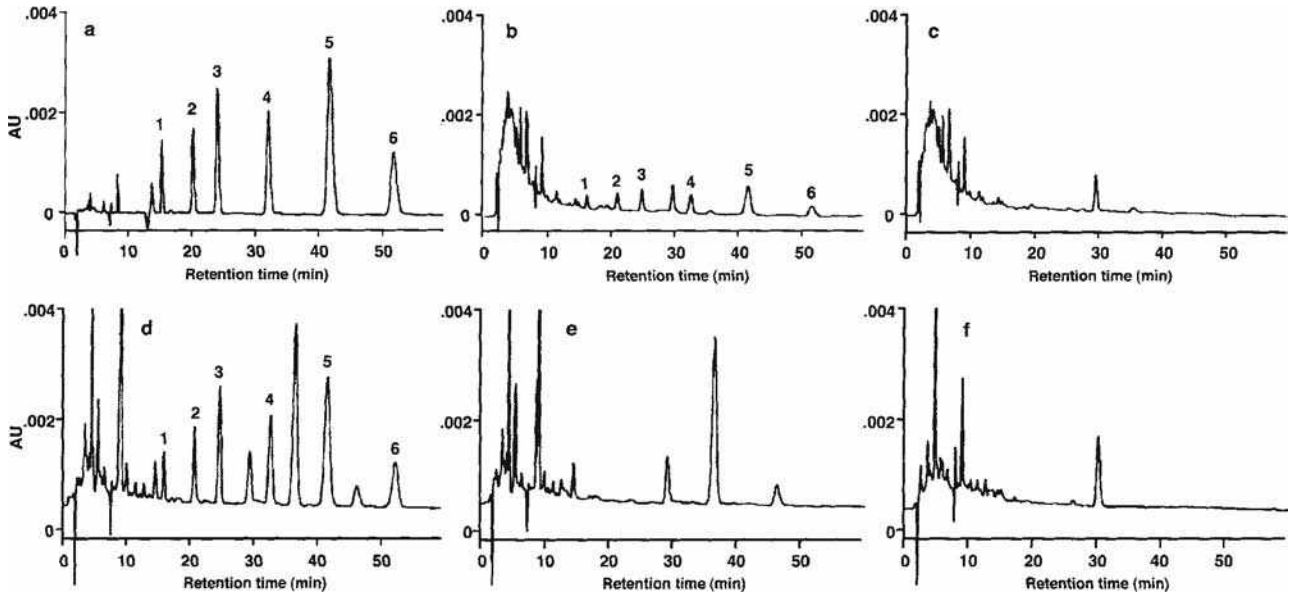

Fig. 1 Typical HPLC chromatograms of bovine tissue samples. a) Standard of six penicillins; b) muscle sample fortified at a concentration of 0.1 mg/kg each of penicillins; c) muscle sample; d) liver sample fortified at a concentration of 0.5 mg/kg each of penicillins; e) liver sample; f) kidney sample. 1) Benzylpenicillin; 2) phenoxymethylpenicillin; 3) oxacillin; 4) cloxacillin; 5) nafcillin; 6) dicloxacillin. Operating conditions—column: TSKgel ODS-80Ts (150 × 4.6 I.D.); mobile phase: acetonitrile-0.02 *M* phosphate buffer, pH 6.2, (4.3 : 5.7, v/v) containing 12 m*M* cetyltrimethylammonium chloride.; flow-rate: 0.8 ml/min; detector: UV 220 nm; column temp.: 30°C.

aqueous solution was used in the same manner as was used for muscle samples.

Purification of Crude Extracts

Pre-cleanup method

Because the tissue extract contains many substances which interfere with the ion-exchange capacity of the cartridge, it was necessary to develop a pre-cleanup method to retain the residual penicillins present in the tissue samples on the ion-exchange cartridge. It had been reported that washing a crude extract-loaded C18 cartridge with an aqueous methanolic solution containing NaCl was effective as a pre-cleanup of samples for the determination of PCG.[5] After several experiments, the following pre-cleanup method was developed: the crude extract-loaded Bond Elut C18 cartridge was washed with 15% methanol containing 2% NaCl, followed by water; finally, the elution was carried out with 5 ml of 55% methanol.

Ion-exchange cartridge cleanup method

It is desirable to use the same solution for HPLC mobile phase and for the elution solvent from the cleanup cartridges to assure good reproducibility of the HPLC determination of the penicillins. After the investigation of the selected ion-exchange cartridges using 2 ml of the above-described mobile phase as the elution solvent, Sep-Pak Accell Plus QMA (QMA) produced the best results with all of the penicillins being completely eluted.

Even after the QMA cartridge cleanup procedure with the C18 cartridge pre-cleanup describe above, there were nevertheless small amounts of the interfering substances overlapping the peaks of the penicillins. We therefore tried to wash the QMA cartridge to improve the cleanup. Judging from the results of several experiments, on the basis of the chemical properties of the QMA cartridge, we decided to use 3 ml each of 55% methanol and water for muscle samples and to use 3 ml each of 55% methanol, 10 m*M* acetic acid methanolic solution, and water for the kidney and liver samples.

Recoveries

Bovine tissue samples were fortified with the six penicillins (0.5 or 0.1, or 0.05 mg/kg of each) and performed the analyses according to the procedure described above. As shown in Table 1, satisfactory recoveries (over 71%) and corresponding coefficients of variation (C.V., less than 8.7%) were obtained for these low concentrations of the penicillins. The detection limit was 0.02 mg/kg for each penicillin in the meat, and those were 0.02 mg/kg for MPIPC, MCIPC, and NFPC, 0.03 mg/kg for PCV, 0.04 mg/kg for PCG, and 0.05 mg/kg for MDIPC in the bovine kidney and liver (S/N ratio = 3). Fig. 1 shows typical chromatograms of standard solution (a), fortified bovine muscle and liver samples (b and d), their

corresponding controls (c and e), and bovine kidney sample (f), respectively. As shown by these chromatograms, satisfactory separation of PCs and cleanup effects were achieved by using the ion-exchange cartridge cleanup in combination with the ion-pair HPLC described above.

LC/MS METHOD

Because mass spectrometric techniques can confirm and determine substances, with high sensitivity and selectivity, LC/MS methods have been published for the analysis of residual penicillins in food. However, only a few methods have been reported for the simultaneous analysis of penicillins in animal tissues; moreover, these methods are less sensitive than the UV–HPLC methods. It seemed that their insufficient sample cleanup and separation under their LC conditions led to the lack of sensitivity. Accordingly, based on our determination method using the UV–HPLC approach described above, we decided to develop an accurate and highly sensitive confirmation method for penicillins in bovine tissues using ESI LC/MS/MS with a product ion scan mode.[6] First, we reconstructed the LC conditions for ESI LC/MS analysis; hence 30% acetonitrile aqueous solution containing 2 m*M* of di-*n*-butylamine acetate (DBAA), which was a volatile ion-pair reagent, was selected as the mobile phase. Gradient elution was used to increase the sensitivity. Then, we investigated whether or not the mobile phase described above can be used as the elution solvent for the cartridges used for cleanup. Because the mobile phase for

[a]*m/z*.

ESI LC/MS analysis did not show satisfactory results, we decided to use the 30% acetonitrile aqueous solution containing 50 m*M* DBAA as the elution solvent.

Next, the optimal MS/MS conditions were investigated. Electrospray ionization mass spectra recorded for the six penicillins gave $[M–H]^-$, $[M–H–CO_2]^-$, and $[M–H–141]^-$. When $[M–H]^-$ serves as a precursor ion for MS/MS, $[M–H–CO_2]^-$ and $[M–H–141]^-$ were generated as product ions (listed in Table 2), and they are very useful for the confirmation of penicillins. After a series of detailed examinations, the other MS/MS conditions including the compound-specific parameters were selected. To provide the applicability of the present method, the fortified bovine tissues, at a concentration of 0.05 mg/kg of each six penicillins, were analyzed. As shown in Fig. 2 left, all six penicillins from the liver sample appeared as separate peaks on the mass chromatograms monitored at $[M–H–141]^-$ under ESI LC/MS/MS conditions. Fig. 2 right shows the tandem mass spectra of the penicillins recorded at the top of each peak on the mass chromatograms shown in Fig. 2 left. All of these mass chromatograms and tandem mass spectra of fortified samples were almost the same as for the respective

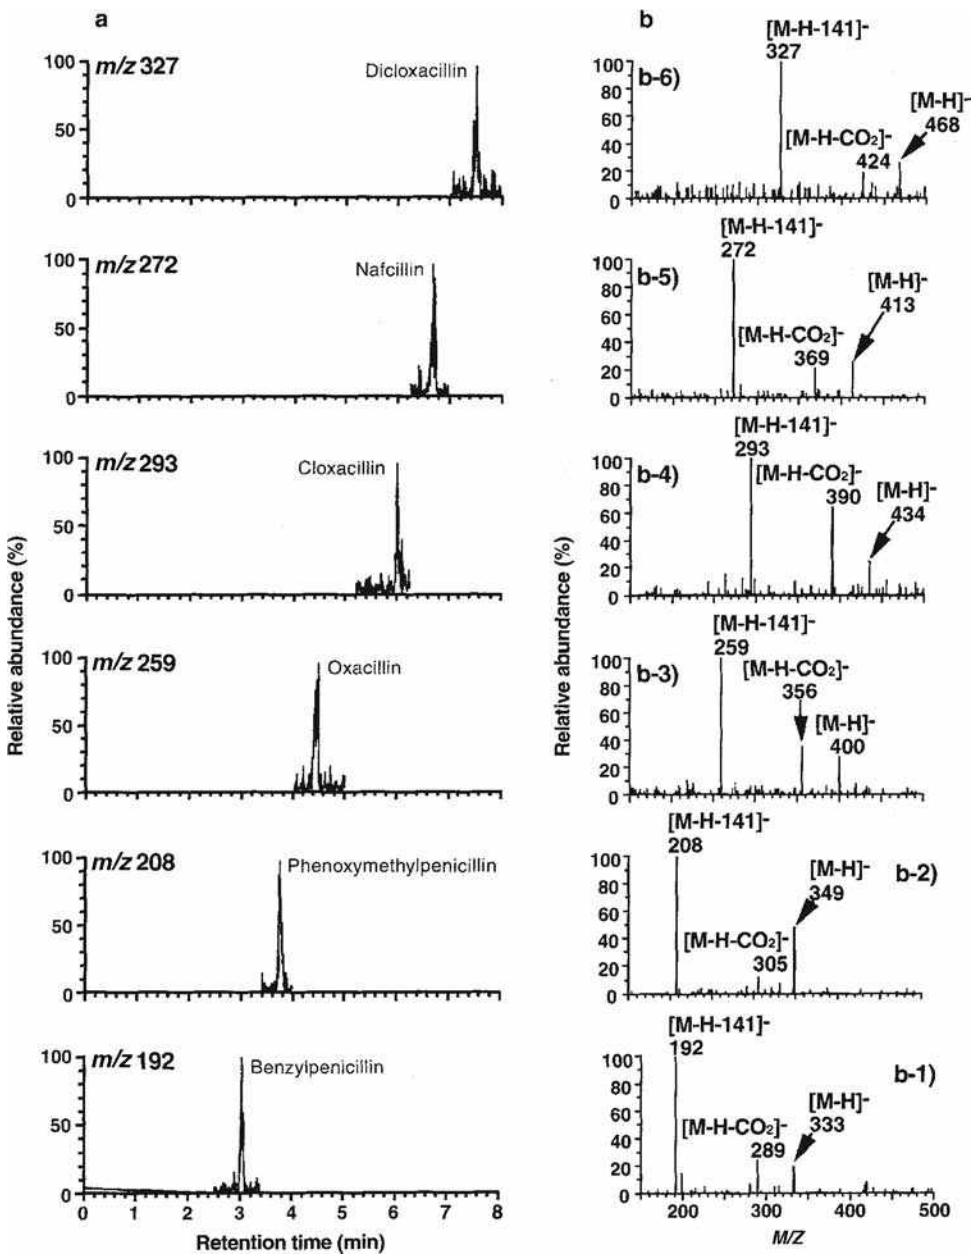

Fig. 2 ESI LC/MS/MS analysis of penicillins fortified at a concentration of 0.05 mg/kg in bovine liver. a, Mass chromatograms monitored at $[M–H–141]^-$; b, tandem mass spectra of penicillins recorded at the top of each peak on the mass chromatograms (a). standards. Based on the results of the analyses of the fortified samples at 0.02 mg/kg, the lower limit of confirmation of the present method for muscle sample was estimated to be 0.02 mg/kg for all six penicillins, and those for kidney and liver were between 0.02 and 0.03 mg/kg.

As described above, we can hardly find the applicable LC/MS determination method of residual penicillins in animal tissue sample; however, those of penicillins in milk sample can be found. Recently, Riediker and Stadler[7] reported the quantitative method for residual amoxicillin, ampicillin, MCIPC, MDIPC, and PCG in milk using ESI LC/MS/MS with a multiple ion monitoring mode and a stable isotope-labeled internal standard. A stable isotopically labeled compound is reasonable and useful for an internal standard of determination method using mass spectrometric techniques. The mixture of acetonitrile and water, including formic acid, as the LC mobile phase and gradient elution were selected. The milk sample with added internal standard (deuterated PCG) was washed with *n*-hexane and condensed before applying C18 cartridge for cleanup. The provided sample solution was filtered through a cutoff filter device (nominal molecular weight limit 10,000). For quantitation, matrix-matched calibration curves were established using a blank milk sample fortified at different concentrations of each target analyte. The mean recoveries of all target penicillins ranged from 76% to 94% at a single analyte concentration of 0.004 mg/kg. The LOQs were in the range of 0.0004–0.0008 mg/kg (mean of blank intensity +10 SD).

CONCLUSIONS

We introduced the LC analysis for residual penicillin antibiotics in food, especially in bovine tissues. To avoid the use of special instruments and toxic reagents, the combination of ion-exchange cartridge cleanup and ion-pair HPLC was very effective and was able to provide sufficient sensitivity and quantitation for the measurement of penicillins. Moreover, it was also able to be used for the development of the confirmation method using ESI LC/MS. The detection limits of all of these methods are able to satisfy the MRLs established by the WHO, FDA, EU, and Japan; so we strongly recommend these methods for the analysis of residual penicillins in tissues to provide safe products for consumers.

Food: Quinolone Antibiotics Analysis by LC

Nikolas A. Botsoglou
Laboratories of Nutrition, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece

Elias Papapanagiotou
Laboratories of Food Hygiene, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract
Quinolone antibiotics, however valuable they may be for increasing food animal productivity, present a concern for public health, considering the potential presence of their residues in the edible products of treated animals. Residues of quinolones in animal-derived food are rather difficult to analyze by chromatographic methods due to their inherent physicochemical characteristics. An overview of the isolation, separation, quantification, and confirmation procedures that may be used to analyze for violative quinolone residues in foods is presented in this entry.

INTRODUCTION

With the extensive use of drugs in animal production, violative residues of the parent drugs and/or metabolites have a high potential to be present in meat, milk, eggs, and honey. The level of residues and the individual drugs they originate from determine the public health significance of such an adulteration of the food supply. The European Union (EU) and the Joint FAO/WHO Expert Committee on Food Additives (JECFA) have established maximum residue limits (MRLs) for several quinolones.

Quinolones constitute an expanding group of synthetic antibiotics that are widely used in combating various diseases in animal husbandry and aquaculture. It is estimated that during the last decade, oxolinic acid, one of the earliest members of this group of drugs, has been by far the most widely used drug in fish farming for prophylaxis and treatment of bacterial fish disease. Oxolinic acid along with nalidixic acid comprises the main members of the first-generation quinolones whose basic molecular structure includes a quinolone ring and a carboxylic acid group. Ciprofloxacin, danofloxacin, difloxacin, enrofloxacin, flumequine, marbofloxacin, norfloxacin, ofloxacin, and sarafloxacin make up the main members of the second-generation quinolones that contain a fluorine atom and a piperazine ring in their molecule, and are collectively called fluoroquinolones. Both first- and second-generation quinolones are analyzed in food of animal origin mainly by liquid chromatographic (LC) methods. An overview of the analytical methodology for the determination of quinolone residues in food is provided in this entry.

ANALYSIS OF QUINOLONES

Quinolones are amphoteric compounds soluble in polar organic solvents such as acetonitrile, methanol, ethanol, dimethylformamide, dichloromethane, and ethyl acetate.[1] They are slightly soluble in water and insoluble in nonpolar solvents such as hexane, petroleum ether, and isooctane. Most of these drugs are fluorescent and are quite stable in aqueous solution toward light except miloxacin, which is reported to be unstable. These inherent characteristics have made quinolones a difficult group of compounds to be analyzed by chromatographic methods.

Sample Extraction

Mincing and/or homogenization of muscle, kidney, and liver samples is usually required before some type of extraction is applied. Drying of tissue samples with anhydrous sodium sulfate prior to extraction is another procedure often employed to enhance the recovery of the analytes.[2–5] Sample extraction and precipitation of concurrent proteins can be accomplished with a great variety of organic solvents including ethyl acetate,[2–4] acetone,[6–8] methanol,[9] acetonitrile,[10,11] ethanol,[5] ethylenediaminetetraacetic acid (EDTA)–McIlvaine buffer solution,[12] EDTA and methanol/water,[13] and trichloroacetic acid and acetonitrile.[14,15]

Enhancement of the extraction efficiency can be achieved by properly acidifying the sample homogenate.[5,9] In acidic conditions, particularly at pH values lower than 3, quinolones, being zwitterions, are fully

protonated and, therefore, are becoming less bound by the matrix and more soluble in organic extraction solvents. Nevertheless, extraction of quinolones from food samples has also been accomplished by aqueous solutions such as water, alkaline buffers, and trichloroacetic acid.[16–18]

Supercritical fluid extraction (SFE) using supercritical CO_2 containing 30% (v/v) methanol has been applied for the extraction of four fluoroquinolones from chicken tissues,[19] while supercritical CO_2 containing 20% (v/v) methanol has also been used for the extraction of the same four fluoroquinolones from eggs.[20]

Another extraction procedure based on buffered QuEChERS methodology (quick, easy, cheap, effective, rugged, and safe) has recently been reported for the multiresidue determination of 18 drugs in milk. In this procedure, extraction of milk samples was carried out with acetonitrile while no extract cleanup was required.[21] Extract cleanup was also not applied in the multiresidue determination of 39 antibiotics, including tetracyclines, quinolones, penicillins, sulfonamides, and macrolides in chicken muscle after extraction with methanol/water containing EDTA and direct injection into an ultra-performance LC–mass spectrometery (MS)–MS system.[13]

Extract Cleanup

Various cleanup procedures including conventional liquid–liquid partitioning, solid-phase extraction, matrix solid-phase dispersion, and online dialysis/trace enrichment have all been employed to eliminate or reduce interfering compounds and also to concentrate the analyte(s). In many instances, more than one of these cleanup procedures have been used in combination to enhance cleanup efficiency.[1]

Liquid–liquid partitioning is employed either to extract the analytes from an organic sample extract into an aqueous solution or to wash out interfering substances from the organic or aqueous sample extracts. In general, quinolones are partitioned from chloroform or ethyl acetate sample extracts into alkaline aqueous buffers, to be then back-extracted into the organic solvent under acidic conditions.[7,8] To remove lipids, sample extracts are often also partitioned with *n*-hexane[2–4,6–8,11,12] or diethyl ether.[10]

Solid-phase extraction is also often used to remove interfering coextracted compounds. Solid-phase extraction columns contain either non-polar reversed-phase C_{18} sorbents or polar sorbents (such as alumina, aminopropyl acid, and propylsulfonic acid).[1,5,15,18,21–23] Matrix solid-phase dispersion cleanup using reversed-phase C_{18} material has been also employed for the determination of oxolinic acid in catfish muscle.[24] In-tube solid-phase microextraction (SPME) based on poly(methacrylic acid–ethylene glycol dimethacrylate) (MAA–EGDMA) monolith coupled to high-preformance liquid chromatography (HPLC) with ultraviolet (UV) and fluorescence detection (FLD) was developed for the determination of five fluoroquinolones in eggs.[25]

Online dialysis and subsequent trace enrichment has been further described for extraction/cleanup of flumequine residues from fish muscle[12] or oxolinic acid and flumequine from chicken liver[6] and salmon muscle.[12] This process involves online use of diphasic dialysis membrane, trapping of the analytes onto a preconcentration column filled with reversed-phase C_{18} or polymeric material, rinsing of the coextracted interfering compounds to waste, and finally, flushing of the concentrated analytes onto the analytical column.

Molecular imprinted polymer microspheres against enrofloxacin have been developed and off-line molecular imprinted solid-phase extraction (MISPE) has been applied for the extraction of enrofloxacin from bovine milk.[26]

LC Separation

Following their extraction and cleanup, residues of quinolones can be analyzed by either gas or liquid chromatography. Among these chromatographic techniques, liquid chromatography seems to be the method of choice since gas chromatography necessitates reduction of analytes such as oxolinic acid, nalidixic acid, and piromidic acid by sodium tetrahydroborate prior to their determination in fish muscle.[27] Since quinolones are polar compounds, LC is generally carried out with non-polar reversed-phase stationary phases that are based on octadecyl, octyl, phenyl, or polymeric sorbents. Recommended mobile phases are fairly polar, containing tetrahydrofuran, methanol, and/or acetonitrile as organic modifiers.[20–22,28] In most applications, phosphoric acid is added into the mobile phase prior to chromatography.[14,17] By acidifying the mobile phase pH at values lower than 3, the ionization of the carboxylate moiety of the analytes is suppressed, and thus, the retention is increased and the separation is improved. Nevertheless, the recorded chromatographic peaks generally tail, and elimination or significant reduction of peak tailing can be generally achieved by addition to the mobile phase of counterions[10,16] or oxalic acid and citric acid.[2–4,13,23]

Detection

Ultraviolet,[23,25] fluorimetric,[12,14,15,17,18,20,25] chemiluminescence,[28] and mass spectrometric[12,13,21–23] detections have been successfully used for the determination of residues of quinolones in food. Quinolones exhibit remarkable UV absorption and are, therefore, ideal for direct determination by UV detection anywhere in the wavelength range of 254–295 nm. However, fluorimetric detection is the most popular because of the inherent fluorescence of these drugs and the advantages in terms of selectivity and sensitivity that this detection offers.

Confirmation

Each detection system has its own advantages and disadvantages, which must be carefully considered in the selection of the most convenient system for a particular analyte in a particular matrix. Screening assays based on ultraviolet and fluorimetric detection offer the advantage to rapidly screen a large number of food samples for potential residues at a low cost, but cannot provide definitive information on the identity of violative residues found in suspected samples. The problem of analyzing drug residues in food is complicated by the fact that it is not known whether residues exist, and if they exist, their type and quantity are not known. In the past, confirmation of the identity of LC peaks in suspected samples was obtained by means of a derivatization process in which the analytes are converted to the corresponding decarboxylated derivatives, which are then analyzed by gas chromatography (GC)–MS.[7,8] Nowadays, the possibility for unambiguous identification of the analytes is offered by coupling LC–MS. MS detection systems use the difference in mass-to-charge ratio (m/z) of ionized atoms or molecules to separate them from each other. Molecules have distinctive fragmentation patterns that provide structural information to identify structural components. Thus, LC–MS–MS in the multiple reaction monitoring mode has been used to detect/confirm residues of eight quinolones in pig muscle.[23] Additionally, ultra-performance LC coupled with MS–MS has been used in confirmatory multiresidue, multiclass analysis of various quinolone residues in poultry, ovine, and porcine tissues,[13] milk,[21] and eggs.[12] The latest introduction of new MS techniques such as the combination of ultra-performance LC with time-of-flight (TOF)–MS has offered an additional powerful analytical tool for both screening and confirmatory analysis of drug residues in foods of animal origin. Applications include ultra-performance LC coupled with TOF–MS for the confirmatory multiresidue, multiclass analysis of 11 quinolones in milk.[22] However, one should always bear in mind that the confirmatory analysis of suspected samples has to be better carried out by MS–MS techniques, since criteria for confirmation of the identity of drug residues by TOF–MS are not yet included in the EU guidelines.[29]

CONCLUSION

An analyst has a wide range of efficient extraction, cleanup, separation, and detection procedures to choose from. The choice will depend on the nature of the sample matrix, whether it is solid or liquid, fatty or non-fatty, and the expected range and levels of quinolone residues in food.

Evropi Botsoglou
Laboratory of Hygiene of Foods of Animal Origin, Department of Veterinary Medicine, University of Thessaly, Karditsa, Greece

Abstract
β-Agonists are synthetic compounds that, in addition to their therapeutic use in veterinary medicine, are able to promote live weight gain in food-producing animals. Such a use, however, may result in the presence of residues in the edible products of treated animals that may cause a real health problem to consumers. An overview of the isolation, separation, quantification, and confirmation procedures that may be used to analyze for violative β-agonist residues in foods is presented in this entry.

INTRODUCTION

β-Agonists are synthetically produced compounds that, in addition to their regular therapeutic role in veterinary medicine as bronchodilatory and tocolytic agents, can promote live weight gain in food-producing animals. They are also referred to as repartitioning agents, because their effect on carcass composition is to increase the deposition of protein while reducing fat accretion. For use in lean-meat production, doses of 5–15 times greater than the recommended therapeutic dose would be required, together with a more prolonged period of in-feed administration, which is often quite near to slaughter to obviate the elimination problem. Such a use would result in significant residue levels in edible tissues of the treated animals which might, in turn, exert adverse effects on the cardiovascular and central nervous system of the consumers.[1]

There are a number of well-documented cases where consumption of liver and meat from animals illegally treated with these compounds, particularly clenbuterol, has resulted in massive human intoxification.[1] In Spain, a food-borne clenbuterol poisoning outbreak occurred in 1989–1990, affecting 135 persons. Consumption of liver containing clenbuterol in the range 160–291 ppb was identified as the common point in the 43 families affected, while symptoms were observed in 97% of all family members who consumed liver. In 1992, another outbreak occurred in Spain, this time affecting 232 persons. Clinical signs of poisoning in more than half of the patients included muscle tremors and tachycardia, frequently accompanied by nervousness, headaches, and myalgia. Clenbuterol levels in the urine of the patients were found to range from 11 to 486 ppb. An incident of food poisoning by residues of clenbuterol in veal liver occurred also in the fall of 1990 in the cities of Roanne and Clermont-Ferrand, France. A total of 22 persons from eight families were affected.[1] An outbreak of poisoning occurred also in Italy in May 1997 affecting 15 individuals who ingested about 200 g veal meat contaminated with clenbuterol residues at 1140–1480 ng/g.[2] In addition, four cases of acute food poisoning in 50 people who ingested lamb and bovine meat containing clenbuterol residues at 300–1400 ng/g levels were recorded in Portugal in 1998–2002.[3] Apart from the above-mentioned cases, two farmers in Ireland were also reported to have died while preparing clenbuterol as feed for livestock.

Although, without exception, these incidents have all been caused by the toxicity of clenbuterol, the entire group of β-agonists is now being treated with great suspicion by regulatory authorities, and the use of all β-agonists in farm animals for growth-promoting purposes has been prohibited by regulatory agencies in Europe, Asia, and the Americas. Clenbuterol, in particular, has been banned by the FDA for any animal application in the United States, whereas it is highly likely to be banned even for therapeutic use in the European Union in the near future. However, veterinary use of some β-agonists such as clenbuterol, cimaterol, and ractopamine is still licensed in several parts of the world for therapeutic purposes. As a result, a recent screening assay in Turkey showed a high incidence rate (68.3%) of clenbuterol residues in ultra-high temperature (UHT) milk, with 21.7% of the samples exceeding the level of 50 ng/L.[4]

Monitoring programs have shown that β-agonists have been used illegally in parts of Europe and United States by some livestock producers.[1] In addition, new analogues, often with deviating structural properties, are continuously introduced in the illegal practice of application of growth-promoting β-agonists in cattle rearing. As a result, specific

knowledge of the target residues appropriate for surveillance is very limited for many of the β-agonists that have potential black-market use.[5] Hence, continuous improvement of detection methods is necessary to keep pace with the rapid development of these new unknown β-agonists. Both gas and liquid chromatography (LC) methods can be employed for the determination of β-agonist residues in biological samples. However, LC methods are receiving wider acceptance, as gas chromatographic methods are generally complicated by the necessity for derivatization of the polar hydroxyl and amino functional groups of β-agonists. In this entry, an overview of the analytical methodology for the determination of β-agonists in food by LC is provided.

ANALYSIS OF β-AGONISTS BY LC

Included in this group of drugs are certain synthetically produced phenethanolamines such as bambuterol, bromobuterol, carbuterol, cimaterol, clenbuterol, dobutamine, fenoterol, isoproterenol, mabuterol, mapenterol, metaproterenol, pirbuterol, ractopamine, reproterol, rimiterol, ritodrine, salbutamol, salmeterol, terbutaline, tulobuterol, and zilpaterol. Except zilpaterol, these drugs fall into two major categories: substituted anilines, including clenbuterol, and substituted phenols, including salbutamol. This distinction is important because most methods for drugs in the former category depend on the pH adjustment to partition the analytes between organic and aqueous phases. The pH dependence is not valid, however, for drugs in the latter category, as phenolic compounds are charged under all pH conditions.

Extraction Procedures

β-Agonists are relatively polar compounds, which are soluble in methanol and ethanol, slightly soluble in chloroform, and almost insoluble in benzene. When analyzing liquid samples for residues of β-agonists, deconjugation of bound residues using β-glucuronidase/sulfatase enzyme hydrolysis before sample extraction is often recommended.[6,7] Semisolid samples, such as liver and muscle, require usually more intensive sample pretreatment for tissue breakup. Most popular approach is sample homogenization in dilute acids such as hydrochloric or perchloric acid or in an aqueous buffer.[6–9] In general, dilute acids allow high extraction yields for all categories of β-agonists because the aromatic moiety of these analytes is uncharged under acidic conditions while their aliphatic amino group is positively ionized. Following centrifugation of the extract, the supernatant may be further treated with β-glucuronidase/sulfatase or subtilisin A to allow hydrolysis of the conjugated residues.

Cleanup Procedures

The primary sample extract is subsequently subjected to cleanup using several different approaches including conventional liquid–liquid partitioning, diphasic dialysis, solid-phase extraction, and immunoaffinity chromatography cleanup. In some instances, more than one of these procedures is applied in combination to achieve better extract purification.

Liquid–liquid partitioning cleanup is generally carried out at alkaline conditions using ethyl acetate, ethyl acetate–*tert*-butanol mixture, diethyl ether, or *tert*-butyl methyl ether/*n*-butanol as extraction solvents.[8,10,11] The organic extracts are then either concentrated to dryness or repartitioned with dilute acid to facilitate back extraction of the analytes into the acidic solution. A literature survey shows that liquid–liquid partitioning cleanup resulted in good recoveries of substituted anilines such as clenbuterol,[10,11] but it was less effective for more polar compounds such as salbutamol.[8] Diphasic dialysis can be also used for purification of the primary sample extract. This procedure was only applied in the determination of clenbuterol residues in liver using *tert*-butyl methyl ether as the extraction solvent.[9]

Solid-phase extraction is, generally, better suited to the multiresidue analysis of β-agonists. This procedure has become the method of choice for the determination of β-agonists in biological matrices because it is not labor- and material intensive. It is particularly advantageous because it allows better extraction of the more hydrophilic β-agonists including salbutamol. β-Agonists are better suited to reversed-phase solid-phase extraction owing, in part, to their relatively non-polar aliphatic moiety, which can interact with the hydrophobic octadecyl- and octyl-based sorbents of the cartridge.[12–14] By adjusting the pH of the sample extracts at values above 10, optimum retention of the analytes can be achieved. Adsorption solid-phase extraction using a neutral alumina sorbent has also been recommended for improved cleanup of liver homogenates.[8] Ion-exchange solid-phase extraction is another cleanup procedure successfully used in the purification of liver and tissue homogenates.[15] As multiresidue solid-phase extraction procedures covering β-agonists of different types, in general, present analytical problems, mixed-phase solid-phase extraction sorbents, which contained a mixture of reversed-phase and ion-exchange material, were also employed to improve the retention of the more polar compounds.[12,16–20] Toward this direction, several different sorbents were designed and procedures that utilized different interaction mechanisms were described, such as those using matrix solid-phase dispersion in combination with molecularly imprinted polymers for the extraction of clenbuterol from liver.[21] Molecular imprints as sorbents for solid-phase extraction are very selective, but the production of a constant-quality material still causes reproducibility problems.[17,22]

Immunoaffinity chromatography, owing to its high specificity and sample cleanup efficiency, has also gained widespread acceptance for the determination of β-agonists in biological matrices.[6,7,15,23] The potential of online immunoaffinity extraction for the multiresidue determination of β-agonists in bovine urine has been demonstrated, using an automated column-switching system.[23]

Separation Procedures

Following extraction and cleanup, β-agonist residues can be analyzed by LC. Gas chromatographic separation of β-agonists is generally complicated by the necessity for derivatization of their polar hydroxyl and amino functional groups. LC reversed-phase chromatography is commonly used for the separation of the various β-agonist residues owing to their hydrophobic interaction with the C_{18} sorbent. Efficient reversed-phase ion-pair separation of β-agonists has also been reported using sodium dodecyl sulfate as the pairing ion.[24]

Detection Procedures

Following LC separation, detection is often performed in the ultraviolet region at wavelengths of 245 or 260 nm. However, poor sensitivity and interference from coextractives may occur at these low detection wavelengths unless sample extracts are extensively cleaned up and concentrated. This problem may be overcome by postcolumn derivatization of the aromatic amino group of the β-agonist molecules to the corresponding diazo dyes through a Bratton–Marshall reaction, and detection at 494 nm.[24] Although spectrophotometric detection is generally acceptable, electrochemical detection appears more appropriate for the analysis of β-agonists, owing to the presence of oxidizable hydroxyl and amino groups on the aromatic part of their molecules. This method of detection has been applied in the determination of clenbuterol residues in bovine retinal tissue with sufficient sensitivity for this tissue.[11] Potentiometric detection with poly(vinyl chloride)-based liquid membrane electrode coatings has also been applied for a series of 18 exogenic β-agonist residues in LC systems.[25] Recently, a novel detection method using chemiluminescence has been reported for multiresidue determination of β-agonists including terbutaline, salbutamol, and clenbuterol in pig liver.[26] The procedure is based on the enhancement effect of β-agonists on the chemiluminescent reaction between the luminal and the complex of trivalent copper and periodate, which was electrogenerated online by constant-current electrolysis. However, the highest sensitivity and selectivity is offered by mass spectrometry (MS). Currently, coupling LC with MS appears to be the method of choice for the determination of β-agonists in biological samples although some drawbacks have started to appear. Main source of these drawbacks is the existence of matrix effects in general, and the ion suppression phenomenon in particular.[27] This phenomenon affects many aspects of the performance of the method, such as detection capability, repeatability, and accuracy. The cause of ionization suppression is a change in the droplet solution properties of the spray arising from the presence of coeluting non-volatile or less volatile solutes. Polar compounds such as β-agonists seem to be particularly susceptible to ion suppression. A possible solution to overcome false compliant results is the use of a proper internal standard, preferably an isotope-labeled one, to incorporate corrections for the ion suppression effect in cases where the ion signal is not suppressed completely.[28]

Confirmation Procedures

The requirements for unambiguous identification of these drugs have led to the large utilization of MS as the confirmatory procedure. Ion spray LC–MS/MS has been used to monitor five β-agonists in bovine urine,[23] while atmospheric-pressure chemical ionization LC–MS/MS has been employed for the identification of ractopamine residues in bovine urine.[12]

CONCLUSION

This literature overview shows that a wide range of efficient extraction, cleanup, separation, and detection procedures is available for the determination of β-agonists in food. However, continuous improvement of detection methods is necessary to keep pace with the continuous introduction of new unknown β-agonists that have potential black-market use, in illegal practice.

Food: Vitamin B_{12} and Related Compound Analysis by TLC

Fumio Watanabe
Emi Miyamoto
Department of Health Science, Kochi Women's University, Kochi, Japan

INTRODUCTION

Vitamin B_{12} (B_{12} or CN-B_{12}) is synthesized only in certain bacteria. Usual dietary sources of B_{12} are animal food products (meat, milk, eggs, and shellfish), but not generally plant food products. However, some plant foods (e.g., edible algae) contain large amounts of B_{12}. Various B_{12} compounds with different upper (L) and/or lower (R) ligands naturally occur (Fig. 1), especially MeB_{12} and $AdoB_{12}$, which function as coenzyme forms of B_{12}. Some food products contain unidentified or inactive B_{12}-related compounds, which may not be bioavailable in humans. Appreciable loss of B_{12} also occurs in foods during cooking and/or other food processing.

This entry summarizes the purification and characterization of B_{12} compounds found in various food products and of B_{12} degradation compounds formed by cooking and/or food processing, using thin-layer chromatography (TLC) as a powerful separation and analytical tool.

PURIFICATION AND CHARACTERIZATION OF VITAMIN B_{12} AND RELATED COMPOUNDS BY TLC

Commercially Available Reagents

Some commercially available B_{12} reagents, especially OH-B_{12} and dicyanocobinamide, contain small amounts of impurities (Fig. 2). Each B_{12} reagent should be purified with silica gel 60 TLC and then used for experiments as an authentic "standard" material. The authentic OH-B_{12}, purified by TLC on silica gel, has been used in the experiments conducted in the authors' laboratory.[1]

Vitamin B_{12} Degradation Products by Cooking and/or Food Processing

To determine whether the loss of B_{12} in microwave-treated foods is derived from the conversion of B_{12} to some inactive B_{12} degradation products, the OH-B_{12} that predominates in food is treated by microwave heating for 6 min and then analyzed by TLC on silica gel 60 with 1-butanol-2-propanol–water (10:7:10 vol/vol) as the solvent. The treated OH-B_{12} is separated into three red spots [major compound I with an R_f of 0.03, identical R_f of intact OH-B_{12}, and minor compound II (about 18.2%) with an R_f of 0.16 and compound III (4.2%) with an R_f of 0.27].[2] Although a novel OH-B_{12} degradation product with an R_f of 0.12 has not been separable from intact OH-B_{12} by the TLC system, it can be completely separated by silica gel 60 column chromatography.[1]

The OH-B_{12} degradation products with R_f values of 0.12 and 0.16 are further purified to homogeneity by the use of silica gel 60 TLC and reversed-phase (RP) high-performance liquid chromatography (HPLC).[1,2] The ^1H nuclear magnetic resonance (NMR) spectra of the OH-B_{12} degradation products show that the degradation product with an R_f of 0.12 is a B_{12} compound with the lower ligand structure changed slightly, but that with an R_f of 0.16 is a B_{12} compound without the base portion in the lower ligand.[1,2] Structural information on the degradation compound with an R_f of 0.27 is not available because a purified sample was not obtained for NMR study. Although the degradation product with an R_f of 0.12 has about 13% and 23% biological activity of authentic B_{12} in hog intrinsic factor (IF; the most specific mammalian B_{12}-binding protein) and *Lactobacillus delbrueckii* ATCC 7830 (a micro-organism for B_{12} bioassay), respectively, the product with an R_f of 0.16 does not show any biological activity.[1,2] Intravenous administration of both purified degradation products to rats indicates that the compounds are not toxic.[1,2] These results indicate that the conversion of B_{12} to these inactive B_{12} degradation products occurs in food during microwave heating.

Appreciable loss of B_{12} occurs in the multivitamin–mineral food supplements containing B_{12} because B_{12} is converted to inactive B_{12} compounds by the addition of substantial amounts of vitamin C in the presence of copper.[3] The destruction of B_{12} is probably concerned with radicals generated by vitamin C in the presence of copper. Although vitamin C alone or metal ion (Cu^{2+}) alone does not decompose B_{12}, B_{12} is destroyed significantly by mixing vitamin C and Cu^{2+} together (vitamin C–Cu^{2+} system).[4] Many B_{12} degradation compounds (ladderlike red-colored spots) are separated from the B_{12} treated with the vitamin C–Cu^{2+} system by TLC on silica gel 60.[4] Some of the B_{12} compounds formed appear to block B_{12} metabolism in mammalian cells.[3]

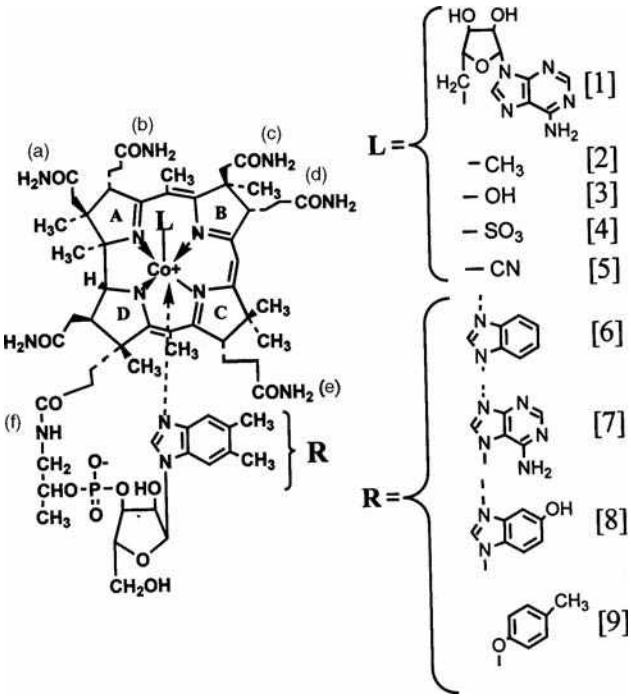

Fig. 1 Structural formulae of B_{12} compounds. The partial structures of B_{12} compounds show only those portions of the molecule that differ from B_{12}. 1, $AdoB_{12}$; 2, MeB_{12}; 3, OH-B_{12}; 4, SO_3^- B_{12}; 5, CN-B_{12} or B_{12}; 6, benzimidazolyl cyanocobamide; 7, pseudovitamin B_{12}; 8, 5-hydroxybenzimidazolyl cyanocobamide; and 9, *p*-cresolyl cyanocobamide.

The concentrated solution (4 μl) was spotted on the silica gel TLC sheet and developed with 2-propanol–NH_4OH (28%)–water (7:1:2 vol/vol) at room temperature in the dark. 1, OH-B_{12}; 2, CN-B_{12}; 3, $AdoB_{12}$; 4, MeB_{12}; and 5, dicyanocobinamide.

Vitamin B_{12} Compounds from Foods

Shellfish

The shellfish that siphon large quantities of B_{12}-synthesizing micro-organisms from the sea are known to be excellent sources of B_{12}. These micro-organisms can synthesize various B_{12} compounds (including inactive B_{12} compounds for humans). B_{12} contents of various edible shellfish were determined by both *L. delbrueckii* ATCC 7830 microbiological and IF chemiluminescence methods. The values determined by the microbiological method were 1.2-fold to 19.8-fold greater in the shellfish than the values determined by the IF chemiluminescence method.[5] To clarify why such differences in the B_{12} contents determined by the two methods occur, some B_{12} compounds have been purified from edible shellfish (oyster, mussel, and short-necked clam) using silica gel 60 TLC and a RP HPLC method, and subsequently characterized.[5]

The R_f values (0.18 and 0.59) of the red-colored B_{12} compounds purified from these shellfish are identical to those of authentic B_{12}, but not to those of benzimidazolyl cyanocobamide (R_f values: 0.15 and 0.55), 5-hydroxybenzimidazolyl cyanocobamide (R_f values: 0.16 and 0.47), pseudo-B_{12} (R_f values: 0.14 and 0.46), and *p*-cresolyl cyanocobamide (R_f values: 0.27 and 0.64) in two solvent systems [1-butanol-2-propanol–water (10:7:10) and 2-propanol–NH_4OH (28%)–water (7:1:2), respectively] by TLC on silica gel.[5] Although the higher values in the determination of B_{12} by the microbiological method may be because of the occurrence of B_{12} substitution compounds (probably deoxyribosides and/or deoxynucleotides), the edible shellfish would be excellent B_{12} sources, judging from the values (6 μg/100 g) determined by the IF chemiluminescence method.

Edible Algae

Edible algae are known to be rich in vitamins and minerals, as well as being good dietary fibers. Dried lavers (nori) appear to be the most widely eaten edible algae worldwide, and they have been reported to contain substantial amounts of B_{12}.[6] As the bioavailability of the laver B_{12} in mammals is not well understood, B_{12} compounds have been purified from the dried purple (*Porphyra yezoensis*) and green (*Enteromorpha prolifera*) lavers using silica gel 60 TLC and a RP-HPLC method and subsequently characterized.[7,8]

The silica gel 60 TLC and RP-HPLC patterns of the pink-colored compound purified from each laver are identical to those of authentic B_{12}, but not to those of B_{12} compounds inactive for humans.[7,8]

Algal Health Food

A health food fad involves tablets of *Spirulina* sp. (blue-green algae). When the B_{12} concentration of algal health food (*Spirulina* tablets) has been determined by both *L. delbrucekii* ATCC 7830 microbiological and IF chemiluminescence methods, the values determined by the microbiological method are about sixfold to ninefold greater in the *Spirulina* tablets than the values determined by the IF chemiluminescence method.[9] To evaluate whether the B_{12} found in the *Spirulina* tablets is true B_{12} or inactive B_{12}-related compound, B_{12} compounds have been purified from the *Spirulina* tablets using silica gel 60 TLC and a RP-HPLC, and then characterized.[9]

The major (83%) and minor (17%) B_{12} compounds purified from the *Spirulina* tablets are identified as pseudo-B_{12} and B_{12}, respectively, judging from TLC, HPLC, ^{1}H NMR spectroscopy, ultraviolet–visible spectroscopy, and biological activity data.[9] The *Spirulina* tablets are not suitable for use as a B_{12} source, especially for vegetarians, because pseudo-B_{12} appears to be inactive for humans.

In the case of other algal health foods (e.g., *Chlorella* tablets[10] and a coccolithophorid alga[11]), some B_{12} compounds have also been purified using TLC on silica gel 60 and then characterized. They contain substantial amounts of true active B_{12}.

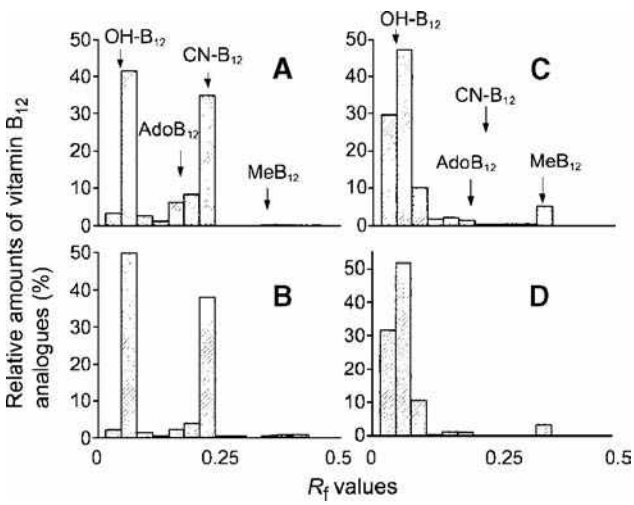

Fig. 3 Silica gel 60 TLC analysis of B_{12} compounds of dried green and purple lavers. The green laver B_{12} compounds were determined according to the chemiluminescence B_{12} assay (A) and microbiological B_{12} assay (B) methods. The purple laver B_{12} compounds were determined according to the chemiluminescence B_{12} assay (C) and microbiological B_{12} assay (D) methods. The R_f values of authentic OH-B_{12}, AdoB$_{12}$, CN-B_{12}, and MeB$_{12}$ on this TLC system [1-butanol-2-propanol–water (10:7:10 vol/vol) as a solvent] were 0.03, 0.20, 0.22, and 0.36, respectively. **Source:** From Vitamin B_{12}, in *Present Knowledge in Nutrition*.[3] © American Chemical Society, 1999.

VITAMIN B_{12} BIOASSAY AFTER TLC SEPARATION

To evaluate whether foods contain true B_{12} or not, B_{12} compounds can be separated by TLC and then assayed. Various kinds of fish sauces, traditional food supplements in the diet, are widely used in the world as condiments, and sometimes substituted for soybean sauces. Although a fish sauce (Nam-pla) appears to contribute a major source of B_{12} in Thailand, B_{12} compounds found in the nine selected fish sauces were separated by TLC on silica gel 60 and then determined with the *Lactobacillus* microbiological method, indicating that most B_{12} is derived from unidentified B_{12} compounds[12] and suggesting that fish sauce may not be suitable for use as a B_{12} source.

Coenzyme forms of B_{12} are also separated by TLC and then assayed. Occurrence of B_{12} coenzymes in the dried purple and green lavers is shown by the use of silica gel 60 TLC (Fig. 3).[13] The dried green laver contains four known types of biologically active B_{12} compounds (approximately OH-B_{12}, 45%; CN-B_{12}, 35%; AdoB$_{12}$, 6%; and MeB$_{12}$, 0.2%), and the non-coenzyme forms (OH and CN forms) of B_{12} predominated. Most B_{12} (about 80%) found in the dried purple laver are recovered in the OH-B_{12} fraction.

ONE-DIMENSIONAL AND TWO-DIMENSIONAL BIOAUTOGRAPHY

Because levels of B_{12} are very low in foods, tissues, and body fluids, bioautography is used before densitometry. A selected strain of *Escherichia coli* is used as the microorganism for the bioautography. Growth spots are enhanced by the addition of 2,3,5-triphenyltetrazolium chloride, which is converted to the red-colored formazan by *E. coli* growth.

The one-dimensional bioautography of authentic B_{12} compounds, cobinamide, and extracts of three edible algae, using TLC on mixture of silica gel and cellulose, is shown in Fig. 4.[14] The R_f value of a dominant red color spot found in the extract of Maruba-amanori is identical to that of authentic MeB$_{12}$. A single spot corresponding to CN-B_{12} is found in the extract of Wakame.

A sensitive two-dimensional bioautography has also been developed to investigate B_{12} metabolism in health and a wide range of diseases,[15] but it has hardly been used for food B_{12} analysis.

CONCLUSIONS

To evaluate whether food products contain true B_{12} or inactive (or unidentified) B_{12}-related compounds, B_{12} compounds were purified and analyzed by TLC on silica gel 60.

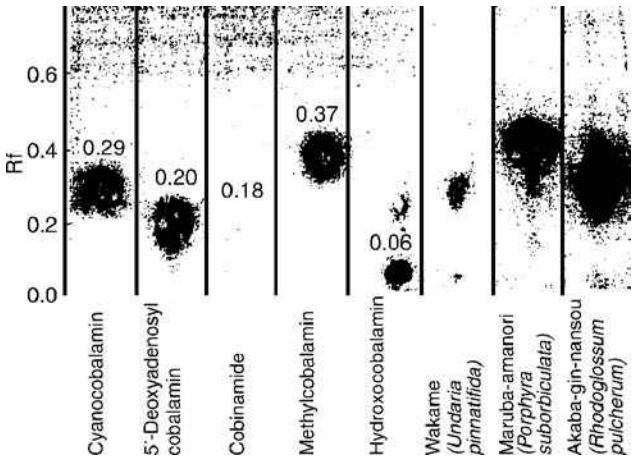

Fig. 4 Bioautogram of B_{12} and related compounds in the edible algae. A TLC plate was prepared from a slurry mixture of three weights of powdered cellulose (Whatman, Microgranular Cellulose, and CC41) and one weight of silica gel (Silica gel G, Type 60; Merck). Extracts of the edible algae, solutions of authentic B_{12} compounds, and cobinamide were applied at one of the plate, and developed with 2-butanol–NH_4OH (28%)–water (75:2:25 vol/vol). After drying the cellulose–silica gel plate, agar containing basal medium and *E. coli* 215 was overlayed and then incubated at 30°C for 20 hr. After spraying methanol solution of 2,3,5-triphenyltetrazolium salt on the gel plate, the position of B_{12} was visualized as red color by *E. coli* growth.
Source: From Effects of microwave heating on the loss of vitamin B_{12} in foods, in Agric. Food Chem.[2] © Center for Academic Publications Japan, 1996.

Sensitive one-dimensional or two-dimensional bioautography was also available in samples with lower levels of B_{12}.

The results presented here indicate that TLC offers great advantages (simplicity, flexibility, speed, and relatively low cost) for the separation and analysis of B_{12} compounds in foods.

Forensic Applications of GC

John Kapolos
Department of Agricultural Products Technology, Technological Educational Institute of Kalamata, Kalamata, Greece

Department of Chemical and Physical Examinations, Forensic Science Division, Hellenic Police Headquarter, Athens, Greece

INTRODUCTION

Forensic science, also referred to as "forensics," is the application of science to law. Forensic science uses various laboratory techniques to detect the presence of substances on a victim or a suspected criminal, or at a crime scene. In a forensic laboratory, quite a large variety of materials, such as explosives, tear gases, other toxic substances, biological fluids (blood, saliva, semen, etc.), bones, ignitable liquids, drugs, firearms and bullets, banknotes and other documents, paints and paint marks, glasses, plastic materials, hairs and fibers, other inorganic or organic materials, etc. as well as debris from explosions or arsons are examined as evidence. All of this evidence is known as "exhibits." The examinations have two purposes: to identify the exhibits (to clarify their chemical composition, their possible uses, etc.) or to compare them with reference materials to determine their common origin or lack thereof.

One of the most widely used forensic techniques for examining most of the above referring exhibits is the gas chromatography (GC) technique. In this entry, the experimental procedures for applying GC to exhibits examination are summarized.

FORENSIC APPLICATIONS OF GC

A court substantiates the imputation of guilt through three methods: a suspect's confession, the testimony of witnesses, and laboratory results from exhibit examinations. Taking into account all the necessary actions for collecting, packaging, and transferring of exhibits into a forensic laboratory to prevent contamination, as well as applying appropriate methodologies for their examination, the third way is the most reliable, because exhibits always tell the truth.

In a forensic laboratory, depending on the types of exhibits (paints, biological fluids, explosives, drugs, explosive devices, firearms, debris, etc.) and cases investigated, a variety of experimental procedures is applied, such as extraction, condensation, dilution, polymerase chain reaction (PCR), etc. as well as analytical techniques like GC, high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), X-ray diffraction (XRD) and X-ray fluorescence spectroscopy (XRF), Fourier transform-infra red spectroscopy (FTIR), UV/Vis spectroscopy, atomic absorption spectroscopy (AAS), scanning electron microscopy (SEM), electrophoresis, etc.

Of the above-mentioned techniques, GC is used for the:

1. Determination of alcohol concentration in biological specimens
2. Detection of ignitable liquid residues
3. Identification of explosive materials and examination of postexplosion exhibits
4. Drug analysis and profiling, as well as determination of drugs of abuse in biological specimens (forensic toxicology)
5. Examination of paints and paint marks from crime scenes
6. Analysis of tear gases.

Determination of Alcohol Concentration in Biological Specimens

Ethyl alcohol, ethanol, or alcohol is the active constituent of alcoholic drinks, in which it is contained in various concentrations (3–5% in beer; 9–12% in wines; and 20–60% in alcoholic distillations, such as brandy, whisky, etc.). Immediately after consumption, the reception of alcohol follows its absorption from the gastrointestinal tract and its rapid distribution into tissues, depending on their water content. Blood is an aqueous tissue; thus, a high percentage of alcohol will exist in blood after consumption of an alcoholic beverage.

After absorption, the metabolism of alcohol begins, mainly in the liver, where approximately 95% of the received quantity is metabolized. Also, because of respiration and eliminations, an amount of the received alcohol is excreted. The rate of alcohol reduction in the blood due to metabolism and excretion depends on many factors (e.g., age, physical fitness, the received quantity of ethanol, etc.) and differs among individuals.

The central nervous system is powerfully influenced by ethyl alcohol; the intensity of this influence is proportional to the content of ethyl alcohol in the blood. This influence is expressed by the weakness of an individual and ensuing difficulty in executing fine work, as well as in controlling a vehicle.[1] In all developed countries, operating any vehicle under the influence of alcohol is prohibited, with special rules established for its prohibition. Either through formal driver controls or at accident investigations by police authorities, but also in many other instances (falls from great heights, other work accidents, etc.), the determination of alcohol concentration is required.

Biological specimens (blood, urine, or other body fluids), as well as air breathed, can be used for measuring alcohol concentration. Blood is the most widely used biological specimen for this purpose in forensic laboratories. The officially recognized method for the determination of blood alcohol concentration is automated headspace GC. According to Henry's Law, at equilibrium in a sealed vessel, volatile compounds in the liquid state will be present in the vapor state at a concentration proportional to the concentration of the liquid. By sampling this vapor (i.e., the headspace) through a GC, volatile compounds may be qualitatively identified and quantitatively measured. The height or area under the chromatographic peaks generally can be used for quantitative determinations.

This is a precise, fast, and specialized method, with no pretreatment of the sample required, and it allows for the simultaneous determination of other volatile substances existing in the sample (methanol, isopropyl alcohol, etc.). The method is offered for continuous operation, does not require any modifications of commercial GCs, and is completely automated.

Experimental Procedure

A commercial GC equipped with a flame ionization detector is required. The GC is connected to an automatic headspace sampler, where sample vials are placed. Helium as carrier gas and *tert*-butanol as internal standard are used. Carbowax 1500 or 1540 (poly ethylene glycols) or other polar materials can be used as stationary phases.

The alcohol concentration in the sample is calculated with the assistance of standard samples containing ethanol in water at known concentrations and the amount of the internal standard added to the samples. A volume of 0.5 ml of the specimen to be analyzed is pipetted into a vessel; 0.1 ml of the internal standard (a 0.2% w/v solution of *tert*-butanol in water) is added; the vessels are sealed with a rubber septum; and the covers are secured with aluminum caps to compensate for the eventuality of an excess pressure buildup. For standard samples, instead of the specimen, 0.5 ml of a known ethanol concentration solution is added. Finally, the vessels are placed into the turntable of the headspace analyzer, which is thermostatted at 60°C.[2]

The standard samples are run parallel to the investigated samples, and from them, the calibration factor is calculated via Eq. 1,

$$f = C_{\mathrm{E}} \frac{H_{\mathrm{B}}}{H_{\mathrm{E}}} \tag{1}$$

where C_{E} is the concentration of ethanol in the standard sample, and H_{B} and H_{E} are the heights of the *tert*-butanol and ethanol peaks, respectively. The concentration of ethanol in the investigated samples is calculated as

$$\%\ \text{Ethanol} = \frac{H'_{\mathrm{E}}}{H'_{\mathrm{B}}} \times fF, \tag{2}$$

where H'_{B} and H'_{E} are the respective heights of the *tert*-butanol and ethanol peaks when unknown samples are analyzed and F is a correction factor. The values of F have been determined experimentally and confirmed by calculation; for blood samples, $F = 1.08$, whereas for serum, $F = 1.26$.

Typical chromatograms for a standard sample and unknown blood samples in the presence, as well as in the absence, of alcohol are shown in Fig. 1.

Exactly the same technique (headspace GC) can be applied for the determination of alcohol concentration in other biological specimens (urine, spinal-column fluid, or fluid from the eyes), with the only difference being the standard solutions.

Finally, GC can be used to determine alcohol concentration in breath specimens obtained from living subjects. Appropriately modified GCs are used, and directly collected or field-collected breath can be analyzed. These chromatographs are equipped with an appropriate multisampling valve for injecting the sample and a flame ionization detector (FID).[1]

Detection of Ignitable Liquid Residues

Generally, it is accepted that when an incident of fire is investigated, the examiner first has to locate the fire's origin and then determine the accelerants used. Many fires are criminal actions (arsons), and in these cases, oil fuels or other organic solvents have often been used as accelerants. Arson can start in two ways: Either the place is impregnated with the ignitable liquids and the fire begins from a naked flame (matches, lighter, a flaming piece of textile, etc.), or an improvised incendiary device is used. In the latter case, the location of the arson's origin will reveal materials (parts of the device) where accelerant residues exist.

Contrary to popular myth, ignitable liquids or accelerants are not completely consumed by fire; small amounts will be absorbed by the material on which they were applied. This includes wood, concrete, tiles, textiles, and

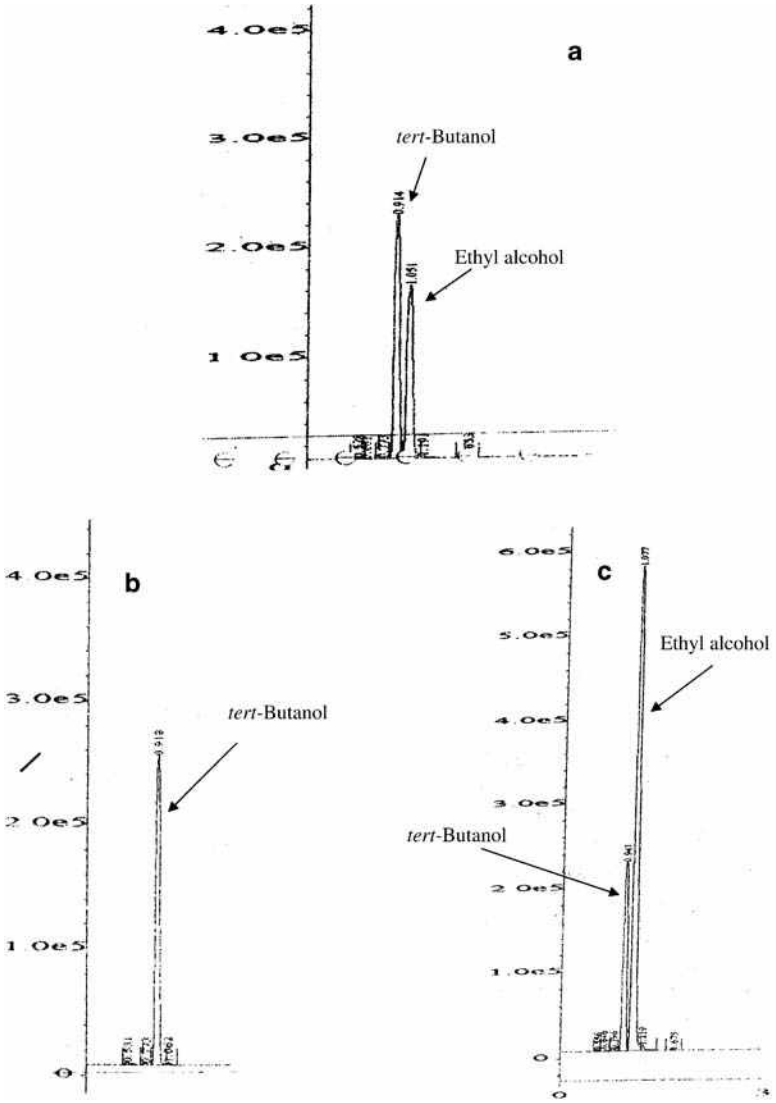

Fig. 1 GCs obtained from (a) a standard solution, (b) a blood sample without alcohol, and (c) a blood sample with alcohol. GC HP-5800 with FID, column HP-INNOWAX (15 m × 0.53 mm × 1 μm), injector temperature = 130°C, detector temperature = 220°C, oven temperature = 65°C. Automated headspace sampler, Perkin Elmer Turbomatix 40, syringe temperature = 85°C, transfer line temperature = 110°C, pressurizing time = 3 sec, inject time = 0.075 sec, and withdraw time = 0.15 sec. Carrier gas He with flow rate = 20 ml/min.

other common construction materials that have some porosity. Sometimes, a sufficient amount will be absorbed into the material, which then outgases after the fire. This may create a recognizable odor that is noticeable right after the fire has been extinguished. Most firefighters are instructed to remain alert for the existence of odors during overhaul after the fire. In "pour pattern" areas, some of the accelerants may have soaked into the material, especially if the material has significant porosity. With appropriate sampling and analysis, the accelerants can be identified via chemical analysis. The sampling and analysis must be performed properly to ensure that the evidence will stand up in court later.[3]

Sampling and Extracting Techniques

Samples of fire debris suspected of containing accelerants must be transported to the laboratory in a specific type of container. The most basic requirements are that the sample be protected from loss of accelerant residues and that it be protected from contamination. Cost and practicality are also important considerations. So glass jars, paint cans, and various plastic bags can be used. Polyester–polyolefin composite bags, however, are preferable.

The extraction of accelerants absorbed from fire debris can be conducted by supercritical fluid extraction (SFE), Soxhlet extraction, distillation after the addition of water and *n*-hexane, or adsorption onto activated charcoal. Of these procedures, SFE was found to have some advantages over conventional extraction procedures, whereas the adsorption techniques were found to be less time consuming, and the distillation method presented a higher degree of efficiency. The use of granular-activated charcoal to store extracts eluted using a dynamic headspace technique has also been examined. Activated charcoal may be used as an adsorbent for the long-term storage of as little as 1 μl of petroleum product from fire-debris samples.[4]

The introduction of commercially produced, activated charcoal strips into fire-debris analysis has provided an easy, efficient, and cost-effective method for accelerant extraction. However, several parameters require consideration to obtain a truly representative sample of accelerant. Newman, Dietz, and Lothridge[5] have investigated the effects of time, temperature, charcoal strip size, and sample concentration on the adsorption of common accelerants.

Carbon disulfide (CS_2) has long been the solvent of choice for the elution of adsorption packages (e.g., activated charcoal strips) used in fire-debris analysis. The selection of CS_2 stems from its efficiency at displacing materials adsorbed onto charcoal and its minimal response with the flame ionization detector. Unfortunately, CS_2 is highly flammable and extremely toxic, and possesses a strong, unpleasant odor. In laboratories that utilize mass selective detectors instead of the F.I.D., diethyl ether, a much friendlier solvent, can be used instead of CS_2.

Detection and Identification

For the detection of the accelerant's residues, which have been extracted by the one of the above techniques, a GC with an F.I.D. detector is used, and the pattern of peaks produced in the chromatogram is compared with the pattern produced by solutions of known accelerants, which have been analyzed separately.

Commercial products—unleaded gasoline, diesel, paraffin, white spirit, lighter fluid, etc.—are used as reference materials. Two characteristics of the accelerant chromatogram should be considered. First, the retention times over which peaks can be observed provides an indication of the boiling range; second, the detailed pattern of the peaks can permit an accelerant to be classified with more specificity. In Fig. 2, chromatograms from commercial products (diesel and unleaded gasoline) are illustrated.

An accelerant can be said to be of the same type as a reference material if the chromatograms produced show similar patterns (i.e., the major components are eluted over approximately the same range of retention times, and the proportions of the major components are similar).

Identification of Explosive Materials and Examination of Postexplosion Exhibits

Explosives can be divided into the following categories:

1. Mechanical explosives (water is instantaneously converted to gas, or gas is suddenly heated in a limited closed area)

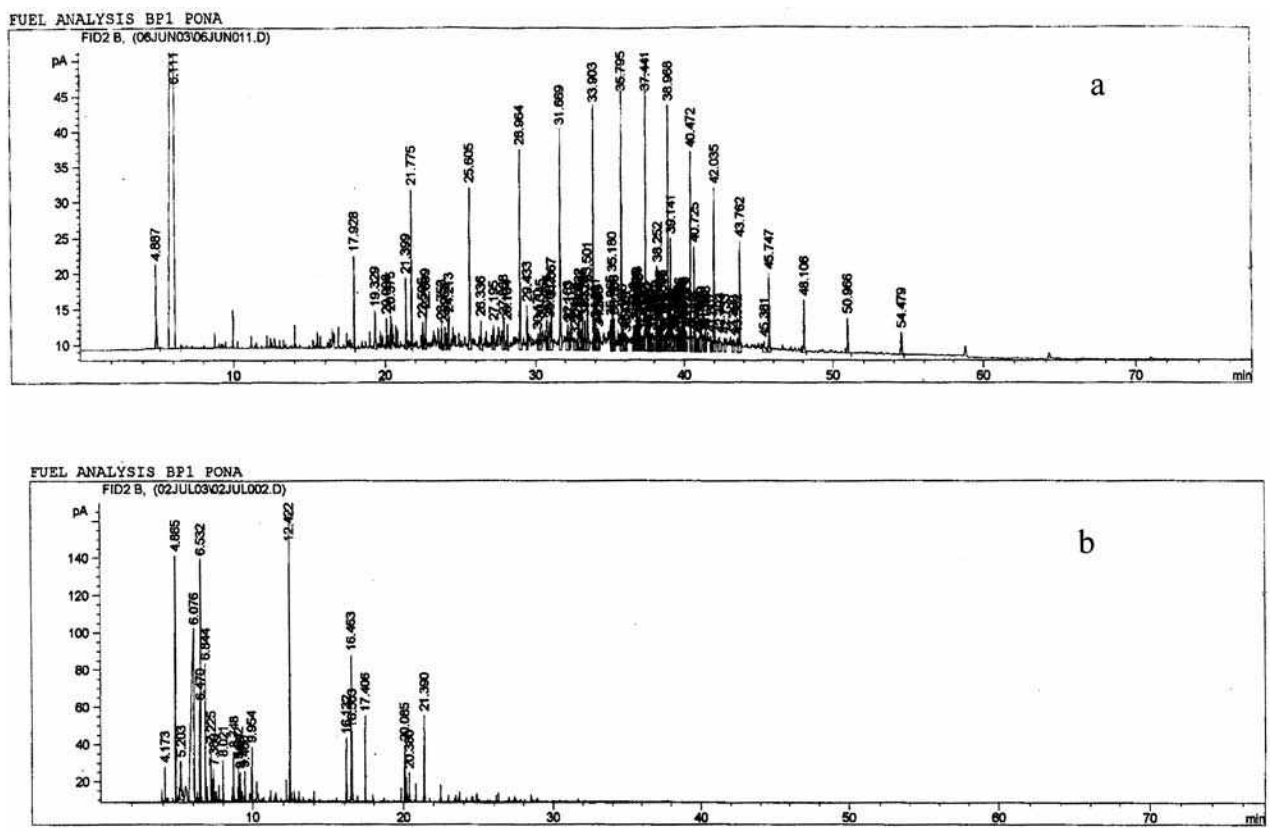

Fig. 2 GCs obtained after injecting 1 μl of (a) diesel and (b) unleaded gasoline. GC HP-6890 with FID, column BP1-PONA from SGE (50 m × 0.15 mm × 0.45 μm), injector temperature = 250°C, detector temperature = 300°C, oven temperature program = initial temp 40°C, rate 5°C/min, final temp 275°C. Carrier gas He with flow rate = 1 ml/min.

2. Nuclear explosives (introduced in 1945 as military weapons)
3. Chemical explosives.

Of the above three categories, the third one is the most interesting for forensic purposes. Every chemical explosive should have at least one oxidant and one reductant part. If these two parts coexist in the same substance, the explosive is called "one-substance explosive". In the other case (where both one oxidant and one reductant are present), we have mixtures. The majority of the one-substance explosives are organic compounds and are also the main substance of the mixtures.

The one-substance explosives are nitrobenzene, *m*-dinitrobenzene, 1,3,5 trinitrobenzene, *o*-nitrotoluene, *m*-nitrotoluene and *p*-nitrotoluene, 2,3-2,4-2,5-2,6-3,4 and 3,5 dinitrotoluene (DNT), 2,4,6 trinitrotoluene (TNT), mononitro- dinitro- and trinitro-naphthalene, trinitrochlorobenzene (Picrylchloride), 2,4,6 trinitrophenol (picric acid), ethyleneglycol dinitrate (EGDN), clycerol trinitrate (nitroglycerin, NG), penta erythritol tetranitrate (PETN), 2,4,6, *N*-tetranitro-*N*-methylamine (Tetryl), 1,3,5 trinitro-1,3,5-triazacyclohexane (RDX), and 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (Octagen, HMX).[6]

Some of the above chemical explosives are exclusively used by the military; some others can be used with a license for demolition purposes in mines, construction, etc.

From all the above, it is obvious that the possession of any explosive material without the appropriate license is a criminal action and the penalty depends on the kind of explosives used. Except for the above, when abandoned explosives are discovered in police researches the possibility of their use in criminal action has to be investigated. In these cases, a forensic laboratory has to analyze them to determine their chemical composition, characterize them (for military or commercial use, their power, and their specialty), and estimate how dangerous they are. Furthermore, in a postblast investigation, the main objectives are the determination of the used explosives and the reconstruction of the explosive device that was utilized.

Detection and Identification

GC is used for the detection and identification of explosives, whether they are found as pure materials or postblast residues. According to Yinon and Zitrin,[7] GC detectors suitable for the determination of explosives are the F.I.D., mass spectrometer (MS), electron capture detector (ECD), nitrogen–phosphorus detector (NPD), and thermal energy analyzer (TEA). The most selective detector is the TEA, which detects only compounds that produce NO or NO_2.

Helium is used as a carrier gas with a flow rate of 2 ml/min; the temperatures of the detector and injector are held at 200°C and 175°C, respectively, while the temperature in the oven is started at 80°C and ramped at 20°C/min up to 200°C. Likewise, three different types of columns are usually applied for GC analysis: dimethylsiloxane, 5% diphenyl-dimethylsiloxane, and 7% cyanopropyl-7% phenyl-1% vinyl-dimethylsiloxane.

When pure explosives are analyzed, a small aliquot of the sample is diluted with ethyl acetate, and identification is based upon the comparison of relative retention times with those of explosives in a standard solution analyzed both before and after the sample. The standard solution is prepared by the dilution of the 11 most common explosives (EGDN, NG, PETN, RDX, 2,4-2,6-3,4 DNT, TNT, *o*, *m*, and *p* nitrotoluene) in ethyl acetate. Also, a mixture of two retention references markers is coinjected with every sample and standard solution, and retention times are measured relative to these substances. The markers commonly used to provide reference peaks in GC analyses are 2 fluoro-5-nitrotoluene (FNT) and 2,6 dinitro-3,4,5-trimethyl-*tert*-butylbenzene (MT).

In postblast investigations, the determination of the explosive material that was used depends mainly on the collection of appropriate debris from the scene. In a forensic laboratory, the debris is first viewed by the naked eye under low-power magnification. If there are any microscopic explosive particles, they are delivered by using acetone; the solution can be analyzed in the GC without further manipulation.

However, postexplosion analysis is usually characterized by small amounts of residues present in a complex, highly contaminated matrix. The exhibits are washed with acetone to dissolve the explosive residues, and the liquid phase is filtered through a 0.45 μm filter. A cleanup procedure based on SPE with C_{18}-bonded phase as adsorbent should be used prior to GC analysis.[8] Furthermore, the cleanup procedure is used to overcome difficulties in the GC analysis of postexplosion residues involving PETN. After the cleanup procedure and the evaporation of the acetone to increase the concentration of the solution, the analysis is similar to that described above.

Drug Analysis, Profiling, and Forensic Toxicology

For every drug seizure, part of the sample is sent to a forensic laboratory, which performs chemical analysis to determine either the type of drug or the origin of samples from different seizures. On the other hand, in many cases of forensic interest, body fluids and tissues have to be analyzed to quantify any drugs that are possibly found.

Drug analysis, either from seizure loads or biological-specimen extraction, is very difficult to describe in detail in this entry due to the different drug classes. Hereinafter, the main steps of the analysis of different drug classes are explained briefly.

Drug Analysis and Profiling

The application of GC for the analysis of illicit heroin samples can proceed after silylation of the samples, using

MSTFA (*N*-methyl-*N*-trimethylsilyl-trifluoracetamide) as the silylation reagent. The same procedure can be applied to the determination of morphine, cocaine, and opium.[9] Strömberg et al. introduced a system for the retrospective comparison of South Asian heroin; this system consisted of an improved GC profiling method and computerized data retrieval. The peaks from the GC profile were investigated for abundance, intensity, GC behavior (reproducibility), and correlations.[10] The basis of the chemical analysis was a capillary GC method for the analysis of heroin trace impurities, which has been described in detail elsewhere.[11,12]

Cannabis and its preparations (loose marijuana, kilobricks, buds, sinsemilla, Thai sticks, hashish, hash oil, etc.) represent the most widely used group of illicit drugs in the world. The various biological effects of cannabis are attributed to the complex chemical composition of the plant material. In addition, the chemical profiles of the variants of marijuana are certainly different and could contribute to the variability of results among investigators. El Sohly et al., investigated more than 35,000 samples of cannabis and its preparations to estimate their qualitative and quantitative determinations.[13]

Amphetamine (AM, *R*, *S*-1-phenyl-2-propanamine) and methamphetamine (MA, *R*, *S*-*N*-methyl-1-phenyl-2-propanamine) are powerful stimulants to the central nervous system. They are drugs of abuse, as well as doping agents in sports, and their abuse has a history as old as the drugs themselves. Amphetamine derivatives, or "designer drugs"—3,4-methylene-diaxyamphetamine (MDA), 3,4-methyl-enedioxymethamphetamine (MDMA), and 3,4-methyl-enedioxyethylamphetamine (MDEA)—are currently abused as psychedelics. Their mean "street" purity is around 5%, with caffeine, glucose, and other sugars being the main cutting agents. For intelligence profiling of amphetamine samples, GC with split/splitless injector and silica capillary column with BP-5 stationary phase can be applied.[14]

Finally, GC detection of the manufacturing impurities of cocaine can be enhanced by chemical derivatization via the use of an electron-capture detector. In this method, unadulterated cocaine hydrochloride samples were derivatized directly in acetonitrile with heptafluorobutyric anhydride (HFBA); the derivatives of the manufacturing impurities were extracted into isooctane. Then the isolated derivatives were subjected to GC-electron capture detection analysis.[15] This methodology is especially suitable for sample comparison analysis.

Determination of Drugs of Abuse in Biological Specimens

The area of toxicological analysis in the forensic field has been, and continues to be, extremely dynamic. When faced with a general unknown, it is normal for the toxicologist to begin with screening techniques that are amenable to mass screening, and if positive, drugs must be extracted, confirmed, and quantified. Immunoassay techniques [radioimmunoassay (RIA)], enzyme-multiplied immunoassay (EMIT), enzyme-linked immunosorbent assay (ELISA), etc. often form the first part of the toxicological analysis. Immunoassay screening for certain drug groups, however, constitutes only part of the total screening requirement. The remaining portion of the screening sequence, involving further extraction of drug groups, is then required and forms an ever-increasing array of screening procedures for particular analytes. The oldest method of extracting drugs from body fluids and tissues, termed liquid/liquid extractions, is still commonly used, although a more recent extraction process, SPE, has gained popularity. Further expansion of SPE involves the collection of a sample of fibers or membranes solid-phase microextraction (SPME), which leads to a cleaner extract for analysis.

Urine, blood, vitreous humor, and tissues were considered to be useful samples, whereas hair, nails, saliva, serum, sweat, and other biological matrices have been determined to be useful samples for drug analysis, as either alternatives or complements to other techniques.

Following initial immunoassay and extraction procedures, the extracts are subjected to various instrumental screening procedures designed to provide some indication of specific drug presence. Preliminary identification of drugs within the extracts is normally conducted via chromatographic techniques. Quantification is performed using GC or HPLC, with the incorporation of suitable quality-control procedures. Mass spectrometry is also used as a screening and quantification tool, as well as a confirmatory technology.

Liquid–liquid or solid-phase procedures for extraction are predominant in the determination of amphetamines, methamphetamines, and other designer drugs in blood and urine. Following the extraction, the derivatization and then the determination—GC–MS with electron impact (EI) ionization operated in the selected ion monitoring (SIM)—are performed.[16–18]

The most widespread abuse of cannabis is by smoking. It occasionally may be abused orally. When smoked, initial metabolism occurs in the lungs, whereas this takes place in the liver when marijuana is taken orally. The identification of 9-carboxy-tetrahydrocannabinol (THC) in urine is considered to be the best indication of previous cannabis consumption. Before SPE, alkaline hydrolysis of the sample is necessary to free the metabolite 9-carboxy-THC. Afterward, *N,O*-bis-trimethylsilyl-trifluoroacetamide (BSTFA) and trimethylchlorodilsne (TMCS) are added for derivatization; the product is analyzed by GC–MS in EI or negative-ion chemical ionization (NICI) mode.[16,17]

In the laboratory analysis of various biological specimens for heroin or related opiates, such as morphine and codeine, acid hydrolysis is required for the isolation of the drug from the urine; then SPE is used for cleanup. Derivatization is required to overcome the poor chromatographic behavior of morphine. Silylation or

fluoracetylation are the preferred methods. GC–NPD or GC–MS in EI mode is used for the determination of opiates in biological specimens.[16,17]

The conversion of cocaine to metabolites, benzoylecgonine (BE), and ecgonine methyl ester (EME) begins to occur soon after absorption. The coadministration of cocaine and ethanol leads to the formation of ethylbenzoylecgonine (EBE, also known as cocaethylene), a transesterification that is hydrolyzed to BE and ecgonine ethyl ester. Other metabolites are norcocaine and benzoylnorecgonine.

Anhydroecgonine methyl ester is produced when cocaine is smoked. The metabolic profiles and detection windows differ, depending on the biological matrix. After cocaine administration, the major compound found in blood and urine is BE, whereas the parent drug has been analyzed as the highest concentration in other matrices (hair, saliva, and sweat). With respect to the detection windows, BE can be detected in blood and saliva during one day; in urine, for several days; in sweat, for two or three weeks; and in hair, for months or years, depending on the length of the hair shaft. There is no need for hydrolysis, and to detect the metabolites of cocaine after SPE, the extract should be derivatized by alkylation/acylation (suitable for GC/FID and GC/NPD) or silylation (suitable for GC/FID or GC/MS).[16]

Benzodiazepines, used therapeutically as tranquilizers, hypnotics, anticonvulsants, and centrally acting muscle relaxants, rank among the most prescribed drugs. They are administered in a wide range of dosages, from less than 0.1 to 100 mg or more each day. Numerous benzodiazepines have been synthesized. They appear mainly as capsules and tablets; however, some are marketed in other pharmaceutical forms, such as injectable solutions. Abuse of benzodiazepines is internationally widespread, which means that any forensic laboratory may encounter a range of these compounds. Many benzodiazepines are hydrolyzed in acid solution to form the corresponding benzophenone; this can be capitalized on for analytical purposes. In the free base/acid form, benzodiazepines are generally soluble in most organic solvents, such as ethyl ether, ethyl acetate, chloroform, and methanol, but most are insoluble in water.

Benzodiazepines are metabolized through a variety of hydroxylation, desalkylation, reduction, and acetylation reactions, followed in many cases by conjugation to glucuronic acid prior to excretion. The most common specimens for the analysis of benzodiazepines are urine, blood, serum/plasma, and liver. Prior to liquid-liquid or SPE, samples should be hydrolyzed.

GC is a suitable technique for the analysis of benzodiazepines. Derivatization techniques are used, and silyl, acyl, and alkyl derivatives are formed. Electron capture detector gives the best detection limits ($\leq$1 ng/ml) for plasma, although NPD provides detection limits down to 5 ng/ml. GC-MS is an excellent confirmatory method for benzodiazepines. All the details for determination of benzodiazepines in biological specimens are provided elsewhere.[19,20]

Finally, GC is used for the determination of lysergic acid diethylamide (LSD) and phencyclidine (PCP) in biosamples. Lysergic acid diethylamide is difficult to detect and to quantify in biosamples because of its very low active dose, whereas there are well-established detection and quantitation procedures for PCP. An analytical approach for both is given in the literature.[21]

Examination of Paints and Paint Marks from Crime Scenes

The importance of paints as physical evidence has been recognized for quite some time. In fact, paints are among those forensic materials that have engaged the attention of crime investigators and concerned scientists since the inception of forensic science laboratories, and they have always played important and crucial roles in crime investigation.

Paint, as a physical clue, is frequently encountered in hit-and-run incidents, burglaries, art forgeries, and other offenses. A paint chip or a paint smear may be transferred to the victim or left at the scene of an accident, or a paint smear could be transferred to a tool during the commission of a burglary. There are numerous possibilities and situations in which the transfer of paint from one surface to another could occur. Routine forensic examination of paint allows for the identification of the organic and inorganic composition of each paint layer.

Automotive paint formulations undergo constant evolution and revision based on the needs of the industry, including appearance, longevity, repair, and economics. Formulation may also include a higher solid load, changed polymer chemistries, water-based products, and the results of other new technologies. The fragments of paint recovered during forensic investigations are often analyzed using pyrolysis-GC/MS (PyGC/MS). Pyrograms generated from intact fragments or separated layers are used to match paint evidence to known paint formulations in an effort to narrow the scope of the search, help identify involved vehicles, and exclude others. The peaks that appear in a pyrogram of automotive paint may be a complex mixture of polymer pyrolyzate, plasticizers, and other ingredients, each of which has a specific function in the performance of the paint as a coating product.[22]

Pyrograms, or the graphical output presentations of a PyGC system, are influenced by numerous sample characteristics and instrumental parameters, such as pyrolytic temperature, pyrolytic temperature ramp rates, preconditioning cycles, etc. This requires that the user maintain adequate reference sets of bulk polymers and copolymers for comparative analyses. Replicate sampling and analysis of each case item are necessary during PyGC testing to ensure pyrogram reproducibility and establish intrasample

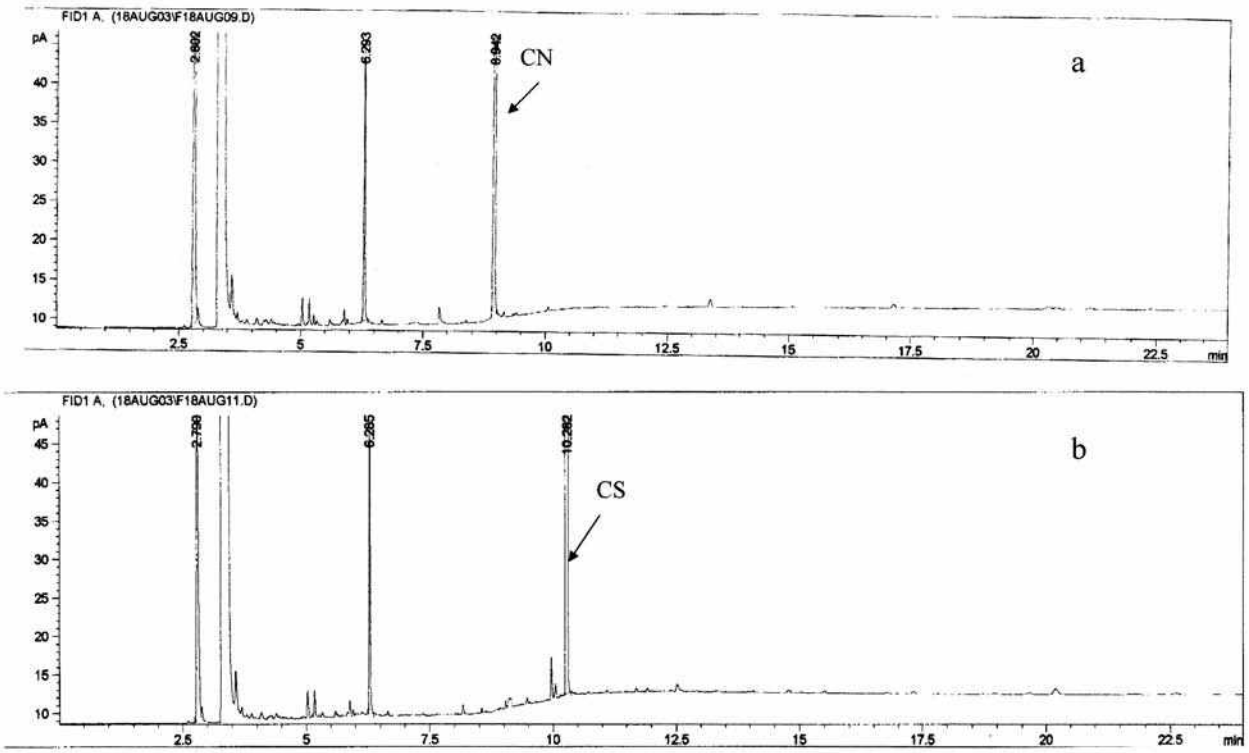

Fig. 3 GCs of tear gases (a) 2-chloroacetophenone (CN) and (b) *O*-chlorobenzylidene malononitrile (CS). Gas chromatograph, HP-6890 with FID, column CP-SIL-5 CB from CHROMPAC (25 m × 0.32 mm × 1.20 μm), injector temperature = 280°C, detector temperature = 300°C, oven temperature program = initial temp 50°C, rate 30°C/min, final temp 260°C. Carrier gas He with flow rate = 1.1 ml/min.

variations prior to pyrogram comparisons. Consideration must be given to the applicability of this procedure to each case, depending on the film's complexity and the amount of sample consumption that can be tolerated.[23]

Blank runs between samples, using all system components and full temperature-time profiles, are also essential to preventing sample carryover. Several pyrolysis systems and techniques are available and are discussed in an overview by Blackledge.[24]

Analysis of Tear Gases

Tear gases are used largely to control civil unrest. Their incapacitating effects involve the eyes, skin, and respiratory tract. Although aerosol sprays containing tear gases are available to the public in some countries, in others, tear-gas aerosols are classified as offensive weapons, and their possession is illegal. Because of the legal restrictions on these products, the identification of their active ingredients is of forensic interest.

The lachrymatory materials commonly used are 2-chloroacetophenone (CN), *O*-chloro-benzylidene malononitrile (CS), and oleoresin capsaicin. In commercial aerosol products, these materials are present with a propellant and a suitable organic solvent. From the above, CN and CS can be determined by GC; the procedure is as follows.

A short burst from the aerosol container is sprayed into a weighed beaker. After standing at room temperature for about 1 hr to allow all the propellant to evaporate, the beaker is reweighed. The residue is dissolved in acetone, and after suitable dilution, 1 μl is injected onto the chromatograph. Because of the vastly different volatilities of the compounds, a temperature program is used. Both flame ionization and ECDs can be used. In Fig. 3, chromatograms of CN and CS produced following the above procedure are illustrated.

Standard solutions of lachrymators can be prepared by diluting a known amount of pure CS and CN in acetone and, when kept refrigerated, remain stable for long periods.

Finally, another forensic application of GC is the determination of carboxyhaemoglobin (COHb) in blood. The carbon monoxide in blood can be identified by using headspace GC, as described in detail elsewhere.[25,26]

CONCLUSION

There isn't any forensic laboratory in the world without at least one GC. GC, a widespread analytical technique, is

used for the analysis of exhibits from crime scenes to obtain answers to questions that have arisen. GC is used for the detection of residues of explosive and inflammable materials, for the determination of the type and the common origin of seized drugs, for the analysis of biological specimens (blood, urine, saliva, etc.), to determine the use of drugs of abuse and alcohol (forensic toxicology), and for the analysis of tear gases and plastic materials derived from crime scenes.

Forensic Ink: TLC Analysis

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Thin-layer chromatography (TLC) and high-performance TLC (HPTLC) have been important methods in forensic analysis since their inception, e.g., for the determination of drugs and pesticides. The analysis of inks for investigations of counterfeiting, fraud, forgery, and other crimes is the most important forensic application of TLC and HPTLC, and these are the most widely used chromatographic techniques for the analysis of inks. Major advantages of TLC in ink analysis are ease of use and low cost. Resolution of the components of ink formulations is high, especially for HPTLC, and the visual detection of the colored components allows convenient and rapid comparison of different ink formulations and batches. The use of densitometric scanning enhances the detection of zones on the layer and comparison of different samples and can provide quantitative data for separated components.

A review paper[1] included selected references on methods for extraction from paper, layers, mobile phases, and component characterization methods used in TLC and HPTLC for separation of ink components and identification and comparison of ink formulations from ballpoint, fountain, and fiber-tipped pens and typewriter ribbons published between 1960 and 1996. This entry describes standard TLC methods for ink analysis published by the ASTM International (West Conshohocken, Pennsylvania, U.S.A.) and advances in the field of forensic ink analysis using these and other TLC and HPTLC procedures published since 1996.

ASTM METHODS

ASTM Designations E-1422-05 and E-1789-04 are standard guides for forensic writing ink comparison and identification using TLC and additional methods. Ink comparisons by E-1422-05 can definitely determine whether an ink is the same (in formula) as that on other parts of the same document or on other documents, and may offer clues about whether two writings with similar ink came from the same writing instrument or ink well, and about the date of ink entries. Non-destructive optical examinations are specified with visible light, ultraviolet (UV) light, reflected infrared (RIR) radiation, and infrared luminescence (IRL) non-destructive optical examinations (Sections 7.1–7.5). Chemical examinations (Section 7.6) involve spot testing and solubility testing (e.g., to differentiate ballpoint and non-ballpoint ink) and TLC.

The TLC procedure is contained in Section 7.7 of Guide E-1422-05. The substrate (e.g., a paper sheet) is sampled by removing 7–10 plugs from a line using a hollow boring hypodermic needle (if a scalpel is used, about 1 cm of the line is removed). The plugs are placed in a vial and extracted by agitation for about 1 min with 3–5 μl of pyridine for ballpoint inks or ethanol–water (1:1) for non-ballpoint inks. A glass plate or plastic sheet commercially precoated with 60 Å particle size silica gel without fluorescent indicator is activated by heating in an oven at 100°C for 10–15 min and then cooled, and then the colored extract is immediately applied as a 2–3 mm spot onto the layer origin with a micropipet along with an extract from a control area of the substrate and a suitable calibration standard. The layer is air-dried and then developed in a previously equilibrated tank with the mobile phase ethyl acetate–ethanol–water (75:35:30). Evaluation is performed by viewing the chromatograms under shortwave (254 nm) and longwave (366 nm) UV light and in ambient light and recording the colors, R_f values, and relative concentrations of all bands in each ink sample. If more information is needed to distinguish similar inks, additional recommended TLC methods are the use of silica gel and a different mobile phase [*n*-butanol–ethanol–water (50:10:15); use of different layers and appropriate mobile phases; evaluation of chromatograms in RIR and IRL; and densitometric scanning of chromatograms to get relative concentrations of the components. Other analytical techniques suggested for obtaining additional information are Fourier transform infrared spectrometry, gas chromatography (GC) and GC/mass spectrometry (GC/MS), high-performance column liquid chromatography (HPLC), microspectrophotometry transmittance or reflectance curves, spectrofluorometry emission spectra, X-ray fluorescence spectrometry (for inorganic components), and capillary electrophoresis.

Guide E-1798-04 gives detailed interpretation procedures that allow an examiner to accurately discriminate between ink formulas, as well as significantly reducing false matches of ink samples from different sources or incorrectly differentiating ink samples from a common source. The results are based on the TLC procedures in Guide E-1422 and comparison against a library of standard inks.

VISUAL CHROMATOGRAM COMPARISON SOFTWARE

A software tool has just now become available for visual comparison of multiple thin layer chromatograms. The Image Comparison Viewer (ICV) from Camag (Muttenz, Switzerland) will greatly aid comparison of different ink sample chromatograms, and sample chromatograms with standard chromatograms.

Chromatogram images are obtained with a CCD (charge coupled device) camera in Camag's DigiStore 2 image documentation system controlled by WinCATS software. The ICV allows simultaneous display, side-by-side, of chromatogram images in separate tracks from the same TLC plate or different plates.

The process involves three steps: selecting the tracks, comparing samples, and printing a report. The tracks of interest are marked and transferred to the ICV with information such as position, width, length, and sample identification (I.D.) taken from the winCATS analysis file. During visual comparison, a table on top of the images automatically displays for each track important data such as sample I.D., original analysis file name, track number, source, etc. The printed report includes the images and the table, assuring traceability of the generated data.

RECENT APPLICATIONS OF TLC IN FORENSIC INK ANALYSIS

Dating Questioned Documents

TLC and GC/MS can be used to determine the age of writing inks on questioned documents.[2] Dating techniques that use TLC are based on analysis of ink dye components, while GC/MS can date inks based on detection, identification, and quantification of the residues of the vehicle solvents in ink lines. Capability to date most ballpoint, porous tip, roller pen, stamp pad, and jet printer inks by analyzing the single ink entry, stamp impression, or printed test in question was shown by testing in the Division of Identification and Forensic Science, Israel Police Headquarters.

Identification of Unknown Black Inks

A college organic chemistry laboratory experiment was devised to demonstrate forensic analysis by having students identify unknown black inks (liquid, ballpoint, and felt tip) by TLC comparison of zone colors and R_f values to standard inks.[3] Silica gel G (gypsum binder) plates are developed with two mobile phases: ethyl acetate–sec-butanol–*n*-propanol–absolute ethanol–water (1:1:1:1:1) and *n*-butanol–absolute ethanol–water–acetic acid (60:10:20:0.5). A second experiment was designed to introduce undergraduate chemistry students to forensic science by applying TLC to decide if more than one ballpoint pen was used to write signatures on a questioned will.[4]

TLC Separation of Pigments in Inks of Different Colors

Pigments in blue, black, green, and purple writing inks were separated into multiple bands on silica gel developed with 95% aqueous ethanol.[5] The inks were initially diluted 1:5 with 95% alcohol before spotting 5 μl initial zones. This is a simple system for comparing commercial inks based on observation of chromatograms under UV light and in visible light.

Analysis of Writing Inks in Changed Documents

Plates are usually developed by capillary flow in the ascending direction in a conventional, large volume glass chamber presaturated for ~15 min with mobile phase vapor. However, in a study of documents changed accidentally or on purpose, by staining with liquids (e.g., coffee) or by exposure to high temperature, a Type DS II horizontal sandwich chamber Type DS II (Chromdes, Lublin, Poland) was used for analysis of blue writing inks from 15 different ballpoint and roller pens.[6] The DS II gave advantages of a small volume of mobile phase and immediate development without vapor saturation. Lines (2 cm) of ink drawn on paper were cut with a scalpel and extracted for 10 min at 100°C in sealed capillaries with dimethylformamide–chloroform (9:1), the layer was Merck (Darmstadt, Germany) silica gel 60, and the mobile phase was ethyl acetate–isopropanol–water–acetic acid (30:25:10:1). The obtained chromatograms were examined in visible light and at 254 and 366 nm to assess the changes, which were greatest in samples treated with raised temperature.

Analysis of Thermal Transfer Inks

TLC with Merck silica gel 60 TLC plates and hexane–methyl ethyl ketone–ethyl acetate (80:3:17) mobile phase was used successfully to analyze 81 different samples, which included 54 thermal transfer printer samples (43 photographic prints on paper and 11 plastic card samples) and 27 printer ribbons, with excellent resolution of the colors.[7] Pyridine was used for extraction of 5 mm hole punches from paper samples, 5 × 5 mm cuttings from ribbons, and scalpel scrapings from cards. Developed plates were examined in daylight and under 254 and 366 nm UV light, and a Foster and Freeman, Ltd. (Evesham, Worcestershire, UK) Video Spectral Comparator 2000 High Resolution (VSC 2000 HR) was used to document and record the TLC plates in black and white and color modes, and to observe and record IRL properties on the TLC plate produced from the D2T2 (dye diffusion thermal transfer) process dyes and/or overlays.

Differentiation of Black Gel Inks

Black gel inks from 29 pens and 17 companies were differentiated by TLC on Merck silica gel 60 layers developed with ethyl acetate–ethanol–water (75:35:30) mobile phase. A VSC 2000 HR was used to examine and document the TLC plates in visible, UV, and near IR reflectance (IRR) modes. Written gel ink lines on filter paper were sampled by extracting 1.3 mm punch holes with 20 μl of ethanol–water (1:1). Spot tests and capillary column GC/MS were also used for ink analyses in this study.[8] A flowchart was developed allowing systematic determination of a questioned ink.

Analysis of Red Inks by TLC/MS

The direct analysis of separated extracts of ink from eight red pens on hydrophobic reversed phase (RP) octyl (C8) chemically bonded silica gel TLC plates using a surface sampling/electrospray emitter probe coupled with a triple quadrupole linear ion trap mass spectrometer was demonstrated.[9] Effects of the composition and flow rate of the eluting solvent and layer surface scan rate on sensitivity and preservation of TLC resolution were studied. The C8 layer was spotted with extracts of 1×1 cm squares of Whatman (Florham Park, New Jersey, U.S.A.) 3 mm chromatography paper covered with ink writing (sonication for 10 min with 0.5 ml of ethanol in a 1.5 ml Eppendorf tube). The mobile phase used for the separation was methanol–water (80:20) containing 200 m*M* ammonium acetate. This TLC/MS method has great potential for forensic ink analysis if it can be extended to the hydrophilic silica gel layers usually used.

Differentiation of Colored Inkjet Printer Cartridges

TLC and HPLC were combined for the differentiation of colored inks of 23 inkjet cartridges from the Canon, Epson, Xerox, and Hewlett Packard companies.[10] The yellow, cyan, and magenta inks stored in individual compartments of the cartridges used to produce a full color image were the target inks. Samples drawn from the cartridges were diluted with ethanol–water (1:1), while small areas of a paper color printout were cut and extracted with pyridine–water (4:1). TLC was on a Macherey-Nagel (Dueren, Germany) Alugran silica gel UV_{254} plate (0.2 mm layer thickness) developed with ethyl acetate–ethanol–water (70:35:30) or *n*-butanol–ethanol–water (10:2:3), and detection was made under white and long wavelength UV light. HPLC was on a chemically bonded C18 RP column with a mobile phase gradient composed of aqueous ammonium acetate and methanol, and detection was with a photodiode array (PDA) detector at 400, 540, and 650 nm. Data from the two methods provided a good tool for discriminating the brand of the cartridges, and a database of ink profiles was generated.

The U.S. International Ink Library

The U.S. Secret Service and Internal Revenue Service National Forensic Laboratory jointly maintain the largest known forensic collection of writing inks in the world, which is composed of over 8500 ink standards collected worldwide dating back to the 1920s. One hundred pens were randomly obtained from a variety of sources, and a study was conducted to evaluate the reliability of matching their respective ink concentrations with standards.[11] A writing sample from each pen was made on Whatman No. 2 filter paper, 5–10 hole punches of ~1 mm diameter were removed from each ink line, and the punches were extracted with an 5 μl of pyridine for ballpoint inks and ethanol–water (1:1) for fiber tip, roller ball, and gel inks in a glass vial by agitation for 20–30 sec. TLC was performed in accordance with Section 7.7 in the ASTM Standard Guide E-1422-05 (described above) using a silica-gel layer and the mobile phase ethyl acetate–ethanol–water (70:35:30). Optical comparison between samples and standards was made using a VSC 2000 HR according to ASTM Standard Guide E-1789-04 (described above). It was found that 15 of the 100 inks evaluated were unsuitable for identification because they lacked any extractable colored components necessary for comparison with standards in the library. The remaining 85 pens examined were categorized into 44 different ink formulations. Three of the inks did not match any specimen on record; one of these inks was similar to an ink from an identical brand of pen in the database, but had a modified formulation. The U.S. International Ink Library is an invaluable tool for reliable forensic ink analysis.

Differentiation of Blue Ballpoint Inks by HPTLC

In a study of 31 blue ballpoint pen inks,[12] Merck silica-gel HPTLC plates were used instead of the usual TLC plates. HPTLC plates are coated with a thinner layer having a smaller mean particle size and particle size distribution, leading in general to higher resolution and faster separations. Ink entries of about 1 cm in length were scraped from paper with a scalpel and extracted by standing in the dark for 24 hr in a sealed conical vial containing 15 μl of methanol. Aliquots of the extract (2.5 and 5 μl) were applied in 5 mm long bands to the plate using a Camag Linomat automated instrument. Development was carried out in a horizontal chamber with two sequential mobile phases: *n*-butanol–isopropanol–water (10:5:0.5) and *n*-butanol–ethanol–water–acetic acid (15:3:3.9:0.45). The resulting chromatograms were scanned at 590 nm with a Camag Scanner III, and detection and semiquantitative analysis were accomplished using the winCATS software. On the basis of number of spots, their R_f values, and their

colors, plus the semiquantitative data, 12 classes of ballpoint inks were distinguished on a qualitative basis. The tested samples could be further discriminated into 18 classes by calculating their relative scan peak intensities. Thirty-seven pairs were not discriminated.

Further classification was obtained by direct analysis of pen strokes on paper (without elution) using laser desorption ionization (LDI) time-of-flight (TOF) mass spectrometry. However, only basic dyes and pigments could be identified by positive mode LDI/MS.

Effect of Electronic Beam Radiation on Forensic Evidence

Since late-2001, when anthrax-tainted letters were discovered in the United States, the U.S. Postal Service began to use an electron beam irradiation process for destroying such biological agents. Some published reports indicated missing or additional dye bands in thin layer chromatograms of irradiated writing inks compared with control (non-irradiated) samples, so writings from 97 different black, blue, red, green, and yellow inks on paper, from ballpoint, gel, plastic/felt tip, and rollerball pens, were tested using TLC with a video spectral comparator and standard mail irradiation conditions.[13]

Extraction and TLC analysis on Merck silica gel 60 layers was carried out in accordance with ASTM Guide E-1422-01, which is essentially the same as E-1422-05 described above. The only deviation from the ASTM method was that the spotted plate was oven dried at 100°C for 10 min, instead of being air dried, before mobile phase development.

The study found that none of the irradiated inks showed significant optical or chemical differences from control samples based on thin layer chromatograms. Therefore, it was proven that evidence is conserved after the irradiation treatment.

CONCLUSION

TLC and HPTLC are the most widely used methods today for forensic analysis of ink formulations and their writings. The methods are simple to perform and inexpensive compared with the other spectrometric and chromatographic methods that have been applied less often. The availability of the International Ink Library is a great advantage for comparative purposes, and its value will increase as more samples are collected in the future. Combination of TLC with MS can give positive identification of ink components from molecular weight data.

Forskolin Purification

Hiroyuki Tanaka
Yukihiro Shoyama
Graduate School of Pharmaceutical Sciences, Kyushu University, Fukuoka, Japan

INTRODUCTION

Forskolin, a labdane diterpenoid, was isolated from the tuberous roots of *Coleus forskohlii* Briq. (Lamiaceae).[1] *C. forskohlii* has been used as an important folk medicine in India. Forskolin was found to be an activator of adenylate cyclase,[2] leading to an increase of c-AMP, and now a medicine in India, Germany, and Japan. The production of forskolin is completely dependent on the commercial collection of wild and cultivated plants in India. We have already set up the production of monoclonal antibodies (MAbs) against forskolin.[3] The practical application of enzyme-linked immunosorbent assay (ELISA) for the distribution of forskolin contained in clonally propagated plant organs and the quantitative fluctuation of forskolin depend on the age of *C. forskohlii*.[4,5] As an extension of this approach, we present the production of the immunoaffinity column using antiforskolin MAb and its application.[6]

MATERIALS AND METHODS

Chemicals

Bovine serum albumin (BSA) was provided by Pierce (Rockford, Illinois, U.S.A.). Forskolin and 7-deacetylforskolin were isolated from the tuberous root of *C. forskohlii*, as previously reported.[1] 1-Deoxyforskolin, 1,9-dideoxyforskolin, and 6-acetyl-7-deacetylforskolin were purchased from Sigma Chemical Company (St. Louis, Missouri, U.S.A.). The mixture (approximately 20 mg) of forskolin and 7-deacetylforskolin, purified by the immunoaffinity column, was acetylated with pyridine and acetic anhydride mixture (each 100 ml) at 4°C for 2 hr to give pure forskolin.

Preparation of Immunoaffinity Column Using Anti-Forskolin Monoclonal Antibody[6]

Purified IgG (10 mg) in PBS was added to a slurry of CNBr-activated Sepharose 4B (600 mg; Pharmacia Biotech) in coupling buffer (0.1 *M* $NaHCO_3$ containing 0.5 *M* NaCl). The slurry was stirred for 2 hr at room temperature and then treated with 0.2 *M* glycine at pH 8.0 for blocking of activated groups. The affinity gel was washed four times with 0.1 *M* $NaHCO_3$ containing 0.5 *M* NaCl and 0.1 *M* acetate buffer (pH 4.0). Finally, the affinity gel was centrifuged and the supernatant was removed. The immunoaffinity gel was washed with phosphate buffer solution (PBS) and packed into a plastic mini-column in volumes of 2.5 ml. Columns were washed until the absorption at 280 nm was equal to the background absorption. The columns were stored at 4°C in PBS containing 0.01% sodium azide.

Direct Isolation of Forskolin from Crude Extractives of Tuberous Roots and Callus Culture of *C. forskohlii* by Immunoaffinity Column

The dried powder (10 mg dry weight) of tuberous root was extracted five times with diethyl ether (5 ml). After evaporation of the solvent, the residue was redissolved in MeOH and diluted with PBS (1 : 16), and then filtered by Millex-HV filter (0.45 μm filter unit; Millipore Products, Bedford, Massachusetts, U.S.A.) to remove insoluble portions. The filtrate was loaded onto the immunoaffinity column and allowed to stand for 90 min at 4°C. The column was washed with the washing buffer solution (10 ml). After forskolin disappeared, the column was eluted with PBSM (45%) at a flow rate of 0.1 ml/min. The fraction containing forskolin was lyophilized and extracted with diethyl ether. Forskolin was determined by TLC developed with C_6H_6–EtOAc (85 : 15) [Rf; forskolin (0.21), 7-deacetylforskolin (0.16)] and ELISA.

RESULTS AND DISCUSSION

We established a simple and reproducible purification method for forskolin using an immunoaffinity column chromatography method. Because forskolin is almost insoluble in water, various buffer solutions were tested for the solubilization of forskolin. It became evident that 6% MeOH in PBS was necessary for the solubilization of forskolin.[3,5] Next, the elution system for the immunoaffinity column was investigated by using various elution buffers based on PBS. Only 9% of bound forskolin can be recovered by the PBS supplemented with 10% of MeOH. The forskolin concentrations eluted increased rapidly from 20% of MeOH, and reached the optimum at 45% of MeOH.

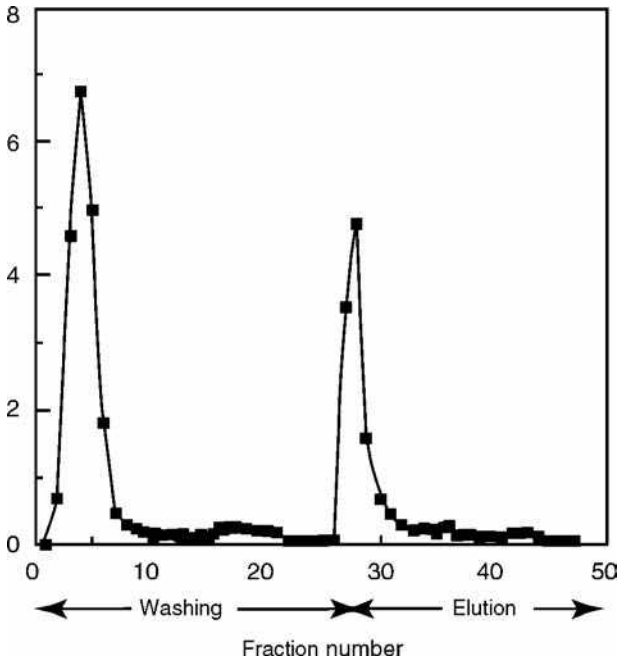

Fig. 1 Elution profile of forskolin in the tuberous root of *C. forskohlii* by purification on immunoaffinity column chromatography. The column was washed with PBSM, then eluted by PBS containing 45% of methanol after the forskolin disappeared. Individual fractions were assayed by ELISA.

To assess the capacity and the recovery of forskolin from the affinity column, 30 μg of forskolin was added and passed through the column (2.5 ml of gel), and the forskolin content was analyzed by ELISA. After washing with 5 column volumes of PBST, 22.5 μg of forskolin remained bound and was then completely eluted with the PBS containing 45% of MeOH. Therefore, the capacity of affinity column chromatography was determined to be 9.4 μg/ml.

The crude diethyl ether extracts of the tuberous root of *C. forskohlii* were loaded onto the immunoaffinity column chromatography system, washed five times with PBS containing 6% of MeOH, and eluted with the PBS containing 45% of MeOH. Fig. 1 shows a chromatogram detected by ELISA. Fractions 2–8 contained 45 μg of forskolin that were over the column capacity, together with the related compounds 1-deoxyforskolin, 1,9-dideoxyforskolin, 7-deacetylforskolin and 6-acetyl-7-deacetylforskolin, and other unknown compounds which were detected by TLC, as indicated in Fig. 2. The peak of fractions 26–30 shows the elution of forskolin (21 μg) eluted with the PBS containing 45% of MeOH. Forskolin eluted by washing solution (fractions 2–8) was repeatedly loaded and finally isolated. However, forskolin purified by the immunoaffinity column chromatography was still contaminated with a small amount of 7-deacetylforskolin (Fig. 2) because this compound has a 5.5% cross-reactivity against Mab, as previously indicated.[3]

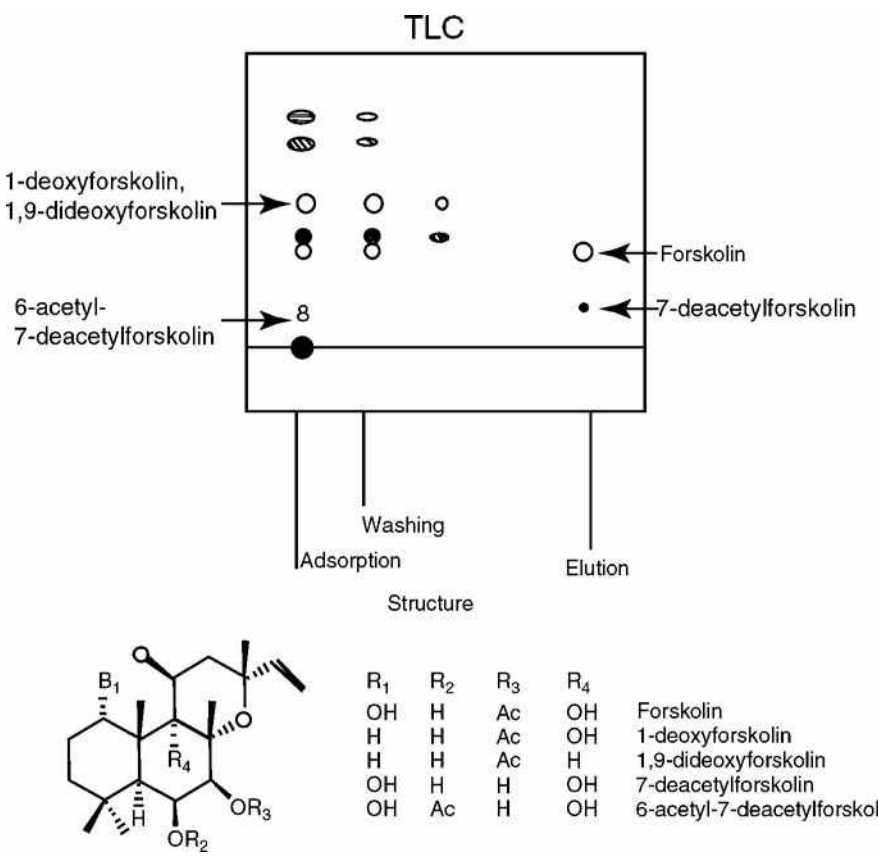

Fig. 2 TLC of adsorption, washing, and elution solutions, and structures of forskolin and the related compounds.

Therefore, the mixture was treated with pyridine and acetic anhydride at 4°C for 2 hr to give pure forskolin. In our case, the stability of antibody against PBS containing 45% MeOH is also quite high, because the immunoaffinity column has been used over 10 times, under the same conditions, without any substantial loss of capacity. Therefore, we concluded that the PBS supplemented with 45% MeOH can be routinely used as an elution buffer solution.

Frontal Chromatography

Peter Sajonz
Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

Frontal chromatography is a mode of chromatography in which the sample is introduced continuously into the column. The sample components migrate through the column at different velocities and eventually break through as a series of fronts. Only the least retained component exits the column in pure form and can, therefore, be isolated; all other sample components exit the column as mixed zones. The resulting chromatogram of a frontal chromatography experiment is generally referred to as a breakthrough curve, although the expression *frontalgram* has also been used in the literature.[1]

The exact shape of a breakthrough curve is mainly determined by the functional form of the underlying equilibrium isotherms of the sample components, but secondary factors such as diffusion and mass-transfer kinetics also have influence. The capacity of the column is an important parameter in frontal chromatography, because it determines when the column is saturated with the sample components and, therefore, is no longer able to adsorb more sample. The mixture then flows through the column with its original composition.

THE USE OF FRONTAL CHROMATOGRAPHY

Frontal chromatography can also be called *adsorptive filtration* because it can be used for the purpose of filtration. The purification of gases and solvents are two classical applications of frontal chromatography. Another important use is the purification of proteins, where a frontal chromatography step is used in the initialpurification procedure.[2,3]

One of the most important applications of frontal chromatography is the determination of equilibrium adsorption isotherms. It was introduced for this purpose by Shay and Szekely and by James and Phillips.[4,5] The simplicity as well as the accuracy and precision of this method are reasons why the method is so popular today and why it is often preferred over other chromatographic methods, for example, elution by characteristic points (ECP) or frontal analysis by characteristic points (FACP).[6,7] Frontal chromatography as a tool for the determination of single-component adsorption isotherms will be discussed in the following section.

FRONTAL CHROMATOGRAPHY FOR THE DETERMINATION OF ISOTHERMS

Theory

First, the column is filled only with sample at concentration C_n; then, a step injection is performed (i.e., sample with the concentration C_{n+1} is introduced into the column). This results in a breakthrough curve, as shown in Fig. 1. The amount adsorbed at the stationary phase Q_{n+1} can be calculated by

$$\begin{aligned} Q_{n+1} &= q_{n+1} Vs \\ &= (C_{n+1} - C_n)(V_{R,n+1} - V_0) + q_n V_s \end{aligned}$$

where q_n and q_{n+1} are the initial and final sample concentrations, respectively, in the stationary phase and C_n and C_{n+1} are the initial and final sample concentrations in the mobile phase, respectively. V_s is the volume of adsorbent in the column, V_0 is the holdup volume, and $V_{R,n+1}$ is the retention volume of the breakthrough curve. The retention volume is calculated from the area over the breakthrough curve:

$$V_R = \int_0^\infty \frac{(C_{n+1} - C)dV}{C_{n+1} - C_n}$$

The retention volume defined by the area method always gives the theoretically correct result for the amount adsorbed. In practice, it is, however, often easier and better to use the retention volume from half-height [i.e., at the concentration $(C_{n+1} + C_n)/2$] or the retention volume derived from the inflection point of the breakthrough curve. The reason for this is that the calculation of the area incorporates signal noise and it is very dependent on the integration limits. This is often a problem, especially when the mass transfer is slow, because, in this case, the plateau concentration C_{n+1} is only reached slowly and, therefore, systematic errors in the calculated area occur. It has been shown that the use of the retention volumes derived from the inflection point or the half-height gives satisfactory results. The half-height method is, however, easier to use and slightly more accurate than the inflection-point method.[5]

It has to be noted that the half-height and inflectionpoint methods do not give reliable results if the isotherm is

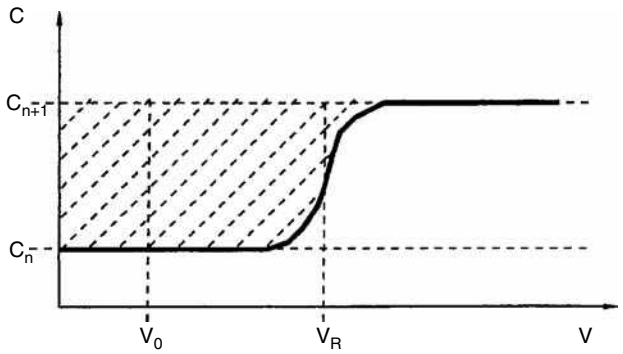

Fig. 1 Example of a frontal chromatography experiment; breakthrough curve of a single component.

concave upward and ascending concentration steps are performed. The same is true for a convex upward isotherm and descending concentration steps. The reason for this is that, in these cases, a diffuse breakthrough profile is obtained and, consequently, errors are made in the accurate determination of the retention volumes when they are derived from the half-height or the inflection point. The diffuse profile can, however, be used for the determination of isotherms by FACP.

MODES OF FRONTAL ANALYSIS

There are two possibilities for performing a frontal chromatography experiment for the purpose of the determination of equilibrium isotherms. The step-series method uses a series of steps starting from $C_n = 0$ to C_{n+1}. After each experiment, the column has to be reequilibrated and a new step injection with a different end concentration C_{n+1} can be performed. In the staircase method, a series of steps is performed in a single run with concentration steps from 0 to C_1, C_1 to C_2, ..., C_n to C_{n+1}. The column does not have to be reequilibrated after each step and, therefore, the staircase method is faster than the step-series method. Both modes of frontal analysis give very accurate isotherm results.

Determination of Multicomponent Isotherms by Frontal Analysis

It is possible to extend the frontal chromatography method for the measurement of binary and multicomponent isotherms. In this case, the profiles are characterized by successive elution of several steep fronts. The use of these profiles for the determination of competitive isotherms in the binary case has been developed by Jacobsen et al.[8]

Combination of Frontal Analysis with Chromatographic Models

Frontal chromatography can be used in combination with chromatographic models to study mass-transfer and dispersion processes (e.g., the equilibrium dispersive or the transport model of chromatography.[7])

CONSTANT PATTERN, SELF-SHARPENING EFFECT, SHOCK-LAYER THEORY

Frontal chromatography generally requires the adsorption isotherm to be convex upward if the step injection is performed with ascending concentration (i.e., $C_{n+1} > C_n$) because, in this case, the profile of a breakthrough curve tends asymptotically toward a limit. After this constant profile has been reached, the profile migrates along the column without changing its shape. This state is called constant pattern.[9] This phenomenon arises because the self-sharpening effect associated with a convex isotherm is balanced by the dispersive effect of axial dispersion and a finite rate of mass-transfer kinetics. If the equilibrium adsorption isotherm is linear or concave upward, no constant pattern behavior is observed and the breakthrough curve spreads constantly during its migration through the column. This case is unfavorable. If the adsorption isotherm is concave upward, then a descending concentration step (i.e., $C_{n+1} < C_n$) leads to the formation of a constant pattern.

A very detailed study of the combined effects of axial dispersion and mass-transfer resistance under a constant pattern behavior has been conducted by Rhee and Amundson.[10] They used the *shock-layer* theory. The shock layer is defined as a zone of a breakthrough curve where a specific concentration change occurs (i.e., a concentration change from 10% to 90%). The study of the shock-layer thickness is a new approach to the study of column performance in non-linear chromatography. The optimum velocity for minimum shock-layer thickness (SLT) can be quite different from the optimum velocity for the height equivalent to a theoretical plate (HETP).[9]

INSTRUMENTATION

There are many possibilities for performing frontal chromatography experiments. In general, standard chromatographic equipment can be used. The preparation of a series of solutions of known concentration can be easily accomplished by using a chromatograph with a gradient delivery system applied as a mobile-phase mixer. If this system is not available, then the solutions have to be prepared manually. Two pumps can be used to perform the step injections or a single pump with a gradient delivery system. An injector having a sufficient large loop can also

be used. Even a single pump without gradient delivery system can be used. In this case, the step injection has to be made by manually switching the solvent inlet line to the prepared sample reservoir. The choice of the system is dependent on the application. For fast and accurate measurements of adsorption isotherms, a multisolvent gradient system with two pumps and a high-pressure mixer is a very good choice.

Fuel Cells: Reversed-Flow GC

Dimitrios Gavril
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

Abstract
Fuel cells are developed as a viable alternative for clean energy generation. The rational operation of the fuel cell units is closely related to the development of very active, selective, and poison-resistant catalysts.

Reversed-flow gas chromatography (RF-GC) has been successfully used to characterize solid catalysts under conditions compatible with the operation of real catalysts. RF-GC is not limited to chromatographic separation; since RF-GC is accompanied by suitable mathematical analysis of the chromatographic data, the simultaneous determination of various physicochemical parameters is possible. Thus, various catalytic processes related to the operation of fuel cell units such as steam reforming, catalytic partial oxidation, autothermal reforming, as well as water-gas shift (WGS) reaction and selective CO oxidation can be studied.

The use of RF-GC methodologies has been successfully extended to the study of selective CO oxidation over various fuel processing candidate catalysts, such as monometallic Rh/SiO_2, bimetallic $Pt–Rh/SiO_2$, and nanosized $Au/\gamma\text{-}Al_2O_3$, under different conditions, compatible with the operation of fuel cell units. These studies concern: 1) activity/selectivity measurements; 2) the determination of kinetic rate constants; and 3) investigation of the surface topography.

INTRODUCTION

Fuel cell technology applications vary from portable/micro power and transportation through to stationary power for buildings and distributed generation. Various fuel cell applications operating at different temperatures have been developed:[1–3] solid polymer fuel cells also known as proton-exchange membrane (PEM) fuel cells operate at ~80°C, alkaline fuel cells (AFC) at ~100°C, phosphoric acid fuel cells (PAFC) at ~200°C, molten carbonate fuel cells (MCFC) at ~650°C, and solid oxide fuel cells (SOFC) at higher temperatures of 800–1,100°C. A series of advantages such as low operating temperature, low weight, compactness, long stack life, suitability to discontinuous operation, as well as potential for low cost make PEM fuel cells the leading candidates for mobile power and/or for small power applications.

The rational operation of the fuel cell units is closely related to the development of very active, poison-resistant catalysts, which result in small catalytic volumes, durability under steady-state and transient conditions, low cost, and versatility to variations in fuel/feed composition.

The method used to produce hydrogen for the fuel cell is a critical factor in the design of fuel processing catalysts. Chemical processes such as steam reforming, catalytic partial oxidation (CPO), and autothermal reforming (ATR) are used for reforming fuels and to produce syngas (a mixture of carbon monoxide and hydrogen); the water-gas shift reaction (WGS) consumes carbon monoxide and water vapors to produce more hydrogen and carbon dioxide. However, trace amounts of carbon monoxide in the hydrogen-rich stream deteriorate the efficiency of the PEM fuel cell by poisoning the platinum (or Pt–Ru) anode, accelerated at CO levels higher than 50 ppm. Another catalytic process such as selective carbon monoxide oxidation (SCO) is considered to be the most promising and the lowest-cost approach.[4] An efficient SCO catalyst must be highly active in CO oxidation at temperatures compatible with the operation of the PEM fuel cell (70–100°C) and very selective toward CO_2 formation.

The characterization of fuel processing catalysts is a necessary step following their design and it usually involves activity/selectivity tests, and investigation of the kinetics of the related reactions as well as of the nature of the active sites. All the above processes are closely related to diffusion, adsorption/desorption, and surface reaction phenomena. Chromatographic separation is also a physicochemical process based on diffusion, adsorption, and chemical kinetics. Based on the broadening factors embraced by the van Deemter equation, precise and accurate physicochemical measurements have been done during the last few decades by gas chromatography, using relatively cheap instrumentation and very simple experimental setup.[4,5]

In conventional GC a gaseous mobile phase flows in a defined direction over a stationary phase or packing, resulting in the selective retention of solute components. In reversed-flow gas chromatography (RF-GC) the system is modified; another column (diffusion column) is placed perpendicularly in the center of the chromatographic

column (sampling column). The carrier gas flows continuously through the sampling column, while it is stagnant in the diffusion column, as is shown in Fig. 1. The reversing of the carrier gas flow for short time intervals results in extra chromatographic peaks on the continuous concentration–time curve. Thus repeated sampling of the physicochemical phenomena occurring in the diffusion column is achieved, and by using appropriate mathematical analysis, the values of the relevant physicochemical quantities are determined. In contrast with conventional GC, where the mobile phase is the center of interest, in RF-GC the solid or liquid substance placed in the diffusion column is under investigation. Thus RF-GC can be assumed as an inverse gas chromatographic method.

EXPERIMENTAL

The experimental setup of RF-GC for the study of catalytic processes comprises[6–11] the "sampling cell," formed by the sampling column $l' + l$ and the diffusion column L, which is connected perpendicularly to the middle of the sampling column. The ends D_1 and D_2 of the sampling column are connected through a four-port valve to the carrier gas inlet and the detector, as shown in Fig. 1. A conventional gas chromatograph is equipped with the appropriate detector (e.g., flame ionization, thermal conductivity). A separation column L' may also be incorporated in the GC oven. This column can be filled with the appropriate material for the separation of the carrier gas constituents due to the reactants and possible reaction products, and it can be heated at the same or at a temperature different from that of the sampling cell.

Performing flow perturbations, negative and positive abrupt fronts appear in the chromatogram, forming the so-called sampling peaks like those shown in Fig. 2.[8] The volumetric carrier gas flow rate does not affect the physicochemical phenomena occurring in the diffusion column, but only the speed of the sampling procedure.

The fuel processing catalyst can be studied either under non-steady-state conditions, having placed it near the injection point at the closed end of the diffusion column, or under steady-state conditions by putting it in the middle of the sampling column, as is shown in Fig. 1. The input of the studied adsorbate under non-steady-state conditions is done by injecting a small amount (e.g., 1 ml of CO at atmospheric pressure) at the closed end of the diffusion column, L (c.f. Fig. 1).

The gas atmosphere of the hydrogen-rich fuel/feed stream (containing CO, O_2, H_2, CO_2, H_2O), which passes through the fuel processing catalyst, can be easily simulated either by using a flowing system with mass flow controllers or by using a carrier gas mixture. Thus, in order to examine the effect of various H_2-rich feed/stream compositions in CO adsorption, three hydrogen/helium mixtures with different compositions were prepared by B.O.C. Gases GmbH (Germany) and were used as carrier gases.[8]

THEORY

All determinations by RF-GC are based on experimental chromatographic data like the height or the area of the extra sample peaks that appear in the chromatogram after each flow reversal, forming the "sampling peaks" as in Fig. 2.[8] The whole treatment of experimental data is based on the fact that the heights of the "sampling peaks" are described by a clear function of time comprising the sum of four exponentials:[6–11]

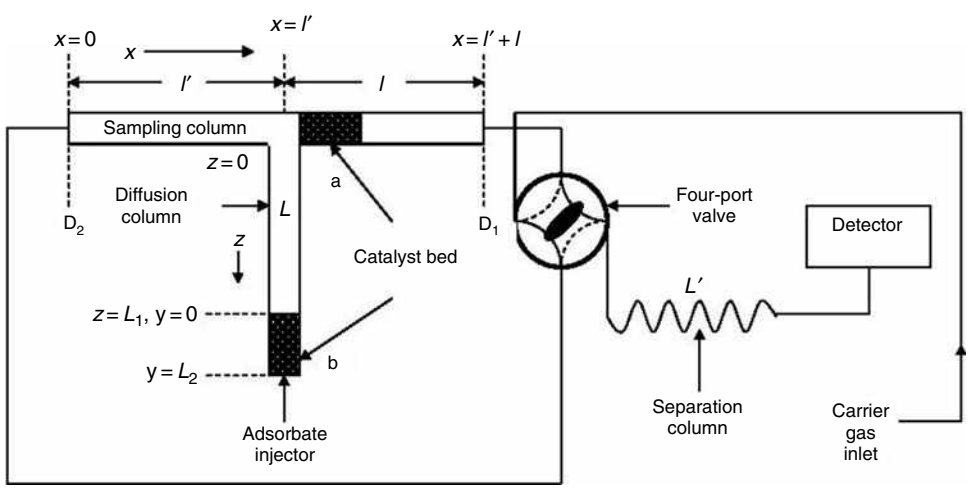

Fig. 1 Experimental setup used by reversed-flow gas chromatography for the characterization of solid catalysts: a) under steady-state conditions, with catalyst bed being put at a short length of sampling column l, near the junction of diffusion and sampling columns; b) under non-steady-state conditions, with catalytic bed being put at the top of diffusion column L.

Source: From An inverse gas chromatographic instrumentation for the study of carbon monoxide's adsorption on Rh/SiO_2, under hydrogen-rich conditions, in Instrum. Sci. Technol.[8]

$$H^{1/M} = \sum_{i=1}^{4} A_i \exp\,(B_i t) \tag{1}$$

where H are the heights of the experimentally obtained chromatographic peaks, M the response factor of the detector and t the time from the beginning of the experiment. The values of the pre-exponential factors A_i and the corresponding coefficients of time B_i are easily determined from the chromatogram by using PC programs of non-linear least-squares regression (c.f. Appendix of Ref. 11).

POTENTIAL OF THE METHODOLOGY AND INDICATIVE RESULTS

Reversed-flow gas chromatography has all the advantages of a dynamic method such as GC and moreover it gives the opportunity for catalytic characterizations under either steady- or non-steady state conditions in a simple experiment under conditions compatible with the operation of real catalysts. All the catalytic processes related to the operation of PEM fuel cells, e.g., autothermal reforming or selective CO oxidation, can be studied. The hydrogen-rich fuel/feed stream atmosphere (CO, O_2, H_2, CO_2, H_2O, etc.) is easily and quantitatively achieved either by using a flowing system with mass-flow controllers or by using prepared carrier gas mixtures.

Chromatographic separation is widely used for conventional catalytic activity/selectivity measurements. RF-GC is not limited to chromatographic separation, since it is accompanied by suitable mathematical analysis of the chromatographic data (e.g., the height or the area of the experimentally obtained sampling peaks), which makes possible the simultaneous determination of various physicochemical parameters. Thus, 1) time-dependent, X_t, and overall, X, conversions, under either steady- or non-steady-state conditions;[6,7] 2) adsorption, k_1, desorption, k_{-1}, and surface reaction, k_2, rate constants and the respective activation energies, E_a;[8] 3) local adsorption energies, ε, local adsorption isotherms, $\theta(p,T,\varepsilon)$, local monolayer capacities, c^*_{max}, and adsorption energy distribution functions, $f(\varepsilon)$, for the adsorption of gases on heterogeneous surfaces;[9,10] 4) the energy of the lateral molecular interactions as well as the surface diffusion coefficients for physically adsorbed or chemisorbed species on heterogeneous surfaces;[10,11] and 5) the nature of the various groups of active sites of solid catalysts[10] have been determined.

Furthermore, the results derived by utilizing RF-GC methodologies for the investigation of the adsorption of CO, O_2, and CO_2 as well as the oxidation of CO over well-studied silica-supported Pt–Rh bimetallic catalysts are in agreement with those obtained by using different techniques and methodologies for the same catalysts, ascertaining the potential of RF-GC for reliable and accurate catalytic characterizations.

The utilization of RF-GC has been extended to CO adsorption under H_2-rich conditions (which is an elementary step of selective CO oxidation), initially over a silica-supported rhodium catalyst, which combines high selectivity and satisfactory activity.[8] The influence of the hydrogen amount in catalyst adsorptive behavior was studied by using three different composition carrier gas hydrogen/helium mixtures. Their compositions were 25.05% H_2 + 74.95% He (v/v, 99.999% pure), 49.95% H_2 + 50.05% He (v/v, 99.999% pure), and 75.05% H_2 + 24.95% He (v/v, 99.999% pure).

Rate constants for carbon monoxide's adsorption, desorption, and irreversible surface binding (e.g., its chemisorption), at different hydrogen compositions, over the

Table 1 Rate constants for CO adsorption (k_1), desorption (k_{-1}), and irreversible surface binding (k_2), at 373.2 K, for a silica-supported rhodium catalyst, under three different H_2-rich carrier-gas compositions.

% H_2	T (K)	$10^2\ k_1$ (sec^{-1})	$10^2\ k_{-1}$ (sec^{-1})	$10^4\ k_2$ (sec^{-1})
25.05	373.2	0.246	1.02	3.34
49.95	373.2	1.11	1.33	4.36
75.05	373.2	11.4	1.83	6.51

studied silica-supported rhodium catalyst at 373.2 K are referred in Table 1 and their variation against hydrogen percentage in the carrier gas mixture is shown in Fig. 2.

The values of the irreversible surface binding rate constants, k_2, increase with increasing carrier gas hydrogen content. Similarly, the desorption rate constants being two orders higher than those of irreversible surface binding are also found to increase with hydrogen amount. Moreover, the adsorption rate, k_1, was found to increase drastically with increasing hydrogen percentage compared to the increase of k_{-1} and k_2.

More quantitative information for the adsorption of carbon monoxide over the studied catalyst was extracted from the variation of local isotherms θ against the local adsorbed concentration of the adsorbate, c_s^*, shown in Fig. 3 of Ref. 8. The values of maximum local monolayer capacity (corresponding to $\theta = 1$) were easily determined from those plots. These values, referred in Table 2, also ascertained that higher amounts of carbon monoxide are present on catalyst surface as the hydrogen amount increases.

From the above results it is obvious that higher amounts of CO can be adsorbed on Rh/SiO_2 as the carrier gas hydrogen amount increases. The increase of the CO adsorption rate, k_1, indicated that the respective activation energy should decrease with increasing H_2 content and consequently higher amounts of CO should be bound less strongly on the studied catalyst active sites at 373.2 K. This fact explains the high selectivity of supported Rh catalysts observed at lower temperatures for SCO due to the almost entire coverage of catalyst surface by CO, which excludes the more weakly adsorbed species H_2 and O_2 from the active sites (CO inhibitive effect).[12,13] An entirely new observation of this preliminary work was that the selectivity of the studied catalyst is expected to increase at higher H_2 compositions of the feeding stream due to the above-mentioned CO inhibition. However, the increase of the desorption rate, k_{-1}, with H_2 amount is much lower than that of k_1, indicating that the studied Rh/SiO_2 catalyst may not be active enough for SCO at higher H_2 compositions, at low temperatures. This observation is consistent with literature information that at lower temperatures CO oxidation over noble metal catalysts (Pt, Pd, Rh) either in the presence or in the absence of hydrogen is CO desorption limited.[12,13]

Table 2 Maximum local monolayer capacities (c^*_{max}) estimated by the plots of the local isotherms θ, against the local adsorbed concentration, (c_s^*), for the adsorption of carbon monoxide over Rh/SiO_2 catalyst, at various H_2-rich carrier-gas compositions.

% H_2	c^*_{max}
25.05	12.1 μmol g^{-1}
49.95	83.5 μmol g^{-1}
75.05	1.98 mmol g^{-1}

CO sorption has been further studied over silica-supported monometallic Rh and $Rh_{0.50}$+$Pt_{0.50}$ alloy catalysts, in a wide temperature range, under various hydrogen atmospheres ranging from 25% to 75% H_2.[14] The variation of the experimentally determined rate constants and the activation energies against the nature of the used catalyst (monometallic or alloy) and the amount of hydrogen in the carrier gas gave useful information for the selectivity as well as the activity of SCO. At low temperatures and under H_2-rich conditions, compatible with the operation of PEM fuel cells, the activity of the monometallic and the alloy catalysts is expected to be similar; however, the selectivity of the $Rh_{0.50} + Pt_{0.50}$ alloy catalyst is expected to be higher, making Pt–Rh alloy catalyst a better candidate for CO preferential oxidation. The determined desorption barriers were in any case much lower than the respective activation energies found for CO desorption in the absence of hydrogen, indicating H_2-induced desorption, explains the rate enhancement of SCO oxidation given in the literature.

The study of the effect of hydrogen in the "topography" of the active sites related to CO adsorption focused on the Rh/Sio_2 catalyst, at 90°C.[15] The comparative presentation of the energy distribution function $\varphi(\varepsilon;t)$ against the lateral interaction energy β for CO adsorption on Rh/SiO_2 catalyst, at 90°C, is shown in Fig. 3, in the absence of hydrogen as well as with excess of hydrogen. These plots clearly indicate that the topography of the catalyst in the absence of hydrogen consists of both randomly and islands of CO bound over chemisorbed CO molecules (groups A, B, C, and D respectively). In contrast, under H_2-rich conditions, the observed topography was almost entirely patchwise because of long-range lateral attractions between adsorbate molecules (group B). Moreover, in excess of hydrogen, CO adsorption is shifted at higher lateral attraction values, β, which correspond to weaker adsorbate–adsorbent interactions and lower surface coverage. This indicated a H_2-induced desorption, which was attributed to the formation of an H–CO complex desorbing from the catalyst surface below the temperature required for CO desorption, in the absence of H_2, and it may explain the enhancement of the SCO rate by H_2, which is well-known in the literature.

Recently, novel studies giving further information on the mechanism of selective CO oxidation over γ-alumina-supported nanoparticle-sized gold catalysts were carried out, utilizing, among other techniques, RF-GC.[16,17] It was observed that: 1) CO_2 formation, increases with rising

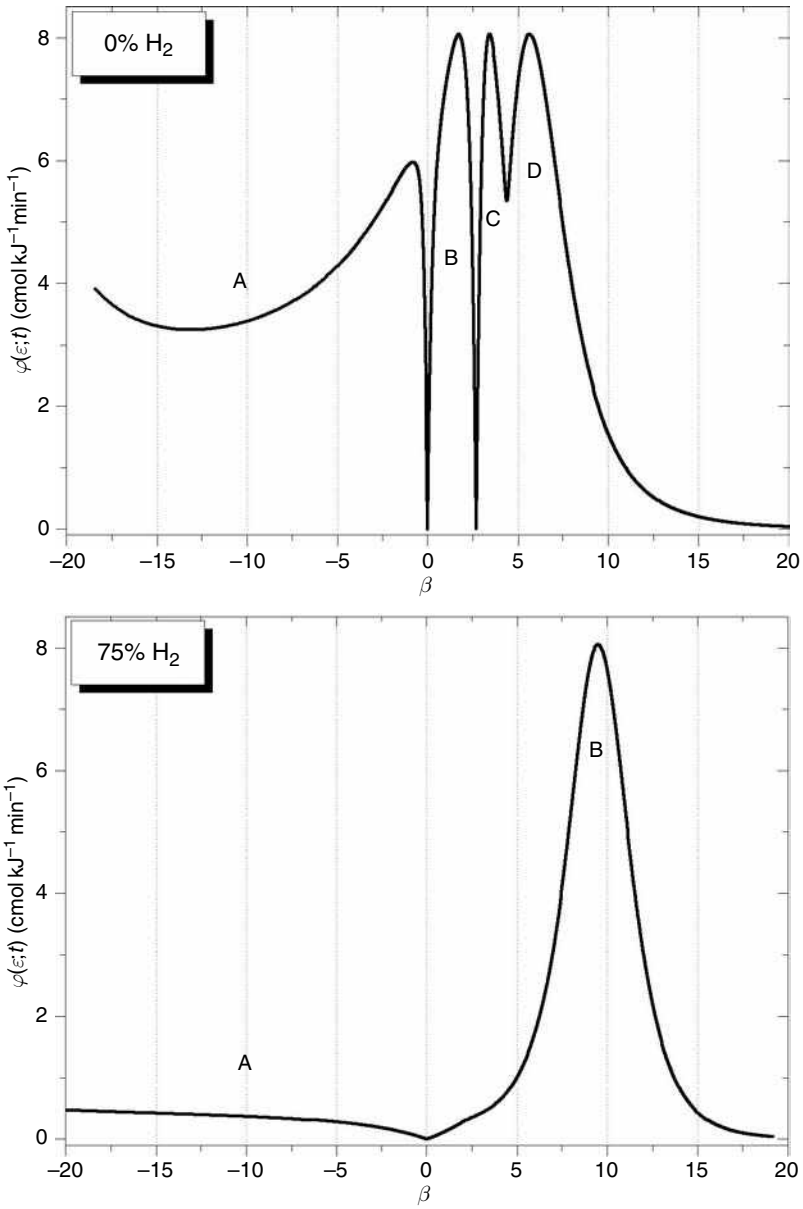

Fig. 3 Comparative presentation of the energy distribution function $\varphi(\varepsilon;t)$ against the lateral interaction energy β for CO adsorption on Rh/SiO_2 catalyst, at 90°C, in the absence of hydrogen (0% H_2) and in excess of hydrogen (75% H_2).

temperature, in the absence of hydrogen and oxygen, pointing to a model of active sites consisting of an ensemble of metallic Au atoms and a cationic Au with a hydroxyl group; 2) at high temperatures (>200°C) in the presence of excess of H_2, reversed water gas shift (RWGS) reaction results in the formation of CO and H_2O with consumption of CO_2; and 3) hydrogen strongly influences the interaction of CO on $Au/\gamma\text{-}Al_2O_3$ by weakening CO adsorption. It was concluded that the presence of hydrogen plays an important role in both decreasing the strength of CO bonding and preventing the deactivation and regeneration.

The nature of the active sites related to CO adsorption over $Au/\gamma\text{-}Al_2O_3$ both in the presence and in the absence of hydrogen in a wide temperature range has also been studied.[18] As has been shown, useful information concerning active sites topography can be extracted by plotting the energy distribution function $\varphi(\varepsilon;t)$ against the lateral interaction energy β, as shown in Fig. 4. The degree of surface heterogeneity increases with rising temperature, since new groups of active sites appear, in the presence as well as the absence of hydrogen. The topography of the $Au/\gamma\text{-}Al_2O_3$ catalyst concerning selective CO oxidation is patchwise at lower temperatures and becomes intermediate at higher temperatures.

Moreover, it was found that: 1) higher amounts of CO can be bound on the catalyst active sites, under conditions compatible with the operation of PEM-FCs; 2) at rising temperatures, catalyst adsorptive capacity decreases while the degree of surface heterogeneity increases since new groups of active sites appear, in the presence as well as in

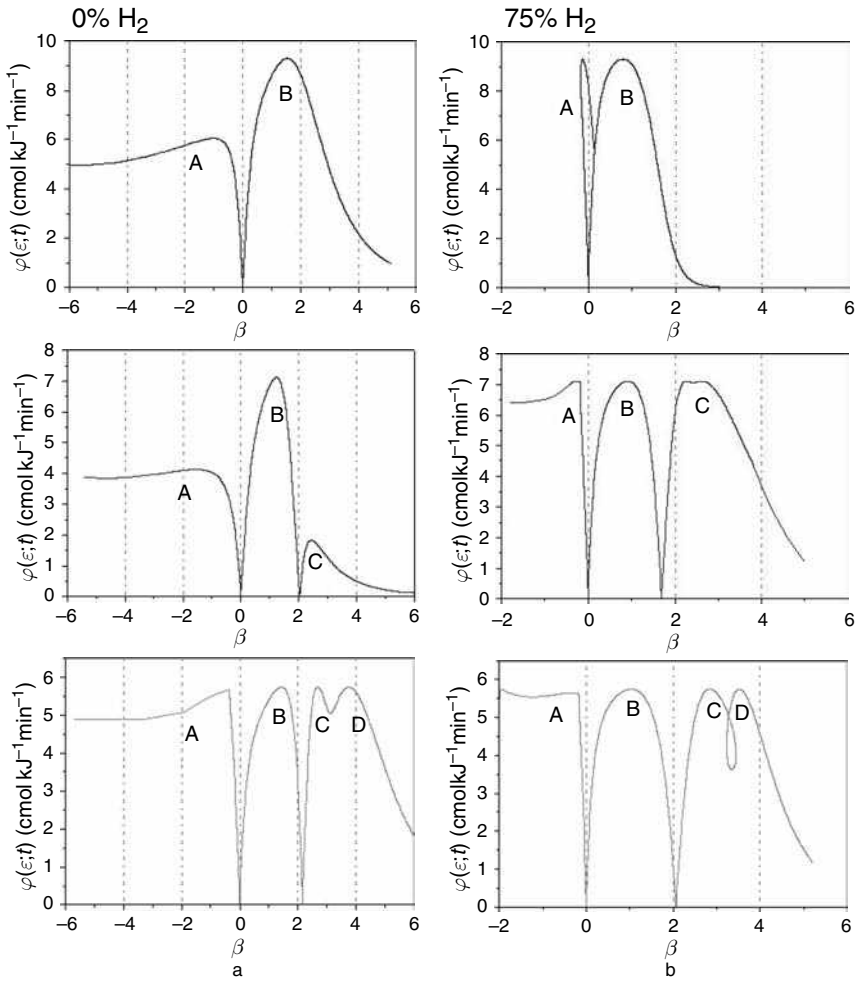

Fig. 4 Comparative presentation of the energy distribution function $\varphi(\varepsilon;t)$ against the lateral interaction energy β for CO adsorption on Au/γ-Al_2O_3 catalyst, at 50°C, 150°C, and 250°C, in the absence of H_2 (a) and under H_2-rich conditions (b). **Source:** From Gas chromatographic investigation of the effects of hydrogen and temperature on the nature of the active sites related to CO adsorption on nanosized Au/γ-Al_2O_3, in J. Chromatogr. A.[18]

the absence of hydrogen; and 3) the experimentally observed high activity of Au/γ-Al_2O_3 for SCO at ambient temperatures was explained as a consequence of weak CO bonding over metallic Au active sites in comparison to strong CO bonding taking place at active sites located on γ-Al_2O_3 support, which is related to deactivation.

CONCLUSIONS

RF-GC has been used to characterize solid catalysts under either steady- or non-steady-state conditions, compatible with the operation of real catalysts. RF-GC is not limited to chromatographic separation; since RF-GC is accompanied by suitable mathematical analysis of the chromatographic data, the simultaneous determination of various physicochemical parameters related to the kinetics of the elementary steps (adsorption, desorption, surface reaction) and the nature of the active sites is possible.

The use of RF-GC methodologies has been successfully extended to the study of selective CO oxidation over various fuel processing candidate catalysts, such as monometallic Rh/SiO_2, bimetallic Pt–Rh/SiO_2, and nanosized Au/γ-Al_2O_3, under different conditions, compatible with the operation of fuel cells units.

These studies concern: 1) activity/selectivity measurements; 2) the determination of kinetic rate constants (adsorption, desorption, surface bonding); and 3) investigation of the surface topography. Important questions answered in the last study are: 1) What amount of CO molecules is adsorbed on the catalyst surface; 2) Where are the molecules on the surface (e.g., Au particles or support); 3) What is the nature of the surface chemical bonds?

It should be noted that all the related catalytic processes such as steam reforming, catalytic partial oxidation, autothermal reforming, as well as WGS reaction and selective CO oxidation can be studied.

Gas Sampling Systems for GC

Piotr Słomkiewicz
Zygfryd Witkiewicz
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

Abstract
The methods for the collection and introduction of gas samples in gas chromatography (GC) are described. Containers for sampling gases, sorption pipes, two- and three-position multiport valves and chambers capable of changing pressure with a mobile piston are presented. The methanizer in which the catalytic reduction of carbon monoxide and carbon dioxide to methane occurs is also presented.

INTRODUCTION

Gases analyzed by gas chromatography (GC) can be divided according to their origin into three large groups. The first group consists of gases occurring in the atmospheres of Earth and other planets, the second group consists of gases present in different types of holders, reactors, and other technological systems, and the third group consists of gases occurring in liquids and solids. Atmospheric gases of planets other than that of Earth are introduced into gas chromatographs automatically and ways of this type are not dealt with in this entry.

Atmospheric air can be injected into a chromatographic column automatically, directly into the place where analysis is performed, with the use of portable chromatographs. In this case, injection is done by means of sampling valves into which air is pressed or sucked. Air can also be injected into a chromatographic column with a gas-tight syringe prior to its direct uptake from the atmosphere.

GAS SAMPLING

Gases in installations and technological systems are under pressures that are usually different from the atmospheric pressure and can be injected into a chromatographic column automatically or manually by means of sampling valves or manually with syringes.

Gases present in liquids can be separated using the following methods:

1. By decreasing pressure above the liquid, which makes gases dissolved in the liquid pass into the gaseous phase whose samples are analyzed.[1]
2. By heating the liquid up to its boiling point. Increasing the temperature of the liquid results in decreasing the solubility of its dissolved gases, which then pass into the headspace phase.[1]
3. By blowing through the liquid containing inert gas; gases dissolved in the liquid are eluted with a stream of inert gas.[2]
4. By microextraction to the stationary phase, gases present in the liquid are adsorbed on to a sorbent from which they are thermally desorbed.[3]
5. By headspace analysis. In a closed container, above the liquid surface there is an equilibrium between a vapor of the liquid sample and gases dissolved in it. The samples of the gaseous phase are taken for analysis.[4]

Gases can be separated from solids by desorption under vacuum, melting under vacuum, and melting in an atmosphere of inert gas.[4]

A number of analyses are done, not in situ but in a laboratory provided with a sample of the gas under analysis. Containers made of glass or of Tedlar® are used in these cases.

Containers for Sampling Gases

Glass containers (Fig. 1) can be expendable (Fig. 1a) or multiusable (Fig. 1b) vacuum vessels or flow vessels called gaseous pipettes (Fig. 2). Vacuum vessels are spontaneously filled after opening, whereas gaseous pipettes are filled by suction or by pressing the gas through them (Fig. 2A). Tedlar containers are bags into which the gas is forced. They are superior to glass containers because they are light, transportable, unbreakable, and capacious.

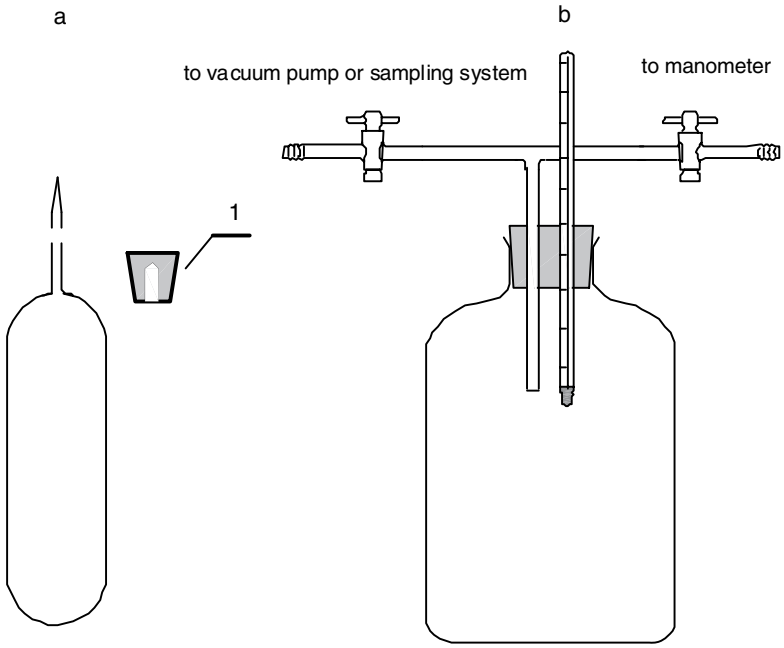

Fig. 1 Glass containers for taking samples of gases: a, expendable sampling ampoule; (1), rubber stopper; b, vacuum bottle.

Analytical samples are taken from containers through a rubber membrane using a syringe (Fig. 2B). When glass containers are used, each sampling decreases the pressure of gas in a container. Consequently, once a syringe needle is extracted, the laboratory atmospheric air gets into the container and changes the composition of the gas. This can be prevented by filling the container with a liquid that is resistant to absorbing analytes, for example, concentrated solution of NaCl, in the course of sampling. Such a problem does not arise when a Tedlar container is used, because an overpressure can be formed in it by exerting external pressure on its elastic walls.

ABSORPTION AND ADSORPTION OF GASEOUS ANALYTES

Gases can be analyzed immediately after sampling if the concentration of the analytes is sufficient for detecting and determining them by means of a detector. If the

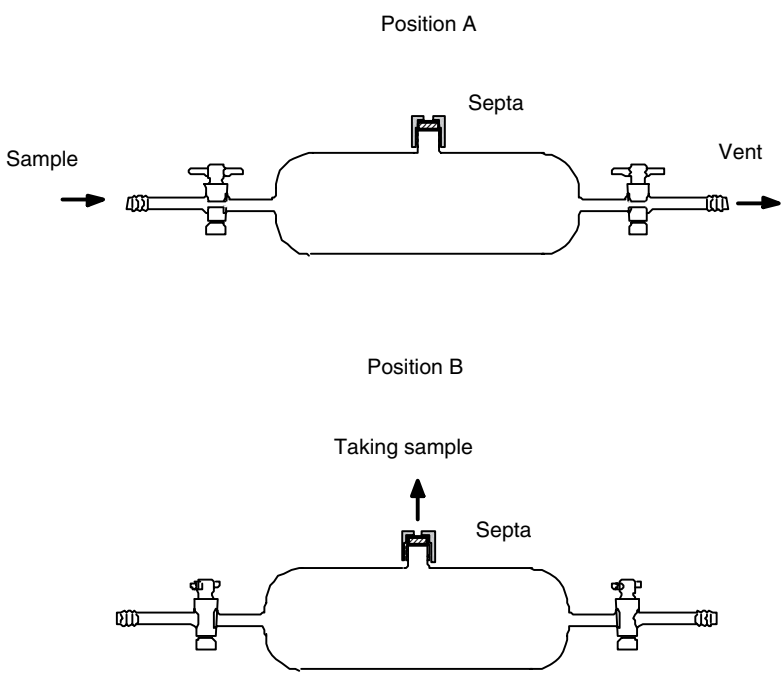

Fig. 2 Taking sample by gas pipette.

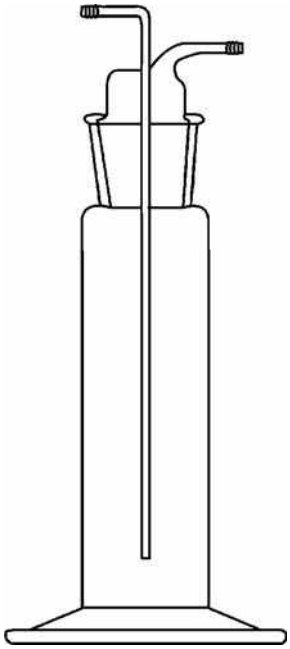

Fig. 3 Gas absorption bulb.

concentration of an analyte is too low, it should then be increased by absorption in a liquid or on to an adsorbent. Absorption in liquids is carried out in bulbs (Fig. 3). A bulb is filled with a solvent or a solution of reagent absorbing an analyte. In the second case, the derivation of the analyte is carried out. The solvent must absorb an analyte well, and the reagent must quantitatively react with the analyte. The liquid in a bulb cannot be readily volatile; cooling is used if necessary. An analysis of the liquid or its headspace phase is done according to the analytical task involved.

Samples of gases for chromatographic analysis can be taken by their adsorption on beds of sorbents. Among others, active carbons, silica gels, molecular sieves, carbon sieves, and graphitized carbon blacks are used as sorbents.[5] Sorption is carried out by pressing or sucking gas through a sorptive tube (Fig. 4). The adsorbed analytes are then subjected to desorption with a solvent or to thermal desorption. The sorption of analytes in sorptive tubes can be made in situ or in a laboratory by connecting a sorptive tube with a container of the gas under analysis. If gaseous analytes dissolved in liquids are to be analyzed, inert gas can be passed through these liquids to elute the analytes from the liquid matrix. The gas mixture obtained is directed into an injector of gas chromatograph or into a sorptive tube or a bulb and the further procedure is followed as described above. Sorptive tubes can be connected with sampling valves.

SAMPLING VALVES

The injection of gas samples into a chromatographic column can be done with gas-tight syringes through the membrane of a sample injector. The syringes of this type, with a capacity from a few cubic millimeters to a great many cubic centimeters, are made of glass. The advantage in using syringes is that a gas sample of chosen capacity can be injected, whereas their disadvantage is in injecting a gas sample of atmospheric or higher pressure and at room temperature.

Sampling valves provide much higher reproducibility of injected gas samples than do syringes. With them, it is possible to inject a sample of pressure different from atmospheric pressure and at elevated temperatures. Moreover, the membrane of a sample injector does not become perforated.

Despite their different construction, most sampling valves are based on the same principle of operation. It is based on switching streams of analyzed gases and carrier gas flowing through the sample loop connected to the valve. A sample loop is usually a section of capillary tubing having a particular capacity. A sample of gas at a particular pressure and at constant temperature is introduced into a sample loop, using its overpressure, and then, after switching the streams of gases, the sample loop is included in the stream of carrier gas and, together with it, the sample of gas is injected into a chromatographic column.

Based on their construction, sampling valves can be divided into rotary, membrane, and piston types. The switching of gas tracks in rotary valves occurs through

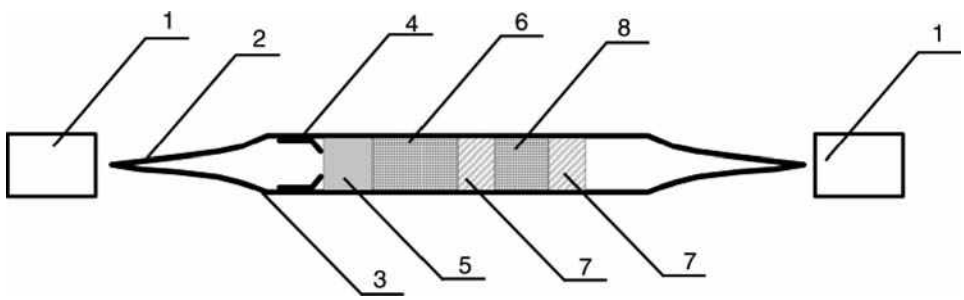

Fig. 4 Sorptive tube by National Institute for Occupational Safety and Health: (1) plastic cap; (2) sealed tube ends (broken before use); (3) glass sorptive tube, (4) spring; (5) glass wool; (6) sorbent; (7) stopper; and (8) protective layer of sorbent.

ducts cut in a rotating disk or in the cone of a rotor that is connected by slots situated in the subrotor plane and that are outlets of gas ducts in the valve body. In membrane valves, the flow of gases through individual ducts of the valve body is opened and shut down by the elastic membrane placed at their outlets, which is mechanically or pneumatically pressed down to these outlets. Piston-type valves assume the shape of a cylinder where individual outlets of gas ducts and the piston with toroidal packings are placed. The reciprocating motion of the piston switches individual outlets of gas ducts in the valve body.

The principle of taking samples of gas by different types of valves equipped with a number of sample loops is given in the following examples. Diagrams illustrating the principle of their operation take rotary valves, which are most frequently used.

Two-position, Multiport Valves

Multiport valves of two working positions are most widely used. One position serves to fill one or many sample loops with the gas under analysis, whereas the other one serves to inject a sample taken from a sample loop into a stream of carrier gas.

A two-position, six-port valve with one sample loop is the simplest one, and sampling from one gas duct is made possible here (Fig. 5). In position A, the gas to be analyzed flows through the sample loop and at the same time the stream of carrier gas flows through the valve into a chromatographic column bypassing the sample loop. When the rotor of the six-port valve is switched to position B, the sample present in the sample loop is introduced into the stream of carrier gas, and the sample, together with the carrier gas, is directed to a chromatographic column. In this position, the stream of gas being

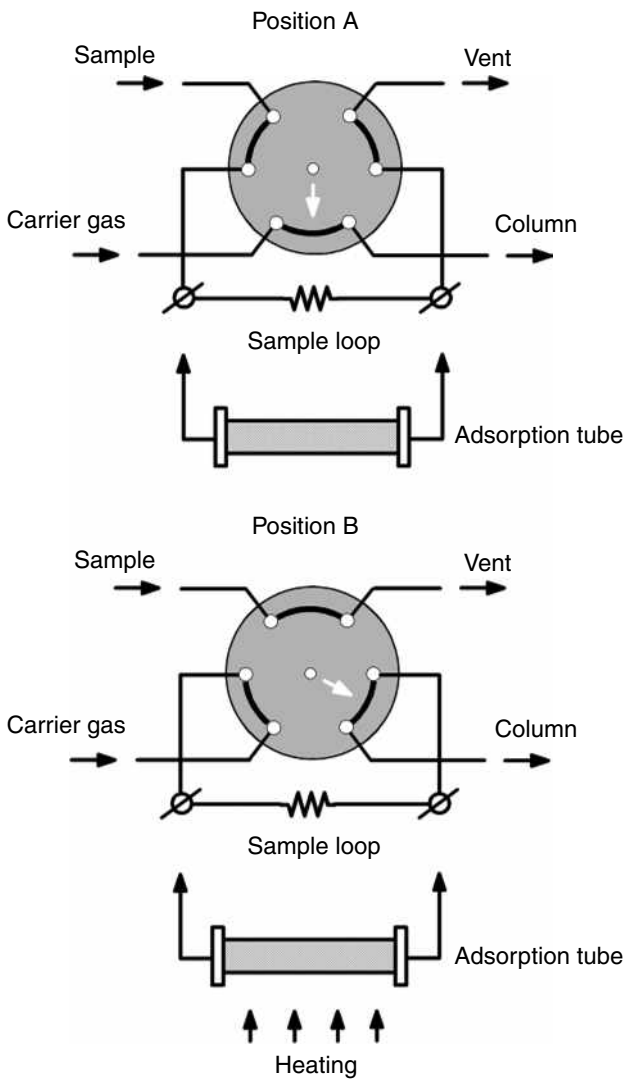

Fig. 5 Two-position, six-port valve with one sample loop, taking sample from one gas track, and an adsorption tube, taking sample from sorbent.

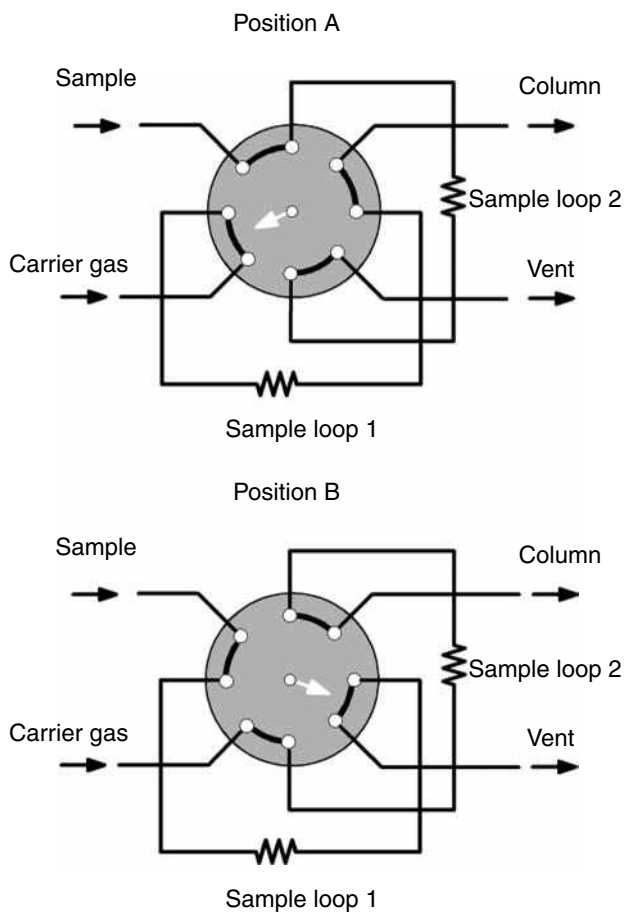

Fig. 6 Two-position, eight-port valve with two sample loops, taking sample from one gas track.

analyzed flows through the valve, bypassing the sample loop.

When the concentration of analytes in the gas is too low to be analyzed, the sample loop can be replaced with a sorptive tube (adsorber). In Fig. 5, the operational principle of a six-port valve equipped with an adsorber is shown. In position A, the gas to be analyzed flows through the sorbent bed into the adsorber, where it is adsorbed, and at the same time, a stream of carrier gas flows through the valve into a chromatographic column. When the six-port valve is switched to position B, a sample of the gas is thermally desorbed and is introduced into the stream of carrier gas, and the sample, together with the carrier gas, is directed to a chromatographic column. In this position, the stream of the analyzed gas flows through the six-port valve, bypassing the adsorber.

To inject two samples of different quantities from one duct of the gas under analysis, a two-position, eight-port valve with two sample loops is used (Fig. 6). In position A, the carrier gas flows through sample loop 1 into a chromatographic column and the gas under analysis flows through sample loop 2 into the outlet. The switching of the valve rotor to position B causes the sample of gas present in sample loop 2 to be injected into a chromatographic column and sample loop 1 is filled with gas. Another switching of the valve rotor to position A causes a sample of gas from sample loop 1 to be injected into a chromatographic column and sample loop 2 is filled with gas.

To inject samples from two ducts of gases under analysis, a two-position, ten-port valve with two sample loops is used (Fig. 7). In position A, the carrier gas flows through sample loop 1, the gas under analysis (gas 2) flows through sample loop 2, and gas 1 flows through the valve, omitting

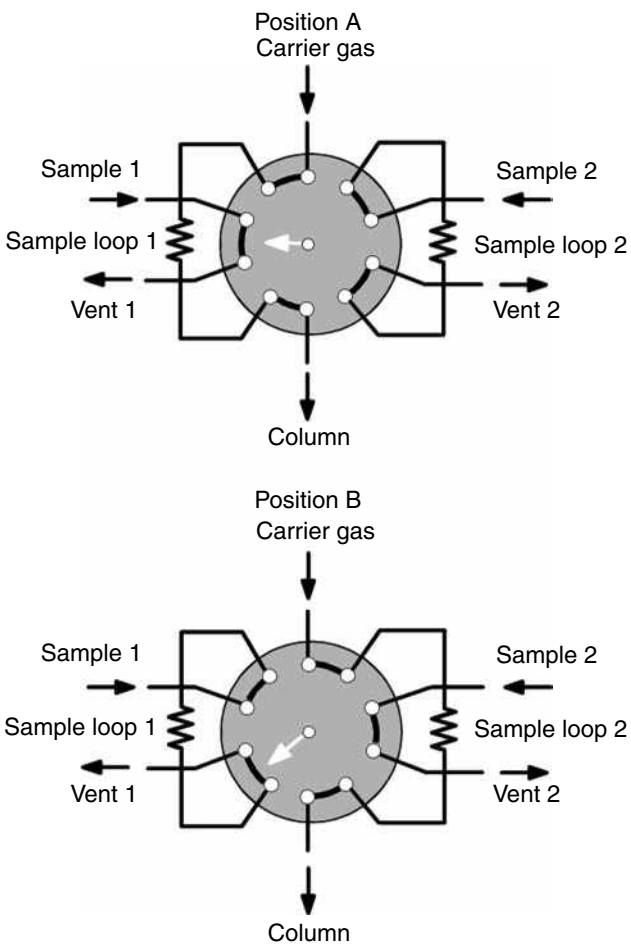

Fig. 7 Two-position, ten-port valve with two sample loops, taking sample from two gas tracks.

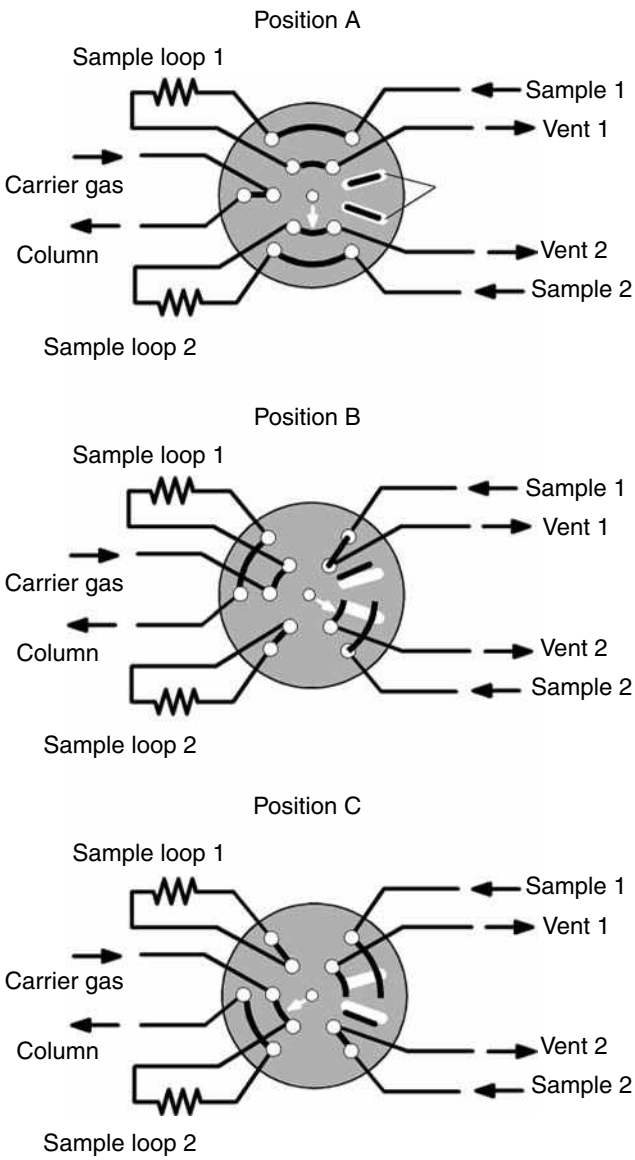

Fig. 8 Three-position, ten-port valve with two sample loops, taking sample from two gas tracks.

the sample loops. The switching of the valve rotor to position B causes the sample of gas 2 from sample loop 2 to be injected into a chromatographic column with carrier gas, and gas 2 flows through the valve, omitting the sample loops, and at the same time gas 1 flows through sample loop 1. Another switching of the valve rotor to position A causes a sample of gas 1 from sample loop 1 to be injected into a chromatographic column with carrier gas, such that gas 1 flows through the valve, omitting the sample loops, and gas 2 flows through sample loop 2.

Three-position, Multiport Valves

The above-mentioned sampling from two tracks of gases under analysis through the two-position, ten-port valve having two sample loops is limited to alternately successive operations.

This shortcoming is absent in the three-position, ten-port valve having two sample loops, which is used for taking samples from two gas tracks (Fig. 8).[6] This valve can be used to analyze two gases in any order. The constructional solution of this valve makes it possible to simultaneously take two samples of different gases into two sample loops and perform their chromatographic analyses.

In position A, the carrier gas flows through the valve, omitting the sample loops, gas 1 flows through sample loop 1, and gas 2 flows through sample loop 2. The switching of the valve rotor to position B injects a sample of gas 1 from sample loop 1 into a chromatographic column with carrier gas, and gas 1 flows through the valve (omitting the sample loops) and gas 2 flows through the duct placed in the valve body on the plane under its rotor and a sample of gas 2 is trapped in sample loop 2. The switching of the valve rotor to position C injects a sample of gas 2 from sample loop 2 into a chromatographic column with carrier gas, and simultaneously, gas 2 flows through the valve and gas 1 flows through the duct placed in the valve body on the plane under its rotor and a sample of gas 1 is trapped in sample loop 1.

Sampling by means of a valve with a sample loop has its own disadvantage, because it cannot adjust the pressure of gas in a sample loop to the pressure of carrier gas at the inlet of a chromatographic column. When the pressure of gas in the sample loop considerably exceeds the pressure of carrier gas, inserting such a sample loop into the circulation of carrier gas results in disturbing the flow that is caused by the impact of the pressure of the expanding gas from the sample loop. The pressure disorder goes through the chromatographic column and disturbs the operation of the detector of the chromatograph. When a flame ionization detector with a small flow of carrier gas and hydrogen is used, high pressure in a sample loop can extinguish the flame. Furthermore, the impacts of the expanding gas from the sample loop impair the efficiency of a chromatographic column.

A method of taking samples of gas of high pressure with a three-position, six-port valve connected with a chamber capable of changing pressure with a mobile piston is described (Fig. 9).[7] The wall of the chamber is provided with a hollow caved duct acting as a sample loop connected with a six-port valve. When the pressure of a sample placed in a duct is decreased with a piston, which increases the volume of a chamber while moving, the pressure of gases taken decreases and, regardless of the position of the piston, the flow of gases through the caved duct in the chamber is stable.

In position A, gas with high pressure flows through the duct of the chamber capable of changing pressure and carrier

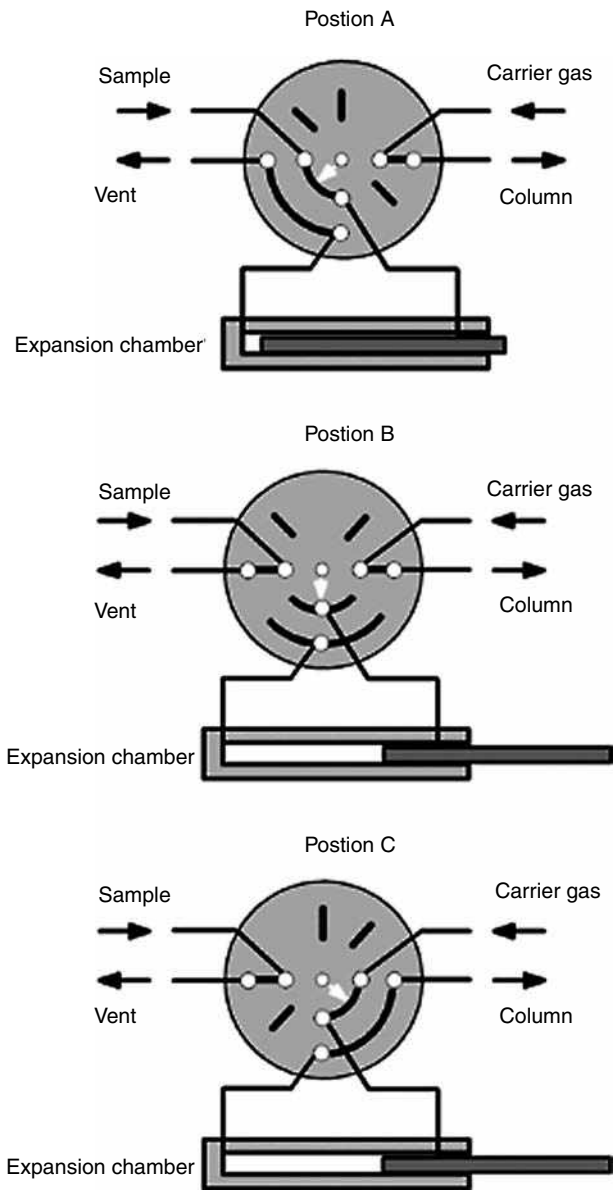

Fig. 9 Three-position, six-port valve with expansion chamber, taking sample from one gas track.

gas flows through the six-port valve, bypassing the chamber. In position B, both the gas under analysis and carrier gas flow through the six-port valve and the chamber is disconnected; therefore, the pressure of a gas sample in it can be decreased by shifting the piston. The switching of the valve rotor to position C injects a sample of the gas from the chamber capable of changing pressure into a chromatographic column with carrier gas, and simultaneously, the gas flows through the valve. The above-mentioned apparatus can also be used to take samples of gas whose pressure is lower than that of the carrier gas. The piston decreasing the volume of the chamber capable of changing pressure can increase the pressure of a sample of the gas taken. If the pressure of the gas under analysis is lower than the atmospheric pressure, its flow through the chamber capable of changing pressure must then be forced by a pump.

According to the quantitative composition of gas under analysis, sample loops of different volumes should be used. The replacement of a sample loop with another in the course of analysis necessitates the interruption of the flow of gases in the carrier gas track of a gas chromatograph or in the track of the gas under analysis. In the first case, air is injected into a chromatographic column, whereas in the second one, air is injected into the track of the gas under analysis, which can be disadvantageous in some cases. The serious disadvantage of valves with sample loops is that they make a quantitative analysis by the method of internal standard impossible.

An apparatus for injecting samples of gas different in size without replacing a sample loop and interrupting the operation of a gas chromatograph, with the possibility of

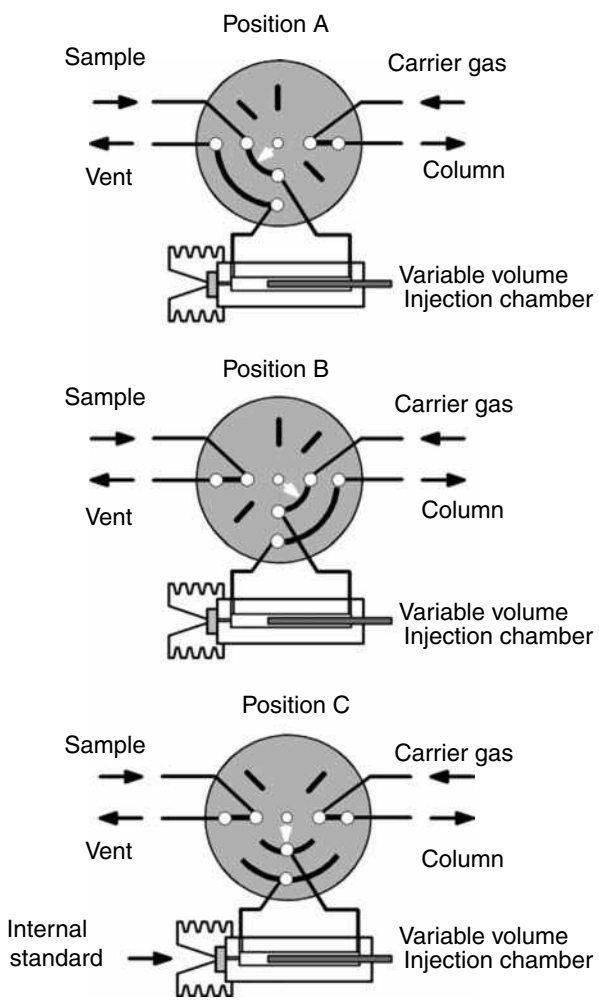

Fig. 10 Three-position, six-port valve with variable volume injection chamber, taking sample from one gas track.

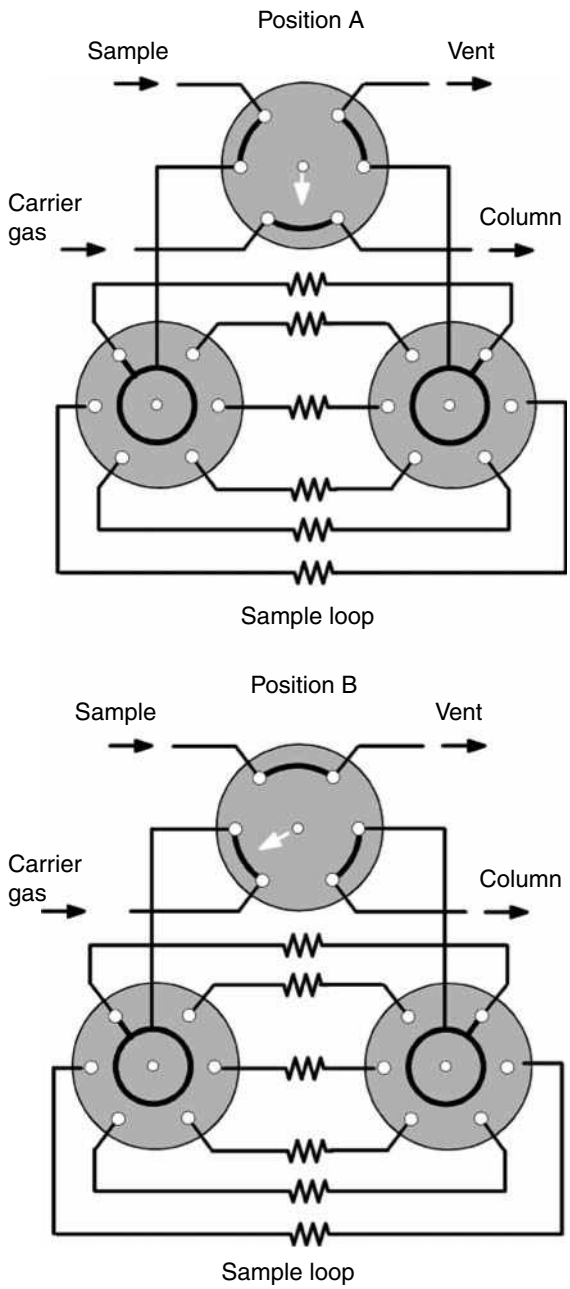

Fig. 11 Two-position, six-port valve with two distributing six-port valves with six sample loops, taking sample from one gas track.

adding the internal standard, is described.[8] It is a combination of a three-position, six-port valve and a chamber of changeable volume that acts as a sample loop (Fig. 10). The volume of a chamber is changed by a piston. In position A, the gas under analysis flows through the chamber and the carrier gas flows through the six-port valve. The switching of the valve rotor to position B results in injecting a sample of the gas under analysis from the chamber into a chromatographic column with carrier gas, and simultaneously, the gas under analysis flows through the valve. In position C, both the gas under analysis and carrier gas flow through the six-port valve and the chamber is disconnected. The internal standard can then be injected, using a syringe, into the sample taken and retained in the chamber with a syringe. The switching of the valve rotor to position B introduces the sample of the gas under analysis together with the internal standard into a chromatographic column.

Sets of Multiport Valves

The use of the above-mentioned multiport valves is limited because a subsequent sample can be injected into a column only after the previous sample has been analyzed. A solution to overcome this limitation and to take successive samples for analysis at shorter intervals is offered.[9]

The number of samples of gas was increased by replacing the sample loop in a two-position, six-port valve (as seen in Fig. 5) with two separate six-port valves combined by rotors with six sample loops (Fig. 11).

In position A (as seen in Fig. 11), the gas under analysis flows through the separating six-port valves and one of the six sample loops, and simultaneously, the carrier gas flows into a chromatographic column through the six-port valve. The switching of the rotors of the separating six-port valves to successive positions makes it possible to fill successive sample loops. When the rotor of the six-port valve is switched to position B, the sample placed in one of the sample loops is introduced into the stream of carrier gas. The switching of the rotors of the separating six-port valves to successive positions makes it possible to direct samples into a chromatographic column.

METHANIZER

A thermal conductivity detector cannot be used to detect low concentrations of carbon monoxide and carbon dioxide in gases because of its low sensitivity. These gases cannot be detected by a flame ionization detector. They can be analyzed by this detector after carbon monoxide and

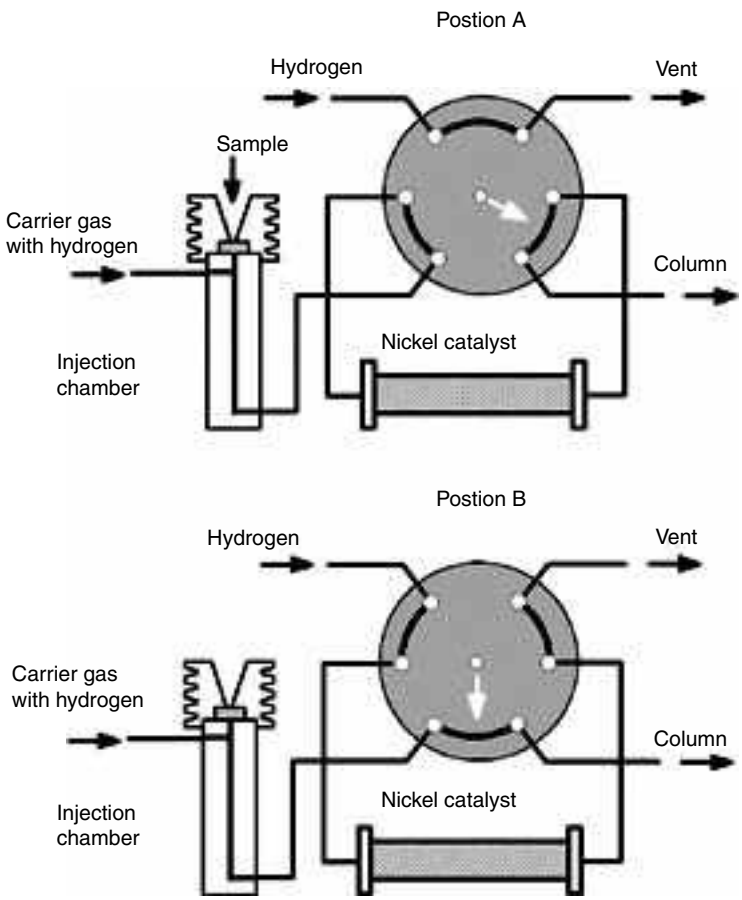

Fig. 12 Scheme of methanizer with six-port valve.

carbon dioxide are catalytically reduced with hydrogen to methane. The microreactors in which the catalytic reduction of carbon monoxide and carbon dioxide to methane occurs are called methanizers. A nickel catalyst in the atmosphere of hydrogen, heated to 350–400°C, is generally used for reduction in methanizers.
