The neck domain contains 7 or 8 complete tandem repeats of 23 amino acids each and 1 incomplete repetitive sequence. It is required for oligomerization, which regulates carbohydrate specificity. Transmembrane region is essential in localization of DC-SIGN on cell surface. The cytoplasmic region contains internalization motifs, such as di-leucine (LL) motif, tri-acidic (EEE) clusters and an incomplete immunoreceptor tyrosine (Y) based activation motif (ITAM) which are believed to regulate ligand binding, uptake, and trafficking. The LL motif participates in antigen internalization and EEE clusters participate in signal transduction (Guo et al. 2004; Feinberg et al. 2001; van Kooyk and Geijtenbeek 2003). DC-SIGNR is homologous to DC-SIGN and is also denoted DC-related protein (L-SIGN), which has a similar structure to DC-SIGN. The genes encoding DC-SIGNR are similar to those of DC-SIGN (Pohlmann et al. 2001). Based on crystal structures and hydrodynamic data, models for the full extracellular domains of the receptors have been generated. The observed flexibility of the CRDs in the tetramer, combined with previous data on the specificity of these receptors, suggests an important role for oligomerization in the recognition of endogenous glycans, in particular those present on the surfaces of enveloped viruses recognized by these proteins (Feinberg et al. 2005). Azad et al. (2008) mutated each of the three conserved cytoplasmic tail motifs of DC-SIGN by alanine substitution and tested their roles in phagocytosis and receptor-mediated endocytosis of highly mannosylated ligands, *M. tuberculosis* ManLAM and HIV-1 surface gp120, respectively, in transfected human myeloid K-562 cells. Azad et al. (2008) indicated a dual role for EEE motif as a sorting signal in the secretory pathway and a lysosomal targeting signal in the endocytic pathway. The DC-SIGN and L-SIGN have been shown to interact with a vast range of infectious agents, including *M. tuberculosis*.

36.5 DC-SIGN versus DC-SIGN-RELATED RECEPTOR [DC-SIGNR or L-SIGN (CD 209)/LSEctin] (Refer Section 36.9)

36.5.1 DC-SIGN Similarities with DC-SIGNR/ L-SIGN/LSEctin

DC- SIGNR is homologous to DC-SIGN and is also denoted as DC- related protein (L-SIGN), which has a similar structure to DC-SIGN. The genes encoding DC-SIGNR are similar to those of DC-SIGN (Pohlmann et al. 2001). The mRNA of L-SIGN shows about 90% similarity with DC-SIGN, which has a similar binding specificity to L-SIGN. L-SIGN like DC-SIGN binds to the cellular ligands i.e. ICAM-2 and ICAM-3 (Bashirova et al. 2001). The sequences of CRDs of DC-SIGN and DC-SIGNR show greatest identity to human asialoglycoprotein receptors (41% and 34% at amino acid level, respectively) and rat CD23 (both 33% at amino acid level). Consistent with previous reports (Curtis et al. 1992; Geijtenbeek et al. 2000a, b), DC-SIGN shows features of a mannose binding lectin, as opposed to the features of a protein-binding NK cell lectin (Weis et al. 1998). DC-SIGNR shows 77% identity to DC-SIGN at the amino acid level and also possesses all the residues shown to be required for the binding of mannose (Weis et al. 1998). The closely linked gene, DC-SIGNR, shows 73% identity to DC-SIGN at RNA level and a similar genomic organization.

The DC-SIGN and DC-SIGNR/L-SIGN (or CLEC4M) directly recognize a wide range of micro-organisms of major impact on public health. Both genes have long been considered to share similar overall structure and ligand-binding characteristics. Both DC-SIGN and DC-SIGNR efficiently bind HIV-1 surface glycoproteins of viruses and other viral as well as nonviral pathogens by interacting with high mannose oligosaccharides and assist either cis or trans infection. DC-SIGNR/L-SIGN (Lozach et al. 2004) is specifically expressed by liver sinusoidal endothelial cells (LSEC), a liver-resident APC, by endothelial cells in lymph nodes (Bashirova et al. 2001; Pohlmann et al. 2001) and by placenta (Soilleux 2003b). Similar *trans* activity for other viruses has been reported, and the receptors can also directly mediate infection of cells in *cis* (Soilleux 2003; Alvarez

et al. 2002; Gardner et al. 2003). There is also evidence that these receptors interact with bacterial pathogens and with parasites (Appelmelk et al. 2003). The L-SIGN/DC-SIGNR functions as a HIV-1 trans-receptor similar to DC-SIGN (Bashirova et al. 2001). Moreover, L-SIGN interacts with other pathogens such as *Ebola virus* (Alvarez et al. 2002), to the envelope glycoproteins from *HIV-1, Hepatitis C virus* and *cytomegalovirus* (Alvarez et al. 2002; Bashirova et al. 2001; Bovin et al. 2003; Gardner et al. 2003; Halary et al. 2002), similar to DC-SIGN. L-SIGN is a liver-specific capture receptor for hepatitis C virus (Bovin et al. 2003).

Both DC-SIGN and DC-SIGNR bind ligands bearing mannose and related sugars through CRDs. The CRDs of DC-SIGN and DC-SIGNR bind $Man_9GlcNAc_2$ oligosaccharide 130- and 17-fold more tightly than mannose (Mitchell et al. 2001). Both DC-SIGN and DC-SIGNR possess a neck region, made up of multiple repeats, which supports the ligand-binding domain. Cross-linking analysis of full-length receptors expressed in fibroblasts confirms the tetrameric state of the intact receptors. The extra-cellular domain of DC-SIGN and DC-SIGNR, each comprises seven 23-residue tandem repeats, encoded by a single exon to form a coiled coil neck region. There is very high sequence identity between the repeat units, within each protein, and between DC-SIGN and DC-SIGNR. By analogy to other lectin receptors, such as the asialoglycoprotein receptors and CD23 (Bates et al. 1999; Beavil et al. 1995), it was suggested that this domain could mediate oligomerization, forming an α-helical coiled coil.

A subset of B cells in the blood and tonsils of normal donors also express DC-SIGN, which increased after stimulation in vitro with IL-4 and CD40 ligand, with enhanced expression of activation and co-stimulatory molecules CD23, CD58, CD80, and CD86, and CD22. The activated B cells captured and internalized X4 and R5 tropic strains of HIV-1, and mediated trans- infection of T cells. DC-SIGN serves as a portal on B cells for HIV-1 infection of T cells in trans. Transmission of HIV-1 from B cells to T cells through DC-SIGN pathway could be important in the pathogenesis of HIV-1 infection (Gupta and Rinaldo 2006).

36.5.2 Domain Organization of DC-SIGN and DC-SIGNR

DC-SIGN and DC-SIGNR consist of an N-terminal cytoplasmic domain, a repeat region consisting of seven 23-amino-acid tandem repeats, and a C-terminal C-type CRD that binds mannose-enriched carbohydrate modifications of host and pathogen proteins. They bind with highest affinity to larger glycans that contain 8 or 9 mannose residues (Mitchell et al. 2001; Guo et al. 2004). In addition, DC-SIGN, but not DC-SIGNR, binds to fucose-containing glycans, such as those present on the surfaces of nematode parasites (Appelmelk et al. 2003; Guo et al. 2004). The sugar-binding activity of each protein is conferred by a Ca^{2+}-dependent CRD that is located at the C terminus of the receptor polypeptide. This domain is separated from the membrane anchor by a neck region consisting of multiple 23-amino acid repeats. The neck forms an extended structure that associates to create a tetramer at the cell surface (Feinberg et al. 2001) (Fig. 36.3). Signals in the N-terminal cytoplasmic domain of DC-SIGN direct internalization of the receptor, which can thus mediate endocytosis and degradation of glycoproteins (Guo et al. 2004). DC-SIGNR lacks such signals and seems not to be a recycling receptor. Although these lectins on primary sinusoidal cells support HCV E2 binding, they are unable to support HCV entry. Lai et al. (2006) provided evidence for binding of circulating HCV with DC-SIGN and DC-SIGNR on sinusoidal endothelium within the liver allowing subsequent transfer of the virus to underlying hepatocytes in a manner analogous to DC-SIGN presentation of HIV on DCs (Lai et al. 2006).

36.5.3 Differences Between DC-SIGN and DC-SIGNR/L-SIGN

DC-SIGN and L-SIGN/DC-SIGNR genes have long been considered to share similar overall structure and ligand-binding characteristics. However, biochemical and structural studies show that they have distinct ligand-binding properties and different physiological functions. Of importance in both these genes is the presence of an extra-cellular domain consisting of an extended neck region encoded by tandem repeats that support the CRD, which plays a crucial role in influencing the pathogen-binding properties of these receptors. The notable difference between these two genes is in the extra-cellular domain. Whilst the tandem-neck-repeat region remains relatively constant in size in DC-SIGN, there is considerable polymorphism in L-SIGN. Homo-oligomerization of the neck region of L-SIGN has been shown to be important for high-affinity ligand binding, and heterozygous expression of the polymorphic variants of L-SIGN in which neck lengths differ could thus affect ligand-binding affinity. Despite DC-SIGN and DC-SIGNR bind HIV and enhance infection, comparison of these receptors reveals that they have very different physiological functions.

Screening an extensive glycan array demonstrated that DC-SIGN and DC-SIGNR have distinct ligand-binding properties. Structural and mutagenesis studies explain how both receptors bind high-mannose oligosaccharides on enveloped viruses and why only DC-SIGN binds blood group antigens, including those present on microorganisms. DC-SIGN mediates endocytosis, trafficking as a recycling receptor and releasing ligand at endosomal pH, whereas

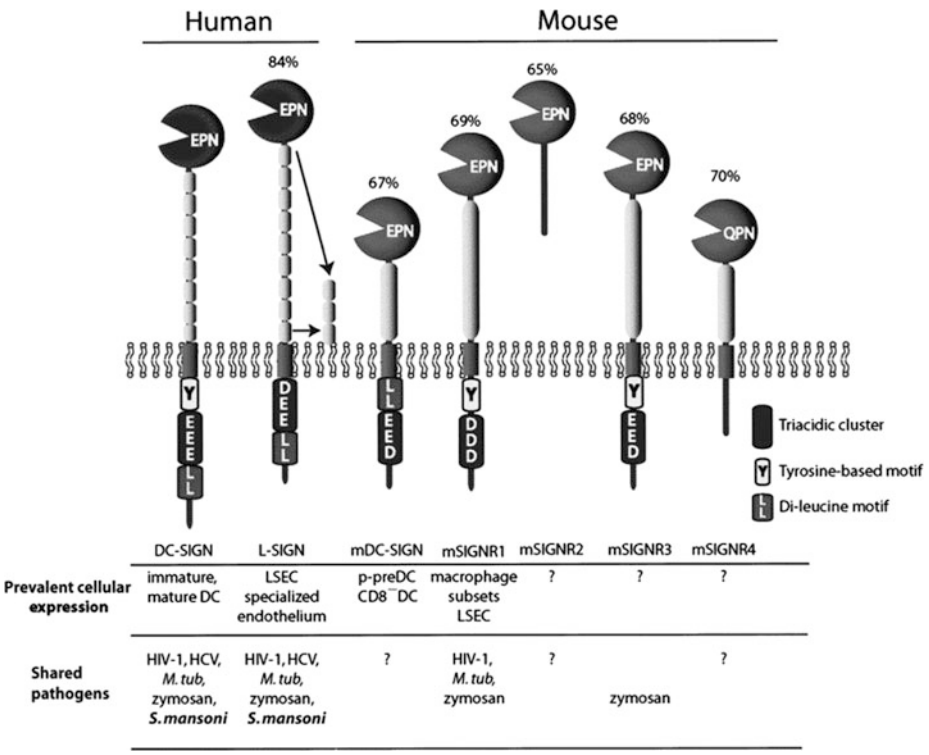

Fig. 36.3 Schematic representation of the structure, expression and binding specificities of DC-SIGN and its human and murine homologs. All SIGN homologs are transmembrane receptors, except for mSIGNR2, which is a soluble receptor. The percentage amino-acid-homology of CRDs of different homologs compared to DC-SIGN is depicted above the CRDs. Within the CRDs the highly conserved EPN sequence is essential for recognizing mannose-containing structures. All SIGN homologs contain the EPN motif, except for mSIGNR4, which has a QPN motif, indicating that mSIGNR4 may have another ligand specificity compared to the other SIGN molecules. In contrast to DC-SIGN that contains seven complete and one incomplete repeats, the number of repeats of L-SIGN is variable and varies between three and nine which is indicated with arrows. Within the cytoplasmic tail several internalization motifs are found. The di-leucin (LL) motif is thought to be important for internalization of DC-SIGN. The tyrosine-based motif and the tri-acidic cluster are also involved in internalization. However, the internalization capacities of the homologs of DC-SIGN have not been extensively explored. Based on its expression pattern, mSIGNR1 seems more similar to the homolog of L-SIGN rather than DC-SIGN whereas the expression of mDC-SIGN seems more homologous to DC-SIGN, although they are expressed by different DC subtypes. Strikingly, DC-SIGN, L-SIGN and mSIGNR1 share the ability to bind a number of pathogens (Reprinted with permission from Koppel et al. 2005 © John Wiley and Sons)

DC-SIGNR does not release ligand at low pH or mediate endocytosis. Thus, whereas DC-SIGN has dual ligand-binding properties and functions both in adhesion and in endocytosis of pathogens, DC-SIGNR binds a restricted set of ligands and has only the properties of an adhesion receptor (Guo et al. 2004). Functional studies on the effect of tandem-neck-repeat region on pathogen-binding, as well as genetic association studies for various infectious diseases and among different populations, have been reported. Worldwide demographic data of the tandem-neck-repeat region showing distinct differences in the neck-region allele and genotype distribution among different ethnic groups have been presented. These findings support the neck region as an excellent candidate acting as a functional target for selective pressures exerted by pathogens (Khoo et al. 2008). Chung et al (2010) identified Trp-258 in the DC-SIGN CRD to be essential for HIV-1 transmission. Although introduction of a K270W mutation at the same position in L-SIGN was insufficient for HIV-1 binding, an L-SIGN mutant molecule with K270W and a C-terminal DC-SIGN CRD subdomain transmitted HIV-1 (Chung et al. 2010).

36.5.4 Recognition of Oligosaccharides by DC-SIGN and DC-SIGNR

Both DC-SIGN and DC-SIGNR bind mannose bearing ligands and related sugars through CRDs. The CRDs of DC-SIGN and DC-SIGNR bind $Man_9GlcNAc_2$ oligosaccharide 130- and 17-fold more tightly than mannose. Results indicate that CRDs contain extended or secondary oligosaccharide binding sites that accommodate mammalian-type glycan structures. When the CRDs are clustered in the tetrameric extracellular domain, their arrangement provides a means of amplifying specificity for multiple glycans on host molecules targeted by DC-SIGN and DC-SIGNR. Binding to clustered oligosaccharides may also explain the interaction of these receptors with the gp120 envelope

protein of HIV-1, which contributes to virus infection (Mitchell et al. 2001). Crystal structures of carbohydrate-recognition domains of DC-SIGN and of DC-SIGNR bound to oligosaccharide, in combination with binding studies, revealed that these receptors selectively recognize endogenous high-mannose oligosaccharides and may represent a new avenue for developing HIV prophylactics (Feinberg et al. 2001) (Fig. 36.4).

Similar to DC-SIGN, DC-SIGNR/L-SIGN can recognize high-mannose type *N*-glycans and the fucosylated glycan epitopes Lewis^{A} (Le^{a}, Galß1-3(Fuc1-4)GlcNAc-), Lewis ^{B} (Le^{b}, Fuc1-2Galß1-3(Fuc1-4)GlcNAc-) and Lewis Y (Le^{Y}, Fuc1-2Galß1-4(Fuc1-3)GlcNAc-) (Geijtenbeek et al. 2003; Guo et al. 2004; van Liempt et al. 2004). L-SIGN, however, does not bind to the Le^{X} epitope, which is one of the major ligands of DC-SIGN, although the formation of crystals between L-SIGN and Le^{X} indicates that a weak interaction is possible (Guo et al. 2004). The inability of L-SIGN to bind to Le^{X} epitopes is mainly due to the presence of a single amino acid in the CRD of L-SIGN, Ser^{363} that prevents interaction with the Fuc(1-3)GlcNAc unit in Le^{X}, but supports binding of the Fuc1-4GlcNAc moiety present in Le^{A} and Le^{B} antigens. The equivalent amino acid residue Val^{351} in DC-SIGN creates a hydrophobic pocket that strongly interacts with the Fuc(1-3/4)GlcNAc moiety of Le^{X}, other Lewis antigens, and probably LDN-F (Guo et al. 2004; van Liempt et al. 2004; van Liempt et al. 2006). The interaction of L-SIGN with *S. mansoni* egg glycoproteins and its location on liver endothelial cells suggest that L-SIGN may function in the recognition of glycan antigens of eggs that are trapped in the liver, thus contributing to glycan-specific immune responses and/or the immunopathology of schistosomiasis.

36.5.5 Extended Neck Regions of DC-SIGN and DC-SIGNR

Two different crystal forms of truncated DC-SIGNR comprising two neck repeats and the CRD reveal that the CRDs are flexibly linked to the neck, which contains α-helical segments interspersed with non-helical regions. Differential scanning calorimetry measurements indicated that the neck and CRDs are independently folded domains. Based on the crystal structures and hydrodynamic data, models for the full extracellular domains of the receptors have been generated. The observed flexibility of the CRDs in the tetramer, combined with reported data on the specificity of these receptors, suggests an important role for oligomerization in the recognition of endogenous glycans, in particular those present on the surfaces of enveloped viruses recognized by these proteins (Feinberg et al. 2005, 2009). To understand the tetramer-based ligand binding avidity, Snyder et al. (2005)

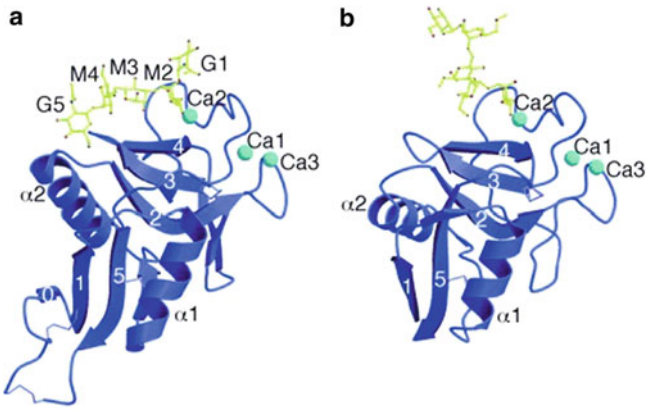

Fig. 36.4 Structure of CRD of DC-SIGN bound to $GlcNAc_2Man_3$. (**a**) Ribbon diagram of the DC-SIGN CRD (*blue*), with the bound oligosaccharide shown in a *ball-and-stick* representation (*yellow-green*, bonds and carbon atoms; *red*, oxygen; *blue*, nitrogen). Oligosaccharide residues are shown with the single letter code G for GlcNAc and M for mannose. Large cyan spheres are three Ca^{2+} ions. Disulfide bonds are shown in *pink*. The DC-SIGNR complex is very similar, except that the fourth disulfide connecting the NH_2 and COOH termini is not visible in either copy. (**b**) Rat serum mannose-binding protein bound to a high-mannose oligosaccharide. The color scheme is same as in (**a**) (Adapted from Feinberg et al. 2001 © American Association for the Advancement of Science)

determined the crystal structure of DC-SIGNR with its last repeat region and showed that compared to the carbohydrate-bound CRD structure, there are conformational differences in the calcium and carbohydrate coordination loops of CRD, an additional disulfide bond between the N and the C termini of the CRD, and a helical conformation for the last repeat. Snyder et al. (2005) generated a tetramer model for DC-SIGN/R using homology modeling and proposed a ligand-recognition index to identify potential receptor ligands. Polymorphisms associated with the length of the extracellular neck region of DC-SIGNR have been linked to differences in susceptibility to infection by enveloped viruses. The heterotetramers provide a molecular basis for interpreting the way polymorphisms affect interactions with viruses (Guo et al. 2006).

CRDs in DC-SIGN and DC-SIGNR are projected from the membrane surface by extended neck domains containing multiple repeats of a largely conserved 23-amino-acid sequence motif. The repeats are largely α-helical. Based on the structure and arrangement of the repeats in the crystal, the neck region can be described as a series of four-helix bundles connected by short, non-helical linkers. Combining the structure of the isolated neck domain with a overlapping structure of the distal end of the neck region with the CRDs attached provides a model of the almost-complete extracellular portion of the receptor. The organization of the neck suggests how CRDs may be disposed differently in DC-SIGN compared with DC-SIGNR and in variant forms of DC-SIGNR assembled from polypeptides with different

numbers of repeats in the neck domain (Feinberg et al, 2009).

CRD of Langerin with Structural Similarity with DC-SIGN: Though DCs are thought to mediate HIV-1 transmission, yet it is becoming evident that different DC subsets at the sites of infection have distinct roles. In the genital tissues, two different DC subsets are present: the LCs and the DC-SIGN$^+$-DCs. Although DC-SIGN$^+$-DCs mediate HIV-1 transmission, recent data demonstrate that LCs prevent HIV-1 transmission by clearing invading HIV-1 particles. However, this protective function of LCs is dependent on the function of Langerin: blocking Langerin function by high virus concentrations enables HIV-1 transmission by LCs. A better understanding of the mechanism of these processes is crucial to understand and develop strategies to combat transmission (de Witte et al. 2008b). The CRD of human Langerin was examined by X-ray analyses for apo-Langerin and for complexes with mannose and maltose. The fold of the Langerin CRD resembles that of DC-SIGN. However, especially in the long loop region (LLR), which is responsible for carbohydrate-binding, two additional secondary structure elements are present: a 3(10) helix and a small β-sheet arising from the extended β-strand 2, which enters into a hairpin and a new strand β2'. However, the crystal structures in presence of maltose and mannose revealed two sugar-binding sites. One is calcium-dependent and structurally conserved in the C-type lectin family whereas the second one represents a calcium-independent type. Based on these data, the differences in binding behavior between Langerin and DC-SIGN with respect to the Lewis X carbohydrate antigen and its derivatives has been explained (Chatwell et al. 2008).

36.5.6 Signaling by DC-SIGN through Raf-1

Adaptive immune responses by DCs are critically controlled by Toll-like receptor (TLR) function. Little is known about modulation of TLR-specific signaling by other pathogen receptors. DC-SIGN has gained an exponential increase in attention because of its involvement in multiple aspects of immune function. Besides being an adhesion molecule, particularly in binding ICAM-2 and ICAM-3, it is also crucial in recognizing several endogenous and exogenous antigens. Additionally, the intracellular domain of DC-SIGN includes molecular motifs, which enable the activation of signal transduction pathways involving serine and threonine kinase Raf-1 and subsequent modulation of DC-maturation status, through direct modification of nuclear factor Nf-kB in DCs. DC-SIGN modulates TLR signaling at the level of the transcription factor NF-kB.

The DC-SIGN has emerged as a key player in the induction of immune responses against numerous pathogens by modulating TLR-induced activation. Upon DC-SIGN engagement by mannose- or fucose-containing oligosaccharides, the latter leads to a tailored Toll-like receptor signaling, resulting in an altered DC-cytokine profile and skewing of Th1/Th2 responses. Gringhuis et al. (2007) demonstrated that pathogens trigger DC-SIGN on human DCs to activate Raf-1, which subsequently leads to acetylation of the NF-kB subunit p65, but only after TLR-induced activation of NF-kB. Acetylation of p65 both prolonged and increased IL10 transcription to enhance anti-inflammatory cytokine responses. Different pathogens such as *M. tuberculosis, M. leprae, Candida albicans, measles virus,* and *HIV-1* interacted with DC-SIGN to activate the Raf-1-acetylation-dependent signaling pathway to modulate signaling by different TLRs. Thus, this pathway is involved in regulation of adaptive immunity by DCs to bacterial, fungal, and viral pathogens (Gringhuis et al. 2007). In addition, other DC-SIGN-ligands induce different signaling pathways downstream of Raf-1, indicating that DC-SIGN-signaling is tailored to the pathogen.

36.6 Functions of DC-SIGN

36.6.1 DC-SIGN Supports Immune Response

Immature DCs are recruited from blood into tissues to patrol for foreign antigens. Cells expressing DC-SIGN stable transfectants were able to mediate phagocytosis of *E. coli*. Ca^{2+} binding sites in the CRD of DC-SIGN were involved in phagocytosis of bacteria as well as multimerization of DC-SIGN, and neck region played a role in efficiency of binding to microbes as well as multimerization of the protein (Iyori et al. 2008; Valera et al. 2008). While analyzing early stages of DC-SIGN-mediated endocytosis, Cambi et al. (2009) demonstrated that both membrane cholesterol and dynamin are required and that DC-SIGN-mediated internalization occurs via clathrin-coated pits. Electron microscopy studies confirmed the involvement of DC-SIGN in clathrin-dependent HIV-1 internalization by DCs. Recent studies showed that some functions of decidual dendritic cells appear to be essential for pregnancy. In humans, decidual dendritic cells are identifiable by their expression of DC-SIGN. In normal decidua, DC-SIGN$^+$ cells expressed antigens associated with immature myeloid dendritic cells. In samples from spontaneous abortions, the decidual DC-SIGN$^+$ cells at a significantly lower proportion compared to normal pregnancies seem to play a role in pathological pregnancy outcomes (Tirado-González et al. 2010).

The dendritic cell-specific DC-SIGN internalizes antigen for presentation to T cells. After antigen uptake and

processing, DCs mature and migrate to the secondary lymphoid organs where they initiate immune responses. As an adhesion molecule, DC-SIGN is able to mediate rolling and adhesion over endothelial cells under shear flow. The normal functions of DC-SIGN and DC-SIGNR include binding to ICAM-2 and ICAM-3. Binding of DC-SIGN to ICAM-2 on endothelial cells facilitates chemokine-induced DC extravasation; binding to ICAM-3 on T lymphocytes provides the initial step for establishing cell-mediated immunity (Liu and Zhu 2005). DCs could activate arrest T cells in the lymph node, but the mechanism is poorly understood. Studies showed that binding of DC-SIGN to both carcinoembryonic antigen (CEA)-related cell adhesion molecule 1 (CEACAM1) and Mac1 was required to establish cellular interaction between DCs and neutrophils, and such interaction promoted T cell proliferation and transformation to Th1 cells (van Gisbergen et al. 2005a, c). Subpopulations of human macrophages express DC-SIGN, to which Le^x-carrying CEACAMs may modulate the immune response in normal tissues such as the human placenta or in malignant tumors, for example in colorectal, pancreatic or lung carcinomas (Samsen et al. 2010). Reports suggest that DCs participate in the contact between itself and resting T cells, and also in T cell activation, and such effect is related to its cytoplasmic ITAM signal transduction (Engering et al. 2002). Martinez et al. discovered that DC-SIGN could promote CD3-activated T cells to produce IL-2 and receive a strong TCR signal, thus strengthening TCR-APC interaction and enhancing immune response (Martinez et al. 2005). Inhibiting DC-SIGN on DCs could reduce T cell proliferation and inhibit co-stimulator CD11c, CD83, CD80 and CD86 expression. Such effects are achieved by NF-κB signaling pathway (Zhou et al. 2006a). Recent evidences suggest that there is a cross-talk between DC-SIGN together with its CLRs and TLRs, and such crosstalk could lead to immune activation or T cells depression (Geijtenbeek et al. 2004; Gantner et al. 2003; Zhou et al. 2006b).

36.6.2 DC-SIGN Recognizes Pathogens

Viral and Bacterial Antigens DC-SIGN plays an important role in recognizing and capturing pathogens, DC migration and initiation of T cell responses. The role of DC-SIGN as a broad pathogen receptor has been well established (Geijtenbeek et al. 2000a; Alvarez et al. 2002; Colmenares et al. 2002; Cambi et al. 2003; Geijtenbeek et al. 2003; Lozach et al. 2003). In addition, DC-SIGN functions as a cell adhesion receptor mediating the interaction between DCs and resting T cells by binding to ICAM-3, and the transendothelial migration of DCs by binding to ICAM-2 (Geijtenbeek et al. 2000b). DC-SIGN has been identified as a receptor for HIV-1, HCV, Ebola virus, CMV, dengue virus, and the SARS coronavirus. Evidences suggest that DC-SIGN can function both as an adhesion receptor and as a phagocytic pathogen-recognition receptor, similar to the Toll-like receptors. Although major differences in the cytoplasmic domains of these receptors might predict their function, findings show that differences in glycosylation of ligands can dramatically alter C-type lectin-like receptor usage (Cambi and Figdor 2003; Engering et al. 2002). As a pathogen receptor, DC-SIGN displays affinity for high mannose moieties and functions as an internalization receptor for *HIV-1*, *hepatitis C virus, Mycobacterium tuberculosis, Helicobacter pylori,* and *Schistosoma manson, Leishmania*, and *Candida albicans* (Appelmelk et al. 2003; Bashirova et al. 2003a; Feinberg et al. 2001; Jack et al. 2001; Colmenares et al. 2004; Geijtenbeek et al. 2000a; Lozach et al. 2003; van Kooyk and Geijtenbeek 2003) and other pathogens that express mannose-containing carbohydrates (Alvarez et al. 2002; Halary et al. 2002; Tassaneetrithep et al. 2003; Zhou et al. 2008). The DC-SIGN molecule is used by HIV to attach to DCs in the genitourinary tract and rectum. Geitjenbeek et al. (2000a, c) suggest that DCs then carry HIV particles to lymph nodes, where the infection of T lymphocytes via receptors such as CD4 and CCR5 may occur. The virus may remain bound to DC-SIGN for protracted periods. DC-SIGN may deliver bound HIV to permissive cell types, mediating infection with high efficiency.

In vitro, DC-SIGN specifically interacts with *S. pneumoniae* serotype 3 and 14 in contrast to other serotypes such as 19F. While DC-SIGN interacts with *S. pneumoniae* serotype 14 through a ligand expressed by the capsular polysaccharide, the binding to *S. pneumoniae* serotype 3 appeared to depend on an as yet unidentified ligand (Koppel et al. 2005b). Leptospirosis is a global zoonotic disease, caused by pathogenic Leptospira species including *Leptospira interrogans* that causes public health and livestock problems. *L. interrogans* binds DC-SIGN and induces DCs maturation and cytokine production, which should provide new insights into cellular immune processes during leptospirosis (Gaudart et al. 2008).

Schistosoma Mansoni Antigens: Schistosomiasis is a human parasitic disease caused by helminths of the genus *Schistosoma*. *Schistosoma mansoni* synthesizes a multitude of carbohydrate complexes, which include both parasite-specific glycan antigens, as well as glycan antigens that are shared with the host. One example for a host-like glycan is the Le^X epitope Galß1-4(Fuc1-3)GlcNAc, which is expressed in all schistosomal life stages, but also on human leukocytes. Glycan antigens expressed by schistosomes induce strong humoral and cellular immune responses in their host (Meyer et al. 2007). The recognition of

carbohydrates is mediated by DC-SIGN, and DC-SIGNR bind to glycans of *S. mansoni* soluble egg antigens (SEA) (van Die et al. 2003; van Liempt et al. 2004; Meyer et al. 2005; Saunders et al. 2009; van Die and Cummings 2006, 2010). L-SIGN binds both SEA and egg glycosphingolipids, and can mediate internalization of SEA by L-SIGN expressing cells. L-SIGN predominantly interacts with oligomannosidic *N*-glycans of SEA. L-SIGN binds to a glycosphingolipid fraction containing fucosylated species with compositions of $Hex_1HexNAc_{5-7}dHex_{3-6}Cer$. Results indicate that L-SIGN recognizes both oligomannosidic *N*-glycans and multiply fucosylated carbohydrate motifs within *Schistosoma* egg antigens, which demonstrate that L-SIGN has a broad but specific glycan recognition profile (Meyer et al. 2007).

DC-SIGN Captures Also Fungi: The DC-SIGN is located in the submucosa of tissues, where they mediate HIV-1 entry. Interestingly, the pathogen *C. albicans*, the major cause of hospital-acquired fungal infections, penetrates at similar submucosal sites. The DC-SIGN is able to bind *C. albicans* both in DC-SIGN-transfected cell lines and in human monocyte-derived DC. Moreover, in immature DC, DC-SIGN was able to internalize *C. albicans* in specific DC-SIGN-enriched vesicles, distinct from those containing the ManR. These results demonstrated that DC-SIGN is an exquisite pathogen-uptake receptor that captures not only viruses but also fungi (Cambi et al. 2003). However, DC-SIGN regulation in monocyte-derived macrophages does not singly predict the transmission potential of this cell type (Bashirova et al. 2003; Chehimi et al. 2003).

Microbial Uptake Capacities of DC-SIGN, SIGNR1, SIGNR3 and Langerin: Using transfected non-macrophage cell lines, Takahara et al. (2004) compared the polysaccharide and microbial uptake capacities of three lectins—DC-SIGN, SIGNR1 and SIGNR3—to another homolog mLangerin. Each molecule shares a potential mannose-recognition EPN-motif in its carbohydrate recognition domain. Using an anti-Tag antibody, it was found that each molecule could be internalized, although the rates differed. However, mDC-SIGN was unable to take up FITC-dextran, FITC-ovalbumin, zymosan or heat-killed *C. albicans*. The other three lectins showed distinct carbohydrate recognition properties. Furthermore, only SIGNR1 was efficient in mediating the capture by transfected cells of Gram-negative bacteria, such as *E. coli and S. typhimurium,* while none of the lectins tested were competent to capture Gram-positive bacteria, *S. aureus*. Therefore, these homologous C-type lectins have distinct recognition patters for microbes despite similarities in the carbohydrate recognition domains (Takahara et al. 2004).

36.6.3 DC-SIGN as Receptor for Viruses

DC-SIGN and L-SIGN can function as attachment receptors for *Sindbis (SB) virus*, an arbovirus of the Alphavirus genus. DC-SIGN is a universal pathogen receptor and can be used by *hepatitis C virus* (HCV) and other viral pathogens including *Ebola* virus, *cytomegalovirus* (CMV), *and Dengue virus* to facilitate infection by a mechanism that is distinct from that of HIV-1, leading to inhibition of the immunostimulatory function of DC and, hence, promotion of pathogen survival. Reports show that DC-SIGN not only plays a role in entry into DC, but HCV E2 interaction with DC-SIGN might also be detrimental to the interaction of DC with T cells during antigen presentation (Zhou et al. 2008). The surface membrane glycoprotein of *Borna disease virus* (BDV) is a polypeptide of 57 kDa and N-glycosylated to a precursor glycoprotein (GP) of about 94 kDa. Analysis showed that the precursor GP contains only mannose-rich N-glycans (Kiermayer et al. 2002) and has the potential to bind with DC-SIGN, L-SIGN in addition to other mannose spectic lectins discussed in different Chapters.

Reduced expression of DC-SIGN in spleen specifically characterizes pathogenic forms of simian immunodeficiency virus (SIV) infection, correlates with disease progression, and may contribute to SIV pathogenesis (Yearley et al. 2008).

N-glycan Status Modifies Virus Interaction: The virus-producing cell type is an important factor in dictating both N-glycan status and virus interaction with DC-SIGN/DC-SIGNR (Lin et al. 2003). In contrast, viruses bearing Ebola (Zaire strain) and Marburg (Musoke strain) envelope glycoproteins bind at significantly higher levels to immobilized MBL compared with virus particles pseudo typed with vesicular stomatitis virus glycoprotein or with no virus glycoprotein. Importantly, the tetrameric complexes, in contrast to DC-SIGN monomers, bind with high affinity to high mannose glycoproteins such as mannan or HIV gp120 suggesting that such an assembly is required for high affinity binding of glycoproteins to DC-SIGN (Bernhard et al. 2004).

36.6.4 HIV-1 gp120 and Other Viral Envelope Glycoproteins

DC-SIGN has been described as an attachment molecule for human HIV-1 with the potential to mediate its transmission. About half of the carbohydrates on gp120 are terminally mannosylated, a pattern common to many pathogens. The DC-SIGN binds to HIV and SIV gp120 and mediates the binding and transfer of HIV from monocyte-derived dendritic cells (MDDCs) to permissive

T cells (Geijtenbeek et al. 2002c). However, DC-SIGN binding to HIV gp120 may also be carbohydrate independent. Hong et al. (2002) formally demonstrated that gp120 binding to DC-SIGN and MDDCs is largely if not wholly carbohydrate dependent.

DC-SIGN was mainly expressed in tubular epithelial cells and DC-SIGN$^+$ DCs were primarily distributed in renal tubulo-interstitial areas during the early stage of nephritis. In a rat model of chronic renal interstitial fibrosis, there was a significant correlation of DC-SIGN expression with DC-SIGN$^+$ DC distribution and the degree of tubulo-interstitial lesion. DC-SIGN plays an important role in DC-mediated renal tubular interstitial lesions induced by immuno-inflammatory responses (Zhou et al. 2009). HIV-1 infection of renal cells has been proposed to play a role in HIV-1-associated nephropathy. The HIV-1 internalization was DC-SIGN receptor mediated. It appeared that HIV-1 routing occurred through nonacid vesicular compartments and the clathrin-coated vesicles and caveosomes may not be contributing to HIV-1-associated membrane traffic (Mikulak et al. 2010). However, Hatsukari et al. (2007) showed no expression of DC-SIGN, or mannose receptors in tubular cells and suggested that DEC-205 (Chap.15 and Chap. 35) acts as an HIV-1 receptor that mediates internalization of the virus into renal tubular cells (HK2), from which the virus can be rescued and disseminated by encountering immune cells.

Herpes Simplex Virus and Human Herpes Virus 8: Of the two Herpes simplex virus (HSV) subtypes described, HSV-1 causes mainly oral-facial lesions, whilst HSV-2 is associated with genital herpes. HSV-1 and -2 both interact with DC-SIGN. Analyses demonstrated that DC-SIGN interacts with the HSV glycoproteins gB and gC. In another setting, human herpesvirus 8 (HHV-8) is the etiological agent of Kaposi's sarcoma, primary effusion lymphoma, and some forms of multicentric Castleman's disease. DC-SIGN is an entry receptor for HHV-8 on DC and macrophages. The infection of B cells with HHV-8 resulted in increased expression of DC-SIGN and a decrease in the expression of CD20 and MHC-I. It was indicated that the expression of DC-SIGN is essential for productive HHV-8 infection of and replication in B cells (de Jong et al. 2008; Rappocciolo et al. 2006, 2008).

West Nile Virus: West Nile virus (WNV), a mosquito-borne flavivirus, has recently emerged in North America. The elderly are particularly susceptible to severe neurological disease and death from infection with this virus. DC-SIGN enhances infection of cells by West Nile virus (WNV) glycosylated strains, which may at least in part explain the higher pathogenicity of glycosylated L1 strains versus most non-glycosylated L2 strains (Martina et al. 2008). Kong et al. (2008) found that the binding of the glycosylated WNV envelope protein to DC-SIGN leads to a reduction in the expression of TLR3 in macrophages from young donors via signal transducer and activator of transcription 1 (STAT1)-mediated pathway. This signaling is impaired in the elderly, and the elevated levels of TLR3 result in an elevation of cytokine levels. This alteration of the innate immune response with aging may contribute to the permeability of blood–brain barrier and a possible mechanism for the increased severity of WNV infection in aged individuals.

Corona Virus Infection and SARS: The MBL deficiency is a susceptibility factor for acquisition of severe acute respiratory syndrome (SARS) corona virus (CoV) (Ip et al. 2005). On similar pattern, entry of the serotype II feline corona virus strains feline infectious peritonitis virus (FIPV) and DF2 into nonpermissive mouse 3T3 cells could be rescued by the expression of human DC-SIGN and the infection of a permissive feline cell line (Crandall-Reese feline kidney) was markedly enhanced by the overexpression of DC-SIGN. Treatment with mannan considerably reduced infection of feline monocyte-derived cells expressing DC-SIGN, indicating a role for FIPV infection in vivo (Regan and Whittaker 2008).

Dengue Virus Envelope Glycoprotein and DC-SIGN: Dengue virus (DV) primarily targets immature DCs after a bite by an infected mosquito vector. Navarro-Sanchez et al. (2003) showed that DC-SIGN is a binding receptor for DV that recognizes N-glycosylation sites on the viral E-glycoprotein and allows viral replication. Mosquito-cell-derived DVs may have differential infectivity for DC-SIGN-expressing cells. There is evidence that infection of immature myeloid DCs plays a crucial role in dengue pathogenesis and that the interaction of the viral envelope E glycoprotein with DC-SIGN is a key element for their productive infection (Kwan et al. 2008).

Measles Virus Targets DC-SIGN: DCs are involved in the pathogenesis of measles virus (MV) infection by inducing immune suppression and possibly spreading the virus from the respiratory tract to lymphatic tissues. The DC-SIGN is the receptor for laboratory-adapted and wild-type MV strains. The ligands for DC-SIGN are both MV glycoproteins F and H. DC-SIGN was found important for the infection of immature DCs with MV, since both attachment and infection of immature DCs with MV were blocked in the presence of DC-SIGN inhibitors. Moreover, MV might not only target DC-SIGN to infect DCs but may also use DC-SIGN for viral transmission and immune suppression (de Witte et al. 2006). Thus, DCs play a prominent role during the initiation, dissemination, and clearance of MV infection (de Witte et al. 2008a).

36.7 Subversion and Immune Escape Activities of DC-SIGN

36.7.1 The entry and dissemination of viruses can be mediated by DC-SIGN

Dendritic cells are likely the first cells to encounter invading pathogens. The entry and dissemination of viruses in several families can be mediated by DC-SIGN. Terminal mannoses at positions 2 or 3 in the trisaccharides are the most important moiety and present the strongest contact with the binding site of DC-SIGN (Reina et al. 2008). Although, the mechanism of DC-SIGN and HIV-1 interaction remains unclear, Smith et al. (2007) identified a cellular protein that binds specifically to the cytoplasmic region of DC-SIGN and directs internalized virus to the proteasome degradation. This cellular protein, leukocyte-specific protein 1 (LSP1) is an F-actin binding protein involved in leukocyte motility and found on the cytoplasmic surface of the plasma membrane. LSP1 interacted specifically with DC-SIGN and other C-type lectins, but not the inactive mutant DC-SIGNΔ35, which lacks a cytoplasmic domain and shows altered virus transport in DCs. Thus, LSP1 protein facilitates virus transport into the proteasome after its interaction with DC-SIGN through its interaction with cytoskeletal proteins. Thus, it has been proposed that attachment of HIV to DC-SIGN enables the virus to hijack cellular transport processes to ensure its transmission to adjacent T cells.

Interestingly, not all interactions between DC-SIGN receptors and pathogenic ligands have beneficial results. During the interaction between body and pathogens or tumors, the latter could escape immune surveillance and survive. Such mechanism is related to suppressions of DCs by DC-SIGN. Thus, though DCs are vital in the defense against pathogens, it is becoming clear that some pathogens subvert DC functions to escape immune surveillance. It appears that some pathogens have evolved immunoevasive or immunosuppressive activities through receptors such as DC-SIGN. For example, HIV-1 targets the DC-SIGN to hijack DCs for viral dissemination. Binding to DC-SIGN protects HIV-1 from antigen processing and facilitates its transport to lymphoid tissues, where DC-SIGN promotes HIV-1 infection of T cells. Studies have also demonstrated that different ligand binding and/or sensing receptors collaborate for full and effective immune responses (McGreal et al. 2005; van Kooyk et al. 2003; Wang et al. 2004). It was also demonstrated that DC-SIGN efficiently reduces the amount of gp120 present on the cell plasma membrane, and completely strips off gp120 from the virions produced by the host cells, suggesting that blockage of HIV budding is due to internalization of gp120 by DC-SIGN (Wang and Pang 2008; Solomon Tsegaye and Pohlmann 2010).

Perhaps, binding of DC-SIGN to gp120 may facilitate or stabilize these transitions. Further studies demonstrated that HIV-1 would lose its activity if it is kept in vitro for 24 h, but DC-SIGN-bound HIV-1 could be kept within DCs for more than 4 days, allowing incoming virus to persist for 25 days before infecting target (Zhou et al. 2004). The mechanism of DC-SIGN prolongating viral infectivity is still poorly understood (Lozach et al. 2005). Thus, HIV sequestration by and stimulation of DC-SIGN helps HIV evade immune responses and spread to cells (Hodges et al. 2007; Marzi et al. 2007).

Many Pathogens Target DC-SIGN to Escape Host Immunity: For Hepatitis C Virus, both DC-SIGN and L-SIGN are known to bind envelope glycoproteins E1 and E2. Soluble DC-SIGN and L-SIGN specifically bound HCV virus-like particles. It is also speculated that HBV exploits mannose trimming as a way to escape recognition by DC-SIGN and thereby subvert a possible immune activation response (Op den Brouw et al. 2008). Reduced expression of DC-SIGN in spleen specifically characterizes pathogenic forms of SIV infection, correlates with disease progression, and may contribute to SIV pathogenesis (Yearley et al. 2008). DC-SIGN acts as a capture or attachment molecule for avian H5N1 virus, and mediates infections in cis and in trans (Wang et al. 2008b). Mittal et al. (2009) demonstrated that *Enterobacter sakazakii* (ES) targets DC-specific DC-SIGN to survive in myeloid DCs for which outer membrane protein A expression in ES is critical, although it is not required for uptake. ES interaction with DC-SIGN seems to subvert the host immune responses by disarming MAPK pathway in DCs (Mittal et al. 2009). *Yersinia pestis* is the etiologic agent of bubonic and pneumonic plagues. It is speculated that *Y. pestis* hijacks DCs and alveolar macrophages, in order to be delivered to lymph nodes. DC-SIGN is a receptor for *Y. pestis* that promotes phagocytosis by DCs in vitro (Zhang et al. 2008b). Accumulating evidence supports that certain pathogens target DC-SIGN to escape host immunity. Unlike certain other host pathogen interactions, activation of DCs by *B. pseudomallei* is not dependent on DC-SIGN. Evidence also indicates that the LPS mutant that binds DC-SIGN has a suppressive effect on DC cytokine production (Charoensap et al. 2008).

36.7.2 DC-SIGN and Escape of Tumors

Recognition of Tumor Glycans: Dendritic cells play an important role in the induction of antitumor immune responses. Glycosylation changes during malignant transformation create tumor-specific carbohydrate structures that interact with C-type lectins on DCs. Studies suggest that tumor glycoproteins, such as carcinoembryonic antigen (CEA) and MUC-1, indeed interact with DC-SIGN and

macrophage galactose-type lectin on APCs. DC-SIGN has been detected on immature DCs that were associated with melanoma and myxofibrosarcoma (Soilleux et al. 2003; Vermi et al. 2003). The consequences for anti-cancer immunity or tolerance induction can be extrapolated from the function of C-type lectins in pathogen recognition and antigen presentation. In addition, in vivo studies in mice demonstrated the potency of targeting antigens to C-type lectins on APCs for anti-tumor vaccination strategies (Aarnoudse et al. 2006).

DC-SIGN and Escape of Tumors: DC-SIGN has been related to immune escape of tumors (van Gisbergen et al. 2005b; Gijzen et al. 2008). Immature DCs are located intratumorally within colorectal cancer and intimately interact with tumor cells, whereas mature DCs are present peripheral to the tumor. The majority of colorectal cancers over-express CEA and malignant transformation changes the glycosylation of CEA on colon epithelial cells, resulting in higher levels of Le^X and de novo expression of Le^Y on tumor-associated CEA. Since DC-SIGN has high affinity for nonsialylated Lewis antigens, it is possible that DC-SIGN is involved in recognition of colorectal cancer cells by DCs. It was shown that immature DCs within colorectal cancer express DC-SIGN, which mediates these interactions through binding of Le^X/ Le^Y carbohydrates on CEA of colorectal cancer cells. In contrast, DC-SIGN does not bind CEA expressed on normal colon epithelium due to low levels of Lewis antigens. This indicates that DCs may recognize colorectal cancer cells through binding of DC-SIGN to tumor-specific glycosylation on CEA. Similar to pathogens that target DC-SIGN to escape immunosurveillance, tumor cells may interact with DC-SIGN to suppress DC functions (van Gisbergen et al. 2005b). At the same time, tumor cells can suppress DC maturation by DC-SIGN and escape immune surveillance. Bogoevska et al. (2006) showed that CEA-related cell adhesion molecule 1 (CEACAM1) selectively attaches and specifically interacts with DC-SIGN, and participates in cancer development. DC-SIGN is involved in the interaction of DCs with colorectal tumor SW1116 cells through the recognition of aberrantly glycosylated forms of Le^a/Le^b glycans on CEA and CEACAM. DC-SIGN ligands containing Le^a/Le^b glycans are also highly expressed on primary cancer colon epithelia but not on normal colon epithelia, and DC-SIGN is suggested to be involved in the association between DCs and colorectal cancer cells in situ by DC-SIGN recognizing these cancer-related Le glycan ligands. Observations imply that colorectal carcinomas affecting DC function and differentiation through interactions between DC-SIGN and colorectal tumor-associated Le glycans may induce generalized failure of a host to mount an effective antitumor response (Nonaka et al. 2008). In acute lymphoblastic leukemia (ALL), aberrant glycosylation of blast cells can alter their interaction with DC-SIGN and L-SIGN, thereby affecting their immunological elimination. High binding of B-ALL peripheral blood cells to DC-SIGN and L-SIGN correlates with poor prognosis. Apparently, when B-ALL cells enter the blood circulation and are able to interact with DC-SIGN and L-SIGN the immune response is shifted toward tolerance (Gijzen et al. 2008).

The role of DCs in progression of primary cutaneous T-cell lymphoma (CTCL) is not established. Schlapbach et al. (2010) found a significant infiltration of CTCL lesions by immature DC-SIGN$^+$ DCs with close contact to tumor cells. Matured and activated DCs were only rarely detected in lesions of CTCL. The preponderance of immature DC-DIGN$^+$ DCs in contact with regulatory T cells in lesions of CTCL points to an important role of this subset in the host's immune reaction to the malignant T cells. Since these immature DCs are known to induce immunotolerance, they might play a role in the mediation of immune escape of the proliferating clone (Schlapbach et al. 2010). In contrast, studies showed that there are CEA specific T cells in colorectal cancer patients which have anti-tumor effects (Nagorsen et al. 2000). Such results suggest that DCs could recognize and bind to colorectal tumor cells by DC-SIGN and participate in anti-tumor immune response.

36.7.3 *Mycobacterial* Carbohydrates as Ligands of DC-SIGN, L-SIGN and SIGNR1

Mycobacteria, including *M. tuberculosis* (Mtb), are surrounded by a loosely attached capsule that is mainly composed of proteins and polysaccharides. Although the chemical composition of the capsule is relatively well studied, its biological function is only poorly understood. *M. tuberculosis*, the causative agent of tuberculosis (TB), is recognized by pattern recognition receptors on macrophages and DCs, thereby triggering phagocytosis, antigen presentation to T cells and cytokine secretion. Mtb spreads through aerosol carrying them deep into the lungs, where they are internalized by phagocytic cells, such as neutrophils (PMNs), DCs, and macrophages. The DC- Mtb manipulates cells of the innate immune system to provide the bacteria with a sustainable intracellular niche (Schaefer et al. 2008). Mannosylated moieties of the mycobacterial cell wall, such as mannose-capped lipoarabinomannan (ManLAM) or higher-order phosphatidylinositol-mannosides (PIMs) of Mtb, were shown to bind to DC-SIGN on immature DCs and macrophage subpopulations. This interaction reportedly impaired dendritic cell maturation, modulated cytokine secretion by phagocytes and dendritic cells and was postulated to cause suppression of protective immunity to TB. However, experimental Mtb infections in mice transgenic for human DC-SIGN revealed

that, instead of favoring immune evasion of mycobacteria, DC-SIGN may promote host protection by limiting tissue pathology. Furthermore, infection studies with mycobacterial strains genetically engineered to lack ManLAM or PIMs demonstrated that manLAM/PIM-DC-SIGN interaction was not critical for cytokine secretion in vitro and protective immunity in vivo (Ehlers 2010).

Reports suggest that *M. tuberculosis* targets DC-SIGN to inhibit the immuno-stimulatory function of DC through the interaction of the mycobacterial ManLAM to DC-SIGN, which prevents DC maturation and induces the formation of immuno-suppressive cytokine IL-10 that helps in the survival and persistence of *M. tuberculosis* (Fig. 36.2). The pathogen-derived carbohydrate structure on ManLAM that is recognized by DC-SIGN has been identified. The synthetic mannose-cap oligosaccharides manara, (Man)2-ara and (Man)3-ara specifically bound by DC-SIGN. The human and murine DC-SIGN homolog L-SIGN and SIGNR1, respectively, also interact with mycobacteria through ManLAM. Both homologs have the highest affinity for the (Man)3-ara structure, similar to DC-SIGN. The identification of SIGNR1 as a receptor for ManLAM enabled in vivo studies to investigate the role of DC-SIGN in *M. tuberculosis* pathogenesis (Geijtenbeek et al. 2003; Tailleux et al. 2003; Koppel et al. 2004). In addition to manLAM, Mtb α-glucan is another ligand for DC-SIGN. The recognition of α-glucans by DC-SIGN is a general feature and the interaction is mediated by internal glucosyl residues. As for manLAM, an abundant mycobacterial cell wall-associated glycolipid, binding of α-glucan to DC-SIGN stimulated the production of immunosuppressive IL-10 by LPS-activated monocyte-derived DCs. This IL-10 induction was DC-SIGN-dependent and also required acetylation of NF-kB (Geurtsen et al. 2009).

The mannose cap of LAM is a crucial factor in mycobacterial virulence. Appelmelk et al. (2008) evaluated the biological properties of capless mutants of *M. marinum* and *M. bovis* BCG, made by inactivating homologs of Rv1635c and showed that its gene product is an undecaprenyl phospho-mannose-dependent mannosyltransferase. Compared with parent strain, capless *M. marinum* induced slightly less uptake by and slightly more phagolysosome fusion in infected macrophages but this did not lead to decreased survival of the bacteria in vitro, nor in vivo in zebra fish. Appelmelk et al. (2008) contradicted the current paradigm and demonstrated that mannose-capped LAM does not dominate the M.-host interaction. Although the mannose caps of the mycobacterial surface (ManLAM) are essential for the binding to DC-SIGN, genetic removal of these caps did not diminish the interaction of whole mycobacteria with DC-SIGN and DCs. Like ManLAM, Hexamannosylated PIM (6), which contains terminal α(1—>2)-linked mannosyl residues identical to the mannose cap on ManLAM showed high affinity and represents a bonafide DC-SIGN ligand but that other, as-yet-unknown, ligands dominate in the interaction between *mycobacteria* and DCs (Driessen et al. 2009) (Fig. 36.1, 36.2).

36.7.4 Decreased Pathology of Human DC-SIGN Transgenic Mice During Mycobacterial Infection

Although, the *M. tuberculosis*, the causative agent of pulmonary tuberculosis, interacts with DC-SIGN to evade the immune system, transgenic mice after high dose aerosol infection with the strain *Mtb*-H37Rv, showed massive accumulation of DC-SIGN$^+$ cells in infected lungs, reduced tissue damage and prolonged survival. Based on these results, it was proposed that instead of favoring the immune evasion of mycobacteria, human DC-SIGN may have evolved as a pathogen receptor promoting protection by limiting tuberculosis-induced pathology (Schaefer et al. 2008). Hedlund et al. (2010) demonstrated that DCs can distinguish between normal and infected apoptotic PMNs via cellular crosstalk, where the DCs can sense the presence of danger on the Mtb-infected PMNs and modulate their response accordingly. Balboa et al. (2010) showed that early interaction of Î-irradiated *M. tuberculosis* with Mo subverts DC differentiation in vitro and suggested that *M. tuberculosis* escapes from acquired immune response in tuberculosis may be caused by an altered differentiation into DC leading to a poor Mtb-specific T-cell response. Since, *M. tuberculosis* interacts with DC-SIGN to evade the immune system, the dominant Mtb-derived ligands for DC-SIGN are presently unknown, and a major role of DC-SIGN in the immune response to Mtb infection may lie in its capacity to maintain a balanced inflammatory state during chronic TB (Ehlers 2010).

36.7.5 Genomic Polymorphism of DC-SIGN (CD209) and Consequences

36.7.5.1 CD209 Genetic Polymorphism and HIV Infectivity

DC-SIGN and DC-SIGNR have been thought to play an important role in establishing HIV infection by enhancing trans-infection of CD4$^+$ T cells in the regional lymph nodes. The variation of DC-SIGNR genotypes affects the efficacy of trans-infection by affecting the amounts of the protein expressed on cell surface and augmenting the infection. A potential association of DC-SIGN and DC-SIGNR neck domain repeat polymorphism and risk of HIV-1 infection is currently under debate. Rathore et al. (2008a) showed that polymorphism in DC-SIGN neck repeats region was rare and not associated with HIV-1 susceptibility among North Indians. But sequencing analysis of DC-SIGN gene

confirmed four novel genetic variants in intronic region flanking exon 4 coding region. A total of 13 genotypes were found in DC-SIGNR neck repeat region polymorphism. Among all the genotypes, only 5/5 homozygous showed significant reduced risk of HIV-1 infection in HIV-1-exposed seronegative individuals. A unique genotype 8/5 heterozygous was also found in HIV-1 seropositive individual, which is not reported elsewhere (Rathore et al. 2008a, b).

The association of polymorphism of homolog of DC-SIGNR gene with susceptibility to virus infection suggests that the tandem-repeat polymorphisms of the DC-SIGNR gene in the Chinese Han population exhibit unique genetic characteristics not recognized earlier in the Caucasian population. Genotype 9/5 seems to be a risk factor for HIV-1 infection in the Chinese population (Wang et al. 2008a). To understand the role of DC-SIGN neck-region length variation in HIV-1 transmission, Zhang et al. (2008a) studied 530 HIV-1-positive and 341 HIV-1-negative individuals in China. The carrier frequency of a DC-SIGN allele with <5 repeat units in the neck-region was 0.9% in HIV-1-positive and 3.8% in HIV-1-negative individuals. This observation suggests that DC-SIGN variation plays a role in HIV-1 transmission. These naturally occurring DC-SIGN neck-region variants were significantly more frequent in the Chinese population than in the US population and in a worldwide population. Several transcripts of DC-SIGN have been identified, some of which code for putative soluble proteins. However, little is known about the regulation and the functional properties of such putative sDC-SIGN variants. Based on the analysis of the cytokine/chemokine content of sDC-SIGN culture supernatants, results confirmed that sDC-SIGN, like membrane DC-SIGN counterpart, may play a pivotal role in CMV-mediated pathogenesis (Plazolles et al. 2011). Variations in genes encoding virus recognition and reactivation and patients following allogeneic stem-cell transplantation suggested that two SNP (rs735240, G > A; rs2287886, C > T) in the promoter region of DC-SIGN are significantly associated with an increased risk of development of hCMV reactivation and disease. These genetic markers influence the expression levels of DC-SIGN on immature DCs, as well as infection efficiency of immature DCs by hCMV and might help to predict the individual risk of hCMV reactivation and the disease (Mezger et al. 2008).

Variations in the number of repeats in the neck region of DC-SIGN and DC-SIGNR possibly influence host susceptibility to HIV-1 infection. Chaudhary et al. (2008a) examined the SNP of DC-SIGN and DC SIGNR in healthy HIV seronegative individuals, high risk STD patients seronegative for HIV, and HIV-1 seropositive patients from northern India. DC-SIGN polymorphism was rare and genotype 7/7 was predominant in all groups studied. DC-SIGNR was highly polymorphic and 11 genotypes were observed among the different study groups. The precise role of the polymorphic variants of DC-SIGNR needs to be elucidated in the population (Chaudhary et al. 2008a, b). GG genotype of SDF-1α 3′UTR polymorphism may be associated with susceptibility to PTB in HIV-1 infected patients in south India. Genotype frequencies of DC-SIGN polymorphisms did not differ significantly between HIV patients with or without TB. A better understanding of genetic factors that are associated with TB could help target preventive strategies to those HIV patients likely to develop tuberculosis (Alagarasu et al. 2009). Whether variants in the DC-SIGN encoding CD209 gene are associated with susceptibility to or protection against HIV-1 infection or development of TB among HIV-1 infected south Indian patients, study suggests that -336G/G genotype while associated with protection against HIV-1 infection the same genotype is also associated with susceptibility to HIV-TB among south Indians (Selvaraj et al. 2009). Olesen et al. (2007) support the report that vitamin D receptor (VDR) gene SNPs modulate the risk for TB in West Africans and suggest that variation within DC-SIGN and PTX3 also affect the disease outcome.

Reports suggest that CD209 promoter SNP-336A/G exerts an effect on CD209 expression and is associated with human susceptibility to dengue, HIV-1 and tuberculosis in humans. The CD209 -336G variant allele is also associated with significant protection against tuberculosis in individuals from sub-Saharan Africa and, cases with -336GG were significantly less prone to develop tuberculosis-induced lung cavitation. Previous in vitro work demonstrated that the promoter variant -336G allele causes down-regulation of CD209 mRNA expression. This report suggests that decreased levels of the DC-SIGN receptor may be protective against both clinical tuberculosis in general and cavitory tuberculosis disease in particular. This is consistent with evidence that *Mycobacteria* can utilize DC-SIGN binding to suppress the protective pro-inflammatory immune response (Vannberg et al. 2008).

Wichukchinda et al. (2007) genotyped two SNPs in DC-SIGN promoter (-139A/G and 336A/G), a repeat number of 69 bp in Exon 4 of DC-SIGN and DC-SIGNR, and one SNP in Exon 5 of DC-SIGNR and showed that the proportion of individuals possessing a heterozygous 7/5 and 9/5 repeat and A allele at rs2277998 of DC-SIGNR in HIV-seronegative individuals of HIV-seropositive spouses was significantly higher than HIV-seropositive individuals. These associations were observed only in females but not in males. The proportion of individuals possessing the 5A haplotype in HIV-seronegative females was significantly higher than HIV-seropositive females. These associations suggested that DC-SIGNR might affect susceptibility to HIV infection by a mechanism that is different in females and males (Wichukchinda et al. 2007; Zhu et al. 2010).

36.7.5.2 Human T-Cell Lymphotropic Virus Type 1 (HTLV) Infection

DC-SIGN plays a critical role in HTLV-1 binding, transmission, and infection, thereby providing an attractive target for the development of antiretroviral therapeutics and microbicides (Jain et al. 2009). Kashima et al. (2009) evaluated four polymorphisms located in the DC-SIGN gene promoter region (positions -336, -332 -201 and -139) in DNA samples from Brazilian ethnic groups (Caucasians, Afro-Brazilian, Asians and Amerindians) to establish the population distribution of these SNPs and correlated DC-SIGN polymorphisms and infection in samples from human T-cell lymphotropic virus type 1 (HTLV-1)-infected individuals. The -336A and -139A SNPs were quite common in Asians and that the -201T allele was not observed in Caucasians, Asians or Amerindians. No significant differences were observed between individuals with HTLV-1 disease and asymptomatic patients. However, the -336A variant was more frequent in HTLV-1-infected patients. In addition, the -139A allele was found to be associated with protection against HTLV-1 infection when the HTLV-1-infected patients as a whole were compared with the healthy-control group. Kashima et al. (2009) suggested that the -139A allele might be associated with HTLV-1 infection, although no significant association was observed among asymptomatic and HAM/TSP patients. Koizumi et al. (2007) showed that RANTES -28G was associated with delayed AIDS progression, while DC-SIGN -139C was associated with accelerated AIDS progression in HIV-1-infected Japanese hemophiliacs. While analyzing DC-SIGN and DC-SIGNR polymorphisms in Caucasian Canadian and indigenous African populations, Boily-Larouche et al. (2007) found several novel nucleotide variants within regulatory 5′- and 3′-untranslated regions of the genes that could affect their transcription and translation. Study demonstrated that Africans show greater genetic diversity at these two closely-related immune loci than observed in other major population groups.

36.7.5.3 CD209 Genetic Polymorphism and Tuberculosis Disease

DC-SIGN is a receptor capable of binding and internalizing *M. tuberculosis*. The CD209 promoter single SNP-336A/G exerts an effect on CD209 expression and is associated with human susceptibility to dengue, HIV-1 and tuberculosis in humans. In vitro studies confirmed that this SNP modulates gene promoter activity. An association study was performed in Tunisian patients comprising tuberculosis and healthy controls. Sequencing of the DC-SIGN promoter region detected four polymorphisms (-939, -871, -601, and -336), but no differences in their allelic distribution were observed between the two groups. In addition, the analysis of length variation in the DC-SIGN neck region indicated extremely low levels of polymorphisms and, again, no differences between patients and controls. Results suggested neither promoter variants nor length variation in the neck region of DC-SIGN is associated with susceptibility to tuberculosis in Tunisian patients (Ben-Ali et al. 2007).

Among Caucasians patients suffering from pulmonary tuberculosis, DC-SIGN revealed no significant differences in loci -336A/G and -871A/G with controls. Analysis of MIRU-VNTR patterns identified 50 unique profiles, among which there were genotypes of the families Beijing, T. LAM, Haarlem, "Ural" (Haarlem 4) and X. Among 90 MIRU-VNTR genotypes, 42 profiles belonged to the Beijing family. Moreover, the minimum spanning tree (MST) test revealed a number of Beijing-like strains. The genotypes of the subjects affected with Beijing and Beijing-like strains and those affected with the strains of other families (non-Beijing) were compared. A significance reduction was found in the incidence of the -336G genotype among the subjects affected with Beijing strains versus those infected with non-Beijing strains at a frequency of 0.09 and 0.24, respectively (Ogarkov et al. 2007). CD209 facilitates severe acute respiratory syndrome (SARS)-coronavirus spike protein-bearing pseudotype driven infection of permissive cells in vitro. Genetic association analysis of SNP with clinico-pathologic outcomes in 824 serologic confirmed that the -336AG/GG genotype SARS patients were associated with lower LDH levels compared with the -336AA patients. High LDH levels are known to be an independent predictor for poor clinical outcome, probably related to tissue destruction from immune hyperactivity. Hence, SARS patients with the CD209 -336 AA genotype carry a 60% chance of having a poorer prognosis. This association is in keeping with the role of CD209 in modulating immune response to viral infection. The relevance of these findings for other infectious diseases and inflammatory conditions would be worth investigating (Chan et al. 2010).

36.8 SIGNR1 (CD209b): The Murine Homologues of DC-SIGN

36.8.1 Characterization

The mouse (m) DC-SIGN family consists of several homologous type II transmembrane proteins located in close proximity on chromosome 8 and having a single carboxyl terminal carbohydrate recognition domain. Initial screening of mouse cDNA libraries led to the identification of multiple mouse homologs of DC-SIGN and DC-SIGNR, designated DC-SIGN and SIGNR1 through SIGNR4 by Park et al. (2001). More murine homologs of human SIGNs have been identified, and the biochemical and cell biological properties of all murine SIGNs have been compared (Fig. 36.3). The SIGNR1 is a C-type lectin domain of murine homolog

of DC-SIGN and functions in vivo as a pathogen recognition receptor on macrophages that captures blood-born antigens, which are rapidly internalized and targeted to lysosomes for processing (Geijtenbeek et al. 2002b). In addition to five SIGNR proteins, a pseudogene, encoding a hypothetical SIGNR6, and a further two expressed proteins, SIGNR7 and SIGNR8, have been identified. Screening of a glycan array demonstrated that only mouse SIGNR3 shares with human DC-SIGN the ability to bind both high mannose and fucose-terminated glycans in this format and to mediate endocytosis. SIGNR3 is a differentiation marker for myeloid mononuclear cells and that some DCs, especially in sLNs, are possibly replenished by Ly6C(high) monocytes (Nagaoka et al. 2010). The mouse homologs of DC-SIGN have a diverse set of ligand-binding and intracellular trafficking properties, some of which are distinct from the properties of any of the human receptors (Powlesland et al. 2006).

SIGN Related 1 (SIGNR1) or CD209b is expressed at high levels on macrophages in lymphoid tissues, especially within the marginal zone of the spleen. SIGNR1 can bind and mediate the uptake of various microbial polysaccharides, including dextrans, lipopolysaccharides and pneumococcal capsular polysaccharides. SIGNR1 mediates the clearance of encapsulated pneumococcus, complement fixation via binding C1q independent of antibody and innate resistance to pneumococcal infection. Recently, SIGNR1 has also been demonstrated to bind sialylated antibody and mediate its activity to suppress autoimmunity (Silva-Martin et al. 2009). The CRD of SIGNR1 has been cloned and overexpressed in a soluble secretory form in CHO cells. The single crystal of CRD protein of SIGNR1 belonged to the monoclinic space group C2 with unit-cell parameters $a = 146.72, b = 92.77, c = 77.06$ A, $\beta = 121.66°$, allowed the collection of a full X-ray data set to a maximum resolution of 1.87 A (Silva-Martin et al. 2009).

36.8.2 Functions

SIGNR1 receptor, involved in the uptake of capsular polysaccharides (caps-PS) by APCs, is necessary for the antibody response to pneumococcal caps-PS and phosphorylcholine (PC). Moens et al. (2007) found that SIGNR1 is not involved in the IgM antibody production to PC and caps-PS serotype 3 or 14 and the IgG immune response to PC and caps-PS serotype 14. There is no direct relation between capture and uptake of caps-PS serotype 14 by SIGNR1 and the initiation of the anti-caps-PS antibody production in mice. Resident peritoneal macrophages (PEMs) express SIGNR1 on the cell surface as a major mannose receptor. These cells also ingest oligomannose-coated liposomes (OMLs) in an oligomannose-dependent manner following intraperitoneal administration. SIGNR1 on macrophages acts as a receptor for recognition of OMLs under physiological conditions (Takagi et al. 2009). Sialylated Fc from IgG require SIGNR1 which preferentially binds to 2,6-sialylated Fc compared with similarly sialylated, biantennary glycoproteins, suggesting that a specific binding site is created by sialylation of IgG Fc. A human DC-SIGN displays a binding specificity similar to SIGNR1 but differs in its cellular distribution. These studies thus identify an antibody receptor specific for sialylated Fc, and present the initial step that is triggered by intravenous Ig to suppress inflammation (Anthony et al. 2008).

SIGNR1 also interacts with *M. tuberculosis* similar to DC-SIGN. Peritoneal macrophages from SIGNR1 deficient (KO) mice produce less IL-10 upon stimulation with ManLAM than those from wild-type mice, suggesting that the interaction of ManLAM with SIGNR1 can result in immuno-suppression similar to its human homolog. Studies suggest that although SIGNR1 has a similar binding specificity as DC-SIGN, its role is limited during murine M. tuberculosis infection (Wieland et al. 2007). Resistance to *M. tuberculosis* was impaired only in SIGNR3-deficient animals. SIGNR3 was expressed in lung phagocytes during infection, and interacted with *M. tuberculosis* bacilli and mycobacterial surface glycoconjugates to induce secretion of critical host defense inflammatory cytokines, including TNF. SIGNR3 signaling was dependent on an intracellular tyrosine-based motif and the tyrosine kinase Syk. Thus, the mouse DC-SIGN homolog SIGNR3 makes a unique contribution to protection of the host against a pulmonary bacterial pathogen (Tanne et al. 2009). The rat CD209b mediates the uptake of dextran or CPS14 within the rat splenic marginal zone, similar to SIGNR1. On microglia, rat CD209b also mediates the uptake of CPS14 of *S. pneumoniae*. Findings suggest that both rat CD209b and SIGNR1 on microglia mediate the SIGNR1 complement activation pathway against *S. pneumoniae*, and thereby plays an important role in the pathogenesis of pneumococcal meningitis (Park et al. 2009).

Marginal zone macrophages in the murine spleen play an important role in the capture of blood-borne pathogens and are viewed as an essential component of host defense against the development of pneumococcal sepsis. However, reports described the loss of marginal zone macrophages associated with the splenomegaly that follows a variety of viral and protozoal infections; this finding raises the question of whether these infected mice would become more susceptible to secondary pneumococcal infection. Contrary to expectations, Kirby et al. (2009) demonstrated that the normal requirement for SIGNR1$^+$ marginal zone macrophages to protect against a primary pneumococcal infection can be readily compensated for by activated red pulp macrophages under conditions of splenomegaly. SIGNR1 is crucial for the capture of *S.*

pneumoniae from blood. SIGNR1 is able to interact in vitro with the juxtaposing marginal zone B cell population, which is responsible for the production of early IgM response against the *S. pneumoniae*-epitope phosphorylcholine. Strikingly, SIGNR1-deficient mice display a reduction in the marginal zone B cell population. In addition, ex vivo B cell stimulation assays demonstrate a decrease in phosphorylcholine specificity in the splenic B cell population derived from SIGNR1-deficient mice, whereas the total IgM response was unaffected. Therefore, interaction of SIGNR1 expressed by marginal zone macrophages with marginal zone B cells is essential to early IgM responses against *S. pneumoniae* (Koppel et al. 2008; Saunders et al. 2009).

Inflammatory Bowel Disease: In context of the etiology of inflammatory bowel disease, there is a less defined function for C-type lectins. The CD209 gene is located in a region linked to inflammatory bowel disease (IBD). Though the CD209 functional polymorphism (rs4804803) has been associated to other inflammatory conditions, it does not seem to be influencing Crohn's disease susceptibility. However, it could be involved in the etiology or pathology of Ulcerative Colitis in HLA-DR3-positive individuals (Núñez et al. 2007). Saunders et al. (2010) demonstrated that mice deficient in SIGNR1 have reduced susceptibility to experimental colitis, with a reduction in the disease severity, colon damage, and levels of the proinflammatory cytokines IL-1β, TNF-α, and IL-6. SIGNR1$^{-/-}$ peritoneal macrophages, but not bone marrow-derived macrophages, had a specific defect in IL-1β and IL-18 production, but not other cytokines, in response to TLR4 ligand LPS. SIGNR1 was associated in the regulation of inflammation in a model of experimental colitis and is a critical innate factor in response to LPS.

36.9 Liver and Lymph Node Sinusoidal Endothelial Cell C-Type Lectin (LSECtin) (or CLEC4G or L-SIGN or CD209L)

36.9.1 Characterization and Localization

The liver is an organ with paradoxic immunologic properties and is known for its tolerant microenvironment, which holds important implications for hepatic diseases. Liver and lymph node sinusoidal endothelial cell C-Type lectin (LSECtin) (or CLEC4G or L-SIGN or CD209L) displays 77% amino acid identity with DC-SIGN, and is expressed on endothelial cells in lymph node sinuses, capillary endothelial cells in the placenta and on liver sinusoidal cells (LSECs) (Soilleux et al. 2000; Bashirova et al. 2001; Pohlmann et al. 2001; Engering et al. 2004). The LSECtin (CD209L), gene encodes a protein of 293 amino acids and maps to chromosome 19p13.3 adjacent to C-type lectin genes, CD23, DC-SIGN, and DC-SIGNR. The four genes form a tight cluster in an insert size of 105 kb and have analogous genomic structures. The LSECtin is a type II integral membrane protein of approximately 40 kDa in size with a single C-type lectin-like domain at the C-terminus, close in homology to DC-SIGNR, DC-SIGN, and CD23. LSECtin mRNA was expressed in liver and lymph node among 15 human tissues tested, intriguingly neither expressed on hematopoietic cell lines nor on monocyte-derived DCs. Colmenares et al. (2007) detected LSECtin expression in human peripheral blood and thymic dendritic cells. LSECtin is also detected in monocyte-derived macrophages and dendritic cells at RNA and protein level (Liu et al. 2004). LSECtin could also be detected in the MUTZ-3DC cell line at mRNA and protein level. Human liver revealed its presence in Kupffer cells coexpressing the myeloid marker CD68 (Domínguez-Soto et al. 2009). In vitro, IL-4 induces the expression of 3 LSECtin alternatively spliced isoforms, including a potentially soluble form (Δ2 isoform) and a shorter version of the prototypic molecule (Δ3/4 isoform).

Full-length porcine (p) CLEC4G (L-SIGN) cDNA encodes a type II transmembrane protein of 290 amino acids. The pCLEC4G gene has same gene structure as human and the predicted bovine, canis, mouse and rat CLEC4G genes with nine exons. The pCLEC4G mRNA expresses in liver, lymph node and spleen tissues. A series of sequential intermediate products of pCLEC4G pre-mRNA were also identified during splicing from pig liver. The chromosomal regions syntenic to the human cluster of genes CD23/CLEC4G/DC-SIGN/L-SIGN have been compared in mammalian species including primates, domesticated animal, rodents and opossum. The L-SIGN homologs do not exist in non-primates mammals (Huang and Peng 2009).

In the liver LSECs functions as liver-resident antigen presenting cells (Knolle and Gerken 2000) and is important in tolerance induction (Knolle and Limmer 2001). LSECs may mediate the clearance of antigens from the circulation in same manner as DCs (Bashirova et al. 2001; Karrar et al. 2007). DC-SIGN and L-SIGN (LSECtin) share a di-leucine motif and a cluster of three acidic amino acids in their cytoplasmic tails, which are known to be essential for antigen uptake (Bashirova et al. 2001; Engering et al. 2002). Recent studies with Ebola virus, Severe Acute Respiratory Syndrome (SARS) virus or antibodies against L-SIGN, clearly demonstrated that L-SIGN indeed is able to internalize antigens (Klimstra et al. 2003; Liu et al. 2004; Jeffers et al. 2004; Ludwig et al. 2004; Dakappagari et al. 2006). DC-SIGN transient expression in HEK293T is a useful model for investigating p38 MAPK pathway

triggered by hepatitis C virus glycoprotein E2, which may provide information for understanding cellular receptors-mediated signaling events and the viral pathogenesis (Chen et al. 2010).

36.9.2 Ligands of LSECtin

LSECtin binds to mannose, GlcNAc, and fucose in a Ca^{2+}-dependent manner but not to galactose (Liu et al. 2004). The DC-SIGN and DC-SIGNR (DC-SIGN/R) bind to high-mannose carbohydrates on a variety of viruses. In contrast, the related lectin LSECtin does not recognize mannose-rich glycans and interacts with a more restricted spectrum of viruses. LSECtin and DC-SIGNR, which are co-expressed by liver, lymph node and bone marrow sinusoidal endothelial cells, bind to soluble Ebola virus glycoprotein (EBOV-GP) with comparable affinities. Similarly, LSECtin, DC-SIGN and Langerin readily bound to soluble HIV-1 GP. However, only DC-SIGN captured HIV-1 particles, indicating that binding to soluble GP is not necessarily predictive of binding to virion-associated GP. Results reveal important differences between pathogen capture by DC-SIGN/R and LSECtin and hint towards different biological functions of these lectins (Gramberg et al. 2008). To compare the sugar and pathogen binding properties of LSECtin with those of related but more extensively characterized receptors, such as DC-SIGN, a soluble fragment of LSECtin consisting of the C-terminal CRD was expressed in bacteria and used to probe a glycan array and to characterize binding to oligosaccharide and glycoprotein ligands. LSECtin binds with high selectivity to glycoproteins terminating in GlcNAcβ1-2Man. Glycan analysis of the surface glycoprotein of Ebola virus reveals the presence of such truncated glycans, explaining the ability of LSECtin to facilitate infection by Ebola virus (Powlesland et al. 2008). A systematic study of DC-SIGN, DC-SIGNR and LSECtin suggested that 'agalactosylated N-glycans' are candidate ligands common to these lectins (Dominguez-Soto et al. 2010).

Polymorphisms of *CLEC4M* have been associated with predisposition for infection by severe acute respiratory syndrome coronavirus (SARS-CoV). LSECtin not only acts as an attachment factor for pathogens, but also recognizes "endogenous" activated T cells. The CD44 on Jurkat T cells is a candidate ligand of LSECtin. Moreover, LSECtin selectively bound CD44s, CD44v4 and CD44v8-10 by screening a series of typical CD44 isoforms. The interaction between CD44 and LSECtin is dependent on protein-glycan recognition. Findings indicate that CD44 is the first endogenous ligand of LSECtin, and that LSECtin is a ligand of CD44 (Tang et al. 2010).

36.9.3 Functions

LSECtin functions as a pathogen receptor, because its expression confers Ebola virus-binding capacity to leukemic cells. Sugar-binding studies indicate that LSECtin specifically recognizes N-acetyl-glucosamine, whereas no LSECtin binding to Mannan- or N-acetyl-galactosamine-containing matrices are observed. Antibody or ligand-mediated engagement triggers a rapid internalization of LSECtin, which is dependent on tyrosine and diglutamic-containing motifs within the cytoplasmic tail. Therefore, LSECtin is a pathogen-associated molecular pattern receptor in human myeloid cells. In addition, LSECtin participates in antigen uptake and internalization, and might be a suitable target in vaccination strategies (Colmenares et al. 2007). In liver, LSECtin specifically recognized activated T cells and negatively regulated their immune responses. In mice with T-cell-mediated acute liver injury, the lack of LSECtin accelerated the disease owing to an increased T-cell immune response, whereas the exogenous administration of recombinant LSECtin protein or plasmid ameliorated the disease via down-regulation of T-cell immunity. Results reveal that LSECtin is a novel regulator of T cells and expose a crucial mechanism for hepatic T-cell immune suppression, perhaps opening up a new approach for treatment of inflammatory diseases in the liver (Tang et al. 2009).

The L-SIGN (or LSECtin) is also expressed in human lung in type II alveolar cells and endothelial cells, both potential targets for SARS-CoV. Since, several other enveloped viruses including *Ebola* and *Sindbis* use CD209L as a portal of entry, and HIV and *hepatitis C virus* can bind to L-SIGN on cell membranes but do not use it to mediate virus entry, it appears that the large S glycoprotein of SARS-CoV may use L-SIGN, in addition to ACE2 in infection and pathogenesis (Jeffers et al. 2004). Capture of *Hepatitis C virus* (HCV) by L-SIGN results in *trans*-infection of hepatoma cells. L-SIGN polymorphism could influence the establishment and progression of HCV infection (Falkowska et al. 2006). There is no significant correlation between the genetic polymorphism of DC-SIGN's exon 4 and HCV infection susceptibility. 9/5 genotype distribution frequency of DC-SIGNR's exon 4 in patients with hepatitis C is significantly higher and may be associated with HCV infection susceptibility (Wang et al. 2007). The L-SIGN binds mycobacterial ManLAM but not AraLAM, suggesting that L-SIGN may bind *M. tuberculosis*. Binding assays suggest that L-SIGN interacts strongly with the (Man)2-ara and (Man)3-ara, but not with the man-ara, similar to DC-SIGN. It indicates that L-SIGN may be involved in the pathogenesis of *M. tuberculosis* infection and that the L-SIGN captures the infection through ManLAM and rapidly internalizes it to lysosomes. This shows that L-SIGN may be involved in the clearance of mycobacteria since L-SIGN is expressed on those sites in lymph nodes and

liver which are ideally suited for antigen capture and clearance. However, mycobacteria may target L-SIGN to invade those tissues. More research is necessary to investigate the specific role of L-SIGN in these infections.

36.9.4 Role in Pathology

LSECtin enhances infection driven by filovirus glycoproteins (GP) and the S protein of SARS coronavirus, but does not interact with HIV-1 and hepatitis C virus envelope proteins. Ligand binding to LSECtin was inhibited by EGTA but not by mannan, suggesting that LSECtin unlike DC-SIGN/R does not recognize high-mannose glycans on viral glycoproteins. LSECtin is N-linked glycosylated and glycosylation is required for cell surface expression. In nut-shell, LSECtin is an attachment factor that in conjunction with DC-SIGNR might concentrate viral pathogens in liver and lymph nodes (Gramberg et al. 2005). Li et al. (2008) genotyped 23 tagSNPs in 181 SARS patients and reported no significant association with disease predisposition. Genetic variations in this cluster also did not predict disease prognosis. However, Li et al. (2008) detected a population stratification of the VNTR alleles in a sample of 1145 Han Chinese collected from different parts of China. Li et al. (2008) indicated that the genetic predisposition allele was not found in this lectin gene cluster and population stratification might have caused the previous positive association.

Part XII

C-Type Lectins: Proteoglycans

Lectican Protein Family

37

G.S. Gupta

37.1 Proteoglycans

Proteoglycans (PGs) are a diverse group of glycoproteins, which are formed through covalent and noncovalent aggregation of proteins and glycosaminoglycans (GAGs) in the extracellular matrix. GAGs are linear polysaccharides, whose building blocks (disaccharides) consist of an amino sugar (either GlcNAc or GalNAc) and an uronic acid (GlcA and IdoA). Virtually all mammalian cells produce proteoglycans and either secrete them into the ECM, insert them into the plasma membrane, or store them in secretory granules. The matrix proteoglycans include small interstitial proteoglycans (decorin, biglycan, fibromodulin), a proteoglycan form of type IX collagen, and one or more members of the aggrecan family of proteoglycans (aggrecan, brevican, neurocan, or versican). Some of these proteoglycans contain only one GAG chain (e.g., decorin), whereas others have more than 100 chains (e.g., aggrecan). The matrix proteoglycans typically contain the GAGs known as chondroitin sulfate (CS) or dermatan sulfate (DS). Exceptions to this generalization exist, since the HS proteoglycans perlecan and agrin are major species found in basement membranes. The size and shape of PGs vary widely that suggests numerous functions for them. The protein components of PGs are synthesized by ribosomes and translocated into the lumen of the rough endoplasmic reticulum. Glycosylation of the proteoglycan occurs in the Golgi apparatus in multiple enzymatic steps. The point of attachment is a Serine (Ser) residue to which the glycosaminoglycan is joined through a tetrasaccharide bridge (For example: chondroitin sulfate-GlcA-Gal-Gal-Xyl-PROTEIN). The Ser residue is generally in the sequence -Ser-Gly-X-Gly- (where X can be any amino acid residue), although not every protein with this sequence has an attached glycosaminoglycan. Thus, a PG contains a core protein and one to many glycosaminoglycans or carbohydrate chains. Along with glycoproteins and glycolipids proteoglycans on the noncytosolic side of the cell membrane form the carbohydrate layer. This layer on top of the bilipid layer serves to protect the cell from both chemical and mechanical damage. These components absorb water, giving the cell a slimy surface. Another main function of PGs is to regulate the movement of molecules through the matrix. Proteoglycans also contribute to the activity and stability of proteins within the matrix.

Proteoglycans being the major component of the animal extracellular matrix, are called the "filler" substances between cells in an organism. Here they form large complexes, both to other proteoglycans, to hyaluronan and to fibrous matrix proteins (such as collagen). They are also involved in binding cations (such as sodium, potassium and calcium) and water, and also regulating the movement of molecules through the matrix. Evidence also shows that they can affect the activity and stability of proteins and signalling molecules within the matrix. Individual functions of proteoglycans can be attributed to either the protein core or the attached GAG chain and serve as lubricants.

37.1.1 Nomenclature of PGs

Nomenclature for PGs is based on the source of glycosylation or the functions of PG. Many PGs can be classified on the basis of the size of core protein. Size is also used for classification of PGs (Table 37.1). Large PGs are considered aggrecans, which are a major part of cartilage (Fig. 37.1). Certain members are considered members of the "small leucine-rich proteoglycan family". These include decorin, biglycan, fibromodulin and lumican. Small interstitial PGs have a high degree of homology in their protein core sequence. Each has between 10 and 12 highly conserved leucine rich tandem repeats which make up the central portion of the core protein. The fibromodulin and lumican are keratan sulfate substituted where as decorin and biglycan are both chondroitin sulfate substituted.

Decorins are small extracellular PGs usually within 90–140 kDa in size. Decorins have a core protein of ~42 kDa in size and one GAG chain consisting of either CS or DS. They were named so because they appeared decorating collagen fibers under EM. Biglycans are

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_37,

Table 37.1 Classification of proteoglycans on the basis of their localization and type of core protein

Localization	GAG-chain	M_r of core protein (kDa)	Principal members
ECM	hyaluronic acid, chondroitin sulfate, keratan sulfate	225–250	Aggrecan (the major proteoglycan in cartilage), versican (present in many adult tissues including blood vessels and skin)
Collagen-associated	chondroitin sulfate, keratan sulfate, dermatan sulfate	40	decorin, biglycan fibromodulin[c]
Basement membrane	hyaluronic acid	120	perlecan
Cell-surface	hyaluronic acid, chondroitin sulfate	33[a]; 60[b]; 92[c]	syndecans[a]; glypican[b]; betaglycan[c], CD44E, cerebroglycan
Intracellular granules	heparin, chondroitin sulfate	17–19	serglycin

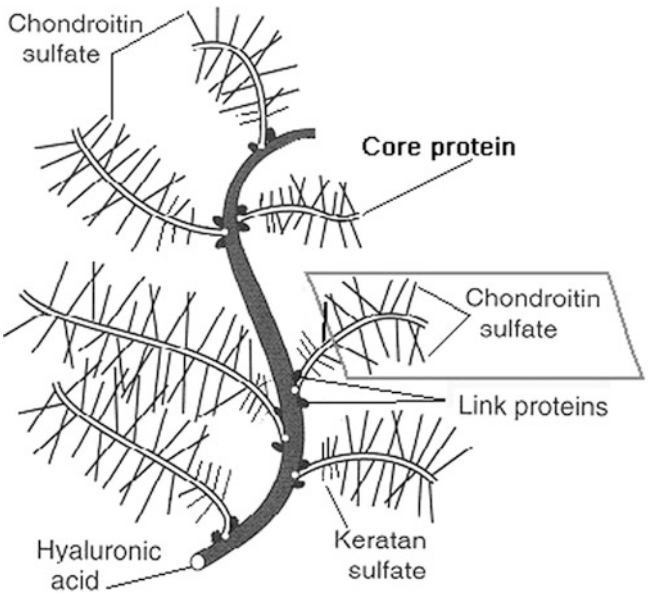

Fig. 37.1 **Proteoglycan Complex**. In the cartilage matrix, individual proteoglycans (in *box*) are linked to a nonsulfated GAG, hyaluronic acid, to form a giant complex with a molecular mass of about 3,000,000. The *box* indicates one of the proteoglycans of the type shown in figure

also small extracellular PGs that are similar to decorins. They are about 150–240 kDa in size and are generally found on the surface of cells, bones, and cartilage. Among small PGs, fibromodulin is the most abundant. Fibromodulin is about 60 kDa in size with a core protein of ~42 kDa. Fibromodulin is very similiar to decorins and biglycans and contains 4 keratan sulfate (KS) chains.

Large proteoglycans are versicans, neurocans, brevicans, and collagens. Chondroitin sulfate proteoglycan or versican is a sulfated glycosaminoglycan attributed for possessing good hydration potential. This property allows for interaction with surrounding cells in cell adhesion, proliferation, and migration. Another type of chondroitin sulfate proteoglycan called neurocan is located in the extracellular matrix within the brain. Proteoglycans can be a main contributor for all types of amyloidosis. High density proteoglycans are also linked to joint autoimmune responses and arthritis in mice. Joint problems such as these may improve with glucosamine and chondroitin added to the diet (Baeurle et al. 2009). Heparan sulfate proteoglycans (HSPGs) interact with many proteins and protein receptors that influence growth factors and structural proteins. Mutations in genes relating to HSPGs are associated with increased cancer risk. HSPGs are involved in several human diseases and affect the cartilage and musculoskeletal systems like hereditary multiple exostoses (HME).

37.1.2 Glycosaminoglycans

Glycosaminoglycans (GAGs) or mucopolysaccharides are long unbranched polysaccharides consisting of a repeating disaccharide unit as a building block. The disaccharides consist of an amino sugar (either GlcNAc or GalNAc) and an uronic acid (GlcA and IdoA) (Figs. 37.2 and 37.3). Protein cores made in the rough endoplasmic reticulum are posttranslationally modified by glycosyltransferases in the Golgi apparatus, where GAG disaccharides are added to protein cores to yield proteoglycans; the exception is hyaluronan, which is uniquely synthesized without a protein core and is "spun out" by enzymes at cell surfaces directly into the extracellular space. This family of carbohydrates is essential or important for life. GAGs form an important component of connective tissues and may be covalently linked to a protein to form proteoglycans. Water sticks to GAGs; this is where the resistance to pressure comes from. The density of sugar molecules and the net negative charge attract salts. Water does not compress, unlike gas. Some examples of glycosaminoglycan uses in nature include heparin as an anticoagulant, hyaluronate as a component in the synovial fluid lubricant in body joints, and chondroitins which can be found in connective tissues, cartilage and tendons. Classification and examples of GAGs are given in Table 37.1.

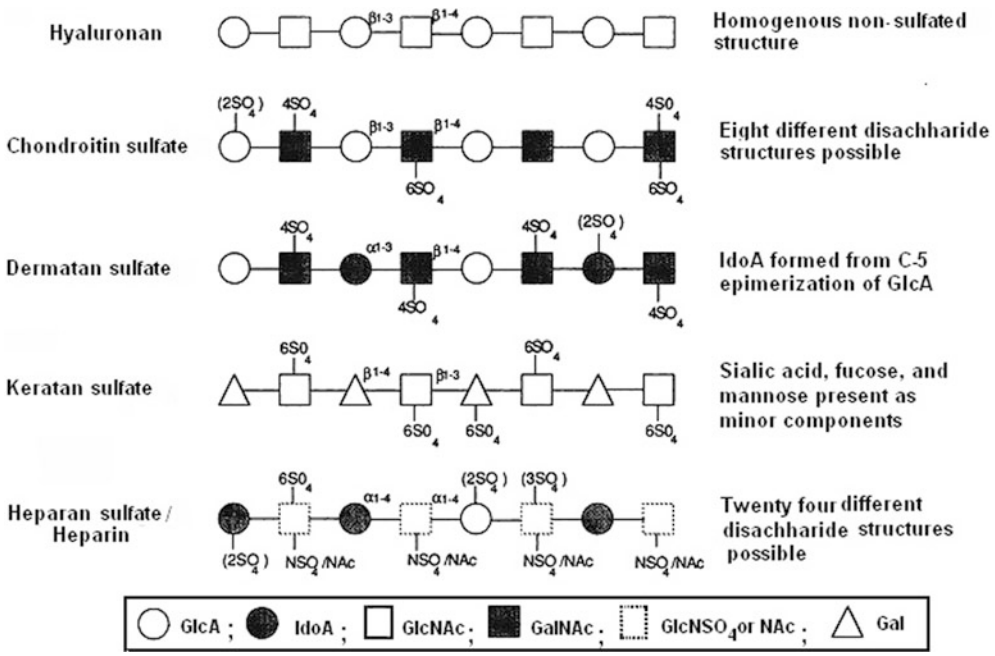

Fig. 37.2 Repeating disaccharide structures of glycosaminoglycans. Glycosaminoglycans, consisting repeating disaccharide units, are composed of an N-acetylated or N-sulfated hexosamine and either a uronic acid (glucuronic acid or iduronic acid) or galactose. Hyaluronan is synthesized without a covalent link to any protein. Hyaluronan lacks sulfate groups, but the rest of the glycosaminoglycans contain sulfates at various positions. Dermatan sulfate is formed from chondroitin sulfate by intracellular eprimenzation of glucuronate (GlcA) to iduronate (IdoA) and distinguished from chondroitn sulfate by the presence of iduronic acid. 2-sulfated hexuronate residues are more common in dermatan sulfate than in chondroitin-sulfate. Keratan sulfates lack uronic acids and instead consist of sulfated galactose and *N*-acetylglucosamine residues. Heparin is a more extensively epimerized and sulfated form of heparan sulfate. Heparan sulfate frequently contains some chain segments with little or no epimerization or sulfation. Heparin is synthesized only on a mast cell granule proteoglycan, whereas heparan sulfate is found on many cell surfaces and on some matrix proteoglycans. Abbreviations: GlcNAc, N-acetyl glucosamine; GaINAc, N-acetyl galactosamine; GlcA, glucuronic acid; Xyl, xylose; Gal, galactose; (Figure adapted with permission from Hardingham and Fosang 1992 © Federation of American Societies for Experimental Biology)

37.1.3 Chondroitin

Chondroitin is a chondrin derivative without "sulfate" and has been used to describe a fraction with no sulfation. Types of chondroitin include: (1) Chondroitin sulfate and (2) Dermatan sulfate. Chondroitin's functions depend largely on the properties of overall proteoglycan of which it is a part. These functions can be broadly divided into structural and regulatory roles. However, this division is not absolute, and some proteoglycans have both structural and regulatory roles (see versican). Chondroitin is an ingredient found commonly in dietary supplements and used as an alternative medicine to treat osteoarthritis and also approved and regulated as a symptomatic slow-acting drug for this disease. It is commonly sold together with glucosamine.

Chondroitin Sulfate: Chondroitin sulfate is a major component of extracellular matrix, and is important in maintaining the structural integrity of the tissue. Chondroitin sulfate is a sulfated GAG composed of a chain of alternating sugars (N-acetylgalactosamine and glucuronic acid). It is usually found attached to proteins as part of a proteoglycan. A chondroitin chain can have over 100 individual sugars, each of which can be sulfated in variable positions and quantities. Chondroitin sulfate is an important structural component of cartilage and provides much of its resistance to compression. Members of the glycosaminoglycan family vary in the type of hexosamine, hexose or hexuronic acid unit they contain (e.g. glucuronic acid, iduronic acid, galactose, galactosamine, glucosamine). They also vary in the geometry of the glycosidic linkage (Figs. 37.2 and 37.3).

Chondroitin sulfate is important in maintaining the structural integrity of the tissue. This function is typical of the large aggregating proteoglycans: aggrecan, versican, brevican, and neurocan, collectively termed the lecticans. As part of aggrecan, chondroitin sulfate is a major component of cartilage. The tightly packed and highly charged sulfate groups of chondroitin sulfate generate electrostatic repulsion that provides much of the resistance of cartilage to compression. Loss of chondroitin sulfate from the cartilage is a major cause of osteoarthritis. Chondroitin sulfate readily interacts with proteins in the extracellular matrix due to its negative charges.

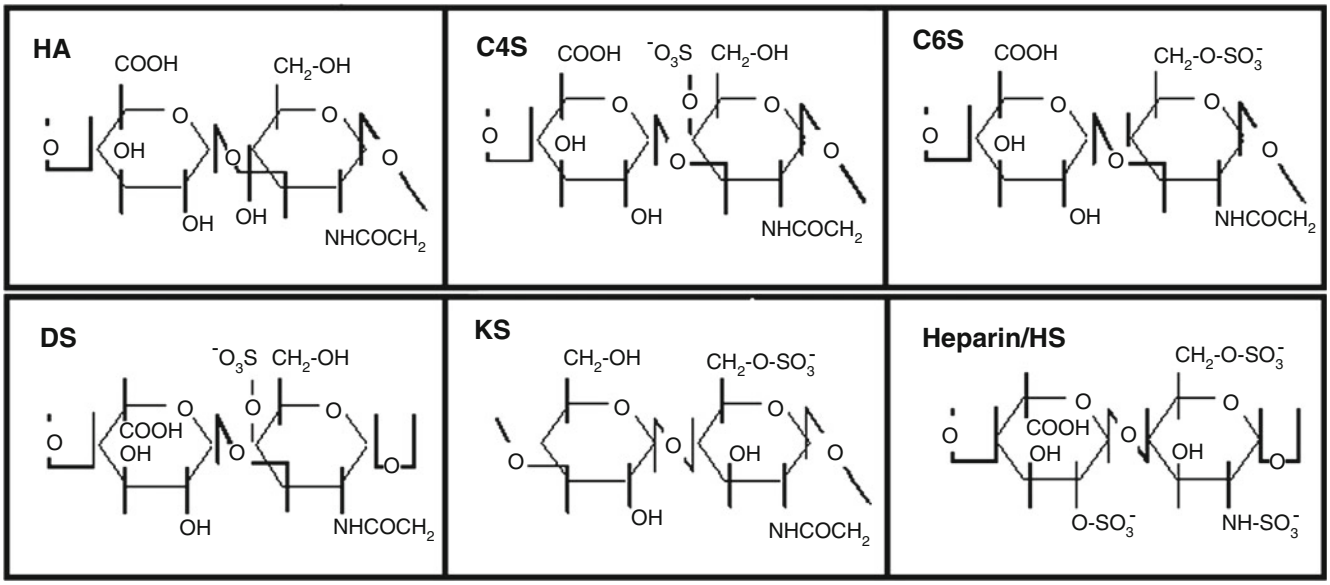

Fig. 37.3 Glycosidic bonds in disachharides present in GAGs. Heparin/HS and hyaluronic acid (HA) are glycosaminoglycans. Heparin has highest negative charge density among any known biological molecule and the only GAG that is exclusively non-sulfated; HS: Highly similar in structure to heparin, however heparan sulfates disaccharide units are organised into distinct sulfated and non-sulfated domains. Since heparin/HS structures are highly heterogeneous, IdoA(2-OSO_3)-GlcNSO_3(6-OSO_3), the most abundant disaccharide unit of HS, is shown here; Chondroitin-4-sulfate (C4S) and chondroitin-6-sulfate (C6S) are most prevalent GAG; C6S and dermatan sulfate (DS) are galactosaminoglycans. DS can be distinguished from chondroitin sulfate by the presence of iduronic acid, although some hexuronic acid monosaccharides may be glucuronic acid; Keratan sulfate (KS) is a sulfated polylactosamine

These interactions are important for regulating a diverse array of cellular activities. The lecticans are a major part of the brain extracellular matix, where the chondroitin sugar chains function to stabilize normal brain synapses as part of perineuronal nets. The levels of chondroitin sulfate proteoglycans are vastly increased after injury to the CNS where they act to prevent regeneration of damaged nerve endings. Although these functions are not as well characterized as those of heparan sulfate, new roles continue to be discovered for the chondroitin sulfate proteoglycans. The dosage of oral chondroitin used in human clinical trials is 800–1,200 mg per day. Most chondroitin appears to be made from extracts of cartilaginous cow and pig tissues (cow trachea and pig ear and nose), but other sources such as shark, fish, and bird cartilage are also used. CSPG is secreted by human B cell lines that closely resembles in its structure the serum-derived C1q inhibitor (C1qI). Strong binding of B cell CSPG to C1q, its inhibition of C1q activity, and its structural similarities to a human serum C1qI indicate that B cells produce a soluble CSPG, which may act as C1qI under physiologic conditions (Kirschfink et al. 1997).

The benefit of chondroitin sulfate in patients with osteoarthritis is likely the result of a number of effects including its anti-inflammatory activity, the stimulation of the synthesis of proteoglycans and hyaluronic acid, and the decrease in catabolic activity of chondrocytes inhibiting the synthesis of proteolytic enzymes, nitric oxide, and other substances that contribute to damage cartilage matrix and cause of death of articular chondrocytes (Monfort et al. 2008). The rationale behind the use of chondroitin sulfate is based on the belief that osteoarthritis is associated with a local deficiency in some natural substances, including chondroitin sulfate. In several prospective controlled trials, chondroitin sulfate had been thought to decrease pain, improve functional disability, reduce NSAID or acetaminophen consumption, and provide good tolerability with an additional carry-over effect. Bruyere and Reginster (2007) suggest that glucosamine and chondroitin sulfate act as valuable symptomatic therapies for osteoarthritis disease with some potential structure-modifying effects.

Structure of Chondroitin Sulfate: Chondroitin sulfate chains are unbranched polysaccharides of variable length containing two alternating monosaccharides: D-glucuronic acid (GlcA) and N-acetyl-D-galactosamine (GalNAc). Some GlcA residues are epimerized into L-iduronic acid (IdoA); the resulting disaccharide is then referred to as dermatan sulfate (Fig. 37.3). Chondroitin sulfate chains are linked to hydroxyl groups on serine residues of certain proteins. Glycosylated serines are often followed by a glycine and have neighboring acidic residues, but this motif does not always predict glycosylation. Attachment of GAG chain begins with four monosaccharides in a fixed pattern: Xyl – Gal – Gal – GlcA. Each sugar is attached by a specific enzyme, allowing for multiple levels of control over GAG

synthesis. Xylose begins to be attached to proteins in endoplasmic reticulum, while rest of the sugars is attached in Golgi apparatus. Each monosaccharide may be left unsulfated, sulfated once, or sulfated twice. In the most common scenario, the hydroxyls of the four and six positions of the N-acetyl-galactosamine are sulfated, with some chains having the two position of glucuronic acid.

Dermatan Sulfate: Dermatan sulfate is a glycosaminoglycan (formerly called a mucopolysaccharide) found mostly in skin, but also in blood vessels, heart valves, tendons, and lungs. Chondroitin sulfate B is an old name for dermatan sulfate, and is no longer classified as a form of chondroitin sulfate. Dermatan sulfate may have roles in coagulation, cardiovascular disease, carcinogenesis, infection, wound repair, and fibrosis. Dermatan sulfate accumulates abnormally in several of the mucopolysaccharidosis disorders. An excess of dermatan sulfate in the Mitral Valve is characteristic of myxomatous degeneration of the leaflets leading to redundancy of valve tissue and ultimately, Mitral Valve Prolapse (into the Left atrium) and insufficiency. This chronic prolapse occurs mainly in women over the age of 60, and can predispose the patient to mitral annular calcification. Mitral valve insufficiency can lead to eccentric (volume dependent or dilated) hypertrophy and eventually Left Heart failure if untreated (Table 37.1).

37.1.4 Heparan Sulfate Proteoglycans (HSPG)

PGs can be classified on the basis of their localization, GAG-chain composition, and on the type of the core protein. As shown in Table 37.1, HSPGs are localized mainly in the basement membrane and on the cell surface (Figs. 37.2 and 37.3). The final structure of heparin/HS depends upon the incompleteness of the reactions that occur during the biosynthetic process. The modification process is more complete in heparin where the final disaccharide IdoA (2-OSO_3)-GlcNSO_3(6-OSO_3) represents up to 70% of the chain, leading to a heavily *O*-sulfated polysaccharide with a high IdoA/GlcA ratio.

Typical concentrations of HSPGs on the cell surface are in the range of 10^5–10^6 molecules/cell. HSPGs can link to plasma membrane through a hydrophobic transmembrane domain of their core protein or through a glycosylphosphatidylinositol (GPI) anchor covalently bound to core protein (transmembrane HSPGs). Also, HSPGs can interact with the cell by non-covalent linkage to different cell-surface macromolecules (peripheral membrane HSPGs). Transmembrane HSPGs are glypican, cerebroglycan, betaglycan, CD44, and the members of the syndecan family: syndecan 1, fibroglycan (syndecan 2), N-syndecan (syndecan 3) and ryudocan (syndecan 4). It is important to know that cell-associated HSPGs can be internalized via endocytosis and metabolized in the lysosomal compartment. In some cell types oligosaccharides originated during intracellular degradation appear to be delivered specifically to the nucleus (Gallagher 2001).

Glypican and cerebroglycan are typical GPI-anchored HSPGs. Syndecans and betaglycan are typical transmembrane HSPGs characterized by a core protein composed of an extracellular domain, a single membrane-spanning domain and a short cytoplasmic domain. In the extracellular domain are present the consensus sequences for glycosylation and a conserved putative proteolytic cleavage site. The cytoplasmic domain of syndecans can interact with the cytoskeleton and contains four conserved tyrosine residues, one of them being a substrate for enzymatic phosphorylation. Perlecan is a typical peripheral membrane HSPG that interacts with the cell surface through its core protein. The cell-adhesion motif Arg-Gly-Asp within the core protein of perlecan binds integrins β_1 or β_3 present on endothelial cell surface. However, HSPGs may associate to the cell surface and/or ECM also through their GAG-chain. In contrast, the modifications that occur during the biosynthesis of HS are less extensive, leading to HS molecules characterized by lower IdoA content and a lower overall degree of *O*-sulfation and resulting in high heterogeneity of distribution of the sulfate groups along the chain. Eventually, disaccharides containing GlcNAc or $GlcNSO_3$ may form clusters ranging from 2 to 20 adjacent GlcNAc-containing disaccharides and from 2 to 10 adjacent $GlcNSO_3$-containing disaccharides. However, about 20–30% of the chain contains alternate GlcNAc- and $GlcNSO_3$-disaccharides units. HSPGs are necessary for structural and functional integrity of endothelium.

37.2 Proteoglycans in Tissues

Skin Proteoglycans: Expression of versican is observed in various adult tissues such as blood vessels, skin, and developing heart. Smooth muscle cells of blood vessels, epithelial cells of skin, and the cells of central and peripheral nervous system are a few examples of cell types that express versican physiologically. Dramatic changes occur in skin as a function of age, including changes in morphology, physiology, and mechanical properties. The major proteoglycans detected in extracts of human skin are dermaton sulfate (DS) proteoglycons, decorin and versican. Studies indicate that human fetal skin is structurally different from adult skin in terms of both the distribution and the composition of the large, aggregating chondroitin sulfate proteoglycan versican (Sorrell et al. 1999). Versican is a significant component of the interstitial extracellular matrix of skin development. An apparent codistribution of versican with the various fiber forms of the elastic network of the dermis suggested an

association of versican with microfibrils. Both dermal fibroblasts and keratinocytes express versican in culture during active cell proliferation. General function of versican is in cell proliferation processes that may not solely be confined to the skin (Zimmermann et al. 1994; Carrino et al. 2003). Human skin fibroblasts, in addition to versican, express a second large chondroitin sulfate/dermatan sulfate proteoglycan, which is produced in cultures of fetal fibroblasts. Proteoglycans have been described in adult human hair follicles. Versican may play an essential role both in mesenchymal condensation and in hair induction (Kishimoto et al. 1999). Glycosaminoglycan (GAG) and PG expression along the human anagen hair follicle has been characterized by Malgouries et al. (2008).

Brain: Many CSPGs have been shown to influence CNS axon growth in vitro and in vivo. These interactions can be mediated through the core protein or through CS GAG side chains. Degrading CS GAG side chains using chondroitinase ABC enhances dopaminergic nigrostriatal axon regeneration in vivo and interfering with complete CSPGs limit axon growth in vivo. Neurocan, versican, aggrecan, and brevican CSPGs may be anchored within extracellular matrix through hyaluronan glycosaminoglycan. Partial degradation of hyaluronan and chondroitin sulfate and depletion of hyaluronan-binding CSPGs enhances local sprouting of cut CNS axons, but long-distance regeneration fails in regions containing residual hyaluronan-binding CSPGs. Hyaluronan, chondroitin sulfate and hyaluronan-binding CSPGs may, therefore, contribute toward the failure of spontaneous axon regeneration in the injured adult mammalian brain and spinal cord (Moon et al. 2003) (see Chap. 38).

Human Eye: Apart from significant amounts of collagen, hyaluronan and sialylated glycoproteins, the human vitreous gel also contains low amounts of versican-like proteoglycan with a molecular mass of 380 kDa. Its core protein is substituted by CS side chains (37 kDa), in which 6-sulfated disaccharides predominated. Versican, which is able to bind lectins via its C-terminal region, may bridge or interconnect various constituents of the extracellular matrix via its terminal domains in order to stabilize large supramolecular complexes at the vitreous, contributing towards the integrity and specific properties of the tissue (Theocharis et al. 2002).

Glomerular Mesangial Cells Synthesize Versican: Mesangial cells derived from human adult glomeruli synthesize a number of proteoglycans including a large chondroitin sulfate proteoglycan (CSPG), two DS proteoglycans (biglycan and decorin) and two HS proteoglycans. Experiments with ^{3H}-labelled mesangial-cell proteoglycans showed that only the large CSPG, with core protein molecular masses of 400 kDa and 500 kDa, interacted with HA. Thus human mesangial large CSPG is a member of the versican family of proteoglycans. The interaction of CSPG and HA within the glomerulus may be important in glomerular cell migration and proliferation (Thomas et al. 1994). Both basement membrane and interstitial PGs are secreted by Madin-Darby canine kidney (MDCK) cells. HSPGs expressed by MDCK cells are perlecan, agrin, and collagen XVIII. Various CSPG core proteins are made by MDCK cells and have been identified as biglycan, bamacan, and versican/PG-M. These PGs are also associated with mammalian kidney tubules in vivo (Erickson and Couchman 2001).

Human Follicular Fluid and Umbilical Cord Vein: Two proteoglycans differing in size and composition are present in human follicular fluid. The larger one of high density had a molecular mass of 3.0×10^6 Da, and was substituted with 15–20 CS chains (Mr 60–65 kDa). EM of CS proteoglycan revealed a versican-like structure, with one globular domain at each end of a long extended segment substituted with CS side chains. The smaller proteoglycan had a molecular mass of 1.1×10^6 Da that showed a globular-protein core structure. The protein core was found to be heterogeneous, with bands occurring at 215, 330 and 400-kDa after enzymic degradation of the glycosaminoglycan chains (Eriksen et al. 1999). PGs from human umbilical cord arteries (UCAs) are especially enriched in CS/DS PGs. The predominant PG fraction included small PGs with molecular mass of 160–200 kDa and 90–150 kDa, i.e. typical for biglycan and decorin, respectively (Gogiel et al. 2007). Wharton's jelly contains mainly small CS/DS proteoglycans, with decorin strongly predominating over biglycan (Gogiel et al. 2003).

Tendons/Ligaments: The major proteoglycans of tendons are decorin and versican. Other species that were detected were biglycan and the large proteoglycans versican and aggrecan. Majority of the large proteoglycans present in the matrix of tendon are degraded and did not contain the G1 globular domain (Samiric et al. 2004a, b). Sulfated glycosaminoglycan content increases in pathologic tendons compared to normal (Tom et al. 2009). Bovine collateral ligament synthesizes a large proteoglycan which contained only chondroitin sulfate chains with a M_r 32 kDa and core proteins with a range of molecular masses above 200 kDa. Findings indicate that the large CS proteoglycan synthesized by bovine collateral ligament may be a versican-like proteoglycan which exhibited the potential to form like protein-stabilized complexes. Approximately 90% of the total proteoglycans in fresh ligament was decorin. Other species that were detected were biglycan and the large proteoglycans versican and aggrecan (Ilic et al. 2005).

Human Articular Cartilage, Intervertebral Disc, and Bone: Splicing variation of versican and size heterogeneity of versican core protein has been observed in human articular cartilage and intervertebral disc. All articular

cartilage extracts from the fetus to the mature adult contained multiple core protein sizes of greater than 200 kDa. The adult cartilage extracts tended to have an increased proportion of the smaller sized core proteins and osteoarthritic cartilage possessed similar core protein sizes to the normal adult. The increased presence of versican in the disc relative to articular cartilage may suggest a more pronounced functional role for this PG, particularly in the nucleus pulposus (Sztrolovics et al. 2002). Large hyaluronate-binding proteoglycans were characrerized in developing mandible of fetal rats at embryonic day 15 (E15) to E18. The large proteoglycan having smaller molecular weight is preferentially localized to bone nodules and may correlate with bone matrix mineralization (Lee et al. 1998). The Versican has been found in osteoarthritic cartilage. Though the control cartilage showed no staining, but in osteoarthritic cartilage there was strong staining of the cytoplasm of chondrocytes with abnormal morphology (Nishida et al. 1994). Cleavage of aggrecan by aggrecanase in articular cartilage characterizes cartilage degeneration in rheumatoid arthritis (Milz et al. 2002).

Tooth: Biglycan, decorin, versican, and link protein mRNAs are expressed in human dental pulp cells. Assuming expression of link protein and versican in vivo, the larger proteoglycans in the dental pulp are capable of forming large proteoglycan aggregates (Yamada et al. 1997; Abiko et al. 2001). Cementum is believed to play a regulatory role in periodontal regeneration through a variety of macromolecules including PGs present in its ECM. Immunoreactivity to versican, decorin, biglycan and lumican was evident at the borders and lumina of a proportion of lacunae and canaliculi surrounding cementocytes in cellular cementum. Versican, decorin, biglycan and lumican are components of the ECM of cellular, but not of acellular cementum. The distribution of PG epitopes around a proportion of cementocytes suggests the existence of different cementocyte subpopulations, or a differential response of these cells to yet undefined stimuli (Ababneh et al. 1999).

37.3 Hyaluronan: Proteoglycan Binding Link Proteins

Hyaluronan (HA) is a ubiquitous component of extracellular matrices, and in several systems it plays a central role in regulating cellular proliferation and differentiation. In the mammalian CNS, HA is present throughout development and into adulthood. The HA plays an important role in tissue reorganization in response to injury. Cell or tissue-specific functions of HA are likely to be mediated by cell or tissue-specific HA-binding proteins. Link proteins are glycoproteins in cartilage that are involved in the stabilization of aggregates of proteoglycans and hyaluronic acid. Link protein (LP), an extracellular matrix protein in cartilage, stabilizes aggregates of aggrecan and hyaluronan, giving cartilage its tensile strength and elasticity. Targeted mutations in mice in the gene encoding LP (Crtl1) showed defects in cartilage development and delayed bone formation with short limbs and craniofacial anomalies. Thue LP is important for the formation of proteoglycan aggregates and normal organization of hypertrophic chondrocytes (Watanabe et al. 1999) (Fig. 37.1).

37.4 Lecticans (Hyalectans)

The term *hyalectans* (or *lecticans*) defines a family of large hyaluronan-binding proteoglycans whose members include versican, aggrecan, neurocan, and brevican. Lecticans are a family of chondroitin sulfate proteoglycans, encompassing aggrecan (abundant in cartilage), brevican and neurocan (nervous system proteoglycans) and versican (also known as chondroitin sulfate proteoglycan core protein 2 or chondroitin sulfate proteoglycan 2). These proteoglycans are characterized by the presence of a hyaluronan-binding domain and a C-type lectin domain in their core proteins. Through these domains, lecticans interact with carbohydrate and protein ligands in the extracellular matrix and act as linkers of these extracellular matrix molecules. Molecular cloning has allowed identification of genes encoding core proteins of various proteoglycans, leading to a better understanding of the diversity of proteoglycan structure and function, as well as the evolution of a classification of proteoglycans. The postulated functions of proteoglycans in basements include: a structural role in maintaining tissue histoarchitecture, or aid in selective filtration processes; sequestration of growth factors; and regulation of cellular differentiation. Furthermore, expression of PGs has been found to vary in several disease states (Yamaguchi 2000). Lecticans contain N-terminal G1 domains and C-terminal G3 domains. Only aggrecan contains the G2 domain. The G1 domain consists of an Ig-like loop and two link modules, whereas the G2 domain consists only of two link modules. The G3 domain consists of one or two EGF repeats, a C-type lectin domain and CRP-like domain (Fig. 37.4). Lecticans share a number of structural features. The amino-terminal domains mediate the interaction with hyaluronic acid (HA) as well as with the link protein, a relatively small polypeptide involved in the aggregation of proteoglycans. The link protein consists basically of a HA binding domain. BEHAB, a protein deduced from its cDNA sequence, has been suggested to constitute a brain-specific link protein. Members of the aggrecan/versican family are soluble chondroitin sulfate proteoglycans whereas most of the membrane-spanning or glycosylphosphatidylinositol (GPI)-

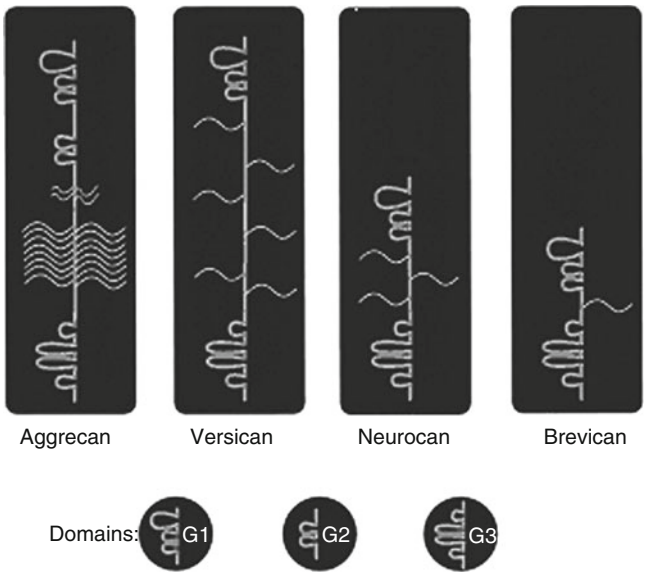

Fig. 37.4 Domain structures of lecticans. Lecticans contain N-terminal G1 domains and C-terminal G3 domains. Only aggrecan contains the G2 domain. The G1 domain consists of an Ig-like loop and two link modules, whereas the G2 domain consists only of two link modules. The G3 domain consists of one or two EGF repeats, a C-type lectin domain and CRP-like domain. All lecticans contain chondroitin sulfate chains (*yellow*) in the central domain. Aggrecan also contains keratan sulfate chains (*pink*) in the N-terminal part of the central domain (Reprinted with permission from Yamaguchi 2000 © Birkhauser Verlag). The number of chondroitin sulfate side chains present in brain aggrecan is not known but appears to be lower than the 100 GAG chains attached to cartilage aggrecan. Because the versicans, neurocan, and brevican form an almost perfect array of functionally related but differently sized molecules, it seems conceivable that the spatiotemporally regulated expression of these hyalectans (lecticans) fine tunes the inhibitory capacity of specialized hyaluronan-rich matrices in the developing and mature CNS (Bandtlow and Zimmermann 2000)

anchored proteoglycans carry heparan sulfate or keratan sulfate side chains.

37.5 Cartilage Proteoglycan: Aggrecan

37.5.1 Skeletogenesis

Skeletogenesis proceeds through a complex process involving patterning signals, cell differentiation, and growth. Most of the skeletal elements including those of limbs, as well as many parts of the craniofacial and axial skeleton, develop through the specialized process of endochondral ossification, in which a cartilaginous rudiment is first formed, then converted to bone. The growth and differentiation of cartilage into bone is controlled in part by interactions between the Indian hedgehog and parathyroid hormone-related peptide signaling pathways in the growth plate, and the induction of the bone- and cartilage-specific transcription factor Cbfa1 (Takeda et al. 2001). Presently, the best candidate for a general chondrogenic transcription factor', Sox9, is implicated in the control of several cartilage-specific genes (Bi et al. 2001). Aggrecan has been shown to interact with versican (Matsumoto et al. 2003). There is association of aggrecan and tenascin in tissues. The expression of aggrecan is mainly restricted to cartilages while tenascin mRNA is present at variable levels in most of the tissues. In the newborn mouse skeleton tenascin and aggrecan mRNAs were expressed essentially in a mutually exclusive manner, tenascin transcripts being present in osteoblasts, periosteal and perichondrial cells, and in cells at articular surfaces. None of these cells expressed the cartilage specific collagen or aggrecan genes. Patterns of gene expression depend on the location of chondrocytes in different cartilages (Glumoff et al. 1994).

37.5.2 Human Aggrecan

37.5.2.1 Domain Organization of Core Protein

The aggregating group of CSPGs is characterized by N-terminal and C-terminal globular (or selectin-like) domains, known as G1, and G3 domains, respectively (Fig. 37.4). The proteoglycans bind hyaluronan through their N-terminal G1 domains, and other ECM proteins through C-type lectin repeat in their C-terminal G3 domains. Members of CSPG family exhibit structural similarity: a G1 domain at the N-terminus and a G3 domain at the C-terminus, with a central sequence for modification by CS chains. However, a unique feature of aggrecan is the insertion of three additional domains, an inter-globular domain (IGD), a G2 domain and a keratan sulfate (KS) domain (sequence modified by KS chains), between the G1 domain and the CS domain (sequence modified by CS chains). The G1 region at the amino terminus of the core protein can be further sub-divided into three functional domains, termed A, B1 and B2, with the B-type domains being responsible for the interaction with HA (Watanabe et al. 1997). The G2 region also possesses two B-type domains, but does not appear to interact with HA (Fosang and Hardingham, 1989) (Fig. 37.4). The domain structure of core proteins of aggrecan/versican family members is reflected at the genomic level. The genes for rat and mouse aggrecan as well as human versican have a very similar exon/intron organization that resembles the arrangement of functional domains of the corresponding proteins (Schwartz et al. 1999). The human form of aggrecan is 2,316 amino acids long and can be expressed in multiple isoforms due to alternative splicing (Doege et al. 1994). Along with Type-II collagen, aggrecan forms a major structural component of cartilage, particularly articular cartilage. Aggrecan is detected as an early event in

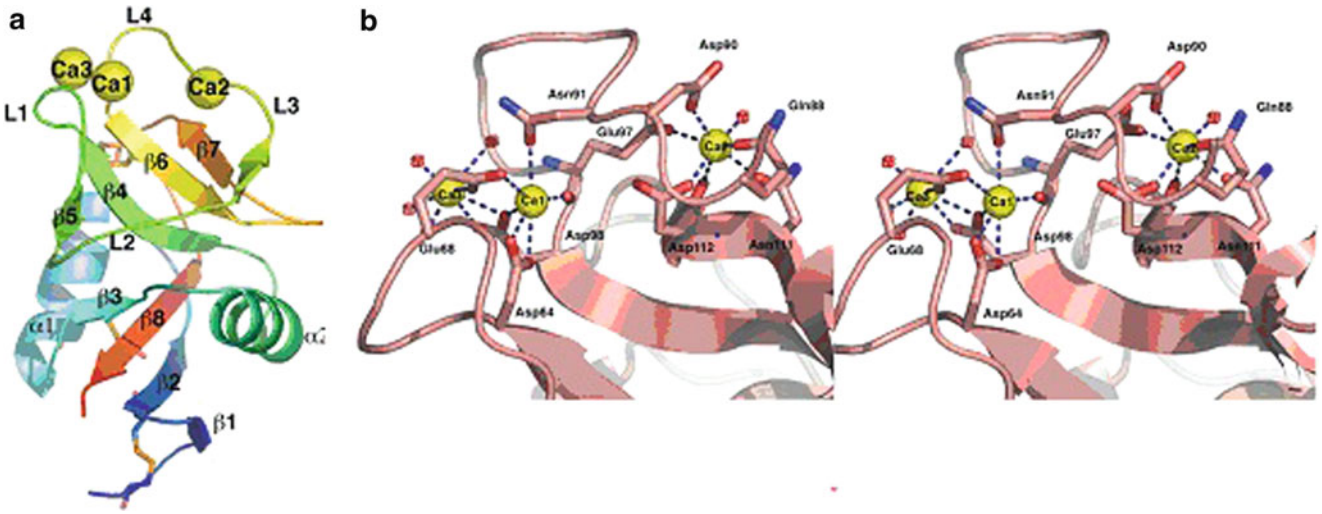

Fig. 37.5 The Aggrecan CLD fold and comparison to other C-type lectin domains (CLD) and Ca^{2+} binding. (**a**) The aggrecan CLD: The elements are colored from *blue* at the N terminus to *red* at the C terminus. The disulfide bridges are highlighted, and the three Ca^{2+} ions are shown as *yellow* spheres. (**b**) A stereoview of Ca^{2+} coordination in the aggrecan CLD. Water molecules are drawn as solid crosses (Reprinted with permission from Lundell et al. 2004 © Elsevier)

chondrocyte differentiation (Sandell 1994). Together with the CLDs of the other lecticans brevican, neurocan, and versican, the aggrecan CLD forms group I of the C-type lectin family. The overall structure is highly canonical for this family (Fig. 37.5). Aggrecan contains a long-form CLD (126 residues) with three disulfide bridges, like, e.g., tetranectin and asialoglycoprotein receptor H1 subunit (ASPGR). A search revealed strong similarity to a variety of other Ca^{2+} binding and non-Ca^{2+} binding CTLDs, including lithostatine, mannose binding protein MBP, and E-selectin (Lundell et al. 2004).

37.5.2.2 The Human Aggrecan Gene

The aggrecan gene has been characterized in several species including rat, human, mouse, and chicken (Schwartz et al. 1999). The basal promoter has been defined and shown to be active in various cell types. The human aggrecan gene, which resides at chromosome 15q26, consists of 19 exons (Doege et al. 2002; Valhmu et al. 1995), with each exon encoding a distinct structural domain of the core protein. Exons 3–6 encode the G1 region and exons 8–10 encode the G2 region. The CS-rich domain and much of the KS-rich domain are encoded by large exon 12. The G3 region is encoded by exons 13–18. It can give rise to different aggrecan transcripts due to alternative splicing (Fülöp et al. 1996), though it was not clear whether this is of any functional consequence. The promoter activity has been shown to be influenced by first exon sequences (Valhmu et al. 1998a), biomechanical stimuli (Valhmu et al. 1998b), sox9 (Sekiya et al. 2000), and a region that inhibits expression in chondrocytes (Pirok et al. 2001).

Glycosaminoglycan (GAG) Chain Attachment Region: The KS-attachment domain residing adjacent to G2 region is composed largely of repeat motifs whose number varies between species (Barry et al. 1994; Funderburgh 2000). The neighbouring CS-attachment domain is divided into two subdomains – the CS1 and CS2 domains. The CS1 domain lies adjacent to the KS-rich domain and is also composed largely of repeat motifs whose number varies between species. In addition, the human CS1 domain exhibits size polymorphism between individuals due to a variable number of 19 amino acid repeats (Doege et al. 1997). This results in the aggrecan molecules of different individuals being able to bear different numbers of CS chains. Irrespective of the number of CS chains present, their structure varies throughout life due to changes in length and sulphation pattern (Roughley and White 1989), though the functional consequence of this change is not clear. The GAG-attachment region also possesses sites for the attachment of O-linked oligosaccharides (Nilsson et al. 1982), which with age may become substituted with KS (Santer et al. 1982). KS may also be present within the G1 region, the IGD and the G2 region, attached to either O-linked or N-linked oligosaccharides (Barry et al. 1995). The KS chains also show age-related changes in structure (Brown et al. 1998).

The GAG-attachment region provides the high anionic charge density needed for unique osmotic properties of aggrecan. Normal cartilage function depends on a high aggrecan content, high GAG substitution and large aggregate size. Loss of cartilage integrity in arthritis is associated with impaired aggrecan function due either to proteolytic cleavage of the aggrecan core protein, which decreases aggrecan charge, or to cleavage of the HA, which decreases

aggregate size. It has also been suggested that aggrecan charge and hence function could be affected by size polymorphism within the CS1 domain, as those individuals with the shortest core protein length would possess aggrecan with the lowest CS substitution. Such individuals might be at risk for premature cartilage degeneration. CS2 domain processing by aggrecanases would result in aggrecan fragments enriched in the CS1 domain and therefore enhance any influence that CS1 domain polymorphism may have on aggrecan function. While size polymorphism in the aggrecan CS1 domain has been associated with both articular cartilage and intervertebral disc degeneration (Horton et al. 1998; Kawaguchi et al. 1999), the reason for the linkage is not clear as it is not always the shorter CS1 domains that have been associated with disease. It is possible that the presence of one short aggrecan allele may be of little functional consequence, and only individuals with two short alleles would be at risk. Such individuals represent less than 1% of the population and have been of little focus.

The G1 and G3 domains have been implicated in product secretion, but G2, although structurally similar to the tandem repeats of G1, performs an unknown function. Each aggrecan domain has been cloned and expressed in various combinations in COS-7 cells (Kiani et al. 2001). Yang et al. (2000) indicated that the presence of G1 domain was sufficient to inhibit product secretion, while the G3 domain enhanced this process. The inhibition of secretion by G1 was mediated by its two tandem repeats, while G3's promotion of glycosaminoglycan chain attachment was apparently dependent on G3's complement-binding protein (CBP)-like motif. The modulatory effects of these two molecular domains contribute to versican's biological activities. Thus, G3 domain enhances product secretion, alone or in combination with the KS or CS domain, and promotes GAG chain attachment (Kiani et al. 2001; Yang et al. 2000; Zheng et al. 1998) (Fig. 37.6).

Effect of Age on Content of C-Terminal Region of Aggrecan: The C-terminal region of aggrecan contains G3 domain which is removed from aggrecan in mature cartilage, by proteolytic cleavage. The content of the C-terminal region decreases with age relative to G1 domain content. The content of this region of the molecule shows a fall of 92% from newborn to 65 years of age. Hence, the content of C-terminal region gives a measure of abundance of newly synthesized aggrecan. The loss of the C-terminal region is not direct part of the process of aggrecan turnover, but it is a slow independent matrix process that occurs more extensively with aging as turnover rates become slower. Young cartilage with the fastest turnover contains least molecules lacking the C-terminal region, whereas in old tissue with slow turnover few molecules retain this region. An increase in the cleavage of this region with age may also contribute to this change (Dudhia et al. 1996; Trowbridge and Gallo 2002).

37.5.3 Rat Aggrecan

Overlapping cDNA clones for coding sequence of rat cartilage proteoglycan core protein from rat chondrosarcoma hybridize to two sizes of RNA transcripts of 8.2 and 8.9 kb pairs, which contain large 3′-untranslated sequences. The entire contiguous cDNA is 6.55 kb pairs in size, and codes for a 2124-residue protein, including a 19-residue signal peptide. The sequence forms a series of eight structural domains including two globules, (Mr = 37,000 and 22,000) at the NH2 terminus of the molecule, one a complete and one a partial copy of the cartilage link protein. The deduced sequence is a 1,104-residue protein, containing 117 Ser-Gly sequences, possible CS attachment sites. These are arranged in three domains of 428, 503, and 173 amino acids. The first domain contains 11 complete or partial repeats of a 40-residue unit, and the second domain is composed of six copies of a 100-residue repeating sequence. The first pattern is the more highly conserved, and may have given rise to the second. The carboxyl-terminal domain is a third globule which has homology with animal lectins (Doege et al. 1987). Two sets of cDNAs encoding isoforms of aggrecan/versican core proteins expressed in rat brain have been characterized. One isoform constitutes most likely the rat homolog of bovine soluble brevican, whereas another group of isoforms represents the first example of GPI-anchored proteins of the aggrecan/versican family. GPI-anchored brevican isoforms are up-regulated late during postnatal development (see Chap. 38).

Nucleotide sequencing of 2 kb of coding sequences for the human protein in comparison with same region in rat and chick indicated that domain 8, the lectin-like domain, is highly conserved among species. In contrast, domain 7 is poorly conserved among species. Some of the cDNA clones also contained an additional structural domain between domains 7 and 8 which was not described in the rat or chick sequences. The additional domain of 38 amino acids was highly homologous to EGF-like sequences seen in other proteins. Because some cDNA clones contained codons for the EGF-like domain and some did not, the results suggested that the EGF-like domain underwent alternative RNA splicing (Baldwin et al. 1989).

37.5.3.1 Rat Aggrecan Gene

Aggrecan DNA sequencing shows 18 exons, most of which encode structural or functional modules; exceptions are domains G1-B and G2-B, which are split into two exons and the G3 lectin domain, which is encoded by three exons. There is one expressed EGF-like exon and in addition a non-

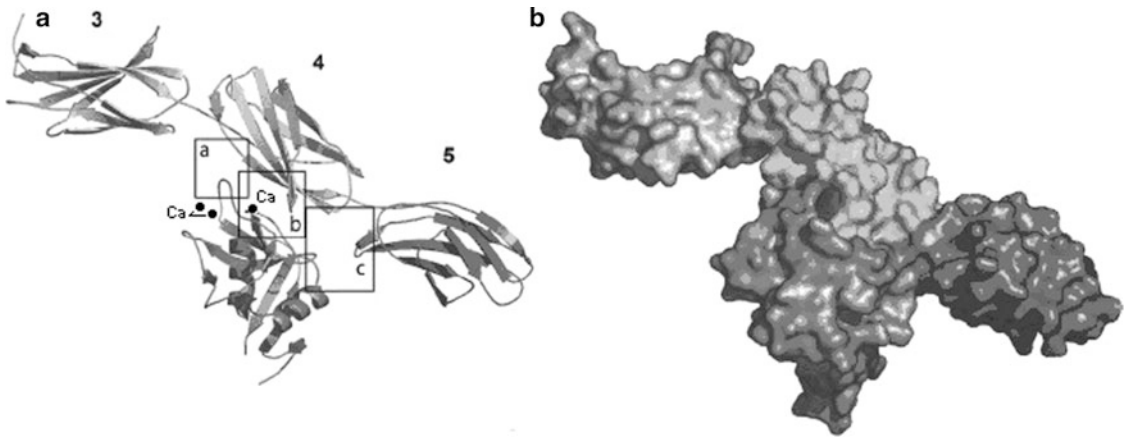

Fig. 37.6 **(a)** Overall structure of the complex between the aggrecan CTLD and FnIII repeats 3–5 of Tenascin-R, TN3–5. A consistent coloring scheme is used throughout for the different domains. Surfaces, cartoon elements, and carbon atoms from domain 3 are colored beige, those in domain 4 are colored cyan, and those in domain 5 are purple. The three Ca^{2+} ions are shown as yellow spheres. The boxes marked *a–c* denote the interaction areas. **(b)** Surface representation colored by domain. The aggrecan CLD amino acid residues mediating interaction with tenascin-R form a surface corresponding to the sulfopeptide binding surface of P-selectin in complex with PSGL-1 (Somers et al. 2000) (Adapted with permission from Lundell et al. 2004 © Elsevier)

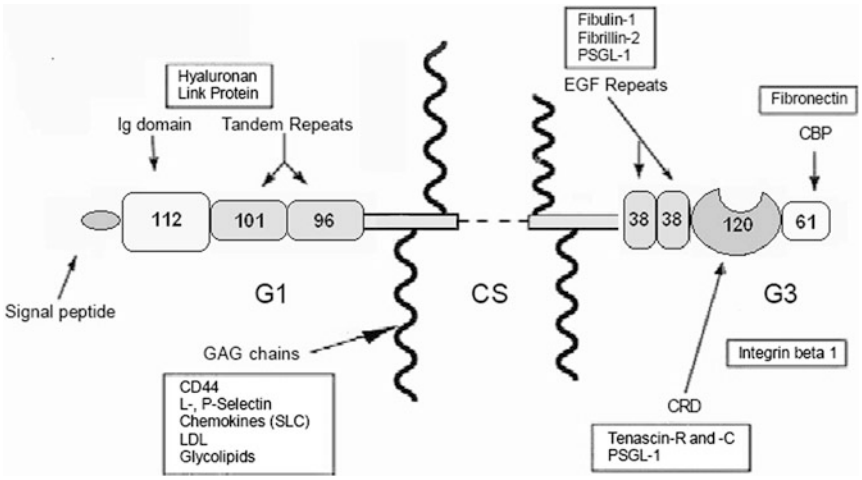

Fig. 37.7 The interaction of versican with various molecules. The locations of versican motifs that interact with other molecules are shown in the figure. Structure shows presence of G1 domain comprising of an Ig domain and two tandom repeats; a proteoglycan with Chondroitin sulfate (CS) region; and G3 domain comprising of an EGF repeats, a carbohydrate recognition domain (CRD) and a complementary binding protein (CBP) region. Molecules interactiong with various domains are boxed (Wu et al. Cell Res 2005)

expressed "pseudo-exon" encoding a heavily mutated EGF-like domain. A 30-kb intron separates exons 1 and 2. Exon 1 encodes 381 bp of 5′-untranslated sequence. There is a minor promoter which initiates transcription of an additional 68 bp 5′ of the major promoter start site. DNA sequence is reported for a 529-bp fragment encompassing exon 1, including 120 bp of 5′-flanking DNA comprising the promoter. This promoter is lacking the TATAA or CCAAT elements but has several putative binding sites for transcription factors. A 922-bp DNA fragment with 640-bp 5′-flanking DNA and 282-bp exon 1 sequence showed higher promoter activity in transfected chondrocytes, is completely inactive in the reverse orientation, and is strongly enhanceable in the forward direction by the SV40 enhancer (Doege et al. 1994).

DNA comprising aggrecan gene (83 kb including the 30-kb first intron) was surveyed for active elements in rat. A 4.7-kb DNA fragment (P3) with cell-specific enhancer activity was discovered ~12 kb upstream of the transcription start site; this active DNA fragment strongly stimulates aggrecan promoter expression in chondrocytes and weakly suppressing transcription in fibroblasts. Most of this activity has been localized to P3-7, a 2.3-kb internal

fragment of P3. Another enhancer element (A23), which is not tissue-specific, was discovered about 70 kb downstream of the transcription start site. Several lines of transgenic mice revealed that neither a short (900 bp) nor a long (3.7 kb) promoter alone showed detectable expression in 14.5-day embryos, whereas placing the P3 tissue-specific enhancer together with P0 gave strong expression restricted to embryonic cartilage of transgenic mice. The A23 downstream enhancer in conjunction with P0 did not confer expression. This gene confers authentic tissue-specific regulation of aggrecan in vitro or in vivo (Doege et al. 2002).

37.5.4 Mouse Aggrecan

Overlapping cDNA clones encoding the entire core protein of aggrecan localized the aggrecan gene in mouse chromosome 7. Walcz et al. (1994) determined 7386 bp of the cDNA sequence, including 132 and 854 nt of 5′ and 3′ untranslated regions, respectively. The core protein precursor is 2,132 amino acids long (M_r 222,008), including a 19-residue secretory signal peptide. The overall amino acid sequence of the mouse aggrecan shows 91.6% identity to rat and 72.5% to human aggrecan. Comparison of the amino acid sequences of various domains and subdomain structures of mouse aggrecan to known sequences of other species and related proteins (versican, neurocan, link protein, and lymphocyte homing receptor CD44) revealed high levels of identity of the G1, G2, and G3 globular domains and relatively less conserved structures in the interglobular and glycosaminoglycan-attachment regions (Walcz et al. 1994).

The mouse aggrecan gene spans at least 61 kb and contains 18 exons. Exon 1 encodes 5′-untranslated sequence and exon 2 contains a translation start codon, methionine. The coding sequence is 6545 bp for a 2,132-amino-acid protein with $M_r = 259{,}131$ including an 18-amino-acid signal peptide. The chondroitin sulfate domain consisting of 1,161 amino acids is encoded by a single exon of 3.6 kb. Although link protein has similar structural domains and subdomains, the sequence identity and the organization of exons encoding the subdomains B and B′ of G1 and G2 domains revealed a strong similarity of mouse aggrecan to both human versican and rat neurocan. Primer extension analysis identified four transcription start sites which are close together. The promoter sequence showed high G/C content and contained several consensus binding motifs for transcription factors including Sp-1 and the glucocorticoid receptor. There are stretches of sequences similar to the promoter region of both the type-II collagen and link protein genes. These sequences may be important for cartilage gene expression (Watanabe et al. 1995, 2006).

37.5.5 Chick Aggrecan

Pirok et al. (1997) cloned and sequenced the 1.8-kb genomic 5′ flanking sequence of the chick aggrecan gene. Sequence analysis revealed potential Sp1, AP2, and NF-I related sites, as well as several putative transcription factor binding sites, including the cartilage-associated silencers CIIS1 and CIIS2. A number of these transcription factor binding motifs are embedded in a sequence flanked by prominent inverted repeats. Although lacking a classic TATA box, there are two instances in the 1.8-kb genomic fragment of TATA-like TCTAA sequences, as have been defined previously in other promoter regions. Primer extension and S1 protection analyses revealed three major transcription start sites, also located between the inverted repeats. Expression of aggrecan is both cell-specific and developmentally regulated. Seven functionally defined *cis* elements in aggrecan promoter region are known to repress aggrecan gene expression. A functional repressor *cis* element, (T/C) TCCCCT(A/C)RRC occurs at multiple locations within the chick aggrecan regulatory region (Pirok et al. 2005).

37.6 Versican or Chondroitin Sulfate Proteoglycan Core Protein 2

Versican, also known as chondroitin sulfate proteoglycan core protein 2 (or chondroitin sulfate proteoglycan 2 (CSPG2), or PG-M), is a large extracellular matrix proteoglycan that is present in a variety of human tissues. It is encoded by the *VCAN* gene. It is a large chondroitin sulfate proteoglycan with M_r of more than 1,000-kDa. Versican is encoded by a single gene, which is located on chromosome 5q12-14 in the human genome. Versican occurs in four isoforms: V0, V1, V2, V3. The central domain of versican V0 contains both the GAG-α and GAG-β domains. V1 isoforms has the GAG-β domain, V2 has the GAG-α domain, and V3 is void of any GAG attachment domains. The GAGs, being composed of repeating disaccharide units, contribute to the negative charge and many other properties of proteoglycans. These proteoglycans share a homologous globular N-terminal, C-terminal, and glycosaminoglycan (GAG) binding regions. The N-terminal (G1) globular domain consists of Ig-like loop and two link modules, and has Hyaluronan binding properties. The C-terminal (G3) globular domain consists of one or two EGF repeats, a C-type lectin domain and complement regulatory protein (CRP)-like domain. The C-terminal domain binds a variety

of ligands in ECM which contribute significantly to the functions of lecticans (Fig. 37.1).

37.6.1 Expression

Expression of versican is observed in various adult tissues such as blood vessels, skin, and developing heart. Smooth muscle cells of blood vessels, epithelial cells of skin, and the cells of central and peripheral nervous system are a few examples of cell types that express versican physiologically. In adult CNS, versican is found in perineuronal nets, where it may stabilize synaptic connections. Also, there is differential temporal and spatial expression of versican by multiple cell types and in different developmental and pathological time frames. To fully appreciate the functional roles of versican as it relates to changing patterns of expression in development and disease, an in depth knowledge of versican's biosynthetic processing is necessary. Rahmani et al. (2006) evaluated the current status of our knowledge regarding the transcriptional control of versican gene regulation with a focuss on the signal transduction pathways, promoter regions, cis-acting elements, and trans-factors that have been characterized.

cDNA Clones: The cDNA clones of versican expressed by human fibroblasts code for 2,389 amino acid long core protein and the 20-residue signal peptide. The sequence predicts a potential hyaluronic acid-binding domain in the amino-terminal portion. This domain contains sequences virtually identical to partial peptide sequences from a glial hyaluronate-binding protein. Putative glycosaminoglycan attachment sites are located in the middle of the protein. The carboxy-terminal portion includes two (EGF) epidermal growth factor-like repeats, a lectin-like sequence and a complement regulatory protein-like domain. Amino- and carboxy-terminal portions of the fibroblast core protein are closely related to the core protein of a large chondroitin sulfate proteoglycan of chondrosarcoma cells. However, the glycosaminoglycan attachment regions in the middle of the core proteins are different and only the fibroblast core protein contains EGF-like repeats. Based on the similarities of its domains with various binding elements of other proteins, it was suggested that the large fibroblast proteoglycan, herein be referred to as versican (Zimmermann and Ruoslahti 1989).

Alternative Splice Variants of Human Versican: Alternative splicing of versican generates at least four isoforms named V0, V1, V2, and V3. An alternatively spliced glycosaminoglycan attachment domain (GAG-α) of human versican was cloned from cDNA libraries. Inserted carboxyl-terminal of the hyaluronan-binding region, this domain adds another 987 amino acids to the original versican (V1) core protein giving rise to the large V0 isoform with 3,396 amino acids and 17–23 putative glycosaminoglycan attachment sites. The GAG-α domain is encoded by exon 7 of the human versican gene. Sequence comparisons revealed a slight similarity to the alternative splice domain of PG-M, further supporting the notion that PG-M is the chicken homologue of versican. Both V0 and V1 isoforms were detected in cerebral cortex, aorta, intervertebral disc, liver, myometrium, and prostate, whereas keratinocytes exclusively expressed versican V1. In brain tissue, a short versican variant (V2) including only the GAG-α domain was identified (Dours-Zimmermann and Zimmermann 1994).

Multiple Forms of Mouse Versican: Versicon from chick limb buds, named as PG-M, was shown to be expressed in the prechondrogenic condensation area of the developing chick limb buds. PG-M shows the presence of a hyaluronic acid binding domain at the amino-terminal side and two EGF-like domains, a lectin-like domain, and a complement regulatory protein-like domain at the carboxyl-terminal side. These domains show high homology to corresponding domains of a human fibroblast versican. The chondroitin sulfate attachment domain of PG-M core protein is about 100 kDa larger than that of versican core protein. The finding of alternatively spliced forms of PG-M core protein suggests that versican might be one of the multiple forms of PG-M (Shinomura et al. 1993). Ito et al. (1995) sequenced cDNA clones that encode the core protein of PG-M-like proteoglycan produced by cultured mouse aortic endothelial cells. A homology search of cDNA revealed that the core protein is a mouse equivalent of chick PG-M-V1, one of the alternatively spliced forms of the PG-M core protein, which may correspond to human versican. Northern blot analysis revealed three mRNA species of 10, 9, and 8 kb in size. The analysis of PG-M mRNA species in embryonic limb buds and adult brain indicated the presence of other mRNA species with different sizes; the one with the largest size (12 kb) was found in embryonic limb buds, and the ones with smaller sizes of 7.5 and 6.5 kb were present in adult brain. Sequencing of cDNA for smaller forms from adult brain showed that they were different from PG-M-V1 in encoding the second chondroitin sulfate attachment domain (CSα) alone. The mRNA of 12 kb in size corresponded to a transcript without the alternative splicing (V0), PG-M-V0. It is likely that multiforms of the PG-M core protein may be generated by alternative usage of either or both of the two different CS attachment domains (α and β) and that molecular forms of PG-M may vary from tissue to tissue by such an alternative splicing. The ectopic expression of versican V1 isoform induced mesenchymal-epithelial transition (MET) in NIH3T3 fibroblasts, and inhibition of

endogenous versican expression abolished the MET in metanephric mesenchyme. Reports indicate the involvement of versican in MET: expression of versican is sufficient to induce MET in NIH3T3 fibroblasts and reduction of versican expression decreased MET in metanephric mesenchyme (Sheng et al. 2006).

Versican Gene: The human VCAN gene is divided into 15 exons over 90–100 kb (Naso et al. 1994). The entire primary structures of versican have been generated from human, murine, bovine and chick cDNA clones; the chick form was originally named PG-M (Shinomura et al. 1993). The exon organization corresponds to the protein subdomains encoded by homologous proteins, with a remarkable conservation of exon size and intron phase. An additional exon is present just proximal to the glycosaminoglycan-binding region that is identical to a splice variant of versican (Dours-Zimmermann and Zimmermann 1994). The versican promoter harbors a typical TATA box located approximately 16 bp upstream of the transcription start site and binding sites for a number of transcription factors involved in regulated gene expression. Stepwise 5′ deletions identified a strong enhancer element between −209 and −445 bp and a strong negative element between −445 and −632 bp (Naso et al. 1994).

37.6.2 Structure

Versican is a large (1–2 × 10^6 Da) chondroitin-sulfate proteoglycan that can form large aggregates by means of interaction with hyaluronan and also binds to a series of other extracellular matrix proteins, chemokines and cell-surface molecules. A recombinant construct corresponding to the C-type lectin domain of versican demonstrates a calcium-dependent self-association of this region. This binding reaction could contribute to the ability of versican to organize formation of the proteoglycan extracellular matrix by inducing binding of individual versican molecules or by modulating binding reactions to other matrix components (Ney et al. 2006) (Fig. 37.4). The large aggregating chondroitin sulfate proteoglycans are characterized by N-terminal and C-terminal globular (or selectin-like) domains known as the G1 and G3 domains, respectively. The modulatory effects of G1 and G3 molecular domains may contribute to versican's biological activities (Yang et al. 2000). Versican, like other members of its family, has unique N- and C-terminal globular regions, each with multiple motifs. A large glycosaminoglycan-binding region lies between them. These structures have been discussed in the context of ECM proteoglycans. All isoforms of versican have homologous N-terminal (HA binding) and C-terminal (lectin-like) domains. The central domain of versican V0 contains both the GAG-α and GAG-β domains. V1 isoforms has the GAG-β domain, V2 has the GAG-α domain, and V3 is void of any GAG attachment domains, and only consists of the N-terminal and C-terminal globular domains.

N-Terminus: The N-terminal (G1) globular domain consists of Ig-like loop and two link modules, and has hyaluronan (HA) binding properties. The N-terminal of versican has an important role in maintaining the integrity of the ECM by interacting with hyaluronan. Its interactions with link protein have also been observed.

C-Terminus: The C-terminal (G3) globular domain consists of one or two EGF repeats, a C-type lectin domain and complement regulatory protein (CRP)-like domain. The C-terminal domain binds a variety of ligands in ECM which contribute significantly to the functions of lecticans. One important family of ligands is the tenascin family. For example, The C-lectin domain of versican interacts with Tenascin R through its fibronectin type III (FnIII) repeat 3–5 domain in a calcium dependent manner, in vivo. Different tenascin domains interact with a wide range of cellular receptors, including integrins, cell adhesion molecules and members of the syndecan and glypican proteoglycan families (Fig. 37.3B). Versican's C-terminal domain interacts with Fibulin-2, a protein whose expression is associated with that of versican in the developing heart. The EGF domain of the C-terminal of Versican also binds the EGF-receptor molecule, in vivo.

GAG Binding Region: The central domain of Versican is decorated with glycosaminoglycans. The structural and functional diversity of Versican is increased by variations in GAG sulfation patterns and the type of GAG chains bound to the core protein. The central domain of versican V0 contains both the GAG-α and GAG-β domains. V1 isoforms has the GAG-β domain, V2 has the GAG-α domain, and V3 is void of any GAG attachment domains. The GAGs, being composed of repeating disaccharide units, contribute to the negative charge and many other properties of proteoglycans.

37.6.3 Interactions of Versican

The diverse binding partners afforded to versican by virtue of its modular design include ECM components, such as hyaluronan, type I collagen, tenascin-R, fibulin-1, and -2, fibrillin-1, fibronectin, P- and L-selectins, and chemokines.

Versican also binds to the cell surface proteins CD44, integrin β1, epidermal growth factor receptor, and PSGL-1. These multiple interactors play important roles in cell behaviour. Roles of versican in modulating such processes have been discussed.. Fibulin-1 is strongly expressed in tissues where versican is expressed, and also expressed in developing cartilage and bone. The interactions with fibulin-1 are Ca^{2+}-dependent with K_D values in the low nM range. The binding site for aggrecan and versican lectin domains was mapped to the EGF-like repeats in domain II of fibulin-1. Solid phase assays with known ligands demonstrated that fibulin-2 and tenascin-R bind the same site on the proteoglycan lectin domains (Wu et al. 2005) (Fig. 37.7).

The interactions of the CS/DS chains of versican with L- and P-selectin and chemokines are sulfation-dependent but the interaction with CD44 is sulfation-independent. The binding of versican to L- and P-selectin was inhibited by CS and HS. On the other hand, the binding to CD44 was inhibited by hyaluronic acid, chondroitin (CH), CS A, CS B, CS C, CS D, and CS E but not by HS or keratan sulfate. A cross-blocking study indicated that L- and P-selectin recognize close or overlapping sites on versican, whereas CD44 recognizes separate sites. Structural analysis showed that versican is modified with at least CS B and CS C (Kawashima et al. 2000). Studies suggest that oversulfated CS/DS chains containing GlcAβ1/IdoAα1-3GalNAc(4,6-O-disulfate) are recognized by L- and P-selectin and chemokines, and imply that these chains are important in selectin- and/or chemokine-mediated cellular responses (Kawashima et al. 2002).

37.6.4 Functions

Versican is a multifunctional molecule with roles in cell adhesion, matrix assembly, cell migration proliferation and angiogenesis, and hence plays a central role in tissue morphogenesis and maintenance. Versican is involved in development, guiding embryonic cell migration important in the formation of the heart and outlining the path for neural crest cell migration. Versican is a key factor in inflammation through interactions with adhesion molecules on the surfaces of inflammatory leukocytes and interactions with chemokines that are involved in recruiting inflammatory cells. Versican is often considered an anti-adhesive molecule. Considering the large size (>1,000 kDa) and hydration capability of versican, it is possible that the interaction of integrins with their cell surface receptors is sterically hindered. In addition, because of negatively charged sulfates or carboxyl groups, chondroitin sulfate chains are attracted to various positively charged molecules such as certain growth factors, cytokines, and chemokines. This interaction in the ECM or on the cell surface is important in the formation of immobilized gradients of these factors, their protection from proteolytic cleavage, and their presentation to specific cell-surface receptors. The binding of versican with leukocyte adhesion molecules L-selectin, P-selectin, and CD44 is also mediated by the interaction of CS chains of versican with the carbohydrate-binding domain of these molecules. Both CD44 and L-selectin have been implicated in leukocyte trafficking. The ability of versican to bind a large panel of chemokines and the biological consequences of such binding has also been examined. Versican can bind specific chemokines through its CS chains and this interaction down-regulates the chemokines function. In light of results that V1 and V2 isoforms of versican have opposite effects on cell proliferation, glycosaminoglycan domain GAG-β has been implicated in versican-enhanced cell proliferation and versican-induced reduction of cell apoptosis.

Versican Guides Migratory Neural Crest Cells: Selective expression of versican V0 and V1 in barrier tissues impede the migration of neural crest cells during embryonic trunk development (Landolt et al. 1995). Pure preparations of either a mixture of versican V0/V1 or V1 alone strongly inhibit the migration of multipotent Sox10/p75NTR-positive early neural crest stem cells. This inhibition is largely core glycoprotein-dependent. Findings support the notion that versican variants V0 and V1 act, possibly in concert with other inhibitory molecules such as aggrecan and ephrins, in directing the migratory streams of neural crest cells to their appropriate target tissues (Dutt et al. 2006).

The versican accumulates in lesions of atherosclerosis and restenosis. The unique structural features make this molecule to bind growth factors, enzymes, lipoproteins, and a variety of other ECM components to influence fundamental events involved in vascular diseases. Versican is upregulated after vascular injury and is a prominent component in stented and nonstented restenotic lesions. The synthesis of versican is highly regulated by specific growth factors and cytokines and the principal source of versican is the smooth muscle cell. Versican interacts with hyaluronan to create expanded viscoelastic pericellular matrices that are required for arterial smooth muscle cell (ASMC) proliferation and migration. Versican is also prominent in advanced lesions of atherosclerosis, at the borders of lipid-filled necrotic cores as well as at the plaque-thrombus interface, suggesting roles in lipid accumulation, inflammation, and thrombosis. Versican influences the assembly of ECM and controls elastic fiber fibrillogenesis, which is of fundamental importance in ECM remodeling during vascular disease. Collectively, studies highlight the importance of this specific ECM component in atherosclerosis and restenosis (Wight and Merrilees 2004).

37.7 Pathologies Associated with PGS

37.7.1 Proteoglycans Facilitate Lipid Accumulation in Arterial Wall

The accumulation of extracellular matrix components such as proteoglycans is a hallmark of an atherosclerotic lesion. Proteoglycans are considered to facilitate lipid accumulation in the arterial wall, as part of the injury and repair process in atherogenesis. Srinivasan et al. (1995) determined (1) characteristics of arterial tissue CS monomers of versican type that vary in binding affinity to low-density lipoproteins (LDL), and (2) the ability of these variants to modulate LDL metabolism by macrophages. A large CS devoid of DS was identified and purified from bovine aorta intima-media under dissociative conditions. Variations in LDL-binding affinity of CS could modulate the lipid accumulation in atherogenesis. LDL enhances mesangial cell (MC) matrix deposition by modulating the production of PG and hyaluronan (HA) in the culture medium and to a lesser extent in the cell layer. The GAG chains did not show difference in either their size or charge. The synthesis of both CS and HS was enhanced as was the production of versican, perlecan and to a lesser extent decorin. An increase in HA synthesis was also demonstrated following LDL stimulation (Chana et al. 2000).

Heparan sulfate in ECM of artery wall possesses antiatherogenic properties and interferes in lipoprotein retention, by suppression of inflammation, and by inhibition of smooth muscle cell (SMC) growth. The amount of HS in atherosclerotic lesions from humans and animals is known to be reduced. The atherosclerotic lesions retrieved from patients undergoing surgery for symptomatic carotid stenosis showed a selective reduction in perlecan gene expression, whereas, expression of other HS proteoglycans in the artery wall, agrin and collagen XVIII, the large CSPG and the versican remained unchanged. This suggests a reduction of perlecan mRNA-expression and protein deposition in human atherosclerosis, which in part explains the low levels of HS in this disease (Tran et al. 2007).

Fatty Acids Modulate the Composition of ECM in Cultured Human Arterial SMCs: In diabetes-associated angiopathies and atherosclerosis, there are alterations in the intima of small and large arteries. High concentrations of nonesterified fatty acids (NEFAs) might alter the basement membrane composition of endothelial cells. In arteries, SMCs are the major producers of proteoglycans and glycoproteins in the intima, which is the site of lipoprotein deposition and modification during atherogenesis. Exposure of human arterial SMCs (ASMCs) to albumin-bound linoleic acid lowered their rate of proliferation and altered cell morphology. ASMCs expressed 2–10 times more mRNA for the core proteins of versican, decorin, and syndecan 4. Studies suggest that some of the NEFA effects are mediated by PPAR-γ. These effects of NEFAs, in vivo, could contribute to changes of the matrix of arterial intima associated with micro- and macroangiopathies (Olsson et al. 1999).

Human hASMC matrix PGs contribute to the retention of apoB lipoproteins in the intima, a possible key step in atherogenesis. The response of ASMC to NEFA could induce ECM alterations favoring apoB lipoprotein deposition and atherogenesis (Rodríguez-Lee et al. 2006). Extracellular matrix changes occur in heart valve pathologies. Decreased expression of the hyaluronan receptor for endocytosis in myxomatous mittral valves suggested that hyaluronan metabolism could be altered in myxomatous mitral valve disease (Gupta et al. 2009).

Perlecan in Atherosclerosis-Prone and Atherosclerosis-Resistant Human Arteries: A large HSPG, perlecan, dramatically increases in the advanced lesion, and vascular SMC are the cell type responsible for the accumulation. In cultured human coronary SMCs indicate that thrombin increases the cell layer-associated HSPG with a core protein size of approximately 400 kDa without any change in the length of the glycosaminoglycan chains when the cell density is high. The HSPG was identified as perlecan. In addition, thrombin elevated the steady-state level of perlecan mRNA but not that of versican, decorin, and syndecan-1 mRNAs, although biglycan mRNA was moderately elevated. It is suggested that thrombin induces the perlecan core protein synthesis without influencing the formation of the heparan sulfate chains in human coronary SMCs at a high cell density. The regulation of proteoglycan synthesis by thrombin may be involved in the accumulation of perlecan in advanced lesions of atherosclerosis (Yamamoto et al. 2005).

A proteomics-based approach indicated that intimal proteoglycan composition in preatherosclerotic lesions was more complex than previously appreciated with up to eight distinct core proteins present, including the large versican and aggrecan, the basement membrane proteoglycan perlecan, the class I small leucine-rich proteoglycans biglycan and decorin, and the class II small leucine-rich proteoglycans lumican, fibromodulin, and prolargin/PRELP (proline arginine-rich end leucine-rich repeat protein). Although most of these proteoglycans seem to be present in similar amounts at the two locations, there was a selective enhanced deposition of lumican in the intima of the atherosclerosis-prone internal carotid artery compared with the intima of the atherosclerosis-resistant internal thoracic artery. The enhanced deposition of lumican in the intima of an atherosclerosis prone artery has

important implications for the pathogenesis of atherosclerosis (Talusan et al. 2005).

Molecular Structure and Organization of Versicon in Human Aneurysmal Abdominal Aortas: Differences have been noted in matrix metalloproteinase expression patterns in cultures of medial smooth muscle cells from tissue affected by abdominal aortic aneurysm (AAA) or atherosclerotic occlusive disease and from normal arterial tissue. Versican, perlecan, and biglycan levels were significantly elevated in AAA smooth muscle cell cultures. Two populations of smooth muscle cell versican were identified. Because heparan sulfate proteoglycans can bind growth factors, their elevated synthesis by AAA smooth muscle cells in combination with an increased expression of matrix metalloproteinases may at least partly explain the differential proliferative capacity of the AAA smooth muscle cells and may govern the pattern of abnormal cellular proliferation and matrix protein synthesis observed in the pathogenesis of vascular disease (Melrose et al. 1998).

Versican in aortic wall participates in various biological functions of the tissue. In human aorta and aneurysmal aortic tissue versican is exclusively substituted with chondroitin sulfate chains, in contrast to other human tissues where both chondroitin and dermatan sulfate chains are attached onto versican core proteins. Except for the significant decrease in the concentration of versican in the aneurysmal tissue, this PG undergoes specific alterations in the aneurysmal tissue. The molecular size of versican isolated from diseased tissue is decreased with a simultaneous increase in the ratio of glycosaminoglycan to protein in this tissue. Although the size of chondroitin sulfate chains was identical in both versican preparations, a significant increase in the percentage of 6-sulfated disaccharides was observed in chondroitin sulfate chains of versican in aneurysmal aortas, which is accompanied by decrease in 4-sulfated and non-sulfated units (Theocharis et al. 2003a). Mature human aorta contains a 70-kDa versican fragment, which appears to represent G1 domain of versican V1 and has been generated in vivo by proteolytic cleavage at the Glu(441)-Ala(442) bond, within the sequence DPEAAE (441)-A(442)RRGQ (Sandy et al. 2001). Increased versican expression is often observed in tumor growth in tissues such as breast, brain, ovary, gastrointestinal tract, prostate, and melanoma, Sarcoma, and mesothelioma. In addition, versican contributes to the development of a number of pathologic processes including atherosclerotic vascular diseases, tendon remodeling, hair follicle cycling, CNS injury, and neurite outgrowth.

37.8 Diseases of Aggrecan Insufficiency

37.8.1 Aggrecanase-Mediated Cartilage Degradation

The linker domain between the N-terminal globular domains, called the interglobular domain, is highly sensitive to proteolysis. Such degradation has been associated with the development of arthritis. Proteases capable of degrading aggrecans are called aggrecanases, and they are members of the ADAM (A Disintegrin And Metalloprotease) protein family. Aggrecanases and matrix metalloproteinases (MMPs) are associated with aggrecan proteolysis (East et al. 2007). The aggrecanases are of particular interest because of their selectivity for aggrecan. Five aggrecanase cleavage sites have been described in aggrecan (Tortorella et al. 2000), with one residing in the IGD domain and four in the CS2 domain. Increasing evidence is accumulating for the importance of the aggrecanases ADAMTS-4 and ADAMTS-5 in cartilage degradation in arthritis. A number of laboratories have provided insight into the regulation of the expression and activity of these proteins and the molecular basis of their role in aggrecan catabolism. Recombinant ADAMTS-4 and ADAMTS-5 cleave aggrecan at five distinct sites along the core protein and aggrecan fragments generated by cleavage at all of these sites have been identified in cartilage explants undergoing matrix degradation. This proteolytic activity of the aggrecanases can be modulated by several means, including altered expression, activation by proteolytic cleavage at a furin-sensitive site, binding to the aggrecan substrate through the C-terminal thrombospondin motif, activation through post-translational processing of a portion of the C-terminus and inhibition of activity by the endogenous inhibitor TIMP-3. ADAMTS-4 and ADAMTS-5 activity is detected in joint capsule and synovium in addition to cartilage, and may be upregulated in arthritic synovium at either the message level or through post-translational processing. Additional substrates include the CSPG brevican and versican. Advances are occurring in the development of selective aggrecanase inhibitors designed to serve as therapeutics for the treatment of arthritis (Arner 2002)

Site of Catabolism of Aggrecan: Characterization of aggrecan core protein peptides present in the matrix of adult human articular cartilage showed that at least 11 aggrecan core proteins were present with M_r between 300,000 and 43,000. All these core proteins were found to

have the same N-terminal sequences as that observed in human aggrecan. Articular cartilage in explant culture in medium containing 10^{-6} M retinoic acid showed a 3.5-fold increase in the loss of aggrecan into the medium compared to tissue maintained in absence of retinoic acid. Analysis showed the presence of N-terminal sequence ARGS-, which starts at residue 393 of the human aggrecan core protein, located within the interglobular region between the G1 and G2 domains and is the site of aggrecan catabolism by the putative protease aggrecanase. The G1 regions may accumulate in the cartilage matrix for many years (Ilic et al. 1995; Maroudas et al. 1998). The structure of aggrecan fragments in human synovial fluid suggests the involvement of a proteinase in osteoarthritis which cleaves the Glu^{373}-Ala^{374} bond of the interglobular domain (Sandy et al. 1992; Fosang et al. 1995).

Induction of Arthritis in BALB/c Mice by Cartilage Link Protein: Both type II collagen and the proteoglycan aggrecan are capable of inducing an erosive inflammatory polyarthritis in mice. The link protein (LP) from bovine cartilage can produce a persistent, erosive, inflammatory polyarthritis when injected repeatedly intraperitoneally into BALB/c mice. Another cartilage protein, LP, like type II collagen and the proteoglycan aggrecan, is capable of inducing an erosive inflammatory arthritis in mice and the immunity to LP involves recognition of both T- and B-cell epitopes. This immunity may be of importance in the pathogenesis of inflammatory joint diseases, such as juvenile rheumatoid arthritis, in which cellular immunity to LP has been demonstrated (Zhang et al. 1998).

37.8.2 A Mutation in Aggrecan Gene Causes Spondyloepiphyseal Dysplasia

Spondyloepiphyseal dysplasia (SED) encompasses a heterogeneous group of disorders characterized by shortening of the trunk and limbs. Mutations in the aggrecan gene leading to chondrodyplasias have been described in the human, mouse and chicken. The autosomal dominant SED type Kimberley (SEDK) is associated with premature degenerative arthropathy and has been mapped in a multigenerational family to a novel locus on 15q26.1. This locus contains the gene AGC1, which encodes aggrecan, the core protein of proteoglycan of cartilage. In the human, A single-base-pair insertion, within the variable repeat region of exon 12 affected individuals from the family with SEDK, that introduces a frameshift of 212 amino acids, including 22 cysteine residues, followed by a premature stop codon and results in a form of spondyloepiphyseal dysplasia (Gleghorn et al. 2005). Roughley et al. (2006) suggested the involvement of aggrecan polymorphism in degeneration of human intervertebral disc and articular cartilage.

In the mouse, a 7 bp deletion in exon 5 results in a premature termination codon arising in exon 6 (Watanabe et al. 1994, 1998). In the chicken, a premature stop codon is present within exon 10 encoding the CS-attachment region (Li et al. 1993), resulting in decreased message accumulation and under-production of a truncated aggrecan. It is likely that the absence of a G3 region impairs secretion of the mutant aggrecan molecules. In the human, chondrodystrophic phenotypes have also been associated with the under-sulphation of aggrecan due to gene defects in a sulfate transporter (Superti-Furga et al. 1996). These disorders illustrate the importance of aggrecan content and charge in embryonic cartilage development and growth.

37.9 Expression of Proteoglycans in Carcinogenesis

Glycosaminoglycans (GAGs) in PG forms or as free GAGs are implicated in the growth and progression of malignant tumors. Human gastric carcinoma (HGC) contained about twofold increased amounts of GAGs in comparison to normal gastric mucosa (HNG). Specifically, increase in chondroitin sulfate (CS) and hyaluronan (HA) contents was associated with HGC. In HGC, the amounts of versican and decorin were significantly increased. Analysis of Δ-disaccharide of versican and decorin from HGC showed an increase of 6-sulfated Δ-disaccharides (Δ di-6 S) and non-sulfated Δ-disaccharides (Δ di-0 S) with a parallel decrease of 4-sulfated Delta-disaccharides (Δdi-4 S) as compared to HNG. In addition, the accumulation of core proteins of versican and decorin in HGC was also associated with many post-translational modifications, referring to the number, size, degree and patterns of sulphation and epimerization of CS/DS chains (Theocharis et al. 2003b). Prostate tumor cells induce host stromal cells to secrete increased versican levels via a paracrine mechanism mediated by transforming growth factor beta1 (Sakko et al. 2001).

Although, versican expression is not an independent prognostic factor in pharyngeal squamous cell carcinoma (Pukkila et al. 2004), Skandalis et al. (2006) provided direct evidence for a significant and stage-related accumulation of versican and decorin in the tumor-associated stroma of laryngeal squamous cell carcinoma (LSCC) in comparison to normal larynx. The accumulated versican and decorin were markedly modified on both protein core and glycosaminoglycan (GAG) levels. Versican was found to undergo stage-related structural modifications. The modified chemical structure of both PGs could be associated with the degree of aggressiveness of laryngeal squamous cell carcinomas (Skandalis et al. 2006).

37.10 Regulation of Proteoglycans

Dex stimulates cell-associated and soluble chondroitin 4-sulfate proteoglycans. During differentiation into adipocytes, there was a 1.68-fold increase in the ^{35} S in medium of 3 T3-L1 preadipocytes, whereas cell-associated proteoglycan showed no increase. Analyses indicated that all ^{35} S label was recovered as two major species of chondroitin 4-sulfate proteoglycans (CSPG-I and CSPG-II) and 7% as heparan sulfate proteoglycan. Cell differentiation was associated with a specific increase in CSPG-I (Calvo et al. 1991). Platelet-derived growth factor (PDGF) and TGF-β1 increase ^{35}Sulfate incorporation into PG by monkey arterial smooth muscle cells but have opposite effects on cell proliferation. Although both of these growth factors increase the net synthesis of a large versican like CSPG, they differ in their effects on the structure of the glycosaminoglycan chains (Schönherr et al. 1991). TGF-β1 markedly enhanced the expression of biglycan and versican mRNAs and the enhancement of biglycan expression was coordinate with elevated type I procollagen gene expression in the same cultures. In contrast, the expression of decorin mRNA was markedly inhibited by TGF-β1. Results indicate differential regulation of PG gene expression in fibroblasts by TGF-β1 (Kähäri et al. 1991; Barry et al. 2001). Changes have been observed in synthesis of proteoglycans by vascular SMCs in response to controlled mechanical strains. Following strain mRNA and protein for versican, biglycan, and perlecan increased. Thus, mechanical deformation increases specific vascular SMC proteoglycan synthesis and aggregation, indicating a highly coordinated extracellular matrix response to biomechanical stimulation (Lee et al. 2001).

37.11 CD44: A Major Hyaluronan Receptor

37.11.1 CD44: A Hyaluronan Receptor

The CD44 is a transmembrane surface glycoprotein widely distributed in both epithelial and nonepithelial normal tissues (Ponta et al. 2003). This protein participates in a wide variety of cellular functions including lymphocyte activation, recirculation and homing, hematopoiesis, and tumor metastasis. CD44 functions as a major hyaluronan receptor, which mediates cell adhesion and migration in a variety of physiological processes (Sillanpää et al. 2003). It can also interact with other ligands, such as osteopontin, collagens, and matrix metalloproteinases (MMPs). A specialized sialofucosylated glycoform of CD44 called HCELL is found natively on human hematopoietic stem cells, and is a highly potent E-selectin and L-selectin ligand. CD44 is encoded by a single gene located on human chromosome 11. However, alternative splicing of mRNA produces several larger CD44 isoforms in addition to the standard isoform, CD44s. The extracellular region of CD44 gives rise to multiple CD44 isoforms. Alternative splicing is the basis for the structural and functional diversity of this protein, and may be related to tumor metastasis All isoforms contain an amino-terminal domain, which is homologous to cartilage link proteins. The cartilage link protein-like domain of CD44 is important for hyaluronan binding. Splice variants of CD44 on colon cancer cells display the HCELL glycoform, which mediates binding to vascular E-selectin under hemodynamic flow conditions, a critical step in colon cancer metastasis.

CD44 is a lectin cell adhesion molecule that is also expressed in keratinocytes. Amino sugars such as NAG may competitively bind to CD44, modulating keratinocyte cellular adhesion. These amino sugars may modulate keratinocyte cellular adhesion and differentiation, leading to the normalization of stratum corneum exfoliation (Mammone et al. 2009). CD44, along with CD25, is used to track early T cell development in the thymus. Its expression is an indicative marker for effector-memory T-cells. It is tracked with CFSE chemical tagging.

37.11.2 Hyaluronan Binding Sites in CD44

CD44 is a receptor for hyaluronic acid and can also interact with other ligands, such as osteopontin, collagens, and matrix metalloproteinases (MMPs). CD44 function is controlled by its posttranslational modifications. CD44 binds hyaluronan ligand via a lectin-like fold termed the Link module, but only after appropriate functional activation. Among twenty-four point mutants, eight residues were identified as critical for binding or to support the interaction. These residues form a coherent surface, the location of which approximately corresponds to the carbohydrate binding sites in MBP and E-selectin (CD62E) (Bajorath et al. 1998). The interaction with hyaluronan is dominated by shape and hydrogen-bonding complementarity. Banerji et al. (2007) identified two conformational forms of the murine Cd44 that differ in orientation of a crucial hyaluronan-binding residue (Arg^{45}, equivalent to Arg^{41} in human CD44). NMR studies indicated that the conformational transition can be induced by hyaluronan binding, the possible mechanisms for regulation of Cd44.

Although full activity of CD44 requires binding to ERM (ezrin/radixin/moesin) proteins, the CD44 cytoplasmic region, consisting of 72 amino acid residues, lacks the Motif-1 consensus sequence for ERM binding found in ICAM-2 and other adhesion molecules of the Ig superfamily. CD44 exists as an extended monomeric form of the cytoplasmic peptide in solution. The crystal structure of the radixin FERM domain complexed with a CD44 cytoplasmic peptide reveals that the KKKLVIN sequence of the peptide

forms a β strand followed by a short loop structure that binds subdomain C of the FERM domain. Like Motif-1 binding, the CD44 β strand binds the shallow groove between strand β5C and helix α1C and augments the β sheet β5C- β7C from subdomain C. Two hydrophobic CD44 residues, Leu and Ile, are docked into a hydrophobic pocket with the formation of hydrogen bonds between Asn of the CD44 short loop and loop β4C- β5C from subdomain C. This binding mode resembles that of neutral endopeptidase 24.11 (NEP) rather than ICAM-2. These results reveal a characteristic versatility of peptide recognition by the FERM domains from ERM proteins, a possible mechanism by which the CD44 tail is released from the cytoskeleton for nuclear translocation by regulated intra-membrane proteolysis, and provide a structural basis for Smad1 interactions with activated CD44 bound to ERM protein (Mori et al. 2008).

37.11.3 CD44 in Cancer

CD44 is involved in cell proliferation, cell differentiation, cell migration, angiogenesis, and as growth factors to the corresponding receptors, and docking of proteases at the cell membrane, as well as in signaling for cell survival. All these biological properties are essential for physiological activities of normal cells, but they are also associated with the pathologic activities of cancer cells. CD44 is remarkable for its ability to generate alternatively spliced forms, many of which differ in their activities. This remarkable flexibility has led to speculation that CD44, via its changing nature, plays a role in some of the methods that tumor cells use to progress successfully through growth and metastasis. Experiments in animals have shown that targeting of CD44 by antibodies, antisense, and CD44-soluble proteins markedly reduces the malignant activities of various neoplasms, stressing the therapeutic potential of anti-CD44 agents (Naor et al. 2002). Variations in CD44 are reported as cell surface markers for some breast and prostate cancer stem cells (Li et al. 2007) and has been seen as an indicator of increased survival time in epithelial ovarian cancer patients (Martin et al. 2004; Sillanpää et al. 2003; Yasuda et al. 2003). The role of CD44 in prostate cancer development and progression is controversial with studies showing both tumor-promoting and tumor-inhibiting effects. However, Patrawala et al. (2006) suggest that the $CD44^+$ prostate cancer cell population is enriched in tumorigenic and metastatic progenitor cells. $CD44^+$ cells displayed clustered growth within colorectal cancer. Knockdown of CD44, strongly prevented clonal formation and inhibited tumorigenicity in xenograft model. Results indicated that CD44 is a robust marker and is of functional importance for colorectal CSC for cancer initiation (Du et al. 2008).

Proteoglycans of the Central Nervous System 38

G.S. Gupta

38.1 Proteoglycans in Central Nervous System

The extracellular matrix (ECM) is a complex molecular framework that provides physical support to cells and tissues, while also providing signals for cell growth, migration, differentiation and survival. Proteoglycans, as part of the extracellular or cell-surface milieu of most tissues and organ systems, play important roles in morphogenesis by modulating cell-matrix or cell-cell interactions, cell adhesiveness, or by binding and presenting growth and differentiation factors. The basic concept, that specialized extracellular matrices rich in hyaluronan (HA), chondroitin sulfate proteoglycans (CS-PG: aggrecan, versican, neurocan, brevican, phosphacan), link proteins and tenascins (TN-R and TN-C) can regulate cellular migration and axonal growth and thus, actively participate in the development and maturation of nervous system, has gained rapidly expanding experimental support (Zimmermann and Dours-Zimmermann 2008). The distribution of ECM molecules displays area-specific differences along the dorso-ventral axis, delimiting functionally and developmentally distinct areas. In gray matter, laminae I and II lack perineuronal nets (PNN) of extracellular matrix and contain low levels of chondroitin sulfate glycosaminoglycans (CS-GAGs), brevican, and tenascin-R, possibly favoring the maintenance of local neuroplastic properties. Conversely, CS-GAGs, brevican, and phosphacan were abundant, with numerous thick PNNs, in laminae III-VIII and X. Motor neurons (lamina IX), surrounded by PNNs, containd various amounts of CS-GAGs (Vitellaro-Zuccarello et al. 2007).

38.1.1 Large Proteoglycans in Brain

Proteoglycans (PGs) of aggrecan family include extracellular PGs: aggrecan, versican (and avian homologue PG-M), neurocan, brevacan and cell surface specific receptor CD44. They are modular PGs containing combinations of structural motifs such as EGF-like domains, lectin like domains, complement regulatory like domains, immunoglobulin folds, and proteoglycan tandem repeats that are found in other proteins (Fig. 38.1). The protein-hyaluronate aggregates in brain ECM contain versican. The bovine versican splice variant, versican V2 is together with brevican, a major component of the mature brain ECM. Versicans V0 and V1 are only present in relatively small amounts (Schmalfeldt et al. 1998). Several other proteins are related to this family of molecules including link proteins, BEHAV and TSG-6 and contain some of the same highly conserved motifs but lack GAG side chains. Aggrecan and CD44 have been characterized and discussed in general in Chap. 37. In this chapter brain specific PGs, related to aggrecan have been discussed. In adult brain, lecticans are thought to interact with hyaluronan and tenascin-R to form a ternary complex. It is proposed that hyaluronan-lectican-tenascin-R complex constitutes the core assembly of adult brain ECM, which is found mainly in pericellular spaces of neurons as 'perineuronal nets'. Brevican is a member of the aggrecan/versican family of proteoglycans, containing a hyaluronic acid-binding domain in its N-terminus and a lectin-like domain in its C-terminus.

PGs in Developing Brain: A diverse set of proteoglycans (phosphocan, neurocan, versican, aggrecan, and neuron-glia antigen 2 (NG2) proteoglycan) is expressed in developing and adult brain. In developing rat brain from embryonic day 14 (E14), the concentration of aggrecan increased steadily up to 5 months of age, when it reached a level that was 18-fold higher than at E14, where as spliced versican isoforms were present at a relatively low level during the late embryonic and early postnatal period, decreased by approximately 50% between 1 and 2 weeks postnatal, and then increased steadily to a maximum at 100 days (Milev et al. 1998a). In contrast, versican isoforms containing β domain doubled between E14 and birth, after which

DOI 10.1007/978-3-7091-1065-2_38, © Springer-Verlag Wien 2012

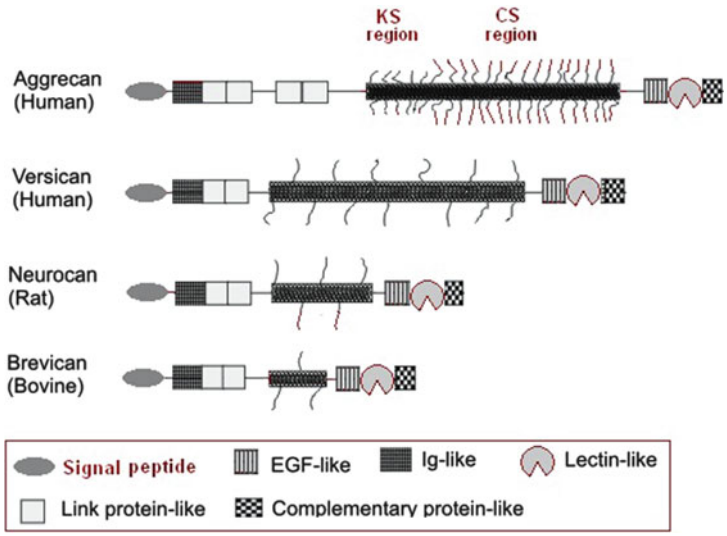

Fig. 38.1 The modular structures of the proteoglycans aggrecan, versican 2, neurocan, and brevican. Aggrecan shows both keratin sulfate (KS) and chondritin sulfate (CS) regions where as versican, neurocan and brevican have CS. Boxes represent putative functional domains shared by all the members of the aggrecan/versican family (Yamada et al. 1994; Fosang and Hardingham 1996)

versican isoforms decreased to reach a low "mature" level that remained unchanged between 2 and 8 months. As in aggrecan, brevican was detected in traces in embryonic brain and increased steadily after birth to reach an adult level that was ~14-fold higher than that in neonatal brain.

Astrocytes as primary site for synthesis of PGs: The CS-PG is primarily synthesized by astrocytes and is believed to influence astroglial motility during development and under certain pathological conditions. The CS-PGs expressed by reactive astrocytes may contribute to the axon growth-inhibitory environment of the injured central nervous system (CNS). In the glial scar, after cortical injury, neurocan and phosphacan can be localized to reactive astrocytes 30 days after CNS injury, whereas brevican and versican are not expressed in the chronic glial scar. Because these CS-PGs are capable of inhibiting neurite outgrowth in vitro, reports suggest that phosphacan and neurocan in areas of reactive gliosis may contribute to axonal regenerative failure after CNS injury. Reports also indicate that brevican is upregulated in areas of brain damage as well as in areas denervated by a lesion and involved in the synaptic reorganization of denervated brain areas (McKeon et al. 1999; Thon et al. 2000). Oligodendrocyte (OL) and their progenitors secrete brevican prior to and during active developmental myelination whereas NG2 is a transmembrane CS-PG produced by early OL progenitors (Table 38.1).

Perineuronal Nets (PNN): Perineuronal nets (PNN) are specialized ECM structures enwrapping CNS neurons, which are important regulators for neuronal and synaptic functions. The decrease in plasticity in CNS during postnatal development is accompanied by appearance of PNNs around the cell body and dendrites of many classes of neuron. These structures are composed of ECM molecules, such as CS-PGs, HA, tenascin-R, and link proteins. In rat deep cerebellar nuclei, only large excitatory neurons were surrounded by nets, which contained the CS-PGs aggrecan, neurocan, brevican, versican, and phosphacan, along with tenascin-R and HA. In the cerebellar cortex, Golgi neurons possessed PNNs and also synthesized HA synthases (HASs), cartilage link protein, and BRAL2 mRNAs. Carulli et al. (2007) proposed that HASs, which can retain HA on the cell surface, may act as a link between PNNs and neurons. Thus, HAS and link proteins might be key molecules for PNN formation and stability. During postnatal development the expression of link protein and aggrecan mRNA is up-regulated at the time of PNN formation, and these molecules may therefore trigger their formation (Galtrey et al. 2008).

38.1.2 Ligands of Lecticans

Interaction Between Tenascin-R and Phosphacan and Neurocan: CS PGs in perineuronal nets include neurocan and phosphacan. Morphological alterations were noticed in Wisteria floribunda labelled nets around cortical interneurones both in tenascin-R knockout and tenascin-R/parvalbumin double knockout mice. This alteration reflects the loss of phosphacan and neurocan from cortical nets in mice deficient in tenascin-R. No effect on the membrane related cytoskeleton, as revealed by ankyrin(R), was observed in any of the mice. These results on mice lacking tenascin-R substantiate in vitro interactions between tenascin-R and phosphacan and neurocan (Haunsø et al. 2000) (Table 38.2).

Table 38.1 Structure and expression of lecticans (Hyalectans) in central nervous system (CNS)[a]

Name	Type	Core protein size (kD) calculated/SDS-PAGE		GAG type	number	Cell origin in CNS	CNS specificity	Sources out side CNS
Brevican	ECM-PG	97	145	CS	0–5	Glial cell/neurons	yes	
GPI-Brevican	GPI-PG	64	140/125	CS	0–5	Glial cells		
Neurocans	ECM-PG	133	245	CS	3	Neurons/Astrocytes	yes	
Versican V0	ECM-PG	370	~550	CS	17–23	Astrocytes	No	Blood vessels; mesenchymes, etc.
Versican V1	ECM-PG	262	500	CS	12–15	Astrocytes	No	Blood vessels; mesenchymes, etc.
Versican V2	ECM-PG	180	400	CS	5–8	Oligodendrocytes	Yes	
Aggrecan	ECM-PG	234	370	CS	?	Neurons	No	Cartilage, notochord

Table 38.2 Ligands of proteoglycans in central nervous system[a]

Name	Growth factors	ECM molecules	Cell surface molecules
Brevican		Hyaluronan; tenacin-R	Sulfatides (glycolipids)
Neurocan	FGF2	Hyaluronan; tenacin-C; Tenacin-R	N-CAM; Ng-CAM/L1
			Tag-1/axonin, sulfatides
Versicans		Hyaluronan; tenacin-R; Fibronectin	Sulfatides
Aggrecan		Hyaluronan	Sulfatides

FGF fibroblast growth factor, *NCAM* neural cell adhesion molecule, *L1* cell adhesion molecule highly enriched on axon, *Ng-CAM* neuron-glia cell adhesion molecule (a chick homolog of L1)
[a]Bbandtlow and Zzimmermann (2000)

Sulfoglucuronylglycolipids: Two classes of sulfated glycolipids: sulfatides and HNK-1-reactive sulfoglucuronyl-glycolipids (SGGLs) act as cell surface receptors for brevican. The lectin domain of brevican binds sulfatides and SGGLs in a calcium-dependent manner as expected of a CTLD. The interaction between the lectin domains of lecticans and sulfated glycolipids suggests that lecticans in ECMs serve as substrate for adhesion and migration of cells expressing these glycolipids in vivo (Miura et al. 1999). The Ig chimera of the brevican lectin domain binds to the surface of SGGL-expressing rat hippocampal neurons. The substrate of the brevican chimera promotes adhesion and neurite outgrowth of hippocampal neurons. The full-length brevican also promotes neuronal cell adhesion and neurite outgrowth. Miura et al. (2001) suggest that the interaction between the lectin domain of brevican and cell surface SGGLs acts as a cell recognition system that promotes neuronal adhesion and neurite outgrowth.

Tenascin-C and Tenascin-R as Ligands of Brevican: Tenascin-C (TN-C) is a ligand for brain lecticans and binding site maps on the tenascin molecule to fibronectin type III repeats, which corresponds to the proteoglycan lectin-binding site on tenascin-R (TN-R). In the G3 domain, the C-type lectin is flanked by EGF repeats and a complement regulatory protein-like motif. In aggrecan, these are subject to alternative splicing. The mRNA for this splice variant was shown to be expressed in human chondrocytes. The alternative splicing in the aggrecan G3 domain may be a mechanism for modulating interactions and ECM assembly (Day et al. 2004).

The TN-R and the proteoglycans of the lectican family show an overlapping distribution in developing brain. In TN-R-deficient animals, the perineuronal nets tend to show a granular component within their lattice-like structure at early stages of development and the staining intensity for brevican was reduced in perineuronal nets, extremely low for hyaluronan and neurocan, and virtually no for phosphacan. It was indicated that the lack of TN-R initially and continuously disturbs the molecular scaffolding of extracellular matrix components in perineuronal nets (Brückner et al. 2000). Differential patterns of co-expression of proteoglycans, hyaluronan and TN-R in the individual regions and laminae of the hippocampal formation and the inhomogeneous composition of these components suggest that the extracellular matrix is specifically adapted to the functional domains of intrahippocampal connections and afferent fibre systems (Brückner et al. 2003). Zacharias and Rauch (2006) suggest that a complex network of protein-protein interactions within the brain extracellular matrix, as shown for TN-R and lecticans, is important for the fine-regulation of developmental processes such as microprocess formation along the neurite and neurite outgrowth.

Though the C-type lectin domain of brevican also binds TN-R, this interaction is mediated by a protein-protein interaction through the fibronectin type III domains 3–5 of TN-R, independent of any carbohydrate or sulfated amino acid. Interestingly, the lectin domains of versican and other lecticans also bind the same domain of TN-R by protein-protein interactions. In earlier study, the C-type lectin domain of versican was shown to bind TN-R and the interaction was mediated by a carbohydrate-protein interaction. Surface plasmon resonance analysis revealed that brevican lectin has at least a tenfold higher affinity than the other

lectican lectins. Reports suggest that C-type lectin domain can interact with fibronectin type III domains through protein-protein interactions, and that brevican is a physiological TN-R ligand in the adult brain (Aspberg et al. 1997; Hagihara et al. 1999; Lundell et al. 2004).

38.2 Neurocan

Neurocan is a multidomain hyaluronan-binding CS-PG with a 136-kDa core protein that is synthesized by neurons and binds to hyaluronic acid, whereas the astroglial proteoglycan phosphacan is an mRNA splice variant representing the entire extracellular portion of a receptor-type protein tyrosine phosphatase. The concentration of neurocan in brain increases during late embryonic development followed by a steep decline during early postnatal period together with hyaluronan. Neurocan also undergoes extensive proteolytic processing during the course of brain development (Miller et al. 1995). Mouse brain neurocan, but not brevican, is retained on a heparin affinity matrix (Feng et al. 2000). Due to its inhibition of neuronal adhesion and outgrowth in vitro and its expression pattern in vivo it was suggested to play an important role in axon guidance and neurite growth. Neurocan of brain is developmentally regulated with respect to its concentration, carbohydrate composition, sulfation, and localization. Although the possible neuroprotective involvement of CS-PG remains to be investigated, Mizuno et al. (2008) suggested that both the reactive astrocytes and the differential accumulation of CS-PGs may create a non-permissive microenvironment for neural regeneration in neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS).

38.2.1 Cellular Sites of Synthesis

Neurocan mRNA was evident in neurons, including cerebellar granule cells and Purkinje cells, and in neurons of the hippocampal formation and cerebellar nuclei. The distribution of neurocan message is more wide spread, extending to the cortex, hippocampal formation, caudate putamen, and basal telencephalic neuroepithelium. Neurocan mRNA is present in both the ependymal and mantle layers of the spinal cord but not in the roof plate. The presence of neurocan mRNA in areas where the proteoglycan is not expressed suggests that the short open reading frame in the 5′-leader of neurocan may function as a cis-acting regulatory signal for the modulation of neurocan expression in the developing CNS (Engel et al. 1996). Ihara's epileptic rat (IER) is an animal model of temporal lobe epilepsy with mycrodysgenesis that exhibits abnormal migration of hippocampal neurons and recurrent spontaneous seizures. It was suggested that the insufficient expression of neurocan may affect the development of neuronal organization in the hippocampus, and that the remodeling of ECM in the dentate gyrus may contribute to the mossy fiber sprouting into the inner molecular layer (Kurazono et al. 2001).

38.2.2 Characterization

The composite sequence of overlapping cDNA clones is 5.2 kb long, including 1.3 kb of 3′-untranslated sequence and 76 bp of 5′-untranslated sequence. An ORF of 1257 amino acids encodes a protein with a molecular mass of 136 kDa containing ten peptide sequences present in the adult and/or early postnatal brain proteoglycans. The deduced amino acid sequence revealed a 22-amino acid signal peptide followed by an immunoglobulin domain, tandem repeats characteristic of the hyaluronic acid-binding region of aggregating proteoglycans, and an RGDS sequence. The C-terminal portion (amino acids 951–1215) has approximately 60% identity to regions in the C termini of the fibroblast and cartilage proteoglycans, versican and aggrecan, including two EGF-like domains, a lectin-like domain, and a complement regulatory protein-like sequence. The proteoglycan contains six potential N-glycosylation sites and 25 potential threonine O-glycosylation sites. In the adult form of the proteoglycan (which represents the C-terminal half of neurocan) a single 32-kDa chondroitin 4-sulfate chain is linked at serine-944, whereas three additional potential chondroitin sulfate attachment sites are present in the larger proteoglycan species. The 1D1 (one of the CS-PG) proteoglycan of adult brain, containing a 68-kDa core protein, is generated by a developmentally regulated in vivo proteolytic processing of 136-kDa species which is predominant in early postnatal brain (Rauch et al. 1992).

Neurocan gene of 25 kb contains the coding sequence for the mRNA on 15 exons. The exon-intron structure reflected the structural organization of neurocan, which is a multidomain protein belonging to proteoglycan family. All introns between conserved modular domains are phase I introns. Primer extension experiments indicate a transcriptional start point 28 bases downstream of a consensus TATA sequence. Analysis of 1 kb of 5′ flanking sequence revealed in addition to AP1, AP2, and SP1 consensus binding sites multiple E-box elements and a glucocorticoid responsive element. Single-strand conformation polymorphism mapped neurocan to chromosome 8 between the microsatellite markers D8Mit29 and D8Mit78. The multidomain structure and the preferential expression of neurocan in the brain suggest its involvement in neurological disorders (Rauch et al. 1995).

The coding sequence of human neurocan mRNA known as CS-PG3 was described by Prange et al. (1998). Sequence

homology searches indicated close homology to the mouse and rat neurocan. Neurocan mRNA is a brain-specific transcript of approx. 7.5 kb. A longer cDNA clone, GT-5 was mapped to the physical map of chromosome 19. Full coding sequence of the mRNA indicates a 3963 bp ORF corresponding to a 1321 amino acid protein, similar to protein in mouse and rat. The amino acid sequence of human neurocan shows 63% identity with both the mouse and rat sequences. The genomic structure of the gene spans approx. 41 kb, and is transcribed in the telomere to centromere orientation.

Two Proteoglycan Fragments of Neurocan: In adult rat brain, neurocan is completely cleaved into some proteoglycan fragments including the C-terminal half known as neurocan-C and an N-terminal fragment with a 130 kDa core glycoprotein (neurocan-130). Results suggested that not only the C-terminal half (CSPG-150) but also the N-terminal half (CSPG-130) of CSPG-220 existed in a CSPG form in rat brain. The contents of CSPG-130 and CSPG-150 in the rat brain reached maximum levels around the time of birth. Both CSPG-130 and 150 were observed when CSPG-220 was hardly detectable in extracts from the adult rat brain (Matsui et al. 1994). The two neurocan-derived CS-PGs are distributed in adult rat cerebrum. Neurocan-130 exhibits pericellular localization around a subset of neurons in addition to diffuse distribution in the neuropil where as, neurocan-C was distributed only diffusely in the neuropil. The neurocan-130 was mainly localized in the cytoplasm of glial cell processes, the so-called glial perineuronal net, encompassing the cell bodies of certain neurons. The presence of neurocan-130 in a limited number of glial cells may reflect some functional heterogeneity of the glia (Matsui et al. 1998). Under electron microscopy neurocan shows two globular domains interconnected by an extended flexible filament of 60–90 nm. Electron microscopic shapes indicated a mucin-like character for the central neurocan region (Retzler et al. 1996b). Neurocan has been shown to bind to the neural cell adhesion molecule N-CAM and to inhibit its homophilic interaction (Retzler et al. 1996a).

The full-length neurocan is detected in juvenile brains but not in adult brains. However, full-length neurocan transiently appeared in adult rat hippocampus when it was lesioned by kainate-induced seizures. The full-length neurocan was detectable also in the adult brain when it was exposed to mechanical incision or epileptic stimulation. The full-length neurocan transiently appeared in the peri-ischemic region of transient middle cerebral artery occlusion (tMCAO) in adult rat. The induction of neurocan expression by reactive astrocytes suggested that juvenile-type neurocan plays some roles in brain repair (Matsui et al. 2002; Deguchi et al. 2005).

Neurocan-Like and 6B4 Proteoglycan: The neurocan-like and 6B4 proteoglycan-like reactivities in rat embryo were investigated from E10.5–15.5. It is likely that neurocan serves as a barrier molecule to regulate the direction of axonal growth from the dorsal root ganglia. By contrast, results suggested possible functions of 6B4 proteoglycan in rat embryo (Katoh-Semba et al. 1998). Within first week postnatally, neurocan expression is strongly downregulated. But it is re-expressed in areas of axonal growth (sprouting) after brain injury as found in the denervated fascia dentata of the rat after entorhinal cortex lesion. In the denervated zone, neurocan-positive astrocytes were confirmed by electron microscopy. In contrast to the situation during development, astrocytes, but not neurons, express neurocan and enrich the ECM with this molecule. Similar to the situation during development it is suggested that neurocan acts to maintain the boundaries of the denervated fascia dentata after entorhinal cortex lesion (Haas et al. 1999).

38.2.3 Ligand Interactions

Neurocan can bind to various structural extracellular matrix components, such as hyaluronan, heparin, tenascin-C and tenascin-R, and the growth and mobility factors FGF-2, HB-GAM, and amphoterin. Neurocan can also interact with several cell surface molecules, such as N-CAM, L1/Ng-CAM, TAG-1/axonin-1, and an N-cadherin-binding N-acetyl-galactosamine-phosphoryl-transferase. In vitro studies have shown that neurocan is able to modulate the cell-binding and neurite outgrowth promoting activites of these molecules. Binding of phosphacan and neurocan to intact tenascin-C, and of phosphacan to the fibrinogen globe, is significantly increased in presence of calcium. These interactions seem to be mediated by the proteoglycan core proteins rather than through the glycosaminoglycan chains (Milev et al. 1997). A divalent cation-dependent interaction between the COOH-terminal domain of neurocan and those fibronectin type III repeats is substantially involved in the binding of neurocan to tenascin-C (Rauch et al. 1997). Neurocan like phosphacan is also high affinity ligand of amphoterin and HB-GAM (K_D = 0.3–8 nM), two heparin-binding proteins that are developmentally regulated in brain and functionally involved in neurite outgrowth (Milev et al. 1998a). Analysis of the molecular structures and substructures involved in homophilic and heterophilic interactions of these molecules and complementary loss-of-function mutations might shed some light on the roles played by neurocan and interacting molecules in the fine tuning of the nervous system (Rauch et al. 2001; Rauch 2004). Treatment with phosphacan and neurocan on poly-L-lysine (PL) significantly impaired both neuronal attachment and neurite extension, and both phosphacan and neurocan are repulsive substrata for adhesion and neurite regeneration of adult rat

dorsal root ganglion (DRG) neurons in vitro (Sango et al. 2003). Li et al. (2005) examined the formation of thalamocortical pathway in the cerebral neocortex of normal and reeler mutant mice. Results support the hypothesis that a heterophilic molecular interaction between L1 and neurocan is involved in determining the thalamocortical pathway within the neocortical anlage.

38.3 Brevican

Brevican has the smallest core protein among aggrecan/versican/neurocan family and is one of the most abundant CS-PG in the adult brain. Expression of brevican is highly specific in the brain and increases as the brain develops. Brevican may play a role in maintaining the extracellular environment of mature brain as a major constituent of the adult brain ECM. Because of smallest core protein, this novel proteoglycan has been named "brevican" (from the Latin word *brevis* meaning "short") (Fig. 38.1).

38.3.1 Characterization

Brevican carries chondroitin sulfate chains and, like other members of the family, contains a hyaluronic acid-binding domain in its N-terminal region, an EGF-like repeat, a lectin-like and a complement regulatory protein-like domain in its C-terminal region (see Fig. 37.4). In contrast, the central region of brevican is much shorter than that of aggrecan, versican, or neurocan, and shows little homology with these proteoglycans. Brevican core protein exists as a 145 kDa full-length form and a 80 kDa N terminally truncated form. A significant amount of brevican devoid of any glycosaminoglycan chains is present in the brain, indicating that brevican is a "part-time" proteoglycan (Yamada et al. 1994).

Two sets of overlapping Brevican cDNA clones from rat brain have been characterized that differ in their 3′-terminal regions. Each set was found to hybridize with two brain-specific transcripts of 3.3 and 3.6 kb. The 3.6-kb transcript encodes a polypeptide that exhibits 82% sequence identity with bovine brevican and is thought to be the rat ortholog of brevican. The polypeptide deduced from ORF of 3.3-kb transcript is truncated just carboxyl-terminal of the central domain of brevican and instead contains a putative glypiation signal. Both soluble and membrane-bound brevican isoforms exist. Isoforms of brevican are indeed glycosylphosphatidylinositol-anchored to the plasma membrane. Brevican is widely distributed in the brain and is localized extracellularly. During postnatal development, amounts of both soluble and phosphatidylinositol-specific phospholipase C-sensitive isoforms increase, suggesting a role for brevican in the terminally differentiating and the adult nervous system (Seidenbecher et al. 1995).

38.3.2 Murine Brevican Gene

The mouse genomic sequence of 13,700 nt revealed that the murine gene has a size of approximately 13 kb and contains the sequence of mRNA for the secreted brevican isoform on 14 exons. The exon-intron structure reflected the structural organization of the multidomain protein brevican. No consensus TATA sequence was found upstream of the first exon, and RNase protection experiments revealed multiple transcriptional start sites for the brevican gene. The first part of the sequence of intron 8 corresponded to an alternative brevican cDNA, coding for a GPI-linked isoform. Single strand conformation polymorphism analysis mapped the brevican gene (*Bcan*) to chromosome 3 between the microsatellite markers D3Mit22 and D3Mit11 (Rauch et al. 1997).

Site of Expression: In rat cerebellar cortex, brevican occurs predominantly in the protoplasmic islet in the internal granular layer after the third postnatal week. Brevican is localized in close association with the surface of astrocytes that form neuroglial sheaths of cerebellar glomeruli where incoming mossy fibers interact with dendrites and axons from resident neurons. Studies indicate that brevican is synthesized by astrocytes and retained on their surface by an interaction involving its core protein. Purified brevican inhibits neurite outgrowth from cerebellar granule neurons in vitro, an activity that requires chondroitin sulfate chains. The brevican present on the surface of neuroglial sheaths may be controlling the infiltration of axons and dendrites into maturing glomeruli (Yamada et al. 1997).

Ogawa et al. (2001) demonstrated that brevican is expressed by both oligodendrocytes and white matter astrocytes in the fimbria, but the expression of brevican in these two glial cell types is differently regulated during development. At P14, brevican immunoreactivity was observed throughout the fimbria, with particularly strong immunoreactivity in the developing interfascicular glial rows. In contrast, the expression in astrocytes started around P21 as oligodendrocytes began to down-regulate the expression. In the adult fimbria, brevican expression was restricted to astrocytes. The secreted brevican transcript was detectable in the pituitary of both male and female adult rats. In posterior lobe of pituitary, pituicytes were heavily labelled. In anterior and intermediate lobes of pituitary, signals for brevican transcripts were observed in cells of various sizes (Dong et al. 2004).

Brevican is expressed by neuronal and glial cells, and as a component of the perineuronal nets it decorates the surface of large neuronal somata and primary dendrites. One

brevican isoform harbors a glycosylphosphatidylinositol anchor attachment site and is indeed glypiated in stably transfected HEK293 cells as well as in oligodendrocyte precursor Oli-neu cells. The major isoform is secreted into the extracellular space, although a significant amount appears to be tightly attached to the cell membrane. Brevican is most prominent in the microsomal, light membrane and synaptosomal fractions of rat brain membrane preparations. The association with the particulate fraction is in part sensitive to chondroitinase ABC and phosphatidylinositol-specific phospholipase C treatment. Furthermore, brevican staining on the surface of hippocampal neurons in culture is diminished after hyaluronidase or chondroitinase ABC treatment. Results provide a mechanism by which perineuronal nets are anchored on neuronal surfaces (Seidenbecher et al. 2002). Brevican, TN-R and phosphacan are present at the nodes of Ranvier on myelinated axons with a particularly large diameter in CNS of rat brain.

Transcripts for Secreted and GPI-anchored Brevican Are Differentially Distributed in Rat Brain: In contrast to the other family members, brevican occurrs both as soluble isoforms secreted into the extracellular space and membrane-bound isoforms which are anchored to the cell surface via a glycosylphosphatidylinositol (GPI) moiety. Expression of both variants, which are encoded by two differentially processed transcripts from the same gene, is confined to the nervous system. Whereas the 3.6-kb transcript encoding secreted brevican displays a widespread distribution in grey matter structures, including cerebellar and cerebral cortex, hippocampus and thalamic nuclei with silver grains accumulating over neuronal cell bodies, the smaller transcript (3.3 kb) encoding GPI-anchored isoforms appears to be largely confined to white matter tracts and diffusely distributed glial cells. During ontogenetic development, both brevican transcripts are generally up-regulated. However, the expression of glypiated brevican is delayed by about 1 week, compared with the expression of the secreted isoform (Seidenbecher et al. 1998).

38.4 Hyaluronan: Proteoglycan Binding Link Protein

Hyaluronan (HA) is a ubiquitous component of extracellular matrices, and in several systems it plays a central role in regulating cellular proliferation and differentiation. Cell or tissue-specific functions of HA are likely to be mediated by cell or tissue-specific HA-binding proteins (Meyer-Puttlitz et al. 1995). The HA plays an important role in tissue reorganization in response to injury. In the mammalian CNS, HA is present throughout development and into adulthood. Link proteins are glycoproteins in cartilage that are involved in the stabilization of aggregates of proteoglycans and hyaluronic acid Link protein (LP), an extracellular matrix protein in cartilage, stabilizes aggregates of aggrecan and hyaluronan, giving cartilage its tensile strength and elasticity. targeted mutations in mice in the gene encoding LP (Crtl1) showed defects in cartilage development and delayed bone formation with short limbs and craniofacial anomalies. Thus LP is important for the formation of proteoglycan aggregates and normal organization of hypertrophic chondrocytes (Watanabe et al. 1999) (Fig. 37.1).

38.4.1 Cartilage link protein 1 and Brain Link Proteins

Spicer et al. (2003) described a vertebrate hyaluronan and proteoglycan binding link protein gene family (HAPLN), consisting of four members including cartilage link protein CRTL1. Human and mouse link proteins share 81–96% amino acid sequence identity. Two of the four link protein genes (HAPLN2 and HAPLN4) are restricted to the brain/CNS, while one HAPLN3 is widely expressed. Genomic structures revealed that all four HAPLN genes are similar in exon-intron organization and also similar in genomic organization to the 5′ exons for the CS-PG core protein genes. The HAPLN genes expressed by most tissues suggest the fundamental importance of the hyaluronan-dependent extracellular matrix to tissue architecture and function in vertebrates.

The CRTL1 stabilizes aggregates of aggrecan and hyaluronan in cartilage (Czipri et al. 2003). The aggrecan forms link protein-stabilized complexes with HA, via its N-terminal G1-domain that provides cartilage with its load bearing properties. Similar aggregates, in which other CS-PGs (i.e. versican, brevican, and neurocan) substitute for aggrecan, may contribute to the structural integrity of many other tissues including skin and brain (Seyfried et al. 2005). A human brain link protein-1 (BRAL1) is predominantly expressed in brain (Hirakawa et al. 2000). The predicted ORF of human *Bral1* encodes a polypeptide of 340 amino acids containing three protein modules: Ig-like fold and proteoglycan tandem repeat 1 and 2 domains, with an estimated mass of 38 kDa. Brain link protein-1 functions to stabilize the binding between hyaluronan and brevican. The deduced amino acid sequence of human BRAL1 exhibited 45% identity with human CRTL1. The immunoreactivity of BRAL1 was predominantly observed in myelinated fiber tracts in the adult brain and could be detected at P20 in the white matter of the developing cerebellum. Furthermore, BRAL1 colocalized with the versican V2 isoform at the nodes of Ranvier. BRAL1 may play a pivotal role in the

formation of the hyaluronan-associated matrix in the CNS that facilitates neuronal conduction by forming an ion diffusion barrier at the nodes (Oohashi et al. 2002).

The *Bral2* gene is predominantly expressed in brain. The *Bral2* mRNA expression is first detected at P20 and continued through adulthood. In situ hybridization revealed that BRAL2 is synthesized by these neurons themselves, especially by the GABAergic neurons in the cerebellar cortex. The colocalization and synergic importance of BRAL2 and brevican in the perineuronal nets is indicated by the analysis using wild-type and brevican-deficient mouse brain, which suggests that BRAL2 is involved in the formation of ECM contributing to perineuronal nets and facilitate the understanding of a functional role of these ECMs (Bekku et al. 2003).

38.4.2 Brain Enriched Hyaluronan Binding (BEHAB)/Brevican

While the functions of HA are mediated by HA-binding proteins, Hockfield S and co-workers reported the characterization of a cDNA with a high degree of sequence homology to members of the proteoglycan tandem repeat (PTR) family of HA-binding proteins. Unlike other HA-binding proteins, the expression of this cDNA is restricted to the CNS. Hockfield S and co-workers proposed the name BEHAB, Brain Enriched Hyaluronan Binding protein, for this gene. The expression of BEHAB mRNA is developmentally regulated. In the embryo, BEHAB is expressed at highest levels in mitotically active cells. The sequence of BEHAB suggests that the encoded protein is functionally important. The size and sequence of BEHAB are consistent with the possibility that it could serve a function like link protein, stabilizing interactions between HA and brain proteoglycans. In rat and cat brain, BEHAB is expressed at very high levels in ventricular zones throughout the neuraxis. Expression is first detected at embryonic day 15 (E15) in the spinal cord, and is detected at progressively more rostral levels at later ages (Jaworski et al. 1996). There exist several BEHAB/brevican isoforms, each of which may mediate different functions. BEHAB/brevican has been cloned from bovine, mouse, rat and human. Two isoforms have been reported: a full-length isoform that is secreted into ECM and a shorter isoform with a sequence that predicts a glycophosphatidylinositol (GPI) anchor. The BEHAB/brevican gene maps to human chromosome 1q31 (Gary et al. 2000).

Glial tumors, gliomas, are the most common primary intracranial tumors. Their distinct ability to invade the normal surrounding tissue makes them difficult to control and nearly impossible to completely remove surgically. The ECM can modulate, in part, the permissiveness of a tissue to cell movement. One ECM molecule that shows dramatic upregulation in gliomas is BEHAB/brevican. The BEHAB/brevican gene is consistently expressed by human glioma and is not expressed by tumors of nonglial origin (Gary and Hockfield 2000; Jaworski et al. 1996; Zhang et al. 1998). BEHAB/brevican expression is also upregulated during periods of increased glial cell motility in development and following brain injury. Experimental evidence suggests that in glioma, in addition to upregulation of BEHAB/brevican, proteolytic processing of the full-length protein also may contribute to invasion. Reports suggest that up-regulation and proteolytic cleavage of BEHAB/brevican increases significantly the aggressiveness of glial tumors. It will be important to determine the therapeutic potential of inhibiting BEHAB/brevican cleavage in gliomas (Nutt et al. 2001).

38.5 Proteolytic Cleavage of Brevican

BEHAB/brevican can be cleaved into an N-terminal fragment that contains a hyaluronan-binding domain (HABD) and a C-terminal fragment (Yamada et al. 1995). The BEHAB/brevican protein is cleaved in invasive human and rodent gliomas. Matthews et al. (2000) suggested a function for ADAMTS family members in BEHAB/brevican cleavage and glioma and indicated that inhibition of ADAMTS in glioma might provide a novel therapeutic strategy (Viapiano et al. 2008). ADAMTS (a disintegrin and metalloproteinase with thrombo- spondin motifs) proteases are complex secreted enzymes containing a prometalloprotease domain of the reprolysin type attached to an ancillary domain with a highly conserved structure that includes at least one thrombospondin type 1 repeat (Lemons et al. 2001). ADAMTS proteases are synthesized as zymogens, with constitutive proprotein convertase removal of the propeptide occurring prior to secretion. Their enzymatic specificity is heavily influenced by their ancillary domain, which plays a critical role in directing these enzymes to their substrates, the cell surface and the extracellular matrix. Known functions of ADAMTS proteases include (1) processing of procollagens N-proteinase; (2) cleavage of the matrix proteoglycans aggrecan, versican and brevican; (3) inhibition of angiogenesis; and (4) blood coagulation homoeostasis as the von Willebrand factor cleaving protease. ADAMTS-1, -4 and -5 are present in CNS, which are able to cleave the aggregating CS-PG, aggrecan, phosphacan, neurocan and brevican. ADAMTS-4 mRNA and protein expression was decreased. Changes in ADAMTS expression during the course of CNS inflammation may contribute to ECM degradation and disease progression (Cross et al. 2006). ADAMTS4 that selectively cleaves lecticans was detected in cultures of neurons, astrocytes and microglia (Hamel et al. 2005). The ADAMTS-induced cleavage of brevican in the

dentate outer molecular layer is closely associated with diminished synaptic density, and may, therefore, contribute to synaptic loss and/or reorganization in this region (Mayer et al. 2005; Porter et al. 2005)

In human glioblastomas ADAMTS4 and ADAMTS5 (aggrecanases 1 and 2) are expressed in considerable amounts. ADAMTS5 expression is confined to proliferating glioblastoma cells of surgical tumor sections and with lower intensity to astroglial cells in normal brain sections, as opposed to brevican. Selective cleavage of the Glu^{395}-Ser^{396} bond of brevican in adult brain tissues is thought to be important for glioma cell invasion. ADAMTS-4 has such an activity (Nakada et al. 2005). In vitro, glioblastoma-derived ADAMTS5 degrades recombinant human brevican to several smaller fragments. Results show that ADAMTS4 and 5 are upregulated on proliferating glioblastoma cells and these proteases may contribute to their invasive potential (Held-Feindt et al. 2006). ADAMTS-5 is capable of degrading brevican and is overexpressed in glioblastoma cells, and that ADAMTS-5 may play a role in glioma cell invasion through the cleavage of brevican (Nakada et al. 2005; Porter et al. 2005).

38.6 Proteoglycans in Sensory Organs

Various proteoglycans are expressed in ocular tissues. The TGF-β2 regulates the expression of proteoglycans in aqueous humor. The expression of CS in stroma was upregulated at early postnatal stages and reduced during development in rat eyes. Decorin is expressed in trabecular meshwork tissues. In retinal tissues, neurocan and phosphacan were expressed mainly in nerve fiber-rich layers during rat postnatal stages. Soluble extracellular proteoglycans in corneal and trabecular meshwork tissues contribute to the stromal transparency in the corneal tissues and the resistance of the aqueous humor outflow in trabecular meshwork tissues (Inatani and Tanihara 2002).

CS and HS proteoglycans are the major constituents expressed in and secreted by retinal tissue. Soluble HS proteoglycans are found in extracellular matrices of the basement membrane, whereas HS proteoglycans with their membrane-binding domain are localized primarily in the neurites of retinal neuronal cells, indicating their role as receptors for cytokines. The expression in the nerve fiber-rich layers of several CS proteoglycans, such as neurocan and phosphacan, is restricted in the nervous tissues, and is upregulated as retinal development proceeds, then decreases after maturation of the retina. In vitro data suggest that these proteoglycans regulate axon guidance and synapse formation during the development of nervous tissue. In contrast, in adult vertebrate retina, the IPM is a rich source of CS proteoglycans (Inatani and Tanihara 2002). Co-localization of the molecule with TN-R in the retina and optic nerve suggested a functional relationship between TN-R and phosphacan-related CS proteoglycan in vivo (Inatani et al. 2001; Xiao et al. 1997).

Aggrecan and versican were first seen at E16 in the optic nerve and retina of rat, whereas neurocan was not detected in the embryonic eye. At postnatal day P0, β-versican is largely confined to the inner plexiform layer whereas α-versican is also apparent in the neuroblastic layer. Both aggrecan and, much more weakly, neurocan immunoreactivity is present throughout the neonatal retina. Aggrecan and α-versican are also present throughout the optic nerve and disk, whereas β-versican and neurocan are confined to the laminar beams of the optic nerve (Popp et al. 2004). In mouse retinofugal pathway, phosphacan but not neurocan is likely the major carrier of the CS glycosaminoglycans that play crucial functions in axon divergence and age-related axon ordering in the mouse optic pathway. These two proteoglycans regulate axon growth and patterning not only through the sulfated sugars but also by interactions of the protein parts with guidance molecules on the optic axons (Leung et al. 2004).

Accumulation of neurocan in association with the retinal vasculature does not correlate with photoreceptor cell loss, because it was not observed in the rhodopsin mutant rats. During the earliest stages of the disease, accumulation of debris in the subretinal space in RCS rats with dystrophic retinas may be sufficient per se to initiate a cascade of metabolic changes that result in accumulation of neurocan. With time, the neurocan accumulated perivascularly may, by interaction with other matrix molecules, modulate at least some of the vascular alterations observed in rat animal model (Zhang et al. 2003). In transient retinal ischemia the intensity of the 220-kDa band as well as the 150-kDa band increased markedly after reperfusion. The neurocan expression by Müller cells suggests that this proteoglycan plays a role in the damage and repair processes in diseased retina (Inatani et al. 2000).

Neurocan was conspicuous in the medial and lateral superior olivary nuclei and much less stained in the cochlear nucleus and posterior colliculus. Different locations of CS-PG, including neurocan, may be associated with focal sites composed of neuronal surface, terminal boutons and ECM in the lower auditory tract of the adult dog (Atoji et al. 1997).

Neurocan was first detected in primary olfactory neurons at E11.5. Neurocan was expressed by primary olfactory axons as they extended toward the rostral pole of the telencephalon as well as by their arbors in glomeruli after they contacted the olfactory bulb. Being a strong promoter for neurite outgrowth neurocan supports the growth of primary olfactory axons through ECM. Phosphacan, unlike neurocan, was present within the mesenchyme surrounding the E11.5 and E12.5 nasal cavity. This expression decreased at E13.5, concomitant with a transient appearance of phosphacan in nerve fascicles. Within the embryonic olfactory bulb, phosphacan was localised to the external and internal

plexiform layers. The spatiotemporal expression patterns of neurocan and phosphacan indicate that these CS-PGs have diverse in situ roles, which are dependent on context-specific interactions with extracellular and cell adhesion molecules within the developing olfactory nerve pathway (Clarris et al. 2000). Glycosaminoglycan chains, such as CS and KS, and core proteins of the CS proteoglycan, neurocan and phosphacan, were barely detected in the migratory pathway from the olfactory placode. N-syndecan mRNA was localized in virtually all of migrating neurons as well as in cells of the olfactory epithelium and the vomeronasal organ. It is likely that a heterophilic interaction between NCAM and N-syndecan participates in the neuronal migration from the rat olfactory placode (Toba et al. 2002).

38.7 Functions of Proteoglycans in CNS

38.7.1 Functions of Chondroitin Sulphate Proteoglycans

In the adult, CS-PGs are generally thought to be inhibitory for tissue plasticity and to have a barrier function during regeneration (Bradbury et al. 2002). However, in the developing CNS, CS-PGs show a functional dualism: depending on the neuronal cell type and the way they are presented to neurons, both growth inhibitory and growth promoting effects have been described (Emerling and Lander 1996; Akita et al. 2004; Wu et al. 2004). The inhibitory properties of CS-PGs have mostly been attributed to their glycosaminoglycan (GAG) chains (Asher et al. 2002; Sivasankaran et al. 2004), however, the core protein may also act as an inhibitor (Monnier et al. 2003; Ughrin et al. 2003). In regions containing low levels of adhesion molecules, various CS-PGs may act as barriers to cell migration and axonal growth. In regions containing high levels of adhesion proteins, brain CS-PGs may still act to maintain certain boundaries while allowing selective axonal extension to proceed. There are numerous regions of overlap in the expression patterns of CS-PGs and adhesion molecules in vivo, and the relative levels of these molecules as well as the organization of the ECM may be important factors that regulate the rate of axonal growth locally. Differential expression of CS-PGs may be important for modulating cell adhesion as well as axonal growth and guidance during neural development, and continued expression may prevent these processes in normal mature nervous system as well as following brain injury (Margolis et al. 1996). The swift assembly and remodeling of ECMs have been associated with axonal guidance functions in the periphery and with the structural stabilization of myelinated fiber tracts and synaptic contacts in the maturating CNS. Particular interest has been focused on the putative role of CS-PG in suppressing CNS regeneration after lesions. The axon growth inhibitory properties of several of these CS-PGs in vitro and the partial recovery of structural plasticity in lesioned animals treated with chondroitin sulfate degrading enzymes in vivo have significantly contributed to the increased awareness of this long time neglected structure.

Little is known about the contribution of CS-PGs to regeneration failure in vivo at dorsal root entry zone (DREZ), a CNS region that blocks regeneration of sensory fibers following dorsal root injury without glial scar formation. It is suggested that the proteoglycans (Brevican, Neurocan, Versican V1, and Versican V2) are abundant in the DREZ at the time regenerating sensory fibers reach the PNS/CNS border and may therefore participate in growth-inhibition in this region (Beggah et al. 2005). Quaglia et al. (2008) demonstrated that (1) neurocan and/or brevican contribute to the non-permissive environment of the DREZ several weeks after lesion and that (2) delayed stimulation of the growth program of sensory neurons can facilitate regeneration across DREZ provided its growth-inhibitory properties are attenuated. Post-injury enhancement of the intrinsic growth capacity of sensory neurons combined with removal of inhibitory CS-PG may therefore help to restore sensory function and thus attenuate the chronic pain resulting from human brachial plexus injury.

In areas of denervation the role of CS-PGs is less clear, since they are enriched in zones of sprouting, i.e. zones of axonal growth. However, results reveal a temporal pattern in CS-PG mRNA expression in the denervated fascia dentata. This suggests specific biological functions for CS-PGs during the denervation-induced reorganization process: whereas the early increase in CS-PGs in the denervated zone could influence the pattern of sprouting, the late increase of aggrecan mRNA suggests a different role during the late phase of reorganization (Schäfer et al. 2008).

Functions of Sciatic Nerve-Derived Versican- and Other CS-PGs: Human sciatic nerves contained two chondroitin sulphate proteoglycans of M_r of 130 and 900 kDa. Following chondroitinase ABC treatment of 130 kDa proteoglycan, a core protein of ~45 kDa was shown to react with polyclonal antibodies against the chondroitin-dermatan sulphate proteoglycan decorin from human fibroblasts. Chondroitinase ABC treatment of 900 kDa proteoglycan yielded a core protein with a M_r of ~400 kDa. Observations suggest two proteoglycans from human sciatic nerve are immunochemically related to chondroitin sulphate proteoglycans versican and decorin that may contribute to successful regeneration in the peripheral nervous system of mammals. The versican- and decorin-like molecules are involved in cell-extracellular matrix interactions and inhibit adhesion of several cell lines, neonatal dorsal root ganglion neurons and Schwann cells.

Observations suggest that binding of the two proteoglycans to fibronectin is involved in the modulation of adhesion of cells to fibronectin (Braunewell et al. 1995).

38.7.2 Functions of Brevican and Neurocan in CNS

Perineuronal nets (PNN) are specialized ECM structures enwrapping CNS neurons, which are important regulators for neuronal and synaptic functions. Brevican is an integral component of PNN, which appear in hippocampal primary cultures. Brevican is primarily synthesized by co-cultured glial fibrillary acidic protein (GFAP-)-positive astrocytes and co-assembles with its interaction partners in PNN-like structures on neuronal somata and neurites. Both excitatory and inhibitory synapses are embedded into PNN. Furthermore, axon initial segments are strongly covered by a dense brevican coat. Altogether, mature primary cultures can form PNN (John et al. 2006). Digestions with chondroitinase ABC and hyaluronidase indicated that aggrecan, versican, neurocan, brevican, and phosphacan are retained in PNNs through binding to HA. A comparison of the brain and spinal cord ECM with respect to CS-PGs indicated that the PNNs in both parts of the CNS have the same composition (Deepa et al. 2006).

Mice lacking brevican gene are viable and fertile and have a normal life span. Brain anatomy was normal, although alterations in the expression of neurocan were detected. The PNN formed but appeared to be less prominent in mutant than in wild-type mice. Brevican-deficient mice showed significant deficits in the maintenance of hippocampal long-term potentiation (LTP). Detailed behavioral analysis revealed no significant deficits in learning and memory. Results indicated that brevican is not crucial for brain development but has restricted structural and functional roles (Brakebusch et al. 2002). A brevican deficiency resulted in a reorganization of the nodal matrices, which was characterized by the shift of tenascin-R (TN-R), and concomitantly phosphacan, from an axonal diameter-dependent association with nodes to an axonal diameter independent association. Bekku et al. (2009) revealed that brevican plays a crucial role in determining the specialization of the hyaluronan-binding nodal matrix assemblies in large diameter nodes. Brevican associates with astrocytes ensheathing cerebellar glomeruli and inhibits neurite outgrowth from granule neurons.

At molecular level, brevican promotes EGFR activation, increases the expression of cell adhesion molecules, and promotes the secretion of fibronectin and accumulation of fibronectin microfibrils on the cell surface. Moreover, the N-terminal cleavage product of brevican, but not the full-length protein, associates with fibronectin in cultured cells and in surgical samples of glioma. Results provide evidence of the cellular and molecular mechanisms that may underlie the motility-promoting role of brevican in primary brain tumors. In addition, these results underscore the important functional implications of brevican processing in glioma progression (Hu et al. 2008).

Neurocan-deficient mice are viable and fertile and have no obvious deficits in reproduction and general performance. Brain anatomy, morphology, and ultrastructure are similar to those of wild-type mice. Perineuronal nets surrounding neurons appear largely normal. Mild deficits in synaptic plasticity may exist, as maintenance of late-phase hippocampal long-term potentiation is reduced. Results indicate that neurocan has either a redundant or a more subtle function in the development of the brain (Zhou et al. 2001; Okamoto et al. 2001). The distal transected cords of infant rats are more permissive for axon extension than those of adults. Neurocan mRNA was up-regulated in the distal cord of adult rats shortly after transection, followed by a longer wide distribution of neurocan activity in both neurons and astrocytes. By contrast, upregulation of neurocan mRNA was not seen in infant rats, although transient expression of neurocan immunoreactivity was seen in neurons. Combined with the different regenerative capacity of infant and adult rats, it indicates that neurocan inhibits spinal cord regeneration (Qi et al. 2003).

Extracellular Matrix Alterations: During hippocampal development, neurocan is expressed throughout the alveus, neuropil layers, and parts of the dentate gyrus from E16 to P2. The CS-PG phosphacan is expressed primarily in the neuropil layers at postnatal stages. After E18, intense labeling of neurocan was observed in regions of the alveus surrounding L1-expressing axon fascicles. In vitro, axons from brain regions that project through the alveus during development would not grow across CS-PG substrata, in a concentration-dependent manner. In addition, hippocampal axons from dissociated neuron cultures only traveled across CS-PG substrata as fasciculated axon bundles. These results implicate CS-PG in the regulation of axon trajectory and fasciculation during hippocampal axon tract formation (Wilson and Snow 2000).

Watanabe et al. (1995) revealed that neurocan was distributed throughout the cerebral cortex of rat during early postnatal development but was absent from the centres of cortical barrels at the time of entry and arborization of thalamocortical axons. At this developmental stage, expression of neurocan mRNA was shown by in situ hybridization to be down-regulated in the barrel centres. It appears that neuronal stimuli through early thalamocortical fibres from the sensory periphery cause reduced expression of neurocan mRNA in neurocan-producing cells in the presumptive barrel centres.

Further, mice lacking neurocan, brevican, tenascin-R, and tenascin-C brain extracellular matrix molecules were found

to be viable and fertile. However, the brains of 1-month-old quadruple KO mice revealed increased levels of fibulin-1 and fibulin-2 with an unusual parenchymal deposition of these molecules. The quadruple KO mice also displayed obvious changes in the pattern of deposition of hyaluronan (Rauch et al. 2005).

Regulation of Cadherin and Integrin Function by Neurocan: Li et al. (2000) showed that the interaction of neurocan with its GalNAcPTase receptor coordinately inhibits both N-cadherin- and β1-integrin-mediated adhesion and neurite outgrowth. The inhibitory activity is localized to an NH_2-terminal fragment of neurocan containing an Ig loop and an HA-binding domain. The coordinate inhibition of cadherin and integrin function on interaction of neurocan with its receptor may prevent cell and neurite migration across boundaries.

The L1/Ng-CAM adhesion molecule of the Ig superfamily is implicated in neural processes including neuronal cell migration, axon outgrowth, learning, and memory formation. It has been suggested that neurocan can block homophilic binding. The sequences involved in neurocan binding are localized on the surface of the first Ig domain and largely overlap with the G-F-C β-strands proposed to interact with the fourth Ig domain during homophilic binding. It was found that the C-terminal portion of neurocan is sufficient to mediate binding to the first Ig domain of L1, and that the sushi domain cooperates with a glycosaminoglycan side chain in forming the binding site for L1 (Oleszewski et al. 2000).

38.7.3 Neurocan in Embryonic Chick Brain

Neurocan has been found in the embryonic avian heart and vasculature. In stage 11 quail embryos, neurocan was prominently expressed in the myocardium, dorsal mesocardium, heart-forming fields, splanchnic mesoderm, and vicinity of the extraembryonic vaculature, and at lower levels in the endocardium. Results suggest that neurocan may function as a barrier that regulates vascular patterning during development (Mishima and Hoffman 2003). Zanin et al. (1999) revealed the presence of aggrecan and versican in stages 12–21 chicken embryo hearts in distinctive spatial and temporal patterns. Versican is found in the myocardium and the myocardial basement membrane. In contrast, aggrecan is specifically colocalized with several groups of migrating cells including endocardial cushion tissue cells, epicardial cells, a mesenchymal cell population in the outflow tract that may be of neural crest origin, and a mesenchymal cell population in the inflow tract. The observations indicated that versican and aggrecan are expressed in unique patterns and that they play different roles in development.

In the chick embryo, aggrecan has a regionally specific and developmentally regulated expression profile during brain development. Aggrecan expression is first detected in chick brain on E7, increases from E7 to E13, declines markedly after E16, and is not evident in hatchling brains. The time course and pattern of aggrecan expression observed in ventricular zone cells suggested that it might play a role in gliogenesis. In aggrecan-deficient model (nanomelic chicks) expression and levels of neurocan and brevican are not affected, indicating a non-redundant role for these members of the aggrecan gene family. Results suggest that aggrecan functions in specification of a sub-set of glia precursors that might give rise to astrocytes in vivo (Schwartz and Domowicz 2004).

38.8 Chondroitin Sulfate Proteoglycans in CNS Injury Response

38.8.1 CS-PGs in CNS in Response to Injury

Injury to the CNS leads to permanent loss of function due to the inability of severed nerve fibers to regenerate back to their targets. Lack of CNS repair has been attributed to several causes, including to extrinsic growth-inhibitory molecules associated with myelin, and to ECM CS-PGs produced by activated glial cells post-injury (Filbin; 2003; Silver and Miller 2004; Zurn and Bandtlow 2006). Treatment with antibodies against the myelin inhibitor Nogo (Schnell and Schwab 1990), with a Nogo-66 receptor antagonist peptide (GrandPre et al. 2002), or with enzymes degrading CS-PGs (Bradbury et al. 2002; Barritt et al. 2006), has provided evidence for the growth-inhibitory function of these molecules. However, the limited ability to regenerate following injury is also due to an intrinsic low capacity of adult axons to grow. Interestingly, the growth capacity of central branches of sensory neurons located in the spinal cord can be increased if their peripheral branches are previously cut (conditioning lesion), i.e. if their axonal growth program is activated before spinal cord lesion (Richardson and Issa 1984; Neumann and Woolf 1999). Yet the timing of this peripheral lesion is critical since peripheral nerve priming delayed by 2 weeks post-lesion fails to promote growth of central sensory axons (Neumann and Woolf 1999). Only the combination of two priming lesions, one at the time of spinal cord injury, and one after 1 week, has been shown to facilitate growth in the same model (Neumann et al. 2005).

Experimental data now indicate that the expression of a number of different CS-PGs is increased following CNS injury. After spinal cord injury, neurocan, brevican, and versican increased within days in injured spinal cord

parenchyma surrounding the lesion site and peaked at 2 weeks. Neurocan and versican were persistently elevated for 4 weeks postinjury, and brevican expression persisted for at least 2 months. On the other hand, phosphacan labeling decreased in the same region immediately following injury but later recovered and then peaked after 2 months. Thus, the production of several CS-PG family members is differentially affected by spinal cord injury, overall establishing a CS-PG-rich matrix that persists for up to 2 months following injury. Optimization of strategies to reduce CS-PG expression to enhance regeneration may need to target several different family members over an extended period following injury (Jones et al. 2003a; b). Upregulation of hyalectans (lecticans) neurocan, versican and brevican, plus NG2 and phosphacan following injury have been shown to exhibit inhibitory effects on neurite outgrowth in vitro. It is likely therefore that the increased expression of these molecules contributes to the non-permissive nature of the glial scar. It is important to remember also that not only does the glial scar contain many different inhibitory molecules, but that these are the products of a number of different cells, including not just astrocytes, but also oligodendrocyte progenitor and meningeal cells. It is arguable that the latter two cell types make a greater contribution than astrocytes to the inhibitory environment of the injured CNS. Evaluation of total soluble CS-PGs 2 weeks after dorsal column lesion in the rat expressed after spinal cord injury (SC-I) demonstrated that NG2 is highly upregulated and is a major CS-PG species. NG2 expression is upregulated within 24 h of injury, peaks at 1 week, and remains elevated for at least an additional 7 weeks (Jones et al. 2002). Attempts have been made to alter the CS-PG component of the glial scar in the hope that this will facilitate improved axonal regeneration. Studies have reported an improved regenerative response following treatment of the injured CNS with chondroitinase ABC. The CS-PGs representing a significant source of inhibition within the injured CNS, studies indicate that successful CNS regeneration may be brought about by interventions which target these molecules and/or the cells which produce them(Morgenstern et al. 2002; Chan et al. 2007).

Axonal Regeneration Through Regions of CS-PG Deposition After Spinal Cord Injury: Jones et al. (2003b). examined growth responses of several classes of axons to this inhibitory environment in the presence of a cellular fibroblast bridge in a spinal cord lesion site and after a growth factor stimulus at the lesion site. Analysis showed dense labeling of NG2, brevican, neurocan, versican, and phosphacan at the host-lesion interface after SC-I. NG2 expression also increased after sciatic nerve injury, wherein axons successfully regenerate. Cellular sources of NG2 in SC-I and peripheral nerve lesion sites included Schwann cells and endothelial cells. Notably, these cellular lesion sites produced the cell adhesion molecules L1 and laminin. Thus, axons grow along substrates coexpressing both inhibitory and permissive molecules, suggesting that regeneration is successful when local permissive signals balance and exceed inhibitory signals (Jones et al. 2003b; Tang et al. 2003). Versican V2 protein levels, however, displayed an opposite trend, dropping below unlesioned spinal cord values at all time points studied (Tang et al. 2003).

Haddock et al. (2007) examined changes in brevican and phosphacan, following transient middle cerebral artery occlusion, a model of stroke in rat and their spatial relationship with ADAMTS-4. The co-localization of ADAMTS or its activity indicated a functional role for this matrix-protease pair in degeneration/regeneration processes that occur in stroke.

Effect of Hypoxic-ischemic Brain Injury in Perinatal Rats: CS-PG are involved in the pathologic process of hypoxia-ischemia (H-I) in the neonatal brain. Brevican is secreted by OLs and their progenitors prior to and during active myelination whereas NG2 is produced by early OL progenitors. In neonatal hippocampus of rat after H-I of unilateral carotid artery ligation and exposure to hypoxia, a cavitary infarct involving the ipsilateral parietal and temporal regions of cerebral cortex, hippocampus, and striatum of most rat pups was evident after H-I. The abundance of brevican was reduced in ipsilateral hippocampus after H-I and the total G1 proteolytic fragment of brevican was lower in the ipsilateral hippocampus and the level of a protease-generated brevican fragment was significantly diminished in OL-rich hippocampal fimbria. Hippocampal NG2 levels were also lower after H-I, but were not different from contralateral side at 14 days. The early events in the process could be involved in apoptotic cell death and/or tissue injury (Aya-ay et al. 2005). In contrast to injured adult CNS, the amount of neurocan was reduced after hypoxia in the neonatal hypoxic-ischemic cerebral hemisphere. The amounts of phosphacan and neuroglycan C were also reduced significantly 24 h after hypoxia at the right injured cortex compared to those at the left cortex. But phosphacan was conversely intensified both at 24 h and 8 days after hypoxia at the infarcted area. Hypoxic-ischemic insult may unmask phosphacan epitopes at the injured sites, resulting in intensified immunostaining. Because intensified immunostaining for neurocan and neuroglycan C was not observed, unmasking seems to be specific to phosphacan among these three CS-PG (Matsui et al. 2005).

Versican and brevican are expressed with distinct pathology in neonatal hypoxic-ischemic injury. Unique expression profiles for lecticans after neonatal H-I

suggested deposition of brevican at elevated rates in response to progressive gray matter injury, whereas diminished versican expression may be associated with deep cerebral white matter injury (Leonardo et al. 2008).

38.8.2 Glial Scar and CNS Repair

Injury to CNS results in the formation of the glial scar, a primarily astrocytic structure that represents an obstacle to regrowing axons. CS-PG are greatly upregulated in the glial scar. The glial scar, a primarily astrocytic structure bordering the infarct tissue inhibits axonal regeneration after stroke. In this environment, axon regeneration fails, and remyelination may also be unsuccessful. The glial reaction to injury recruits microglia, oligodendrocyte precursors, meningeal cells, astrocytes and stem cells. Damaged CNS also contains oligodendrocytes and myelin debris. Most of these cell types produce molecules that have been shown to be inhibitory to axon regeneration. Oligodendrocytes produce NI250, myelin-associated glycoprotein (MAG), and tenascin-R, oligodendrocyte precursors produce NG2 DSD-1/phosphacan and versican, astrocytes produce tenascin, brevican, and neurocan, and can be stimulated to produce NG2, meningeal cells produce NG2 and other proteoglycans, and activated microglia produce free radicals, nitric oxide, and arachidonic acid derivatives. Most of these molecules participate in rendering the damaged CNS inhibitory for axon regeneration. Demyelinated plaques in multiple sclerosis consist mostly of scar-type astrocytes and naked axons. The extent to which the astrocytosis is responsible for blocking remyelination is not established, but astrocytes inhibit the migration of both oligodendrocyte precursors and Schwann cells which must restrict their access to demyelinated axon (Fawcett and Asher 1999; Buss et al. 2009).

Various reports indicate that Neurocan is up-regulated in the scar region after stroke. Neurocan, expressed in the CNS, exerts a repulsive effect on growing cerebellar axons. Immunocytochemistry revealed neurocan to be deposited on the substrate around and under astrocytes but not on the cells. Astrocytes therefore lack the means to retain neurocan at the cell surface. Findings raise the possibility that neurocan interferes with axonal regeneration after CNS injury. In the spinal cord under various types of injury, reactive gliosis emerges in the lesion accompanied by CS-PG up-regulation. Several types of CS-PG core proteins and their side chains have been shown to inhibit axonal regeneration in vitro and in vivo. The bone morphogenetic proteins (BMPs) stimulate glial scar formation in demyelinating lesions of adult spinal cord. BMP4 and BMP7 increase rapidly at the site of demyelination, and astrocytes surrounding the lesion increase expression of phosphorylated Smad1/5/8. Thus, local increase in BMPs at the site of a demyelinating lesion causes upregulation of gliosis, glial scar formation, and heightened expression of CS-PGs such as neurocan and aggrecan that may inhibit remyelination (Fuller et al. 2007). Bone marrow stromal cells (BMSCs) reduce the thickness of glial scar wall and facilitate axonal remodeling in the ischemic boundary zone. Analysis showed that reactive astrocytes were the primary source of neurocan, and BMSC-treated animals had significantly lower neurocan and higher growth associated protein 43 expression in the penumbral region compared with control rats. Neurocan gene expression was significantly down-regulated in rats receiving BMSC transplantation. Shen et al. (2008) suggest that BMSCs promote axonal regeneration by reducing neurocan expression in peri-infarct astrocytes.

38.9 Other Proteoglycans in CNS

In addition to lecticans, phosphacan, NG2, and testicans as proteoglycans are expressed in CNS (Schnepp et al. 2005). The NG2 chondroitin sulfate proteoglycan, a structurally unique, integral membrane proteoglycan, is found on the surfaces of several different types of immature cells. NG2 is associated with multipotential glial precursor cells (O2A progenitor cells), chondroblasts of the developing cartilage, brain capillary endothelial cells, aortic smooth muscle cells, skeletal myoblasts and human melanoma cells (Levine and Nishiyama 1996). Neuroglycan C (NGC), a brain-specific transmembrane proteoglycan, is thought to bear not only CS but also N- and O-linked oligosaccharides on its core protein. The structure of carbohydrate moiety of NGC is developmentally regulated, and differs from those of neurocan and phosphacan. The developmentally-regulated structural change of carbohydrates on NGC may be partly implicated in the modulation of neuronal cell recognition during brain development (Shuo et al. 2004). Brain-specific CS-PGs, including neurocan, phosphacan/receptor-type protein-tyrosine phosphatase beta, and neuroglycan C, have been detected in the CNS. These CS-PGs are involved in the proliferation of neural stem cells as a group of cell microenvironmental factors (Ida et al. 2006). Xiao et al. (1997) isolated a CS-PG from mouse brain with a fragment of ECM tenascin-R that comprises the amino-terminal cysteine-rich stretch and the 4.5 EGF-like repeats. The 173-kDa core protein of phosphacan is synthesized by glia and represents an extracellular variant of the receptor-type protein tyrosine phosphatase RPTP ζ/β. Keratan sulfate-containing glycoforms of phosphacan (designated phosphacan-KS) are also present in brain. In early postnatal rat cerebellum, neurocan, phosphacan, and phosphacan-KS

show the overlapping localization with tenascin, an extracellular matrix protein that modulates cell adhesion and migration. Phosphacan and neurocan are involved in the modulation of cell adhesion and neurite outgrowth during neural development and regeneration (Alliel et al. 2004; Meyer-Puttlitz et al. 1996).

38.10 Regulation of Proteoglycans in CNS

38.10.1 Growth Factors and Cytokine Regulate CS-PGs by Astrocytes

After injury to adult CNS, numerous cytokines and growth factors are released that contribute to reactive gliosis and ECM production. The presence of TGF-β1 and EGF greatly increase the production of several CS-PGs by astrocytes. Treatment of astrocytes with other EGF-receptor (ErbB1) ligands produced increases in CS-PG production similar to those observed with EGF. Treatment of astrocytes, however, with heregulin, which signals through other members of the EGF-receptor family (ErbB2, ErbB3, ErbB4), did not induce CS-PG upregulation. The specificity of activation through the ErbB1 receptor indicated the presence of multiple core proteins containing 4-sulfated or 6-sulfated chondroitin. Further analyses showed that treatment of astrocytes with EGF increased phosphacan expression, whereas treatment with TGF-β1 increased neurocan expression. These results elucidate some of the injury-induced growth factors that regulate the expression of CS-PGs which could be targeted in modulate CS-PG production after injury to the CNS (Smith and Strunz 2005).

ECM alterations in CNS of multiple sclerosis (MS) patients result from blood–brain barrier breakdown, release and activation of proteases, and synthesis of ECM components. In active MS plaque edges, CNS lecticans (versican, aggrecan, and neurocan) and dermatan sulfate PG were increased in association with astrocytosis; in active plaque centers they were decreased in the ECM and accumulated in foamy macrophages, suggesting that these ECM PGs are injured and phagocytosed along with myelin. Results indicate that ECM PG alterations are specific, temporally dynamic, and widespread in MS patients and may play critical roles in lesion pathogenesis and CNS dysfunction (Sobel and Ahmed 2001).

Glutamate activation of excitatory amino acid receptors induces the synthesis and release of PGs with neurite-promoting activity from hippocampal neurones. Both cerebroglycan (CBG), a glycosylphatidylinositol-anchored heparan sulphate PG, and neurocan are expressed in hippocampal neurones. Exposure of hippocampal neurones to 100 μM glutamate resulted in an increase in CBG mRNA levels and an increase in axonal and dendritic length. The increase in CBG mRNA levels following glutamate exposure was mediated via both N-methyl-D-aspartate and metabotropic receptor activation (Wang and Dow 1997).

38.10.2 Decorin Suppresses PGs Expression

Decorin transcripts express in brain on postnatal day 3 followed by a slow decline to the lower adult level. Postnatal decorin expression was observed in the grey matter of neocortex, hippocampus and thalamus, in myelinated fibre tracts and in several mesenchymal tissues (blood vessels, pia mater and the choroid plexus). In the neocortex, decorin is expressed in a specific laminar pattern with intense staining of the cortical plate and its derivatives, which differs remarkably from the distributions observed for other proteoglycans (Miller et al. 1995). Decorin seems to serve yet unknown functions in the developing rat brain parenchyma in addition to its well-established role as a constituent of the mesenchymal ECM (Kappler et al. 1998).

Though the inhibitory CS-PGs and myelin-associated molecules are major impediments to axon regeneration within CNS, decorin infusion can suppress the levels of multiple inhibitory CS-PGs and promote axon growth across spinal cord injuries. Decorin treatment of acute spinal cord injury and cultured adult spinal cord microglia can increase plasminogen/plasmin synthesis and induced 10- and 17-fold increases in plasminogen and plasmin protein levels, respectively, within sites of injury. In addition to potentially degrading multiple axon growth inhibitory components of the glial scar, plasmin is known to play major roles in activating neurotrophins and promoting CNS plasticity (Davies et al. 2004, 2006). The formation of misaligned scar tissue by a variety of cell types expressing multiple axon growth inhibitory proteoglycans presents a physical and molecular barrier to axon regeneration after adult spinal cord injuries. Decorin reduces astrogliosis and basal lamina formation in acute cerebral cortex stab injuries. Decorin pretreatment of meningial fibroblasts in vitro resulted in increase in neurite outgrowth from co-cultured adult sensory neurons and suppression of NG2 immunoreactivity. In addition to suppressing inhibitory scar formation, decorin can directly boost the ability of neurons to extend axons within CS-PG or myelin rich environments. The ability of decorin to promote axon growth across acute spinal cord injuries via a coordinated suppression of inflammation, CS-PG expression and astroglial scar formation make decorin treatment a promising component of future spinal cord regeneration strategies (Minor et al. 2008).

C-Type Lectins: Emerging Groups of C-Type Lectins

Regenerating (Reg) Gene Family

39

G.S. Gupta

39.1 The Regenerating Gene Family

Regenerating (Reg) gene is a multigene super-family grouped into four subclasses, types I, II, III, and IV based on the primary structures of the encoded proteins and represents the products of small secretory proteins, which can function as acute phase reactants, lectins, antiapoptotic factors or growth factors for pancreatic β-cells, neural cells and epithelial cells in the digestive system. Among C-type lectin gene superfamily, the Reg-related genes are classified in group VII and encode small secreted proteins with a single carbohydrate recognition domain linked to a short N-terminal peptide (Drickamer 1999; Zhang et al. 2003a). The genes coding these proteins are tandemly clustered on chromosome 2p12 in humans and may have arisen from the same ancestral gene by gene duplication. The expression of this group of proteins is controlled by complex mechanisms, some members being constitutively expressed in certain tissues while, in others, they require activation by several factors. These members have several apparently unrelated biological effects, depending on the member studied and the target cell. insoluble fibrils at physiological pH (Iovanna and Dagorn 2005).

39.2 Regenerating (*Reg*) Gene Products

Reg and Reg-related genes constitute a multigene family, the Reg family. Identified members of the human *Reg* gene family include Reg Iα, Reg Iβ, Reg IIIα (HIP/PAP), Reg IIIβ and Reg IV (Chakraborty et al. 1995; Dieckgraefe et al. 2002; Hartupee et al. 2001; Lasserre et al. 1994; Laurine et al. 2005). A glycoprotein expressed in exocrine pancreas (where it has been called PSP/LIT) and endocrine pancreas (where it has been called the Reg protein) is encoded by *Reg* gene which maps to 2p12. The *Reg* gene characterized in the exocrine pancreas has been found to be expressed in regenerating islets of 90% depancreatized rats and not in normal islets. In humans, it was identified only in the exocrine pancreas. The Reg gene is known to be involved in the growth of not only pancreatic β-cells, but also epithelial cells of the GI tract and carcinoma of its lineage. The expression of the REG gene is closely related to the infiltrating property of gastric carcinoma, and may be a prognostic indicator of differentiated adenocarcinoma of the stomach (Rosty et al. 2002; Yonemura et al. 2003).

Reg gene, first isolated from a rat regenerating islet cDNA library, (Terazono et al. 1988) and Reg-related genes constitute a multigene family (Reg Family), which consists of four subtypes (type I, II, III, and IV) based on the primary structures of the encoded proteins (Watanabe et al. 1994) that ameliorates the diabetes of 90% depancreatized rats and non-obese diabetic mice. The Reg protein family consists solely of a M_r 16-kDa CTLD and N-terminal secretion signal. Despite having a canonical C-type lectin fold, Reg proteins lack conserved sequences that support Ca^{2+}-dependent carbohydrate binding in other C-type lectins (Drickamer 1999). The human REG family genes have a common gene structure with 6 exons and 5 introns, and encode homologous 158–175-aa secretory proteins. The human REG family genes on chromosome 2, except for REG IV on chromosome 1, were mapped to a contiguous 140 kb region of the human chromosome 2p12. The gene order from centromere to telomere was 5′ HIP/PAP-III′-5′ RS 3′-3′ REG Iα 5′-5′ REG Iβ 3′-3′ REG-III 5′. The human REG gene family is constituted from an ancestor gene by gene duplication and forms a gene cluster on the region (Nata et al. 2004). Okamoto grouped the members of the family, Reg and Reg-related genes from human, rat and mouse, into three subclasses, types I, II, and III (Okamoto 1999). Stephanova et al. determined that the three rat PAP genes and the related Reg gene (REGL, regenerating islet-derived-like/pancreatic stone protein-like/pancreatic thread protein-like) were all located at 4q33–q34 (Stephanova et al. 1996). The mouse Reg family genes were mapped to a contiguous 75 kb region in chromosome 6, including Reg I, Reg II, Reg IIIα, Reg IIIβ, Reg IIIγ, and Reg IIIδ (Abe et al. 2000). Reg IIIδ was expressed predominantly in exocrine pancreas, whereas both Reg I and Reg II

[c]Accession NP_080604

were expressed in hyperplastic islets and Reg IIIα, Reg IIIβ and Reg IIIγ were expressed strongly in the intestinal tract and weakly in pancreas (Table 39.1).

Although Reg IV was not found in the same chromosome as other members of human Reg gene and Reg-related gene (Table 39.1), it shared some common features with other members such as: sequence homology, tissue expression profiles, and exon-intron junction genomic organization (Hartupee et al. 2001). Several Reg III proteins are highly expressed in the pancreas and small intestine, including mouse Reg-IIIγ and human HIP/PAP (hepatointestinal pancreatic/pancreatitis associated protein) (Cash et al. 2006a; Christa et al. 1996) and in the pancreas and GI tract in pathological conditions (Iovanna et al. 1991; Okamoto 1999; Abe et al. 2000). Pancreatitis-associated protein (PAP)-I and -II are members of Reg-III subclass and encoded by gene PAP-I and PAP-II, respectively. PAP-I is also known as peptide 23 in the rat, and regenerating (Reg) islet-derived Reg-IIIβ in mouse, and PAP-II known as Reg-III in the rat and Reg-III-α in the mouse (Narushima et al. 1997). Thus, four types of Reg gene family have been identified. Among these, a total of 17 members have been discovered in mammals across human, pig, mouse, bovine and rat species. Table 39.1 lists some important members of Reg family (Schiesser et al. 2001; Zenilman et al. 1996). Hartupee et al. also suggested that a mouse homologue of Reg IV likely existed (Hartupee et al. 2001) and substantiated (Bishnupuri et al. 2010). While rat Reg cDNA had a single open reading frame that encoded a 165-amino acid protein with a 21-amino acid signal peptide, the human REG cDNA encoded a 166-amino acid protein with a 22-amino acid signal peptide and showed 68% homology to that of rat Reg protein. While some members of the family (Reg 1 and islet neogenesis-associated protein, i.e. INGAP) have been implicated in β-cell replication and/or neogenesis, the roles of the other members have yet to be characterized (Planas et al. 2006).

39.3 Reg 1

39.3.1 Tissue Expression

Reports suggest that the expression of Reg mRNAs and of the corresponding protein(s) was restricted to exocrine tissue irrespective of age, sex, and presence of insulitis and/or diabetes. Moreover, Reg remains localized in acinar cells in the two opposite situations of (a) cyclophosphamide-treated males in a prediabetic stage presenting a high level of both insulin and Reg mRNAs, and (b) the overtly diabetic females with no insulin but a high level of Reg mRNA (Sanchez et al. 2000). The Reg gene was more significantly increased in female mice than in male mice, and in both cases, the expression was not influenced by age. Nondiabetic female mice had a significantly higher expression of the gene than diabetic female mice. Overexpression of the Reg

gene was found in male mice treated with cyclophosphamide, an agent known to be a potent inducer of diabetes in male non-obese diabetic (NOD) mice (Baeza et al. 1997; Baeza et al. 2001). Bimmler et al. (2004) supported the concept that PSP/Reg and PAP are coordinately regulated secretory stress proteins (SSP). The cystic fibrosis (CF) mouse pancreas had constitutively elevated expression of the Reg/PAP cell stress genes, which are suggested to be involved in protection or recovery from pancreatic injury. The severity of caerulein-induced pancreatitis was not ameliorated in the CF mouse even though the Reg/PAP stress genes were already highly upregulated. While Reg/PAP may be protective they may also have a negative effect during pancreatitis due to their anti-apoptotic activity, which has been shown to increase the severity of pancreatitis (Norkina et al. 2006).

The two nonallelic Reg genes and the two insulin genes are expressed differentially during early embryogenesis. The differential expression of Reg-I and -II suggests that they may be induced by different and independent stimuli and have distinct functions (Perfetti et al. 1996). Correlation between Reg and insulin gene expression does not exist in the fetal pancreas during the developmental period but, on the contrary, such a correlation was present in the adult pancreas (Moriscot et al. 1996). Scattered distribution of Reg protein is observed in pancreatic islet cells of streptozotocin (STZ)-treated rats. The increased Reg gene expression in neonatal STZ-treated rat pancreas is a useful model for studying the relationship between Type II (Non-Insulin Dependent) Diabetes (NIDDM) and β cell Regeneration or Reg gene protein.

39.3.2 Gastric Mucosal Cells

Reg mRNA and its product are distributed in the basal part of the oxyntic mucosa and expressed mainly in enterochromaffin-like (ECL) cells. Levels of both Reg mRNA and its product are markedly increased during the healing process of water immersion-induced gastric lesions (Asahara et al. 1996). Although Reg protein is reported to have a trophic effect on gastric epithelial cells, its involvement in human gastric diseases was studied by Fukui et al. (2003). Both gastrin and gastric mucosal inflammation enhance Reg gene expression in the fundic mucosa in rats. The Reg gene is associated with hypergastrinemia and fundic mucosal inflammation and may be involved in *H. pylori*-induced gastritis. The expression of Reg I is controlled through separate promoter elements by gastrin and *Helicobacter* (Bernard-Perrone et al. 1999; Steele et al. 2007). A link between Reg protein and *H. pylori* infection may help explain the molecular mechanisms underlying *H. pylori*-associated diseases, including gastric cancer (Yoshino et al. 2005). During the healing course of gastric erosion, Reg expression is highly increased in ECL cells surrounding the ulcer crater, suggesting its role as a regulator of gastric mucosal regeneration. During healing, the gene expression of several proinflammatory cytokines and Reg was markedly augmented. Among the proinflammatory cytokines, CINC-2 β is the only cytokine in which augmented expression preceded the increase of Reg gene expression. CINC-2 β, expressed in damaged gastric mucosa, stimulates the production of Reg protein in ECL cells via CXCR-2 and may be involved in the accelerated healing of injured gastric mucosa (Kazumori et al. 2000; Fukuhara et al. 2010). REG expression has been observed in various tumors including gastric carcinoma (Dhar et al. 2004; Miyaoka et al. 2004). Gastrin regulates Reg mRNA abundance in human corpus. Mutations of Reg that prevent secretion are associated with ECL cell carcinoids, suggesting a function as an autocrine or paracrine tumor suppressor (Higham et al. 1999).

39.3.3 Ectopic Expression

Ectopic expression of the *Reg* gene occurs in some human colonic and rectal tumors, suggesting that enhanced Reg expression may be related to the proliferative state of tumor cells. Regenerating protein may act not only as a regulator of gastric epithelial cell proliferation but also as a modifier of other multiple physiologic functions (Kazumori et al. 2002). Reg-1 protein is expressed in human hearts obtained from autopsied patients who died of myocardial infarction. In view of emerging evidence of Reg for tissue regeneration in a variety of tissues/organs, it is proposed that the damaged heart may be a target for Reg action and that Reg may protect against acute heart stress (Kiji et al. 2005). While hepatocyte and cholangiocyte proliferation was suppressed, hepatic stem cells and/or hepatic progenitor cells were activated. Reg I was significantly upregulated in liver of the 2-AAF/PH rat model, accompanied by the formation of bile ductules during liver regeneration. The presence of Reg I in normal testis is weak. But its strong expression in the testis cancer suggests its potential role in normal and neoplastic germ cell proliferation (Mauro et al. 2008). Reg I may act through IL-6 to exert effects on squamous esophageal cancer cell biology. Transfecting TE-5 and TE-9 cells with Reg Iα and -Iβ led to significantly increased expression of IL-6 mRNA and protein, but with little or no effect on expression of IL-2, IL-4, IL-5, IL-10, IL-12, IL-13, IL-17A, IFN-γ, TNF-α, GC- or TGF-β1. The elevated IL-6 expression in REG Iα transfectants was silenced by siRNA-mediated knockdown (Usami et al. 2010).

Ectopic expression of Reg also was observed in ductal cell carcinomas. In ductal cell carcinomas, expression of Reg immunoreactivity was considered as one of phenotypic heterogeneity, as seen in AAT, lysozyme, and CMG immunoreactivity (Kimura et al. 1992). The diminution in pancreatic β-cell mass caused by subcutaneous implantation of an insulinoma is associated with reduced Reg gene expression and that the increase in β-cell replication after resection of the tumor is preceded by return of Reg gene expression toward normal. *Reg I* expression in untreated endoscopic biopsy specimens may provide a basis for new treatments of locally advanced thoracic squamous cell esophageal cancers (Motoyama et al. 2006). *Reg I*-knockout mice reveal the role of Reg-1 in the regulation of cell growth that is required in generation and maintenance of the villous structure of small intestine (Ose et al. 2007). Reg I appears to enhance the chemo- and radiosensitivity of squamous esophageal cancer cells, which suggests that it may be a useful target for improved and more individualized treatments for patients with esophageal squamous cell carcinoma (Hayashi et al. 2008).

39.3.4 Reg Protein

Unno et al. (1993) isolated two mouse distinct cDNAs and genes, one of which was a mouse homologue to rat and human Reg gene, the other a novel type of Reg gene. They were designated Reg I and Reg II, respectively. The two proteins encoded by these genes share 76% amino acid sequence identity with each other. Both genes span about 3 kbp, and the genomic organization of six exons and five introns is conserved between them. Chromosomal mapping studies indicated that the Reg I gene is localized on mouse chromosome 12, whereas the Reg II gene is localized on chromosome 3. Both Reg I and Reg II mRNAs are detected in the normal pancreas and hyperplastic islets of aurothioglucose-treated mice, but not in the normal islets. It is remarkable that in the gallbladder Reg I is expressed, but Reg II is not (Unno et al. 1993).

Moriizumi et al. (1994) isolated a novel human gene and cDNA encoding a member of the Reg I proteins, Reg Iβ. The gene encodes a 166-amino acid protein which has 22 amino acid substitutions in comparison with previously isolated human Reg protein, Reg Iα. While Reg Iβ was expressed only in pancreas, RegI α was expressed in kidney and stomach as well as in pancreas. The human REG gene has a high degree of similarity to the rat Reg gene. A REG-related sequence (REGL) is also located in 2p12 and expressed in the pancreas and physically mapped within a 100-kb genomic region (Bartoli et al. 1995; Perfetti et al. 1994). Reg may be involved in the expansion of β-cell mass during regeneration as well as in the maintenance of normal β-cell function. Sequence comparisons of Reg and Reg 1 suggested similar exon-intron organisation. The proteins encoded by Reg and Reg 1 comprise 166 amino acids and differ by 22 amino acids only (Bartoli et al. 1995). The 5′-Regulatory region −304/−237 of rat *Reg I* gene encoding a growth stimulating factor for pancreatic β-cells contained positive cis-acting elements. Gel shift assays showed the formation of a specific complex with the −256/−237 oligonucleotide (Miyashita et al. 1995).

39.3.5 *REGIA (Reg Iα)* Gene in Human Pancreas

[Synonym names for Reg1A protein are: pancreatic stone protein; pancreatic thread protein; Islet of Langerhans regenerating protein; regenerating protein I α; Islet cells regeneration factor; ICRF; regenerating islet-derived 1 α].

In human, four REG family genes, i.e., REG 1α, Reg Iβ, REG-related sequence (RS) and HIP/PAP, have been isolated and characterized but only Reg Iα protein has been isolated from human pancreatic secretion. A discoordinate expression of the two *REG* genes was found with a higher level of Reg Iα mRNA in fetus and a higher level of Reg Iβ in adult. In addition, while Reg Iα mRNA level was correlated with the expression of genes encoding exocrine proteins in adults, Reg Iβ mRNA level presented no correlation with any ductular, endocrine, or exocrine gene expression. In human pancreatic cell lines only Reg Iβ gene and protein expressed. These results suggest that two Reg genes and proteins play different roles in human pancreas (Sanchez et al. 2001). Reg Iα is a growth factor known to affect pancreatic islet β cells. Since tropical calcific pancreatitis (TCP) is known to have a variable genetic basis, reports do not suggest the interaction between mutations in the susceptibility genes: serine protease inhibitor Kazal 1 (*SPINK1*) and *CTSB* (a gene for cathepsin B) with REG 1α polymorphisms (Mahurkar et al. 2007).

Function of REGIA (Reg Iα) in Pancreas: Acinar cells can transdifferentiate into other pancreatic-derived cells. In these cells, Reg I overexpression is linked to acinar cell differentiation, whereas inhibition of Reg I leads to β cell and possibly ductal phenotype. Human and rat Reg I proteins, and recombinant protein are mitogenic to primary cultures of β- and ductal cells. Reg I expression in acinar cells is important in maintaining pancreatic cell lineage, and when decreased, cells can dedifferentiate and move toward becoming other pancreatic cells (Sanchez et al. 2004, 2009). Pancreatic-derived cells exposed to Reg I grow by activation of signal transduction pathways involving the mitogen-activated protein kinase phosphatases and cyclins, with concomitant induction of mitogen-activated protein kinase phosphatase (MKP-1). However, high intracellular levels of Reg I lead to decreased growth, likely via a binding to

and inactivation of MKP-1. Inhibition of cell growth, and possible induction of apoptosis, may lead to differentiation of these cells to other cell types (Mueller et al. 2008; Zenilman et al. 1998; Levine et al. 2000). Induction of Reg I and its receptor may be important for recovery from acute pancreatitis (Bluth et al. 2006)

The administration of Reg protein can be used as a therapeutic approach for diabetes mellitus (Watanabe et al. 1994), although the serum Reg protein level is not a marker for progression of type I diabetes (Christofilis et al. 1999). Infact, Pdx1-Cre-mediated pancreas inactivation of IGF-I gene [in pancreatic-specific IGF-I gene-deficient (PID) mice] results in increased β-cell mass and significant protection against both type 1 and type 2 diabetes, where multiple Reg family genes (*Reg-2, -3α,* and *-3β*,) were significantly upregulated in pancreas. Interestingly, Reg family genes were also activated after streptozotocin-induced β-cell damage and diabetes (wild-type T1D mice) when islet cells were undergoing regeneration and Reg proteins increased in exocrine as well as endocrine pancreas, suggesting their potential role in β-cell neogenesis in PID or T1D mice. Reg proteins (Reg 1 and islet neogenesis-associated protein) were also shown to promote islet cell replication and neogenesis (Lu et al. 2006). The administration of poly (ADP-ribose) synthetase/polymerase (PARP) inhibitors such as nicotinamide to 90% depancreatized rats induces islet regeneration. Reg protein induces β-cell replication via the Reg receptor and ameliorates experimental diabetes. Studies suggest that poly(ADP-ribose) polymerase binds Reg promoter and regulates the transcription by autopoly (ADP-ribosyl)ation (Akiyama et al. 2001). Depletion of Reg I, associated with the pathogenesis of impaired glucose tolerance of pancreatitis-associated diabetes, Bluth et al. (2008) support that replacement therapy could be useful in such patients.

REG Iα gene expression and its promoter activity were enhanced by IFN-γ and IL-6. Reg Iα protein promoted cell growth and cell resistance to H_2O_2-induced apoptosis in AGS cells. REG Iα gene is inducible by cytokine stimulation and its gene product may function as a mitogenic and/or an antiapoptotic factor in the development of early gastric cancer (Sekikawa et al. 2005). The IL-6-responsive element was located within the sequence from −142 to −134 of the REG Iα promoter region. Reg Iα protein mediated the antiapoptotic effects of STAT3 signaling in gastric cancer cells by enhancing Akt activation, Bad phosphorylation and Bcl-xL expression. The expression of Reg Iα protein was significantly correlated with that of p-STAT3 in gastric cancer tissues. It appeared that Reg Iα protein plays a pivotal role in anti-apoptosis in gastric tumorigenesis under STAT3 activation (Sekikawa et al. 2008). The enhanced expression of IL-22 in infiltrating inflammatory cells and concommitant enhancement of Reg Iα in the inflamed epithelium indicated the role of IL-22/REG Iα axis in ulcerative colitis (UC). The IL-22-responsive element was located between −142 and −134 in the REG Iα promoter region. REG Iα protein may have a pathophysiological role as a biological mediator for immune cell-derived IL-22 in the UC mucosa (Sekikawa et al. 2010).

Role in Pathology: PAP and Reg Iα are up-regulated during the pancreas regeneration. The PAP expression represents a subset of low-grade, low-stage human hepatocellular carcinomas (HCC) with frequent β-catenin mutation and hence more favorable prognosis, whereas further genetic or epigenetic alterations, such as p53 mutation and Reg 1α expression, lead to more advanced HCCs (Yuan et al. 2005). Three genes encoding related proteins, PAP, Reg Iα and Reg Iβ, are over-expressed in cancer (Rechreche et al. 1999). Human Reg I protein is ectopically expressed in colorectal mucosa at the transition zone of colorectal cancer, and occasionally within the tumor itself. Although ectopic Reg I expression in colorectal epithelia is not a marker for the presence of carcinoma, it may be a sensitive marker for mucosa at risk for development of neoplasia (Zenilman et al. 1997). High levels of REG 1α expression within tumors are an independent predictor of poor prognosis in patients with breast cancer (Sasaki et al. 2008). Reg 1A is a molecular marker of prognostic value and is associated with peritoneal carcinomatosis in colorectal cancer (Astrosini et al. 2008). High levels of REG 1A expression by tumor cells are an independent predictor of a poor prognosis in patients with NSCLC (Minamiya et al. 2008). Stage Ta/T1 urothelial carcinoma of the bladder (Ta/T1 BC) has a marked tendency to reoccur. Expression of REG 1A is an independent predictor of recurrence in Ta/T1 BC (Geng et al. 2009). Reg Iα protein may play a role in the development of gastric cancers (Fukui et al. 2004).

Reg I-expressing cells are present in the bile ductules and increased during regeneration. Reg I is significantly upregulated in the liver of the 2-acetylaminofluorene-PH rat model, accompanied by the formation of bile ductules during liver regeneration (Wang et al. 2009). Reg Iα protein, which was rarely expressed in ductal epithelial cells of normal minor salivary gland (MSG), was overexpressed in patients with Sjögren's syndrome (SS). Reg Iα protein may play a role in the regeneration of ductal epithelial cells in the MSGs of patients with SS (Kimura et al. 2009). REG expresses in Barrett's esophagus. Expression of Reg Iα was more frequently observed in patients who showed squamous re-epithelialization of Barrett's esophagus at biopsy sites (Chinuki et al. 2008). Yamauchi et al. (2009) demonstrated that PPARγ-agonist thiazolidinediones (TZDs) inhibited cell proliferation and Reg Iα protein/mRNA expression in gastrointestinal cancer through a PPARγ-dependent pathway. TZDs may, therefore, be a candidate for novel anti-cancer

drugs for patients with gastrointestinal cancer expressing both REG Iα and PPARγ.

39.3.6 REGIB (Reg Iβ) Gene in Human Pancreas

Human REG Iβ gene encodes a protein secreted by the exocrine pancreas that is highly similar to the Reg1A (Reg 1α) protein. Human Reg I β, also known as secretory pancreatic stone protein 2 and lithostathine 1 β, is a type I subclass member of Reg family. The Reg 1β protein is associated with islet cell regeneration and diabetogenesis, and may be involved in pancreatic lithogenesis. Reg family members REG1A, REGL, PAP and this gene are tandemly clustered on chromosome 2p12 and may have arisen from the same ancestral gene by gene duplication.

Pancreatic juice in vertebrates contains a group of 16-kDa proteins which is composed of the protein species such as pancreatic stone protein (PSP). PSP is a 16-kDa acidic protein with an isoelectric point in the range of pH 5.5–6. A truncated form of this protein was originally isolated from calcium carbonate stones surgically removed from the main pancreatic duct of humans with chronic pancreatitis. PSP is a secretory protein that is related to C-type lectins.

39.4 Pancreatic Stone Protein/Lithostathine (PSP/LIT)

[Alternative names**:** Lithostathine-1-β*;* Regenerating islet-derived protein 1-β/Regenerating protein I β (REG-1β); Pancreatic stone protein 2 (PSP-2)]

39.4.1 Characterization

Reg protein was first found in pancreatic stones. It was named Pancreatic Stone Protein (PSP) and later renamed lithostathine (LIT), as it was assumed to prevent stone formation. The protein was found in regenerating endocrine pancreas and was named Reg (for Regenerating) protein. The functional human Reg gene is a single copy gene, spans approximately 3.0 kbp, and is composed of six exons and five introns. TATA box and CCAAT box-like sequences are located at 27 and 100 bp upstream from the transcriptional initiation site. The human Reg mRNA was detected predominantly in the pancreas, and at lower levels in the gastric mucosa and the kidney. Furthermore, the Reg gene was found to be expressed ectopically in colon and rectal tumors. Immunoblot analysis demonstrated several molecular forms (15–18 kDa) of the Reg protein in the pancreas. The 166-amino acid sequence encoded by the human Reg gene contains the 144-amino acid sequence of pancreatic stone protein determined by De Caro et al. (1989) and the partially determined 45-amino acid sequence of pancreatic thread protein (Gross et al. 1985), indicating that the Reg protein, pancreatic stone protein, and pancreatic thread protein are simply different names for a single protein deriving from the Reg gene (Watanabe et al. 1990). The 144 amino acid protein is O-glycosylated on Thr-5. The glycan chain is variable in length and in charge. The PSP/LIT 3-D structural organization is of the C-lectin type, even though CRD of PSP'LIT is unlikely to have any functional calcium-binding site. However, the PSP/LIT binds Ca^{2+} with 1:1 stoichiometry (Lee et al. 2003). EPR studies, using divalent vanadyl (VO^{2+}) ion as a paramagnetic substitute for Ca^{2+} also showed that VO^{2+} binds to PSP/LIT with a metal:protein binding stoichiometry of 1:1 and that VO^{2+} competes with Ca^{2+} in binding to PSP/LIT. Mutations of a cluster of acidic residues on the molecular surface resulted in almost complete loss (95–100%) of binding of Ca^{2+} and VO^{2+}, showing that these residues are critical for calcium binding by PSP/LIT (Lee et al. 2003). The Arg^{11}-Ile^{12} bond is readily cleaved by trypsin and the resulting C-terminal polypeptide precipitates at physiological pH and tends to form fibrils.

The rat PSP/LIT gene was characterized over 2.7 kbp of gene sequence and 2.43 kbp of 5′-flanking sequence. The lithosathine sequence spanned over six exons. The promoter region contained the TATAAA and CCAAT consensus sequences 30 and 107 bp upstream of the cap site, respectively. Furthermore, a tract of (TG)22 repeat, with potential Z-DNA conformation, was found at position-1081 (Dusetti et al. 1993). The rat cDNA encoding a protein homologous to Reg encodes a protein, designated Reg-2 and shows 60%, 78% and 61% similarities with the reported amino acid sequences of the rat, bovine and human proteins, respectively (Kamimura et al. 1992). Using in situ hybridization, the three rat PAP, and the related REG genes mappped in the same chromosomes region, namely 4q33—>q39. This rat chromosome region is thus homologous to the human 2p12 region, which also contains the PAP gene, the REG1A gene, and a REG-related gene (REGL) suggesting the tandem organization of Reg/lithostathin genes (Gharib et al. 1993; Stephanova et al. 1996).

Reg-I (PSP) and Reg-III (PAP) are induced after the onset of acute pancreatitis, and both have been proposed as potential markers of pancreatitis. After induction of pancreatitis, serum levels of Reg I and III protein differ significantly. PSP/Reg is up-regulated in blood after trauma and its level is related to the severity of inflammation. The serum PSP/Reg-protein concentration may reflect pancreatic damage, especially in acute pancreatitis, and may be a sensitive a marker for such damage as elastase-1, although false positivity was apparent inrenal failure and in some patients with hepatic

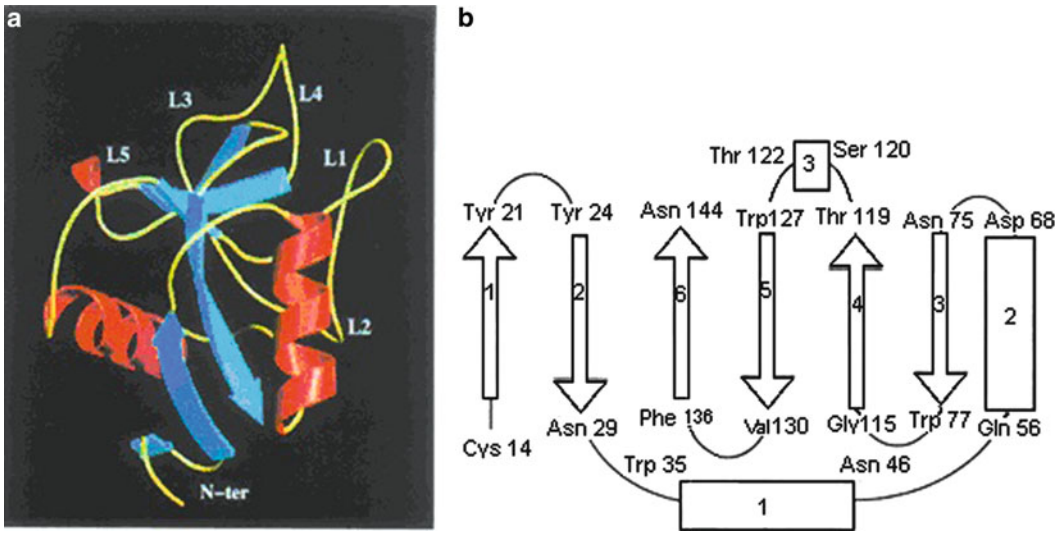

Fig. 39.1 Structure of hPSP/hLIT. The protein folds into one globular domain that consists of three α helices (*Boxed*) and six β-strands, the latter forming two antiparallel β-sheets (**a**). The sequential connectivity follows the scheme β1-β2-αl-α2-β3-β4-α3-β5-β6 (**b**). (**b**) shows schematic diagram of hLIT polypeptide topology. The β-strands are depicted as *arrows*, with the *arrowheads* indicating the direction of the chain. α-Helices are shown as *rectangles* (Reprinted by permission from Macmillan Publishers Ltd: EMBO J, Bertrand et al. © 1996)

dysfunction or digestive system malignancies (Satomura et al. 1995). Furthermore, PSP/Reg binds to and activates neutrophils. Therefore, PSP/Reg and Reg-III/PAP are acute-phase proteins that could serve as a marker for disease severity and posttraumatic complications (Keel et al. 2009; Zenilman et al. 2000). PSP/LIT/Reg mRNA was strongly induced by serum from rats with acute pancreatitis (SAP) in AR-42J cells. Treatment with interleukins (IL) IL-1 or IL-6 or dexamethasone alone was ineffective. Combination of IL-6 with dexamethasone resulted in strong induction of the PSP/LIT/Reg gene, but the further addition of IL-1 to the mixture reduced induction. Treatment with tumor TNFα or IFNγ induced PSP/LIT/Reg mRNA expression. Findings suggest that expression of the PSP/LIT/Reg mRNA during acute pancreatitis could be mediated by specific combinations of cytokines and/or glucocorticoids.

39.4.2 3D-Structure

Crystals of human PSP/LIT grown in PEG 4000 as the precipitating agent, belong to the hexagonal space group $P6_1$ (or its enantiomorph $P6_5$) and diffract to 1.55 A resolution. There is one molecule in the asymmetric unit and the crystals have 39% solvent (Pignol et al. 1995).

The C-terminal part of hPSP/hLIT is homologous with the animal C-type lectins showing the highest percentage of homology with the rat cartilage proteoglycan and the human IgE receptor (Petersen 1988). Amino acid similarities are distributed over regions corresponding to the consensus CRD and two of the three disulfide bridges in hPSP/hLIT are conserved in the C-type lectin sequence motif (Drickamer 1999). Studies on the three-dimensional structure of hPSP/hLIT confirmed that hPSP/hLIT belongs to the family of C-type lectins. Overall protein structure of hPSP/hLIT has the shape of a heart with dimensions 45 × 30 × 25 A (Fig. 39.1a) (Bertrand et al. 1996). The protein folds into one globular domain that consists of three α helices and six 5-strands, the latter forming two antiparallel β-sheets. The sequential connectivity follows the scheme β1-β2-αl-α2-β3-β4-α3-β5-β6 (Fig. 39.1b). The well-defined N-terminal residue of the structure participates in an intramolecular disulfide bond (Cysl4-Cys25) forming a loop. This loop contains a short β-strand (β1; residues 19–21) which forms an anti-parallel β1-sheet with strands β2 and β6. The two major helices αl and α2, of respectively three and four helical turns, are oriented perpendicular to one another framing the three β-strands (β1, β2 and β6) of the lower half of the molecule (Fig. 39.1a). The Cys42- Cys140 disulfide bridge connects αl to α6. The upper half of the molecule includes the other three β-strands (β3, β4 and β5). Two strands of this second antiparallel β-sheet, β4 and β5, are separated by a single helical turn (α3) and are connected at one extremity by the Cys 115-Cys 132 disulfide bridge. In addition to the secondary structure elements, the structure also contains several extended loops and stretches of non-regular secondary structure which represent >60% of the molecule.

39.4.3 Secretory Forms of PSP

Secretory forms of pancreatic stone protein (sPSP, Mr 17,500-22,000) have been purified from human pancreatic juice. Secretory forms of PSP are inhibitors of CaCO3 crystal

growth. Proteins homologous to human sPSP are present in other mammalian species and may act as stabilizers of Ca^{2+}-supersaturated pancreatic juice (Bernard et al. 1991). In mature pancreas, expression of Reg/sPSP gene occurs primarily in acinar cells. The gene product, which encodes a secretory protein inhibiting CaCO3 crystal growth in juice, is unlikely to play a specific role in islet regeneration (Rouquier et al. 1991). A cDNA encoding pre-sPSP revealed that it comprised all but the 5′ end of sPSP mRNA, which was obtained by sequencing the first exon of the sPSP gene. The complete mRNA sequence is 775 nt long, including 5′- and 3′-noncoding regions of 80 and 197 nucleotides, respectively, attached to a poly(A) tail of approximately 125 nt. It encodes a preprotein of 166 amino acids, including a prepeptide of 22 amino acids. PSP-S gene expression is specifically reduced in chronic calcifying pancreatitis (CCP) patients (Giorgi et al. 1989). Ovocleidin 17, a major protein of the chicken eggshell calcified layer shows a C-type lectin domain with a sequence similariy of 30% to that of PSP and lectins and anticoagulant proteins from snake venom (Mann and Siedler 1999).

Serum PSP showed an isoelectric point (pH 9) similar to that reported for the pancreatic thread protein. Schmiegel et al. (1990) did not support the etiopathogenic role postulated for pancreatic stone protein in chronic pancreatitis and chronic calcifying pancreatitis by other investigators. The PSP in human calculi derives from human pancreatic juice (PSP S2-5) through the tryptic cleavage of the Arg-^{11}-Ile-^{12} bond (De Caro et al. 1989; Rouimi et al. 1987). EM studies revealed that the stone protein was markedly present in the zymogen granules and condensing vacuoles of the normal pancreatic acinar cells, the label was found in the acinar and ductal lumen. In chronic pancreatitis, the localization of PSP/LIT, when it occurred, was extremely weak in the acinar cells. No PSP/LIT was specifically characterized in hepatocytes, gastric mucosa, and enterocytes. However, a weak but specific reaction was found in the secretory granules of Paneth cells (Lechene de la Porte et al. 1986).

De Reggi et al. (1995) isolated the major oligosaccharide chains of human pancreatic PSP/LIT and determined their sequences by means of NMR. There were 11 different glycoforms and seven of them were sequenced. They all were from the same site of glycosylation (Thr5) and displayed the same core 2 structure: GlcNAc(β 1–6)[Gal(β 1–3)]GalNAc α-. They ranged in size from 4 to 9 sugar residues. Elongation was found to proceed from a common tetrasaccharidic core: Gal(β 1–4)GlcNAc(β 1–6)[Gal(β 1–3)]GalNAc-ol through N-acetyllactosamine units. The non-reducing ends of some oligosaccharides carry the antigenic determinant H, with presence of external Fuc linked only in (α 1–2) to Gal. All the glycans, except one, carry a sialic acid in (α 2–3) linkage to Gal, with one disialylated form which displays a supplementary (α 2–6) linkage. These findings are consistent with the polymorphism of the protein, either in its native form or after enzymic processing.

39.4.4 Functions of PSP/LIT

39.4.4.1 As Inhibitor of Crystal Growth

Calcium carbonate crystals are observed in the juice of patients suffering with chronic calcifying pancreatitis (CCP), a lithogenic disorder characterized by the presence of stones, which obstruct pancreatic ducts and remain scarce or absent in juice from healthy individuals (De Caro et al. 1988). Several lines of evidence indicate that the inhibition of calcium carbonate crystal nucleation and growth in human pancreatic juice is exerted by human lithostathine (hPSP/hLIT); patients suffering from CCP have an abnormally low concentration of hPSP/hLIT (Bernard et al. 1995). The hPSP/hLIT binds to the surface of calcium carbonate crystals, and provides inhibitory effects (Bernard et al. 1992). Inhibitory effects of hPSP/hLIT can be seen with the entire protein, which shows an activity 100-fold greater (Geider et al. 1996; Gerbaud et al. 2000) than that of 11-residue N-terminal peptide obtained after cleavage with trypsin (Bernard et al. 1992). Consequently, it is likely that both the N-terminal peptide and the C-terminal domain bind to calcium carbonate crystals; a conclusion reinforced by the fact that C-terminal proteolytic fragment (residues 12–144) is a major component of pancreatic stones (De Caro et al. 1988).

As pancreatic juice is supersaturated with respect to calcium carbonate, it was hypothesized that PSP/LIT stabilizes pancreatic juice and calcite precipitation is prevented by PSP/LIT; the decreased PSP levels could be a key factor in the growth of calcium carbonate crystals and stone development during the course of chronic calcifying pancreatitis (CCP) (Multigner et al. 1985). The secretary PSP (sPSP) could play that role, since an activity inhibiting the nucleation and growth in vitro of CaCO3 crystals was found in pancreatic juice, associated with these proteins. Moreover, sPSP concentration was significantly lower in the pancreatic juice of patients with CCP than in control patients. While aiming at discovering how peptides inhibit calcium salt crystal growth, Gerbaud et al. (2000) showed that the peptide backbone governed the binding more than did the lateral chains. The ability of peptides to inhibit crystal growth is essentially based on backbone flexibility. Proteins homologous to sPSP were also found in the dog, rat, swine, monkey and ox. They constitute a new family of pancreatic secretory proteins, whose biological role would be to maintain pancreatic juice in a stable state towards CaCO3 (De Caro et al. 1988).

The inhibition property of crystal nucleation and growth property of hPSP/hLIT is shared by antifreeze proteins (AFPs) in fish. The AFPs are synthesized and secreted in the liver of marine fishes to provide protection from freezing environments and are classified into three groups (Davies and Hew 1990); type I (helical peptides, M_r 3–5 K), type II (cysteine-rich, M_r 14 K), and type III (predominantly

β-sheet, M_r 6–7 K). The type II AFPs are homologous to hPSP/hLIT, showing sequence similarities distributed over both the N- and C-terminal domains (Ewart et al. 1992; Ng and Hew 1992). PSP/LIT is cleaved by trace amounts of trypsin, resulting in a C-terminal polypeptide and an N-terminal undecapeptide. The N-terminal undecapeptide has been identified as the active site of PSP/LIT regarding crystal inhibition. Thus, it has been assumed to inhibit calcium carbonate precipitation and therefore to prevent stone formation in the pancreatic ducts. This function is, however, debatable (Bimmler et al. 1997) since most of these studies have been carried out in vitro. De Reggi (1998) showed conclusively that PSP/LIT does not inhibit calcium carbonate nucleation and crystal growth. Based on the findings it seemed unlikely that PSP/LIT is a physiologically relevant calcite crystal inhibitor (De Reggi et al. 1998).

39.4.4.2 Role in Regeneration of Islets

For several years it was believed that PSP served as an inhibitor of calcium carbonate precipitation in pancreatic juice, and it was proposed that its name should be changed to "lithostathine" (LIT) (Sarles et al. 1990). However, it was later shown that PSP has no more crystal inhibitory activity than several of the pancreatic digestive enzymes (Bimmler et al. 1997; De Reggi et al. 1998). Studies demonstrated that the expression of PSP/LIT protein is increased during regeneration of islets after nicotinamide treatment and partial pancreatectomy (Terazono et al. 1990; Unno et al. 1993). These observations led to suggest that PSP/LIT may be a protein involved in regeneration (Watanabe et al. 1994) and may act as a growth mediator stimulating the proliferation of β-cells. Tissue culture studies implied a mitogenic activity of PSP/LIT on the growth of various cell types (Zenilman et al. 1996; Fukui et al. 1998), and application of PSP/LIT was observed to partially ameliorate diabetes in NOD mice (Gross et al. 1998; Kobayashi et al. 2000). PSP/LIT is a bifunctional protein which might be involved in the control of the bacterial ecosystem in the intestine. PSP/LIT is not expected to present sugar- or calcium-binding properties (Patard et al. 1996).

39.4.4.3 PSP/LIT in Alzheimer's Disease

PSP/LIT is a found precipitated in the form of fibrils in Alzheimer's disease (AD). Recombinant PSP/LIT is essentially monomeric at acidic pH while it aggregates at physiological pH. Electron microscopic studies of aggregates showed an apparently unorganized structure of numerous monomers which tend to precipitate forming regular unbranched fibrils. Aggregated forms seemed to occur prior to the apparition of fibrils. In addition, these fibrils resulted from a proteolytic mechanism due to a specific cleavage of the Arg^{11}-Ile^{12} peptide bond. It is deduced that the NH_2-terminal undecapeptide of PSP/LIT normally impedes fiber formation but not aggregation. A theoretical model explaining the formation of amyloid plaques in neurodegenerative diseases or stones in lithiasis starting from PSP/LIT has been described (Cerini et al. 1999). PSP/LIT and PAP were significantly increased in the cerebrospinal fluid of patients with AD at the very early stages of AD, and their level remained elevated during the course of the AD. Because PSP/LIT undergoes an autolytic cleavage leading to its precipitation and the formation of fibrils, it is likely that it may be involved in amyloidosis and tangles by allowing heterogeneous precipitation of other proteins (Duplan et al. 2001).

Symptoms of pancreaticobiliary maljunction/choledochal cysts are caused by the obstruction of bile and pancreatic ducts due to protein plugs compacted in the common channel. PSP is reported to be a key protein to form protein plugs in chronic pancreatitis (Chen et al. 2005; Ochiai et al. 2004). PSP expression is not increased because of a protein-deficient diet. After a temporary increase in PSP levels due to a carbohydrate-deficient high-protein diet, there were no signs of a diet-dependent regulation of this protein, which may differ from that of other pancreatic secretory proteins. These findings contradict earlier reports that had drawn conclusions based solely on mRNA levels (Bimmler et al. 1999). Both chronic ethanol consumption and dietary protein deficiency increase the capacity of the pancreatic acinar cell to synthesize PSP/LIT (Apte et al. 1996). Alternatively, activated trypsin cleaves soluble PSP and creates insoluble PSP.

39.5 Pancreatic Thread Protein

39.5.1 Pancreatic Thread Proteins (PTPs)

PTPs are acinar cell products and members of the regenerating gene (Reg) family. PTP/Reg protein was mitogenic to both β-cell and ductal cell lines but not to mature, nondividing islets. This supports the hypothesis that PTP/Reg protein is mediator of β-cell growth and may be involved in modulating the duct-to-islet axis (Zenilman et al. 1996). PTP forms double helical threads in the neutral pH range after purification, undergoing freely reversible, pH-dependent globule-fibril transformation. PTP forms filamentous bundles reminiscent of the paired helical filaments of Alzheimer's disease in vitro. A major 0.9-kb as well as several minor transcripts of PTP have been identified in human pancreas. An excess of serum PTP may filter to CSF through blood brain barrier (Blennow et al. 1995). There were significantly higher levels of PTP mRNA in brains with AD compared with aged controls, with increased amounts of 1.2-, 0.6-, and 0.4-kb transcripts (de la Monte et al. 1990; Ozturk et al. 1989). The experimentally derived

secondary structure of human PTP (HPTP) consists of a significant proportion of β-sheets and β-turns and lesser amounts of α-helical structures. The β-sheet component presumably plays an important role in the pH-dependent globule-fibril transformation of HPTP leading to antiparallel β-sheet structure in the aggregated state. The secondary structure of HPTP and its globule-fibril transformation lend credence to the belief that AD may be viewed as a conformational disease (Renugopalakrishnan et al. 1999).

39.5.2 Neuronal Thread Proteins

Neuronal thread proteins (NTP) are phosphoproteins which are expressed during neuritic sprouting. The 15–18-kDa NTP cluster is associated with development and neuronal differentiation, whereas the 21-kDa and 39–42-kDa species are overexpressed in AD, correlating with neurodegenerative sprouting and synaptic disconnection. Both human and experimental (rat) focal cerebral infarcts revealed up-regulation of NTP gene expression in perifocal neurons (de la Monte et al. 1996a). In AD, high levels of NTP immunoreactivity were detected in neuronal perikarya, neuropil fibers, and white matter fibers (axons). NTP accumulates in cortical neurons and colocalizes with phospho-tau-immunoreactive cytoskeletal lesions that correlate with dementia. NTPs overexpression in relation to paired helical filament-associated neurodegenerative lesions in AD has been indicated (de la Monte et al. 1997). In view of the rapid phosphorylation, the accumulation of NTP in AD cortical neuronal perikarya suggests a problem related to post-translational processing and transport of NTP molecules in AD neurodegeneration (de la Monte et al. 1996b). Primary human primitive neuroectodermal tumor (PNETs), malignant astrocytomas, and several human PNET and glioblastoma cell lines also express thread protein immunoreactivity. However, in addition to the 21-kDa species, there are ~8, 17 and ~14-kDa thread protein-immunoreactive molecules expressed in both PNET and glioblastoma cell lines. Glycosylated residues were not detected in either the PNET- or glioblastoma-derived thread proteins. Studies suggest that there are several distinct neuronal and glial derived thread proteins expressed in the central nervous system and that their levels of expression may be modulated with cell growth (Xu et al. 1993).

Insulin, insulin-like growth factor, type 1 (IGF-1), and nerve growth factor modulate NTP gene expression during neuronal differentiation in PNET cell lines. Insulin effected neuronal differentiation and modulation of NTP gene expression in PNET cells utilizes a signal transduction cascade that requires tyrosyl phosphorylation of IRS-1 (Xu et al. 1995b). Ethanol may inhibit NTP expression associated with CNS neuronal differentiation by uncoupling the IRS-1-mediated insulin signal transduction pathway (Xu et al. 1995a). Studies indicate a functional role for NTP in relation to the turnover or processing of neuronal cytoskeletal proteins, attributes that may be modulated by insulin/IGF-1-mediated signaling (de la Monte et al. 2003). Further studies suggest that reduced survival in neurons that over-express AD7c-NTP may be mediated by impaired insulin/IGF-1 (de la Monte and Wands 2004). Brains with AD, AD + Parkinson's disease (PD), and AD + Down's syndrome (DN) contain significantly higher densities of NTP immunoreactive neurons and more frequent immunostaining of neuropil and white matter fibers compared with PD dementia (PDD) and aged controls which had few or no AD lesions.

39.5.3 Pancreatic Proteins Form Fibrillar Structures upon Tryptic Activation

Graf et al. (2001) studied the structural/functional consequences of trypsin activation on 16-kDa proteins with respect to the kinetics of conversion from soluble to insoluble protein forms and the kinetics of assembly of protein subunits into polymerized thread structures. Trypsin activation of recombinant stress proteins or counterparts (PSP/Reg, PAP-I and PAP-III) resulted in conversion of 16-kDa soluble proteins into 14-kDa soluble isoforms [called pancreatic thread protein and pancreatitis-associated thread protein (PATP), respectively] that rapidly polymerize into sedimenting structures. Activated thread proteins show long lived resistance to a wide spectrum of proteases contained in pancreatic juice, including serine proteases and metalloproteinases. In contrast, PAP-II, following activation with trypsin or pancreatic juice, did not form insoluble structures and was rapidly digested by pancreatic proteases. SEM and TEM demonstrated that activated thread proteins polymerized into highly organized fibrillar structures with helical configurations. Through bundling, branching, and extension processes, these fibrillar structures formed dense matrices that span large topological surfaces (Fig. 39.2) (Graf et al. 2001). Such studies suggested that PSP/Reg and PAP-I and III isoforms consist of a family of highly regulated soluble secretory stress proteins, which, upon trypsin activation, convert into a family of insoluble helical thread proteins. Dense extracellular matrices, composed of helical thread proteins organized into higher ordered matrix structures, may serve physiological functions within luminal compartments in the exocrine pancreas.

39.5.3.1 PSP/LIT in Alzheimer's Disease

The term 'cerebral proteopathies' has been proposed to designate all brain diseases the hallmarks of which are the misfolding and subsequent aggregation of proteins (Walker and LeVineH 2000). The most characteristic feature of many neuron-degenerative diseases is the formation of fibrillar

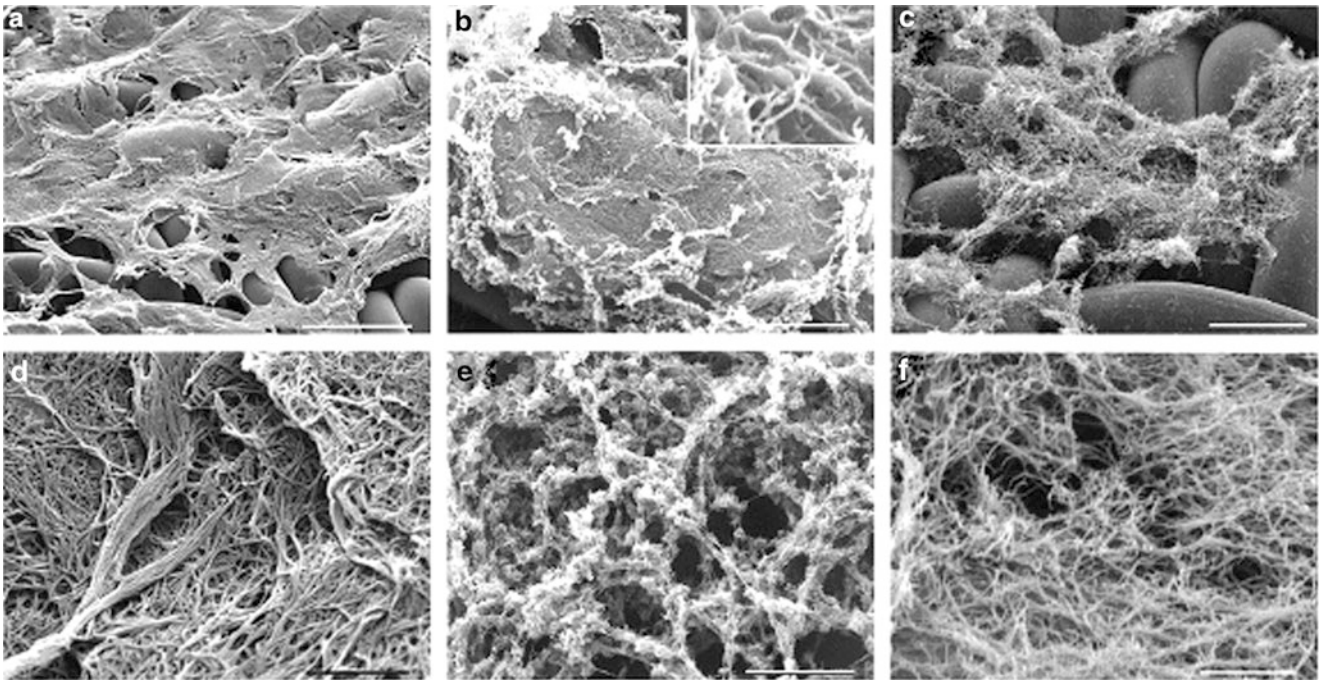

Fig. 39.2 Trypsin activation of purified recombinant secretory stress proteins generates a matrix of highly organized fibrils. Scanning electron microscopy of PTP and PATP generated in vitro. The micrographs demonstrate fibrous networks following activation of PAP-I, PAP-III and PSP/reg with trypsin. (**a**) and (**d**) show the matrix obtained with PATP I (**a**, bar 70 mm; **d**, 3 mm). (**b**) and (**e**) show the matrix obtained with PATP III (**b**, 20 mm; **e**, 7 mm). (**c**) and (**f**) show the matrix obtained with PTP (**c**, 40 mm; **f**, 4 mm). Inset in (**b**) gives a higher magnification micrograph showing individual fibrils that emerge from the dense matrix. (**a**) and (**c**), part of the plastic mesh of the pouch can be seen (Reprinted with permission from Graf et al. 2001© American Society for Biochemistry and Molecular Biology)

aggregates rather than the type of protein involved. Several neuron-degenerative diseases, such as AD are characterized by fibrillar deposits of proteins or peptides in brain. Many of these deposits are characterized by properties similar to those of starch and hence were called amyloid structures. Among proteins that form clinical fibril deposits, PSP/LIT readily polymerizes into fibrils after self-proteolysis of its N-terminal undecapeptide (Cerini et al. 1999). Autocatalytic cleavage leads PSP/LIT to the formation of quadruple-helical fibrils (QHF-litho) that are present in AD, and overexpressed during the very early stages of the disease before clinical signs appear (Duplan et al. 2001). PSP/LIT does not appear to change its native-like, globular structure during fibril formation. Therefore, it was thought that PSP/LIT constitutes an important protein in the deposition of polypeptides in vivo in relation to neurodegenerative diseases

Grégoire et al. (2001) studied 3D structure of hPSP/hLIT protofibrils using atomic force microscopy. These aggregates consisted of a network of protofibrils, each of which had a twisted appearance. Electron microscopy analysis showed that this twisted protofibril has a quadruple helical structure. Three-dimensional X-ray structural data and the results of biochemical experiments demonstrated that when forming a protofibril, hPSP/hLIT was first assembled via lateral hydrophobic interactions into a tetramer. Each tetramer then linked up with another tetramer as the result of longitudinal electrostatic interactions. All these results were used to build a structural model for the PSP/LIT protofibril called the quadruple-helical filament (QHF-litho) (Laurine et al. 2003). Ho et al. (2006) investigated the structural properties of recombinant hPAP lacking N-terminal propeptide, both in the soluble form and as fibrillar aggregates. Based on the solution structure analysis and the TANGO prediction, peptide hPAP84–116 was synthesized and found to form fibrils. The mechanism of fibril formation by hPAP has been compared with that of hPSP/hLIT. Over-all, studies support the idea that PSP/LIT may play a role in the ethiology of AD and hPSP/hLIT strongly resembles the prion protein in its dramatic proteolysis and amyloid proteins in its ability to form fibrils.

39.6 REG-II/REG-2/PAP-I

The 16 kDa Regenerating islet derived-2 (REG-2) has also been referred to as Islet of Langerhans regenerating protein 2, Lithostathine-2, Pancreatic stone protein 2, or Pancreatic thread protein 2. The rat cDNA for this gene has been cloned by Kamimura et al. (1992). Reg-2 is the

murine homologue of the human secreted HIP/PAP C-type lectin. Reg-2, related to the protein encoded by the REG gene, is identical with PAP-1 (pancreatitis-associated protein-1) and a β-cell-derived autoantigen in non-obese diabetic mice. The autoimmune response against this protein may convert a regenerative into an islet-destructive process accelerating development of type 1 diabetes (Gurr et al. 2007; Liu et al. 2008). Reg-2 is a likely mouse exocrine pancreas cytoprotective protein whose expression is regulated by keratin filament organization and phosphorylation (Zhong et al. 2007).

Motor neurons are the only adult mammalian neurons of the CNS to regenerate after injury. This ability is dependent on the environment of the peripheral nerve and an intrinsic capacity of motor neurons for regrowth. The 16 kDa Reg-2, that is expressed solely in regenerating and developing rat motor and sensory neurons, is a potent Schwann cell mitogen in vitro. In vivo, Reg-2 protein is transported along regrowing axons and inhibition of Reg-2 signaling significantly retards the regeneration of Reg-2-containing axons. During development, Reg-2 production by motor and sensory neurons is regulated by contact with peripheral targets. Strong candidates for peripheral factors regulating Reg-2 production are cytokines of leukemia inhibitory factor (LIF)/CNTF family, because Reg-2 is not expressed in developing motor or sensory neurons of mice carrying a targeted disruption of LIF receptor gene (Livesey et al. 1997). Purified Reg-2 can itself act as an autocrine/paracrine neurotrophic factor for a subpopulation of motoneurons, by stimulating a survival pathway involving phosphatidylinositol-3-kinase, Akt kinase and NF-kB and therefore Reg-2 expression is a necessary step in the CNTF survival pathway in late embryonic spinal cord (Nishimune et al. 2000; Fang et al. 2010).

Reg-2 is normally not expressed by dorsal root ganglion (DRG) cells but Reg-2 is rapidly upregulated in DRG cells after sciatic nerve transection and after 24 h recovery is expressed almost exclusively in small-diameter neurons (Averill et al. 2002). Subsequently, expression shifts from small to large neurons (Nishimune et al. 2000). Reg-2 is also upregulated by DRG neurons in inflammation with a very unusual expression pattern. In a rat model of monoarthritis, Reg-2 immunoreactivity was detected in DRG neurons at 1 day. In addition, the presence of Reg-2 in central axon terminals implicates Reg-2 as a possible modulator of second order dorsal horn cells (Averill et al. 2008).

Analysis on gene-expression made in cardiomyocytes during myocarditis, revealed that the Reg-2/PAP-I mRNA level is most markedly increased in cardiomyocytes rather than in noncardiomyocytes. Reg-2/PAP-I mRNA was approximately 2000-fold greater in cardiomyocytes under active myocarditis than in normal. Moreover, Reg-2/PAP-I protein and other Reg/PAP family gene expressions were remarkably increased in EAM hearts. In addition, IL-6 expression was significantly related to Reg-2/PAP-I. Therefore, the Reg/PAP family, which was found to dramatically increase is suspected to play an important role in myocarditis (Watanabe et al. 2008).

To assess the role of Reg-2, Lieu et al. (2006) used Reg-$2^{-/-}$mice in a model of fulminant hepatitis induced by Fas and in the post-hepatectomy Regeneration and demonstrated that Reg-2 deficiency enhanced liver sensitivity to Fas-induced oxidative stress and delayed liver regeneration with persistent TNFα/IL6/STAT3 signaling. In contrast, overexpression of human HIP/PAP promoted liver resistance to Fas and accelerated liver regeneration with early activation/deactivation of STAT3. Reg-2/HIP/PAP-I is therefore a critical mitogenic and antiapoptotic factor for the liver (Lieu et al. 2006).

Reg-2 expression was found to be upregulated in pancreatic islets both during diabetes development and as a result of adjuvant treatment in diabetic NOD mice and in C57BL/6 mice made diabetic by streptozotocin treatment. The upregulation of Reg-2 by adjuvant treatment was independent of signaling through MyD88 and IL-6. Upregulation of Reg-2 was also observed in the pancreas of diabetic mice undergoing β cell regenerative therapy with exendin-4 or with islet neogenesis-associated protein. Adjuvant immunotherapy regulates T1D in diabetic mice and induces Reg-2-mediated regeneration of β cells (Huszarik et al. 2010). In contrast to pancreatic islet neogenesis-associated protein [INGAP, Reg3δ] promote the growth or regeneration of the endocrine islet cells, Reg-2 overexpression did not protect acinar cells against caerulein-induced acute pancreatitis, indicating clear subtype specificities of the Reg family of proteins (Li et al. 2010). Pancreas-specific ablation of IGF-I in mice induced an over-expression of Reg-2 and Reg3β in the pancreas and protected them from streptozotocin (Stz)-induced β-cell damage. This indicated that Reg-2 protects insulin-producing cells against Stz-induced apoptosis by interfering with its cytotoxic signaling upstream of the intrinsic proapoptotic events by preventing its ability to inactivate JNK (Liu et al. 2010).

39.7 Reg-III

39.7.1 Murine *Reg-IIIα, Reg-IIIβ, Reg-III γ,* and *Reg-IIIδ* Genes

Human type III REG gene is divided into six exons spanning about 3 kb, and encodes a 175 aa protein with 85% homology with HIP/PAP. REG-III was expressed predominantly in pancreas and testis, but not in small intestine, whereas HIP/PAP was expressed strongly in pancreas and small intestine.

IL-6 responsive elements existed in the 5′-upstream region of human REG-III gene indicating that human REG-III gene might be induced during acute pancreatitis (Nata et al. 2004). The murine cDNAs type III Reg, Reg-IIIα, Reg-IIIβ and Reg-IIIγ encode 175-, 175- and 174- aa proteins, respectively, with 60–70% homology. All three genes are composed of six exons and five introns spanning approx. 3 kb, and exhibit distinctive structural features unique for members of the Reg gene family. All mouse Reg genes, Reg-IIIα, Reg-IIIβ, Reg-IIIγ, Reg-I and Reg-II, are assigned to the adjacent site of chromosome 6C. The Reg family genes were mapped to a contiguous 75 kb region of mouse genome according to the following order: 5′-Reg-IIIβ-Reg-IIIα-Reg II-Reg I-Reg-IIIγ-3′. Reg-IIIα, Reg-IIIβ and Reg-IIIγ were expressed weakly in pancreas, strongly in intestinal tract, but not in hyperplastic islets, whereas both Reg-I and Reg-II were expressed in hyperplastic islets (Narushima et al. 1997). REG3α is normally expressed in pancreatic acinar and endocrine cells. Transfection assays suggest that REG3α stimulates β-cell replication, by activating Akt kinase and increasing the levels of cyclin D1/CDK4 (Cui et al. 2009).

Abe et al. (2000) sequenced the 6.8 kb interspace fragment between Reg-IIIβ and Reg-IIIα and encountered a novel type III Reg gene, Reg-IIIδ. Reg-IIIδ gene is divided into six exons spanning about 3 kb, and encodes a 175 amino acid protein with 40–52% identity with the other five mouse Reg proteins. Reg-IIIδ was expressed predominantly in exocrine pancreas, but not in normal islets, hyperplastic islets, intestine or colon, whereas both Reg I and Reg II were expressed in hyperplastic islets and Reg-IIIα, Reg-IIIβ and Reg-IIIγ expressed strongly in the intestinal tract. In mouse, type I, type II and type III Reg genes (i.e. *Reg-I, Reg-II*, and *Reg-III* gene) have also been isolated.

The rat PAP-III gene spans over 2.5 kb sequences along with a 1.7 kb of 5′-flanking sequence. The PAP-III coding sequence spanned over six exons. There were striking similarities between PAP-III and PAP-I and II genes, in genomic organization as well as in promoter sequences. Moreover, the rat PAP-III gene was mapped to chromosome 4 which coincides with that of PAP-I and II genes. The three genes are derived from same ancestral gene by duplication. Expression of the PAP-III gene was compared with that of PAPs I and II (Dusetti et al. 1995). Rat cDNA and a regeneration-promoting gene encodes a 174-amino-acid (aa) Reg-III protein with a 25-aa signal peptide. Reg-III was expressed in regenerating pancreatic islets, but not in normal islets (Suzuki et al. 1994). Analysis of the open reading frame of a cDNA indicated that the deduced protein from the mRNA was a polypeptide of 174 amino acids, unexpectedly similar to that of rat PAP-II/Reg-III (Honda et al. 2002). However, the length of the identified mRNA (1,467 bp) was longer than that of rat PAP-II mRNA (885 bp), because the elongated mRNA was generated through a different polyadenylation site in the same gene. The elongated mRNA after acute pancreatitis was strongly induced in the restricted early phase, in comparison with the original mRNA. It was suggested that the elongated mRNA affects the function of PAP-II/Reg-III protein because the elongated mRNA with long three; untranslated regions is known to be involved in the translation efficiency. The identified mRNA may play an important role in the progression of pancreatitis (Honda et al. 2002). Proteomic approach identified that rat Reg-III could be functionally associated with Reg I (Shin et al. 2005).

39.7.2 Human Reg-III or HIP/PAP

Reg-III was strongly induced in gut epithelial cells following bacterial reconstitution, as well as in the colitis initiated by DSS. The mRNA expression of HIP/PAP was enhanced in colonic epithelial cells of patients with inflammatory bowel disease (IBD). Reg-III mRNA expression was localized in the epithelial cells including goblet cells and columnar cells in mice; on the other hand, HIP/PAP-expressing cells were correlated with Paneth cell metaplasia in human colon. Epithelial expression of Reg-III or HIP/PAP was induced under mucosal inflammation initiated by exposure to commensal bacteria or DSS as well as inflamed IBD colon (Dieckgraefe et al. 2002). *Salmonella* infection increased ileal mucosal PAP/Reg-III protein levels in enterocytes located at the crypt-villus junction. Increased colonization and translocation of *Salmonella* was associated with higher ileal mucosal PAP/Reg-III levels and secretion of this protein in feces. PAP/Reg-III protein is increased in enterocytes of the ileal mucosa during *Salmonella* infection and is associated with infection severity. Fecal PAP/Reg-III might be used as a new and non-invasive infection marker (van Ampting et al. 2009).

REG-IIIα and REG-1α are activated in many human hepatocellular carcinomas (HCC), REG-IIIα is down-regulated in most primary human gastric cancer cells. In gastric cancer REG-IIIα might be useful in the diagnosis of cancer (Choi et al. 2007). Two genes involved in HCC belong to REG family. They encode the regenerating islet-derived 3 α (REG-IIIα/HIP/PAP/REG-III) and 1α (REG-1α) proteins, both involved in liver and pancreatic regeneration and proliferation. REG-IIIα is a target of β-catenin signaling in Huh7 hepatoma cells. The upregulation of REG-IIIα and REG-Iα expression is significantly correlated to the β-catenin status in HCC and hepatoblastomas. The Wnt/β-catenin signaling pathway is activated in HCC. Evidence shows that both genes are downstream targets of the Wnt pathway during liver tumorigenesis (Cavard et al. 2006). Results predict that the REGα and REGγ inserts play

virtually no role in oligomerization or in proteasome activation. By contrast, removal of REGβ insert reduces binding of this subunit and REGα/REGβ oligomers to proteasomes. However, findings showed that REG inserts are not required for binding and activating the proteasome (Zhang et al. 1998).

Reg-III proteins bind their bacterial targets via interactions with cell wall peptidoglycan but lack the canonical sequences that support CRD in other C-type lectins. HIP/PAP recognizes the peptidoglycan carbohydrate backbone in a calcium-independent manner via a conserved "EPN" motif that is critical for bacterial killing. While EPN sequences govern calcium-dependent carbohydrate recognition in other C-type lectins, the unusual location and calcium-independent functionality of the HIP/PAP EPN motif suggest that this sequence is a versatile functional module that can support both calcium-dependent and calcium-independent carbohydrate binding. Further, HIP/PAP binding affinity for carbohydrate ligands depends on carbohydrate chain length, supporting a binding model in which HIP/PAP molecules "bind and jump" along the extended polysaccharide chains of peptidoglycan, reducing dissociation rates and increasing binding affinity. The dynamic recognition of highly clustered carbohydrate epitopes in native peptidoglycan is an essential mechanism governing high-affinity interactions between HIP/PAP and the bacterial cell wall.

39.8 Rat PAPs

39.8.1 Three Forms of PAP in Rat

Rat PAP-I, PAP-II, and PAP-III are members of a multigenic family of proteins expressed in several tissues. Rat PAP appears in pancreatic juice after induction of prancreatic inflammation. In acute pancreatitis in rats, PAP was first observed 6 h after induction of pancreatitis with taurocholate or cerulein, reached maximal levels in zymogen granules and in pancreatic tissue during the acute phase (48 h), and disappeared during recovery (day 5). It was never detected in spleen, liver, kidney, heart, or lung. The PAP-I is therefore an acute-phase protein that differs from other proteins of that family because of its exocrine nature. PAP-I is expressed in the pancreas in relation to the severity of cerulein-induced pancreatitis (Keim et al. 1991; Keim et al. 1994). PAP-I was shown to be antiapoptotic, mitogenic, and anti-inflammatory and can promote cell adhesion to the extracellular matrix. PSP/LIT/RegIα can be mitogenic. Because polymerization might regulate activity, the ability of rat PAP-I was examined to interact with itself (homodimerization), PAP-II, PAP-III, and PSP/LIT/RegIα (heterodimerization). PAP-I interacted significantly with all members of the PAP protein family, homodimerization showing the strongest interaction as judged by the β-galactosidase test (Bodeker et al. 1999). A change in gene expression of PAP reflects acute inflammatory changes in the pancreas most sensitively (Funakoshi et al. 1995).

In vitro, dexamethasone and IL-6 induced a marked transcription of PAP-I, II and III genes in AR42J cells. In vivo, pancreas mRNA levels of PAP-I, II or III increased by 2.6-fold, 1.9-fold, and 1.3-fold respectively after dexamethasone treatment. Histopathologic evaluation revealed less inflammation and necrosis in pancreata obtained from dexamethasone treated animals. Thus, dexamethasone significantly decreases the severity of pancreatitis. The protective mechanism of dexamethasone may be via upregulating PAP gene expression during injury (Kandil et al. 2006).

The PAP-I and III**,** but not PAP-II mRNAs are constitutively expressed in the small intestine of rats. Between day 20 of gestation and day 21 of age, PAP mRNAs could barely be detected. Their concentrations increased dramatically from day 21 to day 45 of age and remained constant thereafter. Rats adapted to a diet with low carbohydrate content showed a significant decrease in PAP mRNA concentrations. Gene expression of PAP-I and III mRNAs is regulated in a coordinate manner in the rat small intestine during development and on nutritional and hormonal manipulations (Sansonetti et al. 1995).

Rat PAP mRNA is barely detectable in normal pancreas and overexpressed during acute pancreatitis (Iovanna et al. 1991). Rat PAP mRNA was constitutively expressed in duodenum, jejunum, and ileum, at similar levels as in pancreas during the acute phase of pancreatitis. A weak expression was also detected in several other tissues. Serum from rats with acute pancreatitis (SAP) induced the expression of PAP mRNA in AR-42J cells. in a dose-dependent manner. It suggests that SAP contains factors responsible for the PAP mRNA expression and that the cis-acting elements are localized within the 1.2 kbp upstream region of the transcription initiation site (Dusetti et al. 1994b). Free radicals are involved in the pathogenesis of acute pancreatitis, during which PAP-I is overexpressed. PAP-I expression could be induced by oxidative stress and could affect apoptosis. It appears that during oxidative stress, PAP-I might be part of a mechanism of pancreatic cell protection against apoptosis (Ortiz et al. 1998).

The mRNA level of a PAP-like protein was found to be elevated in the ileal Peyer's patch of lambs during the early phase of scrapie infection. The ovine PAP-like protein cDNA encodes a putative 178 amino acid protein with a signal peptide and a C-lectin binding domain. REG/PAP protein's deduced amino acid sequences were conserved. The overall amino acid identity between the ovine PAP-like protein and

bovine, human and rat REG/PAP proteins varied from 23% to 85%. The expression of the ovine PAP-like protein mRNA was restricted to the ileal and jejunal Peyer's patches. The data provided will offer the possibility to search for a link between this PAP-like protein and early events in the development of scrapie (Skretting et al. 2006).

Although induction of PAP family genes has been reported in peripheral nerve injury models, the expression of PAP in CNS after traumatic brain injury (TBI) induced by weight drop was examined by Ampo et al. (2009). There was a significant upregulation of PAP-I and PAP-III mRNA in the injured cortex beginning at 1 day after TBI. PAP-I and PAP-III staining was localized in a subpopulation of neurons in the peri-injured region. Expression of both PAP-I and PAP-III mRNA was observed following a transient increase in inflammatory cytokines, including TNF-α, IL-6, and IL-1β mRNA. It appears that expression of PAP family members in response to traumatic and inflammatory stimuli are not restricted to the pancreas, intestine, and peripheral nervous system, but are likely a more general cellular response, including the CNS in rat (Ampo et al. 2009). Studies suggest that the Reg family of proteins is protective in acute pancreatitis (Viterbo et al. 2009).

39.8.2 PAP-I/Reg-2 Protein (or HIP, p23)

The rat PAP gene was characterized over 3.2 kb of gene sequence and 1.2 kb of 5′-flanking sequence. Several potential regulatory elements were identified in the promoter region, including a pancreas-specific consensus sequence. The PAP coding sequence spanned over six exons. The first three exons encoded the 5′-untranslated region of the mRNA, the signal peptide, and 39 amino acids of the NH2-terminal end of the mature protein, respectively. The other three exons encoded a domain of the protein with significant homology to the CRD of animal lectins (Dusetti et al. 1993). Analysis of the rat PAP-I promoter indicated that the region between nt −180 and −81 possessed silencer activity in cells that did not express PAP-I. Transient transfection assays revealed that the sequence with silencer activity was located within the rep27 region (position −180/ −153). Suppressor activity was observed when rep27 was inserted upstream from the core PAP-I promoter, in both orientations. Results suggest that the rep27 cis-acting element contributes to the tissue specific expression of PAP-I gene (Ortiz et al. 1997). The promoter of the PAP-I gene represents a potential candidate to drive expression of therapeutic molecules to the diseased pancreas. Studies show that (1) a recombinant adenovirus containing a fragment of the PAP-I promoter allows specific targeting of a reporter gene to the mouse pancreas and (2) expression of the reporter gene in pancreas is induced during acute pancreatitis (Dusetti et al. 1997).

A correlation between PAP-I mRNA levels and glutathione levels seems to exist in the mouse pancreas (Fu et al. 1996). In experimental pancreatitis a correlation was found between the severity of pancreatitis and the amount of PAP in pancreatic homogenates (Keim and Löffler 1986). Consumption of alcohol for short term does not alter serum PAP values during 56 h after drinking. However, longterm drinking induced at least a 10-fold increase in serum PAP. Nordback et al. (1995) support the suggestion that heavy long term drinking often induces subclinical pancreatic damage, but not clinical pancreatitis (Nordback et al. 1995).

Oxidative stress has an important role in the pathogenesis of pancreatitis. PAP-1 is a protein secreted upon induction of acute pancreatitis. As a result, oxidative stress induced PAP-1 mRNA expression in AR42J cells in a time-dependent manner. Cell viability decreased with the concentration of glucose oxides delivered to the cells that had received glucose. Oxidative stress-induced PAP-1 expression was augmented in cells transfected with PAP-1**S** cDNA. PAP-1 induction by oxidative stress decreased in the cells transfected with PAP-1 **AS** cDNA. PAP-1 may be a defensive gene for oxidative stress-induced cell death of pancreatic acinar cells (Lim et al. 2009).

Induction of PAP-I gene was also described in liver during hepatocarcinogenesis. It was noted that expression of PAP-I in hepatocarcinoma (HCC) occurred through inactivation of its silencer element and was not concomitant in all malignant cells. On that basis, PAP-I was assayed in serum from patients with chronic hepatitis, liver cirrhosis or hepatocarcinoma. PAP-I levels were normal in chronic active or persistent hepatitis, significantly higher in cirrhosis and strongly elevated in hepatocarcinoma. Because those clinical entities often develop in that sequence, serum PAP-I appeared as a potential marker of hepatocarcinoma development (Dusetti et al. 1996). However PAP assay can only be recommended in cases of justified suspicion of HCC with negative α-fetoprotein (Montalto et al. 1998). PAP-I was not found in normal melanocytes, melanoma tumors, and melanoma cell lines, even after stress induction. Exogenous PAP-I can modify the adhesion and motility of normal and transformed melanocytes, suggesting a potential interaction with melanoma invasivity (Valery et al. 2001).

39.8.3 PAP-II/PAP2

Frigerio et al. (1993b) cloned two overlapping cDNAs encoding a protein structurally related to PAP. The second PAP, which was called PAP-II, was of same size as the original PAP (PAP-I) and showed 74.3% amino acid homology. PAP-II mRNA concentration increased within 6 h following induction of pancreatitis, reached maximal levels

(>200 times control values) at 24–48 h, and decreased thereafter, similar to PAP-I. However, PAP-II mRNA could not be detected in the intestinal tract or in other tissues. PAP-II genomic DNA fragment was characterized over 2.7 kb of gene sequence and 1.9 kb of 5′ flanking sequence. The PAP-II coding sequence spanned six exons separated by five introns. Several potential Regulatory elements were identified in the promoter region, including two glucocorticoid-response elements and one IL-6-response element. Grønborg et al. (2004) reported a protein that is 85% identical to HIP/PAP and was designated as PAP-II. Two transcripts are generated from PAP-II gene in rat pancreas by alternative splicing in the 5′ untranslated region as shown by the existence of two forms of PAP-II mRNA with identical coding sequence but a different 5′-untranslated region. We demonstrate that this is the result of a differential splicing. (Vasseur et al. 1995).

NR8383 macrophages which were cultured in the presence of PAP2 aggregated and exhibited increased expression of IL-1, IL-6, TNF-α, and IL-10. Chemical inhibition of the NFkB pathway abolished cytokine production and PAP facilitated nuclear translocation of NF-kB and phosphorylation of IkBα inhibitory protein suggesting that PAP2 signaling involves this pathway. Similar findings were observed with primary macrophages derived from lung, peritoneum, and blood but not spleen. Furthermore, PAP2 activity was inhibited by the presence of serum, inhibition which was overcome with increased PAP2. These results demonstrate a new function for PAP2: it stimulates macrophage activity and likely modulates the inflammatory environment of pancreatitis (Viterbo et al. 2008b).

In rats, each of the three PAP-I isoforms has independent immunologic function on macrophages. PAP2 up-regulates inflammatory cytokines in macrophages in a dose-dependent manner and acts through NF-kB mechanisms. Truncation of the first 25 residues on the N terminus of PAP2 did not affect protein activity whereas truncation of the last 30 residues of the C terminus of PAP2 completely inactivated the function of PAP2. Additionally, reduction of three disulfide bonds proved to be important for the activity of this protein. Further investigation revealed two invariant disulfide bonds were important for activity of PAP2 while the disulfide bond that is observed in long-form C-type lectin proteins was not essential for activity. Further, preincubation with select rPAP2 mutant proteins affect translocation of this transcription factor into the nucleus (Viterbo et al. 2008a).

39.8.4 PAP-III

A third member of the rat PAP gene family was described by Frigerio et al. (1993a). The encoded protein, designated PAP-III, shows 66% and 63% identity with the rat PAP-I and II, respectively. The PAP-III gene is constitutively expressed in the small intestine and in the pancreas with acute pancreatitis, but not in the healthy pancreas. In vitro experiments revealed that PAP-III possessed a strong macrophage chemoattractant activity that was comparable with that of monocyte chemoattractant protein-1. PAP-III is involved in peripheral nerve regeneration and provides new insights into Schwann cell-macrophage interactions and therapeutic interventions (Namikawa et al. 2006). The ovulatory process in mammals involves gross physiological events in the ovary that cause transient deterioration of the ovarian connective tissue and rupture of the apical walls of mature follicles. A study revealed that the ovulatory events included induction of mRNA for PAP-III. In situ hybridization indicated that PAP-III mRNA expression was limited mainly to the hilar Region of the ovarian stroma, with most of the signal emanating from endothelial cells that lined the inner walls of blood vessels, and from small secondary follicles. Ovarian transcription of PAP-III mRNA was moderately dependent on ovarian progesterone synthesis. In conclusion, the present evidence of an increase in PAP-III gene expression in gonadotropin-stimulated ovaries provides further evidence that the ovulatory process is comparable to an inflammatory reaction (Yoshioka et al. 2002).

PAP-III is expressed with increased frequency in the bladder urothelium in a rat cystitis model and associated with bladder inflammation and implicates PAP-I in the abnormal sensation in cystitis (Takahara et al. 2008). Reg-III kills Gram-positive bacteria and plays a vital role in antimicrobial protection of the mammalian gut. Reg-III proteins bind their bacterial targets via interactions with cell wall peptidoglycan but lack the canonical sequences that support calcium-dependent carbohydrate binding in other C-type lectins.

Reg-IIIβ is found in many areas of the body and shown to play an important role in both the development and regeneration of subsets of motor neurons. The Reg-IIIβ expressed by motor neurons is both an obligatory intermediate in the downstream signaling of the leukemia inhibitory factor/ciliary neurotrophic factor (CNTF) family of cytokines, maintaining the integrity of motor neurons during development, as well as a powerful influence on Schwann cell growth during regeneration of the peripheral nerve. In mice, Reg-IIIβ positive motor neurons are concentrated in cranial motor nuclei that are involved in the patterning of swallowing and suckling. Suckling was impaired in Reg-IIIβ KO mice and correlated this with a significant delay in myelination of the hypoglossal nerve. In summary, Reg-IIIβ has an important role in the developmental fine-tuning of neonatal motor behaviors mediating the response to peripherally derived cytokines and growth factors and regulating the myelination of motor axons (Tebar et al. 2008).

39.9 Functions of PAP

39.9.1 PAP: A Multifunctional Protein

The fact that PAP is secreted by pancreatic acinar cells into the pancreatic juice initially suggested a role for this protein in pancreatic juice homeostasis. Pancreatic juice is supersaturated in $CaCO_3$ and, in the absence of physiological inhibitors this salt will precipitate in crystal formation. In vitro, the rat HIP/PAP has been reported to prevent cell death in neuronal primary cultures (Nishimune et al. 2000) and pancreatic cells (Malka et al. 2000), promote the growth of epithelial intestinal cells (Moucadel et al. 2001), and stimulate DNA synthesis in Schwann cells (Livesey et al. 1997). The hamster homologue to HIP/PAP, called INGAP peptide (section 39.12), has been shown to enhance nerve outgrowth from explanted dorsal root ganglia (Tam et al. 2004). In vivo, HIP/PAP can function as an acute phase reactant in human pancreatitis (Orelle et al. 1992). Reports also suggest that HIP/PAP could regulate both viability and proliferation in hepatocytes. Human HIP/PAP expressed in hepatocytes exhibits mitogenic and an antiapoptotic properties in primary cultures and liver regeneration after partial hepatectomy is stimulated in HIP/PAP transgenic mice (Simon et al. 2003). HIP/PAP accelerates liver regeneration and protects against acetaminophen injury in mice (Lieu et al. 2005). Despite the obvious interest of these observations, it is difficult to link these effects with the enormous amount of PAP released by pancreas during acute pancreatitis or cellular stress.

39.9.2 PAP in Bacterial Aggregation

Evidence from a large number of studies seemed to indicate that PAP had a variety of activities, which included anti-inflammatory, anti-apoptotic, proliferative, and antibacterial effects (Closa et al. 2007; De Reggi and Gharib 2001; Graf et al. 2006; Iovanna and Dagorn 2005). With respect to the antimicrobial activity, PAP and PSP were shown to induce bacterial aggregation without inhibiting growth, and trypsin appeared to stimulate the effect of PSP (Iovanna et al. 1991, 1993). Cash et al. (2006a) demonstrated that PAP can bind to the peptidoglycan layer of Gram positive bacteria and exert a direct bactericidal effect. PAP also bound to chitin and the mannose polymer mannan, indicating that PAP recognizes carbohydrate patterns (Cash et al. 2006a, b). Cash et al. (2006a) proposed that PAP-I is part of the innate immune system and its intestinal expression plays an important role in the maintenance of the intestinal bacterial flora (Cash et al. 2006a). By analogy, in the pancreas PAP-I is probably upregulated during acute panceatitis to prevent bacterial infection.

PAP and its paralog PSP induce bacterial aggregation. It is proposed that insoluble PAP might be the biologically active form. PAP has been shown to bind to the peptidoglycan of Gram positive bacteria and to exert a direct bactericidal effect. Medveczky et al. (2009) showed that N-terminal cleavage of PAP by trypsin at the Arg^{37}-Ile^{38} peptide bond or by elastase at the Ser^{35}-Ala^{36} peptide bond is a prerequisite for binding to the peptidoglycan of the Gram positive bacterium *Bacillus subtilis*. Trypsin-mediated processing of PAP resulted in the formation of the characteristic insoluble PAP species, whereas elastase-processed PAP remained soluble. N-terminally processed PAP induced rapid aggregation of *Bacillus subtilis* without significant bacterial killing. Thus, N-terminal processing is necessary for the peptidoglycan binding and bacterial aggregating activity of PAP and that trypsin-processed and elastase-processed forms are functionally equivalent. The observations also extend the complement of proteases capable of PAP processing, which now includes trypsins, pancreatic elastases and bacterial zinc metalloproteases of the thermolysin type.

It has been demonstrated that Reg-IIIγ and HIP/PAP are directly bactericidal for Gram-positive bacteria at μM concentrations (Mukherjee et al. 2009), revealing a unique biological function for mammalian lectins. The bactericidal activities of Reg-IIIγ and HIP/PAP depend on binding to cell wall peptidoglycan, a polymer of alternating N-acetylglucosamine (GlcNAc) and N-acetylmuramic acid (MurNAc) cross-linked by short peptides. This finding identified Reg-III lectins as a distinct class of peptidoglycan binding proteins. However, given the lack of canonical carbohydrate binding motifs in Reg-III proteins, the molecular basis for lectin-mediated peptidoglycan recognition remains unknown. Furthermore, Reg-III lectins are secreted into the intestinal lumen where there are abundant soluble peptidoglycan fragments derived from the resident microbiota through shedding or enzymatic degradation of the bacterial cell wall. Thus, it remains unclear how Reg-III lectins selectively bind to bacterial surfaces without competitive inhibition by soluble peptidoglycan fragments in the luminal environment.

39.9.3 PAP-I: An Anti-inflammatory Cytokine

PAP-I has been implicated in the endogenous regulation of inflammation. In addition to its role in acute pancreatitis, PAP-I has also been associated with inflammatory diseases, such as Crohn's disease. During acute pancreatitis, PAP-I may contribute to stress response to control bacterial proliferation (Iovanna et al. 1991). In pancreatic AR4-2J cells, PAP-I is one of the effectors for the TNF-α-induced

apoptosis inhibition (Malka et al. 2000). Although PAP-II is first isolated as a pancreatic secretory protein that contributes to pancreatic regeneration, it is up-regulated during the acute phase of pancreatitis and likely modulates the inflammatory environment of pancreatitis (Iovanna et al. 1991; Cavard et al. 2006; Choi et al. 2007; Dusetti et al. 1994; Lasserre et al. 1992; Viterbo et al. 2008). PAP-II is found to inhibit TNF-α-mediated inflammatory responses (Vasseur et al. 2004; Gironella et al. 2005). In the exocrine pancreas, PAP-I is associated with pancreatic acinar cell and protects cells from oxidative stress and TNF-α-induced pancreatic stress (Malka et al. 2000; Ortiz et al. 1998). Moreover, expression of PAP-II is also increased in gut epithelial cells in human inflammatory bowel disease (Ogawa et al. 2003).

PAP2 mediates the expression of inflammatory cytokines in macrophages through the NF-kB pathway (Viterbo et al. 2008). It was shown that both antisense gene knockdown and Ab neutralization of PAP2 in rats with experimental acute pancreatitis caused a significant increase in disease severity (Zhang et al. 2004). These findings corroborate other studies which showed protective roles served by PAP proteins during tissue injury (Vasseur et al. 2004; Kandil et al. 2006; Gironella et al. 2005). Therefore, PAP proteins are key regulators of inflammation and their absence causes a dysregulated inflammatory process. Truncation of the first 25 residues on the N terminus of PAP2 did not affect protein activity whereas truncation of the last 30 residues of the C terminus of PAP2 completely inactivated the function of PAP2. In addition, reduction of three disulfide bonds proved to be important for the activity of this protein (Viterbo et al. 2008).

Several reports suggest that Reg proteins could also be functional in the nervous system and expressed in the brain during development and Alzheimer's disease (Watanabe et al. 1994; de la Monte et al. 1990) (section 39.5.3.1). PAP-I may contribute to the signaling pathway of ciliary neurotrophic factor and is involved in the regeneration and survival of motor neurons (Livesey et al. 1997; Nishimune et al. 2000). The expression of PAP-I has been found to be induced in urinary tract afferent neurons following cyclophosphamide-induced cystitis (Takahara et al. 2008), suggesting its potential role in the abnormal sensation in cystitis. Moreover, the PAP-I expression in isolectin B4 (IB4)-positive small DRG neurons is up-regulated and followed by a dynamic shift from small to large DRG neurons after peripheral nerve injury (Averill et al. 2002). Increased expression of PAP-I also occurs in neurons following traumatic brain injury (Ampo et al. 2009). These data indicate that PAP-I expression in response to injury and inflammation could be a general response in the pancreas, intestine, and both peripheral and central nervous systems. However, it remains unclear whether PAP-II is involved in the response of primary sensory neurons to the stimulations of peripheral inflammation and nerve injury. A recent study shows that the expression of PAP-II is strongly induced in DRG neurons following peripheral tissue inflammation and nerve injury, suggesting an involvement of PAP-II in the signal processing of the spinal sensory pathways in chronic pain states. PAP-II may play potential roles in the modulation of spinal sensory pathways in pathological pain states (He et al. 2010).

While PAP has been shown to be anti-bacterial and anti-apoptotic in vitro, its definitive biological function in vivo is not clear. In vivo evidence indicate that PAP mediates significant protection against pancreatic injury. PAP may exert its protective function by suppressing local pancreatic as well as systemic inflammation during acute pancreatitis (Heller et al. 1999; Zhang et al. 2004). During pancreatitis, PAP released by the pancreas could mediate lung inflammation through induction of hepatic TNFα expression and subsequent increase in circulating TNFα (Folch-Puy et al. 2003). Since, PAP-I and IL-10 responses share several features, Folch-Puy et al. (2006) assessed their expression and involvement of JAK/STAT and NF-kB signaling pathways in the suppression of inflammation mediated by PAP using pancreatic acinar cell line (AR42J). PAP-I inhibits the inflammatory response by blocking NF-kB activation through a STAT3-dependent mechanism. Important functional similarities to the anti-inflammatory cytokine IL-10 suggested that PAP-I could play a role similar to that of IL-10 in epithelial cells (Folch-Puy et al. 2006).

PAP-I is able to activate the expression of the anti-inflammatory factor: suppressor of cytokine signaling (SOCS)3 through the JAK/STAT3-dependent pathway. The JAK/STAT3/SOCS3 pathway seems to be a common point between PAP and several cytokines. Therefore, it is reasonable to propose that PAP-I is an anti-inflammatory cytokine (Closa et al. 2007). A model of caerulein-induced pancreatitis was used to compare the outcome of pancreatitis in PAP/HIP$^{-/-}$ and wild-type mice**.** PAP can be strongly induced by IL-6 and IL-10 and IL-10-related cytokines through a STAT3-mediated pathway. The expression of PAP itself appears to be induced in pancreatic acinar cells by the presence of PAP in the medium. This is also related to the activation of STAT3 pathway since at least two functional STAT-responsible elements have been reported in the promoter of the PAP gene (Dusetti et al. 1995b). This self-induction suggests the existence of a positive feedback mechanism in pancreatic acinar cells via a PAP receptor and a cross-talk with other cytokines (Closa et al. 2007).

Arginine-induced pancreatic acinar cell injury has been reported in vivo. Arginine inhibits the proliferation of pancreatic aciner AR4-2J cells. The anti-proliferation by arginine was due to an increase in apoptosis. Studies suggest that arginine induces apoptosis and PAP gene expression in

pancreatic acinar cells and that PAP might inhibit the induction of apoptosis (Motoo et al. 2000). The anti-apoptotic and anti-inflammatory functions described in vitro for PAP/HIP have physiological relevance in the pancreas in vivo during caerulein-induced pancreatitis (Gironella et al. 2007). Assuming a protective role of PAP, Li et al. (2009) showed that PAP had no significant effect on proliferation and migration on human pancreatic stellate cell (PSCs). Cell-associated fibrillar collagen types I and III and fibronectin increased after addition of PAP to PSCs. PAP diminished the expression of MMP-1 and −2 and TIMP-1 and −2 and their concentrations in PSC supernatants. Studies offer new insights into the biological functions of PAP, which may play an important role in wound healing response and cell-matrix interactions (Li et al. 2009). The RII α regulatory subunit of cAMP-dependent protein kinase (PKA) is a binding partner of HIP/PAP. The HIP/PAP co-immunoprecipitates with RIIα in HIP/PAP expressing cells. Increase in basal PKA activity in HIP/PAP expressing cells suggests that HIP/PAP may alter PKA signaling (Demaugre et al. 2004).

Ferrés-Masó et al. (2009) described the intracellular pathways triggered by PAP-I in a pancreatic acinar cells and showed that PAP-I increased the transactivation activity of *PAP-I* and the binding on its promoter of the nuclear factors C/EBPβ, P-CREB, P-ELK1, EGR1, STAT3, and ETS2, which are downstream targets of MAPK signaling. p44/42, p38, and JNK MAPKs activity increased after PAP-I treatment. In addition, pharmacological inhibition of these kinases markedly inhibited the induction of PAP-I mRNA. These results indicated that the mechanism of PAP-I action involves the activation of the MAPK superfamily (Ferrés-Masó et al. 2009).

39.10 Panceatitis Associated Protein(PAP)/Hepatocarcinoma-Intestine Pancreas (HIP)

39.10.1 HIP Similarity to PAP

Lasserre et al. (1994) identified a gene (named HIP) the expression of which is markedly increased in 25% of human primary liver cancers. HIP mRNA expression is tissue specific since it is restricted to pancreas and small intestine. Pleiotropic biological activities have been ascribed to this protein, but little is known about the function of HIP/PAP in the liver. HIP protein consists in a signal peptide linked to a CRD, typical of C-type lectins without other binding domains. The analysis of HIP/PAP gene indicates that the HIP/PAP CRD is encoded by four exons, a pattern shared with all members of this group of proteins. This common intron-exon organization indicates an ancient divergence of the free CRD-lectin group from other groups of C-type lectins. Lasserre et al. (1994) provided evidence for the localization of HIP/PAP on chromosome 2, suggesting previous duplication of HIP/PAP and the related Reg Iα and Reg Iβ genes from the same ancestral gene. The sequence of the 5′ upstream region of the HIP gene shows several potential regulatory elements which might account for the enhanced expression of the gene during pancreatic inflammation and liver carcinogenesis (Lasserre et al. 1994). In normal liver, the protein is undetectable in normal mature hepatocytes and found only in some ductular cells, representing potential hepatic progenitor cells. Itoh et al. (1995) especially focussed on the 5′-flanking region, which spans about 3 kb and is composed of six exon. Exon 1 encodes the 5′-noncoding sequence and exon 2 consists of three miniexons, 2a, 2b and 2c; the common exon 2c encodes the sequence including the start codon. Analysis revealed the presence of at least three different types 5′-ends of human PAP/HIP transcripts which were derived from alternative use of 5′-exons. Although all three types of transcripts were expressed in both normal small intestine and pancreas, their gene expression was increased ectopically in gastric cancer, hepatocellular cancer and pancreatic acinar cell carcinoma. Furthermore, significant differences among the transcript types were detected between normal and tumor tissues, and especially between gastric and hepatocellular cancers, suggesting that PAP/HIP expression may vary with differences in 5′-alternative splicing.

Simon et al. (2003) proposed that HIP/PAP acts as a hepatic cytokine that combines mitogenic and anti-apoptotic functions through the PKA signaling pathway and consequently acts as a growth factor in vivo to enhance liver regeneration. The HIP/PAP (=human Reg-2) encoding gene is activated in primary liver cancers. The involvement of HIP/PAP has been suggested in the pathophysiology of interstitial cystitis (IC) patients, because, the urinary HIP/PAP levels were significantly higher and the HIP/PAP expression in the bladder urothelium was more frequently apparent in IC patients (Makino et al. 2010). The rHIP regulatory sequence is a potent liver tumor-specific promoter for the transfer of therapeutic genes, and AdrHIP-NIS-mediated ^{131}I therapy is a valuable option for the treatment of multinodular HCC (Herve et al. 2008).

To test whether HIP/PAP-I is a target of islet-directed autoimmunity, Gurr et al. (2002) measured splenic T-cell responses against HIP/PAP in NOD mice. Differential cloning of Reg from islets of a type 1 diabetic patient and the response of Reg to the cytokine IL-6 suggests that HIP/PAP becomes overexpressed in human diabetic islets because of the local inflammatory response and. HIP/PAP acts as a T-cell autoantigen in NOD mice. Therefore, autoimmunity to HIP/PAP might create a vicious cycle, accelerating the immune process leading to diabetes (Gurr et al. 2002; Shervani et al. 2004).

Laurine et al. (2005) focused on two proteins, REG Iα and newly identified PAP-IB, belonging to more closely related FI and FII families, respectively. REG Iα and PAP-IB share 50% sequence identity. PAP-IB was expressed almost only in pancreas, unlike REG Iα, whose expression was ubiquitous. In addition, the two proteins displayed distinctive surface charge distribution, which may lead to different ligands binding. In spite of their common fold that should result in closely related functions, REG Iα and PAP-IB are a good example of duplication and divergence, probably with the acquisition of new functions, thus participating in the evolution of the protein repertoire.

39.10.2 Characterization of HIP/PAP

Pancreatitis-associated protein hepatocarcinoma-intestine-pancreas (PAP/HIP) is 16-kDa basic protein with an isoelectric point in the range of pH 6.5–7.6. Although most species contain a single PAP form, rat contains three isoforms, PAP-I, PAP-II, and PAP-III, transcribed from three separate genes (Iovanna et al. 1991; Frigerio et al. 1993a, b). PAP levels increase in pancreatic juice during experimental and clinical pancreatitis (Keim et al. 1992). Although showing an acute phase response under conditions of pancreatic disease, the function of PAP is not clear. Several studies have demonstrated that PSP and PAP both act as acute phase reactants in pancreatic juice under a variety of conditions including acute pancreatitis (Keim et al. 1994), post-weaning period (Bimmler et al. 1999). Trypsin cleavage of PSP and PAP has resulted in the appearance of precipitated proteins believed to represent insoluble thread structures in humans (Gross et al. 1985a) and cows (Gross et al. 1985b). It is difficult to understand how precipitation properties could serve a useful function in pancreatic physiology.

The PAP coding sequence spans over six exons and the putative CRD is encoded by exons IV, V, and VI. This gene organization suggests that PAP belongs to C-type lectins, which have evolved from the same carbohydrate-recognition domain ancestral precursor through a different process. It is interesting to note that PAP is the smallest protein reported among the C-type lectins. In fact, it comprises a single CRD linked to a signal peptide whereas other C-type lectins contain the sugar-binding consensus combined with a variety of other protein domains which confer specific functions of lectins. In contrast, PAP does not have additional functional domains. One PAP gene (HIP/PAP) was described by Keim et al. as a 16 kDa secretory protein in rat pancreatic juice which appeared upon induction of pancreatic inflammation and represented up to 5% of total protein (Keim et al. 1991). The human ortholog was isolated in 1992 from pancreatic juice of diabetic patients who underwent combined kidney and pancreas transplantation (Keim et al. 1992). In these patients the donor pancreas developed acute pancreatitis and levels of PAP-I in the juice reached up to 7.5% of the total secretory protein. Because PAP was hardly detectable in the normal pancreatic juice, but became upregulated in inflammation, it was considered a unique acute phase protein, which was targeted to the exocrine secretions. Subsequent cDNA cloning revealed that PAP exhibited homology to the carbohydrate binding region of Ca^{2+}-dependent (C-type) lectins and thus PAP belongs to a larger secretory protein family which contain only a single C-type lectin domain (Iovanna et al. 1991; Orelle et al. 1992). Members of this protein family, which includes pancreatic stone protein (PSP), have been described in excellent reviews (Closa et al. 2007; De Reggi and Gharib 2001; Graf et al. 2006; Iovanna and Dagorn 2005). PAP expression was also detected in the intestines and other extrapancreatic tissues, but the physiological function of PAP in the pancreas or elsewhere has remained contentious.

Graf et al. (2001) demonstrated that trypsin cleaved all three isoforms of PAP at N-terminus after Arg^{37} (Arg^{11} in the mature PAP protein), which in turn forms insoluble fibrils and the processed PAP became resistant to proteases and formed insoluble, fibrillar structures (Graf et al. 2001; Schiesser et al. 2001). Specific PAP-I isoforms have been shown to be normal constituents of intestinal paneth cells (McKie et al. 1996) and, more importantly, serve to maintain gut microbial integrity. PAP proteins also serve important roles within the nervous system, being involved in motor neuron regeneration (Namikawa et al. 2005). Coupling its diffuse expression pattern with the interspecies conservation of this group of proteins supports important functional roles for this network of proteins. In addition, HIP/PAP-I is a promising candidate for the prevention and treatment of liver failure (Christa et al. 2000; Lieu et al. 2005).

The secretory human PAP was structurally related to rat PAP and had the same size as rat PAP. It showed 71% amino acid identity, the six half-cystines being in identical positions. Domains of the proteins showing homologies with calcium-dependent lectins were also conserved. In addition, expression in pancreas of the genes encoding the human protein and rat PAP showed similar characteristics (Orelle et al. 1992). The human PAP synthesis increases during inflammation and its use as biological marker of acute pancreatitis has been siggested. The human PAP gene spans 2748 bp and contains six exons interrupted by five introns. The gene has a typical promoter containing the sequences TATAAA and CCAAT 28 and 52 bp upstream of the cap site, respectively. The human PAP gene was mapped to chromosome 2p12. This localization coincides with that of the Reg/PSP/LIT gene, which encodes a pancreatic secretory protein structurally related to PAP (Dusetti et al. 1994a).

39.10.3 PAP Ligands (PAP Interactions)

HIP/PAP protein has a very high affinity for D-lactose, but insignificantly to α-D-glucopyroanose, α-L-fucose, α-D-galactopyranose, or N-acetyl-β-D-glucosamine (Christa et al. 1994). It promotes rat hepatocyte adhesion in primary culture, and interacts with the proteins of the extracellular matrix (Christa et al. 1996). NMR studies showed that HIP/PAP recognizes the peptidoglycan carbohydrate backbone in a calcium-independent manner via a conserved "EPN" motif that is critical for bacterial killing. While EPN sequences govern calcium-dependent carbohydrate recognition in other C-type lectins (Drickamer 1999), the unusual location and calcium-independent functionality of the HIP/PAP EPN motif suggest that this sequence is a versatile functional module that can support both calcium-dependent and calcium-independent carbohydrate binding. Further, it was shown that HIP/PAP binding affinity for carbohydrate ligands depends on carbohydrate chain length, supporting a binding model in which HIP/PAP molecules "bind and jump" along the extended polysaccharide chains of peptidoglycan, reducing dissociation rates and increasing binding affinity (Fig. 39.3). Lehotzky et al. (2010) proposed that dynamic recognition of highly clustered carbohydrate epitopes in native peptidoglycan is an essential mechanism governing high-affinity interactions between HIP/PAP and the bacterial cell wall. HIP/PAP protein binds laminin and acts as an adhesion molecule for hepatocytes (Christa et al. 1999).

39.10.4 Crystal Structue of human PAP (hPAP)

Crystals of hPAP belong to the orthorhombic space group P2(1)2(1)2(1), with unit-cell parameters a = 30.73, b = 49.35, c = 92.15 A and one molecule in the asymmetric unit (Abergel et al. 1999). hPAP folds into an α + β structure and consists of two α-helices and eight β-strands cross-linked by three disulfide bridges packed into a heart-like shape, similar to that of the C-type lectin domain (Fig. 39.4). However, hPAP was found to have a unique distribution of charged residues on the surface. Nine of the eleven acidic residues (Asp^{37}, Asp^{39}, Glu^{58}, Asp^{82}, Glu^{88}, Glu^{92}, Glu^{95}, Asp^{100}, and Glu^{149}) were found to be clustered on one side, whereas 12 of the 13 basic residues (Arg^{13}, Lys^{16}, Lys^{19}, Lys^{33}, Lys^{44}, Arg^{45}, Lys^{67}, Arg^{109}, Arg^{125}, Arg^{131}, Lys^{133}, and Arg^{140}) were located on the other side. This surface charge distribution results in a highly polarized protein molecule, suggesting strong electrostatic interactions between molecules. In addition, several hydrophobic residues, such as residues Leu^{28}–Pro^{32} and Val^{101}–Trp^{107}, were found to be highly exposed and to constitute a continuous hydrophobic surface. The hydrophobic loop Val^{101}–Trp^{107} is located between the negatively charged and positively charged surfaces and is especially interesting, because the TANGO program predicts that this region in hPAP shows high propensity for β aggregation. Because hPAP forms fibrils with a native-like structure, it is possible that some conformational rearrangements in the loop regions that do not perturb the native secondary structure may drive the assembly of protein into fibril (Ho et al. 2006).

39.10.5 Expression of PAP

HIP/PAP is rapidly overexpressed during the acute phase of pancreatitis (Iovanna et al. 1994). Motor neurons are the only adult mammalian neurons of the CNS that regenerate after injury. The gene corresponding to human HIP/PAP gene in rat, called Reg-2 or rat PAP-I, has been found to be expressed in regenerating motor neurons, and its product exhibits mitogen-like activity in vitro on Schwann cells (Livesey et al. 1997). In the exocrine pancreas, HIP/PAP expression pattern is consistent with that of an acute phase reactant; however, this does not account for its expression in the islets of Langerhans of endocrine pancreas. HIP/PAP was expressed in normal subjects in the intestine (Paneth and neuroendocrine cells), and the pancreas (acinar pancreatic cells and islets of Langerhans), whereas in the liver, its expression was triggered in the event of primary liver cancer (Christa et al. 1996). Lasserre et al. (1992) discovered HIP/PAP by differential screening of a human hepatocarcinoma, and showed its frequent overexpression in liver tumors and regenerative hepatic/ductular diseases (Christa et al. 1999). In human, HIP/PAP is expressed in HCC and increased in serum, suggesting its potential importance in human liver carcinogenesis (Dusetti et al. 1996). During early stages of chemical hepatocarcinogenesis in rat (Petersen et al. 1998), oval cell proliferation was observed during hepatocarcinogenesis in woodchuck virus carriers and in human livers from patients with different pathological conditions (Christa et al. 1999). HIP/PAP mRNA is abundantly expressed in tumoral but not in nontumoral/normal livers. HIP/PAP gene expression is increased in 25% of HCC. HIP/PAP expression is not restricted to hepatocellular carcinoma, but also detected in cholangiocarcinoma cells as well as in reactive non-malignant bile ductules. Altogether, reports suggest that HIP/PAP protein may be implicated in hepatocytic and cholangiolar differentiation and proliferation (Christa et al. 1999).

PAP-I Is Upregulated During Acute and Chronic Pancreatitis: Early after its discovery it became clear that acinar cells of the pancreas are the main source of hPAP in pathological situations. In experimental model of acute pancreatitis in rat, Morisset et al. (1997) found the induction of PAP and its localization in zymogen granules. Bodeker and co-

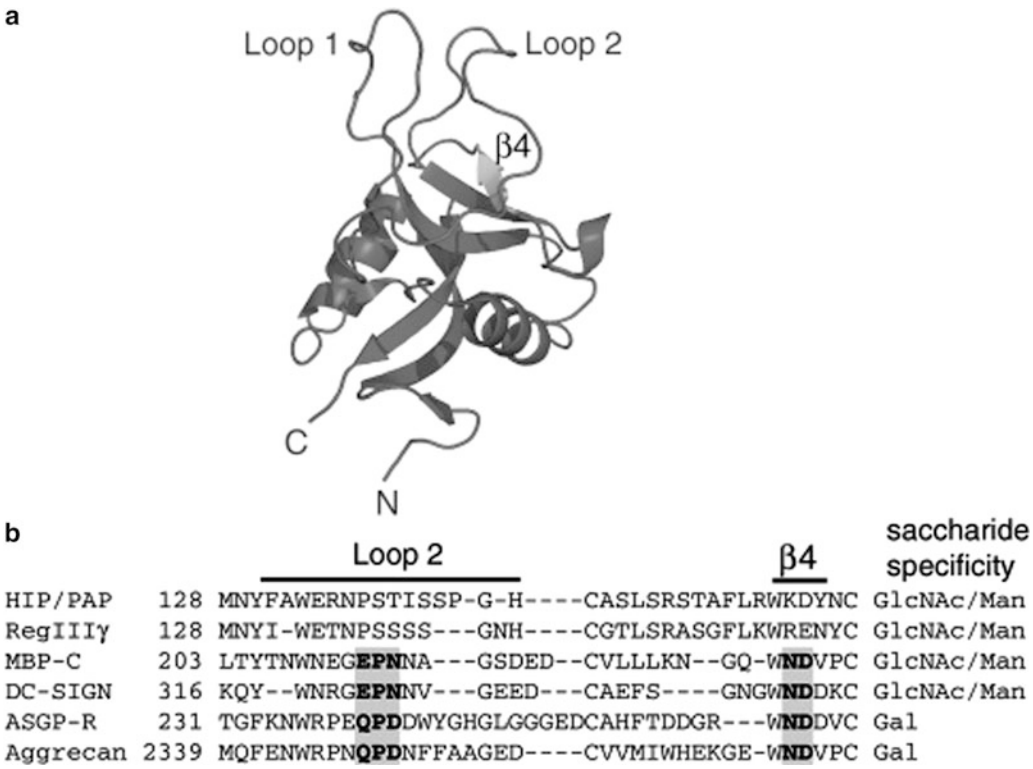

Fig. 39.3 Absence of canonical C-type lectin-carbohydrate binding motifs in Reg-III and HIP/PAP lectins: (**a**) NMR structure of HIP/PAP (PDB code 2GO0) (Ho et al. 2006: Fig. 39.4), with *Loops 1* and *2* of the *long loop* region and the β4 strand marked. (**b**) Alignment of the *long loop* region of Reg-III family members with other C-type lectin family members. MBP-C and DC-SIGN harbor *Loop 2* EPN motifs that govern sugar ligand binding and confer selectivity for mannose (Man) and GlcNAc (Drickamer 1992). Asialoglycoprotein receptor (ASGP-R) and aggrecan contain *Loop 2* QPD motifs that confer selectivity for Gal and GalNAc. Despite their selective binding to GlcNAc and Man polysaccharides RegIII lectins lack the *Loop 2* EPN motif (Cash et al. 2006a) (Adapted with permission from Lehotzky et al. 2010 © National Academy of Sciences)

workers (1998) described the pattern of PAP up-regulation in exocrine pancreas during the progression of the disease. The acute-phase response of pancreas seems to be a powerful emergency defense mechanism against further pancreatic aggression, as shown by the improved survival of the animals (Fiedler et al. 1998). PAP, induced in acute pancreatitis, was decreased by antisense-mediated gene knockdown of PAP gene expression and worsened pancreatitis (Lin et al. 2008).

PAP-I is not only expressed during acute pancreatitis but also in pancreatic adenocarcinoma, gastric carcinoma, hepatocellular carcinoma, and colorectal carcinoma. Expression in carcinoma might be another characteristic of PAP. Elevation of PAP in patients with pancreatic cancer is not merely explained by concomitant pancreatitis, but seems to be due to increased PAP production by the cancer cells and is also correlated to tumor load as expressed by the UICC stages (Cerwenka et al. 2001). PAP was overexpressed in 79% of pancreatic ductal adenocarcinoma, 19%of chronic pancreatitis, and 29% of mucinous cystadenoma. PAP was found in malignant ductular structures in pancreatic carcinomas as well as in benign proliferating ductules and acinar cells in chronic pancreatitis. It was not expressed in normal pancreas. The incidence of PAP overexpression was significantly higher in pancreatic cancer than in the other pancreatic diseases. PAP overexpression was significantly correlated with nodal involvement, distant metastasis, and short survival in pancreatic cancer. The overexpression of PAP in human pancreatic ductal adenocarcinoma indicates tumor aggressiveness (Xie et al. 2003). Functional differences between arteries and veins are based upon differences in gene expression. The most prominent difference was PAP-I, expressed 64-fold higher in vena cava versus aorta (Szasz et al. 2009).

TNF-α contributes to the development of acute pancreatitis. Because TNF-α is involved in the control of apoptosis and antiapoptotic mechanisms are mediated by NF-kB and MAP kinases, PAP-I is one of the effectors of apoptosis inhibition (Malka et al. 2000). The endotoxemia, which is caused by a bacterial infection, can exacerbate acute pancreatitis, whereas PAP has the ability to induce bacterial aggregation and supposed to protect the tissue from infection during inflammation. Studies suggest that PAP-I mRNA might be modulated by endotoxemia, independent of

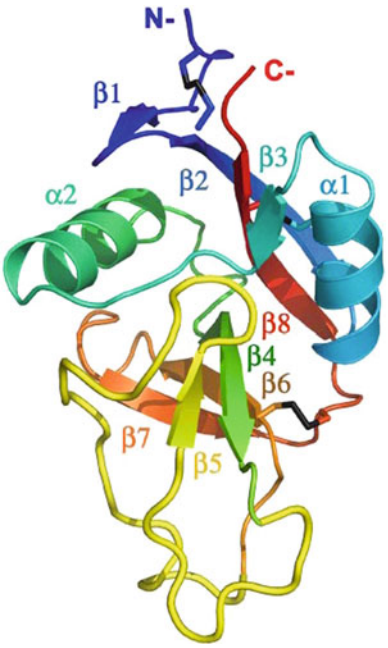

Fig. 39.4 NMR solution structure of hPAP at pH 4.0. Ribbon representation shows native hPAP. The tertiary fold of hPAP resembles that of the C-type lectin domain, which consists of two α-helices and eight β-strands cross-linked by three disulfide bridges (colored in *black*). The N and C termini are indicated. The region from Thr^{84} to Ser^{116} are highlighted in *yellow* (Adapted with permission from Ho et al. 2006 © The American Society for Biochemistry and Molecular Biology)

cerulein-pancreatitis. There were no strong correlations between PAP-I mRNA expression and the severity of pancreatitis (Wang et al. 2001).

PAP in Human Intestinal Tract: Members of the Reg family play regulatory roles in various endocrine cell populations and that their expression in endocrine cells is lineage-specific Analysis shows the presence of a transcript in the jejunum that has the same electrophoretic mobility as the pancreatic mRNA. No signal was detected in colon, however. In addition, PAP revealed the presence of a protein of 16,000 Da (as in pancreatic juice) in the homogenate of jejunum, but not of the colon. Positive immunoreactivity was observed on Paneth cells and in some goblet cells located in jejunum at the bottom of the crypts (Masciotra et al. 1995). In both adult and fetal normal tissues, HIP/PAP expression was detected only in endocrine cells of the small intestine, ascending colon, and pancreas (Hervieu et al. 2006).

Expression of PAP-I is altered in patients with celiac disease, where active phase of the disease is accompanied by an increased serum concentration of PAP (Carroccio et al. 1997). Increased serum level of PAP was diagnosed at ileal location in active CD with a sensitivity of 60%, a specificity of 94%, a positive predictive value of 84% and a negative predictive value of 81%. Elevated serum PAP is significantly associated with disease activity and ileal location (Desjeux et al. 2002). Clinical data suggest that pancreatitis could be an extraintestinal manifestation of inflammatory bowel disease. However, no experimental data support such a clinical relationship. Increased PAP mRNA has been reported in active inflammatory bowel disease (IBD). PAP-I is synthesised by Paneth cells and is overexpressed in colonic tissue of active IBD. PAP inhibits NF-kB activation and downregulates cytokine production and adhesion molecule expression in inflamed tissue. It may represent an anti-inflammatory mechanism and new therapeutic strategy in IBD (Gironella et al. 2005). PAP overexpression in pancreas demonstrates that inflammatory stress early occurs in the mouse pancreas during the course of TNBS-induced colitis. The concomitant pancreatic overexpression of IL-1B supported a pancreatic inflammatory mechanism mediated by cytokines (Barthet et al. 2003). Morphological pancreatic damage is also induced by the inhalation of cigarette smoke, which is likely to be mediated by alterations of acinar cell function (Wittel et al. 2006). PAP-I is also known as a marker for cystic fibrosis. PAP-I is increased in most neonates with cystic fibrosis and could be used for cystic fibrosis screening. Its combination with immunoreactive trypsinogen looks promising (Sarles et al. 1999). There was no evidence for polymorphism of the PAP gene in patients with hereditary or alcoholic pancreatitis. But the expression of the PAP in both groups of patients is related to the degree of cellular damage of the pancreas (Keim et al. 1999).

39.10.6 Similarity of PAP to Peptide 23 from Pituitary

Peptide 23 is a protein secreted by rat pituitary cells in primary culture. Although the secretion of this protein is stimulated by GH-releasing hormone and inhibited by somatostatin, the N-terminal amino acid sequence of peptide 23 shows no homology to rat GH. The cDNA of peptide 23 contained 777 nt and encoded a 175-amino acid protein with a 26-amino acid putative signal peptide with a calculated mol wt of mature protein (16,613 Da). Northern blot analysis revealed a major mRNA species of about 0.9 kb and a minor species of about 1.7 kb in cultured rat anterior pituitary cells. In rats, peptide 23 was most abundant in pancreas and GI tract. Sequence search revealed complete sequence identity between peptide 23 cDNA and PAP cDNA, 73% homology with HHC cDNA, and 55% homology with rat and human Reg cDNAs, expressed in regenerating pancreatic islets. Cloning of peptide-23 c-DNA revealed that it is identical to PAP. A dramatic increase in the expression of both genes was seen at the time of weaning in the third week postpartum. Peptide-23/PAP mRNA is most abundant in the ileum, whereas PSP/Reg is maximally expressed in the pancreas and duodenum. GRF modulates peptide-23/PAP expression

in GI tract in a similar fashion to that previously reported for pituitary cells in primary culture (Chakraborty et al. 1995c; Katsumata et al. 1995). Later studies demonstrated that peptide 23/PAP, previously thought to be of pituitary origin, is widely expressed in GI tract and that it is rapidly removed from the circulation by the kidney and by tissues which express peptide 23/PAP. Peptide 23/PAP is also expressed in rat uterus where estrogen may act as a physiological regulator of peptide 23 (Chakraborty et al. 1995a). Human fetal and adult tissues express at least one of the different transcripts of the PAP/Reg family, suggesting that the regulation of these homologous genes is coordinately controlled (Bartoli et al. 1998). The protein, present in very high concentration in pancreatic secretion, has been detected in brain lesions in AD and Down syndrome and in regenerating rat pancreatic islets (Cai et al. 1990).

39.10.7 Serum PAP: An Indicator of Pancreatic Function

Measuring serum PAP-I in acute pancreatitis has proved valuable in monitoring the course of the disease and the recovery of the patient. However, at admission PAP did not distinguish severe from mild acute pancreatitis better than C reactive protein; the measurement of PAP did not give appreciable diagnostic advantage in the early phase of acute pancreatitis (Kemppainen et al. 1996; Pezzilli et al. 1997). The serum PAP levels were significantly elevated in the patients with gastric, colorectal, biliary tract, hepatocellular, or pancreatic cancers compared with the healthy subjects. The increase of serum PAP levels in patients with gastrointestinal cancers reflects an ectopic expression of PAP-I. In cancer cells, the increased serum levels of PAP are correlated with the disease severity (Motoo et al. 1998, 1999). The PAP mRNA expression and serum PAP levels are closely related to neoplastic proliferative activity in patients with colorectal carcinoma (Cao et al. 2009). Serum PAP levels strongly correlate with creatinine clearance measurements. In patients with a pancreas-kidney transplantation, PAP may prove a useful biological and histological marker of pancreatic graft rejection (van der Pijl et al. 1997). Human PAP could be detected in pancreatic juice from patients with pancreatic diseases. Determination of PAP in pancreatic juice might be helpful for early detection of pancreatic injury (Motoo et al. 2001).

39.11 Reg IV (RELP)

Hartupee et al. (2001) isolated two cDNAs which encode a novel member of this multigene family. Based on primary sequence homology, tissue expression profiles, and shared exon-intron junction genomic organization, gene was assigned to the regenerating gene family as *Reg IV*. *Reg IV* has a highly restricted tissue expression pattern, with prominent expression in mucosal cells of GI tract. Namikawa et al. (2005) identified and sequenced a type-IV Reg gene in rats. Reg family members are mediators among injured neurons and glial cells that may play pivotal roles during nerve regeneration. Unlike other C-type lectins, human Reg IV binds to polysaccharides, mannan, and heparin in the absence of calcium. To elucidate the structural basis for carbohydrate recognition by NMR, mutant protein with Pro91 replaced by Ser (hReg IV-P91S) showed that the structural property and carbohydrate binding ability of hRegIV-P91S are almost identical with those of wild-type protein. The solution structure of hRegIV-P91S adopts a typical fold of C-type lectin. Based on NMR studies, two calcium-independent mannan-binding sites were proposed. One site is similar to the calcium-independent sugar-binding site on human Reg-III and Langerin. Interestingly, the other site is adjacent to the conserved calcium-dependent site 2 at position typical of C-type lectins (Ho et al. 2010)

39.11.1 Tissue Expression

Reg IV gene expresses in human colon, small intestine, stomach and pancreas, in rat spleen and colon and constitutively expressed in neuroendocrine cells of the intestinal mucosa. A potential role for Reg IV protein has been indicated in spleen and colon cell growth (StarceviÄć-Klasan et al. 2008). Heiskala et al. (2006) reported a robust de novo expression of Reg IV (RELP) in the neoplastic goblet cells of appendiceal mucinous cystadenomas and in the epithelial implants of pseudomyxoma peritonei (PMP). Reg IV serves as a marker for appendiceal mucinous cystadenomas and PMP, and may contribute to the pathogenesis of these disorders (Heiskala et al. 2006). Reg IV mRNA expression is significantly up-regulated by mucosal injury from active Crohn's disease or ulcerative colitis (UC). Reg IV mRNA was strongly expressed in inflamed epithelium and in dysplasias and cancerous lesions in UC tissues. Reg IV gene induction promoted cell growth and conferred resistance to H_2O_2-induced apoptosis in human colon cancer (DLD1) cells. Therefore, Reg IV gene is inducible by growth factors and may function as a growth promoting and/or an antiapoptotic factor in the pathophysiology of UC (Nanakin et al. 2007).

Intestinal neuroendocrine neoplasms showed co-expression of Reg IV and Hath1. Lung small-cell carcinoma and gastric mucocellular carcinoma expressed only Reg IV. Pancreatic islet-derived tumors, pheochromocytomas, and paragangliomas expressed only Hath1. The dissimilar expression patterns suggest that the proteins belong to different signaling pathways and are activated at different stages of neuroendocrine differentiation. Local Reg IV

expression may be influenced by the growth factors bFGF and HGF and/or their receptors CD138 and c-met, which were found to co-localize with Reg IV in intestinal neuroendocrine tumors (Heiskala et al. 2010). Reg IV might accelerate cell growth and disease progression of adenoid cystic carcinomas (ACCs) in salivary glands s (Sasahira et al. 2008). Reg IV expression is associated with intestinal and neuroendocrine differentiation in gastric adenocarcinoma (Oue et al. 2005). Bishnupuri et al. (2006a) examined Reg gene expression and associated changes in anti-apoptotic genes in an animal model of GI tumorigenesis and showed that dys-regulation of Reg genes occurs early in tumorigenesis. Furthermore, increased expression of Reg genes, specifically Reg IV contribute to adenoma formation and lead to increased resistance to apoptotic cell death in CRC (Bishnupuri et al. 2006a). Serum olfactomedin 4 (GW112, hGC-1) in combination with Reg IV is a highly sensitive biomarker for gastric cancer patients (Yoshida and Yasui 2009).

Levels of Reg IV protein in peritoneal lavage fluids increased in Reg IV-transfectants inoculated mice, but decreased in Reg IV-knockdown cell inoculated mice. It appears that Reg IV might accelerate peritoneal metastasis in gastric cancer and that Reg IV in lavage might be a good marker for peritoneal metastasis (Kuniyasu et al. 2009). The serum Reg IV concentration in presurgical gastric cancer patients is significantly elevated even at stage I and represents a novel biomarker for gastric cancer (Mitani et al. 2007). Reg IV is involved in gallbladder carcinoma carcinogenesis through intestinal metaplasia and is associated with relatively favorable prognosis in patients after surgery. The serum level of Reg IV may be of use or indicative of neoplasia (Tamura et al. 2009).

39.11.1.1 Colorectal Cancer (CRC)

Regenerating IV gene is overexpressed in HT-29 drug-resistant cells and more strongly expressed in 71% of colorectal tumors (in particular in mucinous carcinomas) than in normal colon tissues. Reg IV overexpression may be an early event in CRC carcinogenesis. A high level of RegIV and RegIV CRD expression was demonstrated in RegIV and RegIV CRD-transfected cells. RegIV enhances LoVo cell migration and invasion, and its CRD domain is critical for these effects (Guo et al. 2010). The comparison of Reg IV expression with that of other REG genes, regenerating Iα (Reg Iα), Reg Iβ and PAP, highlights its predominant expression in colorectal tumors (Violette et al. 2003). The over-expression of Reg IV in CRCs was significantly lower and inversely correlated with poor differentiation and venous invasion. Serum levels of Reg IV may predict CRC recurrence in the liver (Li et al. 2010; Oue et al. 2007). The expression of Reg IV in CRCs was positively linked to MUC2 and phosphorylation of the EGFR on Tyr^{1068}, suggesting that Reg IV may be a useful marker for intestinal type mucinous carcinoma and a good candidate as a molecular therapeutic target for CRCs. Reg IV is a potent activator of the EGF receptor/Akt/AP-1 signaling pathway in CRC (Bishnupuri et al. 2006b). Detection of Reg IV overexpression may be useful in the early diagnosis of carcinomatous transformation of adenoma (Zhang et al. 2003b). Reg IV is an important modulator of gastrointestinal cell susceptibility to irradiation; hence, it is a potential target for adjunctive treatments for human CRC and other gastrointestinal malignancies (Bishnupuri et al. 2010).

To clarify the role of Reg IV in gastric carcinogenesis and subsequent progression, Zheng et al. (2010) indicated that Reg IV expression experienced up-regulation in gastric intestinal metaplasia and adenoma and then down-regulation with malignant transformation of gastric epithelial cells. It was suggested that Reg IV expression is a good biomarker for gastric precancerous lesions and is especially related to the histogenic pathway of signet ring cell carcinoma (Zheng et al. 2010).

39.11.1.2 Marker for Hormone Refractory Metastatic Prostate Cancer

Gene, Reg IV is differentially expressed in the LAPC-9 hormone refractory xenograft. Consistent with its up-regulation in a hormone refractory xenograft, it is expressed in several prostate tumors after neoadjuvant hormone ablation therapy. As predicted by its sequence homology, it is secreted from transiently transfected cells. It is also expressed strongly in a majority of hormone refractory metastases. In comparison, it is not expressed by any normal prostate specimens and only at low levels in approximately 40% of primary tumors. Reports support Reg IV is a candidate marker for hormone refractory metastatic prostate cancer (Gu et al. 2005; Ohara et al. 2008). Serum Reg IV represents a novel biomarker for prostate cancer (Hayashi et al. 2009). Reg IV participates in 5-fluorouracil (5-FU) resistance and peritoneal metastasis, and its expression was associated with an intestinal phenotype of gastric cancer and with endocrine differentiation (Yamagishi et al. 2009; Yasui et al. 2009). Signet-ring cell carcinoma (SRCC) is a unique subtype of adenocarcinoma that is characterized by abundant intracellular mucin accumulation. Reg IV staining and claudin-18 staining can aid in diagnosis of gastrointestinal SRCC (Oue et al. 2008).

39.12 Islet Neogenesis-Associated Protein (INGAP) in Hamster

39.12.1 Characterization

Islet neogenesis-associated protein (INGAP) is expressed in islets and in exocrine pancreatic cells of normal hamsters. INGAP is a 175-amino-acid pancreatic acinar protein that

stimulates pancreatic duct cell proliferation in vitro and islet neogenesis in vivo. The INGAP gene is a novel pancreatic gene expressed during islet neogenesis whose protein product is a constituent of Ilotropin and is capable of initiating duct cell proliferation, a prerequisite for islet neogenesis. Induction of islet neogenesis by cellophane wrapping (CW) reverses streptozotocin-induced (STZ) diabetes. Administration of Ilotropin, a protein extract isolated from CW pancreata, causes recapitulation of normal islet ontogeny and reverses STZ diabetes. Although INGAP shows homology to the PAP and Reg/PSP families of genes, the increased expression of INGAP in CW is unlikely to be a result of acute pancreatitis (Rafaeloff et al. 1997). Sasahara et al. (2000) reported a INGAP-related protein (INGAPrP). While INGAP expressed in cellophane-wrapped pancreas and not in normal pancreas, the INGAPrP was abundantly expressed in normal pancreas. INGAP could be a potentially useful tool to treat conditions in which there is a decrease in β-cell mass (Del Zotto et al. 2000). A 6 kb of hamster genomic INGAP has identified a 3 kb 5-prime region with core promoter elements that is rich in transcription factor binding sites and six exons for the coding region. Analysis of promoter activity reveals stimulus-responsive DNA elements which have been identified though deletion analysis. Comparison of transcription factor binding sites in INGAP to the related gene Reg-IIIδ exposes potential sites for differential gene regulation (Taylor-Fishwick et al. 2003).

The ubiquitous localization of INGAP suggests its possible role in the physiological process of islet growth and its protective effect upon streptozotocin-induced diabetes (Flores et al. 2003). It participates in the regulation of islet neogenesis, and PDX-1/INGAP-positive cells represent a new stem cell subpopulation at an early stage of development, highly activateable in neogenesis (Flores et al. 2003; Gagliardino et al. 2003). Findings implicate PDX-1 in a possible feedback loop to block unbridled islet expansion (Taylor-Fishwick et al. 2006). INGAP expression is probably restricted to pancreas cells exerting its effect in a paracrine fashion. INGAP would be released and circulate bound to a serum protein from where it is bound and inactivated by the liver. Tissue binding could also explain INGAP's immunocytochemical presence in small intestine, where it could affect epithelial cell turnover (Borelli et al. 2007). INGAP stimulates cells in the pancreatic duct epithelium of healthy dogs (putative islet progenitor cells) to develop along a neuroendocrine pathway and form new islets in response to INGAP peptide. The INGAP might be an effective therapy for diabetes (Pittenger et al. 2007)**.** INGAP is localized to the pancreatic endocrine cells in mouse. INGAP- and insulin-immunoreactive cells are mutually exclusive, with INGAP-immunoreactive cells being preserved after streptozotocin-mediated destruction of β-cells. Findings reveal that INGAP and/or related group 3 Reg proteins have a conserved expression in the pancreatic islet (Taylor-Fishwick et al. 2008).

39.12.2 Properties of Pentadecapeptide from INGAP

A pentadecapeptide having the 104–118 amino acid sequence of INGAP (INGAP-PP) affects insulin secretion and transcript profile expression in cultured normal pancreatic neonatal rat islets. Islets cultured with INGAP-PP released significantly more insulin in response to glucose than those cultured without the peptide. INGAP-PP enhances specifically the secretion of insulin and the transcription of several islet genes, many of them directly or indirectly involved in the control of islet metabolism, β-cell mass and islet neogenesis. Studies strongly indicate an important role of INGAP-PP, and possibly of INGAP, in the regulation of islet function and development (Barbosa et al. 2006; Barbosa et al. 2008). Whilst the peptides with scrambled sequences showed no definite prevalent structure in solution, INGAP-PP maintained a notably stable tertiary fold, namely, a conformer with a central β-sheet and closed C-terminal. Such structure resembles the one corresponding to the amino acid sequence of human PAP-1, which presents 85% sequence homology with INGAP. These results explain why the two scrambled sequences tested showed no biological activity, while INGAP-PP significantly increases β-cells function and mass both in vitro and in vivo conditions. These data can help to obtain more potent INGAP-PP analogs, suitable for the prevention and treatment of diabetes (McCarthy et al. 2009)

Administration of the peptide fragment of INGAP (INGAP peptide) has been demonstrated to reverse chemically induced diabetes as well as improve glycemic control and survival in an animal model of type 1 diabetes. Cultured human pancreatic tissue has also been shown to be responsive to INGAP peptide, producing islet-like structures with function, architecture and gene expression matching that of freshly isolated islets. Studies in normoglycemic animals show evidence of islet neogenesis. These clinical studies suggest an effect of INGAP peptide to improve insulin production in type 1diabetes and glycemic control in type 2 diabetes (Lipsett et al. 2007). The INGAP peptide acts as a mitogen in the peripheral nervous system (PNS), and enhances neurite outgrowth from DRGs in vitro. The neuritogenic action of INGAP peptide correlates with an increase in ^{3}H-thymidine incorporation and mitochondrial activity and promotes Schwann cell proliferation in the DRG which releases trophic factors that promote neurite outgrowth (Tam et al. 2002).

Emerging Groups of C-Type Lectins

40

G.S. Gupta

40.1 Layilin Group of C-Type Lectins (Group VIII of CTLDS)

40.1.1 Layilin: A Hyaluronan Receptor

Layilin, a ~55-kDa lectin, is a widely expressed integral membrane hyaluronan receptor, originally identified as a binding partner of talin located in membrane ruffles. It is recruited to membrane ruffles in cells induced to migrate in in vitro wounding experiments and in peripheral ruffles in spreading cells. Layilin is a transmembrane C-type lectin (Fig. 40.1) and binds specifically to hyaluronan (HA) but not to other tested glycosaminoglycans and belongs to group VIII of CTLDs. The other member of this group is chondrolectin. Layilin's ability to bind hyaluronan reveals an interesting parallel between layilin and CD44, because both can bind to cytoskeleton-membrane linker proteins through their cytoplasmic domains and to hyaluronan through their extracellular domains. This parallelism suggests a role for layilin in cell adhesion and motility (Banerji et al. 1999; Bono et al. 2001). There is no sequence homology with known hyaluronan receptors, including CD44, RHAMM (receptor for HA-mediated motility), or LYVE-1 (lymphatic vessel endothelial HA receptor-1). Thus, by binding to HA, layilin may facilitate cell migration by mediating early interactions between spreading cells and the extracellular matrix (ECM). Since, hyaluronan is involved in invasion of a variety of tumor cells and layilin was detected in the human lung cell line A549, layilin might play crucial roles in lymphatic metastasis of lung carcinoma. Suppression of layilin expression by iRNA significantly increased survival of tumor-bearing mice. The suppression of layilin expression might be a promising strategy for treatment of human lung carcinoma (Chen et al. 2008).

40.1.2 Interactions of Layilin

The actin cytoskeleton plays a significant role in change of cell shape and motility. Several adaptor proteins, including talin, maintain the cytoskeleton-membrane linkage by binding to integral membrane proteins and to the cytoskeleton. The talin binds to integrins, vinculin, actin and layilin. A ten-amino acid motif in layilin cytoplasmic domain is sufficient for talin binding. Layilin colocalizes with talin in ruffles and binds to talin's ~50-kDa head domain (amino acids 280–435). This region overlaps a binding site for focal adhesion kinase (Borowsky and Hynes 1998). The other known binding partners of layilin include other members of the talin/band 4.1/ERM (ezrin, radixin, and moesin) family of cytoskeletal-membrane linker molecules. The neurofibromatosis 2 tumor suppressor protein, merlin, is commonly mutated in human benign brain tumors. Merlin and radixin interact with the carboxy-terminal domain of layilin. This suggests that layilin may mediate signals from extracellular matrix to the cell cytoskeleton via interaction with different intracellular binding partners and thereby be involved in the modulation of cortical structures in the cell (Bono et al. 2005; Scoles 2008). The talin F3 domain binds to short sequences in the layilin cytoplasmic domain, integrins, and PIPK1γ (Wegener et al. 2008).

40.1.3 Functions of Layilin

The colocalization of layilin with talin and the binding interaction between them make layilin as a good candidate for a membrane-binding site for talin in ruffles. The colocalization of both epitope-tagged and endogenous layilin with talin in actin-rich membrane ruffles and significant homology to proteins with C-type lectin activity of layilin leads to suggest two general models for layilin

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_40, © Springer-Verlag Wien 2012

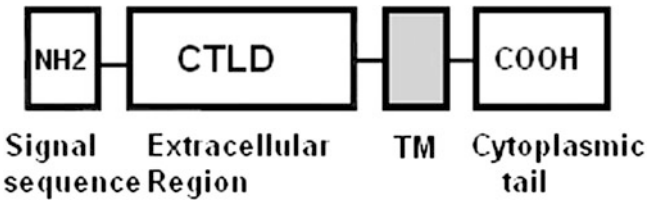

Fig. 40.1 The protein domains of layilin. Sig (NH_2-terminal signal sequence), Lectin (layilin's extracellular part which is homologous to C-type lectins) and TM (transmembrane) domain

function. In the first model, layilin acts in cell migration by anchoring to the membrane talin, which in turn binds F-actin. This chain of interactions may transmit force from actin to the membrane, resulting in its characteristic deformation into ruffles. In this scenario, layilin may serve simply as a talin docking site, or it could be an early-acting adhesion molecule that binds extracellular matrix, nucleating the formation of focal contact precursors at the cell periphery. In this case, layilin would be functioning analogously to selectins, which mediate transient adhesion between rolling leukocytes and the endothelium followed by tight integrin-mediated adhesion. However, whereas selectins mediate cell adhesion in specialized cells of immune system, it was hypothesized that layilin performs fundamental cell adhesion tasks common to most cells because layilin and talin are present in many different tissues. Layilin would thus form transient adhesion sites between ruffles and extracellular matrix that are refined into focal contacts after integrin recruitment. This could occur in both spreading and migrating cells. Talin, which can bind both layilin and integrins, may provide continuity between the two types of cell–matrix linkages as transient layilin-containing structures mature into integrin-containing focal adhesions. Integrin extracellular matrix receptors are known to be signaling as well as adhesion receptors, and if layilin encounters matrix early in the process of cell adhesion it may also signal. The three internally repeated motifs in the layilin cytoplasmic domain are potential binding sites for cytoskeletal or signaling molecules in addition to talin. Conservation of these motifs in hamster and human layilins suggests that they are of importance, and two of these repeats form a binding-site for talin (Borowsky and Hynes 1998). In the second model, layilin may function as an endo- or phagocytic receptor, similar to some other C-type lectins such as the macrophage mannose receptor. This model is suggested by the observation that talin is present in phagocytic cups in macrophages and at the sites of uptake of some bacterial pathogens (Young et al. 1992). In addition, the layilin cytoplasmic domain contains two YXXΦ motifs (YNVI, YDNM). These motifs are similar to sequences that mediate clathrin-dependent endocytosis of other membrane proteins by binding to the μ_2 chain of the AP-2 adaptor complex (Ohno et al. 1995; Marks et al. 1997; Borowsky and Hynes 1998).

40.1.4 Chondrolectin (CHODL)

The *Chondrolectin (Chodl)*, a novel human gene encoding chondrolectin is localized at chromosome 21q21 and consists of six exons and five introns. The ORF of *Chodl* encodes a type I transmembrane protein containing a single CRD of C-type lectins in its extracellular portion. CHODL expresses in testis, prostate, and spleen and the expression of CHODL is mainly limited to vascular muscle of testis, smooth muscle of prostate stroma, heart muscle, skeletal muscle, crypts of small intestine, and red pulp of spleen. CHODL is an N-glycosylated protein with a molecular weight of ~36 kDa and shows a predominantly perinuclear localization in transiently transfected COS1 cells. Although the predicted CHODL protein shares a significant homology (45% overall and 60% within the CRD) with layilin, a hyaluronan receptor, there was no specific interaction between CHODL and hyaluronan using cetylpyridinium chloride precipitation (Weng et al. 2002).

The mouse orthologue of human chondrolectin gene, *Chodl* is located at chromosome 16C3 and consists of six exons and five introns. The putative full-length mouse cDNA of *Chodl* consists of 2393 bp, with an ORF of 839 bp, 243 bp of 5′ untranslated region and 1310 bp of 3′ untranslated region. The predicted CHODL protein containing one CRD of C-type lectin in its extracellular portion shares a similarity (45%) with human layilin. In adult mice, CHODL is preferentially expressed in skeletal muscle, testis, brain, and lung. During gestation, E 7–15 its expression is up-regulated (Weng et al. 2003).

40.2 Tetranectin Group of Lectins (Group IX of CTLDs)

The tetranectin group of CTLD-containing secreted proteins has three members in both human and mouse: tetranectin (TN), cartilage-derived C-type lectin, and stem cell growth factor (SCGF). Each polypeptide has an N-terminal tail rich in charged residues, a central neck region, and a C-terminal CTLD. The neck region mediates homotrimerization through the formation of a coiled-coil of α-helices. It is not known if carbohydrate recognition plays a role in the function of TN group of proteins. The CTLDs in these proteins

resemble CTLDs of the galactose-binding subtype, but attempts to demonstrate sugar-binding activity have not been successful.

40.2.1 Tetranectin

By stimulating plasminogen activation, Tetranectin (TN) may regulate proteolysis of extracellular matrix components in development, tissue remodelling and cancer, and influence the proteolytic activation of proteases and growth factors. Tetranectin is a member of the C-type lectin family and can be detected in serum and the extracellular matrix. It is composed of three identical, non-covalently linked 20 kDa subunits, and binds to the fourth kringle domain of plasminogen, which can stimulate plasminogen activation in vitro (Høgdall 1998). Each of the mature TN monomer of 181 amino acids consists of three functional domains encoded by separate exons (Fuhlendorff et al. 1987; Wewer and Albrechtsen 1992). A short lysine-rich region at the N terminus binds to heparin (Lorentsen et al. 2000). This domain is followed by an α-helical domain responsible for multimerization by forming a triple coiled-coil α-helix (Nielsen et al. 1997). The final 132 amino acids comprise a C-type lectin-like domain, homologous to the CRD of calcium-dependent animal lectins (Drickamer 1999) and contain binding sites for calcium and plasminogen (Graversen et al. 1998). The three intrachain disulfide bonds connect Cys residues 50–60, 77–176, and 152–168. The TN is homologous (17–24% identical positions) with those parts of the asialoglycoprotein receptor family that are considered to be extracellular. The TN has no structures corresponding to those parts of the receptors considered to be intracellular and membrane anchoring. The sequence of TN is also homologous (22–23% identical positions) with the C-terminal globular domain of the core protein of the cartilage proteoglycan (Fuhlendorff et al. 1987). In addition, O-linked glycosylation of the TN molecule at threonine 4 has been described (Fuhlendorff et al. 1987; Jaquinod et al. 1999). Tetranectin has a distinct binding site in its N-terminus that mediates binding to complex sulfated carbohydrates (e.g., heparin) (Lorentsen et al. 2000). The N-terminus of TN could, therefore, mediate binding to ECM components. The crystal structure of TN is similar to that of mannose binding protein, a member of the collectin group of the C-type lectin superfamily, except that the presence of an extra disulfide bridge in TN may restrict the flexibility of the C-type lectin-like domain (Nielsen et al. 1997). The CTLD of TN undergoes structural rearrangements upon calcium binding and in its calcium-free form binds to proteins with kringle domains, such as plasminogen and to isolated kringle-4 (Clemmensen et al. 1986), apparently to its lysine-binding site. Recombinant tetranectin- as well as natural tetranectin from human plasma was shown to be a homo-trimer in solution as are other lectins in collectin family of C-type lectins.

The gene for human TN is about 12 kbp and contains two intervening sequences. The gene encodes a protein of 202 amino acid residues, with a signal peptide of 21 amino acid residues, followed by the TN sequence of 181 amino acid residues (M_r = 20,169 Da) (Wewer and Albrechtsen 1992). The 3′ noncoding region contained a single polyadenylation signal and a 26-residue poly A tail. This protein is produced locally by cells of the stromal compartment of tumors and is deposited into the extracellular matrix. Since TN binds to plasminogen, it could function as an anchor and/or reservoir for plasminogen and similar substances that regulate tumor invasion and metastasis as well as tumor angiogenesis (Wewer and Albrechtsen 1992).

By screening a human chromosome 3 somatic cell hybrid mapping panel, Durkin et al. (1997) localized the human TN gene to 3p22–p21.3, which is distinct from the loci of two human connective tissue disorders that map to the short arm of chromosome 3, MFS2 and LRS. The human TN gene consists of three exons (Durkin et al. 1997). Each separate exon encodes specific functional domains. The short exon 1 encodes the heparin binding site of TN. The second exon encodes an α helix protein, which governs the trimerisation of TN monomers by assembling them into a triple helical coiled structural element. The final exon encodes a C-type lectin-like domain, homologous to the carbohydrate recognition domains of calcium dependent animal lectins (Nielsen et al. 2000). Biochemical evidence shows that an N-terminal domain encoded within exons 1 and 2 of the tetranectin gene is necessary and sufficient to govern subunit trimerization (Holtet et al. 1997). The human, mouse, and chicken TN cDNA sequences and gene structures are very similar (Berglund and Petersen 1992; Ibaraki et al. 1995; Sørensen et al. 1995, 1997; Wewer and Albrechtsen 1992; Xu et al. 2001). Neame et al. (1992) isolated a protein from reef shark (Carcharhinus springeri) cartilage that bears a striking resemblance to TN monomer originally described by Clemmensen et al. (1986). The amino acid sequence had 166 amino acids and a calculated molecular weight of 18,430. The shark protein was 45% identical to human TN, indicating that it was in the family of mammalian C-type lectins and an analog of human TN (Neame et al. 1992).

Murine Tetranectin: The mouse TN 992-bp cDNA with an open reading frame of 606 bp is identical in length to the human TN cDNA encoding a protein of 202 aa including a signal peptide of 21 aa. An overall identity of 79–87% in amino acids between human and murine TN revealed a high evolutionary conservation of the protein. The highest

expression of mouse TN was found in lung and skeletal muscle. The sequence analysis revealed a difference in both sequence and size of the non-coding regions between mouse and human cDNAs. The cloned murine TN was mapped to region F1-F3 on mouse chromosome 9. Mapping of the transcription start point (tsp) suggests that murine TN has more than one of these. In addition, no consensus TATA-box was found uptream for the putative tsp(s) in the 5′-flanking region of the gene, indicating that the murine TN promoter belongs to the TATA-less class of genes (Ibaraki et al. 1995; Sørensen et al. 1997).

40.2.2 Cell and Tissue Distribution

Tetranectin shows a wide tissue distribution. Predominantly, it was found in secretory cells of endocrine tissue like pituitary, thyroid, parathyroid glands, and the liver, pancreas, and adrenal medulla. Endocrine cells with a known protein or glycoprotein hormonal production such as chromophils (pituitary), follicular and parafollicular cells (thyroid), chief cells (parathyroid), hepatocytes (liver), islet cells (pancreas) and ganglion cells of the adrenal medulla displayed a convincing, positive staining reaction for TN, which varied from cell to cell within the different tissues. The liver showed a distinct and universal reaction within almost all hepatocytes, thus raising suspicion of producing the bulk of TN to the blood. Suspicion indicates that this protein might have a dual function, serving both as a regulator in the secretion of certain hormones and as a participant in the regulation of the limited proteolysis, which is considered important for the activation of prohormones (Christensen et al. 1987; Jensen et al. 1987). TN was found in endothelial and epithelial tissues, particularly in cells with a high turn-over or storage function such as gastric parietal and zymogenic cells, absorptive surface epithelium of the small intestine, ducts of exocrine glands and pseudostratified respiratory epithelium. Also mesenchymal cells produced a TN positive staining reaction, which was most conspicuous in mast cells, but also present in some lymphocytes, plasma cells, macrophages, granulocytes, striated and smooth muscle cells and fibroblasts (Christensen et al. 1989). Hermann et al. (2005) described the in vivo and in vitro localisation of TN in human and murine islet cells. The amount and localization of TN is influenced by different culture conditions. Tetranectin may play an important role in the survival of islets in the liver after islet transplantation.

A distinct accumulation of TN was observed in the surrounding extracellular matrix of various carcinomas where it colocalized with plasminogen (De Vries et al. 1996). Plasma levels of TN are approximately 100 nM in healthly adults (Jensen and Clemmensen 1988). Tetranectin is also found in a mobilizable set of granules in neutrophils (Borregaard et al. 1990), in monocytes (Nielsen et al. 1993), fibroblasts (Clemmensen et al. 1991), platelets (Christensen 1992), and in various tissue locations like cartilage and the extracellular matrix of developing or regenerating muscle (Wewer et al. 1994; Clemmensen et al. 1991; Wewer et al. 1998). Furthermore, TN is a crucial component of the extracellular matrix during muscle cell development and regeneration. During muscle cell development and regeneration, TN expression marks active myogenesis in vivo and in vitro (Wewer et al. 1998a). The decrease in concentration of TN in serum after myocardial infarction (Kamper et al. 1998a) suggests consumption of circulating soluble TN during myocardial repair. A role in skeletal formation during development was evidenced since targeted deletion of the protein results in spinal deformity (Iba et al. 2001a). Iba et al. (2009) also supported that TN might play a role in the wound healing process.

Crab-eating macaque serum showed the strongest reaction for TN, followed by horse and cat. Serum from cow, goat, pig, mouse and chicken reacted weakly, while dog, trout, and the amphibian and the reptile species did not react (Thougaard et al. 2001). TN has been demonstrated in normal brain and CSF. In amniotic fluid a significant, positive correlation exists between TN concentration and gestational age. Fetal TN has been correlated to fetal maturation (Høgdall et al. 1998). Tetranectin is enriched in the cartilage of the shark. During osteogenesis, in the newborn mouse, strong TN immunoreactivity was found in the newly formed woven bone around the cartilage anlage in the future bone marrow and along the periosteum forming the cortex. TN may play an important direct and/or indirect role during osteogenesis and my have a potential role in mineralization in vivo and in vitro (Wewer et al. 1994).

40.2.3 Interactions of Tetranectin

Interactions with Complex Sulfated Polysaccharides

Tetranectin interacts with complex sulfated polysaccharides (Clemmensen 1989; Lorentsen et al. 2000), in a lysine sensitive way, specifically with apolipoprotein A (Kluft et al. 1989a), and in a calcium dependent fashion with fibrin (Kluft et al. 1989b). The distinct binding properties of TN to plasminogen and its expression in normal tissue development point to an important physiological function of TN in tissue formation and repair. Fourth kringle domain of plasminogen can stimulate plasminogen activation in vitro. In the search for new ligands for the plasminogen kringle-4 binding-protein TN, it has been found that TN specifically bound to the plasminogen-like hepatocyte growth factor and tissue-type plasminogen activator. The dissociation constants of these complexes were found to be within the same order of magnitude as the one for the plasminogen-tetranectin complex. TN did not interact with the kindred proteins: macrophage-stimulating protein, urokinase-type plasminogen activator and prothrombin (Westergaard et al. 2003).

Kluft et al. (1989a) demonstrated reversible binding of apolipoprotein-A to kringle-4-binding with an apparent K_D of 0.013 μM/l, where as Lys- and Glu-plasminogen showed an apparent K_D of 0.5 μM/l. It suggested that plasminogen and lipoprotein-A show functional analogy in their binding to TN, but TN primarily targets at lipoprotein-A (Kluft et al. 1989a). TN binds to fibrin and the amount of TN bound to fibrin varies with TN in plasma. Normally, it constitutes a constant percentage of 13–17% of plasma TN. The TN, which is reduced in serum after blood clotting can, upon coagulation, be released from platelets and become partially bound to fibrin (Kluft et al. 1989b). TN may interact with angiostatin, which is formed in cancer tissues by proteolytic degradation of plasminogen. The predominant form of angiostatin produced in cancer tissues is AST^{K1-4} (O'Reilly et al. 1994; Gately et al. 1997; Richardson et al. 2002), which inhibits cancer progression and metastasis by inhibiting cancer-related angiogenesis. Mogues et al. (2004) demonstrated that TN binds to the kringle 1–4 form of angiostatin (AST^{K1-4}) and reduces its ability to bind to ECM of endothelial cells or to inhibit endothelial cell growth.

Plasminogen and Heparin-Binding Sites in Tetranectin: TN, related to corresponding regions of the mannose-binding proteins, is known specifically to bind the plasminogen kringle-4 protein domain, an interaction sensitive to lysine. Surface plasmon resonance and isothermal calorimetry binding analyses using single-residue and deletion mutant TN derivatives showed that the kringle-4 binding site resides in the CRD and includes residues of the putative carbohydrate binding site. Furthermore, the interaction is sensitive to calcium in addition to lysine (Graversen et al. 1998). The heparin-binding site in TN resides not in the CRD but within the N-terminal region, comprising the 16 amino acid residues encoded by exon 1. In particular, the lysine residues in the decapeptide segment KPKKIVNAKK (TN residues 6–15) at the N terminus are shown to be of primary importance in heparin binding (Lorentsen et al. 2000).

Tetranectin-Binding Site on Plasminogen Kringle-4: It was reported that all amino acid residues of plasminogen kringle-4 were involved in binding to TN. Notably, one amino acid residue of plasminogen kringle-4, Arg^{32}, not involved in binding trans-aminomethyl-cyclohexanoic acid (t-AMCHA), is critical for binding TN. Moreover Asp^{57} and As ^{55} of plasminogen kringle-4, which both were found to interact with low molecular weight ligand with an almost identical geometry in the crystal of the complex, are not of equal functional importance in t-AMCHA binding. Mutating Asp^{57} to an Asn totally eliminates binding, whereas the Asp^{55} to Asn, like the Arg^{71} to Gln mutation, was found only to decrease the affinity (Graversen et al. 2000a).

A site, involving Lys^{148}, Glu^{150}, and Asp^{165} in TN is known to mediate calcium-sensitive binding to plasminogen kringle-4. Substitution of Thr^{149} in TN with a tyrosine residue considerably increases the affinity for plasminogen kringle-4, and, in addition, confers affinity for plasminogen kringle 2. This new interaction is stronger than the binding of wild-type TN to plasminogen kringle-4. The insight into molecular determinants is important for binding selectivity and affinity of C-type lectin kringle interactions (Graversen et al. 2000b).

40.2.4 Crystal Structure of Tetranectin

Tetranectin is a homotrimeric protein (TN3) which contains a C-type lectin-like domain. The TN3 domain can bind calcium. In absence of calcium, the TN3 domain binds a number of kringle-type protein ligands. The structure of calcium free-form of TN3 (apoTN3) has been studied by NMR. Compared to the structure of the calcium-bound form of TN3 (holoTN3), the core region of secondary structural elements is conserved, while large displacements occur in the loops involved in calcium or K4 binding. A conserved proline, present in *cis* conformation in holoTN3, is in apoTN3 predominantly in the *trans* conformation. Backbone dynamics indicated that, in apoTN3 especially, two of the three calcium-binding loops and two of the three K4-binding residues exhibit increased flexibility, whereas no such flexibility was observed in holoTN3. In apoTN3, the residues critical for K4 binding, are spanned over a large conformational space. Study indicated that the K4-ligand-binding site in apoTN3 is not preformed (Nielbo et al. 2004).

The recombinant human TN and the CRD of TN3 have been crystallized. TN3 crystallizes in the tetragonal space group $P4_22_12$ with cell dimensions a = b = 64.0, c = 75.7 A and with one molecule per asymmetric unit. The crystals of TN are rhombohedral, space group R3, with the hexagonal axes a = b = 89.1, c = 75.8 A, and diffract to at least 2.5 A. The asymmetric unit contains one monomer of TN. The rhombohedral space group indicates that trimers of TN are formed in accordance with the observation of trimerization in solution (Kastrup et al. 1997). The two C-terminal domains, TN23 (residues 17–181) of human recombinant TN have been crystallized in two different space groups. Crystals belonging to the monoclinic space group C2 showed unit-cell parameters: a = 160.4, b = 44.7, c = 107.5 A, β = 127.6º. TN23 crystallizes in a rhombohedral space group, with unit-cell parameters a = b = c = 107.4 A, α = β = γ = 78.3º. A full data set to 4.5 A, collected from the monoclinic crystals, shows that TN23 crystallizes as a trimer, with one trimer in the asymmetric unit (Nielsen et al. 2000).

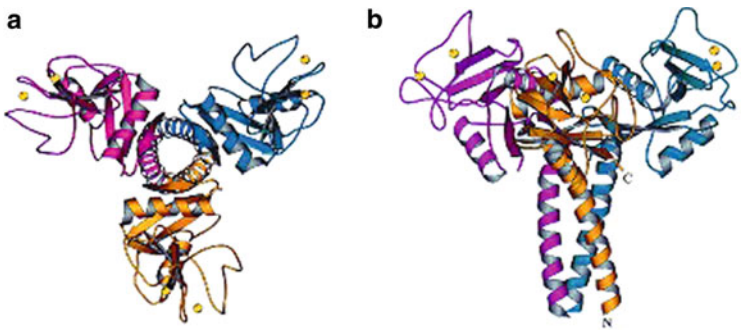

Fig. 40.2 (**a** and **b**): The overall structure of the TN trimer viewed (**a**) along and (**b**) perpendicular to the threefold axis (Reprinted by permission from Macmillan Publishers Ltd: FEBS Letters, Nielsen et al. © 1997)

Human tetranectin is a homotrimer forming a triple α-helical coiled coil. Each monomer consists of a CRD connected to a long α-helix. TN has been classified in a distinct group of the C-type lectin superfamily but has structural similarity to the proteins in the group of collectins. TN has three intramolecular disulfide bridges. Two of these are conserved in the C-type lectin superfamily, whereas the third is present only in long-form CRDs. In TN, the third disulfide bridge tethers the CRD to the long helix in the coiled-coil. The residues 26–52 of TN form a long α-helix (E2), which is connected to the CRD. The CRD of TN has characteristic topology similar to other proteins of the C-type lectin superfamily. However, structural differences occur at insertions and deletions in TN as compared to human lithostathine, human MBP, and human E-selectin (Nielsen et al. 1997). Two calcium ions have been located at same positions as calcium-binding sites 1 and 2 in structures of MBPs. In TN, the ligands are Asp^{116}, Glu^{120}, Gly^{147}, Glu^{150}, and Asn^{151} at calcium site 1 and Gln^{143}, Asp^{145}, Glu^{150}, and Asp^{165} at calcium site 2. TN, as well as lithostathine, contains a long-form CRD with three disulphide bridges in contrast to MBPs and E-selectin, which have short-form CRDs with two disulfide bridges. In TN, the disulfide bridge Cys^{50}-Cys^{60} tethers the E2 helix to a short L-strand of the CRD, whereas this disulfide bridge is part of a loop in lithostathine.

The long E2 helix provides trimerization of TN by the formation of a triple α-helical coiled coil (Fig. 40.2a, b). Only few contacts were observed among the CRDs of the trimer, in agreement with the observation that the isolated CRD of TN is a monomer in solution. The trimeric structure of TN (TN3) resembles those of rat MBP and human MBP, in which the neck region forms a long α-helix. Each monomer is built of two distinct regions, one region consisting of six β-strands and two α-helices, and the other region is composed of four loops harboring two calcium ions. The calcium ion at site 1 forms an eightfold coordinated complex and has Asp^{116}, Glu^{120}, Gly^{147}, Glu^{150}, Asn^{151}, and one water molecule as ligands. The calcium ion at site 2, which is believed to be involved in recognition and binding of oligosaccharides, is sevenfold coordinated with ligands Gln^{143}, Asp^{145}, Glu^{150}, Asp^{165}, and two water molecules. One sulfate ion was located at the surface of TN, forming contacts to Glu^{120}, Lys^{148}, Asn^{106} of a symmetry-related molecule, and to an ethanol molecule (Kastrup et al. 1998). The orientations of the CRDs are determined by the coiled-coil structure, by intramolecular interactions between the helix and its CRD, and also by intermolecular interactions between each of the helices of the coiled-coil and a neighboring CRD. The trimerization of TN as well as the fixation of the CRDs relative to the helices in the coiled-coil indicates a demand for high specificity in the recognition and binding of ligands (Nielsen et al. 1997).

40.2.5 Functions of Tetranectin

Tissue Remodeling

The function(s) of TN in postnatal life have not been elucidated although there is evidence for roles in tissue remodeling, coagulation, and cancer. Tetranectin may affect coagulation and angiogenesis through interaction with fibrin and angiostatin (a plasminogen fragment), respectively. During development, TN stimulates muscle cell differentiation and fibre formation, and promotes bone mineralization. Tetranectin-deficient mice develop a spinal deformity. TN was originally isolated as a plasminogen-binding protein that can enhance plasminogen activation in presence of tissue plasminogen activator (Clemmensen et al. 1986). Tetranectin binds to plasminogen through a calcium-sensitive interaction of its C-terminal domain with kringle-4 domain of plasminogen (Graversen et al. 1998; Graversen et al. 2000b). Because of the distinct binding properties of TN and its dynamic expression in development and disease, one may expect that TN plays a role in tissue remodeling. The precise function of TN in these processes, however, is not known, and no human genetic disorders have yet been associated with mutations in the single-copy TN gene (Durkin et al. 1997).

Osteoblastic Activity

TN is also expressed during bone development, and transfection studies suggest that TN can induce osteogenesis (Wewer et al. 1994). Studies indicated that the expression of TN in osteoblastic cells is regulated by Dex and TGF-β 1 and that the TN expression is tightly linked to the process of mineralization. Expression of TN is completely inhibited by treatment with retinoic acid, irrespective of the stage of cell differentiation. Retinoic acid downregulates the TN expression in human osteoblastic cells independent of the stage of cell differentiation, and is correlated with inhibition of mineralization (Iba et al. 2001a). Targeted loss of TN expression interferes with proper postnatal development of the vertebral bodies and results in a mild spine deformity. The TN-deficient mice exhibit kyphosis, a type of spinal deformity characterized by an increased curvature of the thoracic spine. The spines of these mice revealed an apparently asymmetric development of the growth plate and of the intervertebral disks of the vertebrae. TN-null mice had a normal peak bone mass density and were not more susceptible to ovariectomy-induced osteoporosis than were their littermates (Iba et al. 2001b).

40.2.6 Association of TN with Diseases

The concentration of TN in human serum decreases in pathological conditions such as cancer (Høgdall 1998), myocardial infarction (Kamper et al. 1998a), and rheumatoid arthritis (RA) (Jensen and Clemmensen 1988; Christensen 1992; Kamper et al. 1998b). TN decreases with the increase of RA activity from group to group. Study points to the usefulness of TN assessment as a specific fibrinolytic marker in the evaluation of disease activity in patients with RA. Reports suggest the implication of TN in the impaired regulation of fibrinolysis associated with the inflammatory process (Kamper et al. 1998b). Acute coronary syndrome (ACS) is triggered by the occlusion of a coronary artery usually due to the thrombosis caused by an atherosclerotic plaque (Bugge et al. 1995). Some of the proteins identified have been associated with ACS whereas others (such as ς-1-B-glycoprotein, Hakata antigen, Tetranectin, Tropomyosin-4) constitute novel proteins that are altered in this pathology (Darde et al. 2010). Altered abundance of TN among few proteins suggests that it may be potential biomarker for alcohol abuse (Lai et al. 2009).

In Prognosis of Cancer

Tetranectin is significantly reduced in patients with various malignancies and may be related to the pathogenesis of cancer spread and metastasis (Jensen and Clemmensen 1988). TN has been detected in tumors of the breast, colon, stomach, and ovary, whereas no TN immunoreactivity was seen in the corresponding normal epithelium of the breast, colon, or ovary (Christensen and Clemmensen 1991; Arvanitis et al. 2002; Obrist et al. 2004). Notably, TN was colocalised together with plasminogen at the invasion front of cutaneous melanomas (De Vries et al. 1996). In case of ovarian cancer, decreased plasma levels of TN were a stronger predictor of adverse prognosis than cancer stage (Høgdall 1998). Furthermore, TN is present in the stroma of various cancers (e.g., breast, ovary, colon), whereas it is not present in normal tissue from which the cancers arose (Wewer and Albrechtsen 1992; Christensen and Clemmensen 1991; Tuxen et al. 1995). Positive staining for TN in cancer stroma has also been strongly correlated with cancer progression (Høgdall 1998). While several investigators have reported that plasma and serum TN concentrations in patients with malignant tumors correlate with disease stage and survival (Blaakaer et al. 1995; Høgdall 1998; Jensen and Clemmensen 1988; Høgdall 1998; Obrist et al. 2004), others found that TN expression in tumor tissue correlated with tumor histological grading (Høgdall 1998). A significantly shortened survival was found for patients with low serum TN values compared to patients with serum TN levels above one of the cutoff levels. Thus, serum TN determination may be valuable in the selection of patients with relapse of ovarian cancer for new treatment strategies in future studies (Deng et al. 2000; Høgdall et al. 2002b). While TN was a strong prognostic variable in patients with advanced ovarian cancer, CA125 was a strong prognostic factor in patients with a localised ovarian cancer and of no prognostic value in patients with advanced cancer (Høgdall et al. 2002a). Serum TN seems to be useful prognostic factor in metastatic breast cancer (Høgdall 1998; Begum et al. 2009; 2010). A slight, but significant reduction in serum TN was found in pelvic inflammatory disease patients. The finding is important in the assessment of TN used as a potential screening marker for ovarian cancer, or as a diagnostic tool for pelvic tumors (Høgdall 1998). Low serum levels of TN are associated with high serum levels of CASA or YKL-40 with increased risk of second-line chemoresistance in patients with ovarian cancer (Gronlund et al. 2006).

In patients with multiple myeloma, either untreated or previously treated, serum levels were found to be significantly reduced (Nielsen et al. 1990). The TN, in association with the circulating intercellular adhesive molecule-1 and IL-10, may be involved in the metastatic cascade of B-chronic lymphocytic leukemia (B-CLL). The findings and good performance characteristics of TN and cICAM-1 in B-CLL suggest the potential usefulness of these adhesive molecules as prognostic markers in B-CLL (Kamper et al. 1999). Colonic neoplasia is associated with a decrease in the tissue distribution of TN, without an obvious change in the tissue level, and a low plasma TN level (Verspaget et al. 1994). Høgdall et al. (2002a) confirmed that TN is a strong prognostic factor in patients with colorectal cancer and may be valuable as a prognostic variable in future studies

evaluating new treatment strategies for colorectal cancer. TN is expressed in a subgroup of bladder cancer patients with a higher risk of recurrence who may take benefit from a closer follow-up (Brunner et al. 2007).

Neurological Diseases

TN may play a role in neurological diseases and may serve as a diagnostic aid in multiple sclerosis (MS). TN appears in CSF of MS patients (Stoevring et al. 2005; 2006; Hammack et al. 2004). Wang et al. (2010a) suggest that CSF-TN and serum-TN are potential biomarkers in epilepsy and drug-refractory epilepsy and would be useful for diagnosis. The application of biomarkers may potentially improve the efficiency of the diagnosis for Parkinson's disease (PD), since no reliable biomarker has been identified to date. Preliminary results of Wang et al. (2010b) suggest that TN and apoA-I may serve as potential biomarkers for PD, though further validation is needed.

40.2.7 Cartilage-Derived C-Type Lectin (CLECSF1)

Cartilage-derived C-type lectin is expressed in cartilage, where it may have a role in organizing the extracellular matrix. Cartilage is a tissue that is primarily extracellular matrix, the bulk of which consists of proteoglycan aggregates constrained within a collagen framework. Candidate components that organize the extracellular assembly of the matrix consist of collagens, proteoglycans and multimeric glycoproteins. Neame et al. (1999) described the human gene structure of a potential organizing factor, a cartilage-derived member of the C-type lectin superfamily (CLECSF1; C-type lectin superfamily) related to tetranectin. The CLECSF1 is restricted to cartilage and the gene is located on chromosome 16q23. The 10.9 kb of sequence upstream of the first exon was characterized. Similarly to human TN, there are three exons. The residues that are conserved between CLECSF1 and TN suggest that the cartilage-derived protein forms a trimeric structure similar to that of TN, with three N-terminal α-helical domains aggregating through hydrophobic faces. The globular, C-terminal domain that has been shown to bind carbohydrate in some members of the family and plasminogen in TN, is likely to have a similar overall structure to that of TN.

40.2.8 Stem Cell Growth Factor (SCGF): Tetranectin Homologous Protein

The SCGF is expressed in skeletal and connective tissues, where it stimulates proliferation and differentiation of haematopoietic precursor cells. The cDNA encoding stem cell growth factor (SCGF; 245 aa), a human growth factor for primitive hematopoietic progenitor cells, has been reported by Hiraoka et al. (1997). This protein consists of 323, 328 and 328 aa in the human, murine and rat forms, the latter two of which share 85.1% and 83.3% aa identity, and 90.4% and 90.4% aa similarity to the human protein, respectively. Because the newly identified human clone encodes the protein longer by 78 aa than that identified earlier, the longer clone was termed as hSCGF-α and the shorter one as hSCGF-β. SCGF is a new member of the C-type lectin superfamily, and shows the greatest homology to TN among the members of the family (27.2–33.7% aa identity and 46.0–40.6% aa similarity). SCGF transcripts are detected in spleen, thymus, appendix, bone marrow and fetal liver. The SCGF gene is located on chromosome 19 at position q13.3 for human form, and on chromosome 7 at position B3-B5 for murine form, which are close to flk-2/flt3 ligand and interleukin-11 genes of both human and murine species (Mio et al. 1998).

40.3 Attractin Group of CTLDs (Group XI)

The autosomal recessive gene of attractin has received great attention within last few decades. The attractin group of CTLD-containing type 1 transmembrane proteins has two widely-expressed members in both human and mouse: attractin (ATRN) and attractin-like protein (ATRNL1).

40.3.1 Secreted and Membrane Attractins

Attractin, initially identified as a soluble human plasma protein with dipeptidyl peptidase IV (DPPIV) activity that is expressed and released by activated T lymphocytes, has also been identified as the product of the murine mahogany gene with connections to control of pigmentation and energy metabolism. The mahogany gene product, however, is a transmembrane protein, raising the possibility of a human membrane attractin in addition to the secreted form. The genomic structure of human attractin reveals that soluble attractin arises from transcription of 25 sequential exons on human chromosome 20p13, where the 3′ terminal exon contains sequence from a long interspersed nuclear element-1 (LINE-1) retrotransposon element that includes a stop codon and a polyadenylation signal. The mRNA isoform for membrane attractin splices over the LINE-1 exon and includes five exons encoding transmembrane and cytoplasmic domains with organization and coding potential almost identical to that of the mouse gene. The relative abundance of soluble and transmembrane isoforms is differentially regulated in lymphoid tissues. Since activation of peripheral blood leukocytes with phytohemagglutinin

induces strong expression of cell surface attractin followed by release of soluble attractin, results suggest that a genomic event unique to mammals, LINE-1 insertion, has provided an evolutionary mechanism for regulating cell interactions during an inflammatory reaction (Tang and Duke-Cohan 2000).

40.3.2 Attractin has Dipeptidyl Peptidase IV Activity?

Dipeptidyl peptidase IV (DPPIV) is a serine type protease with an important modulatory activity on a number of chemokines, neuropeptides and peptide hormones. It is also known as CD26 or adenosine deaminase (ADA; EC 3.5.4.4) binding protein. DPPIV has been demonstrated on the plasma membranes of T cells and activated natural killer or B cells as well as on a number of endothelial and differentiated epithelial cells. A soluble form of CD26/DPPIV has been described in serum. Attractin, the human orthologue of mouse mahogany protein, was postulated to be responsible for the majority of DPPIV-like activity in serum. 95% of the serum dipeptidyl peptidase activity is associated with a protein with ADA-binding properties. The natural DPPIV serum enzyme was confirmed as CD26 (Durinx et al. 2000). However, the attractin acts as a receptor or adhesion protein rather than a protease (Friedrich et al. 2007). Human peripheral blood monocytes express a DPPIV-like enzyme activity, which could be inhibited completely by the synthetic DPPIV inhibitor. Drugs directed to DPPIV-like enzyme activity can affect monocyte function via attractin inhibition (Wrenger et al. 2006). The expression of DPPV and attractin in circulating blood monocytes of human subjects are influenced by metabolic abnormalities with obesity being an important factor (Laudes et al. 2010). In the CNS, attractin has been detected in neurons and in glioma cell lines at different degree of transformation. In human U373 and U87 glioma cells, membrane-bound attractin displays hydrolytic activity between 5% and 25% of total cellular DPPIV-like enzyme activity, respectively. Attractin presence in glioma, but not in normal glial cells, together with its differential enzymatic activity, suggests its role in growth properties of tumors of glial cell origin (MalÃk et al. 2001).

Attractin is a normal human serum glycoprotein of 175 kDa that was found to be rapidly expressed on activated T cells and released extracellularly after 48–72 h. There are two mRNA species with hematopoietic tissue-specific expression that code for a 134-kDa protein with a putative serine protease catalytic serine. Both have large extracellular regions consisting of a membrane-distal epidermal growth factor (EGF) domain followed by a CUB domain; two EGF domains; five Kelch domains; a cysteine-rich/plexin domain; a CTLD; a second cysteine-rich/plexin domain; and two laminin EGF domains. Except for the latter two domains, the overall structure shares high homology with the *Caenorhabditis elegans* F33C8.1 protein, suggesting that attractin has evolved new domains and functions in parallel with the development of cell-mediated immunity (Duke-Cohan et al. 1998, 2000). Attractin is found in both membrane-bound and secreted forms as a result of alternative splicing.

40.3.3 Attractin-Like Protein

The gene dosage effect of melanocortin-4 receptor (MC4R) on obesity suggests that regulation of MC4-R expression is critically important to the central control of energy homoeostasis. In order to identify putative MC4-R regulatory proteins, Haqq et al. (2003) identified a positive clone that shares 63% amino acid identity with the C-terminal part of the mouse attractin gene product, a single-transmembrane-domain protein characterized as being required for agouti signaling through MC4R. A direct interaction between this (ATRNL1) and the C-terminus of the mouse MC4-R was confirmed and the regions in this interaction involved residues 303–313 in MC4-R and residues 1280–1317 in ATRNL1. ATRNL1 is highly expressed in brain, but also in heart, lung, kidney and liver. Furthermore, co-localization analyses in mice showed co-expression of ATRNL1 in cells expressing MC4-R in a number of regions known to be important in the regulation of energy homoeostasis by melanocortins, such as the paraventricular nucleus of hypothalamus and the dorsal motor nucleus of the vagus (Haqq et al. 2003).

Attractin and Attractin-like 1 are highly similar type I transmembrane proteins. *Atrn* null mutant mice have a pleiotropic phenotype including dark fur, juvenile-onset spongiform neurodegeneration, hypomyelination, tremor, and reduced body weight and adiposity, implicating ATRN in numerous biological processes. Bioinformatic analysis indicated that Atrn and Atrnl1 arose from a common ancestral gene early in vertebrate evolution. Characterization of Atrnl1 loss- and gain function mutant mice suggested that *Atrnl1* mutant mice were grossly normal with no alterations of pigmentation, CNS pathology or body weight. *Atrn* null mutant mice carrying a β-actin promoter-driven *Atrnl1* transgene had normal, agouti-banded hairs and significantly delayed onset of spongiform neurodegeneration, indicating that overexpression of ATRNL1 compensates for loss of ATRN. Thus, two genes are redundant from the perspective of gain-of-function but not loss-of-function mutations (Walker et al. 2007). The cytoplasmic region of ATRNL1 interacts with the cytoplasmic tail of the MC4R, a G-protein-coupled receptor in the brain which regulates appetite and metabolism, but the

function of ATRNL1 is not understood. The CTLDs in attractin and ATRNL1 contain some of the residues which in other CTLDs are involved in binding mannose-type sugars. It is not known if carbohydrate recognition by the CTLDs is involved in the functions of these proteins.

A heterozygous deletion of the *Attractin-like* (*ATRNL1*) gene in a patient presented with a distinctive phenotype comprising dysmorphic facial appearance, ventricular septal defect, toe syndactyly, radioulnar synostosis, postnatal growth retardation, cognitive impairment with autistic features, and ataxia. The phenotype of mice with homozygous *Atrn* mutations overlaps considerably with the features observed in this patient. It was postulated that patient's phenotype is caused by the deletion of ATRNL1 (Stark et al. 2010).

40.3.4 Functions of Attractin

Multiple Functions: Attractin is known to play multiple roles in regulating physiological processes that are involved in monocyte-T cell interaction, agouti-related hair pigmentation, and control of energy homeostasis. Attractin affects the balance between agonist and antagonist at receptors on melanocytes, modifies behaviour and basal metabolic rate, intervenes in the development of CNS and its functions. Attractin modulates an interaction between activated T cells and macrophages. The loss of murine membrane attractin due to mahogany mutation results with severe repercussions upon skin pigmentation and control of energy metabolism. In each of these latter instances, there is a strong likelihood that attractin is moderating the interaction of cytokines with their respective receptors. Attractin is performing a similar function in the immune system through capture and proteolytic modification of the N-terminals of several cytokines and chemokines. This regulatory activity allows cells to interact and form immunoregulatory clusters and subsequently aids in downregulating chemokine/cytokine activity once a response has been initiated. These two properties are likely to be affected by the balance of membrane-expressed to soluble attractin (Duke-Cohan et al. 2000). The attractin protein is involved in the suppression of diet-induced obesity. Its expression in brain has a significant relationship with obesity and indicates the therapeutic potential of attractin in the treatment of obesity. Furthermore, the murine attractin locus is located in a region harboring several QTL for body weight and fatness.

Membrane-Bound Attractin Is a Co-Receptor for Agouti and Regulates Pigmentation in Skin: Melanocortin-1 receptor (MC1R) and its ligands, α-melanocyte stimulating hormone (αMSH) and agouti signaling protein (ASIP), regulate switching between eumelanin and pheomelanin synthesis in melanocytes. ASIP-MC1R signaling includes a cAMP-independent pathway through attractin and mahogunin, while the known cAMP-dependent component requires neither attractin nor mahogunin. Attractin may be a component of a pathway for regulated protein turnover that also involves mahogunin, a widely-expressed E3 ubiquitin ligase found at particularly high levels in brain. Membrane-bound attractin is a co-receptor for Agouti, the paracrine signaling molecule in the skin which regulates hair pigmentation by antagonizing the MC1R (Hida et al. 2009; Jackson 1999). Genetic, biochemical and pharmacological studies in humans and rodents have established that signaling through the G-protein-coupled melanocortin-4 receptor (MC4R) by pro-opiomelano- cortin (POMC)-derived ligands plays a critical role in the central suppression of appetite. As a consequence, malfunction of this signaling system leads to the development of obesity. It has been shown that melanocortin signaling can be modulated by attractin, apparently acting as a co-receptor for the inhibitory ligand agouti. Haqq et al. (2003) demonstrated that the cytosolic tail of an attractin-like protein binds directly and specifically to the C-terminal region of MC4R, raising the possibility that proteins of the attractin family influence melanocortin receptor function through multiple mechanisms (Carlson and Moore 1999; Yeo and Siddle 2003).

Agouti is expressed ubiquitously, such as lethal yellow, have pleiotropic effects that include a yellow coat, obesity, increased linear growth, and immune defects. The *mahogany* mutation suppresses the effects of lethal yellow on pigmentation and body weight. Results of genetic studies place mahogany downstream of transcription of *Agouti* but upstream of melanocortin receptors. Positional cloning of *mahogany* gene *Mgca* predicted a protein of 1,428 aa with a single-transmembrane-domain that is expressed in many tissues, including pigment cells and the hypothalamus. The extracellular domain of the Mgca protein is the orthologue of human attractin, a molecule produced by activated T cells that has been implicated in immune-cell interactions (Gunn et al. 1999).

Mahogunin Ring Finger-1 and Attractin Act Through Common Pathway: Oxidative stress, ubiquitination defects and mitochondrial dysfunction are common factors associated with neurodegeneration. Mice lacking mahogunin ring finger-1 (MGRN1) or attractin (ATRN) develop age-dependent spongiform neurodegeneration through an unknown mechanism. It has been suggested that they act through a common pathway. As MGRN1 is an E3 ubiquitin ligase, it was suggested that many mitochondrial proteins were reduced in *Mgrn1* mutants. Mitochondrial dysfunction was obvious many months before onset of vacuolation, implicating this as a causative factor. Compatible with the hypothesis that ATRN and MGRN1 act in the same pathway, mitochondrial dysfunction and increased oxidative stress were also observed in the brains of Atrn mutants. Study of *Mgrn1* and *Atrn* mutant mice can provide insight into molecular mechanism common to many neurodegenerative disorders (Sun et al. 2007; Kadowaki et al. 2007; Walker and Gunn 2010).

Cerebral Spongiform Changes: A mutation characterized by mahogany coat color, sprawling gait, tremors, and severe vacuolization of cerebrum, brainstem, granular layer of cerebellum and spinal cord was discovered in a stock of Mus castaneus mice. Histopathological analysis of brains from Mice homozygous for 2 known mahogany attractin (*Atrnmg*) mutants showed that they also have severe spongiform changes. This surprising finding raises questions about the mechanism by which mahogany controls appetite and metabolic rate, as reported (Bronson et al. 2001). A null mutation for *mahoganoid* causes a similar age-dependent neuropathology that includes many features of prion diseases but without accumulation of protease-resistant prion protein. The gene mutated in *mahoganoid* encodes a RING-containing protein with E3 ubiquitin ligase activity in vitro. Similarities in phenotype, expression, and genetic interactions suggest that *mahoganoid* and *Atrn* genes are part of a conserved pathway for regulated protein turnover whose function is essential for neuronal viability (He et al. 2003b).

Secreted Attractin Disrupts Neurite Formation in Differentiating Cortical Neural Cells In Vitro: Mutations at *Atrn* locus affects the secreted form mRNA, which is down-regulated in discrete regions of human brain while membrane attractin mRNA is well represented, resulting in the apparent absence of secreted attractin protein in CSF. In vitro, transcription of secreted form of attractin mRNA is strongly down-regulated upon differentiation of a human cortical neuron-derived cell line (HCN-1A) to a mature neuron phenotype in response to nerve growth factor. Tang and Duke-Cohan (2002) proposed that inappropriate expression of secreted attractin in the CNS blocks membrane attractin function and that its presence, either by leakage from the periphery, aberrant transcription, or release from inflammatory foci may affect neuron extracellular interactions leading to neurodegeneration in the human.

Attractin/Mahogany Protein in Rodent CNS: Both the secreted and membrane-bound forms of ATRN may be involved in the development and maintenance of the CNS. ATRN was intensely expressed in most neurons and dendrites of large neurons, such as cortical pyramidal neurons and cerebellar Purkinje neurons in CNS of rat and mice. Intense ATRN expression was also observed in the neuropil of gray matter in many regions of the CNS and indicates that ATRN is more widely expressed throughout the CNS. Expression of ATRN by various cell types suggests that ATRN serves multiple functions in the CNS (Nakadate et al. 2008). The zitter (zi/zi) rat, a loss-of-function mutant of the glycosylated transmembrane ATRN exhibits widespread age-dependent spongiform degeneration, hypomyelination, and abnormal metabolism of reactive oxygen species (ROS) in the brain. The onset of the impairment of oligodendrocyte differentiation occurs in a non-cell autonomous manner in zi/zi rats (Nakadate et al. 2008; Sakakibara et al. 2008; Ueda et al. 2008).

The Mahogany Is a Receptor Involved in Suppression of Obesity: The pathogenesis of obesity is multifactorial and involves the interaction of genetic and environmental factors. A number of important signaling molecules play important roles in obesity. One family of these molecules is the melanocortin system, which consists of several components: (1) melanocortin peptides; (2) the five seven-transmembrane G-protein coupled melanocortin receptors (MCRs); (3) the endogenous MCR antagonists, agouti and agouti-related protein; (4) the endogenous melanocortin mediators, mahogany, and syndecan. This system plays a key role in the central nervous system control of feeding behaviour and energy expenditure (Carlson and Moore 1999; Yang and Harmon 2003).

Expression of *mahogany* gene is broad; in situ hybridization analysis emphasizes the importance of its expression in the ventromedial hypothalamic nucleus, a region that is intimately involved in the regulation of body weight and feeding. Genetic studies indicate that the *mahogany* locus does not suppress the obese phenotype of the MC4-R null allele or those of the monogenic obese models (Lep^{db}, tub and Cpe^{fat}). However, mahogany can suppress diet-induced obesity, the mechanism of which is likely to have implications for therapeutic intervention in common human obesity. The amino-acid sequence of the mahogany protein suggests that it is a large, single-transmembrane-domain receptor-like molecule, with a short cytoplasmic tail containing a site that is conserved between *Caenorhabditis elegans* and mammals. It was suggested that mahogany can act as a signaling receptor (Nagle et al. 2000).

Attractin in Testis: The ATRN is expressed in Leydig cells, primitive spermatogonia, primary spermato- cytes, spermatids, Sertoli cells and peritubular myoid cells. The attractin protein was mainly located on the cell membrane and cytoplasm, and its mRNA distributed in the nucleus and cytoplasm. The rat testis has the ability of synthesizing the ATRN protein throughout sexual development. The loss of ATRN in mice showed no significantly different pathological changes from the control mice in 3-month-old ATRN (*mg-3J*) mice. But age-related *Atrn* gene progressively lost its function and caused testis vacuolization and impaired sperm function, which may be responsible for the impairment of male reproductive ability (Li et al. 2009). Human sperm-associated antigen 11 (SPAG11) iso-proteins, closely related to β-defensins in structure and function, are predominantly expressed in male reproductive tract, where their best-known roles are in innate host defense and reproduction. Human SPAG11B isoform D (SPAG11B/D) interacts with ATRN. SPAG11B/D and the ATRN interacting proteins are expressed in the proximal epididymis, and function in immunity and fertility control. Radhakrishnan et al. (2009) showed that SPAG11B/D is both a substrate and a potent inhibitor of TPSAB1 activity. Llike SPAG11B/D, ATRN is associated with spermatozoa.

40.3.5 Genetic and Phenotypic Studies of *Mahogany/Attractin* Gene

Pigment-Type Switching: The mouse *mahogany* mutation affects melanocortin signaling pathways that regulate energy homeostasis and hair color. The gene mutated in *mahogany* mice encodes attractin that is broadly expressed and conserved among multicellular animals. The mouse mutations *mahogany (mg)* and *mahoganoid (md)* are negative modifiers of the *Agouti* coat color gene, which encodes a paracrine signaling molecule that induces a switch in melanin synthesis from eumelanin to pheomelanin. Results suggest that *md* and *mg* interfere directly with Agouti signaling, possibly at the level of protein production or receptor regulation (Miller et al. 1997). The mouse *Attractin* (*Atrn*) (formerly *mahogany*) gene has been proposed as a downstream mediator of Agouti signaling because yellow hair color and obesity in lethal yellow (A^y) mice are suppressed by the *mahogany* ($Atrn^{mg}$) mutation. Atrn mRNA was found widely distributed throughout the CNS, with high levels in regions of the olfactory system, some limbic structures, regions of the brainstem, cerebellum and spinal cord. In the hypothalamus, ATRN mRNA was found in specific nuclei including the suprachiasmatic nucleus, the supraoptic nucleus, the medial preoptic nucleus, the paraventricular hypothalamic nucleus, the ventromedial hypothalamic nucleus, and the arcuate nucleus. Results suggest a broad spectrum of physiological functions for *Atrn* gene product (Lu et al. 1999).

Mutations of the mouse *Attractin* gene were originally recognized because they suppress Agouti pigment type switching. Agouti protein, a paracrine signaling molecule normally limited to skin, is ectopically expressed in lethal yellow (A^y) mice, and causes obesity by mimicking agouti-related protein (Agrp), found primarily in the hypothalamus. Mouse attractin is a widely expressed protein whose loss of function in *mahogany* ($Atrn^{mg\text{-}3J}/Atrn^{mg\text{-}3J}$) mutant mice blocks the pleiotropic effects of A^y. Results showed that attractin is a low-affinity receptor for agouti protein, but not Agrp, in vitro and in vivo. Histopathologic abnormalities in $Atrn^{mg\text{-}3J}/Atrn^{mg\text{-}3J}$ mice and cross-species genomic comparisons indicate that Atrn has multiple functions distinct from both a physiologic and an evolutionary perspective (He et al. 2001).

Characterization of two additional *Atrn* alleles, $Atrn^{mg}$ and $Atrn^{mg\text{-}L}$ by Gunn et al. (2001), who examined in parallel the phenotypes of homozygous and compound heterozygous animals showed that the three alleles have similar effects on pigmentation and neurodegeneration, with a relative severity of $Atrn^{mg\text{-}3J} > Atrn^{mg} > Atrn^{mg\text{-}L}$, which also corresponds to the effects of three alleles on levels of normal Atrn mRNA. Animals homozygous for $Atrn^{mg\text{-}3J}$ or $Atrn^{mg}$, but not $Atrn^{mg\text{-}L}$, showed reduced body weight, reduced adiposity, and increased locomotor activity, all in the presence of normal food intake. These results confirm that the mechanism responsible for the neuropathological alteration is a loss—rather than gain—of function and indicate that abnormal body weight in *Atrn* mutant mice is caused by a central process leading to increased energy expenditure, and that the pigmentation is more sensitive to levels of *Atrn* mRNA than the nonpigmentary phenotypes (Gunn et al. 2001).

Pleiotropic phenotype in *dark-like* (*dal*) mutant mouse includes dark dorsal hairs and reproductive degeneration. Their pigmentation phenotype is similar to *Atrn* mutants, which also develop vacuoles throughout brain. Testicular degenerated *dal* mutant males showed reduced serum testosterone and developed vacuoles in their testes. Genetic crosses placed *da*l upstream of the *melanocortin 1 receptor (Mc1r)* and downstream of *agouti,* although *dal* suppressed the effect of agouti on pigmentation but not body weight. $Atrn^{mg\text{-}3J}$ and dal showed additive effects on pigmentation, testicular vacuolation, and spongiform neurodegeneration, but transgenic over-expression of *Attractin-like-1 (Atrnl1)*, which compensates for loss of ATRN, did not rescue *dal* mutant phenotypes. Results suggest that *dal* and *Atrn* function in the same pathway and that identification of *dal* gene will provide insight into molecular mechanisms of vacuolation in multiple cell types (Cota et al. 2008).

The Mouse Coat Color Mutant Mahoganoid (md): *Mahoganoid* is a mouse coat-color mutation whose pigmentary phenotype and genetic interactions resemble those of *Atrn*. The mouse coat color mutant *mahoganoid* (*md*) darkens coat color and decreases the obesity of A^y mice that ectopically over-express agouti-signaling protein. The phenotypic effects of *md* are similar to those of coat color mutant mahogany ($Atrn^{mg}$). The mahoganoid encodes a 494-amino acid protein containing a C3HC4 RING (really interesting new gene) domain that may function as an E3 ubiquitin ligase. The mutations in mahoganoid allelic series (*md,* md^{2J}, md^{5J}) are all due to large retroviral insertions. In *md* and md^{2J}, the result is minimal expression of the normal size transcripts in all tissues examined. Unlike $Atrn^{mg}/Atrn^{mg}$ animals, there was no evidence of neurological deficit or neuropathology in *md*/*md* mice. Body weight and body mass index (a surrogate for adiposity) measurements of B6.C3H-*md-A* *md*/+ and *md*/*md* animals on 9% and 45% kcal fat diets indicate that *mahoganoid* does not suppress body weight in B6.C3H animals in a gene dose-dependent fashion. *Mahoganoid* effects on energy homeostasis are, therefore, most evident in the circumstances of epistasis to hypothalamic over-expression of ASP in A^y and possible other obesity-causing mutations (Phan et al. 2002).

Genes Controlling the Synthesis of Eumelanin and Pheomelanin: Mutations that affect the balance between the synthesis of eumelanin and pheomelanin provide a powerful set of tools with which to understand general aspects of cell signaling. It has been demonstrated that pheomelanin synthesis is triggered by the ability of Agouti protein to inhibit signaling through the *Melanocortin 1 receptor (Mc1r)*. The pigmentary effects of Agouti are suppressed by previously existing coat-color mutations *mg*, *md*, and *Umbrous* (*U*). Double mutant studies, with animals deficient for *Mc1r* or those which carry A^y, indicated that *mg* and *md* are genetically upstream of the Mc1r, and can suppress the effects of A^y on both pigmentation and body weight. Positional cloning has identified the gene mutated in mahogany as a single transmembrane-spanning protein whose ectodomain is orthologous to human ATRN (Barsh et al. 2000). The coat color mutations *mg* and *md* prevent hair follicle melanocytes from responding to Agouti protein. The gene mutated in *mg*, encodes ATRN that functions as an accessory receptor for Agouti protein. The gene mutated in *mahoganoid*, which is also known as *Mahogunin (Mgrn1*), encodes an E3 ubiquitin ligase. Like Attractin, Mahogunin is conserved in invertebrate genomes, and its absence causes a pleiotropic phenotype that includes spongiform neurodegeneration (He et al. 2003a).

Control of Metabolic Rate: Mouse attractin is likely to have additional roles outside melanocortin signaling (Gunn and Barsh 2000). The *mahogany (mg) or Attractin* (*Atrn*)*)* locus was originally identified as a recessive suppressor of *agouti,* a locus encoding a skin peptide that modifies coat color by antagonizing the MSH-R or MC1-R. Certain dominant alleles of *agouti* cause an obesity syndrome when ectopic expression of the peptide aberrantly antagonizes the MC4-R, a related melanocyte-stimulating hormone receptor expressed in hypothalamic circuitry and involved in the regulation of feeding behavior and metabolism. Reports indicate that *mg*, when homozygous, blocks not only the ability of *agouti* to induce a yellow coat color when expressed in the skin of the lethal *yellow mouse* (A^Y), but also the obesity resulting from ectopic expression of *agouti* in the brain. Detailed analysis of *mg*/*mg* A^Y/*a* animals, demonstrates that *mg*/*mg* blocks the obesity, hyperinsulinemia, and increased linear growth induced by ectopic expression of the agouti peptide. Remarkably, however, *mg*/*mg* did not reduce hyperphagia in the A^Y/*a* mouse. Furthermore, *mg*/*mg* induced hyperphagia and an increase in basal metabolic rate in the C57BL/6J mouse in the absence of A^Y. Consequently, although mahogany is broadly required for agouti peptide action, it also appears to be involved in the control of metabolic rate and feeding behavior independent of its suppression of *agouti* (Dinulescu et al. 1998).

Hypomyelination in Rat Zitter: In absence of attractin there is a decline in plasma membrane glycolipid-enriched rafts. The structural integrity of lipid rafts depends upon cholesterol and sphingomyelin, and can be identified by partitioning of ganglioside GM1. Despite a significant fall in cellular cholesterol with maturity, and a lesser fall in both membrane and total cellular GM1, these parameters lag behind raft loss, and are normal when hypomyelination/neurodegeneration has already begun thus supporting consequence rather than cause. These findings can be recapitulated in Atrn-deficient cell lines propagated in vitro (Azouz et al. 2007) Histopathological analysis of brains from Mice homozygous for 2 known mahogany attractin (*Atrnmg*) mutants showed that they also have severe spongiform changes. This surprising finding raises questions about the mechanism by which mahogany controls appetite and metabolic rate, as recently reported (Bronson et al. 2001).

The rat zitter (zi) mutation induces hypomyelination and vacuolation in CNS, which results in early-onset tremor and progressive flaccid paresis. Kuramoto et al. (2001) found a marked decrease in ATRN mRNA in the brain of the zi/zi rat and identified zi as an 8-bp deletion at a splice donor site of *Atrn*. Rat *Atrn* gene encoded two isoforms, a secreted and a membrane form, as a result of alternative splicing. The zi mutation at the *Atrn* locus darkened coat color when introduced into agouti rats, as also described in *mahogany* (*mg*) mice, carrying the homozygous mutation at *Atrn* locus. Transgenic rescue rats showed that the membrane-type ATRN complemented both neurological alteration and abnormal pigmentation in zi/zi rats, but that the secreted-type ATRN complemented neither mutant phenotype. Furthermore, *mg* mice exhibited hypomyelination and vacuolation in the CNS associated with body tremor (Kuramoto et al. 2001). Ultrastructurally these vacuoles mainly consisted of splitting of myelin lamella both in the periaxonal and intermyelinic spaces. Linkage analysis using intercross progeny between the myelin vacuolation (mv) rat, named after the pathologic characteristics, and normal control rat strains showed that the mv phenotypes were cosegregated with polymorphic markers adjacent to the *Atrn* (Attractin, formerly zi [zitter]) locus on rat chromosome 3. Discovery of the rat null mutation *Atrn(mv)*, different from *Atrn(zi)*, provides a new animal model for studying the functions of the attractin protein (Kuwamura et al. 2002). Studies suggest that lack of *Atrn* gene expression induced neurodegeneration by a decrease in active ERK through an intracellular signaling via oxidative stress (Muto and Sato 2003). These studies indicate that membrane ATRN has a critical role in normal myelination in CNS and provide insights into the physiology of myelination as well as the etiology of myelin diseases. Izawa et al. (2008) indicated that the attractin defect results in oligodendrocyte dysfunction, and is associated with astrogliosis and microglial

activation in mv rats. Attractin may be directly involved in the function of oligodendro-cytes in CNS myelination. Results indicate that myelinogenesis but not oligodendrogenesis is severely altered both in the white and gray matter of mv rats (Izawa et al. 2010).

The Hamster Black Tremor (bt) Mutation: The hamster black tremor (bt) mutation induces a black coat color and a defective myelination in CNS that manifests as a tremor. On the other hand, loss-of-function mutations of the *Atrn* gene, such as *Atrnmg*, *Atrnmg-L*, and *Atrnmg-3J* in mice, and *Atrnzi* in rats, induce both darkening of coat color and hypomyelination and vacuolation in CNS. The close resemblance of mutant phenotypes led to postulate that the bt/bt hamster also might harbor a mutation in *Atrn*. While the human and rat *Atrn* genes encode both membrane- and secreted-type proteins, the hamster *Atrn* gene encoded only membrane-type protein with 1,427 amino acids, as in the case of the mouse. Hamster ATRN had 93.6%, 96.8%, and 96.8% identities with human, rat, and mouse membrane-type Attractin. In the brain of the bt/bt hamster, aberrant transcripts with more than three size species were observed, and the most predominant transcript encoded the truncated Attractin without transmembrane domain. The hamster bt mutation was the approximately 10-kb retrotransposon-like insertion into the *Atrn* gene, which resulted in aberrant transcripts (Kuramoto et al. 2002).

40.3.6 Therapeutic Applications of ATRN/*Mahogany* Gene Products

The C-terminal peptide product encoded by *mahogany* gene crosses the blood–brain barrier (BBB) by a transport mechanism that is saturable. The ability of this system indicates the therapeutic potential of mahogany (1377–1428) in the treatment of obesity (Kastin and Akerstrom 2000). Avy/agouti (A^{vy}) mice have late onset obesity related to over-expression of agouti signaling protein (ASP) in the hypothalamus. As mahogany modulates the actions of ASP, Pan and Kastin (2007) tested the transport of mahogany peptide across BBB. The brain uptake of mahogany peptide was significantly higher in young A^{vy} mice, and it preceded the surge of fat mass quantified by NMR. The results suggest a role of accelerated BBB transport in the epigenetics of A^{vy} mice.

The proliferative responses of T lymphocytes of a subset of patients with CVID are abnormally low. This may be due to abnormalities in extracellular interactions or signaling defects downstream from membrane-associated receptors. Attractin is a rapidly expressed T cell activation antigen involved in forming an association between T cells and monocytes. Due to the likely role of attractin in cell guidance and amplification of immune response, results indicate that the lack of up-regulation of the molecule in patients with CVID may in turn affect any further step of productive immune response. This finding may imply a potential therapeutic role for this novel molecule (Pozzi et al. 2001). Attractin is a reliable secreted marker for high-grade gliomas. Additionally, it may be an important mediator of tumor invasiveness, and thus, a potential target in future therapies (Khwaja et al. 2006). ATRN may play a protective role against environmental toxins that implies a potential therapeutic effect of ATRN for neurodegenerative diseases (Paz et al. 2007).

40.4 Eosinophil Major Basic Protein 1 (EMBP1) (Group XII of CTLD)

40.4.1 Characterization of EMBP

Eosinophils are implicated in the combat of infections caused by helminth parasites and viruses and are associated with tissue damage in a variety of diseases (Gleich 2000). A distinctive group of proteins form the eosinophil granule. Among these, the eosinophil major basic protein 1 (EMBP1) is the most abundant eosinophil granule protein that forms the crystalline core of the granule and belongs to Group XII in CTLD classificatiion. Proteoglycan 2, bone marrow (natural killer cell activator, eosinophil granule major basic protein), also known as PRG2, is the protein which in humans is encoded by the *PRG2* gene. EMBP is a 14 kDa (117 amino acid residues) intensely basic protein whose complement of basic residues consists of arginines, giving rise to a calculated pI of 11.4 and a net charge of 15.0 at pH 7 (Barker et al. 1988; McGrogan et al. 1988). However, pro-EMBP is almost neutral with a calculated pI of 6.2, because of the presence of a large number of acidic residues in the 90 residue long pro-portion (pI 3.9). It has been suggested that the pro-portion of EMBP serves predominantly to protect cells from the extreme basicity of EMBP during transport from the Golgi to the eosinophil granule (Barker et al. 1991).

EMBP is a monomer under physiological conditions that readily polymerizes in solution forming insoluble aggregates because of the presence of five free thiol groups (in addition to the four cysteines involved in disulfide bond formation) in the protein (Oxvig et al. 1994a). It has been shown to be non-glycosylated, contrasting with the pro-protein, which is heavily glycosylated with N-glycans, O-glycans, and glycosaminoglycans, raising the molecular weight to between 30 and 50 kDa (Oxvig et al. 1994b). During eosinophilopoiesis, EMBP is initially transcribed as a pro-molecule containing a markedly acidic pro-piece. The promolecule can be identified in eosinophil granules, and current evidence suggests that it is processed here into EMBP, which then condenses to form the eosinophil granule core (Popken-Harris et al. 1998). A EMBP homologue (EMBPH) similar to EMBP has also been identified in human eosinophil granule lysates (Plager et al. 1999).

40.4.2 Functions of EMBP

EMBP is expressed in eosinophils, basophils, and placental X cells. In eosinophils, the protective acidic region is removed and the CTLD covalently polymerizes to form insoluble aggregates that make up the crystalline core of eosinophil granules. EMBP is a cytotoxin deployed against helminth parasites, and possibly also against bacteria, fungi and cancerous or infected cells. EMBP triggers release of histamine from mast cells and basophils, and activates neutrophils and alveolar macrophages. Release of EMBP and its deposition onto tissues is linked to hypersensitivity reactions and causes tissue dysfunction in inflammatory and allergic conditions, including asthma. Towards the end of pregnancy, pro-EMBP circulates in a complex with pregnancy-associated plasma protein A, angiotensin and C3dg. EMBPH is expressed in eosinophils. It is less basic and less potent than EMBP, but has similar biological activities. The CTLDs in these proteins do not contain the sequence motifs associated with sugar-binding activity. However, EMBP binds heparin through a novel calcium-independent carbohydrate-recognition mechanism.

EMBP is a potent helminthotoxin and is cytotoxic toward bacteria and mammalian cells in vitro (Swaminathan et al. (2001) and may have important roles in allergic and inflammatory reactions. The EMBP causes release of histamine from mast cells and basophils, activates neutrophils and alveolar macrophages, and is directly implicated in epithelial cell damage, exfoliation and bronchospasm in asthma (Swaminathan et al. 2001). The exact mechanism of EMBP action is not known, although it has been speculated that the highly basic nature of the protein contributes to its toxicity.

The concentration of EMBP is elevated in biological fluids (e.g. sputa and bronchoalveolar lavage fluids) from patients with asthma and other eosinophil-associated diseases. Deposition of EMBP onto damaged tissues in various human diseases is strongly associated with dysfunction of those tissues, and instillation of EMBP into the lung of monkeys causes a tenfold increase in bronchial hyperreactivity, as well as marked bronchospasm (Gundel et al. 1991). EMBP appears to damage cells by disrupting the bilayer lipid membrane (Gleich et al. 1993) or altering the activity of enzymes within tissues (Hastie et al. 1987). Evidence also implicates pro-EMBP as an inhibitor of human pregnancy-associated plasma protein A (Overgaard et al. 2000).

40.4.3 Crystal Structure of EMBP

EMBP does not exhibit high sequence similarity to any known proteins, but has weak sequence identity (23–28%) with C-type lectin domains of mannose-binding protein, human lithostathine (LIT), and the low affinity IgE receptor FceRII (Patthy 1989). Swaminathan et al. (2001) reported the crystal structure of EMBP at 1.8 Å resolution. This protein is structurally related to members of the CTLD family, but is significantly different from known CTLDs, lacking the potential to bind carbohydrates in a calcium dependent manner. EMBP are likely to be proteoglycans such as heparin, leading to new interpretations for EMBP function (Swaminathan et al. 2005). Evidence of binding of EMBP to heparin and heparin disaccharide has been presented. The crystal structure of EMBP in complex with a heparin disaccharide and in the absence of Ca^{2+} is shown in Fig. 40.3, a report of any C-type lectin with this sugar. Structural analysis shows that the potential carbohydrate ligands recognized by EMBP are likely to be different from those in other CTLDs.

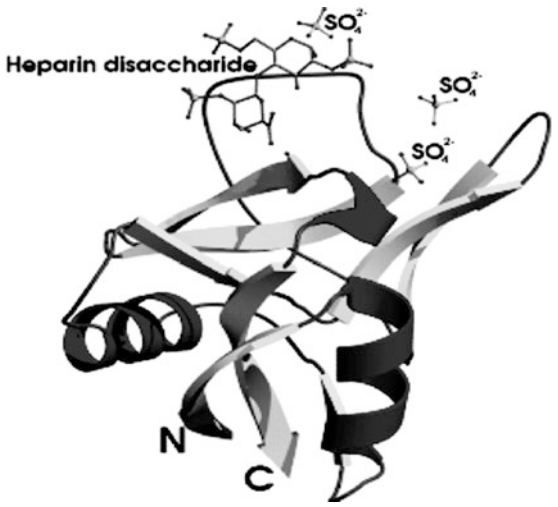

Fig. 40.3 Crystal structure of EMBP in complex with heparin disaccharide (PDB: 2BRS). The sugars recognized by EMBP are likely to be proteoglycans such as heparin, leading to new interpretations for EMBP function (Printed with permission from Swaminathan et al. 2005 © American Chemical Society)

40.4.4 DEC-205-Associated C-Type Lectin (DCL)-1

DEC-205-associated C-type lectin (DCL)-1 was also formerly classified as a member of group XII. However, DCL-1 is a type 1 transmembrane protein with an extracellular CTLD and neck region and may be classified as belonging to a new group of CTLD-containing proteins. DCL-1 was discovered in cells associated with the development of Hodgkin's lymphoma. Intergenic splicing of DCL-1 and DEC-205 (a CTLD-containing type 1 transmembrane protein of the mannose receptor family (Chaps 15 and 35) results in production of a fusion protein containing both DCL-1 and DEC-205 extracellular domains, plus the transmembrane and cytoplasmic regions of DCL-1. Non-intergenically spliced DCL-1 transcripts are present in myeloid and B lymphocyte cell lines.

Fig. 40.4 Domaim organization of Integral membrane protein (IDD/DGCR2) (Group XIII of CTLD)

40.5 Integral Membrane Protein, Deleted in Digeorge Syndrome (IDD) (Group XIII of CTLDs)

Integral membrane protein, deleted in DiGeorge syndrome (IDD) is a unique CTLD-containing type 1 transmembrane protein expressed in a range of cell types and notably in developing nervous system. The extracellular region consists of a CTLD sandwiched between a membrane-distal low density lipoprotein (LDL)-receptor class A domain and a membrane-proximal von Willebrand Factor C domain (Fig. 40.4). IDD also has a sizeable intracellular region.

40.5.1 DiGeorge Syndrome Critical Region 2 (DGCR2)

IDD may function as an adhesion receptor in cell-cell or cell-matrix interactions during cell differentiation and migration, particularly in the nervous system, or may be involved in signaling. The IDD gene lies within the DiGeorge syndrome critical region – the minimal region of chromosome 22. Deletions of the 22q11.2 have been associated with a wide range of developmental defects (notably DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly face syndrome and isolated conotruncal cardiac defects) classified under the acronym CATCH 22. The DGCR2 gene encodes a novel putative adhesion receptor protein, which could play a role in neural crest cells migration, a process which has been proposed to be altered in DiGeorge syndrome (Taylor et al. 1997). The CTLD in IDD is not known to have sugar-binding activity. Alternative splicing of gene results into multiple transcript variants. The DGCR2 gene is conserved in chimpanzee, dog, cow, mouse, rat, chicken, and zebrafish.

SEZ-12 is one of the seizure-related cDNAs which was isolated from primary cultured neurons from mouse cerebral cortex with or without pentylene tetrazol (PTZ). SEZ-12 expression is transiently down-regulated in mouse brain by injection of PTZ. The deduced amino acid sequence of SEZ-12 revealed that it encodes membrane-bound C-type lectin and has a significant homology to that of human cDNA of DGCR2 and IDD, associated with the DiGeorge syndrome. The message was expressed ubiquitously in various organs with low-abundance. The cloned transmembrane protein was probably involved in cell-cell interaction. Findings suggest that transmembrane signaling in neuronal cells may have an important role in PTZ-induced seizure (Kajiwara et al. 1996). Several lines of evidence have established the presence of an association between a 3-Mb deletion in chromosome 22q11 and schizophrenia with a reduced expression of DGCR2 (Iida et al. 2001; Shifman et al. 2006). However, Georgi et al. (2009) did not support a significant role of DGCR2 in the aetiology of schizophrenia in the German population.

Family of CD93 and Recently Discovered Groups of CTLDs

41

G.S. Gupta

41.1 Family of CD93

CD93 is a ~120 kDa *O*-sialoglycoprotein that within the hematopoietic system is selectively expressed on cells of the myeloid lineage. CD93 in humans is encoded by the *CD93* gene (Nepomuceno et al. 1997; Webster et al. 2000). CD93 is a C-type lectin transmembrane receptor which plays a role not only in cell–cell adhesion processes but also in host defence. CD93 belongs to the Group XIV C-Type lectin family, a group containing two other members, endosialin (CD248) and thrombomodulin (TM, CD141), a well characterized anticoagulant. All of them contain a C-type lectin domain, a series of epidermal growth factor like domains (EGF), a highly glycosylated mucin-like domain, a unique transmembrane domain and a short cytoplasmic tail. Due to their strong homology and their close proximity on chromosome 20, CD93 has been suggested to have arisen from thrombomodulin gene through a duplication event. Sequence analysis revealed that CD93 is identical to a protein on human phagocytes termed C1q receptor (C1qRp). The mouse homologue of human C1qRp is known as AA4. The AA4 and TM are derived from a common ancestor since both genes are co-localized to the same region of the chromosome 2 and also because they share similar domain composition and organization.

Endosialin (tumor endothelial marker 1) is expressed preferentially by tumor endothelial cells but not by normal endothelium. Its protein domain architecture is homologous to that of CD93 and TM (CD141), suggesting a similar function in mediating cell-cell interactions. Endosialin colocalization with thrombomodulin suggests that these proteins may have complementary functions in tumor progression (Brady et al. 2004). The complement C1q receptor (C1qRp) and TM are involved in cell-cell interactions and innate immune host defense. However, not much is known on the lectin 14A, a member of CD93 family of C-type lectins.

41.2 CD93 or C1q Receptor (C1qRp): A Receptor for Complement C1q

41.2.1 CD93 Is Identical to C1qRp

The first component of complement, C1, is a multi-molecular complex comprising C1q and the Ca^{2+}-dependent tetramer $C1r_2$-$C1s_2$. The C1q is an essential component of innate complement (C) system and is crucial to ward off infection and clear toxic cell debris (e.g. amyloid fibrils, apoptotic cells) in natural way. Another important function of C1q is its ability to bind to a wide range of cell types resulting in the induction of cell-specific biological responses. These cells include polymorphonuclear leukocytes, monocytes, lymphocytes, dendritic cells, endothelial cells and platelets. Interaction of C1q with endothelial cells and platelets, for example, leads to cellular activation followed by release of biological mediators and/or expression of adhesion molecules, all of which contribute, directly or indirectly to the inflammatory process. These specific responses are mediated by the interaction of C1q with C1q binding proteins or receptors on the cell surfaces. Several candidate C1q receptors [C1q receptor for phagocytosis enhancement (C1qRp/cC1qR/CD93, a 120 kDa, O-sialoglycoprotein), complement receptor (CR) 1, calreticulin (CRT: Chap. 2), and binding protein for globular head of C1q (gC1qR/p33, a 33 kDa homotrimeric protein)] have been studied and reviewed for their structure-function relationships (McGreal and Gasque 2002). Cell-surface molecule, C1qRp, has emerged as a defence collagen receptor for C1q, as well as MBL and surfactant protein A (Chaps. 23–25). C1qRp (known as AA4 antigen in rodents) is the antigen recognized by a pro-adhesive monoclonal antibody (mNI-11) and antibodies against CD93. Although the specific role of each of these receptors in a given C1q-mediated cellular response is yet to be known, all of them may participate in the inflammatory processes associated with vascular or atherosclerotic

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_41, © Springer-Verlag Wien 2012

lesions, autoimmune diseases, or infections. Study of structure of cC1qR/CD93 and gC1qR/p33, both of which have been characterized on the basis of their ability to bind C1q, and their role in infection and inflammation is the subject of recent and future investigations (Ghebrehiwet and Peerschke 2004). Within the hematopoietic system CD93 is selectively expressed on cells of the myeloid lineage. CD93 is identical C1qRp, which was shown to mediate enhancement of phagocytosis in monocytes and suggested to be a receptor of C1q and two other structurally related molecules. Cells expressing CD93 have enhanced capacity to bind C1q. Furthermore, immature DCs express CD93/C1qRp, and mature DCs, known to have reduced capacity for antigen uptake and to have lost the ability to phagocytose, show weak-to-negative CD93/C1qRp expression (Steinberger et al. 2002). Narayanan et al. (1997) investigated the distribution of receptors for C1q-collagen domain (cC1qR) and globular domain (gC1qR) in adult human lung fibroblasts. The cC1qR was expressed predominantly by a population of human lung fibroblasts, while the 38 kD gC1qR was produced by all cells. Therefore, two lung fibroblast subtypes may be distinguished based on production of cC1qR and another protein which binds to C1q-globular domain.

41.2.2 Characterization of CD93/C1qR$_P$

The CD93/C1qR$_P$ is a type I membrane protein of 631 amino acid containing a region homologous to C-type lectin carbohydrate recognition domain. The C1qR$_P$ is a 100 kDa M_r protein (126,000 M_r under reducing conditions). Monoclonal antibodies that immunoprecipitate 126 kDa M_r polypeptide inhibit the enhancement of phagocytosis triggered not only by C1q but also by MBL and pulmonary SP-A providing evidence that this polypeptide is a functional receptor that mediates the enhancement of phagocytosis. Specifically, the *Cd93* gene is located at 84 cM on murine chromosome 2 (Kim et al. 2000) and encodes a type I O-glycosylated transmembrane protein whose domain structure includes an amino-terminal C-type lectin domain, a tandem array of five EGF-like repeats, a single hydrophobic transmembrane region, and a short cytoplasmic domain that contains a PDZ binding domain and a moesin interaction site (Bohlson et al. 2005; Kim et al. 2000; Zhang et al. 2005). This domain structure bears a unique resemblance to the selectin family of adhesion molecules (Dean et al. 2001; Kim et al. 2000; Rosen 2004). Both post-translational glycosylation and the nature of the amino acid sequence of the protein explain to the difference between its predicted molecular weight and its migration on SDS-PAGE. The mature C1qRp contains a relatively high degree of O-linked glycoslyation, and engaged in cell surface ligation of SP-A, as well as C1q and MBL, and enhances phagocytosis. The O-glycosylation is important in the stable cell surface expression of C1qR$_P$/CD93 (Park and Tenner 2003). While the cDNA for C1qRp encodes a 631 amino acid membrane protein, CHO cells transfected with the cDNA of the C1qR$_P$ coding region express a surface glycoprotein with the identical 126,000 M_r as the native C1qR$_P$ (Nepomuceno et al. 1999). CD93, similar to C1qR$_P$, is expressed by endothelial cells, cells of myeloid lineage, platelets, and early hematopoietic stem cells and is an important lineage-specific marker of early B-cell developmental stages (Cancro 2004; Danet et al. 2002; Fonseca et al. 2001; Nepomuceno and Tenner 1998). Normally, CD93 is expressed at high levels on pro-, pre- and immature bone marrow (BM) B-cell progenitors as well as transitional (TR) B cells in the periphery (Cancro 2004). Additionally, CD93 is subject to metalloprotease-mediated ecto-domain cleavage or shedding, which is characteristic of several inflammatory mediators and adhesion molecules including TNF-α, TGF-α, TGF-β, EGF, CD44, and L-selectin (Bohlson et al. 2005a). In phagocytic cells, it has been characterized as contributing to the enhancement of FcR- and CR1-induced phagocytosis triggered by innate immune system defense collagens such as C1q and MBL (Park and Tenner 2003). There seems a novel mechanism of regulated expression of CD93 that may have implications in stem cell development and inflammation. CD93 is susceptible to ectodomain shedding. Bohlson et al. (2005a) identified multiple stimuli that trigger shedding, and identified both a soluble form of CD93 in human plasma and intracellular domain containing cleavage products within cells that may contribute to the physiologic role of CD93 (Bohlson et al. 2005a). The C1qR from U937 cells and human tonsil lymphocytes interacts with C1q, MBP, conglutinin and SP-A (Malhotra et al. 1990). The interaction of SP-A with U937 cells triggers the expression of an intracellular pool of C1qR (Malhotra et al. 1992).

41.2.3 Two Types of Cell Surface C1q-Binding Proteins (C1qR)

Synonyms of C1qR are: C1q/MBL/SPA receptor, C1qR(p), C1qr1, C1qrp, C1qRp, cell surface antigen AA4 and CD93. Selective expression of C1qR$_P$ in specific cell types supports the hypothesis that there is more than one C1q receptor mediating the diverse responses triggered by C1q (Nepomuceno and Tenner 1998; Guan et al. 1994; Tenner 1998). A 60-kDa calreticulin-homologue which binds to the collagen-like "stalk" of C1q (called cC1qR) and a 33-kDa protein with affinity for the globular "heads" of the molecule (called gC1qR), have been described. The two molecules are also secreted by Raji cells and peripheral blood lymphocytes and can be isolated in soluble form from serum-free culture supernatant. The two purified soluble proteins had

immunochemical and physical characteristics similar to their membrane counterparts in the sense that both bound to intact C1q and to their respective C1q ligands, cC1q and gC1q. In addition, N-terminal amino acid sequence analyses of the soluble cC1qR and gC1qR were found to be identical to the reported sequences of the respective membrane-isolated proteins. Ligand blot analyses using biotinylated membrane or soluble cC1qR and gC1qR showed that both bind to the denatured and nondenatured A-chain and moderately to the C-chain of C1q. Moreover, like their membrane counterparts, the soluble proteins were found to inhibit serum C1q hemolytic activity. Although cC1qR was released when both peripheral blood lymphocytes and Raji cells were incubated in phosphate-buffered saline for 1 h under tissue culture conditions, gC1qR was releasable only from Raji cells, suggesting that perhaps activation or transformation leading to immortalization is required for gC1qR release (Peterson et al. 1997).

gC1q-binding Proteins (gC1qR): Differences from cC1qR

Human neutrophils have multiple C1q-binding proteins. Ligand-binding studies with the globular domain of C1q revealed two gC1q-binding proteins (gC1qR): a 33 kDa protein (pI 4.5) mainly in the neutrophil plasma membrane and an 80–90 kDa protein (pI 4.1–4.2) located mainly in the granules. Direct binding studies showed that C1q bound to this higher molecular weight protein under physiological conditions. In contrast, anti-cC1qR antibody, which recognizes a protein binding to collagenous tails of C1q, detected only a 68,000 M_r protein in the plasma membrane. Both the 33,000 and 68,000 M_r receptors appear early on the surface of differentiating HL-60 cells. Phorbol myristate acetate treatment of neutrophils down-regulated both the receptors from cell surface, and significant amounts of soluble gC1qR were in cell media supernatants, suggesting receptor shedding or secretion**.** gC1qR, unlike cC1qR, did not bind to other C1q-like ligands, namely mannose binding protein, surfactant protein-A, surfactant protein-D, or conglutinin under normal ionic conditions, suggesting a greater specificity for C1q than the "collectin" type receptor (cC1qR). Rather, gC1qR only bound purified C1q, and the binding was enhanced under low ionic conditions and in the absence of calcium. C1qR/CD93 is also proteolytically cleaved from the surface of activated human monocytes and neutrophils in response to inflammatory signals in vitro and a soluble form of CD93 (sCD93) exists in human plasma. Inflammation triggers release of sCD93 in vivo and identifies the inflammatory macrophage as a source of sCD93 (Greenlee et al. 2008, 2009).

Ghebrehiwet et al. (1997) showed that biotinylated cC1qR binds to recombinant as well as native gC1qR and the binding sites for cC1qR are located within N-terminal residues 76 through 93 of the mature form of gC1qR and within residues 204 through 218. The evidence suggests that cC1qR is able to form a complex with gC1qR and may associate with gC1qR on the cell surface (Ghebrehiwet et al. 1997).

C1q receptor (C1qR/collectin receptor/cC1qR) with an almost complete amino acid sequence identity with calreticulin (CRT) is located on the surface of many cell types. C1qR also interacts with the collectins SP-A, MBL, CL43 and conglutinin via a cluster of charged residues on the collagen tails of the ligands. The C1q and collection binding site on C1qR/CRT is localised to the residues 160–283 (Stuart et al. 1997).

Collectins and C1q Enhance Mononuclear Phagocytosis Through a Common Receptor: Enhanced monocyte FcR- and CR1-mediated phagocytosis by MBP, C1q, and SP-A suggests acommon structural feature of the collagen-like domains that may provide a basis for this immunologically important function. MBP also enhances FcR-mediated phagocytosis by both monocytes and macrophages, and stimulated CR1-mediated phagocytosis in human culture-derived macrophages and in phorbol ester-activated monocytes. The mAb that recognizes a 126 kDa cell surface protein and inhibits C1q-enhanced phagocytosis, also inhibited the MBP-mediated enhancement of phagocytosis**.** This common feature among defense collagen receptors suggests that the enhancement of phagocytosis by MBP and C1q share at least one critical functional component, the $ClqR_P$ (Nepomuceno et al. 1997; Tenner et al. 1995). mAbs that recognize a cell surface $C1qR_P$ inhibit C1q-, MBL- and SP-A-mediated enhancement of phagocytosis. Similar inhibition of enhancement of phagocytosis by these mAbs suggests that $C1qR_P$ is a common component of a receptor for these macromolecules. The $C1qR_P$ is cross-linked directly by monoclonal anti-$C1qR_P$ or engaged as a result of cell surface ligation of SP-A, C1q and MBL resulting in enhanced phagocytosis (Nepomuceno et al. 1999).

41.2.4 Tissue Expression and Regulation of CD93/C1qRp

$CD93/ClqR_P$ was originally identified in mice as an early B cell marker through the use of AA4.1 monoclonal antibody. Then this molecule was shown to be expressed on an early population of hematopoietic stem cells, which give rise to the entire spectrum of mature cells in the blood. Now CD93 is known to be expressed by a wide variety of cells such as platelets, monocytes, microglia and endothelial cells. In the immune system CD93 is also expressed on neutrophils, activated macrophages, B cell precursors until the T2 stage in the spleen, a subset of DCs and of natural killer cells.

Though C1qRp is identical to CD93 protein, a study failed to demonstrate a direct interaction between CD93 and C1q under physiological conditions. Radioiodinated C1qR and CRT bind to C1q with identical characteristics (McGreal et al. 2002).

Studies show that human monocyte-derived DCs express gC1qR and cC1qR; their expression on the cell surface is maturation dependent, and immature DCs secrete C1q (Vegh et al. 2003). Immature DCs express C1qR, gC1qR and cC1qR/CR and, accordingly, display a vigorous migratory response to soluble C1q with maximal cell movement. In contrast, mature DCs neither express C1qR nor do move to a gradient of soluble C1q. C1q functions as a chemotactic factor for immature DC, and migration is mediated through ligation of both gC1qR and cC1qR/CR (Vegh et al. 2006).

The TGF-β and TNF-α upregulate the mRNA levels of cC1qR and collagen but do not affect gC1qR mRNA levels significantly. It was also indicated that different subsets of human lung fibroblasts respond differently to inflammatory mediators (Lurton et al. 1999). Protein kinases regulate the expression of CD93 on the cell surface. The CD93 expression on human monocyte-like cell line (U937), a human NK-like cell line (KHYG-1), and a human umbilical vein endothelial cell line (HUV-EC-C) involves the PKC isoenzymes (Ikewaki et al. 2006). PKC activator phorbol myristate acetate (PMA) effectively up-regulated CD93 expression on cultured cell lines and its regulation was mainly controlled by a PKCδ-isoenzyme (Ikewaki et al. 2007).

41.2.5 Functions

41.2.5.1 Adhesion, Migration and Phagocytosis

The CD93 was initially thought to be a receptor for C1q, but now is thought to instead be involved in intercellular adhesion and in the clearance of apoptotic cells. The intracellular cytoplasmic tail of this protein contains two highly conserved domains which may be involved in CD93 function. Indeed, the highly charged juxtamembrane (JX) domain has been found to interact with moesin, a protein known to play a role in linking transmembrane proteins to the cytoskeleton and in the remodelling of the cytoskeleton (Fig. 41.1). The interaction of moesin with CD93 cytoplasmic domain is modulated by binding of other intracellular molecules to the C11 region and implies that a PIP_2 signaling pathway is involved in CD93 function (Norsworthy et al. 2004; Zhang and Bohlson 2005). This process appears crucial for adhesion, migration and phagocytosis, three functions in which CD93 may be involved. CD93 is required for efficient engulfment of apoptotic cells via an unknown mechanism. Neonatal rat microglia are known to express C1qRp. Interaction of these cells with substrate-bound C1q was shown to enhance both FcR-and CR1-mediated phagocytosis. Results suggest that C1q in areas of active degeneration may promote the phagocytic capacity of microglia via interaction with microglial C1qRp (Webster et al. 2000). Reports also indicate that besides such-well-known complement regulatory molecules as CD55 (DAF), CD46 (MCP), CD35 (CR1) and CD59(HRF), C1qR too is able to regulate complement activity (van den Berg et al. 1995).

41.2.5.2 CD93 in Maintenance of Plasma Cells in Bone Marrow

In the context of late B cell differentiation, CD93 has been shown to be important for the maintenance of high antibody titres after immunization and in the survival of long-lived plasma cells in the bone marrow. Indeed, CD93 deficient mice failed to maintain high antibody level upon immunization and present a lower amount of antigen specific plasma cells in the bone marrow. CD93, expressed during early B-cell development, appeared to be restimulated during plasma-cell differentiation. High CD93/CD138 expression was restricted to antibody-secreting cells both in T-dependent and T-independent responses as naive, memory, and germinal-center B cells remained CD93-negative. CD93 was expressed on (pre)plasmablasts/plasma cells, including long-lived plasma cells. Strikingly, while humoral immune responses initially proceeded normally, CD93-deficient mice were unable to maintain antibody secretion and bone-marrow plasma-cell numbers, demonstrating that CD93 is important for the maintenance of plasma cells in bone marrow niches (Chevrier et al. 2009).

41.2.5.3 Role in Fertilization

Complement components might play a role in fertilization. C1q has the ability to promote sperm agglutination in a capacitation-dependent manner as well as an effect on sperm-oolemma binding and fusion. The gC1qR is present on the surface of capacitated sperm. Confocal and immunofluorescence microscopy revealed an increase in receptor expression over the rostral portion of the sperm head after capacitation. It appears that gC1qR may play a role in human fertilization (Grace et al. 2002).

41.2.6 CD93 in Pathogenesis of SLE

The association between C1q and autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus (SLE) is well established. The SLE is characterized by the presence of multiple autoantibodies and high levels of circulating immune complexes. In a cross-sectional study it was found that higher titres of antibodies against cC1qR/CRT are present in sera of SLE patients compared with normal donors. Deficiency in C1q is considered to be a

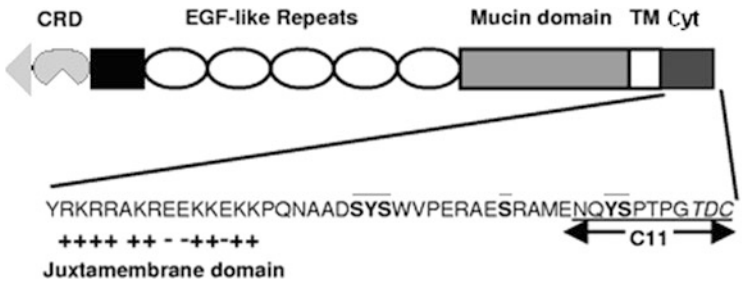

Fig. 41.1 Schematic representation of C1QRp/CD93. CD93 has been shown to influence the phagocytic activity in response to defense collagens such as C1q. CD93 has a 47 amino acid cytoplasmic tail and modulates phagocytosis. The cytoplasmic tail contains a highly charged juxtamembrane (Jx) region, and charge (+ or −) is indicated below the single-letter amino acid residue. Potential sites of serine or tyrosine phosphorylation are marked by horizental line. Cytoplasmic (*underlined*) 11 amino acids region has been implicated in signal transduction; this region contains a class I PDZ-binding domain (*italics*). Abbreviations: CRD, Carbohydrate recognition domain; EGF, epidermal growth factor; TM, transmembrane domain; Cyt, cytosolic region (Bohlson et al. 2005b)

strong susceptibility factor and is corroborated by the fact that ~92% of the known cases of hereditary deficiency in C1q develop rheumatic disease. C1q-deficient mice have shown the presence of glomerulonephritis with immune deposits and a large number of apoptotic bodies in the diseased glomeruli suggesting a defect in the clearance of apoptotic cell by macrophages and DCs. Although these data are consistent with the hypothesis that C1q deficiency may induce a generalized failure to clear immune complexes and apoptotic cells, this concept alone cannot wholly explain why individuals with C1q deficiency are prone to develop SLE. Therefore, C1q in conjunction with other surface molecules must play a more fundamental role in immunoregulation, especially those processes that regulate T cell function and tolerance. In support of this hypothesis is the finding that C1q causes inhibition of mitrogen-induced T cell-proliferative response by interaction with C1q receptors. Furthermore, macrophages and possibly DCs not only synthesize but also display C1q as a type II cell surface molecule, especially at sites of inflammation. Although it is not yet known what role the surface-expressed C1q plays, it is tempting to assume that it plays a role in the priming of naive T cells by DCs (Ghebrehiwet and Peerschke 2004; van den Berg et al. 1998). However, in a contradiction, C1qRp expression and regulation was not altered on peripheral blood monocytes of SLE patients. Possible relations with disease activity and medication need further investigations (Moosig et al. 2006)

41.3 Murine Homologue of Human C1qRp (AA4)

A murine genomic clone is 73% identical in sequence with the coding region for human $C1qR_P$ cDNA. Chromosomal localization of the human and murine genes demonstrated that these genes are syntenic. Murine cell lines of diverse myeloid origins are shown to respond to interaction of C1q with the enhancement of phagocytosis similar to that seen in human peripheral blood monocytes. $mC1qR_P$ is expressed in murine myeloid cell lines, but not in a mouse epithelial cell line, similar to the cell type expression of the human gene product (Kim et al. 2000). A 110–130-kDa membrane glycoprotein, expressed by rat NK cells, is a structural orthologue of the phagocytosis-stimulating receptor for complement factor C1q and mannose-binding lectin on human macrophages, C1qRp (receptor for C1q, regulating phagocytosis). Rat C1qRp is a monomeric type I integral membrane protein consisting of 643 amino acids with an N-terminal lectin-like domain, five epidermal growth factor-like domains, a transmembrane domain and a 45-residue cytoplasmic domain. It is encoded by a single gene on rat chromosome 3q41–q42 and is 67% and 87.5% identical at the amino acid level to human and mouse C1qRp, respectively. Rat C1qRp is expressed by resting and by activated NK cells, on subpopulations of NKR-$P1^+$ T cells (NK/T cells), dendritic cells, macrophages, neutrophils and granulocytes, but not by B cells or NKR-$P1^-$ T cells. Expression of this innate immune receptor is therefore not restricted to hematopoietic cells of the myeloid lineage, but is also expressed on subsets of cells of lymphoid origin (Løvik et al. 2000) The C1qRp, present on macrophages and neutrophils, is presumed to stimulate phagocytosis in these cells. In rat NK cells, an intracellular Ca^{2+}-response is induced upon stimulation of C1qRp with mAbs, LOV3 and LOV8. The response induced by the antibodies was owing to the Ca^{2+} mobilization from intracellular calcium stores (Løvik et al. 2001). Murine mast cells express specific receptors for C1q. Both cC1qR and gC1qR are present on these cells. C1qRs may play a significant role in mast cell function and regulation by providing an important signal through which mast cells can be recruited to inflammatory sites of increased C1q concentration (Ghebrehiwet et al. 1995).

The major site of AA4 expression in all tissue tested is on endothelial cells and that despite the apparent involvement of AA4 in the phagocytic response, it is not expressed by tissue macrophages. Although AA4 has been described on all hematopoietic progenitors, only circulating immature B cells, monocytes and NK cells but not T cells and

neutrophils expressed AA4 (Dean et al. 2001). The CD93-mRNA is highly induced after transient focal cerebral ischemia. CD93 protein is upregulated in endothelial cells, but also in selected macrophages and microglia. Harhausen et al. (2010) speculated that CD93-neuroprotection is mediated via suppression of the neuroinflammatory response through downregulation of CCL21 (Harhausen et al. 2010).

The murine fetal stem cell marker AA4 is a known homologue of the human phagocytic C1q receptor involved in host defense. The rat AA4 displays similar domain composition and organization to thrombomodulin. The rat AA4 was encoded by a single transcript of 7 kb expressed constitutively in all tissues and was expressed predominantly by pneumocytes and vascular endothelial cells. AA4 was identified as a glycosylated protein of 100 kDa expressed by endothelial cells > platelets > NK cells and monocytes (ED1+ cells). The staining was associated to the cell surface and intracytoplasmic vesicles. Interestingly, alveolar epithelial cells (lung) but not other epithelia (e.g. uterus) were strongly stained for AA4. Although AA4 has been described on all hematopoietic progenitors, only circulating immature B cells, monocytes and NK cells but not T cells and neutrophils expressed AA4. These results support the idea that AA4/C1qRp is involved in some cell-cell interactions (Dean et al. 2000, 2001).

The hematopoietic system of mice is established during the early to midgestational stage of development. Although AA4.1$^+$ and AA4.1$^-$ cells had equivalent potency to generate myeloid cell lineages, the lymphoid potential in ES-cell-derived cells was largely restricted to the cells expressing AA4.1. The same cell type was present abundantly in the early yolk sac and in fewer numbers (~5% of that in the yolk sac) in the caudal half of the developing embryos. These results suggest that AA4.1 is a cell surface marker that can identify the earliest lymphohematopoietic progenitors in mouse development (Yamane et al. 2009).

Zekavat et al. (2010) identified a point mutation in the NOD *Cd93* gene, which maps to the *Idd13* locus, a region encoding a high degree of penetrance for diabetes susceptibility in non-obese diabetic (NOD) mice (Kim et al. 2000; Serreze et al. 1998). In addition, they also identified this *Cd93* polymorphism in NZB/W F1 mice, to which the lupus susceptibility loci, *Wbw1* and *Nkt2*, are tightly linked (Rahman et al. 2002; Esteban et al. 2003). This point mutation is associated with aberrant expression of CD93 on NOD and NZB/W F1 B cells in the pro-/pre-, immature, and TR subsets as compared with non-autoimmune B6 mice. The *Idd13* and *Wbw1* and *Nkt2* loci are known to play a role in the regulation of the invariant natural killer T (iNKT) cell compartment (Chen et al. 2007; Esteban et al. 2003; Jordan et al. 2004; Rahman et al. 2002).

This allele carries a coding polymorphism in the first EGF-like domain of CD93, which results in an amino acid substitution from Asn→His at position 264. This polymorphism does not appear to influence protein translation or ecto-domain cleavage, as CD93 is detectable in bone-marrow-derived macrophage and B-cell precursor lysates and in soluble form in the serum. The NOD CD93 isoform causes a phenotypic aberrancy in the early B-cell developmental stages (i.e., pro-, pre-, immature, and transitional), likely related to a conformational variation. Consistent with genetic linkage, B6 CD93$^{-/-}$ and B6.NOD^{Idd13} mice were found susceptible to a profound CD4$^+$ NKT cell deficient state. Data suggest that *Cd93* may be an autoimmune susceptibility gene residing within the *Idd13* locus, which plays a role in regulating absolute numbers of CD4$^+$ NKT cells (Zekavat et al. 2010).

41.4 The gC1qR (p33, p32, C1qBP, TAP)

41.4.1 A Multi-Multifunctional Protein - Binding with C1q

The gC1qR (also named as gC1qBP) is a 33 kDa single chain, highly acidic glycoprotein that binds to the globular 'heads' of C1q. Comparison of the cDNA-derived amino acid sequences of gC1qBP reveals that either of the rodents, rat and mouse, sequences is 89.9% identical to human sequence. Recombinant rat gC1qBP binds avidly to human C1q. gC1qBP mRNA is abundantly expressed in every rat and mouse tissue analysed. Rat mesangial cells synthesise gC1qBP, but do not express gC1qBP on the cell surface. In rat serum, gC1qBP is present at low levels (Lynch et al. 1997).

Tha gC1qR was first isolated from membrane preparation of Raji cells and now appears to be ubiquitously distributed. Although, gC1qR was originally identified as a protein which binds to the globular "heads" of C1q, evidence suggests that the molecule is in fact a multi-ligand binding, multifunctional protein with affinity for diverse ligands which at best are functionally related. These molecules include: thrombin, vitronectin, and high molecular weight kininogen. The gC1qR molecule, which is identical to the transcription factors SF2 and the Tat-associated protein, or TAP, is the product of a single gene localized on chromosome 17p13.3 in human, and chromosome 11 in mouse, and is encoded by an approximately 1.5–1.6 kb mRNA. The full length cDNA encodes a primary translation protein of 282 residues and the 'mature' or membrane form of the protein isolated from Raji cells corresponds to residues 74–282 and is presumed to be generated by a site-specific cleavage and removal of the highly basic, 73-residues long, N-terminal segment during post-translational processing. The translated amino acid sequence does not predict for the presence of a conventional sequence motif compatible with a

transmembrane segment and does not have a consensus site for a GPI anchor. However, there is strong evidence which indicates that gC1qR is expressed both inside the cell and on the membrane. In addition, the membrane expression of gC1qR can be upregulated with inflammatory cytokines such as INF-gamma, TNF-α, or LPS (Ghebrehiwet and Peerschke 1998).

Although expressed on the surface of cells, an intriguing feature of the membrane-associated form of gC1qR is that its translated amino acid sequence does not predict the presence of either a sequence motif compatible with a transmembrane segment or a consensus site for a glycosylphosphatidylinositol anchor. Moreover, the N-terminal sequence of the pre-pro-protein gC1qR contains a motif that targets the molecule to the mitochondria and as such was deemed unlikely to be expressed on the surface. However, several lines of experimental evidence clearly show that gC1qR is present in all compartments of the cell, including the extracellular cell surface. First, surface labeling of B lymphocytes with the membrane-impermeable reagent sulfosuccinimidyl 6-(biotinamido) hexanoate shows specific biotin incorporation into the surface-expressed but not the intracellular form of gC1qR. Second, FACS and confocal laser scanning microscopic analyses demonstrated specific staining of Raji cells surface. Third, endothelial gC1qR, which is associated with the urokinase plasminogen activator receptor, and cytokeratin 1 bind 125I-high molecular weight kininogen in a specific manner. Fourth, native gC1qR purified from Raji cell membranes but not intracellular gC1qR is glycosylated, as evidenced by a positive periodic acid Schiff stain as well as sensitivity to digestion with endoglycosidase H and F. Finally, cross-linking experiments using C1q as a ligand indicate that both cC1qR and gC1qR are co immunoprecipitated with anti-C1q. Taken together, the evidence accumulated to date supports the concept that in addition to its intracellular localization, gC1qR is expressed on the cell surface and can serve as a binding site for plasma and microbial proteins, but also challenges the existing paradigm that mitochondrial proteins never leave their designated compartment. It is therefore proposed that gC1qR belongs to a growing list of a class of proteins initially targeted to the mitochondria but then exported to different compartments of the cell through specific mechanisms which have yet to be identified. The designation 'multifunctional and multicompartmental cellular proteins' is proposed for this class of proteins (Ghebrehiwet et al. 2001).

Platelets are involved in the development of many types of vascular lesions. In addition to their role in primary hemostasis, they participate in inflammatory processes that may contribute to the development of thrombosis, atherosclerosis and vasculitis. C1q has been shown to modulate platelet interactions with collagen and immune complexes, and has been identified at the sites of vascular injury and inflammation, as well as in atherosclerotic lesions. Platelets express a variety of C1q binding sites, including gC1qR/p33 (gC1qR) (Peerschke and Ghebrehiwet 2001).

The gC1qR (or P32) protein is a binding protein for nuclear pre-mRNA splicing factor SF2/ASF and numerous other nuclear and cell surface proteins, yet is targeted to the mitochondrial matrix compartment where these proteins are not present (Soltys et al. 2000). The endothelial protein p33/gC1qR is thought to mediate the assembly of components of the kinin-forming and complement-activating pathways on the surface of cardiovascular cells. Fractionation studies demonstrated that the vesicular but not the membrane fraction of EA.hy926 cells is rich in p33. It seems that externalization of p33 must precede its complex formation with target proteins on the endothelial cell surface (Dedio and Muller-Esterl 1996).

The binding of the ligand C1q by recombinant gC1qR was indistinguishable from binding shown by gC1qR isolated from Raji cells. gC1qR as a novel vitronectin-binding protein that may participate in the clearance of vitronectin-containing complexes or opsonized particles or cooperate with vitronectin in the inhibition of complement-mediated cytolysis (Ghebrehiwet et al. 1994; Lim et al. 1996).

41.4.2 Human gC1qR/p32 (C1qBP) Gene

The 7.8-kbp human gC1qR/p32 (C1qBP) gene was cloned and found to consist of 6 exons and 5 introns. Analysis of a 1.3-kb DNA fragment at the 5′-flanking region of this gene revealed the presence of multiple TATA, CCAAT, and Sp1 binding sites. Subsequent 5′ and 3′ deletion of this fragment confined promoter elements to within 400 bp upstream of the translational start site. Because the removal of the 8-bp consensus TATATATA at -399 to -406 and CCAAT at -410 to -414 did not significantly affect the transcription efficiency of the promoter, GC-rich sequences between this TATA box and the translation start site may be very important for the promoter activity of the C1qBP gene. One of seven GC-rich sequences in this region binds specifically to PANC-1 nuclear extracts and the transcription factor Sp1. Primer extension analysis mapped three major transcription start regions. The farthest transcription start site is 49 bp upstream of the ATG translation initiation codon and is in close proximity of the specific SP1 binding site (Tye et al. 2001).

41.4.3 Ligand Interactions

41.4.3.1 A Receptor for C1q

Although originally isolated as a receptor for C1q by virtue of its specificity for the globular heads of that molecule, a large body of evidence has now been accumulated which shows that in addition to C1q, gC1qR can serve as a receptor for diverse ligands including proteins of the intrinsic coagulation/bradykinin forming cascade, as well as antigens of cellular, bacterial, and viral origin. Furthermore, since gC1qR has been shown to regulate the functions of protein kinase C (PKC), it is postulated that gC1qR-induced signaling cascade may involve activation of PKC. Collective reports suggest that gC1qR plays an important role in blood coagulation, inflammation, and infection. It is still unclear as to how the molecule is anchored on the membrane since its sequence is devoid of a classical transmembrane domain or a glycosylphosphatidylinositol (GPI) anchor. Furthermore, while recombinant gC1qR can bind to cell surfaces suggesting that it may bind directly to the phospholipid bilayer, experiments showed that, at least in vitro, gC1qR does not bind to unilamellar vesicle preparations of either phosphatidylcholine (PC) or phosphatidylserine: phosphatidylcholine. The three-dimensional structure of gC1qR.

41.4.3.2 Interaction of High Molecular Weight Kininogen

Kininogens, the precursor proteins of the vasoactive kinins, bind specifically, reversibly, and saturably to platelets, neutrophils, and endothelial cells. Two domains of the kininogens expose major cell binding sites: domain D3 that is shared by H- and L-kininogen and domain D5H that is exclusively present in H-kininogen. The kininogen cell binding sites were mapped to 27 residues of D3 ("LDC27") and 20 residues of D5H ("HKH20″", respectively) (Herwald et al. 1995; Hasan et al. 1995). An endothelial binding protein of 33 kDa similar to gC1qR has been indicated to mediates the assembly of critical components of the kinin-generating pathway on the surface of endothelial cells, thereby linking the early events of kinin formation and complement activation (Herwald et al. 1996).

To further probe cellular trafficking routes of gC1qR, Dedio et al. (1999) over-expressed human gC1qR in a mammalian cell and monitored cell surface exposure of recombinant gC1qR by virtue of its capacity to bind labeled H-kininogen. Transient transfection of COS1 cells with the full-length cDNA of human gC1qR resulted in a high level of recombinant protein that matched the pool of endogenous gC1qR present in these cells. Overexpression of gC1qR did not significantly increase the number of H-kininogen binding sites exposed by the transfected cells thus denying the possibility that alternative routing of gC1qR to the surface of COS1 cells occurs at significant levels. Hence gC1qR has the capacity to tightly bind H-kininogen, but because gC1qR is routed to mitochondria it cannot fulfill the postulated functions as a cell docking site for kininogens and complement factors (Dedio et al. 1999).

The gC1qR has been shown to bind a number of plasma proteins involved in the coagulation and kinin systems. Biotinylated gC1qR was found to bind to fibrinogen in a manner which was specific and inhibited by excess soluble fibrinogen or polyclonal antibodies directed against either gC1qR or fibrinogen. Observations may suggest a potential role for gC1qR in modulating fibrin formation particularly at local sites of immune injury or inflammation (Lu et al. 1999).

High molecular weight kininogen (HK) and factor XII bind to human umbilical vein endothelial cells (HUVEC) in a zinc-dependent and saturable manner indicating that HUVEC express specific binding site(s) for those proteins. The binding of HK and factor XII to HUVECs occurs via a 33-kDa cell surface glycoprotein that appears to be identical to gC1qR but with a site on gC1qR distinct from that which binds C1q (Joseph et al. 1996; 2001). However, unlike C1q, whose interaction with gC1qR does not require divalent ions, the binding of HK to gC1qR is absolutely dependent on the presence of zinc. Zinc can induce the exposure of hydrophobic sites in the C-terminal domain of gC1qR involved in binding to HK/FXII (Kumar et al. 2002).

Cell surface proteins reported to participate in the binding and activation of the plasma kinin-forming cascade includes gC1qR, cytokeratin 1 and u-PAR. Each of these proteins binds high molecular weight kininogen (HK) as well as Factor XII. The studies suggest that formation of HK (and Factor XII) binding sites along endothelial cell membranes consists of bimolecular complexes of gC1qR-cytokeratin 1 and u-PAR-cytokeratin 1, with gC1qR binding being favored (Joseph et al. 2004).

Human p32 (also known as SF2-associated p32, p32/TAP, and gC1qR) localizes predominantly in the mitochondrial matrix. It is thought to be involved in mitochondrial oxidative phosphorylation and in nucleus-mitochondrion interactions. The three-dimensional structure of gC1qR identified unique structural features that may serve not only to anchor the protein but also to explain its affinity for such a diversity of plasma as well as microbial and viral ligands (Ghebrehiwet et al. 2002; Jiang et al. 1999). The crystal structure reveals that p32 adopts a novel fold with seven consecutive antiparallel β-strands flanked by one N-terminal and two C-terminal α-helices. Three monomers form a doughnut-shaped quaternary structure with an unusually asymmetric charge distribution on the surface. The implications of the structure on previously proposed functions of p32 are discussed and new specific functional properties are suggested (Jiang et al. 1999).

41.4.3.3 Adrenergic Receptor

gC1qR was found to bind with the carboxyl-terminal cytoplasmic domain of the α1B-adrenergic receptor (amino acids 344–516) in a yeast two-hybrid screen of a cDNA library prepared from the rat liver. The gC1qR interaction with an arginine-rich motif in the C-tail of hamster α1B-adrenergic receptors seems to control their expression and subcellular localization. Studies suggest that gC1qR interacts specifically with α1B- and α1D-, but not α1A-adrenergic, and this interaction depends on the presence of an intact C-tail. This suggests a role for gC1qR in regulating the cellular localization and expression of adrenergic receptors (Pupo and Minneman 2003; Xu et al. 1999).

41.4.3.4 Interaction with Bacteria and Viruses

On the surface of activated platelets, gC1qR has been shown to serve as a binding site for *Staphylococcus* aureus and this binding is mediated by protein A. Since the binding of *S. aureus* to platelets is postulated to play a major role in the pathogenesis of endocarditis, gC1qR may provide a suitable surface for the initial adhesion of the bacterium. Recent data also demonstrate that the exosporium of Bacillus cereus, a member of a genus of aerobic, Gram-positive, spore-forming rod-like bacilli, which includes the deadly Bacillus anthracis, contains a binding site for gC1qR. Therefore, by virtue of its ability to recognize plasma proteins such as C1q and HK, as well as bacterial and viral antigens, cell-surface gC1qR not only is able to generate proinflammatory byproducts from the complement and kinin/kallikrein systems, but also can be an efficient vehicle and platform for a plethora of pathogenic microorganisms (Peerschke and Ghebrehiwet 2007).

InlB is a *Listeria monocytogenes* protein that promotes entry of the bacterium into mammalian cells by stimulating tyrosine phosphorylation of the adaptor proteins Gab1, Cbl and Shc, and activation of phosphatidyl-inositol (PI) 3-kinase. However, Braun et al. (2000) demonstrated a direct interaction between InlB and the gC1qR. The platelet gC1qR is a cellular binding site for *Staphylococcal* protein A which suggests an additional mechanism for bacterial cell adhesion to sites of vascular injury and thrombosis (Nguyen et al. 2000).

Circulating, nonenveloped Hepatitis C virus (HCV) core protein interacts with immunocytes through gC1qR. The HCV core protein is the protein expressed during the early phase of HCV infection and suppresses host immune responses, including anti-viral cytotoxic T-lymphocyte responses in a murine model. Like C1q, HCV core protein can inhibit T-cell proliferative responses in vitro. Biochemical analysis of the interaction between core and gC1qR indicates that HCV core binds the region spanning amino acids 188–259, a site distinct from the binding region of C1q (Kittlesen et al. 2000). Binding of HCV core to gC1qR on T cells leads to impaired Lck/Akt activation and T-cell function (Yao et al. 2004). Up-regulation of gC1qR expression is a distinctive feature of MC, and dysregulated shedding of C1qR molecules contributes to vascular cryoglobulin-induced damage via the classic complement-mediated pathway (Sansonno et al. 2009). The gC1qR is the main cellular partner of the hepatitis B virus P22 which was colocalized with the endogenous gC1qR in both the cytoplasm and the nucleus but never in the mitochondria (Lainé et al. 2003). The gC1qR is an effective inhibitor of HIV-1 infection, which prevents viral entry by blocking the interaction between CD4 and gp120. Since gC1qR is a human protein, it is most probably not antigenic in humans. It would seem logical, therefore, to consider gC1qR or its fragments involved in the CD4 binding as potential therapeutic agents (Szabo et al. 2011).

41.4.4 Role in Pathology

The localization of gC1qR and its ligands C1q and HK in atherosclerotic lesions, and the ability of gC1qR to modulate complement, kinin, and coagulation cascades, suggests that gC1qR may play an important role in promoting inflammation and thrombosis in atherosclerotic lesions (Peerschke et al. 2004).

Sequencing of the gene encoding tumor-associated gC1qR did not reveal any consistent tumor-specific mutations. However, histochemical staining demonstrated marked differential expression of gC1qR in thyroid, colon, pancreatic, gastric, esophageal and lung adenocarcinomas compared to their nonmalignant histologic counterparts. In contrast, differential expression was not seen in endometrial, renal and prostate carcinomas. Despite high expression in breast carcinoma, gC1qR was also expressed in nonmalignant breast tissue. Although the precise relation of gC1qR to carcinogenesis remains unclear, the finding of tumor overexpression and the known multivalent binding of gC1qR to a variety of circulating plasma proteins as well as its involvement in cell-to-cell interactions suggest that gC1qR may have a role in tumor metastases (Rubinstein et al. 2004).

Membrane type 1 matrixmetallo-proteinase (MT1-MMP), a key enzyme in cell locomotion, is known to be primarily recruited to the leading edge of migrating cells. MT1-MMP via its cytoplasmic tail directly associates with a compartment-specific regulator gC1qR. Although a direct functional link between these two proteins remains uncertain, observations suggest that the transient associations of gC1qR with the cytoplasmic tail of MT1-MMP are likely to be involved in the mechanisms regulating presentation of the protease at the tumor cell surface (Rozanov et al. 2002).

41.5 Thrombomodulin

The thrombomodulin group of CTLD-containing cell surface proteins has three members in both human and mouse: thrombomodulin, CD93, endosialin, and C-type lectin 14A. The extracellular region of each of these type 1 transmembrane proteins consists of a CTLD projected from the cell surface by a Sushi domain, a number of epidermal growth factor (EGF) domains, and a region rich in proline, serine and threonine that carries multiple O-linked glycans. The short cytoplasmic tail often contains tyrosine-based motifs.

41.5.1 Localization

Thrombomodulin (TM) (CD141) or BDCA-3 is an integral membrane glycoprotein, initially described on an endothelial cell surface. Most of the vascular TM is contained in capillaries which comprise greater than 99% of endothelial surface area. Immunohistochemical analysis of human tissues demonstrated TM on endothelia of blood vessels and lymphatics except for in the CNS (Maruyama et al. 1985; Ishii et al. 1986; DeBault et al. 1986). The syncytiotrophoblast of the placenta contains TM, while hepatic sinusoids and the postcapillary venules of lymph nodes are devoid of it. The TM has been identified on the squamous epithelium of the epidermis (Yonezawa et al. 1987) and in human platelets where their number per endothelial cell is low (Suzuki et al. 1988). TM has been found in a variety of cultured cells, including NIH 3T3 cells, A549 small cell lung cancer cells and CHO cells. Some endothelial neoplasms express TM. Choriocarcinoma but not choriocarcinoma cell lines have been found to express TM (Dittman and Majerus 1990). The antigen described as BDCA-3 has turned out to be identical to TM (Dzionek et al. 2000, 2002). Thus it was revealed that this molecule also occurs on a very rare (0.02%) subset of human dendritic cells called MDC2. Its function on these cells is unknown at present, but apparently, TM has at least one other ligand apart from thrombin, because anticoaglulation is a common place function, in contrast to the rarity of MDC2 cells. In humans, TM is encoded by the THBD gene (Wen et al. 1987).

41.5.2 Characteristics

The human TM is a 75 kDa protein when analyzed on SDS-PAGE. After reduction of disulfide bonds, the Mr was 105 kDa, indicating secondary structure involving multiple cystine bridges. This secondary structure renders TM stable under extremes of pH and under denaturing conditions. The cDNAs for human (Wen et al. 1987; Suzuki et al. 1987) and murine TM (Dittman and Majerus 1989) have been sequenced. The structure resembles the low density lipoprotein (LDL) receptor (Goldstein et al. 1985) (Fig. 41.2). The initiating methionine at amino terminal is followed by an 18 amino acid hydrophobic leader sequence. The mature protein starts with sequences distantly homologous to CTLDs such as the asialoglycoprotein receptor (residues 19–179) (Patthy 1988). The large area of identity between the mouse and human cDNAs in the lectin domain implies that the conserved sequence has some unknown function. Human TM consists of ten structural elements: an N-terminal domain homologous to the family of C-type lectins (residues 1–226), six tandemly repeated epidermal growth factor (EGF)-like1 domains (residues 227–462), a Ser/Thr-rich region (residues 463–497), a transmembrane domain (residues 498–521), and a short cytoplasmic tail (residues 522–557) (Jackman et al. 1986; Suzuki et al. 1987; Wen et al. 1987) (Fig. 41.2). The short cytoplasmic tail contains several potential sites for phosphorylation, and phosphorylation in cells has been associated with increased endocytosis and degradation of TM. Thrombomodulin is glycosylated on asparagine residues (Stearns et al. 1989).

The TM gene (*THBD*) maps to chromosome 20p11.2, contains a single exon and no introns, and spans 4 kb (Ireland et al. 1996; Wen et al. 1987). Both the human (Jackman et al. 1987; Shira et al. 1988) and mouse genes are intronless, for which no special function is known. The TM transcribes a single mRNA of approximately 3,700 bases, consistent with the size of cDNAs for human (3,693 bases) and mouse (3,658 bases) TM. In humans the 5′ untranslated region is 150 bases, the coding region is 1,725 bases encoding 575 amino acids, and the 3′ untranslated region is 1,779 bases. The 3′ untranslated region is highly conserved between species and contains the sequence TTATTTAT, which has been associated with short mRNA half-lives (Shaw and Kamen 1986). Several potential polyadenylation signals, AATAAA are also present in the cDNAs of three species.

41.5.3 Regulation of TM Activity

TM is subject to regulation by internalization of the cell-surface molecule, with loss of protein C activating activity. Thrombin binding to TM can induce internalization of thrombin-TM complexes, with transport to lysosomes, release and degradation of thrombin, and subsequent return of TM to the cell surface (Dittman and Majerus 1990). Cytokines also affect the expression of TM. Tumor necrosis factor (TNF) rapidly alters the anticoagulant properties of the endothelial cell surface by inducing expression of the procoagulant, tissue factor, and reducing TM activity. The reduction in activity is associated with endocytosis and

lysosomal degradation of TM. TNF also inhibits transcription of TM mRNA; the subsequent decrease in TM synthesis may also contribute to the decline in TM activity. Other cytokines, interleukin-1 (Naworth et al. 1986) and endotoxin (Moore et al. 1987) also cause decreased TM activity on endothelial cell surfaces. In fact, thrombin increases TM transcription rates, mRNA levels, and total TM protein in cultured mouse hemangioma cells (Dittman et al. 1989). Infusion of TNF into humans increases the production of fibrin, indicating activation of coagulation. Protein C activation was also increased in contrast to what might have been predicted by the in vitro effect of TNF on TM activity and protein C activation. This observation is consistent with additional regulation of TM in vivo by components of the hemostatic system, perhaps by thrombin as discussed above (Dittman and Majerus 1990).

41.5.4 Structure-Function Relations - Binding to Thrombin

Structural requirements for thrombin binding to TM and cofactor activity have been studied by mutagenesis of recombinant human TM. Deletion of the fourth EGF-like domain abolished cofactor activity but did not affect thrombin binding. Deletion of either the fifth or the sixth EGF-like domain markedly reduced both thrombin binding affinity and cofactor activity. Studies suggest that the anticoagulant function of TM is mediated by EGF-like domains 4, 5, and 6 (EGF456) (Zushi et al. 1989). While TM binds to EGF-like domains 5 and 6 (Kurosawa et al. 1988), EGF-like domain 4 is not required for thrombin binding but is essential for accelerating protein C activation (Tsiang et al. 1992; Parkinson et al. 1992). Membrane association is not necessary for cofactor activity (Kurosawa et al. 1988; Suzuki et al. 1989), and the smallest fully active soluble TM fragment consists of EGF456 (Zushi et al. 1989; Hayashi et al. 1990). The EGF456 contains the region required for thrombin binding and protein C activation. Neither mouse nor bovine TM contains the serine-glycine-X-glycine signal sequence required for heparin-like glycosoaminoglycan attachment 58; human TM has an unfavored site for such modification.

Thrombin binding sequences were also localized by assaying the ability of synthetic peptides derived from TM. The two most active peptides corresponded to (a) the entire third loop of the fifth EGF-like domain ($Kp = 85 \pm 6$ μM) and (b) parts of the second and third loops of the sixth EGF-like domain ($Kp = 117 \pm 9$ μM). Studies suggest that thrombin interacts with two discrete elements in TM. Deletion of the Ser/Thr-rich domain dramatically decreased both thrombin binding affinity and cofactor activity and also prevented the formation of a high molecular weight TM species containing chondroitin sulfate. Substitutions of this domain with polypeptide segments of decreasing length and devoid of glycosylation sites progressively decreased both cofactor activity and thrombin binding affinity. This correlation suggests that increased proximity of the membrane surface to the thrombin binding site may hinder efficient thrombin binding and the subsequent activation of protein C. Membrane-bound TM therefore requires the Ser/Thr-rich domain as an important spacer, in addition to EGF-like domains 4–6 (EGF456), for efficient protein C activation. The EGF456 appears to have anticoagulant properties which make it more suitable anticoagulant in extracorporeal circulation in monkeys (Suzuki et al. 1998).

41.5.4.1 The Disulfide Bonding Pattern

The disulfide bonding pattern of the fourth and fifth EGF-like domains within the smallest active fragment of TM has been determined. The disulfide bonding pattern of the fourth EGF-like domain was (1–3, 2–4, 5–6). Surprisingly, the disulfide bonding pattern of the fifth domain was (1–2, 3–4, 5–6), which is different from EGF or any other EGF-like domain analyzed so far. The observation that not all EGF-like domains have an EGF-like disulfide bonding pattern reveals an additional element of diversity in the structure of EGF-like domains (White et al. 1996).

41.5.4.2 Critical Amino Acids in TM

Studies suggest that the region 333–350 in EGF3-4 is critical for protein C activation by the thrombin-TM complex and the region 447–462 in EGF6 is critical for thrombin binding (Parkinson et al. 1992). The 80–90% of TM activity is lost by oxidation of Met^{388}, located within the short interdomain loop between EGF-like domains 4 and 5. The interdomain loop is critical in the biological anticoagulant properties of TM (Clarke et al. 1993). Site-directed mutagenesis suggested that amino acid Asp^{349} of EGF456, in a recombinant protein is essential for retaining full protein C-activating cofactor activity. Thus, Asp^{349} in the fourth EGF-like structure of TM plays a role in its Ca^{2+}-mediated binding to protein C (Zushi et al. 1991).

Although, the fourth EGF-like domain is unnecessary for high affinity thrombin binding, yet it is required for cofactor activity. Two regions of the fourth EGF-like domain were identified as essential for cofactor activity: (1) the sequence consisting of amino acids Glu^{357}, Tyr^{358}, and Gln^{359} shared by the overlapping first and second disulfide loops, and (2) the amino-terminal region of the third disulfide loop containing amino acids Glu^{374}, Gly^{375}, and Phe^{376} (Lentz et al. 1993). In another study, mutants between Cys^{333} and Cys^{462} of TM were expressed in E. coli. In EGF4, which is essential for protein C activation by the thrombin-TM complex, critical residues were: Asp^{349}, Glu^{357}, Tyr^{358}, and Phe^{376}. In EGF5-EGF6, critical residues within a proposed

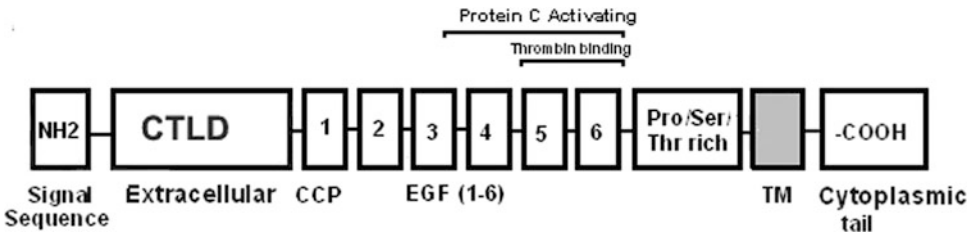

Fig. 41.2 Domain organization of Thrombomodulin: TM is composed of five structural domains. Extending from a short cytoplasmic tail and transmembrane domain is a serine/threonine–rich region to which a chondroitin sulfate moiety that optimizes anticoagulant function is attached. Next is a domain that consists of six epidermal growth factor (EGF)-like repeats, four of which are responsible for the protein's anticoagulant and antifibrinolytic functions. The NH_2-terminal domain has two modules. The first, adjacent to the EGF-like domain, is a ~70–amino acid residue hydrophobic region. The second, which is ~155–amino acid residues long, has homology to C-type lectins (Conway et al. 2002)

acidic thrombin-binding region were: Glu^{408}, Tyr^{413}, Ile^{414}, Leu^{415}, Asp^{416}, Asp^{417}, Asp^{423}, Ile^{424}, Asp^{425}, and Glu^{426}. A potential Ca^{2+}-binding site, which is comprised of residues Asp^{423}, Asp^{425}, Glu^{426}, Asn^{439}, Leu^{440}, and Phe^{444}, overlaps the thrombin-binding region. Asp^{461}, in the C-loop of EGF6 shown to be critical for thrombin and residues Asp^{398}, Asp^{400}, Asn^{402}, and Asn^{429} in EGF5 were critical for binding. Thus, 22 residues are critical in the region comprising EGF4-6, which is essential for thrombin binding and protein C activation by the thrombin-TM complex (Nagashima et al. 1993). These results suggest that amino acids critical for TM cofactor activity are located near the junction between the two subdomains of the fourth EGF-like domain.

41.5.4.3 Methionine Oxidation Is Deleterious for TM

Although TM is a large protein, only EGF4,5-like domains are required for anticoagulant function. These two domains must work together, and the linker between the two domains contains a single methionine residue, Met^{388}. Oxidation of Met^{388} is deleterious for TM activity. Structural studies, both X-ray and NMR, of wild type and variants at position 388 showed that Met^{388} provides a key linkage between the two domains. Oxidation of the methionine has consequences for the structure of the fifth domain, which binds to thrombin. The functional consequences of oxidation of Met^{388} include decreased anticoagulant activity. Oxidative stress from several causes is reflected in lower serum levels of activated protein C and a higher thrombotic tendency, and this is thought to be linked to the oxidation of Met^{388} in TM. Thus, TM structure and function are altered in a subtle but functionally critical way upon oxidation of Met^{388} (Wood et al. 2005).

41.5.4.4 Role of Exosites 1 and 2 in Thrombin Reaction

Thrombin has three main binding sites: the catalytic or active site, where its primary plasma inhibitor, antithrombin, binds and inhibits its coagulation activity; and two anion-binding sites, exosite 1 and exosite 2. Exosite 1 binds to fibrinogen, TM, hirudin, and the amino terminus of heparin cofactor II (HCII) (Becker et al. 1999). Exosite 2 mediates binding of thrombin to heparin and to platelet surface glycoprotein Ib-α (GPIba). Ligand binding to either exosite 1 or exosite 2 may also influence reactivity of the active site of thrombin (Fredenburgh et al. 1997). The cofactors heparin, vitronectin (VN), and TM modulate the reactivity of α-thrombin with plasminogen activator inhibitor (PAI-1). While heparin and VN accelerate the reaction by two orders of magnitude, TM protects α-thrombin from rapid inactivation by PAI-1 in presence of VN. Kinetic studies suggest that (1) heparin binds to exosite 2 of α-thrombin to accelerate the reaction by a template mechanism, (2) VN accelerates PAI-1 inactivation of α-thrombin by lowering the K_D for initial complex formation by an unknown mechanism that does not require binding to either exosite 1 or exosite 2 of α-thrombin, (3) α-thrombin may have a binding site for PAI-1 within or near exosite 1, and (4) TM occupancy of exosite 1 partially accounts for the protection of thrombin from rapid inactivation by PAI-1 in presence of vitronectin (Rezaie 1999).

Exosite 1 of thrombin consists of a cluster of basic residues (Arg^{35}, Lys^{36}, Arg^{67}, Lys^{70}, Arg^{73}, Arg^{75}, and Arg^{77} in chymotrypsinogen numbering) that play key roles in the function of thrombin. Structure suggests that the side chain of Arg^{35} projects toward the active site pocket of thrombin, but all other residues are poised to interact with TM. While studying the role of these residues in TM-mediated protein C activation by thrombin, results suggest that Arg^{35} is responsible for the Ca^{2+} dependence of protein C activation by the thrombin–TM complex and that a function for TM in the activation complex is the allosteric alleviation of the inhibitory interaction of Arg^{35} with the substrate. The results suggest that TM modulates the conformation of Arg^{35}, and a cofactor function of TM is to alleviate the inhibitory interaction of Arg^{35} with protein C in the activation complex (Rezaie and Yang 2003).

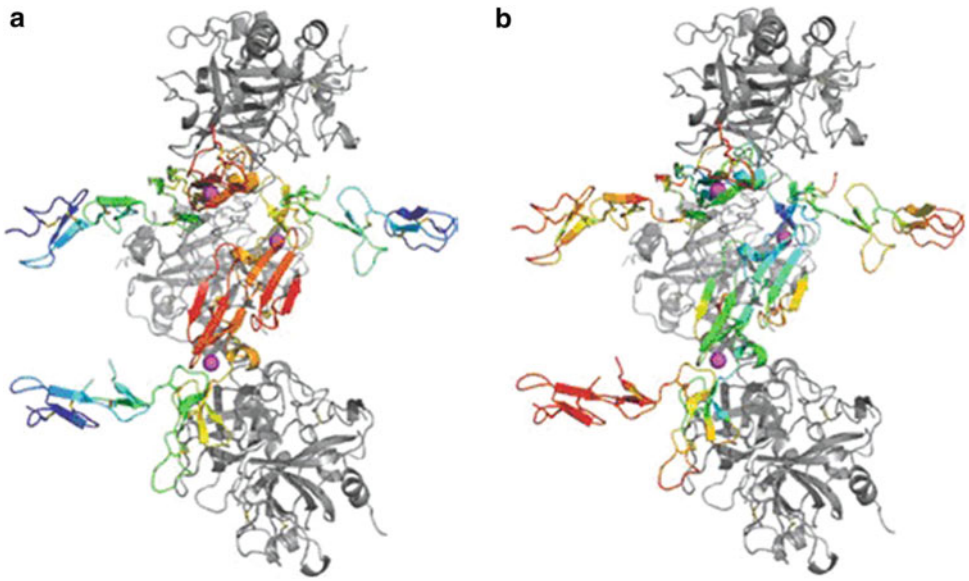

Fig. 41.3 Crystal structure of Na-free thrombin in complex with thrombomodulin: Structure of the thrombin-TM domains 4, 5, 6 (TM456) complex. (**a**) Ribbon diagram of the three complexes in the asymmetric unit, with thrombin coloured *grey* and TM456 coloured from N-to-C terminus from *blue* (EGF4) to *red* (EGF6), with *magenta* balls indicating Ca2 + ions. (**b**) The same image as in (**a**), but coloured according to B-factor to illustrate the inherent flexibility of the 4th EGF domains (Adapted with permission from Adams et al. 2009 © John Wiley and Sons)

Structural and mutagenesis data indicated that the interaction of basic residues of the heparin-binding exosite of protein C with the acidic residues of EGF4 is partially responsible for the efficient activation of the substrate by the thrombin-EGF456 complex. Similar to protein C, protein C inhibitor has a basic exosite (H-helix) that constitutes the heparin-binding site of the serpin. It was suggested that TM enhances the reactivity of protein C inhibitor with thrombin by providing both a binding site for the serpin and a conformational modulation of the extended binding pocket of thrombin (Yang et al. 2003).

41.5.5 The Crystal Structure

The crystal structure of the complex between human thrombin and the minimal cofactor fragment of TM, EGF456 revealed the features of TM-thrombin interaction and corroborated with earlier biochemical information (Fuentes-Prior et al. 2000) (Fig. 41.3). A reasonably small contact interface of ~900 Å is seen between exosite I of thrombin and EGF domains 5 and 6 of TM. Although the surfaces at the interface displayed charge complementarity, which may aid in steering the two fragments together (Myles et al. 2001) only a single salt bridge exists between lysine 110 of thrombin and aspartate^{461} of TM. The TM-thrombin complex crystal structure revealed no obvious conformational changes within the active site of thrombin, but the presence of a bound active-site inhibitor clouds this issue. However, allostery may play a role in switching the substrate preference of thrombin, as several biochemical studies suggest a tightening of the active site in response to TM binding (Koeppe et al. 2005). The cofactor effect of TM may also be partially attributable to an improved accessibility of the activation peptide of TM-bound protein C (Vindigni et al. 1997; Yang et al. 2006; Adams and Huntington 2006). The structure of EGF-like domain 4 has been determined by NMR spectroscopy. These structures are small steps toward an understanding of how TM regulates thrombin (Sadler 1997). The interaction of thrombin with a 28-residue peptide, hTM422-449, corresponding to the N-terminal subdomain of the sixth EGF-like repeat of human TM plus the junction between the fifth and the sixth EGF-like domains, characterized by NMR spectroscopy, is conformationally flexible in absence of thrombin. Upon addition of thrombin, differential resonance perturbations and transferred nuclear Overhauser effects (NOEs) are observed for TM peptide, suggesting specific and rapidly reversible binding and structuring of hTM422-449 in complex with thrombin (Tolkatchev et al. 2000).

Molecular modeling of the protein C activation based on the crystal structure of thrombin in complex with the EGF456 predicts that the binding of EGF56 to exosite 1 of thrombin positions EGF4 so that a negatively charged region on this domain juxtaposes a positively charged region of protein C. It has been hypothesized that electrostatic interactions between these oppositely charged residues of EGF4 and protein C facilitate a proper docking of the substrate into the catalytic pocket of thrombin. To test this hypothesis, Yang and Rezaie

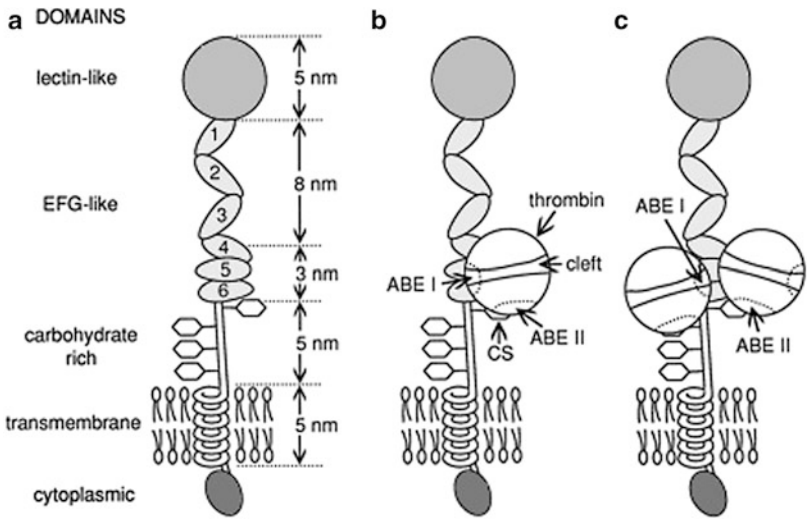

Fig. 41.4 Schematic diagram of Thrombomodulin and TM bound with thrombin. (**a**) schematic diagram of TM based on the electron microscope images of soluble TM. Domains are identified on the *left*, while their sizes are given on the *right*. EGF modules are numbered and carbohydrate moieties are represented as hexagons. The membrane is represented as a lipid bilayer, and the transmembrane region is shown as a typical single helix. (**b**) TM with one thrombin molecule bound. The locations of the catalytic cleft, anion-binding exosite I (ABE I), and anion-binding exosite II (ABE II) of thrombin are shown. Anion-binding exosite I is shown interacting with EGF-like modules 5 and 6 of TM, and anion-binding exosite II is shown interacting with the chondroitin sulfate (CS) residue on TM. (**c**) TM with two thrombin molecules bound, one via interactions of its anion-binding exosite I with EGF modules 5 and 6 and the other via interactions of its anion-binding exosite II with the chondroitin sulfate (Adapted with permission from Weisel et al. 1996 © The American Society for Biochemistry and Molecular Biology)

(2003) constructed several mutants of EGF456 and protein C in which charges of the putative interacting residues on both EGF4 (Asp/Glu) and protein C (Lys/Arg) were reversed. Results of TM-dependent protein C activation studies by such a compensatory mutagenesis approach support the molecular model that EGF4 interacts with the basic exosite of protein C (Yang and Rezaie 2003).

41.5.5.1 TM-Thrombin Complex Under EM

Weisel et al. (1996) determined the shape of SolulinTM, a soluble recombinant form of human TM missing the transmembrane and cytoplasmic domains, by electron microscopy. Solulin appears to be an elongated molecule about 20 nm long that has a large nodule at one end and a smaller nodule near the other end from which extends a thin strand. About half of the molecules form bipolar dimers apparently via interactions between these thin strands. Electron microscopy of complexes formed between Solulin and human α-thrombin revealed that a single thrombin molecule appears to bind to the smaller nodule of Solulin, suggesting that this region contains the EGF41. Epidermal growth factor-like domains 1–4 comprise the connector between the small and large nodule, which is the lectin-like domain; the thin strand at the other end of the molecule is the carbohydrate-rich region. With chondroitin sulfate-containing soluble TM produced from either human melanoma cells or CHO cells, a higher percentage of molecules bound thrombin and, in some cases, two thrombin molecules were attached to one soluble TM in approximately the same region (Weisel et al. 1996) (Fig. 41.4).

41.5.6 Functions

TM is considered a protein involved in coagulation, cancer and embryogenesis. The altered coagulation process leads to a precocious placental failure, but some studies suggest that TM has an anti-inflammatory ability through both protein C dependent and independent pathways.

41.5.6.1 TM Initiates Anticoagulant Process

Thrombomodulin is an endocytic receptor expressed primarily on endothelial cells. It exerts an anticoagulant effect through the sequestration of thrombin and activation of protein C, which degrades coagulation factors. Thrombin sequestration inhibits activation of the G-protein-coupled protease-activated receptor (PAR)-1. TM improves the catalytic efficiency of thrombin toward protein C in the presence of Ca^{2+} by ~3 orders of magnitude by improving both the Km and the kcat of the protein C activation reaction. TM forms a complex with thrombin which is responsible of converting protein C to activated protein C (Maruyama et al. 1985; Rezaie and Yang 2003; Wouwer et al. 2004; Dahlbäck and Villoutreix 2005). The TM-thrombin complex balances the substrate specificity of thrombin, erasing its procoagulant properties, and improving the conversion of protein C into its activated form (Esmon 2000; Fuentes-Prior

et al. 2000). Protein C acts on a variety of targets where as the TM-protein C system is essential for maintaining the placenta during pregnancy. TM influences inflammation and tumor progression and TM polymorphisms have been linked to thrombotic conditions such as heart attack. The activity of TM initiates an essential physiological anticoagulant process (Hofsteenge et al. 1986) which by binding to thrombin inhibits the procoagulant functions of thrombin and acts as a cofactor for thrombin catalyzed activation of protein C. This raises the speed of protein C activation 1,000-fold. Activated protein C degrades clotting factors Va and VIIIa and thereby inhibits blood clotting. TM-bound thrombin has no procoagulant effect. When bound to TM, thrombin also activates the carboxypeptidase B-like enzyme thrombin activatable fibrinolysis inhibitor (TAFI) (Bajzar et al. 1996). The binding site for thrombin has been localized by alanine-scanning mutagenesis and peptide-binding studies to the final 2 EGF domains, EGF56 (Jakubowski and Owen 1989; Kurosawa et al. 1988; Nagashima et al. 1993; Adams and Huntington 2006).

Primarily, TM modifies the substrate specificity of thrombin, apparently by an allosteric mechanism. The thrombin-TM-complex also inhibits fibrinolysis by cleaving thrombin-activatable fibrinolysis inhibitor (TAFI) into its active form, initiating an essential anticoagulant pathway. The cofactor function of membrane-associated TM requires EGF456, as well as a Ser/Thr-rich spacer between EGF-like domain 6 and the transmembrane domain. The Ser/Thr-rich domain is variably modified with a chondroitin sulfate chain that influences the affinity of thrombin binding and the calcium ion dependence of cofactor function. Deletion of the N-terminal lectin-like domain and EGF-like domains 1 and 2 had no effect on TAFI or protein C activation, whereas deletions including EGF-like domain 3 selectively abolished TM cofactor activity for TAFI activation. Thus, the anticoagulant and antifibrinolytic cofactor activities of TM have distinct structural requirements: protein C binding to the thrombin-TM complex requires EGF-like domain 4, whereas TAFI binding requires EGF-like domain 3 (Kokame et al. 1998) (Fig. 41.5).

Deletion and point mutants of soluble TM were used to compare and contrast elements of primary structure required for the activation of TAFI and protein C. The smallest mutant capable of efficiently promoting TAFI activation contained residues including the c-loop of EGF3 through EGF6. This mutant is 13 residues longer than the smallest mutant that functioned well with protein C; the latter consisted of residues from the interdomain loop connecting EGF3 and EGF4 through EGF6. Wang et al. (2000) suggest that structural elements in the thrombin-binding domain are needed for the activation of both protein C and TAFI, but more of the primary structure is needed for TAFI activation. In addition, some residues are needed for one of the reactions but not the other (Wang et al. 2000).

Single-chain urokinase-type plasminogen activator (scu-PA) can be cleaved by thrombin into a virtually inactive form called thrombin-cleaved two-chain urokinase-type plasminogen activator (tcu-PA/T), a process accelerated by TM. TM-EGF56 bound to thrombin but did not accelerate the activation of protein C. In contrast, the inactivation of scu-PA by thrombin was accelerated to the same extent as that induced by TM-LEO and TM-Ei4-6. This study demonstrated that, in addition to the chondroitin sulfate moiety, only EGF-like domains 5 and 6 are essential for the acceleration of the inactivation of scu-PA by thrombin. This differs from the domains that are critical for activation of protein C (EGF-like domains i4–6) and thrombin activatable fibrinolysis inhibitor (EGF-like domains 3–6) (Schenk-Braat et al. 2001).

Molecular Basis of TM Activation of Slow Thrombin

Thrombin is critical enzyme for producing and stabilizing a clot, but when complexed with TM it is converted to a powerful anticoagulant. Thrombin function is also controlled by Na^+. Its apparent affinity suggests that half of the thrombin generated is in a Na^+-free "slow" state and half is in a Na^+-coordinated "fast" state. While slow thrombin is a poor procoagulant enzyme, when complexed to TM it is an effective anticoagulant. A structure of thrombin complexed with EGF456 of TM in absence of Na^+ and other cofactors or inhibitors suggests that TM binds thrombin (Adams et al. 2009). As a result the thrombin component resembles structures of fast form. The Na^+ binding loop in thrombin in thrombin-TM complex is in a conformation identical to the Na^+-bound form, with conserved water molecules compensating for the missing ion. It was shown that activation of slow thrombin by TM principally involves the opening of the primary specificity pocket. Therefore, TM binding alters the conformation of thrombin in a similar manner as Na^+ coordination, resulting in an ordering of the Na^+ binding loop and an opening of the adjacent S1 pocket (Adams et al. 2009) (Fig. 41.5).

41.5.6.2 Regulator of Inflammation

Although, the TM is best characterized as a natural anticoagulant, reports have illuminated the importance of TM in the regulation of inflammation. The antigen described as BDCA-3 is identical to TM (Chap. 35) (Dzionek et al. 2000, 2002). This molecule also occurs on a very rare (0.02%) subset of human dendritic cells called MDC2. Its function on these cells is unknown at present, but apparently, TM has at least one other ligand apart from thrombin, because anticoaglulation is a common place function,

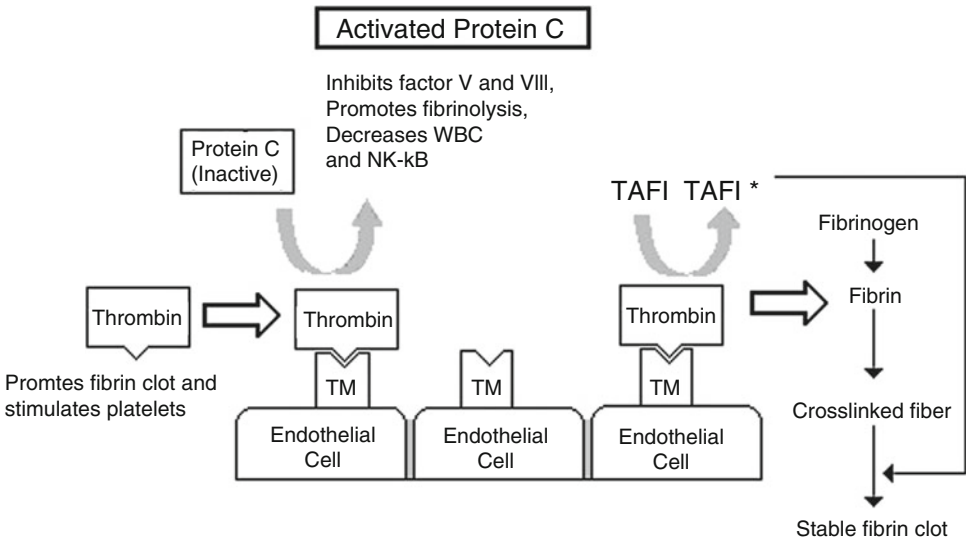

Fig. 41.5 Functions of membrane bound thrombomodulin (TM): (1) TM exerts an anticoagulant effect through the sequestration of thrombin and activation of protein C, which degrades coagulation factors. (2) TM also accelerates the proteolytic activation of a plasma procarboxypeptidase referred to as thrombin-activable fibrinolysis inhibitor (TAFI*). Activated TAFI* can be generated from the binary thrombin-TAFI complex (T-TAFI) or the ternary thrombin-thrombomodulin-TAFI complex (T-TM-TAFI) (Nesheim 2003). The anticoagulant and antifibrinolytic cofactor activities of TM have distinct structural requirements: protein C binding to the thrombin-TM complex requires EGF-like domain 4, whereas TAFI binding also requires EGF-like domain 3 (Kokame et al. 1998)

in contrast to the rarity of MDC2 cells. Thrombomodulin expression on DCs may be involved in the pathogenesis of atopy and asthma (Yerkovich et al. 2009). Thrombomodulin inhibits allergic bronchial asthma by inducing tolerogenic DCs. Treatment of bronchial asthma with TM improved lung function and reduced IgE and cells in alveolar lavage fluid by inducing tolerogenic dendritic dells. These were characterized by high expression of surface CD141/TM$^+$ and low expression of maturation markers and possessed reduced T-cell co-stimulatory activity. The TM effect was independent of its role in coagulation. Rather, it was mediated via the TM lectin domain directly interacting with DCs. Results showed that TM is a modulator of DC immunostimulatory properties and a novel candidate drug for the prevention of bronchial asthma in atopic patients (Takagi et al. 2011; Yerkovich et al. 2009). CD141$^+$ DC subset is an important functionally distinct human DC subtype with characteristics similar to those of the mouse CD8α^+ DC subset. CD141$^+$ DCs play a role in the induction of cytotoxic T lymphocyte and may be the most relevant targets for vaccination against cancers, viruses, and other pathogens (Jongbloed et al. 2010). Thrombomodulin was present in all keratinizing squamous carcinomas and the great majority (87%) of nonkeratinizing tumors in a membrane-staining pattern. It was moderately common in small cell (27%) and large cell carcinomas (25%) but relatively rare in adenocarcinomas (13%) (Miettinen and Sarlomo-Rikala 2003).

41.5.6.3 Regulator of Placental Functions

Thrombomodulin is expressed mainly on the endothelial surface of blood vessels and in the placental syncytiotrophoblast (Maruyama et al. 1985; Dittman and Majerus 1990). The functions of TM are exerted in two distinct tissues: in non-endothelial extra-embryonic tissues, required for proper function of the early placenta, and in embryonic blood vessel endothelium whose absence causes lethal consumptive coagulopathy (Bicheng et al. 2005). Disruption of the mouse gene encoding the TM leads to embryonic lethality caused by an unknown defect in the placenta. Isermann et al. (2003) showed that the abortion of TM-deficient embryos is caused by tissue factor–initiated activation of the blood coagulation cascade at the feto-maternal interface. These findings show a new function for the TM–protein C system in controlling the growth and survival of trophoblast cells in the placenta. This function is essential for the maintenance of pregnancy (Isermann et al. 2003).

41.5.7 Abnormalities Associated with Thrombomodulin Deficiency

41.5.7.1 Polymorphism and the Risk of Heart Disease

The genes encoding proteins in the TM-protein C pathway are promising candidate genes for stroke susceptibility because of their importance in thrombosis regulation and inflammatory response. Thrombosis is a dynamic balance

between factors that promote clot formation, antithrombotic mechanisms, and fibrinolysis. Central to this balance is the TM-protein C antithrombotic mechanism. TM forms a 1:1 complex with thrombin on the vascular endothelium, thereby inhibiting the procoagulant actions of thrombin and converting protein C to activated protein C. Activated protein C promotes fibrinolysis, inhibits thrombosis by inactivating clotting factors Va and VIIIa, and reduces inflammation by decreasing white blood cell and NF-kB activation (Esmon 1987, 1995, 2001; Barnes and Karin 1997). These relationships are demonstrated in Fig. 41.5**.** Because of the central role that the TM-protein C pathway plays in thrombosis regulation and inflammatory response, the genes encoding these pathway proteins are promising candidate genes regarding stroke susceptibility.

Eosinophil (EO) specific major basic protein accumulates on endocardial surfaces in the course of hypereosinophilic heart disease and promotes thrombosis by binding to the anionic TM and impairing its anticoagulant activities. Major basic protein potently inhibits the capacity of cell surface TM to generate the natural anticoagulant activated protein C. Thus, EO cationic proteins potently inhibit anticoagulant activities of the glycosylated form of TM, thereby suggesting a potential mechanism for thromboembolism in hypereosinophilic heart disease (Slungaard et al. 1993).

The TM gene (*THBD*) maps to chromosome 20p11.2, and spans 4 kb (Ireland et al. 1996). A single nucleotide polymorphism (C→T) at position + 1418 (C1418T) encodes for an amino acid change from alanine to valine at protein position 455 ($Ala^{455}Val$) (van der Velden et al. 1991). The location of this amino acid variation corresponds to the sixth EGF region of the TM protein (Fig. 41.2). This location has been shown to be responsible for the high-affinity binding of thrombin and for the suspension of thrombin at a specific position above the endothelial surface in relation to other cofactors, thereby producing optimal protein C activation by thrombin (Esmon 1995; Sadler 1997).

Studies have shown that the *THBD* $Ala^{455}Val$ polymorphism is associated with ischemic heart disease (Norlund et al. 1997; Wu et al. 2001). Based on results of Kittner et al. (1998), Cole et al. (2004) determined the association between the *THBD* $Ala^{455}Val$ polymorphism and the occurrence of ischemic stroke in young women. Schulz et al. (2004) indicated that among women aged 15–44 years, the AA genotype is more prevalent among blacks than whites and is associated with increased risk of early-onset ischemic stroke. Removing strokes potentially related to cardioembolic phenomena increased this association. Whether this association is due to population stratification, needs to be confirmed.

41.5.7.2 Spontaneous Recurrent Abortion

Reduced expression of TM in placental tissue of women were associated with spontaneous recurrent abortion and the loss of TM caused early post-implantation embryonic lethality (Isermann et al. 2001; Kaare et al. 2007; Stortoni et al. 2010). This suggested that TM expression in non-endothelial placental cells is required for a normal function of the early placenta. Further studies are needed to elucidate that the TM expression in non-endothelial placental cells is required for a normal function of the early placenta.

41.6 Endosialin (Tumor Endothelial Marker-1 or CD248)

41.6.1 A Marker of Tumor Endothelium

Endosialin (Tumor Endothelial Marker-1 or CD248) was originally described as a marker of tumor endothelium, and later as a marker of fibroblasts (Rettig et al. 1992; St Croix et al. 2000). Endosialin is a 165-kDa cell surface glycoprotein expressed by tumor blood vessel endothelium in a broad range of human cancers but not detected in blood vessels or other cell types in many normal tissues. A full-length endosialin cDNA with an open reading frame of 2274 bp encodes a type I membrane protein of 757 amino acids with a predicted molecular mass of 80.9 kDa. The sequence matches with an expressed sequence tag of unknown function in public data bases, named Tumor Endothelial Marker-1(TEM-1). Endosialin is classified as a C-type lectin-like protein, composed of a signal leader peptide, five globular extracellular domains (including a C-type lectin domain, one domain with similarity to the Sushi/ccp/scr pattern, and three EGF repeats), followed by a mucin-like region, a transmembrane segment, and a short cytoplasmic tail (Fig. 41.6). The endosialin core protein carries abundantly sialylated, O-linked oligosaccharides and is sensitive to O-sialoglycoprotein endopeptidase, placing it in the group of sialomucin-like molecules. The N-terminal 360 amino acids of endosialin show homology to thrombomodulin, a receptor involved in regulation of blood coagulation (Section 41.5), and to complement receptor C1qRp (Section 41.4) (Christian et al. 2001; Teicher 2007). Endosialin is cell surface receptor of unknown function, with a distinctive pattern of endothelial expression in newly formed blood vessels in human cancers. It is not known if carbohydrate recognition is involved in the function of proteins in the endosialin group. The CTLDs in these proteins do not contain the sequence motifs connected with sugar-binding activity.

The single copy endosialin gene was mapped to chromosome 19. Endosialin gene is intronless and encodes a 92-kDa protein that has 77.5% overall homology to the human protein. This gene is ubiquitously expressed in normal human and mouse somatic tissues and during development.

Fig. 41.6 Domain architecture of endosialin. The diagram shows the arrangement of the N-terminal signal leader peptide (*triangle*), the C-type lectin domain, the domain similar to a Sushi/SCR/CCP domain (*S*), three EGF-like repeats (*EGF*), and the transmembrane region (*TM*), flanked by two segments with low complexity regions, namely a sialomucin-like sequence (*MUCIN*) and a short, putative cytoplasmic tail (*CYT*) (Adapted from Christian et al. 2001© American Society for Biochemistry and Molecular Biology)

The murine orthologue of endosialin has been identified, opening up the analysis of developmental regulation in the embryo and in aberrant tissue remodeling. Its expression at the mRNA level is density-dependent and up-regulated in serum-starved cells. In vitro, its expression is limited to cells of embryonic, endothelial, and preadipocyte origin, suggesting that the wide distribution of its expression in vivo is due to the presence of vascular endothelial cells in all the tissues. The ubiquitous expression in vivo is in contrast to previously reported expression limited to corpus luteum and highly angiogenic tissues such as tumors and wound tissue (Opavsky et al. 2001). Further analyses confirmed selective *TEM-1*/*endosialin* expression in tumor endothelium, pericytes and a subset of fibroblast-like cells of tumor stroma in breast carcinoma, anaplastic astrocytoma and GBM (Simonavicius et al. 2008; Davies et al. 2004; Brady et al. 2004; MacFadyen et al. 2005; Carson-Walter et al. 2001; Christian et al. 2008).

Findings on mouse endosialin suggest that: (1) endosialin protein (also termed as TEM-1) is restricted to vascular endothelium and fibroblast-like cells in developing organs, and largely disappears during adulthood, (2) endothelial expression varies markedly between organs regarding spatial and temporal patterns, (3), circumscribed mesenchymal expression in fibroblast-like cells was evident throughout development, most pronounced adjacent to certain budding epithelia, as in the lung and kidney glomeruli, but unrelated to the endothelial expression. The endosialin protein persists in the stromal fibroblasts of the adult uterus (Rupp et al. 2006). Brain pericytes in culture had higher levels of endosialin/TEM 1 than TEMs-2, -3, -4, -5, -7, and -8. Endosialin was present in the cytoplasmic body and in the elongated extensions essential to pericyte function. It seems that endosialin is strongly expressed by pericytes during periods of active angiogenesis during embryonic and tumor development. With the appropriate agent, targeting endosialin may interfere with blood vessel growth during tumor development (Bagley et al. 2008a).

41.6.1.1 Upregulation of Endosialin Gene by Hypoxia

Angiogenesis is well known to be principally driven by hypoxia in growing solid tumors as well as in developing embryos (Liao and Johnson 2007). The endosialin gene transcription is induced by hypoxia predominantly through a mechanism involving hypoxia-inducible factor-2 (HIF-2) cooperating with the Ets-1 transcription factor. It was shown that HIF-2 activates the endosialin promoter both directly, through binding to a hypoxia-response element adjacent to an Ets-binding site in the distal part of the upstream regulatory region, and indirectly, through Ets-1 and its two cognate elements in the proximal promoter. Results also suggested that the SP1 transcription factor mediates responsiveness of endosialin promoter to high cell density (Ohradanova et al. 2008).

41.6.2 Interactions with Ligands

It is not clear if carbohydrate recognition is involved in the function of proteins in the endosialin group. The CTLDs in these proteins do not contain the sequence motifs connected with sugar-binding activity. Recent evidence suggests that endosialin may interact with extracellular matrix components including fibronectin (FN) and collagen types I and IV as well as Mac-2 BP/90 K in promoting vascular migration and invasion (Tomkowicz et al. 2007; Becker et al. 2008). More importantly, cells expressing endosialin exhibit enhanced adhesion to FN as well as enhanced migration through matrigel and increased adhesive properties (Tomkowicz et al. 2007). Subsequently, endosialin/collagen IV co-localization was confirmed by confocal microscopy. Other studies have demonstrated the importance of endosialin in regulating proliferation tube formation on matrigel (Bagley et al. 2008b). However, the exact mechanism(s) as to how endosialin exerts its pleiotropic cellular effects has not been addressed. Becker et al. (2008) provided evidence that PDGF receptor and the MAP kinase ERK-1/2 are involved with the endosialin-regulated signaling pathways that control proliferation of pericytes. Mac-2 BP/90 K has been identified as a specific interacting partner of endosialin. C-terminal fragment of Mac-2 BP/90 K, a binding partner for galectin-3, and collagens were responsible for endosialin binding. Intriguingly, the expression patterns of Mac-2 BP/90 K and endosialin were mutually exclusive in all human tissues. These studies demonstrate a novel repulsive interaction between endosialin on stromal fibroblasts and Mac-2 BP/90 K on tumor cells (Becker et al. 2008). Tomkowicz et al. (2010) showed that normal pericytes expressing high levels of endosialin were able to proliferate, respond to PDGF-BB stimulation by phosphorylating both the PDGF receptor and the MAP-kinase ERK-1/2, and induce the expression of immediate early transcription factor *c-Fos*. However, when endosialin expression was knocked-down, PDGF-BB-induced proliferation, ERK-1/2-phosphorylation, and *c-Fos* expression were significantly impaired. These results provide evidence for a endosialin-

dependent signal pathway that controls proliferation of human pericytes and suggest targeting this pathway for future strategies aimed at mitigating tumor angiogenesis (Tomkowicz et al. 2010).

41.6.3 Functions

Abundant endosialin expression was found in the vasculature and fibroblast-like cells of the developing mouse and human embryos (Rupp et al. 2006; MacFadyen et al. 2007; Virgintino et al. 2007). Nanda et al. (2006) have shown that endosialin is dispensable for normal development and subcutaneous tumor growth, but can modulate invasiveness and metastatic progression in an orthotopic Xenograft model of colorectal cancer. All these data support the functional involvement of endosialin in angiogenesis, a complex process of vascular branching and sprouting that plays a key role in tumor expansion and progression, and therefore represents an opportunity for therapeutic intervention against cancer. MacFadyen et al. demonstrated that endosialin was expressed by fibroblasts and pericytes associated with tumor vessels, but not on HUVECs or endothelial cells of normal or diseased tissue (MacFadyen et al. 2005, 2007). Moreover, endosialin expression was upregulated on tumor-derived pericytes and confirmed by Virgintino et al. (2007).

The functional significance of endosialin expression on pericytes and stromal cells, its upregulation during cancer, and its role in angiogenesis has largely remained unknown. The knockout (KO) mouse model showed the absence of endosialin expression, reduced growth, invasion, and metastasis of human tumor Xenografts. In addition, lack of endosialin led to an increase in small immature blood vessels and decreased numbers of medium and large tumor vessels. This abnormal angiogenic response could be responsible for the reduced tumor growth and invasion observed in endosialin KO mice, suggesting a role for endosialin in controlling the interaction among tumor cells, endothelia, and stromal matrix (Nanda et al. 2006). Data indicated that the stroma can control tumor aggressiveness and that this control varies with anatomic site. Endosialin is required for complete popliteal LN (pLN) expansion but not for coordination of B and T cell compartmentalisation or antibody production following 4-hydroxy-3-nitrophenyl)acetyl chicken γ-globulin immunisation. In vitro, Endosialin expression in human MG63 stromal cells and mouse embryonic fibroblasts leads to a pro-proliferative and pro-migratory phenotype. This correlates with a proliferating $CD248^{+}$ population observed in vivo during pLN expansion (Lax et al. 2010).

41.6.3.1 Endosialin in Cancer

Several studies confirmed that endosialin is upregulated in blood vessels and activated stromal fibroblasts in human colorectal, brain and breast tumors as well as in mouse Xenograft models (Carson-Walter et al. 2001; Brady et al. 2004; Davies et al. 2004; Madden et al. 2004; Dolznig et al. 2005; MacFadyen et al. 2005, 2007; Huber et al. 2006; Rupp et al. 2006). Endosialin expression is restricted to capillaries and shows a heterogeneous pattern typical for molecules involved in vascular reorganization. Human colon and ovarian Xenografts showed that endosialin expression was largely confined to NG2-expressing perivascular cells and not CD31-positive endothelial cells (Bagley et al. 2008b).

Endosialin is a stromal marker that is differentially expressed on fibroblasts and pericytes in the thymus, lymph node and spleen. Expression is high during LT development but largely disappears in the adult. Endosialin is re-expressed in a Salmonella-induced model of splenic enlargement; peak expression corresponding to the peak of splenic enlargement. These results suggest that endosialin expression helps define a subset of LT stromal cells which play a role in remodelling during tissue development, infection and repair (Dolznig et al. 2005; Lax et al. 2007; MacFadyen et al. 2005; Teicher 2007). Cancer-associated fibroblasts (CAF) have been implicated in promoting tumor development and have been associated with mesenchymal stem cells (MSC). MSC can form networks in a tube formation assay that is inhibited by an anti-endosialin antibody. MSC are a potential target for anticancer therapeutic intervention and endosialin expression offers a tool for the identification of MSC. Endosialin expression by both CAF and MSC further implies the potential contribution of MSC to tumor stroma via differentiation into tumor stromal fibroblasts (Bagley et al. 2009; Demoulin 2010).

In an effort to better characterize the desmoplastic response to human skin tumors, Huber et al. (2006) evaluated the expression pattern of three stromal cell markers, fibroblast-activation protein (FAP), endoglyx-1, and endosialin, in a series of melanocytic and epithelial skin tumors. FAP-positive fibroblasts were detected in all tumor tissues tested, including cases of melanocytic nevi, melanoma metastases, basal cell carcinomas, and squamous cell carcinomas. Endoglyx-1 expression was confined to normal and tumor blood vessel endothelium including 'hot spots' of neoangiogenesis within the cutaneous melanoma metastases. Endosialin was selectively induced in subsets of small- and medium-sized tumor blood vessels in melanoma metastases and squamous cell carcinomas. These data describe novel aspects of targets for novel therapeutic strategies aimed at the tumor stroma (Huber et al. 2006). Christian et al. (2008) claim that endosialin is expressed by tumor-associated myofibroblasts and mural cells and not by endothelial cells. Endosialin expression is barely detectable in normal human tissues with moderate expression only detectable in the stroma of the colon and the prostate. Corresponding cellular experiments confirmed endosialin expression by mesenchymal cells and indicated that it may

in fact be a marker of mesenchymal stem cells. Collectively, experiments validate endosialin as a marker of tumor-associated myofibroblasts and tumor vessel-associated mural cells (Christian et al. 2008).

Brain Tumors

Human brain tumors express endosialin in a heterogeneous manner. Gliomas are the most frequent primary tumors of the central nervous system in adults. The most prevalent and aggressive subclass of these is glioblastoma multiforme, which is characterized by massive neovascularization. The largest proportion of endosialin-expressing tumors was found in highly invasive glioblastoma multiforme, anaplastic astrocytomas, and metastatic carcinomas. Endosialin is not expressed in normal human adult brain but is strongly upregulated in the angiogenic vasculature of all high-grade glioma specimens. Endosialin was localized to the endothelium of small and large CD31 stained vessels and also expressed by Thy-1-positive fibroblast-like cells close to the meninges and α-smooth muscle actin-positive cells in some vessels. Endosialin colocalized with thrombomodulin, suggesting these proteins may have complementary functions in tumor progression (Brady et al. 2004). However, Simonavicius et al. (2008) demonstrated unambiguously that endosialin is not expressed by the glioma endothelial cells but on closely associated perivascular cells. Carson-Walter et al. (2009) characterized the expression pattern of endosialin in astrocytic and metastatic brain tumors and investigated its role as a therapeutic target in human endothelial cells and mouse xenograft models. Eendosialin was induced in the vasculature of high-grade brain tumors where its expression was inversely correlated with patient age. Although lack of endosialin did not suppress growth of intracranial GBM xenografts, it did increase tumor vascularity (Carson-Walter et al. 2009). The recognition of endosialin as an antigen that is selectively over-expressed in human tumor tissues offers new strategies for treating cancer. Not only do the tumor vasculature and stromal compartments upregulate endosialin but, the malignant cells of sarcomas also strongly express endosialin. Thus, endosialin holds potential value both as a therapeutic target and as a biomarker for certain human cancers (Bagley 2009; Rouleau et al. 2008; Simonavicius et al. 2008). The function of C-type lectin 14A is not known.

41.7 Bimlec (DEC 205 Associated C-type lectin-1 or DCL-1) or (CD302) (Group XV of CTLD)

BIMLEC is synonymous with C-type lectin domain family 13 member A (CLEC13A), KIAA0022 and DEC-205-associated C-type lectin-1 (DCL-1). BIMLEC is a Type I transmembrane protein with neck region and CTLD in extracellular region. This new group of C-type lectins was predicted by Zelensky and Gready (2004) in Fugu whole genome and supported by a database cDNA sequences. Group was named Bimlec, linked to DEC-205. Function of Bimlec in humans is unknown, but it is expressed as a fusion protein with DEC-205 in Hodgkin's lymphoma cells (Kato et al. 2003). The cDNA encoding DCL-1 has been identified in Reed-Sternberg cells associated with the development of classic Hodgkin's lymphoma as part of fusion protein between DEC-205 (CD205) and a C-type lectin DCL-1 (Kato et al. 2003). Although the 7.5-kb DEC-205 and 4.2-kb DCL-1 mRNA were expressed independently in myeloid and B lymphoid cell lines, the DEC-205/DCL-1 fusion mRNA (9.5 kb) predominated in the HRS cell lines. The DEC-205 and DCL-1 genes comprising 35 and 6 exons, respectively, are juxtaposed on chromosome band 2q24 and separated by only 5.4 kb. The fusion mRNA predominates in these cells, but both proteins are expressed independently also in myeloid cells and B-lymphoid cell lines. DCL-1 protein is highly conserved among the human, mouse, and rat orthologs. DCL-1 expression in leukocytes is restricted to monocytes, macrophages, granulocytes, and dendritic cells, although DCL-1 mRNA is present in many tissues. These results imply an unusual transcriptional control mechanism in HRS cells, which cotranscribe an mRNA containing DEC-205 and DCL-1 prior to generating the intergenically spliced mRNA to produce a DEC-205/DCL-1 fusion protein. Kato et al. (2007) have suggested that DCL-1 is an unconventional lectin receptor that plays roles in endocytosis and phagocytosis but also in cell adhesion and migration. In nomenclature of CD antigens this protein has been given the designation CD302.

41.8 Proteins Containing SCP, EGF, EGF and CTLD (SEEC) (Group XVI of CTLD)

Souble protein containing SCP, EGF, EGF and CTLD (SEEC) domains is a group of CTLD which has been predicted during Fugu whole-genome analysis and numbered as group XVI of CTLD. Group XVI of CTLD is well conserved between human and fish and supported by available cDNAs. The sperm-coating glycoprotein (SCP) domain, which is present in organisms from yeast and plants to mammals, but whose function is unknown (Szyperski et al. 1998), is rarely observed in combination with other domains in proteins. This SCP/CTLD combination is observed in one known protein – Nowa from hydra (Engel et al. 2002). CTLD has potential Ca-carbohydrate-binding motif (QPD) characteristic of galactose specificity

41.8.1 Nematocyst Outer Wall Antigen (NOWA)

The nematocyst is a unique extrusive organelle involved in the defense and capture of prey in cnidarians. The nematocyst outer wall antigen (NOWA) was identified in nematocysts, explosive organelles of *Hydra*, jellyfish, corals and other *Cnidaria*. Minicollagens along with glycoprotein NOWA form the major components of nematocyst capsule outer wall, which resists osmotic pressure of 15 MPa. NOWA spontaneously assembles to globular macromolecular particles that are sensitive to reduction as the native wall structure. NOWA, the major component of the outer wall, is formed very early in morphogenesis. NOWA is a 90-kDa glycoprotein which comprises a C-terminal eightfold repeat of the minicollagen cysteine-rich domain, suggesting a possible disulfide-dependent hetero-assembly of minicollagens and NOWA protein (Ozbek et al. 2004). NOWA has a modular structure with an N-terminal sperm coating glycoprotein domain, a central C-type lectin-like domain, and an eightfold repeated cysteine-rich domain at the C-terminus. Interestingly, the cysteine-rich domains are homologous to the cysteine-rich domains of minicollagens. The cysteines of these minicollagen cysteine-rich domains undergo an isomerization process from intra- to intermolecular disulfide bonds, which mediates the crosslinking of minicollagens to networks in the inner wall of the capsule. The minicollagen cysteine-rich domains present in both proteins provide a potential link between NOWA in the outer wall and minicollagens in the inner wall. Engel et al. (2002) proposed a model that integrates the role of microtubule cytoskeleton and the interaction of NOWA and minicollagen in forming the nematocyst wall. Data suggest a continuous suprastructure of the nematocyst wall, assembled from wall proteins that share a common oligomerization motif (Meier et al. 2007).

41.8.2 The Cysteine-Rich Secretory Proteins (CRISP) Super-Family

The cysteine-rich secretory proteins (CRISP), antigen 5, and pathogenesis-related 1 proteins (CAP) superfamily members are found in a remarkable range of organisms spanning each of the animal kingdoms. Within humans and mice, there are 31 and 33 individual family members, respectively, and although many are poorly characterized, a majority of them shows a notable expression bias to the reproductive tract (Gupta 2005) and immune tissues or are deregulated in cancers. CAP superfamily proteins are most often secreted and have an extracellular endocrine or paracrine function and are involved in processes including the regulation of extracellular matrix and branching morphogenesis, potentially as either proteases or protease inhibitors; in ion channel regulation in fertility; as tumor suppressor or prooncogenic genes in tissues including prostate; and in cell-cell adhesion during fertilization. Several reviews describing mammalian CAP superfamily gene expression profiles, phylogenetic relationships, protein structural properties, and biological functions draw into focus their potential role in health and disease. The nine subfamilies of the mammalian CAP superfamily include: the human glioma pathogenesis-related 1 (GLIPR1), Golgi associated pathogenesis related-1 (GAPR1) proteins, peptidase inhibitor 15 (PI15), peptidase inhibitor 16 (PI16), cysteine-rich secretory proteins (CRISPs), CRISP LCCL domain containing 1 (CRISPLD1), CRISP LCCL domain containing 2 (CRISPLD2), mannose receptor like and the R3H domain containing like proteins. The overall protein structural conservation within the CAP super-family results in fundamentally similar functions for the CAP domain in all members, yet the diversity outside this core region dramatically alters target specificity and, therefore, the biological consequences (Gibbs et al. 2008).

41.8.2.1 Human Glioma Pathogenesis-Related Protein

Specifically, the human glioma pathogenesis-related protein (GliPR) is highly expressed in the brain tumor glioblastoma multiforme and exhibits 35% amino acid sequence identity with the tomato pathogenesis-related (PR) protein P14a, which has an important role for the plant defense system. GliPR is homologous to group 1 plant pathogenesis-related proteins (PR-1) that are implicated in plant defense responses to viral, bacterial, and fungal infection (Klessig et al. 2000; van Loon et al. 2006). Since GliPR shows structural similarities with its homologous plant PR-1 proteins, mammalian testis proteins (TPX1) and the insect venom Ag-5 protein, which are secretory proteins (van Loon et al. 2006; Foster and Gerton 1996), it has been suspected that GliPR is also secreted. Comparison of the GliPR model with the P14a structure resulted into identification of a common partially solvent-exposed spatial cluster of four amino acid residues, His-69, Glu-88, Glu-110, and His-127 in the GliPR numeration. This cluster is conserved in all known plant PR proteins of class 1, indicating a common putative active site for GliPR and PR-1 proteins and thus a functional link between the human immune system and a plant defense system (Szyperski et al. 1998).

There isTGliPR is related to testes-specific, vespid and pathogenesis protein 1 (RTVP-1) (Rich et al. 1996). Increased expression of GliPR was associated with myelomonocytic differentiation in macrophages (Gingras and Margolin 2000). Whereas GliPR has been reported to act as a tumor suppressor gene inducing apoptosis in prostate cancer (Naruishi et al. 2006; Ren et al. 2004), it appears to be an oncogene in glioblastomas (Rosenzweig et al. 2006) and

Wilms tumors (Chilukamarri et al. 2007). RTVP-1 protein is reported to contain a N-terminal signal peptide sequence and a transmembrane domain (Szyperski et al. 1998). Furthermore, homology studies revealed a putative active enzymatic center in GliPR (Szyperski et al. 1998). GliPR's homology with plant PR-1 proteins raises the question whether GliPR has an evolutionarily conserved role in innate immune response and human host defense of viral infection including HIV-1. There is an early up-regulation of GliPR expression (fivefold) in CEM T cells infected with HIV-1 (Scheuring et al. 1998). Alternatively or additionally, HIV-1 may induce and exploit GliPR for viral replication. The up-regulation of GliPR by HIV-1 and the early significant inhibition of HIV-1 replication mediated by knockdown of GliPR reveal GliPR as an important HIV-1 dependency factor (HDF), which may be exploited for HIV-1 inhibition (Capalbo et al. 2010).

Data from a number of systems suggests that sequences within the C-terminal CAP domain of CAP proteins have the ability to promote cell-cell adhesion. Cloned mouse *Glipr1l1* has a testis-enriched expression profile where GliPR1L1 is post-translationally modified by N-linked glycosylation during spermatogenesis and ultimately becomes localized to the connecting piece of elongated spermatids and sperm. After sperm capacitation, however, GliPR1L1 is also localized to the anterior regions of the sperm head. Zona pellucida binding assays indicate that GliPR1L1 has a role in the binding of sperm to the zona pellucida surrounding the oocyte. Studies suggest that, along with other members of the CAP superfamily and several other proteins, GliPR1L1 is involved in the binding of sperm to the oocyte complex. Results strengthen the role of CAP domain-containing proteins in cellular adhesion and propose a mechanism whereby CAP proteins show overlapping functional significance during fertilization (Gibbs et al. 2010).

41.8.2.2 C9orf19

A human transcript, C9orf19, mapped to the genomic region involved in hereditary inclusion body myopathy (IBM2) at chromosome 9p12-p13, has been characterized. Genomic characterization of the C9orf19 gene identified five exons extending over 27.2 kb of genomic DNA, located 12 kb centromeric to the tumor suppressor RECK gene. C9orf19 mRNA is expressed in a wide range of adult tissues as a single transcript, most abundantly in lung and peripheral blood leukocytes. The predicted protein contains SCP-like extracellular protein signature classified to IPR001283, a family of evolutionary related proteins with extracellular domains, which includes the human GliPR, the human testis specific glycoprotein (TPX-1), and several other extracellular proteins from rodents (SCP), insects venom allergens (Ag5, Ag3), plants pathogenesis proteins (PR-1) and yeast hypothetical proteins (Eisenberg et al. 2002).

41.8.2.3 A 28 kDa Glycoprotein from Human Neutrophils

A 28 kDa glycoprotein has been purified from exocytosed material from human neutrophils. The deduced 245 amino acid sequence of the 2124 bp full-length cDNA showed high degree of similarity to the deduced sequences of human gene TPX-1 and of sperm-coating glycoprotein from rat and mouse. Subcellular fractionation of human neutrophils indicated that the protein is localized in specific granules, hence named SGP28 (specific granule protein of 28 kDa) (Kjeldsen et al. 1996).

41.9 Calx-*b* and CTLD Containing Protein (CBCP) (Group XVII of CTLD)

41.9.1 CBCP/Frem1/QBRICK

CBCP/Frem1/QBRICK large proteoglycan (~2,100 residues) contains a set of chondroitin sulphate proteoglycan (CSPG) repeats (homologous to the NG2 ectodomain) (Nishiyama et al. 1991), a calcium-binding Calx-β domain and a CTLD. The emerging family of extracellular matrix proteins characterized by 12 consecutive CSPG repeats and the presence of Calx-β motif(s) includes Fras1, QBRICK/Frem1, Frem2 and Frem3. Frem1 belongs to a family of structurally related extracellular matrix proteins of which Fras1 is the founding member. Fras1/Frem proteins have been shown to be strictly co-localized in the sublamina densa of mouse epithelial basement membranes during development. Frem3 was present in a broad range of epithelial basement membranes where Fras1, Frem1 and Frem2 were missing. Fras1 and Frem2 were colocalized with Frem3 in the basement membrane of certain skin parts, underlying the thin-layer, of rapidly proliferating keratinocytes, whereas Frem1 was detected only in the basement membrane of the tail (Pavlakis et al. 2008).

41.9.1.1 Fras1 and Frem1 in Sublamina Densa of Epithelial Basement Membranes

Fras1 co-localizes with the markers of epithelial basement membranes and is ultrastructurally detected underneath the lamina densa of embryonic mouse epithelia. The loss of Fras1 mainly affects the cohesiveness of the embryonic skin basement membrane with its underlying mesenchyme. Fras1 could serve as a direct link between the sublamina densa and mesenchyme. The localization of Fras1 is consistent with previous results indicating that Fras1 exerts its function below the lamina densa and that Fras1 displays the same localization pattern in all epithelial basement membranes (Dalezios et al. 2007). It was shown that basement membrane levels of collagen VII rise at late

embryonic life, concomitant with descending Fras1/Frem immunolabeling (Chiotaki et al. 2007).

Mutations in Fras1 and Frem1 have been identified in mouse models for Fraser syndrome, which display a strikingly similar embryonic skin blistering phenotype due to impaired dermal-epidermal adhesion. Frem1 originates from both epithelial and mesenchymal cells, in contrast to Fras1 that is exclusively derived from epithelia. However, both proteins are localized in an absolutely overlapping fashion in diverse epithelial basement membranes. At the ultrastructural level, Frem1 exhibits a clustered arrangement in the sublamina densa coinciding with fibrillar structures reminiscent of anchoring fibrils. Furthermore, in addition to its extracellular deposition, around E16, Frem1 displays an intracellular distribution in distinct epidermal cell types such as the periderm layer and basal keratinocytes. Since periderm cells are known to participate in temporary epithelial fusions like embryonic eyelid closure, defective function of Frem1 in these cells could provide a molecular explanation for the "eyes open at birth" phenotype, a feature unique for Frem1 deficient mouse mutants. Finally, Frem1 localization in the basement membrane is lost but not in periderm cells in the skin of Fras1$^{-/-}$ embryos. Reports indicate that besides a cooperative function with Fras1 in embryonic basement membranes, Frem1 can also act independently in processes related to epidermal differentiation (Petrou et al. 2007a).

FREM1 Mutations Cause Bifid Nose, Renal Agenesis, and Anorectal Malformations Syndrome

An autosomal-recessive syndrome of bifid nose and anorectal and renal anomalies (BNAR) was reported in a consanguineous Egyptian sibship. Alazami et al. (2009) identified a shared region of homozygosity on chromosome 9p22.2-p23 that revealed homozygous frameshift and missense mutations in FREM1, which encodes an extracellular matrix component of basement membranes. The phenotypic variability reported for different Frem1 mouse mutants suggests that the apparently distinct phenotype of BNAR in humans may represent an unrecognized variant of Fraser syndrome (Alazami et al. 2009).

41.9.1.2 Association of Fras1/Frem Family with Fraser Syndrome

Fras1 and the structurally related proteins are involved in the structural adhesion of the skin epithelium to its underlying mesenchyme. Deficiency in the individual murine Fras1/Frem genes gives rise to the bleb phenotype, which is equivalent to the human hereditary disorder Fraser syndrome, characterized by cryptophthalmos (hidden eyes), embryonic skin blistering, renal agenesis, and syndactyly. Recent studies revealed a functional cooperation between the Fras1/Frem gene products, in which Fras1, Frem1 and Frem2 are simultaneously stabilized at the lower most region of the basement membrane by forming a macromolecular ternary complex. Loss of any of these proteins results in the collapse of the protein assembly, thus providing a molecular explanation for the highly similar phenotypic defects displayed by the respective mutant mice. Petrou et al. (2008) reviewed the current knowledge regarding the structure, function, and interplay between the proteins of the Fras1/Frem family and proposed a possible scenario for the evolution of the corresponding genes.

QBRICK (Frem 1) in Hair Morphogenesis

During mouse hair morphogenesis, gene predominantly expressed at the tip of developing hair follicles encodes a protein characterized by the presence of 12 tandem repeats of ~120 amino acids and a novel N-terminal domain containing an Arg-Gly-Asp cell-adhesive motif. The protein encoded by this gene, named QBRICK, was localized at the basement membrane zone of embryonic epidermis and hair follicles, in which it was more enriched at the tip rather than the stalk region. QBRICK was active in mediating cell-substratum adhesion through integrins containing α_v or α_8 chain, but not integrin $\alpha_5\beta_1$. QBRICK colocalized with α_v-containing integrins in the interfollicular region, but with the α_8-containing integrin at the tip region of developing hair follicles. These results indicate that QBRICK is an adhesive ligand of basement membrane distinctively recognized by cells in the embryonic skin and hair follicles through different types of integrins directed to the Arg-Gly-Asp motif (Kiyozumi et al. 2005).

41.9.1.3 Genetics of Frem1 in Fraser Syndrome and Blebs Mouse Mutants

Fraser syndrome is a recessive multi-system disorder characterized by embryonic epidermal blistering, cryptophthalmos, syndactyly, renal defects and a range of other developmental abnormalities. The family of four mapped mouse blebs mutants has been proposed as models of this disorder, given their striking phenotypic overlaps. These loci have been cloned, uncovering a family of three large extracellular matrix proteins and an intracellular adapter protein which are required for normal epidermal adhesion early in development. These proteins have been shown to play a crucial role in the development and homeostasis of the kidney. The cloning and characterization of these genes and the consequences of their loss have been explored (Smyth et al. 2004). Smyth et al. (2004) reported the mutations in Frem1 in both the classic head blebs mutant and in an N-ethyl-N-nitrosourea-induced allele and showed that inactivation of the gene results in the formation of in utero epidermal blisters beneath the lamina densa of the basement membrane and also in renal agenesis. Frem1 is expressed widely in the developing embryo in regions of epithelial/mesenchymal interaction and epidermal

remodeling. Furthermore, Frem1 appears to act as a dermal mediator of basement membrane adhesion, apparently independently of the other known "blebs" proteins Fras1 and GRIP1. Since the collagen VI and Fras1 deposition in the basement membrane was normal, it indicated that the protein plays an independent role in epidermal differentiation and is required for epidermal adhesion during embryonic development (Smyth et al. 2004).

Jadeja et al. (2005) mapped myelencephalic blebs to Frem2, a gene related to Fras1 and Frem1, and showed that a Frem2 gene-trap mutation was allelic to myelencephalic blebs. Expression of Frem2 in adult kidneys correlated with cyst formation in myelencephalic blebs homozygotes, indicating that the gene is required for maintaining the differentiated state of renal epithelia. Two individuals with Fraser syndrome were homozygous with respect to the same missense mutation of FREM2, confirming genetic heterogeneity. This is the only missense mutation reported in any blebbing mutant or individual with Fraser syndrome, suggesting that calcium binding in the CALXβ-cadherin motif is important for normal functioning of FREM2.

In Frem2 mutant mice, not only Frem2 but Fras1 and QBRICK/Frem1 were depleted from the basement membrane zone. This coordinated reduction in basement membrane deposition was also observed in another Fraser syndrome model mouse, in which GRIP1, a Fras1- and Frem2-interacting adaptor protein, is primarily affected. Targeted disruption of Qbrick/Frem1 also resulted in diminished expression of Fras1 and Frem2 at the epidermal basement membrane, confirming the reciprocal stabilization of QBRICK/Frem1, Fras1, and Frem2 in this location. These proteins formed a ternary complex, raising the possibility that their reciprocal stabilization at the basement membrane is due to complex formation. The coordinated assembly of three Fraser syndrome-associated proteins at the basement membrane appears to be instrumental in epidermal-dermal interactions during morphogenetic processes (Kiyozumi et al. 2006, 2007).

41.9.2 Frem3

The Fraser syndrome protein Fras1 and the structurally related proteins Frem1, Frem2 and Frem3 comprise a novel family of extracellular matrix proteins implicated in the structural adhesion of the embryonic epidermis to the underlying mesenchyme. Fras1, Frem1 and Frem2 have been shown to be simultaneously and interdependently stabilized in the basement membrane by forming a ternary complex located underneath the lamina densa. Although Fras1, QBRICK/Frem1 and Frem2 have been shown to localize at the basement membrane through reciprocal stabilization, Frem3 localized at the basement membrane with tissue distribution patterns clearly distinct from those of other 12 CSPG repeats-containing proteins (12-CSPG proteins). In adult mice, Frem3 was present at the basement membrane underlying ductal cells of the salivary gland, retinal ganglion cells, basal cells of epidermis and hair follicles, where other 12-CSPG proteins were barely expressed. Frem3 is distinct from other 12-CSPG proteins in its tissue distribution and competence to assemble into the basement membrane (Kiyozumi et al. 2007). In absence of Fras1 the basement membrane localization of Frem3 remains unaffected in contrast to Frem1 and Frem2 which are completely abolished from the basement membrane (Petrou et al. 2007b).

41.9.3 Zebrafish Orthologues of FRAS1, FREM1, or FREM2

Using forward genetics, Carney et al. (2010) identified the genes mutated in two classes of zebrafish fin mutants. The mutants of these genes display characteristic blistering underneath the basement membrane of the fin epidermis. Three of them are due to mutations in zebrafish orthologues of FRAS1, FREM1, or FREM2, large basement membrane protein encoding genes that are mutated in mouse bleb mutants and in human patients suffering from Fraser Syndrome. In addition to mutations in Hemicentin1 (Hmcn1) Carney et al. (2010) identified the extracellular matrix protein Fibrillin2 as an indispensable interaction partner of Hmcn1 (Carney et al. 2010).

42.1 Pathogen Recognition

In pathogen recognition by C-type lectins, several levels of complexity can be distinguished; these might modulate the immune response in different ways. Firstly, the pathogen-associated molecular pattern repertoire expressed at the microbial surface determines the interactions with specific receptors (Fig. 42.1). Secondly, each immune cell type possesses a specific set of pathogen-recognition receptors. Thirdly, changes in the cell-surface distribution of C-type lectins regulate carbohydrate binding by modulating receptor affinity for different ligands. Crosstalk between these receptors results in a network of multimolecular complexes, adding a further level of complexity in pathogen recognition (Cambi and Figdor 2005; Jack et al. 2001; Thiel et al. 2006) (see Chap. 23). MBL deficiency is genetically determined and predisposes to recurrent infections and chronic inflammatory diseases. MBL deficiency has been implicated in susceptibility and course of viral, bacterial, fungal, and protozoan infection. More than 10% of the general population may, depending on definition, be classified as MBL deficient, underlining the redundancy of the immune system. MBL-disease association studies have been a fruitful area of research, which implicates a role for MBL in infective, inflammatory and autoimmune disease processes. MBL deficiency predisposes both to infection by extra-cellular pathogens and to autoimmune disease.

42.1.1 MBL Characteristics

Mannose-binding lectin is a C-type serum lectin and is primarily produced by the liver (Bouwman et al. 2005) in response to infection, and is part of many other factors termed "http://en.wikipedia.org/wiki/Acute_phase_protein" \o "Acute phase protein" acute phase proteins. MBL is made up of 96-kDa structural units, which in turn are composed of three identical 32-kDa primary subunits. The subunits consist of an N-terminal cross-linking region, a collagenlike domain, and a C-terminal carbohydrate-recognition domain (CRD) (Chap. 23; Turner and Hamvas 2000). Circulating MBL is composed of higher-order oligomeric structures, which include dimers, trimers, tetramers, pentamers, and hexamers of the structural homotrimeric unit. The oligomeric configuration of the structural units allows the MBL molecule to have multiple CRDs, facilitating multivalent ligand binding. Each CRD of MBL is structurally identical and is able to bind a range of oligosaccharides including N-acetylglucosamine D-mannose, Nacetylmannosamine, and L-fucose (Turner 1996). Although the various sugars are bound with different affinities, the cluster-like array of multiple binding sites allows activation of complement to be most effective. MBL is considered to play a major role in innate defense against pathogens, involving recognition of arrays of MBLbinding carbohydrates on microbial surfaces. However, recent studies have shown that MBL is also involved in the recognition of self-targets, such as apoptotic and necrotic cells (Nauta et al. 2003). In plasma, MBL is associated with MBL-associated serine proteases (MASPs). Currently, three MASPs have been identified, MASP-1, MASP-2, and MASP-3 (Chap. 23).

42.1.2 Pathogen Recognition and Role in Innate Immunity

MBL belongs to the class of collectins in the C-type lectin superfamily, whose function appears to be pattern recognition in the first line of defense in the pre-immune host. MBL recognizes carbohydrate patterns, found on the surface of a large number of pathogenic micro-organisms, including bacteria, viruses, protozoa and fungi. Mannose-binding lectin binds to the repeating sugar arrays on surfaces of pathogens through multiple lectin domains and, following binding, is able to activate the complement system via an associated serum protease, MASP-2. Importantly, MBL activates the complement system through a distinctive third pathway, independent of

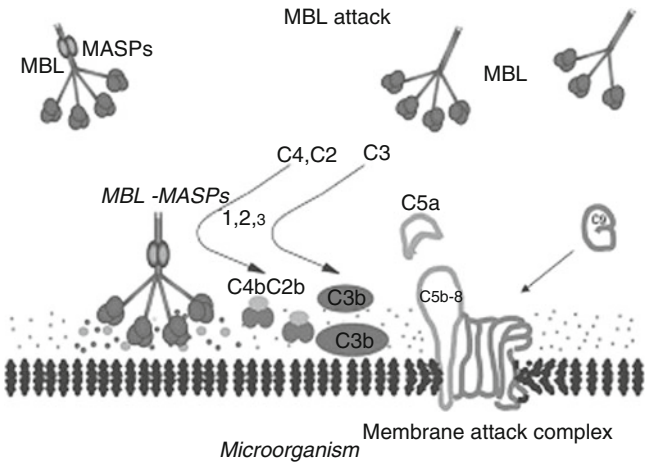

Fig. 42.1 *MBL-mediated complement attack*. Mannose-binding lectin (MBL) complexed with the MASPs binds to sugar arrays on a microorganism and mediates a complement attack through MASP2. MASPs denote MBL-associated serine proteases (Reprinted by permission from Macmillan Publishers Ltd: Genes Immun. Garred et al. © 2006). Mannan-binding lectin binds to patterns of carbohydrate groups in the correct spatial orientation. MBL is composed of two to six clusters of carbohydrate-binding lectin domains that interact with each other via a collagen-like domain (Chap. 23). Within each cluster are three separate binding sites that have a fixed orientation relative to each other; all three sites can therefore only bind when their ligands – mannose and fucose residues in bacterial cell-wall polysaccharides – have the appropriate spacing

Table 42.1 Some clinically relevant microorganisms recognized by MBL

Bacteria	Viruses
Staphylococcus aureus	HIV-1 and HIV-2
Staphylococcus pneumoniae	Herpes simplex-2
Staphylococcus pyrogenes	Influenza A
Enterococcus spp.	Hepatitis B virus
Listeria monocytogenes	Hepatitis C virus
Haemophilus influenzae	**Fungi**
Neisseria meningitidis	*Aspergillus fumigatus*
Neisseria gonorrhoeae	*Candida albicans*
Escherichia coli	*Cryptococcus neoformans*
Klebsiella spp.	*Saccharomyces cerevisiae*
Pseudomonas aeroginosae	**Protozoa**
Salmonella montevideo	*Plasmodium falciparum*
Salmonella typhimurium	*Cryptosporidium parvum*
H. pylori	Trypanosoma

Mycobacterium leprae	
Leishmania chagasi	

both antibody and the C1 complex (Table 42.1). The MBL binds to neutral carbohydrates on microbial surfaces and recognises carbohydrates such as mannose, glucose, L-fucose, N-acetyl-mannosamine (ManNAc), and N-acetyl-glucosamine (GlcNAc). Oligomerisation of MBL enables high avidity binding to repetitive carbohydrate ligands, such as those present on microbial surfaces, including *E. coli*, *Klebisella aerogenes*, *Neisseria meningitides*, *Staphylococcus aureus*, *S. pneumonia*, *A. fumigatus and C. albicans* (c/r Kerrigan and Brown 2009). However, there is also a great variation in the binding of MBL to various organisms; *Candida albicans*, β-haemolytic group A *Streptococci* and *Staphylococcus aureus* bind with high affinity, while *Clostridium* sp. *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, b-haemolytic streptococci and *Streptococcus pneumoniae* exhibit low or no binding (Santos et al. 2001). It is also observed that some organisms (e.g. *Klebsiella* sp. and *Escherichia coli*) show a variable pattern of binding. Later, it was shown that the absence of sialic acid from the lipo-oligosaccharide (LOS) of *Neisseria meningitidis* serogroup B, serogroup C and *Neisseria gonorrhoeae* permits MBL binding and presence of sialic acid on LOS results in poor or no MBL binding. In a similar study on *Salmonella* sp, it was found that MBL binds to rough chemotype but exhibits low or no binding with smooth chemotype (Ambrosio and De Messias-Reason 2005). In order to activate the complement system after MBL binds to its target (for example, mannose on the surface of a bacterium), the MASP protein functions to cleave the blood protein C4 into C4a and C4b. The C4b fragments can then bind to the surface of the bacterium, and initiate the formation of a C3 convertase. The subsequent complement cascade, catalyzed by C3 convertase, results in creating a membrane attack complex, which causes the lysis of the pathogen to which MBL is bound (Worthley et al. 2005, 2006) (Fig. 42.1). Being an important component of innate immunity, acting as an ante-antibody and/or as a disease modifier, MBL is thought to influence disorders as diverse as meningococcal disease, rheumatoid arthritis, cystic fibrosis and recurrent miscarriage. Vulvovaginal candidiasis is a yeast infection of vulva and vagina; millions of women suffer from vulvovaginal candidiasis 5 worldwide. Women bearing MBL variant allele are at a higher risk for vulvovaginal candidiasis syndrome 343. The cervicovaginal lavage (CVL) MBL levels and gene mutation frequency were both higher in women suffering from vulvovaginal candidiasis than in controls (Liu et al. 2006b). On the other hand, MBL levels were low (0.30 ng/mL) in women with recurrent vulvovaginal candidiasis and were associated with a high gene mutation frequency compared to controls (1.28 ng/mL) (Ip and Lau 2004). Parenteral administration of MBL increased resistance

of mice to hematogenously disseminated candidiasis. Thus, MBL plays an important role in innate resistance to candidiasis, suggesting a protective role of lectin in female genital tract infection (Pellis et al. 2005).

The autologous function for MBL, perhaps, is to perform a regulatory role within the immune system. The MBL interacts with human peripheral blood cells such as B lymphocytes and natural killer cells. The MBL is capable of binding to differently glycosylated ligands on several autologous cell types via its carbohydrate-recognition domain. It was speculated that this could have functional significance at extravascular sites, but perhaps only in individuals possessing MBL genotypes conferring MBL sufficiency (Downing et al. 2003, 2005).

Nevertheless, MBL genotyping of various populations has led to the suggestion that there may be some biological advantage associated with absence of the protein. In addition, the protein also modulates disease severity, at least in part through a complex, dose-dependent influence on cytokine production. Moreover, there appears to be a genetic balance in which individuals generally benefit from high levels of the protein. These findings suggest that the concept of MBL as a protein involved solely in first line defense is an over-simplification and the protein should rather be viewed as having a range of activities including disease modulation (Turner and Hamvas 2000; Dommett et al. 2006; Worthley et al. 2006). The mechanisms and signaling pathways involved in such processes remain to be elucidated. Though the deficiency of MBL is associated with increased susceptibility to infections, Roos et al. (2004) indicated that antibody-mediated classical pathway activation can compensate for impaired target opsonization via MBL pathway in MBL-deficient individuals. Lack of MBL may be most relevant in the context of a co-existing secondary immune deficiency. Replacement therapy appears promising. The development of a recombinant product should permit the extension of MBL therapy to randomized clinical trials of sufficient size to provide clear evidence about the physiological significance of this intriguing glycoprotein. The MBL has attracted great interest as a potential candidate for passive immunotherapy to prevent infection (Gupta et al. 2008).

42.2 MBL Deficiency as Risk of Infection and Autoimmunity

42.2.1 MBL Deficiency and Genotyping

The single point mutations in exon 1 of human *MBL-2* gene appear to impair the generation of functional oligomers leading to the secondary structural abnormalities of the collagenous triple helix and a failure to form biologically functional higher order oligomers. Such deficiencies of the functional protein are common in certain populations, e.g. in sub-Saharan Africa, but virtually absent in others, e.g. indigenous Australians. There is an increased incidence of infections in individuals with such mutations and an association with the autoimmune disorders such as SLE and rheumatoid arthritis. Thus, the MBL is a potential candidate for passive immunotherapy to prevent infection.

42.2.1.1 Polymorphism in MBL Gene Is Associated in Exon 1 at Codon 52, 54, and 57

The concentration of MBL in plasma is determined genetically, primarily by the genetic polymorphism of the first exon of the structural gene and promoter region. The gene encoding MBL, *MBL2* (*MBL1* is a pseudogene), is located on long arm chromosome 10q11.2–q21 and contains four exons. A number of single nucleotide polymorphisms (SNPs) have been characterized in the gene. Exon 1 harbours three missense SNPs, giving rise to amino acid exchanges in the first part of the collagenous region. Two of these SNPs: $Gly^{54}Asp$, named 'B' and $Gly^{57}Glu$, named 'C' exchange glycine with an acetic amino acid. The third ($Arg^{52}Cys$, 'D') introduces a cysteine in the collagen region (the residue numbers includes the leader sequence of 20 residues) (Fig. 42.2). The wild type is denoted 'A'. Heterozygous individuals for D, B, and C mutations have a substantial decrease in MBL serum concentration, whereas MBL is undetectable in the serum of homozygous individuals. Three structural mutations within exon 1 at codons 52, 54, and 57 have been invariably referred to as the D, B and C variants. In addition to these three variant structural alleles, the promoter region also shows a number of SNPs as well, some of which influences the expression of MBL. The three SNPs in the coding region of the MBL2 gene those are associated with abnormal polymerization of the MBL molecule, decreased serum concentrations of MBL and strongly impaired function. These MBL SNPs are associated with increased susceptibility to infections, especially in immune-compromised persons, as well as with accelerated progression of chronic diseases. Normal serum levels of MBL range from 800 to 1,000 ng/mL in healthy Caucasians, however, wide variations can occur due to point mutations in codons 52, 54 and 57 of exon 1 and in the promotor region of the MBL gene (Turner 2003). Separate point mutations in the collagenous domain of human MBL are associated with immune-deficiency, caused by reduced complement activation by the variant MBLs as well as by lower serum MBL concentrations.

MBL deficiency with B mutation is associated with 26% of Caucasian populations (Steffensen et al. 2000). In a cohort of 236 Australian blood donors, 5 MBL promoter and coding SNPs were genotyped. Significant associations were found between both coding and promoter polymorphisms and MBL antigenic and functional levels (Minchinton et al. 2002). Point mutations in exon 1 at codons 52, 54 and 57

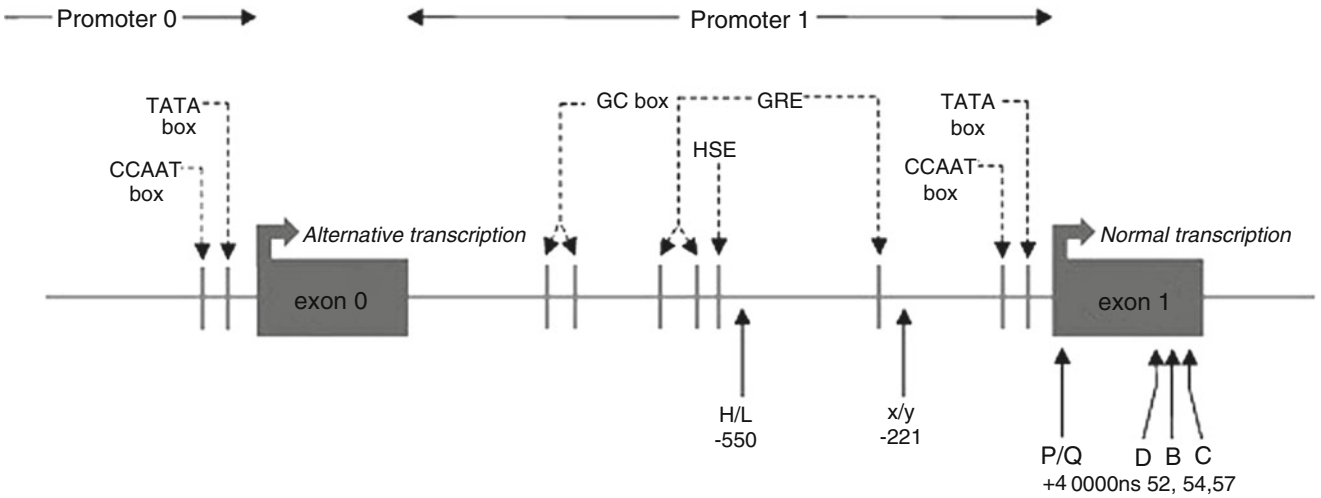

Fig. 42.2 *MBL2 polymorphisms*. Two promoters, promoter 1 and promoter 0 regulate the transcription of the human MBL2 gene. Similar to promoter 1 promoter 0 also includes a TATA box for transcription initiation, and transcription factor binding DNA sequences. Six DNA polymorphisms in the MBL2 gene are known to be associated with variation in quantity and/or function of MBL in serum. Three variants affect the expression of the MBL2 gene. They are localized in the promoter 1 (position −550, H/L variant and −221, X/Y variant) and in the 5′-untranslated region (position þ4, P/Q variant) of the MBL2 gene. Three base substitutions in exon 1 in codons 52 (D), 54 (B) and 57 (C) result in amino-acid changes (arginine to cysteine, glycine to aspartic acid and glycine to glutamic acid, respectively) and decreased level and function of MBL. The normal allele is named A proteases (Reprinted by permission from Macmillan Publishers Ltd: Genes Immun. Garred et al. © 2006)

and a promoter polymorphism at −221 bp of MBL gene were associated with increased susceptibility to various infectious diseases (Steffensen et al. 2003; Roos et al. 2006). The codon 54 mutation was frequent in both a British Caucasian and a Hong Kong Chinese population. The replacement of glycine-54 with an aspartic acid residue disrupts the fifth Gly-Xaa-Yaa repeat in the collagen-like domain of each 32 kDa MBP peptide chain and prevents the formation of the normal triple helix (Sumiya et al. 1991). Super et al. (1992) suggested that this genotype occurs in 5% of the population and encodes a functional protein. Super et al. (1992) also suggested that the $Gly^{54}Asp$ allele does not account for a deficiency state, but instead suggested that MBP may have two predominant allelic forms that have overlapping function and differ only in their ability to activate the classical pathway of complement.

Of 123 healthy Danish individuals investigated, 93 were homozygous (743.6%) for GGC, 28 heterozygous (22.8%), and 2 homozygous for GAC (1.6%). The gene frequency of the GAC allele was found to be 0.13. DNA sequencing of the cloned exon 1 from one GAC homozygous individual revealed no other substitution. The median MBP concentration in the group containing the GAC allele was 43.4 times lower than in the GGC homozygous group. However, the range of MBP in plasma was wide and overlapping between the groups. MBP protein was detected in both the GAC homozygotes. This study suggested that the GAC allele is able to produce a functional MBP protein which may be detected in serum at low concentrations (Garred et al. 1992).

The point mutation (GGA to GAA) involving codon 57 of exon 1 has been reported in Gambians from West Africa. In the Gambians the codon 57 mutation was remarkably common whereas the codon 54 mutation was very rare. In contrast, the codon 54 mutation was frequent in both the British Caucasian and the Hong Kong Chinese population. It was predicted that both homozygous and heterozygous individuals would have profoundly reduced serum levels of the protein and this was confirmed by immunoassay complement activation through lectin pathway. These two mutations have arisen independently because of the divergence of African and non-African populations.

Codon 52 Polymorphism Increases Risk of Premature Delivery: MBL2 gene polymorphisms are associated with an increased risk of neonatal infections. A relation between the maternal *MBL2* genotype and the risk of premature delivery has been indicated. Bodamer et al. (2006) suggested that the frequency of the codon 52 polymorphism was higher in the pre-term group compared to the term group (10.8% vs. 4.9%), while the frequency of codon 54 polymorphism was equal in both groups (11.3% vs. 11.8%). Data suggest that the fetal MBL2 genotype might be an additional genetic factor contributing to the risk of premature delivery.

SNPs at Codon 54 in MBL Are Associated with Increased Prevalence of Respiratory Infection: The SNPs of the innate immunity receptors CD14, MBL, and Toll-like receptor-2 with clinical phenotype in critically ill patients with systemic

inflammatory response syndrome are associated with increased prevalence of positive bacterial cultures and sepsis but not with altered prevalence of septic shock or decreased 28-day survival. Furthermore, CD14 SNPs were associated with Gram-negative bacteria and Toll-like receptor-2 with Gram-positive bacteria, whereas MBL was not associated with a particular organism class. The prevalence of the codon 54 mutation of the MBL gene in patients having repeated respiratory infections as well as the prevalence of the MBL mutant genotype among patients with diffuse panbronchiolitis was further supported (Gomi et al. 2004).

MBL Gene Polymorphisms in Gestational Diabetes Mellitus: Insulin resistance is a feature of gestational diabetes mellitus (GDM). A genetic predisposition to a pro-inflammatory state could favor the appearance of GDM during pregnancy. An association has been found between G54D and GDM. GDM patients carrying the G54D mutation require insulin therapy more frequently and have heavier infants than GDM women homozygous for the wild-type allele. An inverse correlation in GDM patients between neonatal weight and plasma MBL levels has been reported. Thus, pregnant women bearing the G54D MBL allele have a greater risk for developing GDM and having heavier infants (Megia et al. 2004).

MBL Genotypes in Acute Lymphoblastic Leukemia: Epidemiological studies show that acute lymphoblastic leukemia (ALL) can be induced by interactions between the immune system and early childhood infections. Since, certain types of childhood acute lymphoblastic leukemia develop as a multiple step process involving both pre- and postnatal genetic events, the MBL may play a critical role in the immune response in early childhood before specific immune protection develops. Schmiegelow et al. (2002) indicated that low-level MBL genotypes is associated with an increased risk of childhood ALL, particularly with early age at onset. Childhood ALL may often be initiated in utero. The prenatal origin of childhood leukemia was ascertened in children with B-precursor acute lymphoblastic leukemia carrying the chromosomal translocation t(12;21), the most common subtype of all childhood ALL. Study provided evidence that the development of t(12;21) B-precursor ALL may be initiated in utero. However, age at leukemia may be inversely correlated with the burden of cells with leukemia clonal markers, i.e. leukemia predisposed cells at birth (Hjalgrim et al. 2002).

MBL Genotypes in Viral Hepatitis: The prevalence of mutations in MBL gene was assessed in patients of hepatitis B. A mutation in codon 52 of the MBP gene was present in two (11%) of 19 Caucasian patients with acute hepatitis B and nine (27%) of 33 Caucasian patients with chronic hepatitis B, compared with four (4%) of 98 Caucasian controls. By contrast the prevalence of the mutation was similar in Asian patients with chronic hepatitis B and in Asian controls (one [5%] of 20 vs. two [2%] of 117). Mutations in codon 54 and codon 57 were found in similar proportions of patients and controls. These findings showed in Caucasian, but not Asian, patients an association of the codon 52 mutation of the MBL gene with persistent hepatitis B virus (HBV) infection. They suggest an important role for this gene, or a gene in linkage disequilibrium with MBL, in determining outcome after HBV infection in adult but not neonatal life (Thomas et al. 1996).

Bellamy et al. (1998) investigated the association between variant MBP alleles and malaria, tuberculosis, and HBV in adults and children in Gambia. Of the 2,041 Gambians screened for MBP mutations, 944 (46%) were homozygous for the wild-type allele, 922 (45%) were carriers of a single variant allele, and 175 (8.6%) possessed 2 mutant alleles. The most common mutation in Africans – the codon 57 variant allele – was weakly associated with resistance to tuberculosis in both patients and controls. Although MBP deficiency may predispose to recurrent infections, this study failed to provide evidence that such a deficiency is a major risk factor for infectious diseases (Bellamy et al. 1998).

The hepatitis C virus (HCV) envelope glycoprotein E2 binds the DC-SIGN and the related liver endothelial cell lectin through high-mannose N-glycans. Several high-mannose N-glycans in a structurally defined cluster on E2 bind to several subunits of the oligomeric lectin CRD and represent a strategy by which HCV targets to and concentrates in the liver and infects dendritic cells (Lozach et al. 2003). To determine the relevance of MBL polymorphism to hepatitis C virus infection, Matsushita et al. (1998) determined the MBL genotypes in 159 hepatitis C virus-infected chronic hepatitis patients and 218 healthy controls in Japan by looking at 4 polymorphic loci: 2 (H/L and X/Y) within the promoter region and 2 (P/Q and A/B) within exon-1 of the *MBL* gene. It indicated that the MBL-related innate immune system plays an important role in elimination of hepatitis C virus during interferon therapy (Matsushita et al. 1998). Matsushita et al. (2001) demonstrated that the MBL genotype can be significantly associated with increased risk for to primary biliary cirrhosis (PBC), and that increased production of MBL plays a critical role in immunopathogenesis.

42.2.1.2 Loss of Carbohydrate Binding and MASP-2 Auto-Activation in Mutated MBL

The mutations Gly25→Asp and Gly^{28}→Glu disrupt the disulfide-bonding arrangement of the protein and cause at least a fivefold increase in the half-time of secretion of MBP compared with wild-type rat serum MBP. A similar phenotype, including a threefold increase in the half-time of

secretion, disruption of the disulfide bonding arrangement, and inefficient complement fixation, was observed when nearby glucosylgalactosyl hydroxylysine residues at positions 27 and 30 were replaced with arginine residues. The results suggest that defective secretion resulting from structural changes in the collagen-like domain is likely to be a contributory factor for MBP immunodeficiency (Heise et al. 2000).

To investigate the molecular defects associated with heterozygosity, rat serum MBP polypeptides (MBP-A: 56% identical in sequence to human MBP) and rat MBP polypeptides containing mutations associated with human immunodeficiency were co-expressed in mammalian expression system. The resulting proteins are secreted almost exclusively as heterooligomers that were defective in activating the complement cascade. Functional defects were caused by structural changes to the N-terminal collagenous and cysteine-rich domains of MBP, disrupting interactions with associated serine proteases. These mutations demonstrated how a SNP gives rise to the molecular defects that lead to the disease phenotype in heterozygous individuals (Wallis 2002). Wallis et al. (2005) analyzed the molecular and functional defects associated with two variant proteins of lectin pathway. Mutations $Gly^{25} \rightarrow Asp$ and $Gly^{28} \rightarrow Glu$ created comparable structural changes in rat MBL but the G28E variant activated complement >10-fold less efficiently than the G25D variant, which in turn had approximately sevenfold lower activity than wild-type MBL. Analysis of mutant MBL-MASP-2 complexes formed from recombinant proteins showed that reduced complement activation by both mutant MBLs was due to failure of activation of MASP-2 efficiently on binding to a mannan-coated surface. Disruption of MBL-MASP-2 interactions as well as to changes in oligomeric structure and reduced binding to carbohydrate ligands compared with wild-type MBL probably account for the intermediate phenotype of the G25D variant. However, carbohydrate binding and -MASP-2 activation are ostensibly completely decoupled in complexes assembled from the G28E mutant, such that the rate of MASP-2 activation is no greater than the basal rate of zymogen MASP-2 autoactivation. Analogous molecular defects in human MBL probably combine to create the mutant phenotypes of immunodeficient individuals (Wallis et al. 2005).

Since it is difficult to evaluate MBL in patients blood on the only basis of protein contents, or in combination with MBL genotyping due to possible association of altered oligomeric state of MBL, Dumestre-Perard et al. (2002) purified MBL from human plasma and showed the presence of MBL in two different oligomeric forms. Data on the specific activity of these forms showed that the higher oligomeric forms of MBL had the ability to induce C4 cleavage more efficiently than the corresponding lower oligomers (Dumestre-Perard et al. 2002).

How to Define Abnormal MBL Pathway and Disease Associations: Although, the association between MBL deficiency and risk of infection with other common diseases and death during years of follow-up has established the role of MBL in innate immune system, yet, in a large ethnically homogeneous Caucasian population, there was no evidence for significant differences in infectious disease or mortality in MBL-deficient individuals versus controls and suggested that MBL deficiency is not a major risk factor for morbidity or death in the adult Caucasian population (Dahl et al. 2004; Eisen and Minchinton 2003; Kilpatrick 2002; Summerfield et al. 1997). While addressing possible correlation between MBL levels and clinical conditions an issue is how to define MBL deficiency. The physiologically relevant MBL level leading to clinical manifestations is likely to differ in different diseases. In the examples given below, a number of different levels have been used as cut-off values defining MBL deficiency. Judged from clinical trials it appears that at least 200 ng MBL/mL plasma is needed for reconstituting in vitro functional activity (C4b deposition) after MBL infusion in MBL deficient individuals (Valdimarsson et al. 2004). On the other hand, in leukaemic patients a cut-off level of 500 ng/mL or more has been suggested (Peterslund et al. 2001; Neth et al. 2001), and in the cases of obstetric problems even lower levels (100 ng/mL) have been indicated.

42.2.2 MBL and Viral Infections

42.2.2.1 MBL and HIV Interaction

A broad range of proteins binds high-mannose carbohydrates found on the surface of the envelope protein gp120 of the HIV and thus interfere with the viral life cycle, providing a new method of controlling HIV infection. While glycosylation of HIV gp120/gp41 provides a formidable barrier for development of strong antibody responses to the virus, it also provides a potential site of attack by the innate immune system through MBL/MBP. The MBL that binds to HIV depends on the high-mannose glycans present on gp120 while host cell glycans incorporated into virions do not contribute substantially to this interaction. The MBL has been shown to interact with all tested HIV strains. However, drugs that alter processing of carbohydrates enhance neutralization of HIV primary isolates by MBL. Complement activation on gp120 and opsonization of HIV due to MBL binding have also been observed but these immune mechanisms have not been studied in detail. MBL has also been shown to block the interaction between HIV and DC-SIGN. Clinical studies show that levels of MBL, an acute-phase protein, increase during HIV disease. Because of apparently universal reactivity with HIV strains, MBL clearly represents an important mechanism for recognition

of HIV by the immune system. However, further studies are needed to define the in vivo contribution of MBL to clearance and destruction of HIV (Botos and Wlodawer 2005; Ji et al. 2005). MBL that binds to high mannose glycans on HIV-1 (gp120), has been shown to neutralize the cell line-adapted strain HIV(IIIB). But HIV primary isolates (PI) are generally more resistant to neutralization by antibodies. Considering that PI are produced in primary cells that could alter the number of high mannose glycans on HIV relative to cell lines, Ying et al. (2004) showed that both PI and cell line-adapted HIV, despite binding of MBL, are relatively resistant to neutralization by levels of MBL normally present in serum. However, binding and opsonization of HIV by MBL may alter virus trafficking and viral-antigen presentation during HIV infection (Ying et al. 2004).

In search of the effect of MBL-2 polymorphisms on susceptibility and progression of HIV-1 infection in children, Dzwonek et al. (2006) observed MBL deficiency more frequently in patients with severe disease. The study suggested that MBL-2 variants may be less frequent in children classified as long-term non-progressors (LTNPs) and hence MBL analysis can be useful in identifying children with slow disease progression and, consequently, may not require immediate antiretroviral treatment (Dzwonek et al. 2006). Production of HIV in the presence of the mannosidase I inhibitor deoxymannojirimycin (dMM) significantly enhanced binding of HIV to MBL and increased MBL neutralization of an M-tropic HIV primary isolate. In contrast, HIV cultured in presence of alpha-glucosidase I and II inhibitors, castanospermine and deoxynojirimycin showed only slight effect on virus binding and neutralization by MBL. The study suggested that specific alterations of the N-linked carbohydrates on HIV gp120/gp41 can enhance MBL-mediated neutralization of virus by strengthening the interaction of HIV-1 with MBL (Hart et al. 2003).

42.2.2.2 Susceptibility to RSV, CoV and HTLV

Respiratory syncytial virus (RSV) is the most important microbiological cause of lower respiratory tract infection (LRTI) in infants. MBL deficiency is the most common immunodeficiency on the African Continent. MBL deficiency has an impact on the hospitalization for LRTI caused by RSV in infants from Soweto, South Africa. But in contrary to expectations, results suggested no association between low levels of MBL or carriage of variant alleles and LRTI caused by RSV (Kristensen et al. 2004).

Corona Virus Infection and Acute Respiratory Syndrome: Little is known about the innate immune response to severe acute respiratory syndrome (SARS) corona virus (CoV) infection. The MBL plays an important role in SARS-CoV infection. The distribution of MBL gene polymorphisms was significantly different between patients with SARS and normal subjects, with a higher frequency of haplotypes associated with low or deficient serum levels of MBL in patients with SARS. There was, however, no association between MBL genotypes, which are associated with low or deficient serum levels of MBL, and mortality related to SARS. MBL could bind SARS-CoV in calcium-dependent and mannan-inhibitable fashion in vitro, suggesting that binding is through the carbohydrate recognition domains of MBL. Furthermore, deposition of complement C4 on SARS-CoV was enhanced by MBL. Inhibition of the infectivity of SARS-CoV by MBL in fetal rhesus kidney cells suggested that MBL contributes to the first-line host defense against SARS-CoV and that MBL deficiency is a susceptibility factor for acquisition of SARS (Ip et al. 2005).

Susceptibility to T-cell Lymphotropic Virus: Pontes et al. (2005) investigated the association between MBL gene polymorphism and the susceptibility to human T-cell lymphotropic virus (HTLV) infection in 83 HTLV-infected asymptomatic subjects. Detection of MBL*A, MBL*B, and MBL*C was performed by amplifying a fragment of 349 bp (exon 1) and restriction fragment length polymorphism analysis with BanI and MboII endonucleases. A strong association has been demonstrated between MBL polymorphism and HTLV infection. Presence of genotype BB may be associated with the susceptibility to HTLV. Though further studies, with a larger number of individuals, are necessary, MBL polymorphism could have a possible impact on diseases associated with HTLV infection (Pontes et al. 2005).

42.3 Autoimmune and Inflammatory Diseases

Studies demonstrating the binding of MBL to the endothelium and causing excessive complement activation and subsequent tissue damage are known (Jordan et al. 2003), where as MBL deficiency may be advantageous in some circumstances since MBL may lead to an increased cytokine secretion by macrophages (Takahashi et al. 2002). There seems to be a delicate balance as to when MBL levels may be involved in harmful or in beneficial inflammation such as in the cardiovascular and other systems.

42.3.1 MBL Gene in Rheumatoid Arthritis

The etiology of autoimmune diseases is largely unknown. Studies on associations between MBL deficiency and rheumatoid arthritis (RA) have been discussed in reviews (Graudal 2004; Barton et al. 2004). Results depend on ethnic groups, type of

patients and the symptoms studied. Low levels of serum MBL are associated with a higher erythrocyte sedimentation rate (ESR), joint swelling score, limitation of joint motion score, and annual increase in radiographic destruction score. Despite this, indications are that low MBL levels may be linked with symptoms indicating a poor prognosis as well as an earlier debut. Whether variant alleles of the MBL gene causing low serum concentrations of MBL are associated with increased susceptibility to RA and erosive outcome in an inception cohort of patients with early polyarthritis was studied by Jacobsen et al. (2001). Jacobsen et al. (2001) suggested that MBL variant alleles appear to be weak susceptibility markers for RA, and patients with early polyarthritis and homozygous for MBL structural variant alleles have a higher risk of developing early erosive RA. These findings, together with the positive association between MBL variant alleles and the increased serum levels of IgM RF and CRP, point at the MBL gene as a relevant locus in the pathophysiology of RA. Graudal (2004) indicated that MBL-deficient patients have a relative risk of a severe radiographic event of 3.1 compared with the MBL competent group. The relative risk (RR) of early IL-1α auto-antibodies positive patients developing serious radiographic joint destruction was significantly lower than for IL-1α auto-antibodies-negative patients. Perhaps MBL and IL-1α auto-antibodies are predictors of prognosis of RA and play important roles in the pathogenesis of RA (Graudal 2004; Lee et al. 2005). Low levels of the protein have been related to a poor prognosis in rheumatoid arthritis perhaps due to the modulatory action that MBL exerts on the secretion of tumor necrosis factor α, a central molecule in the pathogenesis of rheumatoid arthritis (Graudal et al. 2000). Low MBL levels have also been associated with adult dermatomyositis and are probably related to a reduced clearance of apoptotic keratinocytes (Werth et al. 2002). Genotypes related to a lower production of MBL have also been linked to the development of systemic lupus erythematosus (Villarreal et al. 2001; Davies et al. 1995).

42.3.2 Systemic Lupus Erythematosus

Genetic factors play a major role in the development of SLE. More than 5% of cases are familial and the concordance rate between identical twins is 40%. Genetic studies in mice suggest a complex mechanism of transmission involving interactions among several susceptibility genes and, probably, protective genes. Genetic studies in humans have identified nearly 50 chromosomal areas possibly involved in lupus transmission. Significant linkage has been found for at least six regions, two on chromosome 1, one near the HLA region on chromosome 6, and three on chromosomes 2, 4, and 16, respectively. The genetic polymorphism of cytokines and, perhaps, of the T-cell receptor (TCR) may contribute to deregulate lymphocyte activity. The polymorphism of the Fc receptors of immunoglobulins may affect immune complex clearance, thereby promoting tissue damage. Further genetic studies are needed to enrich the fund of knowledge on lupus and to identify new targets for treatment (Perdriger et al. 2003).

From the several investigations on MBL and SLE the consensus is emerging that low levels of MBL predisposes to development of the disease. However, the connection is not like for C1q where SLE develops in almost all of the rare cases of deficiency. Rather, it seems that MBL deficiency aggravates the disease or the development (Ohlenschlaeger et al. 2004; Takahashi et al. 2005). In SLE patients, MBL deficiency increase the risk for respiratory tract infections (Garred et al. 2001; Takahashi et al. 2005) as well as the risk of developing arterial thromboses (Ohlenschlaeger et al. 2004).

As with infectious disease, there is some evidence that the risk of pathology increases if there is another co-existing immune defect. For example, in a cohort of Spanish patients, the odds ratio for developing SLE was 2.4 for individuals with MBL deficiency, but this increased to 3.2 when there was also a co-existing partial C4 deficiency (Davies et al. 1997). Studies in patients with SLE have reported that MBL deficiency also influences their risk of developing certain complications, which include arterial thromboses (Ohlenschlaeger et al. 2004) and respiratory tract infections (Garred et al. 2001; Takahashi et al. 2005).

42.3.2.1 MBL Polymorphisms in SLE

Whether dysfunctional or deficient MBP variants are found with increased frequency in black patients with SLE was determined (Sullivan et al. 1996). Two structural polymorphisms of MBP, associated with low serum levels of MBP, were found with significantly increased frequency in the SLE patient population. In contrast, a promoter haplotype associated with particularly high serum levels of MBP was negatively associated with SLE. Thus, it seemed that deficiencies of MBP predispose individuals to SLE (Sullivan et al. 1996). The distribution of promoter variants of the MBL gene and correlations between the promoter variants and serum MBL concentrations in Chinese patients with SLE were investigated. Significant differences in the distribution of the two pairs of promoter polymorphisms, H/L and Y/X, between SLE patients and controls, were observed. Analysis of the correlation between promoter haplotypes and serum MBL levels revealed HY as the highest-producing, LY as the intermediate-producing, and LX as the lowest-producing haplotypes. The LX haplotype was present at a frequency of 0.259 in SLE patients and 0.154 in controls and was significantly associated with SLE. The low-producing promoter polymorphism of the MBL gene is associated with SLE, and a low serum MBL level is a risk factor for SLE (Ip et al. 1998). Whether occurrence, characteristics, and progression of SLE are associated with polymorphism of the MBL gene and with serum MBL concentration, Takahashi et al. (2005) reported that MBL gene

polymorphism influences susceptibility to SLE, but has no direct effect on disease characteristics. Serum MBL levels fluctuate during the course of SLE in individual patients. MBL genotyping may be useful in assessing the risk of infection during treatment of SLE (Takahashi et al. 2005). MBL and FcγRII (CD32) polymorphisms have both been implicated as candidate susceptibility genes in SLE. These patients carried MBL codon 54 mutant allele more frequently than controls and the haplotype HY W52 W54 W57 was significantly lower in cases compared with controls. The MBL gene codon 54 mutant allele appears to be a risk factor for SLE, whilst haplotypes encoding for high levels of MBL are protective against the disease. However, differences between controls and patients were not significant when FcγRIIa polymorphisms were considered (Villarreal et al. 2001).

42.3.2.2 Lectin Pathway in Murine Lupus Nephritis

In SLE, hypocomplementaemia and complement deposition have been described both in man and in experimental models. In mice, MBL is expressed in two forms, MBL-A and MBL-C. In young and old MRL-lpr and control MRL+/+, the declining levels of MBL-A and MBL-C showed a high degree of correlation. In aged MRL-lpr mice in which autoimmunity is most pronounced, high auto-Ab titers and strong deposition of glomerular immune complexes were associated with deposition of C1q, C3, MBL-A and MBL-C. Thus, in addition to the classical pathway and the alternative pathway, the lectin pathway of complement activation is also involved in murine lupus nephritis (Trouw et al. 2005). SLE patients were associated with a reduced functional activity of the MBL pathway of complement, in relation to expression of MBL variant alleles, increased levels of autoantibodies against cardiolipin and C1q, but not against MBL. The enhanced production of autoantibodies may be related to disturbed clearance of apoptotic material due to impaired MBL function (Seelen et al. 2005). Cohorts of MRL-lpr mice, which are known to develop age-dependent SLE-like disease showed that at 2 months of age all mice already had elevated levels of anti-C1q autoantibodies, and elution of kidneys confirmed the presence of these antibodies in renal immune deposits in MRL-lpr mice and not in control MRL+/+ mice. Thus, anti-C1q antibodies are already present in serum and immune deposits of the kidney early in life and therefore can play a role in nephritis during experimental SLE-like disease in mice (Trouw et al. 2004).

Effect of (S)-Armepavine on Autoimmune Disease of MRL/MpJ-lpr/lpr Mice: (S)-Armepavine (C19H23O3N; MW313) from *Nelumbo nucifera* suppresses T cells proliferation. (S)-armepavine prevents lymphadenopathy and elongated life span of MRL/MpJ-lpr/lpr mice, which have disease features similar to human SLE. The action seemed to be mediated by inhibition of splenocytes proliferation, suppression of IL-2, IL-4, IL-10, and IFN-γ gene expressions, reduction of glomerular hypercellularity and immune complexes deposition, and decrease of urinary protein and anti-double stranded DNA autoantibody production. It has been suggested that (S)-armepavine is an immunomodulator for the management of autoimmune diseases like SLE (Liu et al. 2006a).

42.3.2.3 Autoantibodies to C1q and MBL in SLE

In SLE patients, there is an association between the occurrence of autoantibodies to C1q and MBL and renal involvement. The presence of autoantibodies to MBL, analogous to autoantibodies to C1q in patients with SLE, contributes to the disease development. Anti-MBL autoantibodies were of the IgG isotype and the binding site of IgG anti-MBL was located in the F(ab')2 portion. Anti-MBL are present in sera from SLE patients and influence the functional activity of MBL (Seelen et al. 2003). More SLE patients have IgG anti-MBL antibodies than normal controls. However, in SLE, these antibodies are neither sensitive nor specific for this condition. They occur more frequently in (proliferative) lupus nephritis, particularly during active disease. Furthermore, levels of anti-C1q rise, in many cases, prior to a relapse of lupus nephritis, suggesting a pathogenic role for the autoantibodies in immune complex-mediated renal disease. In addition, anti-C1q may interfere with the clearance of apoptotic cells, so influencing induction and expression of autoimmunity (Kallenberg 2008; Mok et al. 2004).

Cardiovascular Disease and SLE: Cardiovascular disease is an important complication in patients with SLE. Variant alleles of the MBL gene are associated with SLE as well as with severe atherosclerosis. Ohlenschlaeger et al. (2004) determined whether *MBL* variant alleles were associated with an increased risk of arterial thrombosis among Danish patients with SLE and suggested that among patients with SLE, homozygosity for *MBL* variant alleles is associated with an increased risk of arterial thrombosis. The risk of venous thrombosis is not increased, indicating that MBL has a specific role in providing protection against arterial thrombosis (Ohlenschlaeger et al. 2004).

42.3.3 Systemic Inflammatory Response Syndrome/Sepsis

A systemic inflammatory response syndrome (SIRS) is well known in patients after major surgery (Bone 1992). Clinical studies of critically ill patients requiring intensive care management have shown that individuals who are MBL deficient are more likely to develop the SIRS and progress to septic

shock and death (Garred et al. 2003b; Fidler et al. 2004), findings which may well relate to the proinflammatory cytokine response. In some cases, SIRS occurs in response to infection and "sepsis" is then used to describe the symptoms. More severely a septic shock may develop with multi-organ dysfunctions (MOD). The MBL levels and genotypes were investigated in 272 adults (197 with sepsis) prospectively admitted to the ICU. No difference was seen between genotype frequencies in patients with SIRS as compared to healthy controls. But the frequency of MBL variant genotypes was significantly higher in patients with sepsis compared with the patients without sepsis, and the risk ratios for the development of "severe sepsis" and "septic shock" ranged from 1.3 to 3.2 times higher in patients with A/O or O/O versus A/A genotype. MBL levels were inversely related to the severity of sepsis (Garred et al. 2003a, b). The SNP of MBL with clinical phenotype in critically ill Caucasians with SIRS are associated with increased prevalence of positive bacterial cultures at admission to the ICU. Patients in low MBL haplotype group did not have significantly increased rates of sepsis or septic shock at admission to the ICU. Survival at day 28 did not differ significantly between the low MBL haplotype and high MBL haplotype groups. Furthermore, MBL was not associated with a particular organism class. The prevalence of the codon 54 mutation of MBL gene in patients having repeated respiratory infections as well as the prevalence of MBL mutant genotype among patients with diffuse panbronchiolitis was further supported (Gomi et al. 2004).

In contrast, the prevalence of the MBL mutant genotype among patients with nontuberculous mycobacteria or Aspergillus chronic infection was not different from that in control subjects. Thus, SNPs in innate immunity receptors may alter recognition and clearance of bacteria without changing outcomes of critically ill adults with systemic inflammatory response syndrome (Sutherland et al. 2005). Polymorphisms of both codon 54 allele and promoter variants of the mannose MBL gene in patients with primary Sjogren's syndrome (SS) was suggested as one of the genetic factors that determines susceptibility to SS (Wang et al. 2001).

Fidler et al. (2004) analyzed the MBL levels and genotypes levels in 100 critically ill children admitted to ICU. A sevenfold greater risk of developing SIRS within 48 h of admission (60% of the patients) was observed for those carrying MBL variant alleles than those with wild type alleles (A/O + O/O vs. A/A). A significant relation was also found between severity of the systemic response to infection and the presence of an MBL mutation. If the severity of illness among the patients admitted with infections was divided into localized infection, sepsis, and septic shock, the median MBL levels were inversely related to severity, and the children with MBL levels below 1,000 ng/mL had a greater chance of developing SIRS. A study of the frequency of sepsis in very low birth weight infants did not reveal statistical significance in clinical data between infants with and without specific mutations in a number of genes, including MBL genotypes (Ahrens et al. 2004). Following surgery of 156 patients undergoing major elective gastrointestinal surgery for malignant disease, Siassi et al. (2003) reported that patients who developed sepsis or SIRS showed significantly lower mean post-operative MBL levels. In colorectal cancer patients, postoperative infection is associated with poor prognosis. Ytting et al. (2005) have reported significantly increased frequency of pneumonia after primary operation in colorectal carcinoma patients who were having low MBL levels. MBL deficiency appears to play an important role in susceptibility of critical ill patients to the development and progression of sepsis and septic shock, and confers a substantially increased risk of fatal outcome. There is clearly a need for improvement in defining which patient groups and which clinical data are relevant to examine.

42.3.4 MBL and Inflammatory Bowel Diseases

Inflammatory bowel disease (IBD) is a pathological spectrum encompassing ulcerative colitis (UC), Crohn's disease (CD), and indeterminate colitis. The resultant IBD phenotype is the consequence of multiple interactions between environmental factors, particularly enteric flora, and the host response to this environment, determined by immunogenetic, epithelial, and other non-immune genetic factors. MBL, as an important component of innate immunity, has engendered considerable research interest. In an early study of 340 unrelated patients with IBD genotyped for *MBL2* exon 1 coding mutations, the frequency of deficient alleles was significantly lower in patients with UC than either the control group, or those with CD (Rector et al. 2001). The study by Rector et al. (2001) suggests that MBL deficiency could be protective against UC; alternatively, it could be interpreted that MBL deficiency, in individuals otherwise predisposed to IBD, may skew the phenotype away from the UC spectrum of disease towards CD. This concept is supported by another study that genotyped *MBL2* in patients with CD, UC, or healthy controls (Seibold et al. 2004). The study also assessed anti-*Saccharomyces cerevisiae* antibody (ASCA) and MBL levels within the same subsets of patients, albeit slightly different numbers within each group. CD patients with MBL deficiency were significantly more likely to be positive for ASCA and for their lymphocytes to proliferate in response to mannan. Thus, it appears that MBL deficiency could impair normal processing of mannan-expressing microbial antigens, such as those found on the cell surface of many common microorganisms. The accumulated antigens could then stimulate the immune system, and contribute to the production of ASCA and possibly the pathogenesis of Crohn's disease. Thus, MBL deficiency

might act primarily to influence IBD-specific phenotype in these patients. It should be noted, however, that a follow-up study, testing a larger cohort of CD patients ($n = 241$), failed to confirm the significant association between variant MBL genotypes and ASCA positivity (Joossens et al. 2006). Seibold et al. (2004) suggested that the frequency of homozygous and compound heterozygous for variant exon 1 alleles differed significantly between patients suffering from CD or UC and the healthy controls.

42.3.4.1 Celiac Disease and MBL

Celiac disease is a multi-factorial/auto-immune disorder caused in genetically susceptible patients, by the ingestion of dietary gluten. Though very little is known about the genetic factors, but there is a strong association of two HLA haplotypes (DQ2 or α1*05, β1*02 and DQ8 or α1*0301, β1*0302) with the disease. Boniotto et al. (2002) indicated an association between celiac disease and the presence of variant MBL alleles. Boniotto et al. (2005) and Iltanen et al. (2003) reported the frequency of homozygosity for variant MBL alleles to be higher in the patients. Among 149 Italian celiac patients, 116 showed the presence of DQ2 or DQ8. MBL2 allele and genotype frequencies varied significantly between celiac patients and healthy humans. It is likely that in those rare cases of celiac disease that are negative for DQ2 and DQ8, the non-HLA susceptibility genotypes would exert a greater effect. The study also analyzed apoptosis within small intestinal biopsy specimens, and showed that MBL tended to aggregate to areas of apoptosis within the epithelium. MBL has been implicated in the normal clearance of apoptotic bodies (Nauta et al. 2003; Ogden et al. 2001). The authors postulated that the association between MBL and celiac disease, and indeed other autoimmune conditions, could relate to impaired apoptosis, whereby MBL deficiency impairs the normal removal and clearance of apoptotic cells that may subsequently reveal previously hidden self-antigen, causing loss of self-tolerance, and spreading of autoimmunity (Boniotto et al. 2005). The association between variant *MBL2* alleles and coeliac disease has also been confirmed within the Finnish population (Iltanen et al. 2003) (Worthley et al. 2006). The low MBL genotypes were strongly associated with more celiac disease symptoms as well with increased frequency of secondary autoimmune diseases. By immunohistochemistry MBL was found to be present, together with apoptotic cells, in the basal lamina under the intestinal epithelium, where they had previously found mRNA for MBL. Boniotto et al. suggested that impaired removal of apoptotic cells due to MBL deficiency might predispose to the development of autoimmune symptoms. Mice lacking MBL have been shown to be less efficient in removal of apoptotic cells (Stuart et al. 2005). In vitro studies have also implicated MBL in removal of apoptotic cells (Ogden et al. 2001; Nauta et al. 2004). Alternative explanation could be that increased susceptibility to intestinal infections and diarrhea, associated with low MBL, may change the intestinal epithelia thus allowing for abnormal stimulation of anti-gliadin immune responses and triggering of the cascade leading to celiac disease. A role for MBL like in celiac disease could be easily applied to other autoimmune disorders.

42.3.4.2 MBL and Gastrointestinal Infection

Despite the well-established role of MBL in innate immunity, there have been relatively few studies describing the clinical effect of MBL deficiency in enteric infections. One notable exception is the association between MBL deficiency and risk of *Cryptosporidium parvum* enteritis. This study indicated that patients with biallelic coding mutations (*O*/*O*) had a significantly greater chance of cryptosporidiosis compared to those who were either wild-type or heterozygous for *MBL2* mutation (Kelly et al. 2000). The association between MBL deficiency and cryptosporidiosis was confirmed in young Haitian children by Kirkpatrick et al. (2006). However, the two combined studies present compelling evidence for the role of MBL in the host defense against *Cryptosporidium spp*. infection. However, MBL deficiency was not associated with an increased risk of *Escherichia coli* 0157: H7 colitis nor the complication of HUS (Proulx et al. 2003). *H. pylori* is one of the most common human bacterial infections, affecting approximately 50% of humans. Several immunogenetic polymorphisms are associated with clinical outcomes in *H. pylori* infection, as well as with the risk of infection itself. *H pylori* activates MBL in vitro (c/r Worthley et al. 2006). Studies demonstrated that *H. pylori*-related chronic gastritis causes an increase in gastric mucosal MBL expression, but no association was found between *MBL2* genotype and risk of chronic gastritis (Bak-Romaniszyn et al. 2006; Worthley et al. 2007).

MBL has been implicated in mediating gastrointestinal ischemia/reperfusion injury in mice (Hart et al. 2005). But MBL-null mice (deficient in the murine genes encoding MBL) developed only minor gut injury after induced ischemia/reperfusion insult compared to the wild-type mice. On the contrary, MBL has been implicated as a mediator of ischemia/reperfusion injury in both the myocardium (Walsh et al. 2005) and the kidney (Møller-Kristensen et al. 2005).

42.3.5 Rheumatic Heart Disease

Whereas MBL deficiency has been associated with rheumatic disorders, high MBL levels associated to disease has been reported by Hansen et al. (2003). Rheumatic fever (RF) is the most common cause of acquired valvular disease in

children and young adults. The pathogenic mechanisms responsible for the development of RF/RHD are associated to an abnormal host immune response (both at humoral and cellular level) to cross-reactive streptococcal antigens. The significantly elevated circulating MBL levels in patients with RHD together with the greater prevalence of MBL deficiency in controls suggest that MBL may cause undesirable complement activation contributing to the pathogenesis of RHD (Schafranski et al. 2004). Probably, MBL deficiency may represent an advantage against the development of rheumatic mitral stenosis and that increased MBL levels may be related to the development of RHD. Under normal conditions, MBL does not bind to the organism's own tissues, but in situations of cellular hypoxia, glycosylation of cell surfaces may occur, leading to the deposition of MBL followed by complement activation. The significantly elevated levels of MBL observed in chronic RHD suggest that MBL may represent a pathogenic factor in the complex physiopathology of the disease, whereas MBL deficient individuals might be less susceptible to develop chronic RHD. Studies demonstrating the binding of MBL to the endothelium and causing excessive complement activation and subsequent tissue damage are known (Jordan et al. 2003), where as MBL deficiency may be advantageous in some circumstances since MBL may lead to an increased cytokine secretion by macrophages (Takahashi et al. 2002). Under some other conditions, MBL is associated to disease severity in both infectious and autoimmune disease (Garred et al. 1997, 1999). Although MBL is an acute-phase protein produced by the liver, its level only shows a moderate increase and determined genetically in inflammatory diseases. The elevated MBL levels in patients with chronic RHD might corroborate the chronic inflammatory activity present in these individuals and contribute to valve injury through complement activation. In addition, MBL may act as an immunomodulatory molecule, inducing a higher secretion of cytokines by macrophages (Turner and Hamvas 2000).

42.3.6 MBL in Cardio-Vascular Complications

There seems to be a delicate balance as to when MBL levels may be involved in harmful or in beneficial inflammation in the cardiovascular system. For example, Kawasaki disease is a systemic vasculitis in childhood possibly caused by infections and in the developed world Kawasaki disease is the most common cause of acquired heart disease in children (Royle et al. 2005). MBL as an initiator of inflammation, Biezeveld et al. (2003) while studying the frequency of MBL genotypes with Kawasaki disease in Dutch patients found a higher frequency of MBL mutations as compared to the genotypes in controls. Children younger than 1 year were at higher risk of development of CAD. Kawasaki disease occurs more frequent in oriental children (10 times more frequent than in Caucasians) (Royle et al. 2005). In Chinese, Cheung et al. (2004) did not see a difference between the MBL genotypes of patients and controls. The recent observation of an association between a human coronavirus and Kawasaki disease (Esper et al. 2005) fits with the many indications of MBL having antiviral activity. Plaque material may be removed from inside of the carotid artery (e.g., by endarterectomy) to avoid cerebral attack. Rugonfalvi-Kiss et al. (2005) indicated that female patients with genotypes associated with lower MBL levels had a slower rate to early restenosis, suggesting that a high level of MBL may be part of the pathophysiology of this condition.

In a study of 76 patients with severe atherosclerosis, Madsen et al. (1998) found that there were more patients with myocardial infarcts among Norwegians with low MBL allotypes than in controls. Saevarsdottir et al. (2005) found in a cohort study in Iceland that the risk of developing myocardial infarction was higher in MBL deficient individuals. The relationship between markers of innate immunity and clinical outcomes in patients with heart failure (HF) after acute myocardial infarction (AMI) suggested that atherogenesis and heart failure are associated with the altered control of inflammation by innate immune defenses, which include TLRs and MBL. Circulating levels of MBL and sTLR2 may reflect different aspects of the innate immune response and the involvement of innate immunity responses in the pathogenesis of post-MI heart failure (Ueland et al. 2006).

Lectin Pathway in Myocardial Ischemia-Reperfusion: MBL plays a dual role in modifying inflammatory responses to sterile and infectious injury. Although complement is widely accepted as participating in the pathophysiology of ischemia-reperfusion injury, the specific role of the lectin pathway has been addressed by Jordan et al. (2001). Since, blockade of the lectin pathway with inhibitory mAbs protects the heart from ischemia-reperfusion by reducing neutrophil infiltration and attenuating pro-inflammatory gene expression, it appears that the lectin complement pathway is activated after myocardial ischemia-reperfusion and leads to tissue injury.

Mice devoid of MBL-dependent lectin pathway activation but fully active for alternative and classical complement pathways, are protected from cardiac reperfusion injury with resultant preservation of cardiac function. Significantly, mice that lack a major component of the classical complement pathway initiation complex (C1q) but have an intact MBL complement pathway are not protected from injury. Thus, the MBL-dependent pathway of complement activation is the key regulator of myocardial reperfusion ischemic injury (Walsh et al. 2005).

Diabetic Patients at High Risk for Diabetic-Nephropathy: Whether lectin pathway of complement activation plays a role in the pathogenesis of human glomerulonephritis, is not well known. It has been proposed that MBL may bind to altered self components, which may possibly be found in diabetic patients, and MBL could thus be a potential pathogenic factor for diabetic cardiovascular complications, e.g., nephropathy (Hansen et al. 2005; Saevarsdottir et al. 2005). Normo-albuminuric type 1 diabetics have been found to have higher MBL levels than non-diabetic controls, with a stepwise increase in circulating MBL levels with increasing levels of urinary albumin excretion (Hansen et al. 2003). In another study, a significantly larger proportion of patients with diabetic nephropathy presented a MBL genotype associated with higher MBL level, when compared to the group with MBL genotypes associated with low MBL levels (Hansen et al. 2004). The elevated serum MBL levels in type 1 diabetic patients with diabetic nephropathy were confirmed by Saraheimo et al. (2005). In a long follow up study on 270 type 1 diabetic patients, it was found that for patients with type 1 diabetes and MBL-levels below the median of 1.6 μg/mL the risk of developing micro or macro-albuminuria was 26%, while the patients with MBL-levels above the median had a risk of 41% of developing micro or macro-albuminuria (Hovind et al. 2005). These studies suggested that a high MBL geno- and phenotype is associated with an increased risk of developing diabetic kidney disease and that assessing MBL status may prove beneficial in identifying patients at risk for micro- and macro-vascular complications (c/r Thiel et al. 2006).

MBL has been detected in the glomeruli of patients with lupus nephropathy, membranous nephropathy, membranoproliferative glomerulonephritis type I and anti-GBM nephritis. It was proposed that MBL binds to agalactosyl oligosaccharides of IgG that terminate in N-acetylglucosamine (Lhotta et al. 1999). Elevated serum MBL levels of were implicated in the pathogenesis of renal manifestations of Henoch-Schönlein purpura (Endo et al. 2000), in IgA nephropathy (Endo et al. 1998), in other forms of human glomerulonephritis (Lhotta et al. 1999), and in vascular complications of diabetes mellitus type 1 (Hansen et al. 2003).

42.3.7 Other Inflammatory Disorders

42.3.7.1 Sarcoidosis and MBL Variants

Sarcoidosis is a chronic granulomatous disease of unknown aetiology. The causative agent may be an infectious micro-organism. MBL variants predisposed to sarcoidosis by increasing their susceptibility to micro-organisms among sarcoidosis patients showed that the frequencies of variants were similar regardless of severity of disease outcome. MBL gene variants did not indicate to influence susceptibility to sarcoidosis, age of disease onset, or severity of disease. The average patient ages at time of diagnosis were similar for all MBL genotypes (Foley et al. 2000). However, a 57-year-old woman patient with pulmonary sarcoidosis suggested interstitial nephritis without proteinuria and hematuria, whereas a renal biopsy showed granulomatous interstitial nephritis and mild mesangial proliferative glomerulonephritis. From this case of renal sarcoidosis, it was hypothesized that *P. acnes* might be involved in pathogenesis of granulomatous interstitial nephritis and that it plays a role in glomerular complement activation via the lectin pathway (Hagiwara et al. 2005).

42.3.7.2 Behcet's Disease

Behcet's disease (BD) is a multisystemic, recurrent inflammatory disease caused by the combination of genetic and environmental factors. The haplotypes of the MBL2 gene can influence therapeutic response in BD, thus affecting the clinical symptoms in BD patients. The promoter region, MBL2-550*C/*C (L/L) homozygote was found to have a lower frequency in BD patients than that in controls. No difference was observed in the allele frequencies of G-221 C (Y/X), C + 4 T (P/Q) or Gly54Asp (A/B) of the MBL2 gene in BD patients and in controls. The HYPA haplotype contributed to BD occurrence, whereas the LYPA haplotype was negatively associated with BD. BD patients with several symptoms and with an earlier disease-onset age had a higher HYPA haplotype frequency. BD patients showing poor response (S) to therapy had a higher HYPA frequency than those showing good response (M). It appeared that possessing HYPA increases the risk of BD and that the MBL2 HYPA haplotype plays a role in MBL levels and increases the susceptibility to BD (Park et al. 2005).

42.3.7.3 Cystic Fibrosis (CF) Lung Disease

The MBL deficiency has been associated with poor outcome in cystic fibrosis (CF) lung disease. A mutation in MASP-2 and higher serum levels of MBL than healthy controls belonging to the MBL pathway in serum have been described. Thus, MBL pathway function is affected both by MBL and by MASP-2 genotypes (Carlsson et al. 2005). Patients undergoing abdominal aortic aneurysm (AAA) repair are exposed to an ischaemia-reperfusion injury (IRI), which is in part mediated by complement activation. During IRI, the patients undergoing AAA repair experience a mean decrease in plasma MBL level of 41% representing significant lectin pathway activation. This indicated that consumption of MBL occurs during AAA repair, which suggested an important role for lectin pathway in IRI. Hence, specific transient inhibition of lectin pathway activity can be of significant therapeutic value in patients undergoing open surgical AAA repair (Norwood et al. 2006).

In Guillain-Barre syndrome (GBS), complement activation plays a crucial role in the induction and extent of the post-infectious immune-mediated peripheral nerve damage. The MBL2 genotype, serum MBL level, and MBL complex activity are associated with the development and severity of GBS. The MBL2 B allele was associated with functional deficiency and relatively mild weakness. Studies support the hypothesis that complement activation mediated by MBL contributes to the extent of nerve damage in GBS, which is codetermined by the MBL2 haplotype (Geleijns et al. 2006).

42.3.7.4 Experimental Polymicrobial Peritonitis

Peritonitis is the most common and major complication in the treatment modality of peritoneal dialysis (PD) for uraemic patients. The contribution of the different complement activation pathways was studied in the host defense against experimental polymicrobial peritonitis induced by cecal ligation and puncture by using mice deficient in either C1q or factors B and C2. The C1q-deficient mice lack the classical complement activation pathway. Mice with a deficiency of both factors B and C2 lack complement activation via the classical, the alternative, and the lectin pathways and exhibited the maximum mortality of 92%, indicating a significant contribution of the lectin and alternative pathways of complement activation to survival (Windbichler et al. 2004). While examining the role of serum MBL concentration and point mutations in MBL gene in PD-related peritonitis, Lam et al. (2005) found that both homozygous and heterozygous patients had profoundly reduced serum level of MBL. Thus, dialysis patients having lower MBL levels may increase the susceptibility of infection.

42.4 Significance of MBL Gene in Transplantation

MBL Replacement Therapy Following Stem Cell Transplantation: Life-threatening complications such as graft versus host disease and infection remain major barriers to the success of allogeneic hemopoietic stem cell transplantation (SCT). Among various factors, MBL deficiency is a risk factor for infection in other situations where immunity is compromised. MBL2 coding mutations were associated with an increased risk of major infection following transplantation. MBL2 promoter variants were also associated with major infection. The high-producing haplotype HYA was associated with a markedly reduced risk of infection. Donor MBL2 coding mutations and recipient HYA haplotype were independently associated with infection in multivariate analysis. Thus, these results suggest that MBL2 genotype influences the risk of infection following allogeneic SCT and that both donor and recipient MBL2 genotype are important (Mullighan et al. 2002).

A retrospective study examining associations between polymorphisms in the gene encoding MBL, MBL2 and risk of major infection post-SCT was conducted in 96 related myeloablative transplants. The study showed that "low-producing" MBL2 coding alleles, when present in the donor, were significantly associated with increased risk of major infection in the recipient following neutrophil count recovery. Furthermore, a "high-producing" MBL2 haplotype, HYA, when present in the recipient, was protective against infection. Since MBL is under development as a therapeutic agent, findings suggest that administration of MBL may reduce the risk of infection post-transplant. Further work is required to confirm these results. These results indicate a report of a genetic determinant of risk of infection post-SCT, and highlight the importance of non-HLA genetic factors in determining the risk of transplant complications (Mullighan and Bardy 2004).

Genetic MBL variants are frequent and associated with low MBL serum levels. Higher MBL levels may be associated with more complement-mediated damage resulting in inferior graft survival. Berger et al. (2005) showed no significant difference in incidence of delayed graft function in recipients with a low MBL level ($<$ or $=$ 400 ng/mL) compared to those with a higher MBL level ($>$400 ng/mL). If these data can be confirmed, pre-transplant MBL levels may provide additional information for risk stratification prior to kidney transplantation (Berger et al. 2005).

Complement Activation Is Harmful for the Allograft Endothelium: In heart transplant recipients, Fiane et al. (2005) recorded transplant-associated coronary artery disease and observed an association with MBL deficiency. They also recorded that acute rejection of the transplant was seen in 6 out of 6 with MBL deficiency as compared to 15 out of 32 with higher MBL levels. Assuming that MBL may interact with the transplanted tissue and initiate complement activation, this study added to the list of studies, which suggested that complement activation is harmful for the endothelium in general, and possibly for the allograft endothelium in particular.

MBL Pathway and SPKT Graft Survival: Simultaneous pancreas-kidney transplantation (SPKT) is the treatment of choice for patients with type 1 diabetes and renal failure. However, this procedure is characterized by a high rate of postoperative infections, acute rejection episodes, and cardiovascular mortality. The lectin pathway of complement activation contributes to cardiovascular disease in diabetes and may play an important role in inflammatory damage after organ transplantation. MBL serum levels and MBL genotypes in patients who received an SPKT from 1990 through 2000 and related graft survivals revealed that survival was significantly better in recipients with MBL gene polymorphisms associated with low MBL levels. Thus,

MBL is a potential risk factor for graft and patient survival in SPKT. It is hypothesized that MBL contributes to the pathogenesis of inflammation-induced vascular damage both in the transplanted organs and in the recipient's native blood vessels (Berger et al. 2007). To address further the role of MBL deficiency, Verschuren et al. (2008) showed that high levels of serum MBL are associated with protection against urinary tract infections and, more specifically, against urosepsis after SPKT. These results indicate an important role for the lectin pathway of complement activation in antimicrobial defense in these transplant recipients (Verschuren et al. 2008).

42.5 MBL in Tumorigenesis

42.5.1 Polymorphisms in the Promoter

In paediatric oncology patients with febrile neutropenia, MBL levels are correlated to clinical and laboratory parameters. Structural exon-1 MBL2 mutations and the LX promoter polymorphism were related to deficient MBL levels. The capacity to increase MBL concentrations during febrile neutropenia was associated with MBL2 genotype. Infectious parameters did not differ between MBL-deficient and MBL-sufficient neutropenic children. However, most patients (61%) were severely neutropenic, compromising the opsonophagocytic effector function of MBL. MBL substitution might still be beneficial in patients with phagocytic activity (Frakking et al. 2003).

Five polymorphisms in the promoter and first exon of the MBL2 gene alter the expression and function of MBL in humans and are associated with inflammation-related disease susceptibility. These five polymorphisms create six well-characterized haplotypes that result in lower (i.e., LYB, LYC, HYD, and LXA) or higher (i.e., HYA and LYA) serum MBL concentrations. A statistically significant association was found between the X allele of the promoter Y/X polymorphism (which results in a lower serum MBL concentration) and improved lung cancer survival among white patients but not among African American patients. The functional Y/X polymorphism of the innate-immunity gene MBL2 and MBL2 haplotypes and diplotypes appear to be associated with lung cancer survival among white patients (Pine et al. 2007). A significantly higher incidence of MBL deficiency/insufficiency-associated genotypes was found among patients with malignant disease. Findings reflecting anti-tumorigenic activity of MBL protein suggest potential therapeutic application. However, it cannot be excluded that mbl-2 mutant alleles may be in linkage disequilibrium with an unidentified tumor susceptibility gene(s) (Swierzko et al. 2007).

The genetic variations in key genes of MBL2 could influence the risk for breast cancer. A preliminary analysis of SNPs in MBL2 in breast cancer [166 African-American (AA) patients vs. 180 controls and 127 Caucasian (CAU) patients vs. 137 controls] presents evidence that common genetic variants in the 3′-UTR of MBL2 might influence the risk for breast cancer in AA women, probably in interaction with the 5′ secretor haplotypes that are associated with high concentrations of MBL (Bernig et al. 2007).

42.5.2 MBL Binding with Tumor Cells

Changes in cell surface structures during oncogenic transformation appear to promote binding of MBL to cancer cells (Hakomori 2001) where the protein can mediate cytotoxic effects including MBL-dependent cell mediated cytotoxicity (Ma et al. 1999; Nakagawa et al. 2003). Experimental studies suggest that MBL (both wild-type and the mutant *B* allele) may possess anti-colorectal cancer tumor activity (Ma et al. 1999). The MBP/MBL binds specifically to oligosaccharides expressed on the surface of human colorectal carcinoma cells, SW1116. MBL binding occurs in colon adenocarcinoma cell lines (Colo205, Colo201 and DLD-1), but not in any of the leukemic cell lines. The binding of MBL to these cell lines was sugar-specific and calcium-dependent. The degree of MBL binding was correlated with the expression of Lewis A and Lewis B antigens on these cell lines (Muto et al. 1999). Intra-tumoral administration of the recombinant vaccinia virus carrying a *MBL2* gene significantly reduced tumor size as compared to controls, along with prolonged survival of mice (Ma et al. 1999). However, these results were not reflected in clinical trials. In fact, patients with colorectal cancer have increased activation of the lectin-complement pathway and increased levels of serum MBL (Ytting et al. 2004). In patients undergoing surgery for colorectal cancer, however, low preoperative levels of serum MBL have been linked to an increased risk of developing post-colectomy pneumonia (Ytting et al. 2005). Further studies may clarify the role of the lectin-complement pathway in colorectal cancer.

42.6 Complications Associated with Chemotherapy

42.6.1 Neutropenia

Secondary immunodeficiencies due to disease or treatment have provided interesting patient populations within which to study the role of MBL. One such group comprises those receiving chemotherapy for malignancy. In these patients,

chemotherapy induces neutropenia and increased risk of infection. Studies have thus attempted to analyze the correlation between MBL deficiency and infections in such patients. It is difficult to compare these studies since these studies include patients with a variety of underlying malignancies and variety of chemotherapy, different combinations of antimicrobial agents and various other factors (Klein and Kilpatrick 2004). However, there is clear evidence of the importance of MBL for protection in leukemia patients. MBL genotypes and MBL levels were correlated to the causes, frequency and duration of febrile neutropenic periods in children receiving chemotherapy (Neth et al. 2001). The majority of children were patients of acute lymphoblastic leukemia (ALL). Children with variant MBL alleles exhibited twice as many days of febrile neutropenia as children with wild type genotypes. Analysis by MBL quantification supported this as children with less than 1 μg MBL/mL had a higher number of days with febrile neutropenia. Peterslund et al. (2001) described infections defined as bacteremia, pneumonia or both in hematological malignancies of 54 adults treated with chemotherapy. All patients with the infections, except one, showed MBL levels below 0.5 μg/mL. Vekemans et al. (2005) conducted a prospective observational study focusing on assessment of MBL as a risk factor for infection during chemotherapy induced neutropenia in adult hematological cancer patients. They included 255 patients and determined MBL levels as well as MBL genotypes. A higher rate of severe infection was seen in MBL deficient patients. The impact was further increased when acute leukaemic patients were excluded. In a contrasting study, Bergmann et al. (2003) followed 80 adults undergoing therapy for acute myeloid leukaemia (AML), which involves intense highly myelosuppressive treatment. They found no effect of MBL deficiency on frequency, severity or duration of fever and suggested that the severe immunosuppression induced by the combination of the myeloid cancer and chemotherapy may obscure the normal effector functions of MBL, though, Kilpatrick et al. (2003) failed to see anything but a modest effect of MBL levels below 100 ng/mL in a retrospective study on 128 patients, most of whom were prepared for bone marrow transfer and more than half presented with AML. Results cast doubt on the potential value of MBL replacement therapy in this clinical context (Kilpatrick et al. 2003). A growing body of evidence indicates that genetic factors are involved in an increased risk of infection. MBL gene polymorphisms that cause low levels of MBL are associated with the occurrence of major infections in patients, mainly bearing hematological malignancies, after high-dose chemotherapy (HDT) rescued by autologous peripheral blood stem cell transplantation (auto-PBSCT). A retrospective examination of 113 patients treated with HDT and auto-PBSCT revealed that the low-producing genotypes, B/B and B/LXA, were associated with major bacterial infection. A nation-wide study, conducted to assess the allele frequency of the MBL coding mutation in a total of 2,623 healthy individuals in Japan, revealed the frequency of allele B as 0.2, almost the same in seven different areas of Japan. This common occurrence suggested that MBL deficiency may play an important role in the clinical settings of immune-suppression (Horiuchi et al. 2005). Studies by Aittoniemi et al. (1999) in patients with chronic lymphocytic leukemia did not observe any effect of MBL on infections. A possible association between MBL genotypes and severe infections in patients with multiple myeloma receiving moderate strength induction chemotherapy has been studied. From the MBP genotypes, identified in bone marrow biopsies, the study concluded that during induction chemotherapy in patients with multiple myeloma, a general protective effect of wild-type MBL2 against chemotherapy-related infections was not apparent. However, indications were there of a reduced occurrence of septicaemia in patients with wild-type compared with variant MBL2. Further studies in larger cohorts of patients are relevant (Molle et al. 2006). Thus, further studies are required to describe the patients particularly at risk when being MBL deficient.

42.6.2 Animal Studies

The MBL knock-out mice have made possible experimental investigations of the effect of MBL deficiency. The mouse has two genes encoding different MBL molecules (MBL-A and -C) compared to one in humans. Both MBLs in mice are able to bind to carbohydrate surfaces and activate the complement system. A slight difference in carbohydrate specificity has been reported for the two mouse MBLs. Mice with only MBL-A knocked-out were first produced, but only mice with both MBL-A and -C knocked out (MBL DKO) are suitable as animal model of human MBL deficiency. In 2004, Shi et al. demonstrated that MBL DKO sepsis model mice were highly susceptible to intravenous inoculation via tail vein with *Staphylococcus aureus*, all dying within 48 h, compared with 55% survival of MBL wild-type mice. Infusion of recombinant MBL reversed the phenotype. No difference was seen when the bacteria were injected intra-peritoneally. However, if the mice were treated with cyclophosphamide, simulating chemotherapy-induced neutropenia, before the intra peritoneal infection, the MBL DKO had more abscesses than the wild type. The MBL DKO mice were also more susceptible to challenge with herpes simplex virus type 2 (Gadjeva et al. 2004). In line with the suggested involvement of MBL in autoimmune diseases the MBL DKO mice were examined for autoimmune symptoms when 18-month-old (Stuart et al. 2005). No such signs were observed. On the other hand, the ability to clear apoptotic

cells was less efficient in the MBL knock-outs. It has been hypothesized that while MBL does not bind significantly to healthy tissue, changes due to abnormal conditions might reveal MBL ligands. Indeed, MBL is expressed by some tumor cell lines, and gene therapy with an MBL-vaccinia construct was found protective in nude mice transplanted with a human colorectal cancer cell line (Ma et al. 1999). In vitro studies have indicated binding of MBL to cells exposed to hypoxia-reoxygenation (simulating ischemia/reperfusion) and subsequently it was shown that infusion of a blocking anti-MBL antibody would protect against myocardial destruction following ischemia/reperfusion in a rat model (Jordan et al. 2001). Using MBL DKO mice Møller-Kristensen et al. (2005) found, in a model of kidney ischemia reperfusion (I/R) injury, that the MBL DKO were partially protected as evidenced by a better kidney function in these mice after ischemia/reperfusion. Increased deposition of the complement factor C3 was seen in wild type mice, and binding of MBL to sections of kidney could be inhibited with mannose. In agreement with this, deVries et al. (2004) found MBL-A and -C deposited in the kidneys after ischemia/reperfusion in MBL wild type mice. The recombinant vaccinia virus carrying human MBP gene possesses a potent growth-inhibiting activity against human colorectal carcinoma cells transplanted in KSN nude mice. The treatment resulted into a prolonged life span of tumor-bearing mice. Local production of MBP had a cytotoxic activity, which was proposed as MBP dependent cell-mediated cytotoxicity (MDCC). This study offers a model for the development of an effective and specific host defense factor for cancer gene therapy (Ma et al. 1999; Thiel et al. 2006).

42.7 MBL: A Reconstitution Therapy

Since genetically determined MBL deficiency is very common and can be associated with increased susceptibility to a variety of infections, the potential benefits of MBL reconstitution therapy need to be evaluated. In a phase I trial on 20 MBL-deficient healthy adult volunteers receiving a total of 18 mg of MBL in three 6 mg doses given (i.v.), once a week for a period of 3 weeks did not show adverse clinical changes or any sign of infusion-associated complement activation. Study suggested that infusion of purified MBL as prepared by Statens Serum Institut (SSI) is safe. However, adults have to be given at least 6 mg twice or thrice weekly for maintaining protective MBL levels assumed to be about 1,000 ng/mL (Valdimarsson et al. 2004). Considerations of MBL genotyping and association with infection opens the possibility of producing clinical grade recombinant MBL that resulted to establishing a company having this aim (Jensenius et al. 2003). The treatment of chronic disorders may possibly also be considered on the longer term. The invention led to use of at least MBL oligomer comprising at least one MBL subunit, for the manufacture of a medicament for prophylaxis and/or treatment of infection (Thiel and Jensenius 2007).

Pulmonary Collectins in Diagnosis and Prevention of Lung Diseases

43

Anita Gupta

43.1 Pulmonary Surfactant

Pulmonary surfactant is a complex mixture of lipids and proteins, and is synthesized and secreted by alveolar type II epithelial cells and bronchiolar Clara cells. It acts to keep alveoli from collapsing during the expiratory phase of the respiratory cycle. After its secretion, lung surfactant forms a lattice structure on the alveolar surface, known as tubular myelin. Surfactant proteins (SP)-A, B, C and D make up to 10% of the total surfactant. SP-B and SPC are relatively small hydrophobic proteins, and are involved in the reduction of surface-tension at the air-liquid interface. SP-A and SP-D, on the other hand, are large oligomeric, hydrophilic proteins that belong to the collagenous Ca^{2+}-dependent C-type lectin family (known as "Collectins"), and play an important role in host defense and in the recycling and transport of lung surfactant (Awasthi 2010) (Fig. 43.1). In particular, there is increasing evidence that surfactant-associated proteins A and -D (SP-A and SP-D, respectively) contribute to the host defense against inhaled microorganisms (see Chaps. 24 and 25). Based on their ability to recognize pathogens and to regulate the host defense, SP-A and SP-D have been recently categorized as "Secretory Pathogen Recognition Receptors". While SP-A and SP-D were first identified in the lung, the expression of these proteins has also been observed at other mucosal surfaces, such as lacrimal glands, gastrointestinal mucosa, genitourinary epithelium and periodontal surfaces. SP-A is the most prominent among four proteins in the pulmonary surfactant-system. The expression of both SP-A and SP-D is complexly regulated on the transcriptional and the chromosomal level. SP-A is a major player in the pulmonary cytokine-network and has been described to act in the pulmonary host defense. This chapter gives an overview on the understanding of role of SP-A and SP-D in for human pulmonary disorders and points out the importance for pathology-orientated research to further elucidate the role of these molecules in adult lung diseases. As an outlook, it will become an issue of pulmonary pathology which might provide promising perspectives for applications in research, diagnosis and therapy (Awasthi 2010).

43.2 SP-A and SP-D in Interstitial Lung Disease

SP-A and SP-D appear in the circulation in specific lung diseases. Interstitial lung disease (ILD), also known as diffuse parenchymal lung disease (DPLD), refers to a group of lung diseases affecting the interstitium of lung: alveolar epithelium, pulmonary capillary endothelium, basement membrane, perivascular and perilymphatic tissues. The term ILD is used to distinguish these diseases from obstructive airways diseases. Most types of ILD involve fibrosis, but this is not essential; indeed fibrosis is often a later feature. The phrase "pulmonary fibrosis" is no longer considered a synonym, but the term is still used to denote ILD involving fibrosis. The term is commonly combined with idiopathic in "idiopathic pulmonary fibrosis", denoting fibrotic ILD that cannot be ascribed to a distinct primary cause.

43.2.1 Pneumonitis

Chronic hypersensitivity pneumonitis (HP) eventually ensues to extensive lung fibrosis when exposure to causative antigen continues. Klebs von den Lungen (KL)-6, a mucin-like glycoprotein and SP-D are elevated in most cases. Correct diagnosis in the early stage is crucial, since chronic summer-type HP can result in a fatal outcome after continuous exposure to the causative antigen (Inase et al. 2007). In pulmonary tissues of collagen vascular disease-associated interstitial pneumonia (CVD-IP) and hypersensitivity pneumonitis (HP), SP-D can be a marker for maturity of regenerating epithelial cells. SP-A along with KL-6 is detected in intimate relationship to the stage of regeneration

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_43,

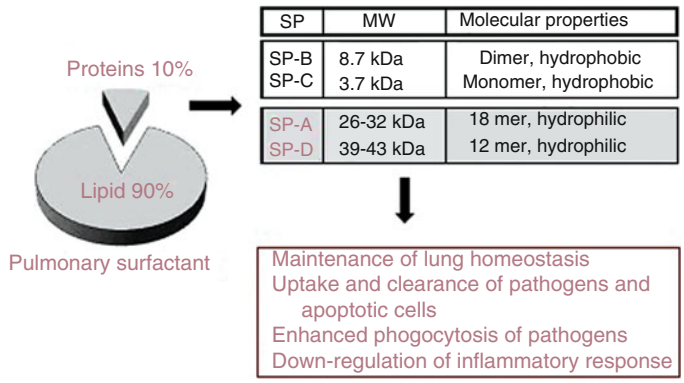

Fig. 43.1 Presence of surfactant proteins (SP) in lung surfactant, their properties and major functions of SP-A and SP-D

of alveolar epithelial cells and expressed before SP-D (Ohtsuki et al. 2007). Radiation pneumonitis (RP) is most common complication of radiotherapy for thoracic tumors. Both SP-A and SP-D concentrations in sera from patients with RP were significantly higher than those from patients without RP. Serum SP-A and SP-D may be of diagnostic value for detection of RP, even when radiographic change is faint (Takahashi et al. 2001). Despite the rise of SP-D and KL-6 in serum in adult patients with various types of interstitial pneumonia (IP) and collagen diseases with interstitial pneumonia, KL-6 may be superior in sensitivity of IP, where as SP-D may be more specific for IP than KL-6. Early decrease of SP-D contrasts with the transient increase of KL-6 levels after prednisolone pulse therapy (Arai et al. 2001). High serum KL-6 value is an indicator of ILD of Wilson-Mikity syndrome and better than SP-D and LDH levels (Takami et al. 2003). Thus serum SP-A and SP-D monitoring along with KL-6 is useful indicator for estimating RP (Matsuno et al. 2006).

43.2.2 Interstitial Pneumonia (IP)

SP-A and SP-D in BAL as Indicator of Pneumonia in Children

SP-A and SP-D in serum significantly increase in patients with pulmonary alveolar proteinosis (PAP), idiopathic pulmonary fibrosis (IPF) and interstitial pneumonia with collagen vascular diseases (IPCD) (Kuroki et al. 1998; Takahashi et al. 2006b). The concentrations of SP-A and SP-D in BAL fluids from patients with IPF and IPCD are rather lower than those in healthy controls; and the SP-A/phospholipid ratio may be a useful marker of survival prediction. SP-D-deficient patients have more frequently pneumonias and their long-term outcome is worse than those with detectable SP-D. Among children with recurrent bronchitis and SP-D detectable in bronchoalveolar lavage (BAL), patients with allergic asthma had threefold levels of SP-D compared with controls. In contrast, SP-D deficiency due to consumption or failure to up-regulate SP-D may be linked to pulmonary morbidity in children (Griese et al. 2008).

SP-A Levels can Differentiate Usual Interstitial Pneumonia with Non-Specific Interstitial Pneumonia (NSIP)

There is a need to use serum markers for differentiating usual interstitial pneumonia (UIP) from other ILD. Serum levels of SP-A and SP-D in patients with UIP and nonspecific interstitial pneumonia (NSIP) are significantly higher than in healthy volunteers. In particular, serum SP-A levels in patients with UIP are significantly higher than in patients with NSIP, where as SP-D in BAL fluid in UIP patients were significantly lower than in patients with NSIP. Thus, serum SP-A level seems useful marker to differentiate UIP from NSIP (Ishii et al. 2003).

Abnormal tracheal aspirate surfactant phospholipids and SP-A are noted in children with bacterial pneumonia, viral pneumonitis, and ARDS, but not in children on cardiopulmonary bypass (Baughman et al. 1993; LeVine et al. 1996). SP-A in pneumonia group is significantly reduced and the reduction was better indicator in the Gm^{+}-pneumonia group than in Gm^{-}-pneumonia group patients (Baughman et al. 1993). Fulminant early-onset neonatal pneumonia is associated with ascending intrauterine infection (IUI) and alveolar M showed significantly less nitric oxide synthase 2 (NOS2) isoform than in the controls. In the airway samples, the infants with fulminant pneumonia after birth had low intracellular NOS2 and significantly low IL-1β and SP-A than noninfected IUI infants (Aikio et al. 2000).

Foster et al. (2002) suggested that signaling of EGF axis and differential regulation of SPs persist during postnatal lung development, and SP-A and SP-D may modulate post-pneumonectomy (PNX) lung growth in dogs. SP-D in patients, hospitalized for community-acquired pneumonia of suspected bacterial origin, indicates significant changes during pulmonary infection (Daimon et al. 2005; Leth-Larsen et al. 2003). The SA-A and SP-D in sera are useful

for identification of the clinical condition of horses with bacterial pneumonia (Hobo et al. 2007).

43.2.3 ILD Due to Inhaled Substances

Cigarette smoke may alter component and function of pulmonary surfactant. Alterations in serum levels of SP-A may reflect smoking habits since serum SP-A was higher in active smokers than in nonsmokers (Nomori et al. 1998). However, SP-A is not a sensitive discriminating factor to separate smokers from nonsmokers. The contents of SP-A and SP-D in BAL fluids were significantly decreased in smokers compared to those in nonsmokers, although there was no significant difference of total phospholipid content between two groups (Honda et al. 1996). SP-A may decrease due to the cumulative effects of long-term smoking and development of emphysema, while SP-D decreases due to long-term smoking (Betsuyaku et al. 2004; Shijubo et al. 1998). Emphysema can be induced in mice by chronic cigarette smoke exposure with increase of SP-D in emphysema lungs. While accumulation of foamy alveolar macrophages may play a key role in the development of smoking-induced emphysema, increased SP-D may play a protective role in the development of smoking-induced emphysema, in part by preventing alveolar cell death (Hirama et al. 2007).

Although effects of maternal smoking on fetal growth and viability are overwhelmingly negative, there is a paradoxical enhancement of lung maturation as evidenced, in part, by a lower incidence of RDS in infants of smoking mothers. Epidemiologic and experimental evidence further support the view that a tobacco smoke constituent, possibly nicotine, affects the development of the lung in utero. The murine embryonic lungs explanted at 11 days gestation showed a 32% increase in branching after 4 days in culture in presence of 1 μM nicotine and 7–15-fold increases in mRNAs encoding SP-A and SP-C after 11 days. The nicotine-induced stimulation of surfactant gene expression could, in part, account for the effect of maternal smoking on the incidence of RDS (Wuenschell et al. 1998).

Intratracheal administration of crystalline silica to rats elicits a marked increase in alveolar accumulation of surfactant lipids and SP-A. The extracellular accumulation of SP-D is markedly increased in silica-induced lipoproteinosis, and that SP-D is associated with amorphous components identified by electron microscopy. SP-D may be useful biomarkers for early diagnosis and serum SP-D concentration may associate with the pathogenesis of silicosis (Barbaro et al. 2002; Wang et al. 2007b). Alcohol consumption at high levels during pregnancy is associated with immuno-modulation and premature birth. Chronic maternal ethanol consumption during the third trimester of pregnancy alters SP-A gene expression in fetal lung. These alterations may underlie increased susceptibility of preterm infants, exposed to ethanol in utero, to RSV and other microbial agents (Lazic et al. 2007). The exposure to moderate and high occupational levels of Diesel exhaust (DE) causes an increase in lung injury and inflammation, and a decrease in host defense molecules, which could result in increased severity of infectious and allergic lung disease. Several inflammatory and immune cytokines are upregulated at various time points and concentrations, in contrast to SP-A and SP-D which were significantly decreased at protein level. (Gowdy et al. 2008).

43.2.4 Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) is a progressive disease of lung characterized by an inflammatory infiltrate, alveolar type II cell hypertrophy and hyperplasia, and ultimate parenchymal scarring. The phospholipid composition of the surface-active material recovered by BAL is abnormal in this disease. The content of SP-A in lavage was reduced, even when normalized for the total amount of surface-active material (SP-A/total phospholipids (PL)) recovered. The reduction in SP-A was not specific to IPF but also occurred in other interstitial lung diseases. Despite this, SP-A/PL in BAL is a biochemical marker that predicts survival in patients with IPF (McCormack et al. 1995; Phelps et al. 2004).

The serum SP-A and SP-D levels are significantly elevated in patients with IPF and systemic sclerosis compared to sarcoidosis, beryllium disease and normal controls, and correlated with radiographic abnormalities in patients with IPF. Dohmoto et al. (2000) hypothesized that regenerated or premature bronchoepithelial cells may circulate in the blood in patients with IPF. RT-PCR for cytokeratin 19 (CK19) and pulmonary SP-A in peripheral blood in patients with IPF and pulmonary fibrosis (PF) associated with collagen vascular disorders suggests that there were some circulating bronchoepithelial cells expressing mRNA for SP-A in peripheral blood of patients associated with collagen vascular disorders. Thus, both serum SP-A and SP-D levels are highly predictive of survival in patients with IPF (Greene et al. 2002; Takahashi et al. 2006b) and the measurement of SP-D in sera can provide an easily identifiable and useful clinical marker for the diagnosis of IPF, IPCD, and PAP, and can predict the disease activity of IPF and IPCD and the disease severity of PAP (Honda et al. 1995). However, KL-6 is the best serum marker for ILD (Ohnishi et al. 2002). Serum KL-6 and SP-D were also prognostic markers in acute exacerbation of IPF after treatment with Sivelestat (Endo et al. 2006; Nakamura et al. 2007). High levels of SP-D in BAL fluids are associated in patients with PAP, but not with IPF and IPCD.

Selman et al. (2003) examined associations between IPF and genetic polymorphic variants of SP-A1, SP-A2, SP-B, SP-C, and SP-D. One SP-A1 ($6A^4$) allele and SNPs that characterize the $6A^4$ allele and one SP-B (B1580_C) were found with higher in nonsmoker and smoker IPF subgroups, respectively, compared with healthy controls. To explore whether a tryptophan (in $6A^4$) or an arginine (in other SP-A1 alleles and in all SP-A2 alleles) at amino acid 219 alters protein behavior, two truncated proteins that varied only at amino acid 219 were oxidized by exposure to ozone. Differences in the absorption spectra (310–350 nm) between the two truncated rSP-A proteins, before and after protein oxidation, suggested allele-specific aggregation attributable to amino acid 2143. The SP-B SNP B1580_C, to be a risk factor for IPF smokers, was also shown to be a risk factor for other pulmonary diseases. The SP-C and SP-D SNPs and SP-B-linked microsatellite markers did not associate with IPF. These findings indicated that surfactant protein variants may serve as markers to identify subgroups of patients at risk. The observed alleles of SP-A and SP-D in association with various diseases are summarized in Table 43.1. Different alleles of these genes seem to predispose the individuals to various diseases. A logical explanation seems to be that different SNPs lead to different alterations in function or expression. However, common SNPs predispose Caucasians to RDS and Mexicans to TB. Similarly, common SNPs predispose the Indian population to ABPA and TB. Furthermore, Met11 SP-D allele is predisposing Mexicans to TB and Finns to RSV infection. It is also interesting to note that some of the alleles of SP-A interact with other alleles of SP-A and SP-B and thus increase the susceptibility of subjects to a disease (Kishore et al. 2005).

43.2.5 Cystic Fibrosis

Cystic fibrosis (CF) is an inherited disorder of CFTR gene, a chloride ion channel. The lack of this channel causes reduced water content of secretions. This affects the mucus secreted as part of the lung's defence and creates sticky, viscous mucus. In patients with CF, neutrophils are recruited in excess to the airways yet pathogens are not cleared and the patients suffer from chronic infections. In CF, the disease-causing gene has been clearly identified as the CF transmembrane conductance regulator gene, but genetic variants of the MBP and SP-A have been associated with disease severity in CF.

Table 43.1 Broad range of pathogens interacting with surfactant protein (SP)-A and SP-D

Type	Name of pathogen	Surfactant protein	Reference(s)
Bacteria	*E. coli*	SP-D	Kuan et al. (1992)
	Salmonela minnesota	SP-D	Kuan et al. (1992)
	H. pylori	SP-D	Appelmelk et al. (2005)
	Klebsiella pneumoniae	SP-D	Keisari et al. (2001), Ofek et al. (2001)
	Mycoplasma pneumoniae and *Histoplasma capsulatum*	SP-A and SP-D	Ernst (1998), Chiba et al. (2002), Gaynor et al. (1995)
	Haemophilus influenzae	Minimal effects of SP-D	Tino and Wright (1996), Restrepo et al. (1999)
	Pseudomonas aeruginosa *Stenotrophomonas maltophilia*	SP-D, not SP-A	Malloy et al. (2005), Giannoni et al. (2006), Bufler et al. (2004)
	Mycobacterium tuberculosis	Virulent and attenuated M. tuberculosis strains bind best	Ferguson et al. (1999, 2002), Hall-Stoodley et al. (2006)
	Mycobacterium avium	SP-A and SP-D	Kudo et al. (2004)
	Group B streptococcus' (*Streptococcus agalactiae*) and *S. pneumoniae*	SP-A and SP-D	Jounblat et al. (2004), Kuronuma et al. (2004)
	B. bronchiseptica (LPS); *Ruminant bronchopneumonia*	SP-D	Schaeffer et al. (2004), Grubor et al. (2004)
	Alloiococcus otitidis	SP-A	Konishi et al. (2006)
Yeast and fungi	*Cryptococcus neoformans*	SP-A and SP-D	Schelenz et al. (1995), Walenkamp et al. (1999), van de Wetering et al. (2004)
	Aspergillus fumigatus	SP-A and SP-D	Allen et al. (1999), Madan et al. (1997a, b)
	Coccidioides posadasii	SP-A and SP-D	Awasthi et al. (2004), Awasthi (2010)
	Candida albicans	SP-D	Van Rozendaal et al. (2000)
	Pneumocystis carinii	SP-D	O'Riordan et al. (1995), Vuk-Pavlovic et al. (2001), Atochina et al. (2004a), Yong et al. (2003)
Viruses	Influenza A virus	SP-A and SP-D	Malhotra et al. (1994), Hartshorn et al. (1994, 1997), Levine et al. (2001), Tecle et al. (2007b)
	HIV	SP-D binds HIV – gp120	Meschi et al. (2005)
	Respiratory syncytial virus	SP-A and SP-D	Ghildyal et al. (1999), Hickling et al. (1999), Griese (2002)

Allele associations and allele interaction of surfactant protein genes in relation to RDS have been discussed (Floros and Fan 2001). Studies have shown a deficiency of SP-A in airway fluids from patients with CF and other inflammatory pulmonary conditions. Findings suggest that the neutrophil serine proteases cathepsin G and/or elastase and/or proteinase-3 may contribute to degradation of SP-A and SP-D, thereby diminishing innate pulmonary antimicrobial defence (Rubio et al. 2004; von Bredow et al. 2001, 2003).

The dramatic decrease of SP-A and SP-D in the presence of normal surfactant phospholipid may be a mechanism underlying the relative ineffectiveness of cellular inflammatory response in killing invading bacteria in lungs of patients with CF. In bronchoalveolar lavage fluids (BALFs), although SP-A levels tend to decline in CF patients compared with non-CF, and the decline was only significant in presence of bacterial infection. Among CF patients, SP-A concentrations in BALF were inversely related to inflammation and age (Hull et al. 1997; Noah et al. 2003). Reports suggest that decreasing protease activity and increasing collectin activity may be beneficial in early CF (Alexis et al. 2006; Baker et al. 1999).

However, both, SP-D and TNF-α, are significantly increased in CF patients compared with patients of allergic fungal rhinosinusitis (AFRS), suggesting activation of both innate immunity and Th1-mediated inflammation and potential correlation between SPs and downstream adaptive immune responses (Skinner et al. 2007). Rat SP-D is highly resistant to degradation by a wide range of proteolytic enzymes. Patients with CF and chronic rhinosinusitis (CRS) with nasal polyposis demonstrated elevated SP-A1, -A2, and -D. While in patients with AFS, SP-A1, SP-A2, and SP-D, were not significantly different, these proteins are upregulated in various forms of CRS, particularly in CF-CRS (Woodworth et al. 2007).

43.2.6 Familial Interstitial Lung Disease

Amin et al. (2001) studied the development of chronic lung injury in a familial form of ILD. An 11-year-old girl, her sister, and their mother who were diagnosed with chronic ILD were negative for SP-C and decreased levels of SP-A and SP-B in BALF. Lung biopsy from both children demonstrated a marked decrease of pro-SP-C in the alveolar epithelial cells but strong staining for pro-SP-B, SP-B, SP-A, and SP-D. The apparent absence of SP-C and a decrease in the levels of SP-A and SP-B were related to familial ILD. Several linkage and association studies have been done using SPs genes as markers to locate pulmonary disease susceptibility genes, but few have studied markers systematically in different ethnic groups.

43.3 Connective Tissue Disorders

43.3.1 Systemic Sclerosis

Significant progress is being made in terms of understanding the pathogenesis and various options for therapy of systemic sclerosis patients whose disease course is complicated by ILD. The significance of serum SP-A, SP-D and KL-6 for diagnosis and treatment of ILD in connective tissue disorders has been evaluated by different workers. Serum KL-6 and SP-D levels are more specific and useful markers for diagnosis and evaluation of ILD compared with serum LDH in connective tissue disorders (Ogawa et al. 2003; Suematsu et al. 2003). Characteristics or disease activity of early ILD has been evaluated in subjects. In abnormal group, curvilinear subpleural lines or thickened interlobular and intralobular lines were observed more frequently in lower lung fields and SP-A and SP-D were higher in true abnormalities group than in control group. True parenchymal abnormalities in posterior subpleural aspect of lung may indicate early ILD activity (Al-Salmi et al. 2005; Kashiwabara 2006). Since higher levels of SP-A and SP-D are associated with more severe lung function impairment at presentation, and better recovery over time, Janssen et al. (2005) suggested that SP-A, SP-D and KL-6 are especial markers of disease activity. Nevertheless, serum pulmonary and activation-regulated chemokine (PARC) levels may be more useful marker for active PF in systemic sclerosis (SSc) (Kodera et al. 2005) since elevated PARC values correlated more sensitively reflecting the PF activity than serum KL-6 or SP-D levels.

In lung fibrosis in patients with SSc and inflammatory myopathies, KL-6, von Willebrandt factor (vWF), soluble E-selectin (sES), SP-D are good surrogate factors of PF but cannot replace conventional diagnostic procedures. However, these markers are suitable for the assessment of progression and severity of PF in systemic autoimmune disorders once the diagnosis is established (Kumánovics et al. 2008). Takahashi et al. (2006b) indicated that elevated levels of serum SP-A and SP-D reflect the presence of ILD and the combination of SP-D and X-ray contributes to reduce the risk of clinicians overlooking ILD complicated by SSc (Highland and Silver 2005; Yanaba et al. 2004).

Maeda et al. (2001) compared serum SP-D in collagen diseases such as systemic scleroderma (SSd), scleroderma spectrum disorders (SSD), systemic lupus erythematodes (SLE), Sjogren syndrome (Sjs), dermatomyositis (DM), rheumatoid arthritis (RA), and dermatitis (DE) as a control. Patients with SSc possess higher levels of SP-D than those with other collagen diseases and dermatitis, which may correspond to severity of pulmonary fibrosis (Maeda et al. 2001). The basic and clinical studies of SSc patients with ILD are yielding promising data that may be translated in to

more effective diagnostic and therapeutic strategies Although the SP-D level in sera of patients with polymyositis/dermatomyositis (PM/DM) is significantly elevated, the serum SP-D in patients with ILD was still higher than those without ILD, suggesting that serum SP-D level is a useful marker for ILD in patients with PM/DM (Ihn et al. 2002). However, there is a need to investigate whether another connective tissue disease has developed when laboratory findings cannot be explained by usual clinical course of an existing connective tissue disease (Ishiguro et al. 2007).

43.3.2 Sarcoidosis

Sarcoidosis also called sarcoid, Besnier-Boeck disease or Besnier-Boeck-Schaumann disease, is a disease in which abnormal collections of chronic inflammatory cells form as nodules in multiple organs. KL-6, SP-A and SP-D levels in BALF were increased in pulmonary sarcoidosis. Since these markers are specifically derived from epithelial cells, it is considered that KL-6 and SP-D levels are reflecting damage or release of these markers from epithelial cells due to the inflammatory response. Among serum Clara cell 16 (CC16), KL-6, and SP-D as markers of ILD, and their ability to reflect pulmonary disease severity and prognosis in sarcoidosis, KL-6 is the best marker in differentiating patients from healthy controls (Günther et al. 1999; Hamm et al. 1994; Janssen et al. 2003; Kunitake et al. 2001). The median amounts of SP-A in BAL fluid in control subjects was 2.82 mg/L (range, 0.92–5.17 mg/L). In comparison to control, SP-A in patients with asthma had a lower value of SP-A, which remained unchanged in patients with pulmonary sarcoidosis (van de Graaf et al. 1992). In contrast, SP-A levels in BAL fluids from patients with sarcoidosis were markedly higher than in control subjects and it was comparable with patients of hypersensitivity pneumonitis (HP). In both conditions, SP-A^+ alveolar macrophages were increased (Günther et al. 1999; Hamm et al. 1994).

The serum levels of SP-A in patients with IPF (205 ± 23 ng/mL) and PAP (285 ± 23 ng/mL) were significantly higher than those in healthy controls (45 ± 3 ng/mL). In patients of sarcoidosis, pneumonia, and tuberculosis SP-A values were 52 ± 27 ng/mL, 65 ± 11 ng/mL, and 49 ± 23 ng/mL, respectively. The SP-A appears to circulate in the bloodstream as a complex with Ig in IPF and in PAP (Kuroki et al. 1993).

43.4 Pulmonary Alveolar Proteinosis

A diffuse lung process of unknown etiology is characterized by the presence of alveolar spaces filled with amorphous eosinophilic (but sometimes basophilic) PAS-positive material of predominantly phospholipid nature in alveolar lumina. It is generally regarded as type of response to alveolar injury and results from accumulation of surfactant apoprotein through either: increased secretion by granular pneumocytes, or abnormal uptake and handling by alveolar macrophages. The prominent increase of SP-A and SP-D in BAL fluids and sputum is diagnostic for pulmonary alveolar proteinosis (PAP) (Kuroki et al. 1998; Brasch and Müller 2004; Takahashi et al. 2006a). There are reports about polymorphisms and mutations on the surfactant protein genes, especially SP-B that may be associated with congenital alveolar proteinosis.

43.4.1 Idiopathic Pulmonary Alveolar Proteinosis

SP-A in BALF of PAPs patients is significantly increased in comparison to normal volunteers and hence can be used as a diagnostic tool in the clinical laboratory (Brasch et al. 2004; Honda et al. 1996). PAP is a rare lung disorder and can be caused by inactivation of either granulocyte-macrophage colony-stimulating factor (GM-CSF) or GM receptor common β-chain (βc) genes in mice [$GM^{-/-}$, $\beta c^{-/-}$], demonstrating a critical role of GM-CSF signaling in surfactant homeostasis. Studies demonstrate abnormal accumulation of SP-A and SP-D in air spaces of patients with PAP (Crouch et al. 1993) and the precursors of SP-B, SP-B and SP-C. Although lung histology in $\beta c^{-/-}$ and $GM^{-/-}$ mice was indistinguishable, distinct differences were observed in surfactant phospholipid and surfactant protein concentrations in lungs of $\beta c^{-/-}$ and $GM^{-/-}$ mice. The defect in clearance was significantly more severe in $GM^{-/-}$ than in $\beta c^{-/-}$ mice. GM-CSF concentrations, increased in BALF but not in serum of $\beta c^{-/-}$ mice, were consistent with a pulmonary response to the lack of GM-CSF signaling. The observed differences in surfactant metabolism suggest the presence of alternative clearance mechanisms regulating surfactant homeostasis in mice and may provide a molecular basis for the range in severity of PAP symptoms (Reed et al. 2000). In a young patient with idiopathic PAP, the enhanced serum anti-GM-CSF antibody level demonstrated a striking difference in the distribution of SP-A and SP-D in intra-alveolar substance with idiopathic PAP (Ohtsuki et al. 2008; Kobayashi et al. 2008b).

Evidence suggests that not only an impairment of surfactant clearance by alveolar macrophages, but also an abnormal secretion of transport vesicles containing precursors of SP-B (but not SP-C) and an insufficient palmitoylation of SP-C, which may lead to the formation of di- and oligomeric SP-C forms, play a role in the pathogenesis of pulmonary alveolar proteinosis.

43.4.2 Structural Changes in SPs in PAP

The primary structures of human pulmonary SPs isolated from lung lavage of patients with alveolar proteinosis demonstrate significant differences from lung surfactant proteins isolated from lungs of healthy individuals. In contrast to SP-A from normal lungs, PAP-SP-A was shown to contain large amounts of non-reducable cross-linked β chains, where as proteinosis SP-B showed a significantly increased molecular weight by approx. 500 Da for the unreduced protein dimer. In contrast, SP-C from proteinosis patients was modified by (1) partial or even complete removal of palmitate residues and (2) additional N-terminal proteolytic degradation (Voss et al. 1992).

Pathophysiological structural modifications in SP-A seemed to occur in the alveolar space, and may lead to a reduced surfactant function (Voss et al. 1992). Multimerized form of SP-A oligomer (alveolar proteinosis protein-I, APP-I) has been detected besides the normal-sized octadecamer (APP-II) in SP-As isolated from PAP patients. Analysis of APP revealed that it was composed of two proteins. The M_r of APP-I and APP-II were 1.65 MDa and 0.93 MDa, respectively. APP-I and APP-II showed almost identical amino acid compositions. Electron microscopy revealed that APP-II was a hexameric particle, presumably consisting mainly of octadecamers whose diameter was approximately 30 nm. In contrast, APP-I was made of multimerized larger aggregates whose diameter appeared to be about 70–90 nm. Both APP-I and APP-II retained the abilities to bind DPPC. Reconstitution experiments with porcine SP-B and phospholipids revealed that multilamellated membranes in structures formed from APP-I consisted of several layers of doubled unit membranes. APP-I failed to form tubular myelin structures. In contrast, APP-II formed well-formed lattice structures seen in tubular myelin The multimerized form of human SP-A oligomer exhibits the reduced capacity to regulate phospholipid secretion from type II cells, and lower affinity to bind to type II cells. It is to be reminded that the integrity of a flower-bouquet-like octadecameric structure of SP-A oligomer is important for the expression of full activity of this protein, indicating the importance of the oligomeric structure of mammalian lectins with collagenous domains. Thus there exists an abnormal multimerized form of SP-A oligomer in the alveoli of patients with PAP that exhibits abnormal function on phospholipid membrane organization (Hattori et al. 1996a, b).

In alveolar proteinosis, cholesterol/disaturated phospholipid ratios (CHOL/DSP) are invariably elevated, whereas the SP-A/DSP and SP-B/DSP ratios are generally elevated. Because the SP-B/SP-A ratio was normal in all cases, it was suggested that structural changes to the proteins occurred secondarily and that caution must be used in comparing functional data derived using SP-A obtained from patients with PAP (Doyle et al. 1998). The major part of SP-A from a proteinosis patient consisted of SP-A2 gene product while SP-A1 gene product was present in only a small amount. The disulfide bridges in the carbohydrate recognition domain were identified to be in the 1–4, 2–3 pattern common for collectins. Interchain disulfide bridges were discovered between two Cys-48 residues and cysteine residues in the N-terminal region. However, the exact disulfide bridge connections within the bouquet-like ultrastructure could not be established (Berg et al. 2000).

43.5 Respiratory-Distress Syndrome and Acute Lung Injury

43.5.1 ARDS and Acute Lung Injury

Acute respiratory distress syndrome (ARDS), also known as respiratory distress syndrome (RDS) or adult respiratory distress syndrome (in contrast with IRDS) is a serious reaction to various forms of injuries to lung. ARDS is caused by a variety of direct and indirect issues. It is characterized by inflammation of lung parenchyma leading to impaired gas exchange with concomitant systemic release of inflammatory mediators causing inflammation, hypoxemia and frequently resulting in multiple organ failure. A less severe form is called acute lung injury (ALI). Clinical and biochemical evidences suggest that the etiology of RDS is multifactorial with a significant genetic component. There are reports about polymorphisms and mutations on the surfactant protein genes, especially surfactant proteins-B that may be associated with RDS, ARDS, and congenital alveolar proteinosis. The measurement of SP-A and SP-D in amniotic fluids and tracheal aspirates reflects lung maturity and the production level of the lung surfactant in infants with RDS. The SP-A concentrations in BAL fluids are significantly reduced in patients with ARDS and also in patients at risk to develop ARDS (Kuroki et al. 1998; Takahashi et al. 2006a). Patients with low concentrations of SP-A and SP-B in the BAL are at risk for ARDS before onset of clinically defined lung injury, though the SP-D concentrations remain in normal range. Thus, SP abnormalities occur before and after the onset of ARDS, and the responses of SP-A, SP-B, and SP-D differ in important ways. However, plasma SP-D is a valuable biomarker in ALI/ARDS and SP-A increases during the early phase of ARDS, including some molecular alteration followed by decrease during the late phase (Endo et al. 2002; Kuroki et al. 1998; Takahashi et al. 2006b; Zhu et al. 2001).

Elevated level of SP-A has also been reported in the sera of patients with acute cardiogenic pulmonary edema (APE) and in patients with ARDS relative to healthy subjects and ventilated patients with no cardio-respiratory disease. Serum SP-A was inversely related to blood oxygenation and to

static respiratory system compliance both at the time of patient's entry into the study and during the course of admission. Since SP-B is synthesized as a precursor smaller than alveolar SP-A, Doyle et al. (1995, 1997) suggested that immunoreactive SP-B that enters more readily than SP-A, is cleared acutely, and provides a better indicator of lung trauma (Shimura et al. 1996).

Prematurely born infants can develop the neonatal RDS because of a deficiency of pulmonary surfactant. At autopsy RDS lungs lacked tubular myelin and had decreased immunoreactivity for antisera to SP-A, an important component of tubular myelin. Therefore, a role for SP-A in the conversion of lamellar bodies to tubular myelin and in the pathogenesis of RDS was proposed. It was postulated that if SP-A is indeed necessary for the conversion of lamellar bodies to tubular myelin, in RDS either there is a deficiency of adequate amounts of functional SP-A, or some other important component of surfactant is missing (deMello et al. 1993). Mechanical ventilation is the main modality of treatment of ARDS. On mechanical ventilation, there is a progressive increase in SP-A levels in patients with ARDS, and may be one of the contributors for recovery in ARDS. A significant increase within the first 4 days was found in those infants who survived, whereas no such change was found in those infants who died (Balamugesh et al. 2003; Stevens et al. 1992). Intratracheal aerosolization of LPS in rats produces typical features of human ARDS. The SP-D binds inhaled LPS-endotoxin in vivo, which may help to protect the lung from endotoxin-induced disease (van Rozendaal et al. 1999). The SP-D was reduced in lung of young rats following ALI at early stage and early administration of Dex could reverse the SP-D content (Shu et al. 2007). SP-A in sera of cord blood from infants born at gestational ages <32 weeks with RDS was 15.1 ng/mL compared to without RDS (5.8 ng/mL) and significantly related to the non-RDS outcome (Cho et al. 2000). Shimoya et al. (2000) suggested that IL-6 elevation in fetuses with chorioamnionitis promotes fetal lung maturation by inducing SP-A synthesis, thereby decreasing the incidence of RDS in the preterm neonates.

Acute Lung Injury (ALI): Plasma SP-A, but not SP-D, was higher in patients with fewer days of unassisted ventilation and in patients with an absence of intact alveolar fluid clearance. In contrast, pulmonary edema fluid SP-D, but not SP-A, was lower in patients with worse oxygenation. Reduced pulmonary edema fluid SP-D and elevated plasma SP-A concentrations at the onset of ALI may be associated with more severe disease and worse clinical outcome and may serve as valuable biochemical markers of prognosis (Cheng et al. 2003). The BALF proteome analysis showed the presence of several isoforms of SP-A, in which an N-non-glycosylierte form and several proline hydroxylations were identified (Bai et al. 2007). In the plasma and edema fluid, protein profile of ALI patients showed multiple qualitative changes. Nearly all ALI patients also had protein spots that indicated truncation or other posttranslational modifications (Bowler et al. 2004).

43.5.2 Bronchopulmonary Dysplasia (BPD)

The pathophysiology of bronchopulmonary dysplasia (BPD) as an inflammatory disorder, secondary to neonatal RDS represents a major complication of prematurity. Maximum SP-A and anti-SP-A antibodies (SAS) immune complex values between 2 and 4 weeks after birth correlate with subsequent development of BPD independently and may be useful in analyzing the course and outcome of neonatal RDS, in particular the likelihood of subsequent development of BPD (Strayer et al. 1995). Weber et al. (2000) investigated an association of polymorphisms of SP-A1 and SP-A2 encoding genes and the risk of BPD in Caucasian preterm infants below 32 weeks of gestation matched for immaturity and year of birth. BPD was defined as oxygen dependency or need for mechanical ventilation at day 243. A significantly increased frequency of SP-A1 polymorphism $6A^6$ in infants was associated with BPD compared with controls. In addition to established risk factors for BPD, $6A^6$ polymorphism for SP-A1 gene is an independent co-factor.

BPD_28D (O2 dependency at 28 days of life) and BPD_36W (O2 dependency at 36 week post-menstrual age) are diseases of prematurely born infants exposed to mechanical ventilation and/or oxygen supplementation. Genetic variants of SP-A, B, C, and D and SP-B-linked microsatellite markers are risk factors in BPD. Significant associations were observed for alleles of SP-B and SP-B-linked microsatellite markers, and haplotypes of SP-A, SP-D, and SP-B. Unlike SP-A, SP-D does not contribute to lowering surface tension. SP-D-deficient mice have no respiratory abnormalities at birth, but it causes development of emphysema and predisposition to specific infections. No human infant or child with respiratory distress and mutation in the SP-D gene has been identified (Yurdakök 2004). Studies in larger sample size are warranted to confirm these observations and delineate genetic background of BPD subgroups (Pavlovic et al. 2006).

43.5.2.1 SP-A Deficiency in Primate Model of BPD with Infection

In a baboon model of hyperoxia-induced BPD and superimposed infection, animals constituting a group- pro re nata (PRN) were delivered by hysterotomy at 140 days gestational age and ventilated on clinically appropriate

oxygen for a 16-day experimental period and served as controls. Immunostaining with SP-A, SP-B, and SP-C antibodies showed variable staining patterns. The study demonstrated that a deficiency of SP-A mRNA expression persists in chronic lung injury and variable protein staining patterns are manifested depending upon the underlying pathology (Coalson et al. 1995; King et al. 1995).

Awasthi et al. (1999) measured SP-A and SP-D levels and their mRNAs in three groups of animals: (1) nonventilated premature baboon fetuses; (2) neonatal baboons delivered prematurely at 140 d gestation age (ga) and ventilated with PRN O_2; (3) animals of same age ventilated with 100% O_2 to induce chronic lung injury. In chronic lung injury, SP-A is significantly reduced in alveolar space. SP-D concentration in lavage was nearly equal to that in normal adults, but the total collectin pool in lavage was still significantly reduced. Because these collectins may bind and opsonize bacteria and viruses, decrements in their amounts may present additional risk to those premature infants who require prolonged periods of ventilatory support (Awasthi et al. 1999). Reduced SP-D expression in BAL fluid was associated with progression of bronchial dysplasia in heavy smokers. SP-D levels in BAL fluid may serve a potential biomarker to identify smokers who are at risk of early lung cancer (Sin et al. 2008b). Cheng et al. (2003) proved the hypothesis that reduced pulmonary edema fluid SP-D and elevated plasma SP-A concentrations at onset of ALI may be associated with more severe disease and worse clinical outcome and may serve as valuable biochemical markers of prognosis (Cheng et al. 2003).

43.6 Chronic Obstructive Pulmonary Disease (COPD)

43.6.1 COPD as a Group of Diseases

Obstructive lung disease is a category of respiratory disease characterized by airway obstruction. Chronic obstructive pulmonary disease (COPD), also known as chronic obstructive airways disease (COAD) or chronic airflow limitation (CAL) is a group of illnesses characterised by airflow limitation that is not fully reversible. The flow of air into and out of the lungs is impaired. The COPD is characterized by chronic inflammation. It is most likely the result of complex interactions of environmental and genetic factors. Term COPD includes the conditions of emphysema and chronic bronchitis although most patients with COPD have characteristics of both conditions to varying degrees. Asthma being a reversible obstruction of airways is often considered separately, but many COPD patients also have some degree of reversibility in their airways. The most common cause of COPD is cigarette smoking. COPD may also be caused by breathing in other particles and gases. Diagnosis of COPD is established through spirometry and chest X-ray although other pulmonary function tests can be helpful. Emphysema can only be seen on CT scan. COPD is generally irreversible although lung function can partially recover if the patient stops smoking. α1-antitrypsin deficiency is a rare genetic condition that results in COPD (particularly emphysema) due to lack of antitrypsin protein which protects fragile alveolar walls from protease enzymes released by inflammatory processes.

The prevalence of COPD is age-dependent, suggesting an intimate relationship between the pathogenesis of COPD and aging. Genetic polymorphism in SP-A is associated with the development of COPD in Chinese Hans. The genotypes of patients with COPD and healthy smoking subjects as controls for SP-A gene showed that in COPD group, the frequencies of +186 locus genotypes AA, AG and GG were 86.4%, 12.5% and 1.1%i respectively; compared to 66.7%, 27.6% and 5.7% in control group. The frequencies of polymorphic genotypes at +655 locus and +667 loci showed no significant difference between the COPD group and control group (Xie et al. 2005).

43.6.1.1 Serum SP-A in COPD and Its Relation to Smoking

SP-A occurs physiologically in small amounts in blood. Tobacco smoke induces increased alveolo-capillary leakage of SPs into blood and its level in blood may help in the assessment of lung injury caused by smoke. SP-A is occasionally elevated in non-ILD pulmonary patients. Serum SP-A increased in current smokers than in never- or ex-smokers and in COPD and pulmonary thromboembolism than in other diseases. Serum SP-D and KL-6 were unaffected by smoking. Therefore, different baseline levels of serum SP-A need to be established for smokers and non-smokers. Serum SP-A may be a useful marker for predicting COPD in the preclinical stage (Behera et al. 2005; Kobayashi et al. 2008a). Different alleles of SP-A and SP-D associated with various diseases have been summarized by Kishore et al. (2005) and given in Table 43.2. Analysis between COPD and smokers revealed several COPD susceptibility alleles (AA62_A, B1580_C, D2S388_5), based on an odds ratio (OR $>$ 2.5). Results indicate that surfactant protein alleles may be useful in COPD by either predicting the disease in a subgroup and/or by identifying disease subgroups that may be used for therapeutic intervention (Guo et al. 2001).

Proteome research revealed increased levels of SP-A in COPD but not in normal or fibrotic lung. Furthermore, elevated SP-A protein levels were detected from the induced sputum supernatants of COPD patients. The levels of other surfactant proteins (SP-B, SP-C, SP-D) were not altered. It is suggested that SP-A is linked to the pathogenesis of COPD and can be considered as a potential COPD biomarker (Ohlmeier et al. 2008). Toxic metals and transition elements

are detectable in exhaled breath condensate (EBC) of studied subjects (Mutti et al. 2006).

43.6.1.2 SP-D Is an Ideal Biomarker in COPD

In COPD, SP-D is an ideal biomarker that is produced mostly in lungs and can be measured in the peripheral circulation. It changes with the clinical status of the patient and has inherent functional attributes that suggest a possible causal role in pathogenesis of disease (Sin et al. 2008b, c).

In a multivariable linear regression model, COPD was independently associated with lower SP-D levels. Given the importance of this molecule in lung, low levels may play a role in the pathogenesis and/or progression of COPD (Sims et al. 2008). Inhaled corticosteroids alone or in combination exhibited partial systemic anti-inflammatory effects, reducing significantly only SP-D serum levels. ICS in conjunction with long-acting β2-adrenergic agonist significantly reduced serum SP-D levels. These drugs reduce lung-specific but not generalized biomarkers of systemic inflammation in COPD. Hydrofluoroalkane-beclomethasone dipropionate (HFA-BDP) controls eosinophilic inflammation, including in distal airways, more effectively than fluticasone propionate (FP) Diskus (Ohbayashi and Adachi 2008; Sin et al. 2008a).

43.6.2 Emphysema

Emphysema is a chronic pulmonary disease marked by an abnormal increase in size of air spaces. Pulmonary emphysema, a major component of COPD, is pathologically characterized by destructive alterations in pulmonary architectures as a result of persistent inflammation. Emphysema may be a dynamic disease process in which alveolar wall cell death and proliferation are repeated. The decrease of surfactant protein secreted by the alveolar type II cell is one of the important causes of limiting air of pulmonary emphysema and the changes of SP-A may be related to emphysematous changes in the lung. Cigarette smoke and LPS alter lung SP-A gene activity and protein homeostasis (Hu et al. 2008). Mice deficient in SP-D$^{-/-}$ develop progressive emphysema with age. SP-D gene-targeted mice develop severe pulmonary lipidosis, and foamy macrophage infiltrations. By lowering surface tension at the air-water interface in the surfactant deficient premature lung, exogenous surfactant replacement therapy for neonatal RDS has been highly successful in decreasing mortality after preterm birth. It has emerged that SP-A and SP-D have additional roles in host defence distinct from the surface tension lowering effects of surfactant. Recombinant forms of SP-D could be useful therapeutically in attenuating inflammatory processes in neonatal chronic lung disease, cystic fibrosis, and emphysema (Clark and Reid 2003).

43.6.3 Allergic Disorders

43.6.3.1 Allergic Inflammation in Asthma

Asthma is an obstructive lung disease where the bronchial tubes (airways) are extra sensitive (hyperresponsive). The airways become inflamed and produce excess mucus and muscles around the airways tighten making the airways narrower. Asthma is usually triggered by breathing in things present in air such as dust or pollen that produces an allergic reaction. It may be triggered by other things such as an upper respiratory tract infection, cold air, exercise or smoke. Asthma is diagnosed by the characteristic pattern of symptoms. A peak flow meter can record variations in the severity of asthma over time. Spirometry can provide an assessment of the severity, reversibility, and variability of airflow limitation, and help confirm the diagnosis of asthma. Significant changes occur in levels of SP-A and SP-D during the asthmatic response in animal models as well as in asthmatic patients. The impact of the SP-A and SP-D on asthmatic allergic inflammation and vice versa has been reviewed (Hohlfeld et al. 2002). Serum SP-D concentrations are affected in allergic patients and correlate with changes in allergic airway inflammation. Serum SP-D levels may give additional information, beside bronchial hyperresponsiveness (BHR) and sputum eosinophils, about the degree of bronchial inflammation in allergic patients (Koopmans et al. 2004).

Immunoregulatory Roles of SP-A and SP-D

Studies on allergen-sensitized murine models and asthmatic patients show that SP-A and SP-D can: specifically bind to aero-allergens; inhibit mast cell degranulation and histamine release; and modulate the activation of alveolar macrophages and DCs during the acute hypersensitive phase of allergic response (Erpenbeck et al. 2005; Wang et al. 1998). They also can alleviate chronic allergic inflammation by inhibiting T-lymphocyte proliferation as well as increasing phagocytosis of DNA fragments and clearance of apoptotic cell debris. Furthermore, it has emerged, from the studies on SP-D-deficient mice, that, when these mice are challenged with allergen, they develop increased eosinophil infiltration, and abnormal activation of lymphocytes, leading to the production of Th2 cytokines. Intranasal administration of SP-D significantly attenuated the asthmatic-like symptoms seen in allergen-sensitized wild-type, and SP-D-deficient, mice. These findings provide a new insight of role that surfactant proteins play in handling environmental stimuli and in their immunoregulation of airway inflammatory disease (Wang and Reid 2007).

Both SP-A and SP-D can inhibit histamine release in the early phase of allergen provocation and suppress lymphocyte proliferation in the late phase of bronchial inflammation, the two essential steps in the development of asthmatic

symptoms (Wang et al. 1998). Studies suggest that the increased levels of SP-A and D may play a protective role in an allergic inflammation in the pathogenesis of bronchial asthma. Structural remodelling of airways in asthma that follows inflammation may be affected by SP-D-mediated effects on immune response. SP-D accumulation is increased in this model of allergen-induced eosinophilia, both in upper and lower airways (Cheng et al. 2000; Kasper et al. 2002). SP-D gene-deficient mice (*Sftpd*$^{-/-}$) have an impaired systemic Th-2 response at baseline and reduced inflammation and airway responses after allergen exposure. Translational studies revealed that a polymorphism in *SFTPD* gene was associated with lower atopy and possibly asthma susceptibility. Thus, SP-D-dependent innate immunity influences atopy and asthma (Brandt et al. 2008). Dex significantly down-regulates SP-D in allergic airways and lavage fluid. In addition, Dex promoted airway expression of vitamin D-binding protein, heptoglobin and α1-antitrypsin (Zhao et al. 2007).

Serum SP-D is increased in acute and chronic inflammation in mice. Profiles of SP-A and SP-D in acute and chronic inflammation indicated that serum SP-D can serve as a biomarker of lung inflammation in both acute and chronic lung injury in mice (Fujita et al. 2005). Because of their capability to directly inhibit T-cell activation and T-cell-dependent allergic inflammatory events, SP-A and SP-D may be significant contributors to the local control of Th-2 type inflammation in the airways. SP-D is able to reduce the immediate allergen-induced mediator release and the early bronchial obstruction in addition to its effects on airway inflammation and bronchial hyperresponsiveness in an *A. fumigatus* mouse asthma model. Thus, SP-D not only reduces allergen-induced eosinophilic inflammation and airway hyper-responsiveness but also provides protection against early airway obstruction by inhibition of early mediator release (Erpenbeck et al. 2006; Takeda et al. 2003). However, mice sensitized and challenged with either *A. fumigatus* or OVA increased SP-D levels in their lung. Allergen exposure induced elevation in SP-D protein levels in an IL-4/IL-13-dependent manner, which in turn, prevents further activation of sensitized T cells. This negative feedback regulatory circuit could be essential in protecting the airways from inflammatory damage after allergen inhalation (Haczku et al. 2006). Haczku (2006) support the hypothesis that SP-A and SP-D have a role in regulation of allergic airway sensitization.

Murine Model of Asthma

Dust mite allergens can directly activate alveolar macrophages (AΦs), induce inflammatory cytokines, and enhance T-helper type 2 cytokine production. The SP-D is able to bind mite allergens and alleviates allergen-induced airway inflammation and may be an important modulator of allergen-induced pulmonary inflammation (Liu et al. 2005a). There is marked reduction in SP-A and SP-D levels in the BALF of dust mite (*Dermatophagoides pteronyssinus*, Der p)-sensitized BALB/c mice after allergen challenge. Both SP-A and SP-D were able to suppress Der p-stimulated intrapulmonary lymphocyte proliferation of naïve mice with saline or allergen challenge, or of Der p-sensitized mice with saline challenge. On the contrary, this suppressive effect was mild on lymphocytes from sensitized mice after allergen challenge. These results indicated the involvement of pulmonary surfactant proteins in the allergic bronchial inflammation of sensitized mice (Wang et al. 1996, 2001). Both SP-A and SP-D down-regulate the eosinophilic inflammation in murine asthma models and shift the cytokine profile towards a T helper cell type 1 response. In addition, they are effective at alleviating bronchial hyperresponsiveness. There is evidence of activation of innate immune system in asthma which results in the production of pro-inflammatory cytokines and may contribute to the pathogenesis of neutrophilic asthma (Simpson et al. 2007).

43.6.3.2 Chronic Sialadenitis and Chronic Rhinosinusitis

SP-A and mRNA and protein were detected in glands of patients with chronic sialadenitis. The expression in salivary glands of patients with chronic sialadenitis was significantly higher than from healthy salivary glands. SP-A immunoreactivity, localized in the epithelial cells and submucosal glands of paranasal sinus mucosa in normal and chronic sinusitis patients, was enhanced in chronic rhinosinusitis mucosa as compared with normal paranasal sinus mucosa (Lee et al. 2004, 2006). SP-A expression in human nasal tissue was correlated with symptoms suggestive of allergic rhinitis. (Wootten et al. 2006).

43.6.4 Interactions of SP-A and SP-D with Pathogens and Infectious Diseases

Microbial targets for SP-D include both Gram-positive and Gram-negative respiratory pathogens, influenza, and respiratory syncytial viruses, *Cryptococcus neoformans, Pneumocystis carinii*, and *Aspergillus fumigatus*. Both monocytes/macrophages and neutrophils express surface receptors that can interact with SP-D. The interactions between SP-D and microorganisms and in many instances immune cells promote both microbial aggregation and enhanced phagocytosis. SP-D has been shown to bind to a variety of bacteria, including rough strains of *Salmonella Minnesota* and *E. coli* as well as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* (Lim et al. 1994). SP-D also stimulates the phagocytosis of *Pseudomonas aeruginosa* (Restrepo et al. 1999). The interaction of SP-D with bacteria

often results in CRD-dependent bacterial aggregation or agglutination. Unlike SP-A (van Iwaarden et al. 1994), SP-D does not bind to lipid A. It interacts with *E. coli* through the core polysaccharides and/or the O-specific antigens. The core region of the LPS of other gram-negative bacteria is broadly recognized by SP-D as well (Kuan et al. 1992). SP-D can be used as a biomarker for chronic periodontitis. As no significant associations of SFTPD gene polymorphisms could be detected, other mechanisms influencing SP-D serum/plasma expression might exist (Glas et al. 2008).

SP-D has been shown to bind to the influenza A virus, resulting in aggregation of the target (Hartshorn et al. 1996a). The binding and inhibition of hemagglutination was inhibited by chelation of calcium and by carbohydrates, suggesting that the interaction of SP-D with the virus was mediated via the CRD. SP-D also enhances the neutrophil uptake of the virus in a calcium-dependent manner (Hartshorn et al. 1997). Further enhanced antiviral and opsonic activity for influenza A virus was obtained by making a human MBP and SP-D chimera (White et al. 2000) (Table 43.1). The degree of multimerization of SP-D also appears to be important for its interactions with viruses (Brown-Augsburger et al. 1996; Hartshorn et al. 1996b). SP-D induces massive aggregation of influenza A virus particles (Hartshorn et al. 1996a). This massive agglutination of organisms could contribute to lung host defence by promoting airway mucociliary clearance, but it could also promote internalization by phagocytic cells. Recombinant SP-D inhibited RSV infectivity both in vitro and in vivo (Hickling et al. 1999; Le Vine et al. 2004), and reduced SP-D protein levels have been detected in RSV infection (Kerr and Paton 1999). A direct interaction between the yeast *Candida albicans* and SP-D confirms the importance of SP-D in innate immunity (van Rozendaal et al. 2000).

43.6.4.1 Distinct Effects of SP-A or -D Deficiency During Bacterial Infection

Surfactant proteins A and D expressed in respiratory tract bind bacterial, fungal and viral pathogens, enhancing their opsonization and killing by phagocytic cells. Clearance of bacterial pathogens including group *B streptococci, Haemophilus influenza, Pseudomonas aeruginosa* and viral pathogens, *respiratory syncytial virus, adenovirus and influenza A virus*, was deficient in SP-A$^{-/-}$ mice (Table 43.1). Mice lacking SP-A (SP-A$^{-/-}$) or SP-D (SP-D$^{-/-}$) and wild-type mice, infected with group *B streptococcus* or *Haemophilus influenzae*, are associated with increased inflammation and inflammatory cell recruitment in lung after infection. Although, decreased killing of group B *streptococcus* and *H. influenzae* was observed only in SP-A$^{-/-}$ mice but not in SP-D$^{-/-}$ mice, bacterial uptake by alveolar macrophages was reduced in both SP-A- and SP-D-deficient mice. Isolated alveolar macrophages from SP-A$^{-/-}$ mice generated significantly less, whereas those from SP-D$^{-/-}$ mice generated significantly greater superoxide and H_2O_2 compared with wild-type alveolar macrophages.

In SP-D$^{-/-}$ mice, bacterial killing was associated with increased lung inflammation and increased oxidant production. Where as, bacterial killing was decreased and associated with increased lung inflammation and decreased oxidant production in SP-A$^{-/-}$, macrophage phagocytosis was decreased in both SP-A and SP-D deficient mice. SP-A deficiency was associated with enhanced inflammation and synthesis of pro-inflammatory cytokines. SP-D$^{-/-}$ mice cleared these bacteria as efficiently as wild-type mice; however, clearance of viral pathogens was deficient in SP-D$^{-/-}$ mice and associated with increased inflammation. Study suggests that SP-A and SP-D play distinct roles during bacterial infection of lung (LeVine et al. 2000, 2001).

Alloiococcus otitidis has been found to be associated with otitis media with effusion. SP-A and MBL interact with *A. otitidis* in Ca^{2+}-dependent manner. Results demonstrate that *A. otitidis* is a ligand for SP-A and TLR2, and that the collectins enhance the phagocytosis of *A. otitidis* by macrophages, suggesting important roles of collectins and TLR2 in the innate immunity of the middle ear against *A. otitidis* infection (Konishi et al. 2006). Meningococcal disease occurs after colonization of nasopharynx with *Neisseria meningitidis*. Variation in genes of surfactant proteins affects the expression and function of SPs. Gene polymorphism resulting in substitution of glutamine with lysine at residue 223 in the CRD of SP-A2 increases susceptibility to meningococcal disease, as well as the risk of death (Jack et al. 2006). In contrast to defensive function, SP-D in BALF binds β-glucan onB. *Dermatitidis and*, blocks BAM access to β-glucan, thereby inhibiting TNF-α production. Thus, whereas BALF constituents commonly mediate antimicrobial activity, *B. dermatitidis* may utilize BALF constituents, such as SP-D, to blunt the host defensive reaction; this effect could reduce inflammation and tissue destruction but could also promote disease (Lekkala et al. 2006)

43.7 Pulmonary Tuberculosis

43.7.1 Enhanced Phagocytosis of *M. tuberculosis* by SP-A

During initial infection with *M. tuberculosis*, bacteria that reach the distal airspaces of lung are phagocytosed by AMΦs in presence of pulmonary surfactant. Studies indicated a direct interaction between SP-A and macrophage in mediating enhanced adherence of *M. tuberculosis* (Gaynor et al. 1995). Since, SP-A binds mannose, it was hypothesized that SP-A attaches to *M. tuberculosis* and serves as a ligand

between *M. tuberculosis* and AΦs. Stokes et al. (1998) demonstrated that explanted alveolar AΦs do not efficiently bind *M. tuberculosis* in a serum-free system, although a small subpopulation of these AΦs could bind mycobacteria. In contrast, almost 100% of peritoneal AΦs bind mycobacteria under similar conditions. Evidence suggests that opsonic binding of *M. tuberculosis* by differentiated alveolar Ms is mediated by complement and CR3, and that the poor binding by resident alveolar AΦs is due to their poor expression of CR3. Thus, attachment of *M. tuberculosis* to AΦs is an essential early event in primary pulmonary tuberculosis and SP-A helps in early capture and phagocytosis of *M. tuberculosis* by AΦs. Ferguson et al. (2002) provided evidence for specific binding of SP-D to *M. tuberculosis* and indicated that SP-D and SP-A serve different roles in the innate host response to this pathogen in lung.

43.7.1.1 Lipomannan and ManLAM are Major Mycobacterial Lipoglycans as Potential Ligands

The SP-A binds to *M. bovis Bacillus Calmette-Guerin* (BCG), the vaccinating strain of pathogenic mycobacteria, and also to a lesser extent to *M. smegmatis*, which indicates that SP-A does not discriminate virulent from nonpathogenic strains. Lipomannan and mannosylated lipoarabinomannan (ManLAM) are two major mycobacterial cell-wall lipoglycans, which act as potential ligands for binding of SP-A. Both the terminal mannose residues and the fatty acids are critical for binding. It appears that recognition of carbohydrate epitopes on lipoglycans by SP-A is dependent on the presence of fatty acids (Sidobre et al. 2000, 2002).

Rivière et al, (2004) claim that the hydrophobic aglycon part of ManLAM is associated to a supra-molecular organization of these complex molecules. Furthermore, the deacylated ManLAMs or the lipid-free mannosylated arabinomannans, which do not exhibit characteristic ManLAM activities, do not display this supra-molecularorganization. These observations suggest that the ManLAMs immunomodulatory activities might be associated to their particular organization. The critical micellar concentration of ManLAMs obviously supports the notion that this supra-molecularorganization may be responsible for the specific biological activities of these complex molecules (Rivière et al. 2004).

As indicated, the molecular recognition of ManLAM terminal mannose units by CRDs of SP-A depends on the presence of lipid moiety of ManLAMs associated to a characteristic supra-molecular organization of ManLAM complex. On the other hand, the deacylated ManLAM or the lipid-free mannosylated arabinomannans, which do not exhibit characteristic ManLAM activities, do not display this supra-molecular organization. Therefore the ManLAM immunomodulatory activities might be associated to their particular organization. The critical micellar concentration of ManLAM supports the notion that this supra-molecular organization is responsible for specific biological activities of these complex molecules.

Apa Glycoprotein on *M.* tuberculosis: A Potential Adhesion to SP-A: Although lipoglycan ManLAM is considered as the major C-type lectin target on mycobacterial surface, Ragas et al. (2007) identified Apa (alanine- and proline-rich antigenic) glycoprotein as new potential target for SP-A, which binds to purified Apa. Apa is associated to the cell wall for a long time to aid in the attachment of SP-A. Because, Apa seems to be restricted to the *M. tuberculosis* complex strains, it was proposed that it may account for selective recognition of complex strains by SP-A containing homologous functional domains.

SP-A Enhances *M. avium* Ingestion by Macrophages: Tuberculosis leads to immune activation and increased HIV-1 replication in lung. SP-A promotes attachment of *M. tuberculosis* to AΦs during infection with HIV. SP-A levels and attachment of *M. tuberculosis* to AΦs inversely correlate with peripheral blood CD4 lymphocyte counts (Downing et al. 1995). *M. avium* complex (MAC) is a significant cause of opportunistic infection in patients with AIDS. Once in lung, MAC can interact with SP-A. Work on pulmonary pathogens including *M. bovis* BCG suggests that SP-A participates in promoting efficient clearance of these organisms by AMs. Lopez et al. (2003) reported that SP-A can bind to and enhance the uptake of MAC by AΦs, similar to BCG and *M. tuberculosis*. However, unlike BCG and other pulmonary pathogens that are cleared in presence of SP-A via a NO-dependent pathway, macrophage-mediated clearance of MAC is not enhanced by SP-A.

Suppression of Reactive Nitrogen Intermediates by SP-A in AMs in Response to *M. tuberculosis:* Reactive nitrogen intermediates (RNIs) play a significant role in the killing of *mycobacteria*. RNI levels generated by AΦs were significantly increased when IFNγ-primed AΦs were incubated with *M. tuberculosis*. However, the RNI levels were significantly suppressed in presence of SP-A. Furthermore, incubation of deglycosylated SP-A with *M. tuberculosis* failed to suppress RNI by AΦs, suggesting that the oligosaccharide of SP-A, which binds to *M. tuberculosis*, is necessary for this effect. Pasula et al. (1999) showed that SP-A-mediated binding of *M. tuberculosis* to AΦs and decreased RNI levels may be one mechanism by which *M. tuberculosis* diminishes the cytotoxic response of activated AΦs.

43.7.2 SP-A Modulates Inflammatory Response in AΦs During Tuberculosis

There is a severe reduction in SP-A levels in BAL during tuberculosis only in the radiographically involved lung

segments, and the levels returned to normal after 1 month of treatment. The SP-A levels were inversely correlated with the percentage of neutrophils in BAL fluid, suggesting that low SP-A levels were associated with increased inflammation in the lung. SP-A has pleiotropic effects even at low concentrations found in tuberculosis patients. This protein augments inflammation in presence of infection and inhibits inflammation in uninfected macrophages, protecting uninvolved lung segments from the deleterious effects of inflammation (Gold et al. 2004).

SP-A modulates phenotypic and functional properties of cells of adaptive immune response such as DCs and lymphocytes. Bone marrow-derived DCs generated in presence of SP-A fail to increase LPS-induced up-regulation of MHC class II and CD86 co-stimulatory molecule on DCs surface and behaves like "tolerogenic DCs". SP-A may also induce tolerance by suppressing the proliferation of activated T lymphocytes (Hussain 2004). SP-A suppresses lymphocyte proliferation and IL-2 secretion, in part, by binding to its receptor, SP-R210. However, the mechanisms underlying this effect are not well understood. The effects of antibodies against the SP-A-binding (neck) domain (α-SP-R210n) or nonbinding C-terminal domain (α-SP-R210ct) of SP-R210 on human peripheral blood T cell immune responses against *M. tuberculosis* support the hypothesis that SP-A, via SP-R210, suppresses cell-mediated immunity against *M. tuberculosis* via a mechanism that up-regulates secretion of IL-10 and TGF-β1 (Samten et al. 2008). Role of SP-A and SP-D in linking innate and adaptive immunity to regulate host defense has been suggested by Wright (2005). Although both SP-A and SP-D can bind to T cells and directly inhibit proliferation, SP-A can also indirectly inhibit T-cell proliferation via suppression of dendritic cell (DC) maturation. SP-D has been shown to enhance antigen uptake and presentation. Taken together, these in vitro results suggest that the combined role of SP-A and SP-D is to modulate the immunologic environment of the lung so as to protect the host, yet thwart an overzealous inflammatory response that could potentially damage the lung and impair gas exchange (Wright 2005)

43.7.3 Marker Alleles in *M. tuberculosis*

Regression analyses of tuberculosis and tuberculin-skin test positive groups, on the basis of odds ratios, revealed tuberculosis susceptibility (DA11_C and GATA_3) and protective (AAGG_2) marker alleles. Similarly, between tuberculosis patients and general population control subjects, susceptibility $1A^3$, $6A^4$, and B1013_A and protective AAGG_1, and AAGG_7 marker alleles were observed. Moreover, interactions were seen between alleles $6A^2$ and $1A^3$ and between $1A^3$ and B1013_A. Studies indicate a possible involvement of SP alleles in tuberculosis pathogenesis (Floros et al. 2000). Malik et al. (2006) investigated polymorphisms in the *SFTPA1* and *SFTPA2* genes for association with tuberculosis in 181 Ethiopian families comprising 226 tuberculosis cases. Four polymorphisms, SFTPA1 307A, SFTPA1 776T, SFTPA2 355C, and SFTPA2 751C, were associated with tuberculosis. Additional subgroup analysis in male, female and more severely affected patients provided evidence for SFTPA1/2-covariate interaction. Among five intragenic haplotypes identified in SFTPA1 gene and nine identified in SFTPA2 gene, $1A^3$ was most significantly associated with tuberculosis susceptibility (Table 43.2).

SNPs in Collagen Region of SP-A2 as a Contributing Factor: Relation exists between polymorphisms in the collagen regions of SP-A2 genes and pulmonary tuberculosis. Seven SNPs (4 exonic and 3 intronic) were identified in collagen regions of SP-A1 and SP-A2 genes in Indian population. Two intronic polymorphisms, SP-A1C1416T and SP-A2C1382G showed significant association with pulmonary tuberculosis. A redundant SNPA1660G of SP-A2 gene showed significant association with pulmonary tuberculosis. This polymorphism, when existing along with a non-redundant polymorphism, SP-A2G1649C (Ala91Pro) resulted in a stronger association with pulmonary tuberculosis. The SNPs in collagen region of SP-A2 may be one of the contributing factors to the genetic predisposition to pulmonary tuberculosis (Madan et al. 2002).

43.7.4 Interaction of SP-D with *M. tuberculosis*

Since many mycobacteria are facultative intracellular pathogens, their ability to cause disease involves entry, survival and replication within host cells. Although much progress has been made in our understanding of entry by mycobacteria, we anticipate that clarification of role of entry in pathogenesis will require further application of newly developed molecular tools to dissect each of the proposed mechanisms.

SP-D is known to bind *M. tuberculosis*. Binding of SP-D to *M. tuberculosis* is calcium dependent, and carbohydrate inhibitable. The binding of SP-D to Erdman lipoarabinomannan is mediated by terminal mannosyl oligosaccharides of this lipoglycan. Incubation of *M. tuberculosis* with subagglutinating concentrations of SP-D leads to reduced adherence of bacteria to macrophages, whereas incubation of

Table 43.2 SP-A and SP-D alleles associated with various diseases (Kishore et al. 2005).

Polymorphism		Disease association, population, type of study
Gene	Allele	
SP-A2	1A0	Susceptibility, RDS, Caucasian
SP-A1	6A2	Susceptibility, RDS, Caucasian
SP-A1	6A3	Protection, RDS, Caucasian
SP-A2	1A2	Protection, RDS, Caucasian

RDS respiratory distress syndrome, *BPD* bronchopulmonary dysplasia, *COPD* chronic obstructive pulmonary disease, *IPF* idiopathic pulmonary fibrosis, *TB* tuberculosis, *RSV* respiratory syncy–tial virus, *ABPA* allergic bronchopulmonary aspergillosis (Adapted with permission from Kishore et al. 2005 © Springer)

bacteria with SP-A leads to significantly increased adherence to monocyte-derived macrophages. Ferguson et al. (2002) provided evidence for specific binding of SP-D to *M. tuberculosis* and indicated that SP-D and SP-A serve different roles in the innate host response to this pathogen in lung. Further studies provide direct evidence that inhibition of phagocytosis of *M. tuberculosis* affected by SP-D occurs independently of aggregation process. SP-D limits the intracellular growth of bacilli in macrophages by increasing phagosome-lysosome fusion but not by generating a respiratory burst (Ferguson et al. 2006). Results also provide evidence that SP-A and SP-D enhance mannose receptor-mediated phagocytosis of *M. avium* by macrophages (Kudo et al. 2004). Virulent and attenuated *M. tuberculosis* strains bind best to immobilized SP-A (Hall-Stoodley et al. 2006). *Mycobacterium avium* has developed numerous mechanisms for entering mononuclear phagocytes. The SP-A, and SP-D, exhibit a concentration-dependent binding to *M. avium*. Studies provide evidence that SP-A and SP-D enhance mannose receptor-mediated phagocytosis of *M. avium* by macrophages (Kudo et al. 2004).

43.7.5 Association of SPs with Diabetes

Insulin decreased SP-A gene transcription in human lung epithelial cells (Miakotina et al. 2002). Alveolar type II cells and nonciliated bronchiolar epithelial (Clara) cells in lungs of rats with diabetes have decreased SP-A, but increased mRNA. This is on account of differential expression in the level of SP-A, SP-B, and SP-C mRNAs in both alveolar and bronchiolar epithelial cells from diabetic lungs in comparison to control lungs (Sugahara et al. 1994). Nonetheless, Fernández-Real et al. (2008) reported circulating SP-A significantly higher among patients with glucose intolerance and type 2 diabetes than in subjects with normal glucose tolerance, even after adjustment for BMI, age, and smoking status. In amniotic fluid from diabetic women, SP-A levels were significantly less than in nondiabetic pregnancies. Hypertension did not modify SP-A in diabetic women. Although Snyder et al. (1988) suggested that the concentration of amniotic fluid SP-A is decreased in diabetic pregnancies, McMahan et al. (1987) concluded that in well controlled diabetic pregnancies fetal lung maturation is not adversely affected. SP-A and SP-B were significantly elevated in amniotic fluid from black mothers and in amniotic fluid from mothers who smoked during pregnancy (Pryhuber et al. 1991).

43.8 Expression of SPs in Lung Cancer

43.8.1 Non-Small-Cell Lung Carcinoma (NSCLC)

Molecular mechanisms underlying carcinogenesis of non-small cell lung cancer(NSCLC) may provide gene targets in critical pathways valuable for improving the efficacy of therapy and survival of patients with NSCLC (Chong et al. 2006). SP-A is described for a portion of NSCLC facilitating a diagnostic marker for these carcinomas (Goldmann et al. 2009). Studies in human lung carcinoma reported positive staining of tumor cells for SP-A, especially in peripheral airway cell carcinoma, which include bronchioloalveolar carcinoma and in some reports also papillary subtypes. The SP-A gene is expressed at higher levels in hyperplastic cells; the expression occurs predominantly, but not exclusively, in adenocarcinomas (Broers et al. 1992; Linnoila et al. 1992). The determination of SP-A in malignant effusions may help in distinguishing primary lung adenocarcinoma from adenocarcinomas of

miscellaneous origin. Analysis of SP-A gene transcript in pleural effusion is useful for diagnosis of primary lung adenocarcinoma (Saitoh et al. 1997; Shijubo et al. 1992). Gene expression of SP-A and SP-C was restricted to metastatic pulmonary adenocarcinomas (Betz et al. 1995). Camilo et al. (2006) suggested that all adenocarcinomas were negative for p63 where as 4 (26.6%) of 15 were positive for SP-A.

Uzaslan et al. (2005) studied 169 primary adenocarcinomas of lung (109 acinar, 32 solid with mucin, 24 papillary and 4 mucinous) for SP-A expression. Twenty-five percent of acinar, 38% of papillary and 3% of solid adenocarcinoma with mucin showed a positive intracytoplasmic SP-A reaction of the tumor cells. Results support the theory that SP-A-producing cells may generate not only bronchioloalveolar and papillary carcinoma, but also other subtypes of lung adenocarcinoma (Stoffers et al. 2004; Uzaslan et al. 2005). Tsutsumida et al. (2007) advocate that high MUC1 expression on the surface is an important characteristic of a micropapillary pattern, where as reduced surfactant apoprotein A expression in the micropapillary pattern may be an excellent indicator for poor prognosis in small-size lung adenocarcinoma.

43.8.1.1 Genetic Factors as Lung Cancer Risk

Deletions of the SP-A gene are specific genomic aberrations in bronchial epithelial cells adjacent to and within NSCLC, and are associated with tumor progression and a history of smoking. SP-A deletions might be a useful biomarker to identify poor prognoses in patients with NSCLC who might therefore benefit from adjuvant treatment (Jiang et al. 2005). Seifart et al. (2005) genotyped for SP-A1, -A2, -B, and -D marker alleles in lung cancer subgroups, which included 99 patients with small cell lung carcinoma (SCLC), or non-SCLC (NSCLC, n = 68) consisting of squamous cell carcinoma (SCC), and adenocarcinoma (AC); controls and healthy individuals (population control). Seifart et al. (2005) found (a) no significant marker associations with SCLC, (b) rare SP-A2 ($1A^9$) and SP-A1 ($6A^{11}$) alleles associate with NSCLC risk when compared with population control, (c) the same alleles (1A9, $6A^{11}$) associate with risk for AC when compared with population ($6A^{11}$) or clinical control ($1A^9$), and (d) the SP-A1-$6A^4$ allele (found in ~10% of the population) associates with SCC, when compared with control. A correlation between SP-A variants and lung cancer susceptibility appears to exist, indicating that SP-A alleles may be useful markers of lung cancer risk.

The SP mRNAs with SP-A, B, and C were coexpressed in 10/12 (83%) of adenomas and 4/5 (80%) of carcinomas in both solid and tubulopapillary areas. SP-D mRNA signals were not noted in normal or neoplastic lung. ISH for SP A, B, or C mRNA was a helpful aid in the diagnosis of proliferative lesions of the murine lung (Pilling et al. 1999). In ovine pulmonary adenocarcinoma, caused by jaagsiekte sheep retrovirus, SP-A and C were expressed in 70% and 80% of tumor cells, respectively, whereas Clara cell 10-kDa protein was expressed in 17% of tumor cells (Platt et al. 2002).

43.8.1.2 TTF-1 and SP-A in Differential Diagnosis

Results suggest that TTF-1 can play an important role for the maintenance and/or differentiation process in bronchiolar and alveolar cells (Nakamura et al. 2002). TTF-1 is frequently expressed in human lung cancer, especially in adenocarcinoma and small cell lung cancer, and TTF-1 expression is closely related to the expression of surfactant protein. Zamecnik and Kodet (2002) described positive results for TTF-1 and SP-A in 75% and 46% of pulmonary adenocarcinomas and in 50% and 25% of pulmonary non-neuroendocrine large cell carcinomas (LCCs), respectively. Small cell lung carcinomas were TTF-1 positive in 89% of cases and completely negative for SP-A. Squamous cell carcinomas and carcinoid tumors were negative for both proteins. The frequency of TTF-1 expression in the nucleus was very low in human lung cancer cell lines; however, their cytoplasmic positivities should be further investigated (Fujita et al. 2003. Rossi et al. (2003) (1) support the metaplastic histogenetic theory for pulmonary carcinomas group of tumors; (2) show that cytokeratin 7 and TTF-1, but not SP-A, are useful immunohistochemical markers in this setting, and (3) suggest that this group of tumors has a worse prognosis than conventional NSCL carcinoma at surgically curable stages I, justifying their segregation as an independent histologic type. Lu et al. (2006) suggested that nuclear inclusions positive for SP-A antibody staining in adenocarcinomas of lung were derived from accumulated content in the perinuclear cistern resembling pseudoinclusion processes and composed of proteins antigenically cross-reactive with SP-A. Because of its diagnostic utility TTF-1 should be added to a panel of antibodies used for assessing tumors of unknown origin. The combination of anti-TTF-1 with anti-SP-A does not increase the diagnostic usefulness of TTF-1 alone (Lu et al. 2006). Suzuki et al. (2005) and Ueno et al. (2003) reported that Napsin is better marker than SP-A for diagnosis of lung adenocarcinoma. Napsin A is an aspartic proteinase expressed in lung and kidney. Napsin A is expressed in type II pneumocytes and in adenocarcinomas of lung.

43.8.1.3 SPs as a Tool for Diagnosis of Lung Tumors

Most bronchioloalveolar carcinomas of lung react positively for SP-A. Positive SP-A staining of large cell carcinoma of the lung could indicate that at least part of these tumors have the same cellular origin or differentiation as bronchioloalveolar carcinoma. Twenty of 63 (32%) tumors stained positive for SP-A. This may imply that about one third of large cell

carcinomas of lung have a similar cellular origin or differentiation as bronchioloalveolar carcinoma (Uzaslan et al. 2006).

SP-A, a marker for lung adenocarcinomas, can be used to differentiate lung adenocarcinomas from other types and metastatic cancers of other origins (Kuroki et al. 1998; Takahashi et al. 2006b). RT-PCR and primers specific for SP-A, SP-B, SP-C and SP-D genes were used to detect nodal metastases and occult tumor spread of pulmonary adenocarcinomas. A combination of SP-A and SP-D may help to establish a differential prognosis in patients with gefitinib-induced ILD (Kitajima et al. 2006). ILD is a serious adverse event in lung cancer patients treated with gefitinib, an epidermal growth factor receptor tyrosine kinase inhibitor (EGFR-TKI). Pretreatment with gefitinib exacerbated LPS-induced lung EGFR-TKI by reducing SP-A expression in lung. EGFR- TKI may reduce SP-A expression in lungs of lung cancer patients and thus patients treated with EGFR tyrosine kinase inhibitor may be susceptible to pathogens (Inoue et al. 2008).

SP mRNAs were present in all lung tumors, with SPs A, B, and C being co-expressed in 83% of adenomas and 80% of carcinomas in both solid and tubulopapillary areas. No signals for SP D mRNA were noted in normal or neoplastic lung. Additionally, no staining for any SP transcript was observed in the hepatocellular carcinoma metastases. In situ hybridization for SP A, B, or C mRNA was helpful in diagnosis of proliferative lesions of the murine lung, enabling differentiation from hepatocellular metastases (Pilling et al. 1999; Qi et al. 2002).

43.9 Other Inflammatory Disorders

43.9.1 Airway Inflammation in Children with Tracheostomy

The long-term tracheostomy in infants and children may perpetuate chronic airway inflammation and airway remodeling due to easier access to the lungs for microorganisms. The SP-A and SP-D may directly interact with invading microorganisms and also modulate the activity of local immune cells. Children with tracheostomy had an increased total number of cells, increased neutrophils, and more frequently bacteria, but no viruses were recovered. SP-D concentration was reduced to half, though SP-A, SP-B, and SP-C were not different from controls. SP-D was inversely correlated to neutrophils, and high numbers of bacteria were associated with lower SP-D concentrations. It was suggested that bacteria and low SP-D support neutrophilic inflammation in the lower respiratory tract of nonsymptomatic with children with tracheostomy (Griese et al. 2004). BAL fluids from patients carrying a chronic tracheostoma agglutinated *P. aeruginosa*, which was completely inhibited by maltose. The agglutination of *P. aeruginosa* by BAL fluid was related in part to the concentration of SP-D. Additional factors, such as the multimeric organization of SP-D, are likely to contribute to the agglutination of microorganisms by BAL or other body fluids (Griese and Starosta 2005).

Pulmonary Alveolar Microlithiasis (PAM): Pulmonary alveolar microlithiasis (PAM) is an uncommon chronic disease characterized by calcifications within the alveoli and a paucity of symptoms in contrast to image findings. PAM occurs in the absence of any known disorder of calcium metabolism. Takahashi et al. (2006a) reported two cases of PAM, with markedly elevated sera concentrations of SP-A and SP-D, which showed a tendency to increase as the disease progressed. Therefore, SP-A and SP-D may function as serum markers to monitor the disease activity and progression of PAM.

Gastroesophageal Reflux Disease: Children with gastroesophageal reflux often suffer from chronic, severe lung damage and recurrent infections. The mechanisms may involve reflux induced lung injury with alterations of the SP-A and SP-D, which bind specifically to various microbes and increase their elimination by granular leukocytes and macrophages. In children with gastroesophageal reflux disease (GERD), the macromolecular organization of SP-A and SP-D were significantly reduced. The more active SP-A and especially those of SP-D were diminished, whereas the smaller sized forms of SP-D were markedly increased. Reduced amounts of SP-A and SP-D and an altered structural organization of the surfactant proteins may contribute to pathogenesis of chronic lung disease commonly observed in these children (Griese et al. 2002).

43.9.2 Surfactant Proteins in Non-ILD Pulmonary Conditions

Infants with increased pulmonary blood flow secondary to congenital heart disease suffer from tachypnea, dyspnea, and recurrent pulmonary infections. In congenital heart disease with pulmonary hypertension secondary to increased pulmonary blood flow, there is a decrease in SP-A gene expression as well as a decrease in SP-A and SP-B protein contents (Gutierrez et al. 2001). In an experiment involving 4-week-old lambs with pulmonary hypertension secondary to increased pulmonary blood flow following an in utero placement of an aortopulmonary vascular graft, Lee et al. (2004) found a decrease in SP-A gene expression as well as a decrease in SP-A and SP-B protein contents. But in a lamb model of congenital heart disease with pulmonary hypertension and increased pulmonary blood flow, the effect of the shunt on SP gene expression and protein content was not

apparent within first week of life (Lee et al. 2004). No significant association between the common genetic variants of SP-A and SP-D and victims of sudden infant death syndrome (SIDS) was disclosed by Stray-Pedersen et al. (2009). However, low SP-A protein expression may possibly be determined by the 6A2/1A0 SP-A haplotype, which should be a subject for further investigation.

The SP-A level decreases significantly in acute pulmonary embolism, which may play an important role in hypoxemia in pulmonary embolism (Xie et al. 2005). Although an immunohistochemical investigation of pulmonary SP-A suggested a characteristic increase in fatal asphyxiation, no particular change was observed in the total amount of SP-A mRNA. The analysis of the SP-A1/A2 ratio may assist interpretation of the molecular alterations of SP-A related to acute asphyxial death (Ishida et al. 2002).

In hyperpnea there is a significant increase in lamellar bodies (LB) SP-A, lysozyme, and phospholipid (PL) but no change in the protein-to-prolonged hyperpnea ratios. It was suggested that (1) surfactant-associated lysozyme is secreted with LB, (2) the majority of SP-A is linked to lipid secretion but not necessarily with LB, and (3) the majority of SP-B secretion is independent of PL secretion. (4) Hyperpnea did not alter the mRNA expression of SP-A, SP-B, SP-C, or lysozyme in alveolar type II cells, but expression of SP-A and SP-B mRNA was significantly increased in lung tissue (Yogalingam et al. 1996).

43.10 DNA Polymorphisms in SPs and Pulmonary Diseases

Though the genes underlying susceptibility to RDS are insufficiently known, genes coding for SP-A and B have been assigned as the most likely genes in the etiology of RDS. Acute-RDS (ARDS) develops in association with many serious medical disorders. Mortality is at least 40%, and there is no specific therapy. The deficiency in SP-A level has been implicated in the pathophysiology of ARDS. Associations between single nucleotide polymorphisms (SNPs) of human gene coding *SFTPA1, SFTPA2,* and *SFTPD* and infectious pulmonary diseases have been established by several groups.

43.10.1 Association Between SP-A Gene Polymorphisms and RDS

Evidences suggest that the etiology of RDS is multifactorial with a significant genetic component. There are reports about polymorphisms and mutations on the surfactant protein genes, especially surfactant proteins-B, that may be associated with RDS, ARDS, and congenital alveolar proteinosis. The human SP-A gene locus includes two functional genes, *SFTPA1* and *SFTPA2* which are expressed independently, and a pseudo gene. SP-A polymorphisms play a role in respiratory distress syndrome, allergic bronchopulmonary aspergillosis and idiopathic pulmonary fibrosis. The levels of SP-A are decreased in lungs of patients with CF, RDS and chronic lung diseases (Heinrich et al. 2006).

Both low levels of SP-A and SP-A alleles have been associated with RDS. Floros et al. characterized four allelic variants of SP-A1 gene (6A, $6A^2$, $6A^3$, and $6A^4$) and five allelic variants of the SP-A2 gene (1A, $1A^0$, $1A^1$, $1A^2$, and $1A^3$) and hypothesized that specific SP-A alleles/genotypes are associated with increased risk of RDS. Because race, gestational age (**GA**), and sex are risk factors for RDS, Kala et al. (1998) studied the distribution and frequencies of SP-A alleles/genotypes while adjusting for these factors as confounders or effect modifiers in control and RDS populations with GAs ranging from 24 week to term. Although the odds ratios of several alleles and genotypes were in opposite directions for black and white subjects, the homogeneity of odds ratio reached statistical significance only in case of $6A^3/6A^3$. Although differences were observed in subgroups with different GAs of RDS white population, definitive conclusions could not be made regarding the effect of modification by GA or as a function of sex. Study suggested that (1) the genetic analyses of RDS and SP-A locus should be performed separately for black and white populations and (2) SP-A alleles/genotypes and SP-B variant may contribute to the etiology of RDS and/or may serve as markers for disease subgroups. In a genetically homogeneous Finnish population, Rämet et al. (2000) showed that certain SP-A1 alleles ($6A^2$ and $6A^3$) and an SP-A1/SP-A2 haplotype ($6A^2/1A^0$) were associated with RDS. The $6A^2$ allele was over-represented and the $6A^3$ allele was under-represented in infants with RDS. According to results, diseases associated with premature birth did not explain the association between the odds of a particular homozygous SP-A1 genotype ($6A^2/6A^2$ and $6A^3/6A^3$) and RDS. In the population evaluated, SP-B intron 4 variant frequencies were low and had no association with RDS. Thus, SP-A gene locus is an important determinant for predisposition to RDS in premature infants.

Floros et al. (2001b), in family-based linkage studies to discern linkage of SP-A to RDS, showed a link between SP-A and RDS; certain SP-A alleles/haplotypes are susceptibil ($1A^0$, $6A^2$, $1A^0/6A^2$) or protective ($1A^5$, $6A^4$, $1A^5/6A^4$) for RDS. Some differences between blacks and whites with regard to SP-A alleles may exist. In a 107 father-mother-offspring trios, divided into two sets according to proband's phenotype, Haataja et al. (2001) evaluated familial segregation of candidate gene polymorphisms by the transmission disequilibrium test. A set of 76 trios were analyzed for transmission disequilibrium from parents to affected offspring. Another set of

31 trios were studied for allele transmission from parents to hypernormal offspring born very prematurely before GA of 32 weeks. SP-A1-A2 haplotype $6A^2$-$1A^0$ showed significant excess transmission to affected infants and SP-A1 allele $6A^2$ decreased transmission to the hypernormals. Study provides a support for a role of SP-A alleles as genetic predisposers to RDS in premature infants.

43.10.2 SP-A and SP-B as Interactive Genetic Determinants of Neonatal RDS

Haataja et al. (2000) investigated if SP-B gene or interaction between SP-A and SP-B genes has a role in genetic susceptibility to RDS. Of the two SP-B polymorphisms genotyped, the Ile131Thr variation, a putative N-terminal N:-linked glycosylation site of proSP-B and length variation of intron 4 have been suggested to associate with RDS. Neither of the two SP-B polymorphisms associated directly with RDS or with prematurity. Instead, results showed that known association between SP-A alleles and RDS was dependent on the SP-B Ile131Thr genotype. Hence, the SP-B Ile131Thr polymorphism is a determinant for certain SP-A alleles as factors causing genetic susceptibility to RDS ($6A^2$, $1A^0$) or protection against it ($6A^3$, $1A^2$).

Floros et al. (2001a) studied genotypes for SP-B intron 4 size variants and for four SNPs [−18 (A/C), 1013 (A/C), 1580 (C/T), 9306 (A/G)] in SP-B in black and white subjects. Based on odds ratio: (1) the SP-B intron 4 deletion variant in white subjects is more of an RDS risk factor for males and for subjects of 28 weeks < gestational age (GA) <33 weeks; (2) the SP-B intron 4 insertion variant in black subjects is more of an RDS risk factor in females; (3) in white subjects, SP-A1 ($6A^2/6A^2$) or SP-A2 ($1A^0/1A^0$ or $1A^0$/*) genotypes in subjects of certain GA and with a specific SP-B genotype (9306 (A/G) or deletion/*) are associated with an enhanced risk for RDS; (4) in black subjects, SP-A1 ($6A3/6A^3$ or $6A^3$/*) genotypes in subjects of 31 weeks < or = GA < or = 35 weeks and with the SP-B (1580 (T/T)) genotype are associated with a reduced risk for RDS. The SP-B polymorphisms are important determinants for RDS. These may identify differences between black and white subjects, as well as, between males and females regarding the risk for RDS. Moreover, SP-A susceptibility or protective alleles, in specific SP-B background, are associated with an increased or reduced risk for RDS.

43.10.3 RDS in Premature Infants

DNA samples from 441 premature singleton infants and 480 twin or multiple infants were genotyped for SP-A1, SP-A2, and SP-B exon 4 polymorphisms and intron 4 size variants in a homogeneous white population. Distribution of SP-A and SP-B gene variants between RDS and no-RDS infants were determined alone and in combination. The SP-A1 allele 6A2 and homozygous genotype 6A2/6A2 are over-represented in RDS of singletons when SP-B exon 4 genotype was Thr/Thr, and under represented in RDS of multiples when the SP-B genotype was Ile/Thr. The SP-A 6A2 allele in SP-B Thr131 background predisposed the smallest singleton infants to RDS, whereas near-term multiples were protected from RDS. There was a continuous association between fetal mass and risk of RDS, defined by SP-A and SP-B variants. Labeled lung explants with the Thr/Thr genotype showed proSP-B amino-terminal glycosylation, which was absent in Ile/Ile samples. Hence, Genetic and environmental variation may influence intracellular processing of surfactant complex and the susceptibility to RDS (Marttila et al. 2003b). However, the association between SP-A polymorphisms and RDS may not be applicable to entire population of premature infants. In twins, the association between SP-A polymorphism and RDS is different from that seen in premature singleton infants. The factor associated with SP-A genotype-specific susceptibility to RDS appears to be related to the size of uterus and length of gestation at birth (Marttila et al. 2003a). Zhai et al. (2008) reported that the frequency of SP-A1 allele $6A^2$ and $6A^3$ expression of SP-A in Chinese premature infants was low in neonatal RDS. In contrast, the frequency of SP-A2 allele $1A^0$ and $1A^1$ was high in normal Chinese premature infants. It supports that SP-A1 allele $6A^2$ may be a susceptible gene for RDS.

43.10.4 Gene Polymorphism in Patients of High-altitude Pulmonary Edema

A pathogenetic cofactor for development of high-altitude pulmonary edema (HAPE) is an increase in capillary permeability, which could occur as a result of an inflammatory reaction and/or free-radical-mediated injury to lung. Pulmonary SP-A has potent antioxidant properties and protects unsaturated phospholipids and growing cells from oxidative injury (Swenson et al. 2002). In view of protective role of SP-A against oxidative damage, Saxena et al. (2005) examined the association of constitutional susceptibility to HAPE with polymorphisms in SP-A1 and SP-A2. Allele frequencies of three loci in SP-A1 and one in SP-A2 were significantly different between low-altitude native (LAN) HAPE patients and LAN control subjects. Heterozygous individuals, with respect to SP-A1 C1101T and SP-A2 A3265C, showed less severity in oxidative damage in comparison with homozygous subjects (SP-A1 T1101 and SP-A2 C3265). The polymorphisms in SP-A1 might be one of the genetic factors contributing to susceptibility to HAPE (Saxena et al. 2005).

43.10.5 SNPs in Pulmonary Diseases

Four validated SNPs were genotyped with sequence-specific probes (TaqMan 7000) in 284 newborn infants below 32 weeks of GA. The finding of an association of a variant of the *Sftpd* gene, that has previously been shown to be associated with increased SP-D serum levels in adult patients with RDS in preterm infants, may provide a basis for the initial risk assessment of RDS and modification of surfactant treatment strategies. A role for SP-D in neonatal pulmonary adaptation has to be postulated. Genotyping for three SNP altering amino acids in the mature protein in codon 11 ($Met^{11}Thr$), 160 ($Ala^{160}Thr$), and 270 ($Ser^{270}Thr$) of the SP-D gene was performed and related to the SP-D levels in serum. Individuals with Thr/Thr-11-encoding genotype had significantly lower SP-D serum levels than individuals with Met/Met (11) genotype. Polymorphic variation in the N-terminal domain of the SP-D molecule influences oligomerization, function, and the concentration of the molecule in serum (Hilgendorff et al. 2009; Leth-Larsen et al. 2005; Sorensen et al. 2007).

Studies on twins indicated very strong genetic dependence for serum levels of SP-D. Sequencing of 5′ untranslated region (5′UTR), the coding region and the 3′ region of *Sftpd* gene of 32 randomly selected blood donors indicated one single *Sftpd* haplotype (allele frequency 13.53%) that showed a negative association with serum SP-D levels. The discovery of a frequent negative variant of *Sftpd* gene provides a basis for genetic analysis of function of SP-D in resistance against pulmonary infections and inflammatory disorders in humans (Heidinger et al. 2005). The presence of SP-D in non-pulmonary tissues, such as gastrointestinal tract and genital organs, suggest additional functions located to other mucosal surfaces. Sorensen et al. (2007) summarized studies on genetic polymorphisms, structural variants, and serum levels of human SP-A and SP-D and their associations with human pulmonary disease.

Polymorphisms of genes are transmitted together in haplotypes, which can be used in study of development of complex diseases such as RDS. Genetic haplotypes of these SP genes are associated with the development of RDS. Studies identify protective haplotypes against RDS and support findings related to SP genetic differences in children who develop RDS. An allele association study of 19 polymorphisms in SP-A1, SP-A2, SP-B, and SP-D genes in ARDS was carried out. Analysis revealed differences in frequency of alleles for some of the microsatellite markers flanking SP-B, and for one polymorphism (C/T) at nucleotide 1580 [C/T (1580)], within codon 131 ($Thr^{131}Ile$) of the SP-B gene. The latter determines the presence or absence of a potential N-linked glycosylation site. Based on the odds ratio, the C allele may be viewed as a susceptibility factor for ARDS. These data suggest that SP-B or a linked gene contributes to susceptibility to ARDS (Lin et al. 2000; Thomas et al. 2007).

Amino Acid Variants in SP-D Are Not Associated with Bronchial Asthma: As SP-D binds and neutralizes common allergens like house dust mites it is especially important in allergic asthma. Levels of SP-D are elevated in serum and alveolar lavage of asthmatic patients. Three common amino acid variants have been identified in SP-D and association of first variant has been described to severe infection with respiratory syncytial virus. The three polymorphisms leading to amino acid exchanges ($Met^{11}Thr$, $Ala^{160}Thr$, and $Ser^{270}Thr$) were typed in 322 asthmatic children and none of these polymorphisms was associated with bronchial asthma. Haplotype analyses revealed four major haplotypes all of which were evenly distributed between the populations. Functional amino acid variants in SP-D do not seem to play a major role in the genetic pre-disposition to bronchial asthma in children (Krueger et al. 2006).

Following allergen exposure in vivo, $SP\text{-}D^{-/-}$ mice expressed higher bronchoalveolar lavage (BAL) eosinophils and IL-13 and lower FN-γ expression at early time points compared with wild mice. IL-10 expression was increased at early time points in $SP\text{-}D^{-/-}$ compared with wild mice. SP-D may be critical for the modulation of early stages of allergic inflammation in vivo (Schaub et al. 2004).

Pettigrew et al. (2006, 2007) evaluated gene polymorphisms in loci encoding SP-A and risk of otitis media during first year of life among a cohort of infants at risk for developing asthma in white infants. Polymorphisms at codons 19, 62, and 133 in SP-A1, and 223 in SP-A2 were associated with race/ethnicity. In regression models incorporating estimates of uncertainty in haplotype assignment, the $6A^4/1A^5$ haplotype was protective for otitis media among white infants. On similar line, analyses suggested that polymorphisms within *SFTPA* loci may be associated with wheeze and persistent cough in white infants at risk for asthma. These associations require replication and exploration in other ethnic/racial groups.

43.10.6 Allergic Bronchopulmonary Aspergillosis and Chronic Cavitary Pulmonary Aspergillosis (CCPA)

Individuals with any structural or functional defects in SP-A and SP-D due to genetic variations might be susceptible to aspergillosis. Single nucleotide polymorphism in genes of collagen region of SP-A1 and SP-A2 has been associated with allergic bronchopulmonary aspergillosis (ABPA) and its clinical markers. SP-A2 G1649C and SP-A2 A1660G, polymorphisms in the collagen region of SP-A2, might be one of the contributing factors to genetic predisposition and

severity of clinical markers of ABPA. SNPs in SP-A2 and MBL genes showed significant associations with patients of ABPA in an Indian population. Patients carrying either one or both of GCT and AGG alleles of SP-A2 and patients with A allele at position 1011 of MBL had markedly higher eosinophilia, total IgE antibodies and lower FEV1. Therapeutic administration of SP-D and MBL proteins in a murine model of pulmonary invasive aspergillosis rescued mice from death. In mice mimicking human ABPA, SP-A and SP-D suppressed IgE levels, eosinophilia, pulmonary cellular infiltration and cause a marked shift from a pathogenic Th2 to a protective Th1 cytokine profile. Thus, collectins play an important role in Aspergillus mediated allergies and infections (Madan et al. 2005; Saxena et al. 2003).

Patients with CCPA or ABPA of Caucasian origin were screened for SNPs in collagen region of SP-A1 and SP-A2 and MBL. The T allele at T1492C and G allele at G1649C of SP-A2 were observed at slightly higher frequencies in ABPA patients (86% and 93%) than in controls (63% and 83%), and the C alleles at position 1492 and 1649 were found in higher frequencies in CCPA patients (33% and 25%) than in ABPA patients (14% and 7%). However, the CC genotype at position 1649 of SP-A2 was significantly associated with CCPA. Similarly, ABPA patients showed a higher frequency of TT genotype (71%) at 1492 of SP-A2 than controls (43%) and CCPA patients (41%). In case of MBL, the T allele and CT genotype at position 868 (codon 52) were significantly associated with CCPA, but not with ABPA. Further analysis of genotype combinations at position 1649 of SP-A2 and at 868 of MBL between patient groups showed that both CC/CC and CC/CT SP-A2/MBL were found only in CCPA patients, while GG/CT SP-A2/MBL was significantly higher in CCPA patients in comparison to ABPA patients. SNPs in SP-A1 did not differ between patients and controls. Distinct alleles, genotypes and genotype combinations of SP-A2 and MBL may contribute to differential susceptibility of the host to CCPA or ABPA (Vaid et al. 2007).

Allergic Airway Inflammation: The SP-A has potent immunomodulatory activities. SP-A protein levels in the BAL fluid showed a rapid, transient decline that reached the lowest values (25% of controls) 12 h after intranasal Af provocation of sensitized mice. It was speculated that a transient lack of SP-A following allergen exposure of airways may significantly contribute to the development of a T-cell dependent allergic immune response (Scanlon et al. 2005). After acute ovalbumin-induced allergic airway inflammation (1) alveolar epithelial type II cells (AEII) but not Clara cells show a significantly higher expression of SP-A and SP-D in rats leading also to higher amounts of both SPs in BALF and (2) macrophages gather predominantly SP-A (Schmiedl et al. 2008).

43.10.7 Autoreactivity Against SP-A and Rheumatoid Arthritis

Circulating SP-D is decreased in early rheumatoid arthritis and SP-A and SP-D levels in synovial fluid from patients correlated with rheumatoid factor, CRP, IgA, IgM, and IgG, and total lipid content. SP-A and SP-D seem to participate in initiation of immune system and joint inflammation within the joint (Kankavi 2006) and may be an additional RA disease modifier like MBL. The $Met^{11}Thr$ polymorphism in the N-terminal part of SP-D is important determinant in serum SP-D. But this polymorphism is also essential to the function and assembly into oligomers. SP-D levels did not correlate with traditional disease activity measures. The Thr^{11}/Thr^{11} genotype and the Thr^{11} allele tended to be more frequent in RA patients. Therefore, the low serum level of SP-D and the lack of correlation with traditional disease activity measures indicate that SP-D reflects a distinctive aspect in the RA pathogenesis (Hoegh et al. 2008; Miyata et al. 2002). Trinder et al. (2000) were able to show autoreactivity to SP-A, as expressed by IgG and IgM autoantibodies, and present in synovial fluid (SF) from patients with RA. There was no cross-reactivity between autoantibodies reactive with type II collagen (CII) and those reactive with SP-A or C1q; However, autoantibodies reacted with polymeric (dimers and larger) SP-A, but not with monomeric SP-A subunits, indicating that a degree of quaternary structure is required for antibody binding.

43.11 Inhibition of SP-A Function by Oxidation Intermediates of Nitrite

43.11.1 Protein Oxidation by Chronic Pulmonary Diseases

The oxidation of proteins may play an important role in the pathogenesis of chronic inflammatory lung diseases, and may contribute to lung damage. Higher levels of protein oxidation than in healthy controls were observed in patients with interstitial lung disease, gastro-esophageal reflux disease, and PAP. The proteins most sensitive to oxidation were serum albumin, SP-A, and α1-antitrypsin. Abundance of reactive oxygen species produced during neutrophilic inflammation may be a deleterious factor that leads to pulmonary damage in these patients (Starosta and Griese 2006). Primary chain and quaternary structure of SP-D in BALFs

showed significant changes under oxidative conditions in vitro and in vivo and functional capacity to agglutinate bacteria was impaired by oxidation. Free radicals generated in lungs resulting in oxidation of SP-D may impair host defense and may contribute to the suppurative lung diseases like cystic fibrosis (Starosta and Griese 2006).

43.11.2 Oxidation Intermediates of Nitrite

Nitration of protein tyrosine residues by peroxynitrite ($ONOO^-$) has been implicated in a variety of inflammatory diseases such as ARDS. A mixture of hypochlorous acid (HOCl) and nitrite (NO_2^-) induces nitration, oxidation, and chlorination of tyrosine residues in human SP-A, and inhibits SP-A's ability to aggregate lipids and bind mannose. Nitration and oxidation of SP-A was not altered by the presence of lipids, suggesting that proteins are preferred targets in lipid-rich mixtures such as pulmonary surfactant. Moreover, both horseradish peroxidase and myeloperoxidase (MPO) can utilize NO_2^- and H_2O_2 as substrates to catalyze tyrosine nitration in SP-A, and inhibit its lipid aggregation function. SP-A nitration and oxidation by MPO is markedly enhanced in presence of Cl^- and the lipid aggregation function of SP-A is completely abolished. Studies suggest that MPO released by activated neutrophils during inflammation utilizes physiological or pathological levels of NO_2^- to nitrate proteins, and may provide an additional mechanism in addition to ONOO – formation, for tissue injury in ARDS and other inflammatory diseases associated with upregulated NO* and oxidant production. The oxidant-mediated tissue injury is likely to be important in the pathogenesis of ARDS/ALI (Davis et al. 2002; Lang et al. 2002; Narasaraju et al. 2003).

In vitro and in vivo data suggest that NO alters surfactant protein gene expression. The role of NO in ALI remains controversial. Although inhaled NO increases oxygenation in clinical trials, inhibiting NOS can be protective. However, inhalation of NO may not be indicated in sepsis because of excessive NO production. Aikio et al. (2003) indicated that inhaled NO is effective in a select group of small premature infants and that the responsiveness to NO is associated with low NOS2 enzyme. Very low birth-weight infants (birthweight <1,500 g), infants with progressive respiratory failure and infection at birth have deficient pulmonary NOS2 and cytokine response. After surfactant therapy, these infants responded strikingly to inhaled NO. An acute pulmonary inflammatory response may contribute to respiratory adaptation in early-onset pneumonia. In intact lambs inhaled NO increased SP-A and SP-B mRNA and protein content with no change in DNA content. The mechanisms and physiological effects of these findings warrant further investigation (Stuart et al. 2003; Hu et al. 2007). Exposure of rats to NO2 showed impairment of SP-A and a higher alveolar pool size after in vivo exposure. The NO2-induced alterations of SP-A may contribute to the pulmonary toxicity of this oxidant (Müller et al. 1992). NO production from NOS2 expressed in lung parenchymal cells in a murine model of ARDS correlates with abnormal surfactant function and reduced SP-B expression. $NOS2^{-/-}$ null mice exhibit significantly less physiologic lung dysfunction and loss of SP-B expression. Study indicated that the expression of NOS2 in lung epithelial cells is critical for the development of lung injury and mediates surfactant dysfunction independent of NOS2 inflammatory cell expression and cytokine production (Baron et al. 2004).

43.11.3 BPD Treatment with Inhaled NO

Inhaled NO is used to treat a number of disease processes. BPD is characterized by arrested alveolar and vascular development of immature lung. The increased expression of SP-A mRNA under hyperoxia can be attributed, at least in part, to an induction of mRNA and protein expression in bronchial Clara cells. The expanded role of Clara cells in the defence against hyperoxic injury suggests that they support alveolar type 2 cell function and may play an important role in the supply of surfactant proteins to the lower airways (ter Horst et al. 2006). The inhaled nitric oxide treatment of premature infants at risk for bronchopulmonary dysplasia does not adversely affect endogenous surfactant function or composition and may improve surfactant function transiently (Ballard et al. 2007). Chorioamnionitis is a risk factor for the development of bronchopulmonary dysplasia. Endotoxin-induced oxidative stress to the fetus in the uniquely hypoxic intrauterine environment has been reported. SP-A and B mRNAs were highest at Day 2, suggesting that oxidative stress did not contribute to the lung maturation response. A modest lung oxidative stress in chorioamnionitis could contribute to bronchopulmonary dysplasia (Cheah et al. 2008).

43.12 Congenital Diaphragmatic Hernia

Pulmonary hypoplasia is one of the main causes for high mortality rate in patients with congenital diaphragmatic hernia (CDH). The expression of SP-A in hypoplastic CDH lung is reduced, and its concentration is decreased in amniotic fluid of pregnancies complicated by CDH. In animal models, surfactant deficiency contributes to the pathophysiology of the disease. In humans surfactant disaturated phosphatidylcholine (DSPC) synthesis and SP-A were significantly lower in infants with CDH than in control subjects (Cogo et al. 2002).

SP-A is altered in developing lungs from rat fetuses with CDH induced by maternal ingestion of Nitrofen on Day 9 of

gestation. There is decreased expression of SP-A in rat fetuses with CDH secondary to Nitrofen exposure (Mysore et al. 1998). In rat CDH model, induced in pregnant rats following administration of nitrofen, SP-A, SP-B, and SP-D mRNA expression in CDH lung were significantly decreased compared to controls at birth and 6 h after ventilation. The inability of O2 to increase SP mRNA expression in hypoplastic CDH lung suggests that the hypoplastic lung is not responsive to increased oxygenation for synthesis of SP (Shima et al. 2000). Though, SP's deficiency appears to be a common feature among various CDH models, TTF-1 expression was not altered in surgical model in contrast to nitrofen model, indicating different molecular mechanisms in two models (Benachi et al. 2002).

43.13 Protective Effects of SP-A and SP-D on Transplants

Surfactant treatment has been shown to improve lung transplant function, but the effect is variable. Erasmus et al. (2002) indicated that SP-A enrichment of surfactant improves the efficacy of surfactant in lung transplantation. After instillation of SP-A-enriched surfactant, P_{O2} values were reached to control values, whereas after SP-A-deficient surfactant treatment, the P_{O2} values did not improve (Erasmus et al. 2002). The impairment of surfactant adsorption from transplanted lungs may be correlated with decreased levels of SP-A, and increased levels of serum acute-phase protein C-reactive protein (CRP). The elevated levels of CRP in BAL can be a very sensitive marker of lung injury (Casals et al. 1998).

Bronchiolitis obliterans syndrome (BOS) affects long-term survival of lung transplant recipients (LTRs). Among 11 differentially expressed proteins in BALF, peroxiredoxin 2 (Prdx2) exclusively expressed in BOS; and SP-A expressed consistently less in BOS patients than in stable LTRs. The reduction of SP-A in BALF was detectable early after lung transplant, preceding BOS onset in four of five patients and indicated that SP-A levels in BALF could predict LTR patients who are at higher risk of BOS development (Meloni et al. 2007) BOS and IPS cause high mortality and impaired survival after allogeneic hematopoietic stem-cell transplantation (allo-HSCT). The pretransplant serum SP-D levels but not SP-A, KL-6 in BOS/IPS patients were lower than those in non-BOS/IPS patients. However, the patients with lower pretransplant serum SP-D level had a trend toward frequent development of BOS/IPS. Constitutive serum SP-D level before allo-HSCT may be a useful, noninvasive predictor for the development of BOS/IPS (Nakane et al. 2008).

Keratinocyte growth factor (KGF) given before bone marrow transplantation (BMT) can prevent allogeneic T cell-dependent lung inflammation, but the antiinflammatory effects of KGF were impaired in mice injected with both T cells and conditioning regimen of cyclophosphamide. Yang et al. (2000, 2002) demonstrated that addition of cyclophosphamide interferes with the ability of KGF to enhance SP-A production. The systemic pre-BMT injection of KGF in recipients of allogeneic T cells up-regulates SP-A, which may contribute to the early antiinflammatory effects of KGF. Exogenous and basal endogenous SP-A can suppress donor T-cell-dependent inflammation that occurs during the generation of idiopathic pneumonia syndrome after BMT. Wild-type and SP-A-deficient mice, given allogeneic donor bone marrow plus inflammation-inducing spleen T cells, showed that basal endogenous SP-A, and enhanced alveolar SP-A level modulate donor T-cell-dependent immune responses and prolong survival after allogeneic BMT.

43.14 Therapeutic Effects of SP-A, SP-D and Their Chimeras

43.14.1 SP-A Effects on Inflammation of Mite-sensitized Mice

SP-A and SP-D interact with a wide range of inhaled allergens, competing for their binding to cell-sequestered IgE resulting in inhibition of mast cell degranulation. SP-D interacts with glycoprotein allergens of house dust mite (*Dermatophagoides pteronyssinus*, Derp) via its CRDs and thus inhibits specific IgE, isolated from mite-sensitive asthmatic patients, from binding these allergens, and blocking subsequent histamine release from sensitized basophils. Exogenous administration of SP-A and SP-D diminishes allergic hypersensitivity in vivo. A fragment of recombinant human SP-D (rfh SP-D) has a therapeutic effect on allergen-induced bronchial inflammation through its inhibitory effect on NO and TNF-α production by AΦs, and thus preventing the development of Th-2 type cytokine response (Liu et al. 2005b; Singh et al. 2003). The rfhSP-D that is effective in diminishing allergic hypersensitivity in mouse models of dust mite allergy was more susceptible to degradation than the native full-length protein. The degradation and consequent inactivation of SP-A and SP-D may be a mechanism to account for the potent allergenicity of these common dust mite allergens (Deb et al. 2007). Evidence suggests for an antiinflammatory role for SP-D in response to noninfectious, subacute lung injury via modulation of oxidative-nitrative stress (Casey et al. 2005).

43.14.2 SP-D Increases Apoptosis in Eosinophils of Asthmatics

The effect of exogenous rfhSP-D on protection of adult mouse lung from LPS-induced and lipoteichoic acid (LTA)-induced injury was assessed in *Sftpd*$^{+/+}$ and *Sftpd*$^{-/-}$

mice. Intratracheal rhSP-D inhibited inflammation induced by intratracheal LPS and LTA instillation in lung. The antiinflammatory effects of rhSP-D were enhanced by addition of pulmonary surfactant, providing a potential therapy for the treatment of lung inflammation (Ikegami et al. 2007). In view of therapeutic effects of exogenous SP-D or rfhSP-D (composed of eight Gly-X-Y collagen repeat sequences, homotrimeric neck and lectin domains) in murine models of lung allergy and hypereosinophilic SP-D gene-deficient mice, Mahajan et al. (2008) suggested that rfhSP-D mediated preferential increase of apoptosis of primed eosinophils while not affecting the normal eosinophils. The increased phagocytosis of apoptotic eosinophils may be important mechanisms of rfhSP-D and SP-D-mediated resolution of allergic eosinophilic inflammation in vivo.

43.14.3 Targeting of Pathogens to Neutrophils Via Chimeric SP-D/Anti-CD89 Protein

Intratracheal rfhSP-D prevents shock caused by endotoxin released from the lung during ventilation in the premature newborn (Ikegami et al. 2006). In lambs, preterm infants experience enhanced susceptibility and severity to respiratory syncytial virus (RSV) infection. This was observed when SP-A, -D and TLR4 mRNA expression increased from late gestation to term birth, where as in preterm lungs, studies showed reduced SP-A, -D, and TLR4 expression and enhanced RSV susceptibility (Meyerholz et al. 2006).

A chimeric protein, consisting of a recombinant fragment of human SP-D coupled to a Fab' fragment directed against human Fc α receptor (CD89) (chimeric rfSP-D/anti-Fc), effectively targets pathogens recognized by SP-D to human neutrophils. A recombinant trimeric fragment of SP-D (rfSP-D), consisting of CRD and neck domain of human SP-D, cross-linked to the Fab' of an Ab directed against the human Fc α RI (CD89) (chimeric rfSP-D/anti-CD89 protein) enhanced uptake of *E. coli*, *C. albicans*, and *influenza A virus* by human neutrophils (Tacken et al. 2004). Both chimeric rfSP-D/anti-Fc receptor proteins increased internalization of *E. coli* by human promonocytic cell line U937, but only after induction of monocytic differentiation. Both CD64 and CD89 on U937 cells proved suitable for targeting by rfSP-D/anti-Fc receptor proteins (Tacken and Batenburg 2006). Collectin-based chimeric proteins may thus offer promise for therapy of infectious disease.

43.14.4 Anti-IAV and Opsonic Activity of Multimerized Chimeras of rSP-D

A recombinant human SP-D, consisting of a short collagen region (two repeats of Gly-Xaa-Yaa amino acid sequences), the neck domain and CRD can form a trimeric structure owing to neck domain and exhibits sugar-binding activity and specificity similar to those of native human SP-D. Though the truncated SP-D could bind to IAV, like native SP-D, but the truncated human SP-D was less effective in agglutinating bacteria than the native structure and failed to inhibit haemagglutination by IAV (Eda et al. 1997). On the other hand, chimeric collectin containing N-terminus and collagen domain of human SP-D and CRD of MBL showed greater anti-IAV activity than similarly multimerized preparations of SP-D or incompletely oligomerized preparations of the chimera. Highly multimerized preparations of chimera also caused greater increases in uptake of IAV by neutrophils. These studies may be useful for development of collectins as therapeutic agents against IAV infection (Hartshorn et al. 2000b; White et al. 2000).

Bovine serum conglutinin has greater ability to inhibit IAV infectivity than other collectins. Altering the carbohydrate binding properties of SP-D [e.g., by replacing its CRD with that of either MBL or conglutinin] can increase its activity against IAV. Hence, recombinant conglutinin and a chimeric protein containing NH_2 terminus and collagen domain of rat SP-D (rSP-D) fused to neck region and CRD of conglutinin (termed SP-D/Cong(neck + CRD)) have markedly greater ability to inhibit infectivity of IAV than wild-type recombinant rSP-D, confirming that potent IAV-neutralizing activity of conglutinin resides in its neck region and CRD. Furthermore, SP-D/Cong(neck + CRD) also caused substantially greater enhancement of neutrophil binding and H_2O_2 responses to IAV than r-conglutinin or rSP-D. Hence, chimeric SP-D/Cong(neck + CRD) protein showed favorable antiviral and opsonic properties of conglutinin and SP-D (Hartshorn et al. 2000a). Thus, the SP-D N-terminal and/or collagen domains contribute to the enhanced bacterial binding and aggregating activities of SP-D. Although replacement of neck recognition domains and CRDs of SP-D with those of MBL and conglutinin confer increased viral binding activity, it does not favorably affect bacterial binding activity, suggesting that requirements for optimal collectin binding to influenza virus and bacteria differ (Hartshorn et al. 2007).

Chimera of Trimeric Neck + CRDs of Human SP-D: The recombinant trimeric neck + CRDs of human SP-D (NCRD) retains binding activity for some ligands and mediates some functional activities. In comparison to strong neutralizing activity of lung SP-D for IAVs in vitro and in vivo, the NCRD derived from SP-D has weak viral-binding ability and lacks neutralizing activity. Using a panel of mAbs against NCRD, Tecle et al. (2008) showed that antiviral activities of SP-D can be reproduced without the N-terminal and collagen domains and that cross-linking of NCRDs is

essential for antiviral activity of SP-D with respect to IAV (Tecle et al. 2008).

Incubation of native SP-D or NCRDs with peroxynitrite results into nitration and nondisulfide cross-linking. Modifications could be blocked by peroxynitrite scavengers or pH inactivation of peroxynitrite. Abnormal cross-linking leads to defective aggregation. Thus, modification of SP-D by reactive oxygen-nitrogen species could contribute to alterations in the structure and function of SP-D at sites of inflammation in vivo (Matalon et al. 2009). In contrast, a trimeric neck and CRD construct of bovine serum collectin CL-46 induces aggregation of IAV and potently increases IAV uptake by neutrophils. CL-46-NCRD showed calcium-dependent and sugar-sensitive binding to both neutrophils and IAV. Results indicate that collectins can act as opsonins for IAV even in the absence of the collagen domain or higher order multimerization. This may involve increased affinity of individual CRDs for glycoconjugates displayed on host cells or the viral envelope (Hartshorn et al. 2010).

Insertion of Arg-Ala-Lys in NCRD Increases Inhibitory Activity: Arg-Ala-Lys (RAK) (immediately N-terminal to the first motif) in CL-43 contributes to differences in saccharide selectivity and host defense function. Insertion of CL-43 RAK sequence or a control Ala-Ala-Ala sequence (AAA) into corresponding position in NCRD increased the efficiency of binding to mannan and changed the inhibitory potencies of competing saccharides to more closely resemble those of CL-43. In addition, RAK resembled CL-43 in its greater capacity to inhibit infectivity of IAV and to increase uptake of IAV by neutrophils (Crouch et al. 2005).

43.15 Lessons from SP-A and SP-D Deficient Mice

SP-D deficient (SP-D$^{-/-}$) mice exhibit an increase in the number and size of airway macrophages, peribronchiolar inflammation, increases in metalloproteinase activity, and development of emphysema. Mice deficient in SP-D$^{-/-}$ develop progressive emphysema with age, associated with loss of parenchymal tissue, subpleural fibrosis, and accumulation of abnormal elastin fibers. The changes in lung structure in SP-D$^{-/-}$ mice are reflected in the mechanical properties of both airway and lung parenchyma measured in vivo (Yoshida and Whitsett 2006).

Gene-targeted mice deficient in SP-D develop abnormalities in surfactant homeostasis, hyperplasia of alveolar epithelial type II cells, and emphysema-like pathology. Alveolar and tissue phosphatidylcholine pool sizes are markedly increased in SP-D$^{-/-}$ mice. The pulmonary lipoidosis in SP-D$^{-/-}$ mice was not associated with accumulation of SP-B or C, or their mRNAs, distinguishing the disorder from alveolar proteinosis syndromes. Surfactant protein A mRNA was reduced and, SP-A protein appeared to be reduced in SP-D$^{-/-}$ compared with wild type mice. Targeting of mouse SP-D gene caused accumulation of surfactant lipid and altered phospholipid structures, demonstrating a unsuspected role for SP-D in surfactant lipid homeostasis in vivo (Botas et al. 1998; Korfhagen et al. 1998; Ikegami et al. 2005). HDL cholesterol was significantly elevated in SP-D$^{-/-}$ mice while treatment of SP-D$^{-/-}$ mice with rhSP-D resulted in decreases of HDL-cholesterol as well as total cholesterol, and LDL cholesterol along with reduced plasma TNF-α in SP-D$^{-/-}$ mice. It shows that SP-D regulates atherogenesis in mouse model (Sorensen et al. 2006). SP-D plays a critical role in the suppression of alveolar macrophage activation, which may contribute to the pathogenesis of chronic inflammation and emphysema (Wert et al. 2000). Oxidant production and reactive oxygen species were increased in lungs of SP-D$^{-/-}$ mice, in turn activate NF-kB and MMP expression. SP-D plays an unexpected inhibitory role in the regulation of NF-kB in AΦs (Yoshida et al. 2001).

Studies indicate that GM-CSF-dependent macrophage activity is not necessary for emphysema development in SP-D-deficient mice, but that type II cell metabolism and proliferation are, either directly or indirectly, regulated by GM-CSF in this model (Hawgood et al. 2001; Ochs et al. 2004). SP-D and GM-CSF play distinct roles in the regulation of surfactant homeostasis and lung structure (Ikegami et al. 2001).

SP-A and SP-D Double Deficient Mice SP-A and SP-D proteins have overlapping as well as distinct functions. Mice singly deficient in SP-A and SP-D have distinct phenotypes and produce altered inflammatory responses to microbial challenges. Adult mice deficient in both SP-A and SP-D ($A^{-}D^{-}$) show fewer and larger alveoli, an increase in the number and size of type II cells, as well as more numerous and larger alveolar macrophages. Chronic deficiency of SP-A and SP-D in mice leads to parenchymal remodeling, type II cell hyperplasia and hypertrophy, and disturbed intracellular surfactant metabolism (Jung et al. 2005) In double deficient mice, there is a progressive increase in bronchoalveolar lavage phospholipid, protein, and macrophage content through 24 week of age. The macrophages from doubly deficient mice express high levels of the MMP-12 and develop intense but patchy lung inflammation. Qualitative changes resemble the lung pathology seen in SP-D-deficient mice (Hawgood et al. 2002).

Treatment of SP-D deficient mice with a truncated recombinant fragment of human SP-D (rfhSP-D) decreased lipidosis and alveolar macrophage accumulation as well as

production of proinflammatory chemokines. The rfhSP-D treatment reduced the structural abnormalities in parenchymal architecture and type II cells characteristic of SP-D deficiency and reduced degree of emphysema and a corrected type II cell hyperplasia and hypertrophy. This suggests that rfhSP-D might become a therapeutic option in diseases that are characterized by decreased SP-D levels in the lung (Knudsen et al. 2007; Zhang et al. 2002).

Treatment with a recombinant fragment of human SP-D consisting of a short collagen-like stalk (but not the entire collagen-like domain of native SP-D), neck, and CRD inhibited development of emphysema-like pathology in SP-D deficient mice. On the other hand, the entire collagen-like domain was necessary for preventing SP-D knockout mice from pulmonary emphysema development. The fragment of SP-D lacking the short collagen-like stalk failed to correct pulmonary emphysematous alterations demonstrating the importance of the short collagen-like stalk for the biological activity of the recombinant fragment of human SP-D (Knudsen et al. 2009; Breij and Batenburg 2008).

NO Production and S-Nitrosylation of SP-D Controls Inflammatory Function SP-D$^{-/-}$ mice exhibit an increase in the number and size of airway macrophages, peribronchiolar inflammation, increases in metalloproteinase activity, and development of emphysema. SP-A inhibited production of NO and inducible nitric oxide synthase (iNOS) in rat AΦ stimulated with smooth LPS. In contrast, SP-A enhanced production of NO and iNOS in cells stimulated with IFN-γ or IFN-γ plus LPS. SP-A contributes to the lung inflammatory response by exerting differential effects on the responses of immune cells, depending on their state and mechanism of activation (Stamme et al. 2000). NO is involved in a variety of signaling processes, and because altered NO metabolism has been observed in inflammation, it is predicted that alterations in its metabolism would underlie the proinflammatory state observed in SP-D deficiency (Atochina et al. 2004a, c). Treatment with the iNOS inhibitor 1,400 W can inhibit inflammatory phenotype and can attenuate inflammatory processes within SP-D deficiency. Mice treated with 1,400 W reduced total lung NO synthase activity (Atochina-Vasserman et al. 2007). Guo et al. (2008) suggest that NO controls the dichotomous nature of SP-D and that posttranslational modification by S-nitrosylation causes quaternary structural alterations in SP-D causing it to switch its inflammatory signaling role. This represents new insight into both the regulation of protein function by S-nitrosylation and NO's role in innate immunity (Guo et al. 2008). Thus, inflammation that occurs in SP-D deficiency is due to an increase in NO production and a shift in the chemistry and targets of NO from a disruption of NO-mediated signaling within the innate immune system. However, purified preparations of SPs often contain endotoxin and the functions of SP-A and SP-D are affected by endotoxin. Therefore, the monitoring of SP preparations for endotoxin contamination is important (Wright et al. 1999).

Selectins and Associated Adhesion Proteins in Inflammatory disorders

44

G.S. Gupta

44.1 Inflammation

Inflammation is defined as the normal response of living tissue to injury or infection. It is important to emphasize two components of this definition. First, that inflammation is a normal response and, as such, is expected to occur when tissue is damaged. Infact, if injured tissue does not exhibit signs of inflammation this would be considered abnormal and wounds and infections would never heal without inflammation. Secondly, inflammation occurs in living tissue, hence there is need for an adequate blood supply to the tissues in order to exhibit an inflammatory response. The inflammatory response may be triggered by mechanical injury, chemical toxins, and invasion by microorganisms, and hypersensitivity reactions. Three major events occur during the inflammatory response: the blood supply to the affected area is increased substantially, capillary permeability is increased, and leucocytes migrate from the capillary vessels into the surrounding interstitial spaces to the site of inflammation or injury. The inflammatory response represents a complex biological and biochemical process involving cells of the immune system and a plethora of biological mediators. Cell-to-cell communication molecules such as cytokines play an extremely important role in mediating the process of inflammation. Inflammation and platelet activation are critical phenomena in the setting of acute coronary syndromes. An extensive exposition of this complex phenomenon is beyond the scope of this article (Rankin 2004).

Inflammation can be classified as either acute or chronic. Acute inflammation is the initial response of the body to harmful stimuli and is achieved by the increased movement of plasma and leukocytes (especially granulocytes) from the blood into the injured tissues. A cascade of biochemical events propagates and matures the inflammatory response, involving the local vascular system, the immune system, and various cells within the injured tissue. Prolonged inflammation, known as chronic inflammation, leads to a progressive shift in the type of cells present at the site of inflammation and is characterized by simultaneous destruction and healing of the tissue from the inflammatory process. However, chronic inflammation can also lead to a host of diseases, such as hay fever, atherosclerosis, rheumatoid arthritis, and even cancer (e.g., gallbladder carcinoma). It is for that reason that inflammation is normally closely regulated by the body. Acute and chronic inflammation differ in matter of causative agent, major cells involved, primary mediators, onset, duration and final outcomes. Generally speaking, acute inflammation is mediated by granulocytes, while chronic inflammation is mediated by mononuclear cells such as monocytes and lymphocytes.

44.2 Cell Adhesion Molecules

Cell adhesion molecules are glycoproteins expressed on the cell surface and play an important role in inflammatory as well as neoplastic diseases. There are four main groups: the integrin family, the immunoglobulin superfamily, selectins, and cadherins. The integrin family has eight subfamilies, designated as β1 through β8. The immunoglobulin superfamily includes leukocyte function antigen-2 (LFA-2 or CD2), leukocyte function antigen-3 (LFA-3 or CD58), intercellular adhesion molecules (ICAMs), vascular adhesion molecule-1 (VCAM-1), platelet-endothelial cell adhesion molecule-1 (PE-CAM-1), and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). The selectin family includes L-selectin (CD62L), P-selectin (CD62P), and E-selectin (CD62E). Cadherins are major cell-cell adhesion molecules and include epithelial (E), placental (P), and neural (N) subclasses. The binding sites (ligands/receptors) are different for each of these cell adhesion molecules (e.g., ICAM binds to CD11/CD18; VCAM-1 binds to VLA-4). The specific cell adhesion molecules and their ligands that may be involved in pathologic conditions and potential therapeutic strategies by modulating the expression of these molecules have been discussed (Elangbam et al. 1997). Most adhesion molecules

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_44, © Springer-Verlag Wien 2012

play fairly broad roles in the generation of immune responses. The three selectins act in concert with other cell adhesion molecules e.g., intracellular adhesion molecule (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and leukocyte integrins to effect adhesive interactions of leukocytes, platelets, and endothelial cells. The structure and functions of selectins, which belong to C-type lectins family, have been reviewed in Chaps. 26, 27, and 28.

44.2.1 Selectins

The selectin family of lectins consists of three closely related cell-surface molecules with differential expression by leukocytes (L-selectin), platelets (P-selectin), and vascular endothelium (E- and P-selectin). Structural identity of a selectins resides in its unique domain composition (Chap. 26). E-, P-, and L-selectin are >60 % identical in their NH2 terminus of 120 amino acids, which represent the lectin domain (Chaps. 26, 27, and 28). The ligands (counter structures) of selectins are sialylated and fucosylated carbohydrate molecules which, in most cases, decorate mucin-like glycoprotein membrane receptors. Their common structure consists of an N-terminal Ca^{2+}-dependent lectin-type domain, an epidermal growth factor (EGF)-like domain, multiple short consensus repeat (SCR) domains similar to those found in complement regulatory proteins, a transmembrane region, and a short cytoplasmic C-terminal domain. Together this arrangement results in an elongated structure which projects from the cell surface, ideal for initiating interactions with circulating leucocytes. The lectin domain forms the main ligand binding site, interacting with a carbohydrate determinant typified by fucosylated, sialylated, and usually sulphated glycans such as sialyl Lewis X (s-Le^X). The EGF domain may also play a role in ligand recognition. The short consensus repeat (SCR) domains (two for L-selectin, six for E-selectin, and nine for P-selectin) probably act as spacer elements, ensuring optimum positioning of the lectin and EGF domains for ligand interaction. The EGF repeats have comparable sequence similarity. Each complement regulatory-like module is 60 amino acids in length and contains six cysteinyl residues capable of disulfide bond formation. This feature distinguishes the selectin modules from those found in complement binding proteins, such as complement receptors 1 and 2, which contain four cysteines (Chap. 26).

The selectins cell-surface receptors play a key role in the initial adhesive interaction between leukocytes and endothelial cells at sites of inflammation. Selectins (P, E and L) and their ligands (mainly P-selectin ligand) are involved in the rolling and tethering of leukocytes on the vascular wall. Activation of endothelial cells (EC) with different stimuli induces the expression of E- and P-selectins, and other adhesion molecules (ICAM-1, VCAM-1), involved in their interaction with circulating cells. Lymphocytes home to peripheral lymph nodes (PLNs) via high endothelial venules (HEVs) in the subcortex and incrementally larger collecting venules in the medulla. HEVs express ligands for L-selectin, which mediates lymphocyte rolling (Horstman et al. 2004). For structure and functions of selectins, the readers are advised to consult Chaps 26–28. In this chapter we will emphasize mainly on the role of selectins in inflammatory disorders including cancer.

44.3 Atherothrombosis

Atherothrombosis, defined as atherosclerotic plaque disruption with superimposed thrombosis, is the leading cause of mortality in the Western world. Atherosclerosis is a diffuse process that starts early in childhood and progresses asymptomatically through adult life. Later in life, it is clinically manifested as coronary artery disease (CAD), stroke, transient ischaemic attack (TIA), and peripheral arterial disease. From the clinical point of view, we should envision this disease as a single pathologic entity that affects different vascular territories. A suggestive analogy is that TIA and intermittent claudication are the unstable angina of the brain and lower limbs, respectively; and stroke and gangrene are the myocardial infarction. Circulating platelets display reversible interactions with atherosclerotic lesions. Atherosclerotic arterial disease is associated with an increased share of platelets unable to express P-selectin and an increased fraction of platelets that microaggregate in citrate anticoagulant. These platelet alterations are not completely explained by either focal arterial injury or abnormal rheology associated with arterial stenosis but appear to be an effect of the atherosclerotic process (McBane et al. 2004). The pathogenesis of arterial thrombotic disease involves multiple genetic and environmental factors related to atherosclerosis and thrombosis.

44.3.1 Venous Thrombosis

Venous Thrombosis is a world wide health problem in the general population. Injury to the endothelium leads to dysfunction. The causes of injury include lipids, immune complexes, microorganisms, smoking, hypertension, aging, diabetes mellitus and trauma. The selectins are thought to be largely responsible for the initial attachment and rolling of leukocytes on stimulated vascular endothelium. Platelet activation is an important process in the pathogenesis of atherothrombosis. Platelet adhesion, activation, and aggregation at the sites of vascular endothelial disruption caused by atherosclerosis are key events in arterial thrombus formation. Platelet tethering and adhesion to the arterial wall,

particularly under high shear forces, are achieved through multiple high-affinity interactions between platelet membrane receptors (integrins) and ligands within the exposed subendothelium, most notably collagen and von Willebrand factor (vWF). Platelet adhesion to collagen occurs both indirectly, via binding of the platelet glycoprotein (GP) Ib-V-IX receptor to circulating vWF, which binds to exposed collagen, and directly, via interaction with platelet receptors GP VI and GP Ia/IIb. Platelet activation, initiated by exposed collagen and locally generated soluble platelet agonists (primarily thrombin, ADP, and thromboxane A2), provides the stimulus for the release of platelet-derived growth factors, adhesion molecules and coagulation factors, activation of adjacent platelets, and conformational changes in the platelet α(IIb)β3 integrin (GP IIb/IIIa receptor). Platelet aggregation, mediated primarily by interaction between the activated platelet GP IIb/IIIa receptor and its ligands, fibrinogen and vWF, results in the formation of a platelet-rich thrombus (Steinhubl and Moliterno 2005).

44.3.2 Arterial Thrombosis

P-selectin expression in platelets is elevated in disorders associated with arterial thrombosis such as coronary artery disease, acute myocardial infarction, stroke, and peripheral artery disease. During thrombosis, P-selectin is expressed on the surface of activated endothelial cells and platelets. P-selectin mediates rolling of platelets and leukocytes on activated endothelial cells as well as interactions of platelets with leukocytes. Platelet P-selectin interacts with PSGL-1 on leukocytes to form platelet-leukocyte aggregates. Furthermore, this interaction of P-selectin with PSGL-1 induces the upregulation of tissue factor, several cytokines in leukocytes and the production of procoagulant microparticles, thereby contributing to a prothrombotic state. P-selectin is also involved in platelet-platelet interactions, i. e. platelet aggregation which is a major factor in arterial thrombosis. P-selectin interacts with platelet sulfatides, thereby stabilizing initial platelet aggregates formed by GPIIb/IIIa-fibrinogen bridges. Inhibtion of the P-selectin-sulfatide interaction leads to a reversal of platelet aggregation. Thus, P-selectin plays a significant role in platelet aggregation and platelet- leukocyte interactions, both important mechanisms in the development of arterial thrombosis. Following activation, P-selectin is rapidly translocated to the cell surface (Merten and Thiagarajan 2004; Wang et al. 2005).

44.3.3 Thrombogenesis in Atrial Fibrillation

Platelet activation occurs in peripheral blood of patients with rheumatic mitral stenosis (MS). The plasma levels of soluble P-selectin are elevated in permanent atrial fibrillation (AF) patients; the plasma levels of soluble P-selectin in the left atrium do not significantly differ from those in the right atrium, femoral vein, or femoral artery. The venous plasma levels of sP-selectin in patients with moderate-to-severe MS are significantly higher than those in healthy volunteers or patients with lone AF. In addition, in patients with MS, there was no difference in the plasma levels of sP-selectin between the left and right atrial blood and between peripheral and atrial blood. Moreover, there was no change in sP-selectin levels as a result of percutaneous transluminal mitral valvuloplasty (PTMV) (Chen et al. 2004). Lip et al. (2005) studied the relations of plasma vWf (an index of endothelial damage and dysfunction) and sP-selectin levels in relation to the presence and onset of clinical congestive heart failure (CHF) and degree of left ventricular dysfunction in patients taking part in SPAF (stroke prevention in AF). While plasma vWf was higher among patients with AF and CHF, plasma P-selectin concentrations were not affected by presence, onset, or severity of heart failure.

44.3.4 Atherosclerosis

Atherosclerosis is a complex chronic inflammatory disease of the arterial wall. Though the inflammatory nature of atherosclerosis has been established, the initial events that trigger this response in the arterial intima remain obscure. Studies reveal a significant rate of genomic alterations in human atheromas. The accumulation of genomic rearrangements in vascular endothelium and smooth muscle cells are important for disease development. It is well accepted that the induction of EC adhesion molecules is a critical component in acute inflammatory responses as well as allogeneic interactions in vascularized allografts and, possibly, atherogenesis. Inflammation and genetics are both prominent mechanisms in the pathogenesis of atherosclerosis and arterial thrombosis. Accordingly, population studies have explored the association of ischaemic heart disease with gene polymorphisms of the inflammatory molecules: tumor necrosis factors (TNF) α and β, transforming growth factors (TGF) β1 and 2, P and E selectins, and platelet endothelial cell adhesion molecule (PECAM) 1. The partly conflicting data provide some evidence that alterations in the genetics of the inflammatory system may modify the risk of ischaemic heart disease.

44.3.4.1 Formation of Reactive Oxygen Species (ROS) as an Initial Event

In recent years, reactive oxygen species (ROS) are considered as initial event in causing atherosclerosis. ROS are a family of molecules including molecular oxygen and its derivatives produced in all aerobic cells. Excessive

production of ROS, outstripping endogenous antioxidant defense mechanisms, has been implicated in processes in which they oxidize biological macromolecules, such as DNA, protein, carbohydrates, and lipids. Many ROS possess unpaired electrons and thus are free radicals. These include molecules such as superoxide anion (O_2^-), hydroxyl radical ($HO^\bullet$), nitric oxide ($NO^\bullet$), and lipid radicals. Other reactive oxygen species, such as hydrogen peroxide (H2O2), peroxynitrite ($ONOO^-$), and hypochlorous acid (HOCl), are not free radicals per se but have oxidizing effects that contribute to oxidant stress. The cellular production of one ROS may lead to the production of several others via radical chain reactions. For example, reactions between radicals and polyunsaturated fatty acids within cell membrane may result in a fatty acid peroxyl radical ($R\text{-}COO^\bullet$) that can attack adjacent fatty acid side chains and initiate production of other lipid radicals. Lipid radicals produced in this chain reaction accumulate in the cell membrane and may have a myriad of effects on cellular function, including leakage of the plasmolemma and dysfunction of membrane-bound receptors. Of note, end products of lipid peroxidation, including unsaturated aldehydes and other metabolites, have cytotoxic and mutagenic properties. A decline in NO bioavailability may be caused by decreased expression of the endothelial cell NO synthase (eNOS), a lack of substrate or cofactors for eNOS (Fig. 44.1 and 44.2).

In mammalian cells, potential enzymatic sources of ROS include the mitochondrial respiration, arachidonic acid pathway enzymes lipoxygenase and cyclooxygenase, cytochrome p450s, xanthine oxidase, NADH/NADPH oxidases, NO synthase, peroxidases, and other hemoproteins. Although many of these sources could potentially produce ROS that inactivate $NO^\bullet$, 3 sources have been studied extensively in cardiovascular system. These include xanthine oxidase, NADH/NADPH oxidase, and NO synthase (Cai and Harrison 2000; Hamilton et al. 2004; Vijya Lakshmi et al. 2009).

44.3.4.2 CAMs as Predicators of Atherosclerosis

During initial step in atherosclerosis, there is rapid targeting of monocytes to the sites of inflammation and endothelial injury; the adhesion of leukocytes to activated endothelial cells is mediated by ICAM-1. The induction of EC adhesion molecules is a critical component in acute inflammatory responses as well as allogeneic interactions in vascularized allografts and, possibly, atherogenesis. The "inflammatory triad" of IL-1, TNF, and LPS are potent stimulators of the EC activation and adhesion molecules E-selectin or ELAM-1 (or also known as CD62E), ICAM-1 and VCAM-1. PECAM-1 plays also a key role in the transendothelial migration of circulating leukocytes (diapedesis) during vascular inflammation. ICAM-1 and VCAM-1 are inflammatory predicators of adverse prognosis in patients with acute coronary syndromes (ACS) (Postadzhiyan et al. 2008) (Fig. 44.2).

Levels of P-selectin are increased in the blood of patients with familial hypercholesterolemia (FH) in spite of long-term intensive extracorporeal LDL-elimination, documenting the activity of atherosclerosis. Low levels of P-selectin and MCP-1 after hypolidemic procedure can be used as a marker showing the effectivity of the extracorporeal LDL-cholesterol elimination (Blaha et al. 2004). In an extended study, the levels of expression of tissue factor, ICAM-1, P- and E-selectin, and PAI-1 were found low, whereas those of endothelial protein C receptor and VCAM-1 were high (Merlini et al. 2004).

44.3.4.3 Gene Polymorphisms in E-Selectin

Polymorphisms in the E-selectin gene are associated with accelerated atherosclerosis in young (age <40 years) patients, further suggesting a role of inflammation in atherosclerosis. A further change in endothelial physiology is an increase in the surface expression of E-selectin, which regulate adhesive interactions between certain blood cells and endothelium. Intravascular fibrinolysis induced by tissue-type plasminogen activator or urokinase may contribute to the initiation of atherosclerosis by inducing P-selectin and platelet activating factor as well as to plaque rupture, either directly or indirectly, by activating metalloproteinases. As E-selectin is only expressed on activated endothelium, it provides an opportunity to study pathophysiological aspects of this cell in cardiovascular and other disease. However, sE-selectin can be found in the plasma, which has potential role in the pathogenesis of cardiovascular disease as raised levels have been found in hypertension, diabetes and hyperlipidemia, although its association in established atherosclerosis disease and its value as a prognostic factor is more controversial (Holvoet and Collen 1997).

Polymorphisms for three genes, P-selectin, L-selectin, and E-selectin (genes *P-sel, L-sel*, and *E-sel*, respectively) showed that the selectin cluster is linked to markers at chromosome 1q23 (Vora et al. 1994). Significant genomic alterations were found on 1q22-q25 in *Sel-L* gene. The message indicated somatic DNA rearrangements, on loci associated to leukocyte adhesion, vascular smooth muscle cells growth, differentiation and migration, to atherosclerosis development as an inflammatory condition (Arvanitis et al. 2005). Wenzel et al. (1999) and Yoshida et al. (2003) described an adenine to cytosine (A/C) substitution for cDNA position 561 resulting in an amino acid exchange from serine to arginine at position 128 (S/R or $Ser^{128}Arg$) was detected in the epidermal growth factor (EGF) domain. A higher mutation frequency was observed in patients aged 50 years or less with proven severe atherosclerosis as well as in patients aged 40 years or less. If $Ser^{128}Arg$ substitution

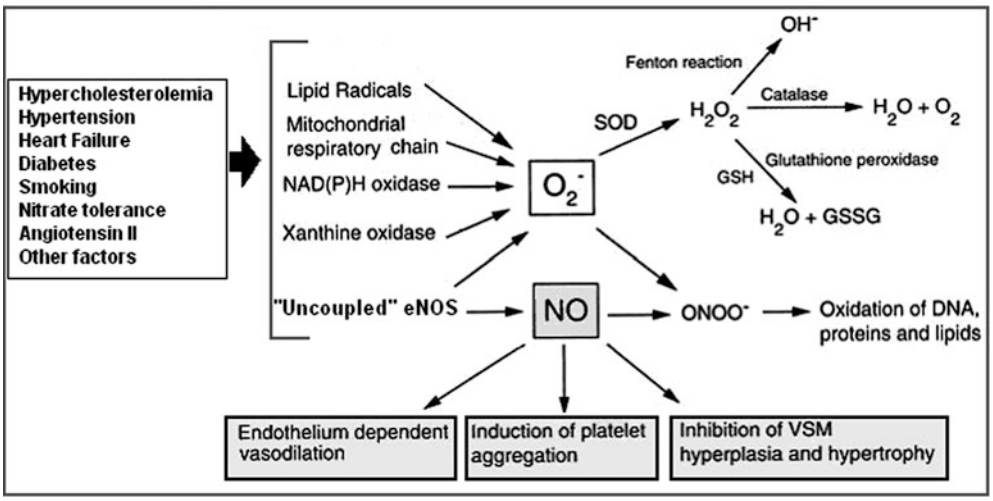

Fig. 44.1 *Mechanisms for oxidant stress-induced endothelial dysfunction in cardiovascular diseases* (Hamilton et al. 2004). Excessive production of ROS has been implicated in processes in which they oxidize biological macromolecules, such as DNA, protein, carbohydrates, and lipids. Many ROS possess unpaired electrons and thus are free radicals. These include molecules such as superoxide anion (O_2^-), hydroxyl racial ($HO^•$), nitric oxide ($NO^•$), and lipid radicals. The cellular production of one ROS may lead to the production of several others via radical chain reactions. A decline in NO bioavailability may be caused by decreased expression of the endothelial cell NO synthase (eNOS), a lack of substrate or cofactors required for eNOS action. Low-density lipoprotein (LDL) is oxidized to oxidized form of LDL (ox-LDL) and initiates the atherosclerotic process in the vessel wall (see Fig. 44.2). Abbreviations: O2−, superoxide; NO, nitric oxide; ONOO−, peroxynitrite; H2O2, hydrogen peroxide; OH−, hydroxyl radical; SOD, superoxide dismutase; GSH, reduced glutathione; GSSG, oxidised glutathione; VSM, vascular smooth muscle

had an effect on the adhesion of blood cells to the endothelium, the polymorphism could be of interest with respect to association studies in a number of pathological conditions, such as cardiovascular diseases. The $Ser^{128}Arg$ polymorphism is associated with a higher risk for early severe atherosclerosis. Yoshida et al. (2003) suggested that the E-selectin $Ser^{128}Arg$ polymorphism could functionally alter leukocyte-endothelial interactions as well as biochemical and biological consequences, which may account for the pathogenesis of myocardial infarction (Li et al. 2005).

Leu^{554}Phe E-selectin mutations in Hypertension and CAD

Wenzel et al. (1996, 1999) detected 17 mutations, five of which resulted in an amino acid substitution. In E-selectin, exchange at $Ser^{128}Arg$ in EGF domain and $Leu^{554}Phe$ in membrane domain, and a DNA mutation from guanine to thymine (position 98) presented different allele frequencies in young patients with severe atherosclerosis, compared with an unselected population. The bi-allelic A/C polymorphism in the E-selectin gene may be implicated in the clinical expression of erythema nodosum (EN) secondary to sarcoidosis (Amoli et al. 2004). However, the E-selectin polymorphism may be associated with severity of atherosclerotic disease, but it is unknown if it is actually a risk factor for atherosclerosis (Ghilardi et al. 2004). **A** strong relationship was confirmed between 561A > C and 98G > T polymorphisms of E-selectin gene and susceptibility to CAD by Zak et al. (2008). A body mass index (BMI)-specific effect of $Leu^{554}Phe$ polymorphism of E-selectin gene on blood pressure has been reported by Marteau et al. (2004) who strengthened the view that E-selectin is implicated in hypertension (Marteau et al. 2004). Serum levels of E- and P-selectin in patients with essential hypertension (EH) are significantly higher than in controls, where as differences in serum levels of soluble L-selectin, VCAM-1, or ICAM-1 between the patients with EH and the controls were not different (Sanada et al. 2005).

44.3.4.4 Genomic Arrangement of P-Selectin Gene

P-Selectin Thr^{715}Pro (A/C) Polymorphism

Genetic analyses of P-selectin in the progression of atherosclerosis have provided conflicting results regarding the role of variation within the P-selectin gene and risk for heart disease. Miller et al. (2004b) suggested that the $Thr^{715}Pro$ C allele was rare in blacks (0.8 %) and intermediate in South Asians (3.0 %) compared to whites (11.2 %). sP-selectin levels were significantly lower in the individuals with the AC or CC compared to the AA genotype in both whites and South Asians. Thus, in whites and South Asians the C allele of the $Thr^{715}Pro$ P-selectin polymorphism is associated with

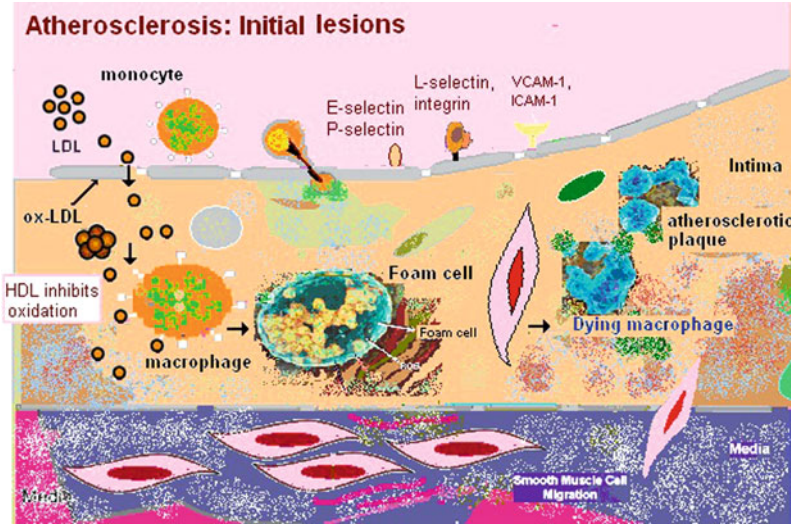

Fig. 44.2 Oxidation of LDL initiates the atherosclerotic process in the vessel wall by acting as a potent stimulus for the induction of inflammatory gene products in vascular endothelial cells. By activating the NF-kB transcription factor, oxidized LDL (ox-LDL) stimulates increased expression of cellular adhesion molecules. There are several different types of adhesion molecules with specific functions in the endothelial leukocyte interaction: The selectins tether and trap monocytes and other leukocytes. Importantly, VCAMs and ICAMs mediate firm attachment of these leukocytes to the endothelial layer. Ox-LDL also augments expression of monocyte chemoattractant protein 1 (MCP-1) and macrophage colony stimulating factor (M-CSF). MCP-1 mediates the attraction of monocytes and leukocytes and their diapedesis through the endothelium into the intima. M-CSF plays an important role in the transformation of monocytes to macrophage foam cells. Macrophages express scavenger receptors, which internalize oxLDL in their transformation into foam cells. Migration of smooth muscle cells (SMCs) from the intima into the media is another early event initiating a sequence that leads to formation of a fibrous atheroma

lower sP-selectin levels (Miller et al. 2004b). The P-selectin Thr^{715}Pro polymorphism is not associated with incident CHD or ischemic stroke in either whites or African-Americans (Volcik et al. 2006).

44.3.4.5 Predictive Value of sE-Selectin in CAD

In CAD, inflammatory biomarkers have been extensively investigated; more evidence exists for C-reactive protein (CRP; Chap. 8). Fatty acid (FA) composition in serum has been associated with CRP and E-selectin but not with other inflammatory markers (Petersson et al. 2009). Studies suggest that, besides CRP, other inflammatory biomarkers such as cytokines, s-CD40 ligand, serum amyloid A (SAA), selectins (E-selectin, P-selectin), ICAM-1, VCAM-1, and several others may have a potential role for the prediction of risk for developing CAD and may correlate with severity of CAD (Eikemo et al. 2004; Fang et al. 2004; Potapov et al. 2005; Zakynthinos and Pappa 2009). The combination of natriuretic peptide (BNP) and E-selectin offers increased predictive value. Plasma levels of adhesive molecules are correlated in patients with stable IHD. Cigarette smoke condensate (CSC)-induced surface expression of ICAM-1, E-selectin, and VCAM-1 in HUVEC. Fang et al. (2005) reported a significant decrease in C allele frequency of PECAM-1 gene and showed that Leu^{125}Val polymorphism of PECAM-1 gene and elevated soluble PECAM-1 were related to severe coronary artery stenosis in CAD patients.

44.3.5 Myocardial Infarction

sP-Selectin is Associated with Myocardial Damage: Platelets are known to be activated during myocardial infarction (MI). Though, the levels of sP-selectin, sE-selectin and sPECAM-1 did not differ significantly in the pathogenesis of atherosclerosis, sP-selectin was substantially increased in patients with acute myocardial infarction (AMI). Yip et al. (2006) tested the hypothesis that platelet activity shown by CD62P is enhanced and predictive of both the extent of myocardial damage and 30-day clinical outcome in patients with ST-se AMI undergoing primary coronary stenting. Xu et al. (2006) suggested that activated-platelets play an important role in the process of myocardial ischemia-reperfusion injury, and platelet-derived P-selectin is a critical mediator. P-selectin expression, along with CD40 ligand and tissue factor is significantly increased in infarcted rabbits with respect to controls. Clopidogrel administration reduced P-selectin expression and CD40 ligand (Molero et al. 2005).

Hyperhomocysteinemia and Selecins in MI: Hyperhomocysteinemia is regarded as an independent risk factor for vascular diseases, and homocysteine is supposed to contribute to oxidative stress and endothelial damage. Hyperhomocysteinemia is significantly associated with MI in comparison with controls with an odd ratio of 6.26 (Khare et al. 2005). Folic acid corrected and reduced hyperhomocysteinemia in a large majority of the cases. Although the levels of sP-selectin, sE-selectin and sPECAM-1 decrease after folic acid therapy, it was only sE-selectin which was significantly reduced. Apart from their lipid-lowering capacity, statins also exert anti-inflammatory and antioxidant effects.

DNA Polymorphism in MI: Some polymorphisms may increase the risk of MI within specific ethnic groups or in certain populations. P-selectin expression is increased in atherosclerotic plaques, and high plasma levels of this molecule have been observed in patients with unstable angina. DNA polymorphisms in P-selectin gene may be a possible candidate for MI. The P-selectin gene is situated on chromosome 1q21-q24, spans >50 kb and contains 17 exons. Four polymorphisms ($Ser^{290}Asn$, $Asn^{562}Asp$, $Leu^{599}Val$ and $Thr^{715}Pro$) predicted a change in the amino acid sequence of P-selectin. In patients with MI from four regions of France and Northern Ireland (the ECTIM study) the P-selectin polymorphisms provided a heterozygosity of 91 %. The polymorphisms were tightly associated with one another and displayed patterns of linkage disequilibrium suggesting the existence of highly conserved ancestral haplotypes. Study illustrates the complexity of the relationship between gene variability and disease and the necessity to explore in detail the polymorphisms of candidate genes (Herrmann et al. 1998; Tregouet et al. 2002).

The E-selectin gene Arg128, 98 T, and Phe554 alleles and PECAM1 $Leu1^{25}Val$ and $Ser^{563}Asn$ polymorphisms may increase the risk of atherosclerosis, but not necessarily the risk of MI. This association seems to be more pronounced in younger patients and may be especially important in patients with a low risk for developing atherosclerosis. Reports indicated that screening for CD14-260 C/T genotypes is unlikely to be a useful tool for risk assessment and it remains unclear whether CD14 polymorphisms significantly increase the risk of MI. The $A^{252}G$ polymorphism of lymphotoxin-α (LTA) gene, a member of the TNF family, is strongly related with the onset of AMI (Auer et al. 2003). Quantitative real-time RT-PCR confirmed that LTA increased the expressions of E-Selectin and VCAM1 both in HUVEC and HCAEC, suggesting the roles of LTA in the development of atherosclerosis. Aminian et al. (2007) determined the possible role of $Gly^{241}Arg$ and $Lys^{469}Glu$ polymorphisms in development of CAD and acute or chronic MI. Although the frequency of Gly-Arg and Arg-Arg genotypes were higher in the control group compared to the CHD patients, no strong corelation was found between $Gly^{241}Arg$ and $Lys^{469}Glu$ polymorphisms and occurrence of CHD and MI in population from Iran.

44.3.6 Atherosclerotic Ischemic Stroke

In ischemic event in patients with atherosclerotic ischemic stroke, though the platelet aggregability was decreased after day 3 compared to that at day 1 of stroke onset, platelet CD63 and P-selectin/CD62P expression remained high even 90 days after the events. This suggested that platelet hyperactivation in atherosclerotic ischemic stroke might be sustained for a considerable period (Cha et al. 2004; Nadar et al. 2004b; Yip et al. 2006). Blood levels of ICAM-1 and CD62P expression in different typing of patients with ischemic stroke are different. Evidences suggest that MPS (Meridian-phlegm stagnancy) group of patients is the key pathogenic factor of ischemic stroke.

Mucosal tolerance to E-selectin after booster tolerization can relieve cerebral ischemia-reperfusion injury and induce ischemia tolerance in rats. The mechanisms may involve decreased frequencies of $CD8^+$ T cells, heightened mRNA expression of IL-10 and lowered mRNA expression of E-selectin in the ischemic hemisphere (Yun et al. 2008). Selakovic et al. (2009) defined changes of soluble CAMS in cerebrospinal fluid and plasma in the patients with the acute brain infarction, in which significant increase in the level of soluble adhesion molecules occurs within the first seven days. Studies show that hypoxia/reoxygenation stimulates ICAM-1 and apoptosis (Antonova et al. 2009).

Cerebral arteriovenous malformations (AVMs) showed significant upregulation of E-selectin, VCAM-1 and ICAM-1 (Storer et al. 2008; Chan and Sukhatme 2008; Tuttolomondo et al. 2009). Li et al. (2008) showed that ICAM-1 $Lys^{469}Glu$ polymorphism was involved in the causation of ischemic stroke, especially in female but not in male (Rodrigues et al. 2008). Two allelic variants were related to ischemic stroke. Multivariable regression analysis after adjustment for vascular risk factors demonstrated that alleles Arg of $Ser^{128}Arg$ and Phe of $Leu^{554}Phe$ polymorphisms are independent risk factors for ischemic stroke. The combination of two minor alleles of E-selectin genes appeared to be the strongest susceptibility factor for ischemic stroke (Haidari et al. 2009). Sarecka-Hujar et al. (2010) could not confirm the relationship between the 98 G > T polymorphism of the E-selectin gene and childhood ischemic stroke. The G allele of the E- selectin 98 G > T polymorphism was more frequently transmitted to the children after stroke compared to the T allele. There is a need for further studies in these areas.

44.3.7 Hypertension

The association between blood pressure and different adhesion molecules appeared to be present in women younger than 50 years, who were likely to be pre-menopausal (Miller et al. 2004a). Serum levels of E- and P-selectin in patients with essential hypertension (EH) are significantly higher than in the controls (Sanada et al. 2005). After adjustment for age, only sE-selectin concentrations were significantly associated with blood pressure. Higher levels of plasma sP-selectin were confirmed in hypertensive patients alone with VEGF (Nadar et al. 2004a). It is stated that decrease in blood pressure may reduce the rate of progression of atherosclerosis by affecting the expression of E- and P-selectin in the endothelium, the platelets, or both.

44.3.8 Reperfusion Injury

In vitro studies indicate that complement activation regulates the expression of P-selectin on endothelial cells. This suggests that in disorders such as ischemia/reperfusion injury, in which both complement and P-selectin have been shown to play a role, complement activation is a primary event and the effects of P-selectin are secondary. In mouse kidney model of I/R injury, results indicated that complement and P-selectin-mediated pathways of renal reperfusion injury are mutually independent (Farrar et al. 2004). Induction of circulating polymorphonuclear neutrophils (PMNs) might contribute to the superior outcome following stenting and early intervention compared to conventional balloon angioplasty (PTCA). A substantial increase in sE-selectin levels early after PTCA and stent implantation may predict development of restenosis (Heider et al. 2006; Kilickap et al. 2004). After reperfusion of myocardial vessels, P-selectin expressed on majority of vessels (77 %) though the expression decreased during subsequent remaining duration of reperfusion (Chukwuemeka et al. 2005). In rats, the mRNA expression for several genes was associated with inflammation after transient middle cerebral artery occlusion (MCAO). Gene expression increased in the injured hemisphere for IL-1β, IL-6 and ICAM-1. TNF-α mRNA was upregulated in the injured versus uninjured hemisphere, while E-selectin mRNA showed a significant increase from 6 to 24 h after MCAO (Berti et al. 2002). Both P-selectin and LFA-1 may be important targets to control pathologic inflammation in I/R-induced tissue injury in the colon (Riaz et al. 2002). The study in intestinal ischemia and reperfusion injury (IR/I) using murine models demonstrated the importance of P-selectin in warm and cold IR/I. The blockade of P-selectin using rPSGL1-lg or the absence of P-selectin KO mice confers a survival advantage and reduction in tissue injury. The mechanism appears to be independent of neutrophil infiltration (Carmody et al. 2004). Enterocyte apoptosis is increased following intestinal I/R injury. Hyperoxia following intestinal I/R in rat increased E-selectin expression in the jejunum and ileum and a concomitant increase in neutrophil recruitment in the ileum, accompanied by increased cell apoptosis (Braun et al. 2004; Sukhotnik et al. 2008). Germ cell-specific apoptosis that occurs after I/R of murine testis is dependent on neutrophil recruitment to the testis and is dependent on E-selectin. Blockage of E-selectin may be a strategy to treat post-ischaemic testis (Celebi and Paul 2008).

44.4 CAMS in Allergic Inflammation

Allergic inflammation is characterized by recruitment of specific leukocyte subpopulations from blood into tissue and requires a series of cell adhesion-molecule-mediated interactions between postcapillary vascular endothelium and the leukocyte cell surface. Three major groups are involved: selectins, integrins, and the immunoglobulin gene superfamily. P- and E-selectin mediate initial leukocyte adhesion, whereas beta 2-integrin/ICAM-1 and VLA-4/VCAM-1 pathways mediate leukocyte arrest and transendothelial migration. Because VLA-4 expression is restricted to eosinophils and lymphocytes, VCAM-1 has been implicated in selective eosinophil recruitment characterizing allergic inflammation. However, additional factors such as profile of cytokine release are likely to operate since tissue eosinophilia has been observed in the absence of VCAM-1 expression (Smith et al. 1993a).

44.4.1 Dermal Disorders

E-selectin is highly expressed on vascular endothelium in atopic dermatitis and psoriasis, and in patients with measles. The cutaneous lymphocyte-associated antigen (CLA), which is expressed on peripheral skin-homing helper memory T cells in healthy persons, is at least partly the sialyl 6-sulfo Le^x determinant (Ohmori et al. 2006) and a ligand for selectins. The differential polyadenylation of E-selectin transcripts may provide the molecular basis for the observed chronic expression of E-selectin in human dermal disorders. In atopic dermatitis, patients express ICAM-1 and ICAM-3, E-selectin and L-selectin (60 %) in the dermis, without expression of E- and L-selectins in the epidermis. A high expression of adhesion molecules in the skin lesions of atopic dermatitis patients may play an important role in the pathogenesis of atopic dermatitis (Lugovic et al. 2006). The blood markers for atopic dermatitis, including soluble forms of E-selectin, VCAM-1 and ICAM-1 were reduced after treatment with cetiridine (Izu and Tokura 2005). The extracts from dust

mites, *Dermatophagoides farinae*, *D. pteronyssinus* and *Euroglyphus maynei* with and without endotoxin (LPS) stimulated endothelial cells to express ICAM-1, VCAM-1, and E-selectin and to secrete IL-6, IL-8, MCP-1, and GM-CSF. Serum levels of sE-selectin are higher in children with measles than in children with atopic dermatitis, atopic asthma and healthy controls. But it was not correlated with measles. There was no correlation between sE-selectin and TNF-α level (Park et al. 2008). Pollinosis from Parietaria judaica is one of the main causes of allergy in the Mediterranean area. The treatment of endothelial cells with pollen extract causes an increase of E-selectin and VCAM-1 protein levels as well as an increase of IL-8 production. The stimulation of cell adhesion molecules was paralleled by an increase of adhesion of polymorphonuclear cells (PMNs) to HMVEC-L monolayer (Taverna et al. 2008).

44.4.2 Rhinitis and Nasal Polyposis

Allergic rhinitis is an inflammatory disease of the nasal mucosa, caused by an IgE-mediated reaction after exposure to the allergen. Persistent inflammation is induced by the presence of an inflammatory cell infiltrate, together with ICAM-1 expression in the epithelial cells of the mucosa exposed to the allergen to which they are sensitized, in the absence of clinical symptoms (Montoro et al. 2007). Nasal polyposis is a chronic non-infectious inflammatory disease of the nasal and paranasal cavity mucosa. Eosinophil migration from blood stream to nasal polyps involves different molecules such as ICAM-1, VCAM-1, and L-, P- and E-selectins. Patients with nasal polyposis exhibit a higher expression of VCAM-1, E-selectin, and L-selectin compared to healthy controls (Corsi et al. 2008). *Staphylococcal enterotoxin A* (SEA) and staphylococcal enterotoxin B (SEB) infection increased ICAM-1 expression and cytokine secretion (Wang et al. 2007).

44.4.3 Lung Injury

Excessive leukocyte accumulation is involved in the pathogenesis of the sepsis-induced acute lung injury. Studies suggest that P-selectin has a substantial role in the pathogenesis of the lung injury induced by LPS (Ohnishi et al. 1999). In bleomycin-induced fibrosis in mice, the L-selectin and/or ICAM-1 deficiency inhibited skin and lung fibrosis with decreased Th2 and Th17 cytokines and increased Th1 cytokines. In contrast, P-selectin deficiency, E-selectin deficiency with or without P-selectin blockade, or PSGL-1 deficiency augmented the fibrosis in parallel with increased Th2 and Th17 cytokines and decreased Th1 cytokines. Yoshizaki et al. (2010) suggest that L-selectin and ICAM-1 regulate Th2 and Th17 cell accumulation in skin and the lung, leading to the development of fibrosis, and that P-selectin, E-selectin, and PSGL-1 regulate Th1 cell infiltration, resulting in the inhibition of fibrosis (Yoshizaki et al. 2010). Adult respiratory distress syndrome (ARDS) appears to develop as the acute lung injury in the course of many severe diseases, as the result of damage of alveolar-capillary barrier. Clinical observations suggest that analysis of E-, P-selectin and ICAM-1 concentrations in the serum of patients with ARDS may be helpful in monitoring the course and treatment of the disease (Skiba-Choińska and Rogowski 1996). In the pathogenesis of paracoccidioidomycosis, Gonzalez et al. (2005) suggest that during early stages, up-regulation of ICAM-1, VCAM-1, CD18 and Mac-1 expression may participate in the inflammatory process.

44.4.4 Bronchial Asthma and Human Rhinovirus

The house dust mite (HDM) is the common indoor allergen associated with bronchial asthma. ICAM-1, VCAM-1, and E-selectin are newly synthesized prior to spontaneous asthma attacks, and their expression may play a key role in eosinophil infiltration into the airway (Ohkawara et al. 1995). Crude extract of *D. farinae* induces ICAM-1 expression in EoL-1 cells through signaling pathways involving both NF-kB and JNK (Kwon et al. 2007). Kirchberger et al. (2006) demonstrated that signaling via ICAM-1 induces adhesiveness of mononuclear phagocytes, which critically involves PECAM-1 and is mediated via LFA-1/ICAM-3. The most common acute infection in humans, Human Rhinovirus (HRV) is a leading cause of exacerbations of asthma and chronic obstruction pulmonary disease. ICAM-1 is a critical target-docking molecule on epithelial cells for 90 % HRV serotypes. ICAM-1 regulates not only viral entry and replication but also signaling pathways that lead to inflammatory mediator production (Lau et al. 2008; Lee et al. 2008). The sICAM-1 but not sE-selectin from patients with asthma is significantly higher than healthy controls. Although serum levels of sICAM-1 are higher in asthmatics, it may be necessary to establish individual baseline values for serial estimation to evaluate their clinical relevance (Bijanzadeh et al. 2009). The serum levels of sICAM-1 were significantly higher in obese nonasthmatic and obese asthmatic children versus control and lean asthmatic children (Huang et al. 2008). P-selectin is an important controller of the inflammation by mediating selective eosinophil cell influx to the lung. It can be used as a sensitive marker in mild asthma (Sjosward et al. 2004).

44.5 Autoimmune Diseases

Adhesion molecule expression and interactions are involved in initiation and propagation of autoimmune diseases including rheumatoid arthritis (RA), systemic lupus erythematosus, Sjögren's syndrome, autoimmune thyroid disease, multiple sclerosis, systemic sclerosis (SSc) and diabetes mellitus. Increased adhesion molecule expression and avidity changes occurring with cellular activation are the principal methods regulating leukocyte adhesion. Although differences between specific autoimmune diseases exist, key interactions facilitating the development of autoimmune inflammation appear to include L-selectin/P-selectin/E-selectin, LFA-1/ICAM-1, very late antigen-4 (VLA-4)/VCAM-1, and α4B7/MadCAM or VCAM-1 adhesion. A vast array of adhesive interactions occurs between immunocompetent cells, endothelium, extracellular matrix, and target tissues during the evolution of an autoimmune disease. Dermatitis herpetiformis (DH) and bullous pemphigoid (BP), the autoimmune diseases, are characterized by destruction of the basement membrane zone (BMZ) and anchoring fibres by autoantibodies and infiltration. Skin biopsies from patients with DH, with BP, and from healthy subjects showed the expression of E and L selectins mainly in the skin leukocytes in all samples where as β1, β3 integrins was detected mainly in basal keratinocytes. Integrins and selectins seem to play an important role in the destruction of BMZ in DH and BP (Erkiert-Polguj et al. 2009). P-selectin levels were significantly higher than normal in RA and SSc, but not in SLE. In contrast, mean L-selectin levels were significantly higher than normal in SLE, but not in RA or SSc. Where as soluble IL-2 receptors in patients with active RA, SSc and SLE were almost double the normal level, showing a strong positive correlation only between L-selectin and sIL-2R, and only in patients with SLE. These findings indicated a distinct pattern of immune cell activation in chronic diseases that share an over-activation of T-lymphocytes (Sfikakis and Mavrikakis 1999).

44.5.1 Endothelial Dysfunction in Diabetes (Type 1 Diabetes)

Adhesion molecules have been implicated in the development and progression of cardiovascular disease, particularly in people with diabetes. Diabetes mellitus type 1 (Type 1 diabetes or T1DM, also called insulin-dependent diabetes mellitus—IDDM, or, formerly, juvenile diabetes) is a form of diabetes mellitus that results from autoimmune destruction of insulin-producing β cells of the pancreas. The chronic hyperglycemic state in T1DM patients produces an aggression to vascular endothelium leading to a premature development of atherosclerosis. In both boys and girls, sE-selectin is an early marker of endothelial dysfunction and a probable risk marker of atherosclerosis in children with T1DM (Carrizo et al. 2008). The levels of C-reactive protein, E-selectin, and cytokines in association with severity index were significantly increased in T1DM and type 1 diabetic patients with microvascular complications (T1DM-MV patients) compared with control subjects (Devaraj et al. 2007). Nerve microvasculitis and ischemic injury appear to be the primary and important pathogenic alterations in lumbosacral radiculoplexus neuropathy (LRPN) of patients with diabetes mellitus (DLRPN) and without diabetes mellitus (LRPN). The up-regulation of inflammatory mediators target different cells at different disease stages and that these mediators may be sequentially involved in an immune-mediated inflammatory process that is shared by both DLRPN and LRPN (Kawamura et al. 2008).

Adhesion molecules are upregulated in endothelial cells of the placental bed in pregnancies complicated by T1DM in association with increased adherence of peripheral blood monocytes. The increase in monocyte adhesion to decidual endothelial cells from diabetic pregnancies was associated with increased endothelial cell expression of ICAM-1, but not VCAM-1. ICAM-1 expression in normal decidual endothelial cells was stimulated by pro-atherogenic and pro-inflammatory stimuli (Xie et al. 2008; Telejko et al. 2009).

Type 2 Diabetes: In contrast to T1DM, type 2 diabetes mellitus (T2DM) results from insulin resistance, a condition in which cells fail to use insulin properly, sometimes combined with an absolute insulin deficiency (Formerly referred to as non-insulin-dependent diabetes mellitus, NIDDM for short). Endothelial dysfunction in type 2 diabetic patients is associated with inflammation, increased levels of circulating soluble adhesion molecules (VCAM-1 and E-selectin), and inducing production of ROS, and urinary albumin excretion (Potenza et al. 2009). Diabetic patients have increased susceptibility to infection, which may be related to impaired inflammatory response observed in experimental models of diabetes, and restored by insulin treatment (Riad et al. 2008; West et al. 2008).

Serum Levels of CAMs in Diabetic Patients: Abnormal levels some of serum ICAM-1, VICAM-1, E-selectin, P-selectin, L-selectin have been detected in T2DM. High-fat load and glucose alone produce an increase of nitrotyrosine, ICAM-1, VCAM-1, and E-selectin plasma levels in normal and diabetic subjects. A decrease in neutrophil surface CD62L expression and significantly higher concentrations of sICAM-1, sVCAM-1, sE-selectin, vWF, hsCRP, IL-6 and fibrinogen in patients with diabetic microangiopathy in comparison with diabetic group without microangiopathic complications and

healthy controls suggested that: (1) diabetic microangiopathy is accompanied by increase in CD11b expression and decrease in CD62L (L-selectin) expression on peripheral blood neutrophils; (2) neutrophil activation and intensified adhesion; (3) the development of diabetic microangiopathy is accompanied by an increase in soluble adhesion molecules and inflammatory markers concentrations in the blood (Lim et al. 2004; Mastej and Adamiec; 2008). Levels of E-selectin positively correlated with high triglyceride levels in type 2 diabetic subjects with silent ischemia (Adamikova et al. 2008; Okapcova and Gabor 2004; Rubio-Guerra et al. 2008). Though, baseline plasma levels of vascular markers (hsCRP, sICAM-1, sVCAM-1, E-selectin and P-selectin) were significantly elevated, they did not improve after aerobic exercise. The sE-selectin and vWF are elevated in chronic heart failure patients with DM but not in those without DM. High sE-selectin levels may be associated with ischaemic events in patients with DM (Kistorp et al. 2008).

Diabetic Nephropathy (DN) and Diabetic Heart: Diabetic nephropathy (DN) is the leading cause of end stage renal disease (ESRD) (Malatino et al. 2007). Although the pathogenesis of DN is multifactorial, local inflammatory stress may result from both the metabolic and hemodynamic derangements observed in DN. The current evidence supporting the role of inflammation in the early phases of clinical and experimental DN has been reviewed (Fornoni et al. 2008). Inflammatory markers such as IL-18 and TNF-α are increased in the serum of patients with diabetes and DN. This occurs at an early stage of disease, and correlates with the degree of albuminuria. The pharmacologic interventions for DN by angiotensin converting enzyme inhibitors, angiotensin receptor blockers and aldosterone antagonists may have anti-inflammatory effects, which are independent of their hemodynamic effect.

Diabetic Retinopathy: The association between soluble adhesion molecules levels and retinopathy in type 2 diabetic patients has been clarified. sE-selectin levels are elevated in diabetic patients compared to control subjects, with no significant difference in sICAM-1 and sVCAM-1 levels. The progression of retinopathy was not associated with an increase in soluble adhesion molecules. However, Nowak et al. (2008) observed that serum levels of sICAM-1 and sELAM-1 were significantly elevated and the concentration sVCAM-1 was elevated but not significantly in diabetic patients. Increase in sICAM-1 and sVCAM-1 levels, as well as their correlation with high vitreous IL-6 and TNF-α concentrations in patients with diabetic retinopathy seems to confirm the inflammatory-immune nature of this process. Significantly increased TNF-α concentration in the vitreous body was related to the rise of VCAM-1 (Adamiec-Mroczek and Oficjalska-Młyńczak 2008; Leal et al. 2008; Khalfaoui et al. 2008). Intravitreal injection of corticosteroid has been used to treat diabetic macular edema.

44.5.2 Rheumatic Diseases

Plasma levels of vWF and sP-selectin (but not sE-selectin) are significantly higher among Rheumatoid disease (RD) patients compared to controls. Levels of vWF progressively rise with increasing cardiovascular risk (Bhatia et al. 2009). Serum levels of ICAM-1, ICAM-3, VCAM-1, L-selectin, and E-selectin have been detemined in children with a variety of pediatric rheumatic diseases. A trend toward higher levels of sE-selectin was found in vasculitis vs other diagnoses. The sICAM-1 was higher in patients with active vs inactive disease across all diagnoses. Report suggests that (1) elevated E-selectin levels in vasculitis likely reflect the high degree of endothelial activation and possibly overt vascular damage in those conditions. (2) The correlation of sL-selectin with C4 in SLE may indicate that downregulation of shedding of cell surface L-selectin is involved in continued adherence of leukocytes to endothelium, possibly causing further damage and immune complex deposition in this condition. (3) The trend toward inverse correlation between sE-selectin and vWF:Ag in diabetes mellitus is interesting. (4) Levels of sICAM- I may be a useful marker of active vs quiescent disease in general in the pediatric rheumatic diseases, although lack of correlation with disease activity indices indicates that it is too insensitive to smaller differences in disease activity to be recommended for routine clinical use (Bloom et al. 2002).

44.5.3 Rheumatoid Arthritis

Considerable evidence indicates that patients with Rheumatoid arthritis (RA) are at greater risk of developing atherosclerosis and cardiovascular disease. Atherosclerotic cardiovascular mortality is increased in RA patients. The markers proposed for assessing RA activity include rheumatoid factor, anti-citrullinated protein/peptide antibodies, IgM anti-IgG advanced glycation end products, markers of bone/cartilage metabolism, mannose-binding lectin, E-selectin, IL-6, and leptin. Various studies have investigated the correlation between some of these markers and other variables that might indicate disease activity, e.g., inflammatory activity tests and disease activity scores. However, there is as yet insufficient evidence that any of these markers, in isolation or in combination, are useful in the assessment of RA activity. Many numerous endothelial cells become positive for E-selectin and E-selectin mRNA in RA synovial membranes

and the E-selectin expression appeared to correlate with inflammatory activity. P-selectin deficiency in mice resulted in accelerated onset of joint inflammation in the murine collagen-immunized arthritis model. Mice deficient either in E-selectin or in E- selectin and P-selectin (E/P-selectin mutant) also exhibit accelerated development of arthritis compared with wild type mice in CIA model. The strong vascular expression of E-selectin indicates an activation of endothelial cells in the recruitment of cells associated with the chronic inflammation of RA (Foster et al. 2009; da Mota et al. 2009). E-Selectin and ICAM-1 are upregulated on the synovial endothelium, while VCAM-1 plays an important role in synovial lining layer cells and within the synovial stroma. The expression of CAMs may be blocked by mAbs and modified by nonsteroidal anti-inflammatory drugs and disease-modifying antirheumatic drugs. (Cobankara et al. 2004). Serum soluble adhesion molecules concentrations are down-regulated following anti-TNF-α antibody therapy combined with methotrexate (MTX) (Klimiuk et al. 2004, 2007; Levälampi et al. 2007; Bosello et al. 2008).

In comparison with osteoarthritis (OA), patients with early RA are characterized by high serum concentrations of sICAM-1, sVCAM-1, and sE-selectin (Yildirim et al. 2005), while LDL-cholesterol was decreased in all RA patients (Pemberton et al. 2009). P-selectin deficiency in mice results in accelerated onset of joint inflammation in the murine collagen-immunized arthritis model. Mice deficient either in E-selectin or in E-selectin and P-selectin (E/P-selectin mutant) also exhibit accelerated development of arthritis compared with wild type mice, suggesting that these adhesion molecules perform overlapping functions in regulating joint disease. Ruth et al. (2005) suggested that E-selectin and P-selectin expression can significantly influence cytokine and chemokine production in joint tissue, and that these adhesion molecules play important regulatory roles in the development of RA in E/P-selectin mutant mice (Singh et al. 2008).

In RA patients, P-selectin expression, PMC and sCD40L levels were increased when compared with controls. The increase in markers of active platelets, P-selectin and sCD40L, and platelet-monocyte levels might be associated with the increased cardiovascular mortality in RA. Psoriatic arthritis (PsA) is associated with the development of endothelial dysfunction and increased atherosclerotic complications. Endothelial activation might have a role in the pathogenesis of both psoriasis and PsA. Among parameters of platelet activation, only PMC might play a role in the pathogenesis of PsA (Pamuk et al. 2008, 2009). Though, sE-selectin correlated with severity of joint disease, further follow-up studies should evaluate if sE-selectin is useful as prognosis marker for progression of articular damage (Corona-Sanchez et al. 2009).

44.5.4 Other Autoimmune Disorders

Systemic Lupus Erythematosus (SLE): Elevated serum concentrations of ET-1, s-thrombomodulin (TM), and sE-selectin reflect persisting endothelial cell activation in SLE, and point to an important role of ET-1 in the pathogenesis of internal organ involvement (Kuryliszyn-Moskal et al. 2008). The s-E-selectin, TM and s-VCAM-1 are significantly elevated in lupus nephritis (LN) with renal vascular lesions (VLS) than in LN without VLS. A positive correlation was found between TM and serum creatinine in patients with vascular lesions. Therefore, serum TM and s-VCAM-1 can be biomarkers of VLS in LN patients (Yao et al. 2008, Rho et al. 2008).

Autoimmune Thyroiditis: Autoimmune thyroiditis is multifactorial in etiology with genetic and environmental factors contributions. Patients with untreated Graves' disease (GD) show high serum level of sE-selectin, which correlated with the activity of the disease. The expression of ICAM-1 and VCAM-1 was increased in EC from patients from Graves' disease (GD) and Hashimoto's thyroiditis (HT). Results suggest that both the LFA-1/ICAM-1, ICAM-3 and VLA-4/VCAM-1 pathways could play a relevant role in autoimmune thyroid disorders (Marazuela et al. 1994). In patients with GD, the 721 G-A polymorphism was associated with an earlier age of GD onset (before age 40) and that the 1405A-G polymorphism could predispose to Graves ophthalmopathy. It was concluded that G241R and K469E amino acid substitutions in the ICAM1 molecule could influence the intensity/duration of the autoimmunity process and the infiltration of orbital tissues (Kretowski et al. 2003). Chen et al. (2008) suggested that common *SELE* variants may be associated with susceptibility to GD in Chinese population, though the limitation of sample size and multiple test problems exists (Chen et al. 2008).

Sjogren's Syndrome: CAMs are involved in the lymphoid cell infiltration of the salivary and lacrimal glands in Sjogren's syndrome (SS) patients. Biopsies from SS patients showed a marked expression of VCAM-1 and ICAM-1 in the venules surrounded by infiltrated $CD4^+$ $CD45RO^+$ T cells. E-selectin was expressed on vascular endothelium with weak intensity (Saito et al. 1993). Pisella et al. (2000) reported that a significant increase of HLA-DR and ICAM1 expression by epithelial cells was consistently found in patients with keratoconjunctivitis sicca (Sjogren syndrome). These markers were well correlated with each other and correlated inversely with tear break-up time and tear production. Cytokine-mediated up-regulation of VCAM-1 and ICAM-1 that facilitates the recruitment of VLA-4 and LFA-1 expressing T cells might contribute to lymphoid cell infiltration in the salivary and lacrimal glands in SS

44.6 CAMs in System Related Disorders

44.6.1 Gastric Diseases

CAMs mediate the extravasation of leukocytes and their accumulation in inflamed intestinal mucosa. Eosinophilic inflammation is a common feature of numerous eosinophil-associated gastrointestinal (EGID) diseases. Increased intestinal expression of E-selectin has been associated with multiple organ failure and an adverse outcome. VCAM-1 is not altered in in mucosa of patients with inflammatory bowel disease (IBD) regardless of the activity of the inflammatory process. In contrast, E-selectin was not detected in normal colonic mucosa or in colonic mucosa of patients with IBD. However, high levels of E-selectin were consistently found on endothelial surfaces in association with active inflammation in affected areas of colonic mucosa in patients with either ulcerative colitis or Crohn's colitis. In addition, E-selectin appeared to be present within neutrophils which had migrated into crypt abscesses in affected mucosa. Thus E-selectin may play an important role in facilitating leukocyte migration into sites of active IBD involvement (Koizumi et al. 1992)

ICAM-1 was expressed to a greater degree in ulcerative colitis (UC) specimens. Serum ICAM-1 levels in UC patients showed lower levels than those in the control group and were found to vary according to degree of clinical severity (Ogawa et al. 2008). Characterization of integrin expression on colonic eosinophils revealed that colonic CC chemokine receptor 3^+ eosinophils express ICAM-1 counter-receptor integrins αL, αM, and β2. It appears that β2-integrin/ICAM-1-dependent pathways are integral to eosinophil recruitment in colon during GI inflammation associated with colonic injury (Forbes et al. 2006).

McCafferty et al. (1999) examined the role of P-selectin in intestinal inflammation in P-selectin deficient mice alone or in combination with either ICAM-1 or E-selectin and suggested that anti-adhesion therapy might play only a limited, beneficial role and often a detrimental role in intestinal inflammation. The sE-selectin levels of Crohn's disease patients with active disease are higher than those with remission of the disease. L-selectin does not change in patients with active disease compared to those with remission. Thus, determination of sE-selectin in children with Crohn's disease is of significance in estimation of inflammation activity (Adamska et al. 2007).

Khazen et al. (2009) investigated mutations in CAM genes in Tunisian patients, implicated in determining susceptibility to ulcerative colitis (UC) and Crohn's disease (CD). A significant increase in allele frequencies of 206 L of L-selectin and the associated genotype F/L was observed in patients with UC and CD compared with controls; the L206 allele and F/L206 genotype frequencies were significantly increased in UC patients with left-sided type; whereas, the F/L206 genotype was significant in CD patients with ileocolonic location. No significant differences in allele or genotype frequencies were observed for ICAM-1 K469E, E-selectin, and PECAM-1 polymorphisms between UC patients, CD patients, and controls. Khazen et al. (2009) suggest an association of inflammatory bowel disease with allele L206 of L-selectin gene, whereas genotype L/F was associated with a subgroup of UC (left-sided type) and CD patients with more extensive location of disease and stricturing behavior.

However, Vischer et al. (2008) did not reveal any difference in mRNA and protein expression levels for any construct or a major impact of missense variants on ICAM-1 biological function. Pulse-chase experiments showed that two variants, K469E and arg478 to trp (R478W), had a prolonged half-life compared with wildtype ICAM1, whereas two other variants, G241R and pro352 to leu (P352L), had a decreased half-life, implying differences in protein degradation.

Celiac Disease: Celiac disease is a chronic intestinal inflammatory disease that develops in genetically susceptible individuals after gluten ingestion. The *ICAM-1* gene, located in the Celiac disease linkage region 19p13, encodes ICAM-1 involved in inflammatory processes. Increased levels of ICAM-1 were observed in intestinal biopsies and in sera of Celiac disease patients. In addition, an association between the ICAM1 polymorphism G241R and Celiac disease patients has been described in a French population.though, in spanish population results discard the importance of ICAM1 G241R in celiac disease (Dema et al. 2008).

Behçet Syndrome: Behçet's disease/syndrome (BD/BS) is a multisystemic inflammatory disorder of which oral aphthous ulceration is a major feature. CD3 and γδ T-cell expression and other adhesion molecules including VCAM-1 and ICAM-1 were upregulated, whereas CD40 showed little change in BD. The changes in cell-cell and cell-extracellular matrix interactions may affect cell homeostasis and participate in the formation of oral ulcers in BD (Kose et al. 2008). However, Demirkesen et al. (2008) found no significant differences between the BS and control groups in regard to E-selectin, P-selectin, VCAM-1, PNCAM-1 except for ICAM-1.

Systemic Sclerosis or Systemic Scleroderma: Systemic sclerosis or systemic scleroderma is a systemic autoimmune disease or systemic connective tissue disease that is a subtype of scleroderma. Severe fibrosis and increased expression of profibrotic cytokines are important hallmarks in the gastric wall of patients with systemic sclerosis (SSc; scleroderma). The $CD4^+/CD8^+$ T cell ratio is significantly increased in SSc specimens. T cells strongly express the activation markers

VLA-4, LFA-1, and ICAM-1. Endothelial cells showed corresponding surface activation with strong expression of VCAM-1 and ICAM-1. These results provide the evidence that endothelial/lymphocyte activation leading to prominent $CD4^+$ T cell infiltration may play a key pathogenetic role within the gastric wall of patients with SSc (Manetti et al. 2008). In patients with SSc with and without pulmonary arterial hypertension (PAH), serum sICAM-1, sVCAM-1, sP-selectin and sPECAM-1 levels were higher than in healthy donors (HD) at baseline and fell to normal values after 12 months of bosentan therapy. Endothelial activation occurs in SSc, and that changes in the T cell/endothelium interplay take place in SSc-associated PAH. Bosentan seems to be able to hamper these changes and restore T cell functions in these patients (Iannone et al. 2008).

44.6.2 Liver Diseases

Soluble adhesion molecules play a significant role in hepatitis. Biliary atresia (BA) is a congenital or acquired liver disease and one of the principle forms of chronic rejection of a transplanted liver allograft. In the congenital form, the common bile duct between the liver and the small intestine is blocked or absent. The acquired type most often occurs in the setting of autoimmune disease, and is one of the principle forms of chronic rejection of a transplanted liver allograft. The serum sE-selectin of BA patients was higher than that of controls. Subgroup analysis showed that there was an increase in sE-selectin levels of BA patients with jaundice compared to those without jaundice. Also, sE-selectin was positively correlated with serum alanine transferase (ALT), a marker for liver injury, but not with serum gamma glutamyl transpeptidase (GGT) (Vejchapipat et al. 2008).

Cholangitis without a modifier—from Greek *chol-*, bile + *ang-*, vessel + *itis-*, inflammation) is an infection of the bile duct (cholangitis). In secondary cholangitis, ICAM-1 expression is increased along with de novo VCAM-1 and E-selectin appearance on the endothelium of microvessels in chronic exacerbated cholangitis (Gulubova et al. 2008).

Primary biliary cirrhosis (PBC) is an autoimmune disease of the liver marked by the slow progressive destruction of the small bile ducts (bile canaliculi) within the liver. Patients with PBC, primary sclerosing cholangitis and chronic active hepatitis (autoimmune) show significant increase in sICAM-1 compared with normal healthy subjects. Significant elevation in sICAM-1 is also detected in patients with inactive alcoholic cirrhosis, suggesting that impaired liver may, in part, account for the increased serum level in patients with autoimmune liver disease. In contrast, sE-selectin did not differ significantly from healthy controls. Although, peripheral blood mononuclear cells (PBMC) may be a source of sICAM-1, Thomson et al. (1994) suggested that PBMC may not be a significant source of sICAM-1 in this disease. The differential expression of CAMs in the liver is consistent with the suggestion of selectins involvement in neutrophil rolling in the vasculature and ICAM-1 in transendothelial migration and adherence to parenchymal cells (Essani et al. 1995).

Wu et al. (2009) investigated the relationships between the polymorphisms of E-selectin gene and plasma sE-selectin levels in relation to disease progression in a hepatitis B virus (HBV)-infected Chinese Han population. The frequency of C allele (AC or CC) of the $A^{561}C$ polymorphism was significantly increased in patients with liver cirrhosis (LC) compared to normal population. There was no difference in allele distribution of the $G^{98}T$ polymorphism. The $A^{561}C$ polymorphism of E-selectin gene may be associated with disease progression in patients with chronic HBV infection and control the expression of plasma soluble levels, while the $G^{98}T$ polymorphism may be related to fibrotic severity in Chinese population (Wu et al. 2009).

Mice with targeted deletion of the P-selectin gene developed unpolarized type 1/type 2 cytokine responses and severely aggravated liver pathology following infection pathogen *Schistosoma mansoni*. Liver fibrosis increased 6 fold, despite simultaneous induction of IFN-γ and increase in inflammation in absence of P-selectin. This suggested a critical role of P-selectin in the progression of chronic liver disease caused by schistosome parasites (Wynn et al. 2004).

44.6.3 Neuro/Muscular Disorders

Axonal degeneration was confirmed as the major pathological feature of critical illness polyneuropathy (CIP). Expression of E-selectin was significantly increased in endothelium of epineurial and endoneurial vessels, suggesting endothelial cell activation (Fenzi et al. 2003). Increasing evidence indicates that inflammatory responses are implicated in the pathogenesis of cerebral vasospasm after aneurismal subarachnoid hemorrhage (SAH). Murine SAH model provided the evidence of effective prevention of SAH-induced vasospasm by a mAb implied the possible role of E selectin in the pathogenesis of vasospasm after SAH (Lin et al. 2005).

Neuroinflammation is present in the substantia nigra (SN) of patients of Parkinson disease (PD). A large number of ICAM-1-positive reactive astrocytes have been observed in the SN of patients with neuropathologically confirmed PD, including three of familial origin. The ICAM-1-positive reactive astrocytes were mainly concentrated around residual neurons in areas of heavy neuronal loss and extracellular melanin accumulation (Miklossy et al. 2006). The sVCAM-1 plasma levels were higher in late onset Alzheimer's disease (LOAD) and vascular dementia (VD) compared with controls. Among patients (LOAD, VD, and not-dementia

(CDND), sE-selectin levels were higher in individuals with most severe cerebrovascular disease on CT scan. Increased sVCAM-1 plasma levels in LOAD and VD suggest the existence of endothelial dysfunction in both types of dementia. Results support the possible role of E-selectin in the pathogenesis of cerebrovascular disease (Zuliani et al. 2008).

44.6.4 Acute Pancreatitis

Upregulation of ICAM-1, LFA-1, Mac-1 and subsequent leukocyte infiltration appears to be significant events of pancreatic and pulmonary injuries in Acute pancreatitis (AP) (Sun et al. 2006). Proinflammatory cytokines and oxidative stress seem to be involved in the development of local and particularly systemic complications in AP patients. Acute pancreatitis patients show VCAM-1 and P-selectin concentrations significantly lower and L-selectin concentrations significantly higher than the healthy subjects. Only E-selectin was significantly higher in severe than in mild disease (Pezzilli et al. 2008). Kleinhans et al. (2009) showed that the endothelial cell expression of PECAM-1, VCAM, E-selectin, and P-selectin was upregulated in severe porcine pancreatitis. In acute pancreatitis, plasma levels of sE-selectin and soluble thrombomodulin (sTM) serve as endothelial markers; the former is an endothelial activation marker, while the latter is an endothelial injury marker (Chooklin 2009; Ida et al. 2009).

44.6.5 Renal Failure

In patients affected by microscopic polyangiitis (MPA) and associated with myeloperoxidase (MPO)-anti-neutrophil cytoplasmic antibodies (ANCA), higher sICAM-1 and sE-selectin levels during active phase and their slower decline during the treatment period, could be a prognostic risk factor for chronic renal failure development (Di Lorenzo et al. 2004; Musial et al. 2005). An increased level of sE-selectin in patients susceptible to restenosis supports a role for white blood cell/endothelial interaction in restenosis after angioplasty (Sainani and Maru 2005). The impairment of vascular endothelial function was obvious in uremic patients with maintaining hemodialysis (MHD). The changes of ICAM-1 and E-selectin could be accepted as biochemical criterions of vascular endothelial injury (Li et al. 2005). Diuresis, serum creatinine, urea, and enzyme elimination are pathological among patients with acute renal failure (ARF). Higher elimination rates of sICAM-1 and higher values of sE-selectin compared to patients without ARF indicated additional parameters for early signs of kidney damage (Dehne et al. 2008). Both circulating and urinary TNF-α levels are increased in inflammatory chronic renal diseases. TNF-α appeared to play a crucial role in the immunopathogenesis of nephritis by the induction of chemokine, ICAM-1 and VCAM-1 expression via the activation of the intracellular MAPK signaling pathway, which may contribute to macrophage and lymphocyte infiltration (Ho et al. 2008; Li et al. 2008).

SNPs in Selectin genes and IgA Nephropathy: Although intensive efforts have been made to elucidate the genetic basis of Ig A nephropathy (IgAN), genetic factors associated with the pathogenesis of this disease are not well understood. A case–control study, based on linkage disequilibrium among SNPs in selectin gene cluster on chromosome 1q24-25 revealed two SNPs in the E-selectin gene (*SELE8* and *SELE13*) and six SNPs in the L-selectin gene (*SELL1, SELL4, SELL5, SELL6, SELL10,* and *SELL11*), that were significantly associated with IgAN in Japanese patients. *SELE8* and *SELL10* caused amino acid substitutions from His to Tyr and from Pro to Ser for His-to-Tyr substitutions; and *SELL1* could affect promoter activity of the L-selectin gene. The TGT haplotype at these three loci was associated significantly with IgAN. These SNPs in selectin genes may be useful for screening populations susceptible to the IgAN phenotype. (Takei et al. 2002)

Transplant Rejection: Soluble adhesion molecules are not valuable markers for stable kidney graft (STx) rejection reaction. However, patients with chronic renal failure showed increased levels of adhesion molecules, which could reflect an impaired elimination (Alcalde et al. 1995). The expression levels of ICAM-1 and VCAM-1 show positive correlation with the severity of graft rejection and can provide evidence for early diagnosis and prevention of CR. Chronic allograft failure (CAF) is the major cause for late graft loss in renal transplantation. ICAM-1 polymorphisms may represent a predetermined genetic risk factor for CAF. This was substantiated by the polymorphism in exon 4 at the Mac-1 binding site and in exon 6 at fifth Ig-like domain (McLaren et al. 1999). Khazen et al. (2007) found no evidence for an association of any polymorphism with acute rejection in E- and L-selectin. During kidney reperfusion, E-selectin, ICAM-1, and VCAM-1 concentrations correlated positively with hypoxanthine concentrations during reperfusion, whereas concentrations of ICAM-1 correlated negatively with xanthine concentrations, indicating metabolic changes in renal tissue (Domanski et al. 2009).

44.6.6 Other Inflammatory Disorders

Serum CAM levels have been analyzed in many organ diseases, including diseases of nervous system, endocrine disorders and others. Immune dysfunction has been

proposed as a mechanism for pathophysiology of autistic-spectrum disorders. Levels of sP-selectin and sL-selectin were significantly lower in patients than in controls. Furthermore, sP-selectin levels were negatively correlated with impaired social development during early childhood (Iwata et al. 2008). In multiple sclerosis and in its animal model experimental autoimmune encephalomyelitis (EAE), inflammatory cells migrate across the endothelial blood–brain barrier (BBB) and gain access to the CNS. The role of E- and P-selectin in this process has been controversial. Döring et al. (2007) suggest that absence of E- and P-selectin did neither influence the activation of myelin-specific T cells nor the composition of the cellular infiltrates in the CNS during EAE. Thus, E- and P-selectin are not required for leukocyte recruitment across BBB and the development of EAE in C57BL/6 and in SJL mice (Döring et al. 2007). No significant differences in allelic or genotypic frequency in all the SNPs (rs6133, rs4987310 and rs5368 substitutions) tested were found in the Italian population (Fenoglio et al. 2009).

The pathophysiology of cluster headache (CH) is supposed to involve the lower posterior part of the hypothalamus, the trigeminal nerve, autonomic nerves and vessels in the orbital/retro-orbital region. Remahl et al. (2008) compared serum levels of sICAM-1, sVCAM-1 and sE-selectin in patients with episodic CH and in patients with biopsy-positive giant cell arteritis (GCA), a vasculitic disorder of large and medium-sized arteries. Within the CH group, sICAM-1, sVCAM-1 and sE-selectin showed an increasing trend in remission compared with active cluster headache period, but sE-selectin only was significant. Remahl et al. (2008) suggest that cluster headache is not a vasculitic disorder of medium-sized arteries, but CH patients may have an immune response that reacts differently from that of healthy volunteers.

Adhesion molecules have a role in many vasculitic disorders. Compared to controls, Takayasu's arteritis (TA) patients had elevated levels of sE-selectin, sVCAM-1, and sICAM-1. Compared to controls, patients with inactive TA also had elevated levels of sE-selectin, sVCAM-1, and sICAM-1. There was no difference between active TA and controls. The sE-selectin had a trend towards increased levels in inactive versus active TA, but there was no difference in sVCAM-1 and sICAM-1 levels between the groups. Patients with inactive TA had elevated levels of sE-selectin, sVCAM-1, and sICAM-1 that might indicate persistent vasculopathy in clinically inactive disease (Tripathy et al. 2008).

44.6.7 Inflammation in Hereditary Diseases

Serum levels of sVCAM-1, sICAM-1, sTM, P-selectin, E-selectin and CRP levels as inflammation markers are increased in patients of β-thalassemia intermedia and not influenced by treatment (Kanavaki et al. 2009). Pseudoxanthoma elasticum (PXE) is a hereditary disorder predominantly affecting the skin, retina and vascular system. P-selectin concentrations were increased in male and female PXE patients and levels correlated with the ABCC6 gene status of the patients. Patients harboring two mutant ABCC6 alleles had 1.5-fold increased P-selectin concentrations in comparison to patients with at least one wild-type allele. E- and L-selectin levels were within normal range and the allelic frequencies did not differ between from controls. Elevated P-selectin levels in PXE patients are potentially due to oxidative stress and elevated protease activity in PXE (Götting et al. 2008).

Fabry disease, an X-linked systemic vasculopathy, is caused by a deficiency of α-galactosidase A resulting in globotriaosylceramide (Gb_3) storage in cells. Accumulation of Gb_3 in the vascular endothelium of Fabry disease is associated with increased production of reactive oxygen species (ROS) and increased expression of CAMs. Increased Gb_3 induces expression of ICAM-1, VCAM-1, and E-selectin. Reduction of endogenous Gb_3 by treatment of the cells with an inhibitor of glycosphingolipid synthase or α-galactosidase A led to decreased expression of adhesion molecules. This study indicates that excess intracellular Gb_3 induces oxidative stress and up-regulates the expression of CAMs in vascular endothelial cells (Shen et al. 2008).

44.7 Role of CAMs in Cancer

Recent reports have expanded the concept that inflammation is a critical component of tumor progression. Many cancers arise from sites of infection, chronic irritation and inflammation. It is now becoming clear that the tumor microenvironment, which is largely orchestrated by inflammatory cells, is an indispensable participant in the neoplastic process, fostering proliferation, survival and migration. In addition, tumor cells have co-opted some of the signaling molecules of the innate immune system, such as selectins, chemokines and their receptors for invasion, migration and metastasis. These insights are fostering new anti-inflammatory therapeutic approaches to cancer development

44.7.1 Selectin Ligands in Cancer cells

Sialosyl Lewis^a in Adhesion of Colon and other Cancers: The complexity of the tumor microenvironment has been revealed in the past decade. The CAMs in the process of inflammation are responsible for recruiting leukocytes onto the vascular endothelium before extravasation to the injured tissues. Some circulating cancer cells have been shown to extravasate to a secondary site using a process similar to inflammatory cells. The most studied ligands for CAMs expressed on cancer cells, s-Lewis^a and s-Lewis^x antigens, are shown to be involved in adhesion to endothelial cells by binding to E-selectin. This process, shared by inflammatory cells and cancer cells, may partially explain the link between inflammation and tumorigenesis. The adhesion of colon cancer cells to E-selectin can be directly affected by changes in the expression level of sialosyl Le^a antigen. The specific lack of expression of sialosyl Le^a carbohydrate structure on the surface of colon cancer cells completely abolished their adhesion to E-selectin. It is proposed that glycoproteins as well as gangliosides carrying sialosyl Le^a structures, when properly exposed and present in high density on surface of cancer cells, can effectively support the adhesion of cancer cells to E-selectin (Klopocki et al. 1998; Kobayashi et al. 2007). In addition to endogenous ligands for L-, P-, and E-selectins (Chap. 26, 27, and 28), several proteins are found in cancer cell lines or solid tumors that act as ligands for E, L, and P selectins. Selectin ligands present in cancers are:

(1) Glycodelin A (GdA) is primarily produced in endometrial and decidual tissue and secreted to amniotic fluid. GdA is expressed in ovarian cancer where it can act as an inhibitor of lymphocyte activation and/or adhesion (Jeschke et al. 2009); (2) The cysteine-rich fibroblast growth factor receptor (FGF-R) represents the main E-selectin ligand (ESL-1) on granulocytes. Hepatic stellate cells (HSC) are pericytes of liver sinusoidal endothelial cells, which are involved in the repair of liver tissue injury and angiogenesis of liver metastases. HSC express FGF-R together with FucT7 and exhibit a functional E-selectin binding activity on their cell surface (Antoine et al. 2009). (3) Although B-cell precursor acute lymphoblastic leukemia (BCP-ALL) cell lines do not express the ligand PSGL-1, a major proportion of carbohydrate selectin ligand was carried by another sialomucin, CD43, in NALL-1 cells. CD43 plays an important role in extravascular infiltration of NALL-1 cells and the degree of tissue engraftment of BCP-ALL cells may be controlled by manipulating CD43 expression (Nonomura et al. 2008). (4) Thomas et al. (2009a) identified podocalyxin-like protein (PCLP) as an alternative selectin ligand. PCLP on LS174T colon carcinoma cells possesses E-/L-, but not P-, selectin binding activity. PCLP functions as an alternative acceptor for selectin-binding glycans. The finding that PCLP is an E-/L-selectin ligand on carcinoma cells offers a unifying perspective on the apparent enhanced metastatic potential associated with tumor cell PCLP overexpression and the role of selectins in metastasis (Thomas et al. 2009b). (5) E-selectin has been shown to play a pivotal role in mediating cell-cell interactions between breast cancer cells and endothelial monolayers during tumor cell metastasis. The counterreceptor for E-selectin was found as CD44v4. However, CD44 variant (CD44v) isoforms was functional P-, but not E-/L- selectin ligands on colon carcinoma cells. Furthermore, a ~180-kDa sialofucosylated glycoprotein(s) mediated selectin binding in CD44-knockdown cells. This glycoprotein was identified as carcinoembryonic antigen (CEA). CEA serves as an auxiliary L-selectin ligand, which stabilizes L-selectin-dependent cell rolling against fluid shear (Thomas et al. 2009b). Zen et al. (2008) identified a ~170 kDa human CD44 variant 4 (CD44v4) as E-selectin ligand, which has a high affinity for E-selectin via sLe^x moieties.

44.7.2 E-Selectin-Induced Angiogenesis

Angiogenesis plays an important role in a variety of pathophysiologic processes, including tumor growth and rheumatoid arthritis. Studies on capillary morphogenesis and angiogenesis in vitro have suggested a role for E-selectin in the process of differentiation into tube-like structures. Soluble E-selectin is a potent mediator of human dermal microvascular endothelial cell (HMVEC) chemotaxis, which is predominantly mediated through the Src and the phosphatidylinositiol 3-kinase (PI3K) pathways (Kumar et al. 2003). Gastrin-17 (G17) has marked proangiogenic effects in vivo on experimental gliomas and in vitro on HUVECs and transiently decreased the expression of E-selectin, but not P-selectin, whereas IL-8 increased the expression of E-selectin. Specific antisense oligonucleotides against E- and P-selectin decreased HUVEC tubulogenesis processes in vitro. This showed that gastrin has marked proangiogenic effects in vivo on experimental gliomas and in vitro on HUVECs. This effect depends in part on the level of E-selectin activation, but not on IL-8 expression/release by HUVECs (Lefranc et al. 2004).

44.7.3 E-Selectin in Cancer Cells

Adhesion molecules are thought to have a role in the host defense against carcinogenesis. Significantly increased P-selectin, s-VCAM-I and s-ICAM-I levels were observed in patients with bladder cancer, and s-VCAM-I levels correlated with tumor stage (Coskun et al. 2006). Selectins mediate attachment of leukocytes to activated endothelium

as well as the adhesion reaction of tumor cells during malignancy (Borsig 2007). In a breast tumor xenograft model, the effect of combined TNF-α and IFN-γ therapy involved the selective destruction of the tumor vasculature and death of tumor cells. Concomitant with these changes RT-PCR analysis revealed the increase of stromal mRNA levels for a series of stromal cytokines, cytokine receptors including TNF-α, sICAM-1, VCAM-1, P-selectin, which could be implicated in the observed events (de Kossodo et al. 1995).

Squamous Cell Carcinomas: In order to evaluate the risk of postoperative haematogenic recurrence of esophageal squamous cell carcinoma (SCC) patients, Shimada et al. (2003) examined the preoperative serum levels of sE-selectin and pathological status of the patients. The patients with a high serum soluble E-selectin concomitant with expression of s-Lewis antigens had a significant risk of postoperative haematogenic recurrence. SCCs of sun-induced skin cancers are particularly numerous in patients on T cell immunosuppression. Blood vessels in SCCs did not express E-selectin, and tumors contained few cutaneous lymphocyte antigen (CLA^+) T cells, the cell type thought to provide cutaneous immunosur-veillance. Clark et al. (2008) found that SCCs evade the immune response at least in part by down-regulating E-selectin and recruiting T_{reg} cells.

Cutaneous T-Cell Lymphoma (CTCL): The CTCL is characterized by accumulation of malignant $CD4^+$ T cells in the skin. In malignant T cells from Sezary syndrome (SS), a leukemic variant of CTCL, in dermal microvessels in mouse skin, Hoeller et al. (2009) found that SS cells rolled along dermal venules in a P-selectin- and E-selectin-dependent manner at ratios similar to $CD4^+$ memory T cells from normal donors. Chemokine CCL17/TARC was sufficient to induce the arrest of SS cells in the microvasculature. Together, experiments suggested molecular adhesion cascade operant in SS cell homing to the skin in vivo. Patients with CTCL showed increased levels of sICAM-1 and sICAM-3 when compared with healthy individuals and patients with inflammatory dermatosis. The sE-selectin and sVCAM-1 levels were not affected (López-Lerma and Estrach 2009).

Hodgkin's Disease: Increased sICAM-1 and sE-selectin have been observed in Hodgkin's Disease/lymphoma (HD/HL) patients at diagnosis and sVCAM-1 at diagnosis correlated with both sICAM-1 and sE-selectin levels. Chemotherapy resulted in a significant decrease of sICAM-1 and sE-selectin (Syrigos et al. 2004). Serum sICAM-1 level increases at advanced stages of untreated multiple myeloma (MM) patients, but did not differ significantly from controls. A positive correlation of IL-6 appeared with sICAM-1 and sE-selectin (Uchihara et al. 2006). Epstein-Barr virus (EBV)-positive NK/T cells showed affinity to vascular components. EBV-positive NK lymphoma cells express ICAM-1 and VCAM-1 at much higher levels than those in EBV-negative T cell lines. Furthermore, NK lymphoma cell lines exhibited increased adhesion to cultured endothelial cells stimulated with TNF-α or IL-1β. The up-regulated expression of VCAM-1 on cytokine-stimulated endothelial cells can be important to initiate the vascular lesions (Kanno et al. 2008).

Non-small Cell Lung Cancer: Serum levels of ICAM-1 increased in advanced stage non-small cell lung cancer (NSCLC) patients, whereas sE-selectin levels were not significantly different from healthy controls Reports suggest that higher serum ICAM-1 can be useful for diagnosis while E-selectin levels have prognostic significance and could be a potential prognostic factor in NSCLC patients (Dowlati et al. 2008; Guney et al. 2008). The Cyfra 21–1 and sE-selectin showed good performance in detecting lung cancer from normal groups. However, Cyfra 21–1 was superior to sE-selectin in discriminating lung cancer from benign lung diseases (Swellam et al. 2008).

44.7.3.1 Thyroid Cancer

Maspin, a serine protease inhibitor belonging to serpin family, is known as a tumor-suppressor protein and also exhibits an inhibitor effect on angiogenesis. Positive correlations were found for maspin positivity and lymph node metastases; E-selectin positivity and lymph node metastases, and P-selectin positivity and lymph node metastases and lymphovascular invasion. Correlations do exist between maspin, E- and P-selectin expressions with each other and with tumor stage. Inactive cytoplasmic maspin cannot act as a tumor suppressor. Expression of E- and P-selectins in tumor cells facilitates the occurrence of metastases, lymphovascular invasion, and perithyroidal soft tissue invasion. Further studies are needed to reveal detailed interactions between maspin, E-selectin, and P-selectin expression (Bal et al. 2008).

Primary Hyperparathyroidism: Patients with primary hyperparathyroidism (PHPT) have impaired vasodilation. Based on small number of patients, a study suggested that classic cardiovascular risk factors seem to be the main determinants for the high plasma levels of sE-selectin and vWF in PHPT. Together with unaltered thrombomodulin and sE-selectin levels, the vWF decrease in plasma after parathyroidectomy reflects a specific mechanism of its endothelial calcium- and/or PTH-stimulated secretion in some PHPT patients without risk factors (Fallo et al. 2006).

Colorectal Cancer: Plasma level of sP-selectin, sE-selectin and ICAM-1 were significantly higher in colorectal cancer (CRC) patients. The highest levels of sE-selectin and ICAM-1 were observed in patients with liver metastasis. There was no correlation between sP-selectin and sE-selectin, but a significant correlation was seen between sE-selectin and ICAM-1 in all patients. Plasma concentration of E-selectin and ICAM-1 may indicate tumor progression and liver metastasis (Dymicka-Piekarska and Kemona 2009; Sato et al. 2010).

The interaction between rE-selectin and CRC cells alters the gene expression profile of cancer cells. A DNA microarry analysis indicated that E-selectin-mediated alterations were significantly more pronounced in metastatic CRC variants SW620 and KM12SM than in the corresponding non-metastatic local SW480 and KM12C variants. The number of genes altered by E-selectin in metastatic variants was 10-fold higher than the number of genes altered in the corresponding local variants. Analysis indicated that E-selectin down regulated (at least by 1.6-folds) the expression of seven genes in a similar fashion, in both metastatic cells. Confocal microscopy indicated that E-selectin down-regulated the cellular expression of HMGB1 protein and enhanced the release of HMGB1 into the culture medium. The released HMGB1 in turn, activated endothelial cells to express E-selectin (Aychek et al. 2008).

The entrapment of malignant cells within the hepatic sinusoids and their interactions with resident non-parenchymal cells are considered very important for the whole metastatic sequence. In the sinusoids, cell connection and signaling is mediated by multiple cell adhesion molecules, such as the selectins. The three members of the selectin family, E-, P- and L-selectin, in conjunction with sialylated Lewis ligands and CD44 variants, regulate colorectal cell communication and adhesion with platelets, leucocytes, sinusoidal endothelial cells and stellate cells. Therefore, trials have already commenced aiming to exploit selectins and their ligands in the treatment of benign and malignant diseases. Multiple pharmacological agents have been developed that are being tested for potential therapeutic applications (Schnaar et al. 2008; Paschos et al. 2010; Zigler et al. 2010).

44.7.4 Metastatic Spreading

The degree of selectin ligand expression by cancer cells is well correlated with metastasis and poor prognosis for cancer patients. Initial adhesion events of cancer cells facilitated by selectins result in activation of integrins, release of chemokines and are possibly associated with the formation of permissive metastatic microenvironment. While E-selectin is one of the initiating adhesion events during metastasis, it is becoming apparent that P-selectin and L-selectin-mediated interactions significantly contribute to this process as well (Gout et al. 2008; Läubli and Borsig 2010).

E-Selectin in Progression of Metastasis of Breast Cancer: Extravasation of cancer cells is a pivotal step in the formation of hematogenous metastasis. Extravasation is initiated by the loose adhesion of cancer cells to endothelial cells via an interaction between endothelial selectins and selectin ligands expressed by the tumor cells. Metastatic spreading is a dreadful complication of neoplastic diseases that is responsible for most deaths due to cancer. It consists in the formation of secondary neoplasms from cancer cells that have detached from the primary site. Leukocytes and tumor cells use E-selectin binding ligands to attach to activated endothelial cells expressing E-selectin during inflammation or metastasis. The formation of these secondary sites is not random and several clinical observations indicate that the metastatic colonization exhibits organ selectivity. This organ tropism relies mostly on the complementary adhesive interactions between cancer cells and their microenvironment. E-selectin and sLewis antigens might play important role in breast tumor, lymph node and liver metastasis. High levels of sE-selectin have been reported in melanoma and some epithelial tumors, especially in colorectal carcinoma. But sE-selectin may not be used as a predictive marker of metastasis in colorectal carcinoma, though high levels of sE-selectin may support diagnosis of liver metastasis (Uner et al. 2004; Eichbaum et al. 2004). It appeared that serum levels of sE-selectin are associated with the clinical course of liver metastases from breast cancer. Eichbaum et al. (2004) observed a possible trend for certain unfavorable prognostic parameters (e.g., young women, low-graded tumors, human epidermal growth factor receptor 2 over-expression) that could be related to higher serum levels of sE-selectin.

Role of E-Selectin in Diapedesis of Cancer Cells: Diapedesis is a vital part of tumor metastasis, whereby tumor cells attach to and cross the endothelium to enter the circulation. E-selectin was found to regulate initial attachment and rolling of colon cancer cells and also the subsequent diapedesis through the endothelium. Evidence indicates that E-selectin-dependent paracellular extravasation is independent of ICAM and VCAM and that it requires the activation of extracellular signal-regulated kinase (ERK) mitogen-activated protein kinase downstream of E-selectin. Studies establish the role of E-selectin in diapedesis of circulating cancer cells (Tremblay et al. 2008; Woodward 2008).

Polymorphisms within E-selectin gene, especially the $S^{128}R$ polymorphism, may increase the risk of metastases by facilitating adhesion of tumor cells to endothelium. Blood DNA from patients treated for stage II or III colorectal

cancer (CRC) and from healthy controls was assessed for three polymorphisms within E-selectin gene ($S^{128}R$, $G^{98}T$ and $L^{554}F$) and one within the P-selectin gene ($V^{640}L$). The $S^{128}R$ polymorphism was detected in 22.3 % patients and was correlated with $G^{98}T$ polymorphism. In multivariate analysis, the $S^{128}R$ polymorphism was associated with shorter event-free survival (EFS) and overall survival (OS) in whole population, in patients with stage II CRC, and in patients with stage III CRC. $L^{554}F$ and $V^{640}L$ polymorphisms had no prognostic value. The $S^{128}R$ polymorphism is a constitutional factor associated with a higher risk of relapse and death in patients treated for CRC and its detection may permit better selection of patients suitable for adjuvant therapy, especially among those with stage II disease (Hebbar et al. 2009).

P-selectin Deficiency Attenuates Tumor Growth and Metastasis: Metastasis is thought to involve the formation of tumor-platelet-leukocyte emboli and their interactions with the endothelium of distant organs. A link between these observations shows that P-selectin, which normally binds leukocyte ligands, can promote tumor growth and facilitate the metastatic seeding of a mucin-producing carcinoma. P-selectin-deficient (P-sele$^{-/-}$) mice showed three potential pathophysiological mechanisms: (1) intravenously injected tumor cells home to the lungs of P-sele$^{-/-}$ mice at a lower rate; (2) P-sele$^{-/-}$ mouse platelets fail to adhere to tumor cell-surface mucins; and (3) tumor cells lodged in lung vasculature after intravenous injection often are decorated with platelet clumps, and these are markedly diminished in P-selectin$^{-/-}$ animals (Kim et al. 1998). However, the surgical procedure did not totally eliminate the factors responsible for platelet activation and did not normalize platelet activation (Dymicka-Piekarska et al. 2005; Hanley et al. 2006).

Role of Sialyl-Lewis Antigens: During inflammation, E- and P-selectins appear on activated endothelial cells to interact with leukocytes through sialyl-Lewis X (sLe^x) and sialyl-Lewis A (sLe^a). These selectins can also interact with tumor cells in a sialyl-Lewis-dependent manner and hence, they are thought to play a key role in metastasis. Diverting the biosynthesis of sialyl-Lewis antigens toward nonadhesive structures is an attractive gene therapy for preventing the hematogenous metastatic spread of cancers. The transduced α1,2-fucosyltransferase-1 (FUT1) efficiently fucosylated the P-selectin ligand PSGL-1 without altering P-selectin binding (Mathieu et al. 2004).

The metastasis of cancer cells and leukocyte extravasation into inflamed tissues share common features. Carbohydrate antigen sLe^a (CA19-9) is the most frequently applied serum tumor marker for diagnosis of cancers in the digestive organs. The normal counterpart of the determinant, namely disialyl-Le^a is predominantly expressed in non-malignant epithelial cells of the digestive organs. The disialyl-Le^a determinant carries one extra sialic residue attached through a 2 → 6 linkage to GlcNAc moiety compared to cancer-associated sLe^a, which carries only one 2 → 3 linked sialic acid residue (monosialyl Lewis A) (Fig. 44.3). Disialyl-Le^a in normal epithelial cells serves as a ligand for immunosuppressive receptors such as sialic acid binding Ig-like lectins (siglec-7 and -9) expressed on resident monocytes/macrophages and maintains immunological homeostasis of mucosal membranes in digestive organs. Epigenetic silencing of a gene for a 2 → 6 sialyl-transferase in the early stages of carcinogenesis results in impairment of 2 → 6 sialylation, leading to incomplete synthesis and accumulation of sLe^a, which lacks the 2 → 6 linked sialic acid residue, in cancer cells. Simultaneous determination of serum levels of sLe^a and disialyl-Le^a, and calculation of the sLe^a/disialyl-Le^a ratio provides information useful for excluding a false-positive serum diagnosis. During cancer progression in locally advanced cancers, tumor hypoxia induces transcription of several glyco genes involved in sLe^a synthesis. Expression of the determinant, consequently, is further accelerated in more malignant hypoxia-resistant cancer cell clones, which become predominant clones in advanced stage cancers and frequently develop hematogenous metastasis. sLe^a, as well as its positional isomer sLe^a, serves as a ligand for vascular E-selectin and facilitates hematogenous metastasis through mediating adhesion of circulating cancer cells to vascular endothelium. Patients having both strong sLe^a expression on cancer cells and enhanced E-selectin expression on vascular beds are at a greater risk of developing distant hematogenous metastasis (Kannagi 2007). In a human-mouse model, the selectin ligand s-Le^a is involved in in vivo extravasation of colorectal carcinoma (CRC) cells. Highly metastatic CRC cells expressing high levels of s-Le^a extravasate more efficiently than non-metastatic CRC cells expressing low levels of s-Le^a. Down-regulating the expression of s-Le^a in CRC cells by genetic manipulations, significantly reduced CRC extravasation. The arrest and adhesion of CRC cells, and possibly of other types of cancer cells as well, to endothelium depend on the expression of the selectin ligand sLe^a by the tumor cells (Ben-David et al. 2008). 3'-Sulfo-Le^a is known to be the potent ligand of E-selectin which is important in cell adhesion and migration. The serum 3'-sulfo-Le^a can provide important information in patients with primary gastric cancer, which might be useful as a predictive marker especially for the detection of tumor metastasis (Zheng et al. 2009).

Specialized carbohydrates modified with sLe^x antigens on leukocyte membranes are ligands for selectin adhesion molecules on activated vascular endothelial cells at

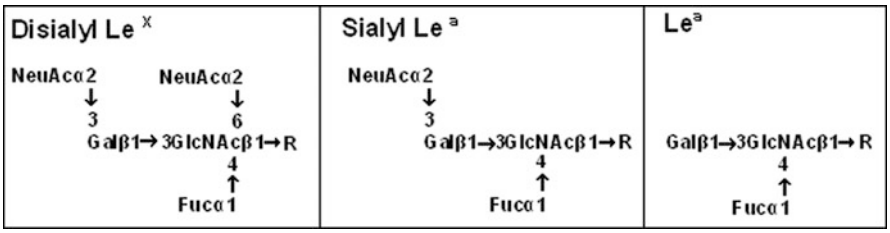

Fig. 44.3 Structures of three carbohydrate determinants, disialyl Lewis x (Le^x), sialyl Lewis a and Lewis a (Le^a). In panel, note that the only difference between the three determinants is the linkage of sialic acid residues. The $\alpha(2 \rightarrow 6)$ sialic acid residue in disialyl Le^a is synthesized by a sialyltransferase ST6GalNAcVI, which shows a significant decrease in its mRNA level upon malignant transformation

inflammatory sites. The sLe^x expression of invasive micropapillary carcinoma was higher than that of invasive ductal carcinoma, which was also associated with lymph node metastasis. E-selectin combined with sLe^x might play an important role in lymph node metastasis in invasive micropapillary carcinoma. The expression pattern of sLe^x in invasive micropapillary carcinoma suggested that the reversal of cell polarity of invasive micropapillary carcinoma might be as an important factor for the morphogenesis and possibly the pathogenesis, especially their higher rates of lymph node metastasis (Wei et al. 2010). The activity of core 2 β1,6 N-acetylglucosaminyltransferase (C2GnT1) in leukocytes greatly increases their ability to bind to endothelial selectins. C2GnT1 is essential for the synthesis of core 2-branched O-linked carbohydrates terminated with sLe^x (C2-O-sLe^x). E-selectin and its ligand-sLe^x are closely correlated with the metastasis of hepatocellular carcinoma. C2-O-sLe^x is a potentially useful early predictor of metastasis (Zhang et al. 2002). The expression profiles of C2-O-sLe^x in the malignant progression and metastasis of colorectal adenocarcinomas is upregulated in colorectal adenocarcinomas and metastatic liver tumors (St Hill et al. 2009).

44.7.5 Survival Benefits of Heparin

Endothelial P-Selectin as a Target of Heparin Action: Metastasis can be effectively inhibited by the anticoagulant heparin in different tumor models. At the cellular level, many of the antimetastatic effects of heparin in vivo are due to its action on P-selectin-mediated binding. Ludwig et al. (2007) addressed the potential contribution of endothelial P-selectin expression to adhesive events between the microvasculature and melanoma cells in vivo. Heparin not only inhibits P-selectin-mediated melanoma cell rolling but also attenuates melanoma metastasis formation in vivo, supporting the concept that endothelial P-selectin expression may represent an additional target of heparin in experimental melanoma lung metastasis (Ludwig et al. 2007). The low molecular weight heparin (LMWH) significantly improved colonic inflammation in rats with trinitrobenzene sulphonic acid (TNBS) induced colitis. The effect is possibly related to inhibition of proinflammatory cytokine IL-8, but not involved platelet surface P-selectin expression (Xia et al. 2004). The survival benefits in patients with cancer treated with LMWH may result from a LMWH-mediated effect on the immune system or on the cross-talk between platelets and tumor cells. However, survival observed with LMWH in patients with cancer apparently cannot be explained by a LMWH effect on these circulating markers (Di Nisio et al. 2005). Nonetheless, in vivo antimetastatic effects of heparins reflect their action on P-selectin-mediated binding. Therefore, these commonly used anticoagulants widely differ in their potential to interfere with P-selectin mediated cell binding. Importantly, the superior inhibitory capacity on P-selectin function of unfractionated heparin and LMWH nadroparin as opposed to LMWH enoxaparin and synthetic heparin pentasaccharide fondaparinux strongly correlated to the inhibitory potency of each in inhibiting experimental lung metastasis in vivo. Hence, P-selectin inhibition constitutes a valuable feature to identify anticoagulants that are suitable for anticancer therapy (Ludwig et al. 2006). Stevenson et al. (2005) studied metastasis inhibition by clinically relevant levels of various heparins and investigated the structural basis for selectin inhibition differences. Five clinically approved heparins were evaluated for inhibition of P-selectin and L-selectin binding to carcinoma cells and showed differing abilities to inhibit selectins, likely explained by size distribution. It should be possible to size fractionate heparins and inhibit selectins at concentrations that do not have a large effect on coagulation. Gao et al. (2005) prepared periodate-oxidized, borohydride-reduced heparin (RO-heparin) and tested its anticoagulant and anti-inflammatory activities. Compared with heparin, RO-heparin had greatly reduced anticoagulant activity. Intravenous administration of this compound led to reduction in the peritoneal infiltration of neutrophils in a

mouse acute inflammation model. In vitro studies showed that the effect of RO-heparin on inflammatory responses was mainly due to inhibiting the interaction of P-selectin with its ligands. These results indicate that RO-heparin may be a safer treatment for inflammation than heparin, especially when selectin is targeted.

To clarify the mechanism of heparin antimetastatic activity, several biological effects are being investigated. Cancer progression and metastasis are associated with enhanced expression of heparanase, which is inhibited efficiently by heparin. Heparin is also a potent inhibitor of selectin-mediated interactions. P- and L-selectin were shown to contribute to the early stages of metastasis, which is associated with platelet-tumor cell thrombi formation. Low anticoagulant heparin preparations still inhibited metastasis efficiently indicating that anticoagulation is not a necessary component for heparin attenuation of metastasis. Modified heparins characterized for heparanase inhibitory activity are also potential inhibitors of selectins. Selectin inhibition is a clear component of heparin inhibition of metastasis. The contribution of selectin or heparanase inhibition by heparin can provide evidence about its antimetastatic activity (Borsig 2007). One of the mechanisms by which heparin inhibits metastasis is by blocking the P-selectin-based interaction of platelets with tumor cell. The sulfate groups at C6/N and especially C6, but not C2 and C3, of heparin play a critical role in P-selectin recognition and that 2-O,3-O-desulfated heparin can block P-selectin-mediated A375 human melanoma cell adhesion. Thus chemical modification of heparin, especially 2-O,3-O-desulfation, may result in a therapeutic agent that is anti-metastatic because it blocks unwanted P-selectin-dependent adhesion but that lacks dose-limiting anticoagulant effects (Wei et al. 2005).

Heparin-Induced Thrombocytopenia: The pathophysiology of heparin-induced thrombocytopenia (HIT) is a complex process which involves platelets, vascular endothelium, and leukocytes. The activation products from these sites also contribute to the activation of coagulation and to the fibrinolytic deficit. Many of the markers of hemostatic activation processes have been found to be at increased levels during acute phases of the HIT syndromes. Since the pathophysiology of HIT involves the activation of platelets, endothelium, and leukocytes, it is expected that activation products related to these hemostatic systems, including soluble selectins, will also be increased in circulating blood. These alterations may provide an index of the pathophysiologic process. Fareed et al. (1999) reviewed on the circulating levels of P-, E-, and L-selectins in HIT patients and their modulation after therapeutic intervention. With the availability of recombinant hirudin, it is now possible to provide alternate anticoagulants to HIT patients. However, Fareed et al. (1999) suggest that the immunoactivation of platelets and other cells may require additional adjunct therapeutic approaches.

44.8 Adhesion Proteins in Transplantation

Activated protein C (APC) is the major physiological anticoagulant with concomitant anti-inflammatory properties. Turunen et al. (2005) suggest that APC has an anti-inflammatory role in I/R injury in clinical renal transplantation (Turunen et al. 2005). Bimosiamose prolongs survival of kidney allografts. Binding of the P-, L-, and E-selectins to sLe X retards circulating leukocytes, thereby facilitating their attachment to the blood vessels of allografts. Selectin inhibitor bimosiamose (BIMO) inhibits the rejection process of kidney allografts in a rat model in association with reduced intragraft expression of P-selectin glycoprotein ligand-1, CX(3)CL1, CCL19, CCL20, and CCL2. Thus, BIMO blocks allograft rejection by reduction of intragraft expression of cytokines and chemokines (Langer et al. 2004).

Brain death (BD), a significant antigen-independent process, the donor-related injury up-regulates variety of inflammatory mediators in peripheral organs. One of the immediate responses is the expression of selectins by endothelial cells of the transplanted tissues, which in turn trigger a cascade of nonspecific events that may enhance host alloresponses. Using a rat model in which donor BD accentuates subsequent renal allograft injury, Gasser et al. (2005) tested the effects of therapy with rPSGL-Ig alone, or in combination with sirolimus (SRL) and cyclosporin A. It was found that in contrast to the effects of standard doses of SRL or cyclosporine, rPSGL-Ig decreased inflammation in the early posttransplant period such that lower doses of maintenance immunosuppression were sufficient to maintain long-term graft function.

Intestinal transplantation (ITx) is severely limited by ischemia-reperfusion (I/R) injury. T lymphocyte is an important regulatory cell in this inflammatory process (Farmer et al. 2005a). rPSGL-Ig treatment leads to marked improvement in the outcome. The mechanism of action seems to involve the blockade of neutrophil and lymphocyte infiltration that leads to a decreased inflammatory response possibly driven by Th2 cytokines (Farmer et al. 2005b).

It was suggested that liver transplantation and liver resection, together with portal clamping time, might be a potential stimulus for platelet activation. Becker et al. (2004) indicated that neither liver transplantation nor liver resection influences GPIIb/IIIa and P-selectin expression on circulating platelets (Becker et al. 2004).

44.9 Inflammation During Infection

44.9.1 Microbial Pathogens

Endothelial activation contributes significantly to the systemic inflammatory response to bacteraemia. Release of soluble endothelial markers into the circulation has been demonstrated together with elevated plasma levels of CAMs and has been reported in bacteraemic patients. It has been proposed that the infection of endothelial cells with *Staphylococcus aureus, Streptococcus sanguis, or Staphylococcus epidermidis* induces surface expression of ICAM-1 and VCAM-1 and monocyte adhesion. In general, leukocyte/endothelial cell interactions such as capture, rolling, and firm adhesion should be viewed as a series of overlapping synergistic interactions among adhesion molecules resulting in an adhesion cascade. These cascades thereby direct leukocyte migration, which is essential for the generation of effective inflammatory responses and the development of rapid immune responses (Golias et al. 2007). *Helicobacter pylori* is a common bacterial pathogen that infects world's population up to 50 %. Carbohydrate components on *H. pylori* (sequences related to Le^x or Le^a antigens) are responsible for the persistent inflammation through interactions with leukocyte-endothelial adhesion molecules of the host. *H. pylori* isolates from patients with chronic gastritis, duodenal ulcer and gastric cancer interact with E- and L-selectins (Galustian et al. 2003). Expression of E-selectin was specifically upregulated in *H. pylori*-induced gastritis but not in gastritis induced by acetylsalicylic acid or pouchitis. The upregulated E-selectin expression was localized to the gastric mucosa rather than being a systemic response to the infection (Svensson et al. 2009).

Although mice with mutations in individual selectins showed no spontaneous disease and had a mild or negligible deficiencies of inflammatory responses, Bullard et al. (1996), in contrast, found that mice with null mutations in both endothelial selectins (P and E) develop a phenotype of leukocyte adhesion deficiency characterized by mucocutaneous infections in response to intraperitoneal *S. pneumoniae* peritonitis. These mice provide strong evidence for the functional importance of selectins in vivo (Bullard et al. 1996). Anthrax lethal toxin (LT), a key virulence factor of *Bacillus anthracis*, enhanced VCAM-1 expression on primary human endothelial cells suggesting a causative link between dysregulated adhesion molecule expression and the poor immune response and vasculitis associated with anthrax. Results suggest that LT can differentially modulate NF-kB target genes and highlight the importance of VCAM-1 enhancement (Warfel and D'Agnillo 2008). Vascular endothelium stimulation in vitro that lead to the upregulation of CAMs is known for the pathogenic spirochaetes, including rLIC10365 of *Leptospira interrogans*. The recombinant proteins of *L. interrogans* in *E. coli* as a host were capable to promote the upregulation of ICAM-1 and E-selectin on monolayers of HUVECS. In addition, pathogenic and non-pathogenic Leptospira are both capable to stimulate endothelium E-selectin and ICAM-1, but the pathogenic *L. interrogans serovar Copenhageni* strain promoted a higher activation than the non-pathogenic *L. biflexa serovar Patoc* (Atzingen et al. 2009; Gómez et al. 2008). *Chlamydia pneumoniae* has been associated with cardiovascular disease and atherosclerosis. To determine the ability of *C. pneumoniae* to elicit inflammation, Högdahl et al. (2008) infected human coronary artery endothelial cells (HCAEC) with *C. pneumoniae*. Secretion of IL-8, MCP-1, and ICAM-1 was significantly increased after *C. pneumoniae* infection of HCAEC in comparison with uninfected controls, where as release of E-selectin or MMP-1did not change. This suggested that *C. pneumoniae* initiates and propagates vascular inflammation in ways that contribute to coronary artery disease (Högdahl et al. 2008).

CAMs in Gingival Crevicular Fluid: The sICAM-1, sVCAM-1, and sE-Selectin are present in gingival crevicular fluid (GCF) and changes in their levels may be a sensitive indicator to differentiate healthy sites from those with periodontitis (Hannigan et al. 2004; Tamai et al. 2007). *Porphyromonas gingivalis* is a Gram-negative bacterium that is an important etiologic agent of human adult periodontitis. *E. coli* LPS and isoforms of *P. gingivalis* LPS were potent in stimulating the expression of inflammatory markers, with *E. coli* LPS being more potent (Liu et al. 2008). DNA samples from blood of periodontitis patients genotyped for E-selectin $Ser^{128}Arg$ and L-selectin $Phe^{206}Leu$ revealed a significant difference in the $Ser^{128}Arg$ polymorphism of E-selectin, but not in L-selectin, between periodontal patients and controls; the 128Arg allele was present more frequently in patients. Houshmand et al. (2009) suggested that $Ser^{128}Arg$ polymorphism of E-selectin might contribute to the susceptibility of Iranian individuals to periodontitis.

CAMs in Subjects with HIV Disease: Swingler et al. (2003) suggested that while both soluble CD23 and ICAM1 promote resting cell HIV1 infection, productive infection of cycling cells requires soluble ICAM1. Swingler et al. (2003) noted that these results may explain in part the existence of a resting T-cell reservoir infected with HIV-1. Subjects with HIV disease have multiple risk factors for cardiovascular disease, including elevated levels of ICAM-1 and VCAM-1. Many of the variables associated with

ICAM-1 and VCAM-1 levels can be related to their impact on inflammation (Melendez et al. 2008). The LFA-1, ICAM-1, and ICAM-3 are enriched at virological synapse (VS). The cognate adhesion molecule interactions at VS are important for HIV-1 spread between T cells (Jolly et al. 2007).

44.9.2 Yeasts and Fungi

Zuccarello et al. (2002) described a distinct form of familial chronic mucocutaneous candidiasis characterized by early-onset infections by different species of Candida, restricted to the nails of the hands and feet and associated with low serum concentration of ICAM-1. Phan and Filler (2009) measured the effects of *C. albicans* on the endothelial cell production of E-selectin and TNF-α in vitro. During invasive pulmonary aspergillosis, *A. fumigatus* hyphae invade the abluminal endothelial cell surface, whereas they invade the luminal endothelial cell surface during haematogenous dissemination. Infection with hyphae stimulates endothelial cells to synthesize E-selectin, VCAM-1, IL-8, and TNF-α in vitro. In neutropenic mice infected with wild-type *A. fumigatus*, increased pulmonary expression of E-selectin and TNF-α occurred only when neutropenia had resolved. In nonneutropenic mice immunosuppressed with corticosteroids, *A. fumigatus* stimulated earlier pulmonary expression of E-selectin and VCAM-1, while expression of ICAM-1 and TNF-α was suppressed. In both mouse models, expression of E-selectin was associated with high pulmonary fungal burden, angioinvasion, and neutrophil adherence to endothelial cells (Chiang et al. 2008; Kamai et al. 2009).

44.9.3 Parasites and Amoeba

44.9.3.1 Falciparum Malaria

Significant differences are observed between falciparum malaria patients and the healthy people in term of levels of both sE-selectin and thrombomodulin (TM). The levels of both sE-selectin and TM correlated positively with temperature, levels of IFN-γ and levels of TNF-α; and negatively with hemoglobin levels. Trends of positive correlations were observed between sP-selectin or vWF and temperature (Matondo et al. 2008). Evidence from autopsy and in vitro binding studies suggests that adhesion of erythrocytes infected with *Plasmodium falciparum* to the human host ICAM-1 receptor is important in the pathogenesis of severe malaria. Fernandez-Reyes et al. (1997) identified a mutation (K29M) in the ICAM1 gene, which they designated 'ICAM1 Kilifi,' that was associated with susceptibility to cerebral malaria with relative risks of 2.23 and 1.39 for homozygotes and heterozygotes, respectively. The available epidemiological, population genetic and functional evidence link ICAM-1(Kilifi) to severe malaria susceptibility (Fry et al. 2008; Cojean et al. 2008).

Increased serum concentrations of soluble sICAM-1, CD54 and of soluble E-, but not soluble P- and L-selectins were detected in Malagasy patients living in hyperendemic focus of Schistosoma mansoni. Serum levels of ICAM-1 were significantly correlated with the disease severity (Esterre et al. 1998). Studies in several models of inflammation have underscored the importance of P- and E-selectins in the migration of T cells to inflamed tissues. $CD4^+$ T cells recruited to the cutaneous compartment during infection with Leishmania major express P- and E-selectin ligands. Results suggest that by blocking P- and E-selectins, the immune pathology associated with cutaneous leishmaniasis might be ameliorated without compromising immunity to infection (Zaph and Scott 2003). Invasive amebiasis offers a new model that poses an inadequate immune response leading to a continuous and prolonged activation of endothelial cells (ECs) by amebas, amebic molecules and cytokines, leading to necrosis. Hyperactivated endothelial cells continuously express ICAM-1 and E-selectin, pro-coagulant molecules (tissue factor, vWF, and the plasminogen activator inhibitor), resulting in ever greater inflammation and thrombosis (Campos-Rodríguez et al. 2009)

44.9.3.2 Sepsis

Sepsis is a multifactorial, and often fatal, disorder typically characterized by widespread inflammation and immune activation with resultant endothelial activation. Though bacterial sepsis is most common, sepsis occurs with fungal, parastic and mycobacterial organisms. During bacterial sepsis in vivo, in wild-type mice and mice with E-, P-, or E-/P-selectin deficiencies, a phenotypic abnormality in E-selectin-deficient mice suggested that E- and P-selectin are important in the host defense against *S. pneumoniae* infection (Munoz et al. 1997). P-selectin is an important mediator of eosinophil recruitment to the cornea from limbal vessels to the corneal stroma, suggesting that P-selectin interactions may be potential targets for immunotherapy in eosinophil-mediated ocular inflammation (Kaifi et al. 2000).

Staphylococcus aureus is one of the most significant pathogens in human sepsis and endocarditis. Peptidoglycan induced surface expression of EC inflammation markers ICAM-1 and VCAM-1, which supported the adhesion of monocytes to these ECs (Mattsson et al. 2008). Teoh et al. (2008) assigned adiponectin as a modulator of survival and endothelial inflammation in experimental sepsis and a potential mechanistic link between adiposity and increased sepsis. Newborn infants with clinical diagnosis of sepsis demonstrated significantly higher plasma sE-selectin levels

in infected infants. Infants with gram-negative sepsis had higher sE-selectin levels than did those with gram-positive sepsis. C-reactive protein was the best test for diagnosis of neonatal sepsis (Zaki and el-Sayed 2009).

Hofer et al. (2008) compared two different models of sepsis LPS-induced endotoxemia and cecal ligation perforation (CLP) bacteremia in rats with respect to changes in endothelial expression of CAMS as a marker for capillary breakdown of the blood brain barrier. Increased ICAM-1 expression might be an early factor involved in these pathogenic events. Although the role of PECAM-1 could not be determined, it was possible to show its expression on cerebral endothelium in all groups (Hofer et al. 2008). In mouse models of sepsis, Shapiro et al. (2009) demonstrated increased circulating levels of sE-selectin, sICAM-1, sVCAM-1 and sP-selectin at 24 h, while CLP was associated with increased levels of sE-selectin alone. In real-time PCR, mRNA levels for P-selectin, ICAM-1 and PAI-1 were increased in skin from endotoxemic mice. In CLP, mRNA levels for P-selectin, ICAM-1, E-selectin and PAI-1 were elevated, while VCAM-1 expression was reduced in skin. Most, but not all of these changes correlated with alterations in immunohistochemical staining (Shapiro et al. 2009).

44.10 Action of Drugs and Physical Factors on CAMS

The field of selectin inhibition has matured significantly in recent years in the ability to inhibit selectin/ligand interactions with drug-like molecules and to demonstrate disease modification in human trials. A comprehensive review of new developments in the field of selectin inhibition through discussion of patents/patent applications from 2003 to August 2009 has been reported by Bedard and Kaila (2010)

44.10.1 Inhibitors of Gene Transcription

Treatment of human endothelial cells with cytokines such as IL-1, TNF-α or IFN-γ induces the expression of specific leukocyte adhesion molecules on the endothelial cell surface. Interfering with either leukocyte adhesion or upregulation of adhesion protein is an important therapeutic target as evidenced by the potent anti-inflammatory actions of neutralizing antibodies to these ligands in various animal models and in patients. The induction of E-selectin, VCAM-1, and ICAM-1 genes requires the transcription factor NF-κB. Pharmaceutical agents, which prevent the induced expression of one or more of cell adhesion molecules on endothelium, might be expected to provide a novel mechanism to attenuate the inflammatory responses associated with chronic inflammatory diseases. E-selectin expression is induced on the endothelial cell surface of vessels in response to inflammatory stimuli but is absent in the normal vessels. Thus, E-selectin is an attractive molecular target, and high affinity ligands for E-selectin could be powerful tools for the delivery of therapeutics and/or imaging agents to inflamed vessels. Zimmerman and Blanco (2008) reviewed the structure and regulation of LFA-1 and different classes of inhibitors that interfere LFA-1/ICAM-1 interactions. Alicaforsen (ISIS 2302), an antisense to ICAM-1, designed to inhibit ICAM-1 expression did not reveal significant effect in Crohn's disease. However, topical enemas for ulcerative colitis demonstrated some effect in secondary outcomes, and initial studies in pouchitis are promising (Philpott and Miner 2008). ICAM-1 antibody (UV3) was highly effective at slowing the growth of tumors and/or prolonging survival in SCID mice xenografted with human multiple myeloma, lymphoma, melanoma and other cell lines (Brooks et al. 2008). A structurally diverse collection of small molecule inhibitors has been characterized and developed either to bind the IDAS site of α_L I-domain or to the MIDAS of the β_2 I-like domain.

44.10.2 Anti-NF-kB Reagents

CAMs play important roles in a critical step of tumor metastasis and arrest of tumor cells onto the venous or capillary bed of the target organ. In this process, IL-1β induces nuclear translocation of NF-kB in HUVE cells, followed by induction of cell surface expression of E-selectin, ICAM-1, and VAM-1, and subsequent adhesion of those cancer cells expressing sialyl Le^X antigen, which is a ligand to E-selectin. The adhesion of tumor cells to IL-1β-treated HUVE cells can be inhibited by anti-NF-kB reagents such as N-acetyl L-cysteine, aspirin, or pentoxifylline. These observations indicate the involvement of NF-kB in cancer metastasis and the feasibility of using anti-NF-kB reagents in preventing metastasis (Tozawa et al. 1995). Incubation of HUVEC with N,N,N-trimethylsphingosine (TMS) resulted in a dose-dependent inhibition of IL-1β-induced E-selectin expression. Sphingosine or N,N-dimethylsphingosine had no effects on the expression. This inhibitory effect of TMS on IL-1β-dependent endothelial cell activation may partly explain the known anti-inflammatory or anti-metastatic effect of TMS in vivo (Masamune et al. 1995). Cimetidine inhibits the expression of E-selectin on vascular endothelial cells in gastric- and colorectal cancer patients, treated for chemotherapy (Kawase et al. 2005). Since the expression of E-selectin and Mac-1 is regulated either directly or indirectly by NF-kB, studies provide in vivo evidence that

tepoxalin is a potent inhibitor of NF-kB mediated events in animal models and this novel molecular mechanism clearly defines it as a new class of anti-inflammatory compounds. E-selectin transcription requires binding of transcription factors, NF-kB, ATF-2, and HMG-I(Y). HUVE cells treated with TNF-α showed E-selectin surface expression, which peaked at 4 h and then declined. However, ATF-2 binding was unchanged after stimulation with TNF-α. The termination of E-selectin expression is controlled at the level of transcription, with loss of protein-DNA interactions at only one of three NF-kB-binding sites in the E-selectin promoter (Boyle et al. 1999).

E-selectin is synthesized following X-ray exposure to doses as low as 0.5 Gy. X-ray-induced expression of E-selectin and ICAM-1 has been proposed to contribute to radiation injury in normal tissues. E-selectin expression does not require cytokine synthesis, but involves NF-kB activation (Hallahan et al. 1995). NFκB inhibition using NFκB inhibitors abrogates X-ray induced inflammatory mediators (Hallahan et al. 1998). Andrographolide, the principal component of medicinal plant Andrographis paniculata, has been shown to inhibit NF-kB activity and may attenuate allergic asthma via inhibition of the NF-kB signaling pathway. Andrographolide attenuated OVA-induced lung tissue eosinophilia and airway mucus production, mRNA expression of E-selectin, and inducible NOS in lung tissues. Findings implicate a potential therapeutic value of andrographolide in the treatment of asthma (Bao et al. 2009; Jiang et al. 2007).

Effects of TGF-β and IFN-γ on E-Selectin Expression: Transforming growth factor (TGF-β) has been shown to decrease the adhesiveness of endothelial cells for neutrophils, lymphocytes, and tumor cells. TGF-β inhibits the basal E-selectin expression and TNF-stimulated expression. While TGF-β had no effect on the expression of VCAM-1 and ICAM-1, the effect was additive with IL-4 in inhibiting the expression of E-selectin. Thus, perivascular TGF-β appears to act as an inhibitor of inflammatory responses involving neutrophils and a subset of lymphocytes (Gamble et al. 1993). IFN-γ down-regulates the induction by a viral mimetic, polyinosinic-polycytidylic acid [poly-(I:C)], of E-selectin. The inhibitory effect of IFN-γ on poly(I:C)-induced E-selectin was specific for dsRNA. Results indicated the role for IFN-γ in the regulation of E-selectin gene expression in response to dsRNA by a transcriptional mechanism independent of NF-kB, as well as by a minor decrease in message stability (Faruqi and DiCorleto 1997).

Retinoic Acid Inhibits the Expression of VCAM-1 but not E-Selectin: Several genes are regulated by tocopherols which can be categorized, based on their function. Genes that are related to inflammation, cell adhesion and platelet aggregation include E-selectin, ICAM-1, and others (Azzi et al. 2004). Retinoic acid and synthetic derivatives are known to exert anti-inflammatory effects in cutaneous diseases. Pretreatment with all-trans-retinoic acid (t-RA) specifically prevented TNFα-induced VCAM-1 expression, but not ICAM-1 and E-selectin induction (Gille et al. 1997). The TNFα-mediated activation of the human VCAM-1 promoter was also inhibited after t-RA treatment, while the ICAM-1 promoter activation was unaffected, indicating that the selective inhibition of CAM expression is regulated in part at the level of gene transcription. Furthermore, the transcriptional inhibition by t-RA appears to be mediated by its effects upon the activation of NF-kB-dependent complex formation. The specific inhibition of cytokine-mediated VCAM-1 gene expression in vitro provides a potential basis by which retinoids exert their biological effects at sites of inflammation in vivo (Gille et al. 1997). Radiation-induced expression of E-selectin was also blocked by t-RA, whereas 9-cis retinoic acid was ineffective. Application of statins and t-RA might have clinical impact in protecting against E-selectin-promoted metastasis, which might arise as an unwanted side effect from radiation treatment (Holler et al. 2009; Nubel et al. 2004).

Methylation of E-Selectin Promoter Gene Represses NF-kB Transactivation: The E-selectin promoter in cultured endothelial cells is under-methylated in comparison with non-expressing HeLa cells. Thus, methylation is likely to play a role in blocking E-selectin expression in non-endothelial cells (Smith et al. 1993). In intestine, MUC2 is the main mucin carrying s-Le^x, which interacts with E-selectin. This interaction may contribute to the extravasation of tumor cells and thus to the metastases. In several colorectal carcinoma cell lines the methylation of the 5'-flanking region of MUC2 correlated with the suppression of the MUC2 gene. The increase in MUC2 expression after the inhibition of the methylation with 5-aza-2' deoxycytidine strongly supports the notion that the suppression of MUC2 gene is related to the methylation of the promoter (Riede et al. 1998).

44.10.3 Strategies to Combat Atherogenesis and Venous Thrombosis

The advances in the development of adhesion molecule blocking agents, as well as an insight into the potential of these molecules in cardiovascular therapy have been reviewed from time to time (Lutters et al. 2004). Prophylactic dosing of a recombinant P-selectin ligand decreases venous thrombosis in a dose-dependent fashion in both feline and nonhuman primate animal models. Additionally,

treatment of 2-day iliac thrombi with a recombinant protein, P-selectin inhibitor, significantly improves vein reopening in nonhuman primates (Register 2009). It is interesting to note that P-selectin inhibition decreases thrombosis without adverse anticoagulation. Myers et al. (2005) evaluated an orally bioavailable inhibitor of P-selectin (PSI-697), which decreased thrombosis. Since, P-selectin is expressed on the surface of activated endothelial cells and platelets during thrombosis, targeting the plasminogen activator (PA) to P-selectin would enhance local thrombolysis and reduce bleeding risk. A urokinase (uPA)/anti-P-selectin antibody (HuSZ51) fusion protein is known to increase fibrinolysis in a hamster pulmonary embolism (Dong et al. 2004)

Aspirin reduces risks of myocardial infarction, stroke and cardiovascular death (Serebruany et al. 2004). The impact of cyclooxygenase (COX)-2 antagonist treatment on acute coronary risk is controversial. Prolonged COX-2 inhibition attenuates CRP and IL-6, does not modify P-selectin and MMP-9, and has no deleterious effect on endothelial function in stable patients with a history of recurrent acute coronary events and raised C-reactive protein (CRP) (Bogaty et al. 2004). Statins used in the control of hypercholesterolemia exert a protective effect on the endothelium reflected by a reduced level of circulating adhesion molecules. Statins exert a beneficial effects on endothelial function and atherosclerotic plaque, modulating oxidative stress and inflammation, with subsequent, well documented, primary and secondary prevention of CAD. Following statin treatment, sP-selectin, and ICAM-1 and highly sensitive CRP decreased compared to baseline levels. Other proteins (sVCAM-1, sE-selectin and platelet ECAM-1) did not show significant changes. In contrast to CRP, the reduction of sP-selectin concentrations correlated directly with the lowering of total cholesterol and inversely with the progression of CAD (Marschang et al. 2006)

44.10.4 Anti-inflammatory Drugs

While diclofenac is capable of inhibiting the expression of E-selectin, ICAM-1 and VCAM-1, the SJC13 is selective in inhibiting the expression of E-selectin and VCAM-1, but not ICAM-1 in endothelial cells. Nonsteroidal anti-inflammatory agents, such as sodium salicylate and aspirin, inhibit NF-κB-dependent gene activation. Salicylate blocked the TNF-α-induced increase in mRNA levels of adhesion molecules and gave a dose-dependent inhibition of TNF-α-induced surface expression of VCAM-1 and ICAM-1 with higher doses required to inhibit E-selectin expression. Ibuprofen appeared a potent inhibitor of IL-1α and TNF-α-induced surface expression of VCAM-1 and a less potent inhibitor of ICAM-1. Indomethacin, a nonsalicylate cyclooxygenase inhibitor, had no effect on surface expression of adhesion molecules, suggesting that the effects were not due to inhibition of cyclooxygenase (Pierce et al. 1996). Methimazole, used in treating autoimmune diseases, may also diminish pathological inflammation by suppressing E-selectin expression. The phenyl methimazole can also reduce cytokine-induced E-selectin expression and consequent leukocyte adhesion. Compound 10, which dramatically inhibits TNF-α-induced VCAM-1 mRNA and protein expression in human aortic endothelial cells, has a modest inhibitory effect on TNF-α induced E-selectin expression and has no effect on ICAM-1 expression (Dagia et al. 2004).

A thieno(2,3-d)pyrimidine, A-155918 inhibits the TNFα-induced expression of E-selectin, ICAM-1, or VCAM-1 on HEVCs (Stewart et al. 2001). Co-treatment of human endothelial cells with certain hydroxyflavones and flavanols blocks cytokine-induced ICAM-1, VCAM-1, and E-selectin expression on human endothelial cells. One of the potent flavones, apigenin, exhibited a dose- and time-dependent, reversible effect on adhesion protein expression as well as inhibiting adhesion protein upregulation at the transcriptional level (Gerritsen et al. 1996). Enalapril and losartan but not placebo induced a small but stable decrease of cardiovascular ICAM-1 and VCAM-1, while E-selectin and leukocyte expression of ICAM-1 remained unchanged. The lowering of plasma adhesion molecules may indicate an antiatherogenic effect of angiotensin II blockade in hypercholesterolemia (Graninger et al. 2004).

Carbohydrates, Synthetic Oligopeptides and Steroids

Targeting interaction of selectins and appropriate carbohydrate ligand is a promising approach to treat chronic inflammation. β-1,3-glucan sulfate (PS3) has inhibitory activity toward L and P-selectins under static conditions (Alban et al. 2009). Access to synthetic carbohydrates is an urgent need for the development of carbohydrate-based drugs, vaccines, adjuvants as well as novel drug delivery systems. Besides traditional synthesis in solution, synthetic carbohydrates have been generated by chemoenzymatic methods as well as automated solid-phase synthesis. Synthetic oligosaccharides have proven to be useful for identifying ligands of carbohydrate-binding proteins such as C-type lectins and siglecs using glycan arrays. Furthermore, glyconanoparticles and glycodendrimers have been used for specific targeting of lectins of the immune system such as selectins, DC-SIGN, and CD22 (Lepenies et al. 2010).

Compounds that target both heparanase and selectins offer a promising approach for cancer therapy. Borsig et al.

(2011) reported semisynthetic sulfated tri mannose C-C-linked dimers (STMCs) which are endowed with heparanase and selectin inhibitory activity. STMC hexasaccharide is an effective inhibitor of P-selectin in vivo. P-selectin-specific STMC attenuated metastasis in animal models, indicating that inhibition of tumor cell interaction with the vascular endothelium is critical for cancer dissemination. The small size, the stability of the C-C bond, and the chemically defined structure of STMCs make them superior to heparin derivatives and signify STMCs as valuable candidates for further evaluation.

Steroids down-regulate the expression of CAMs in endothelial cells stimulated by LPS in vitro. Low-dose hydrocortisone is a new treatment of patients with septic shock, a state that is characterized by an endothelial injury. Treatment with glucocorticoids differently affected the pattern of evolution of sCAMs, with sE-selectin being decreased and sICAM-1 being increased. Expression of sP-selectin and sVCAM-1 was not affected (Leone et al. 2004). Methotrexate (MTX) markedly reduces the expression of vascular E-selectin. A positive correlation between disease severity and the frequency of cutaneous lymphocyte-associated antigen (CLA)-positive T cells in the blood of untreated patients with psoriasis has been observed. It is suggested that MTX decreases the expression of CLA and E-selectin and that this may be a major mechanism for the therapeutic effect of MTX on psoriatic skin lesions (Sigmundsdottir et al. 2004).

Polycystins and Autosomal Polycystic Kidney Disease

45

G.S. Gupta

45.1 Polycystic Kidney Disease Genes

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common monogenic disorders, and globally is the third most common cause of end-stage kidney disease. Although cystic renal disease is the major cause of morbidity, the occurrence of nonrenal cysts, most notably in the liver (occasionally resulting in clinically significant polycystic liver disease) and the increased prevalence of other abnormalities including intracranial aneurysms, indicate that ADPKD is a systemic disorder. Approximately 85% of ADPKD cases are attributable to mutations in polycystic kidney disease (PKD) gene 1 (*PKD1*) on chromosome 16, while mutations in *PKD2* gene on chromosome 4 account for almost all of the remaining cases. These two diseases are phenotypically almost identical, differing only by the higher age of diagnosis with *PKD2*, and its slower progression to end-stage renal disease (Rapoport 2007). The product of *PKD1*, polycystin-1 (PC-1), is a very large protein (4,303 amino acids), and is a membrane glycoprotein widely expressed in epithelial cells. It is also expressed in tight junctions, adherens junctions, desmosomes, apical junctions and primary cilia. Polycystin-2 (PC-2), the product of *PKD2*, is a smaller protein (968 amino acids) mainly present in the endoplasmic reticulum, but also in the cell plasma membrane. PC-1 and -2 are joined via a domain in the carboxy-tail of PC-1, and appear to act in concert (Ong and Harris 2005). PC-2 acts as a Ca^{2+} channel. It appears that PKD1 and PKD2 proteins associate physically in vivo and may be partners of a common signaling cascade involved in tubular morphogenesis (Qian et al. 1997). Qian et al. (1997) defined naturally occurring pathogenic mutations of *PKD1* and *PKD2* that disrupt their associations. Portions of the cellular populations of PC-1 and PC-2 localize to the primary cilium. The ADPKD is the founding member of the "ciliopathies," a recently defined class of genetic disorders that result from mutations in genes encoding cilia-associated proteins.

The human *PKD1* gene encodes an ~14-kb transcript, but full characterization was complicated, because most of the gene lies in a genomic region that is duplicated elsewhere on chromosome 16; the duplicate area encodes three genes with substantial homology to *PKD*. The *PKD1* has been identified in the chromosome region 16p13.3. Other *PKD1*-like loci on chromosome 16 are approximately 97% identical to *PKD1*. The 14.5 kb *PKD1* transcript encodes a 4303/4 amino acid protein with a calculated mass of ~460 kDa with a novel domain architecture. The PKD1 gene covers ~52 kb of genomic DNA and is divided into 46 exons. The amino-terminal half of the protein consists of a mosaic of domains, including leucine-rich repeats flanked by characteristic cysteine-rich structures, LDL-A and C-type lectin domains, and 16 units of a novel 80–85 amino acid domain. The presence of these domains suggests that the PKD1 protein is involved in adhesive protein-protein and protein-carbohydrate interactions in the extracellular compartment. The C-terminal third of the protein has multiple hydrophobic regions, and modeling of this region suggests the presence of many transmembrane domains and a cytoplasmic C terminus. The ADPKD phenotype suggests that polycystin may play a role in cell-matrix communication, which is important for normal basement membrane production and for controlling cellular differentiation (Harris et al. 1995; International Polycystic Kidney Disease Consortium 1995). Mutations in PKD1 gene are the most common cause of ADPKD.

Mouse gene transcript homologous to human PC-1 predicted 79% protein identity to human PC-1 and showed the presence of most of the domains identified in the human sequence. The mouse homolog is transcribed from a unique gene and there are no transcribed, closely related copies as observed in human *PKD1*. In mouse at the junction of exons 12 and 13, several different splicing variants lead to a predicted protein that would be secreted. These forms are predominantly found in newborn brain, while in kidney the

transcript homologous to human RNA predominates (Löhning et al 1997). The murine homolog of human *PKD2* gene, *Pkd2* is localized on mouse Chromosome 5 proximal to anchor marker D5Mit175, spans at least 35 kb of the mouse genome, and consists of 15 exons. Its translation product consists of 966 amino acids, and the peptide shows a 95% homology to human PC-2. Functional domains are particularly well conserved in the mouse homolog. The expression of mouse PC-2 in the developing embryo at day 12.5 post conception is localized in mesenchymally derived structures. In adult mouse, the protein is mostly expressed in kidney, which suggests its functional relevance for this organ (Pennekamp et al. 1998).

45.1.1 Regulatory Elements in Promoter Regions

The *PKD1* and *PKD2* genes are developmentally regulated and their aberrant expression leads to cystogenesis. The 5′-flanking regions of the murine and canine *PKD1* genes have been characterized and compared with sequences from human and Fugu rubripes orthologues as well as the *PKD2* promoters from mouse and human (Lantinga-van Leeuwen et al. 2005). Sequences revealed a variety of conserved putative binding sites for transcription factors and no TATA-box element. Nine elements were conserved in the mammalian *PKD1* promoters: AP2, E2F, E-Box, EGRF, ETS, MINI, MZF1, SP1, and ZBP-89; six of these elements were also found in the mammalian *PKD2* promoters. Deletion studies with the mouse *PKD1* promoter defined a functional promoter region for *PKD1* and implied that E2F, EGRF, Ets, MZF1, Sp1, and ZBP-89 are potential key regulators of *PKD1* and *PKD2* gene products in mammals. The proximal *PKD1* promoter region is a potential target of Ets family transcription factors, which regulate the polycystic kidney disease-1 promoter (Puri et al. 2006).

45.2 Polycystins: The Products of PKD Genes

45.2.1 Polycystins

Polycystins are transmembrane proteins that form a distinct subgroup of the transient receptor potential (TRP) superfamily of channels (Montell 2005; Clapham 2003). The polycystin family is divided structurally and functionally into two subfamilies, the polycystin 1 (PKD1)-like or TRPP1 and polycystin 2 (PKD2)-like or TRPP2 proteins, both of which have a modest degree of sequence similarity between subfamilies (Delmas 2004; Igarashi and Somlo 2002; Nauli and Zhou 2004). In humans, the PKD2-like subgroup contains three homologous proteins—PKD2, PKD2L1 and PKD2L2—which are now referred to as TRPP2, TRPP3 and TRPP5. The PKD1-like subgroup contains five homologous proteins—all with an 11-transmembrane topology and by virtue of their structure are not considered as members of the TRP superfamily. Although channel activity has not been demonstrated for PKD1, it has 11 transmembrane segments of which the last 6 are similar to both PKD2 and other voltage-gated calcium channels (Hughes et al. 1995; Mochizuki et al. 1996). PKD2 assembles with PKD1 to form a functional Ca^{2+}-permeable cation channel complex in the plasma membrane (Delmas et al. 2004; Hanaoka et al. 2000) and the primary cilium (Nauli et al. 2003). In addition to currents observed at the plasma membrane in conjunction with PKD1, PKD2-mediated channel activity has also been shown in other sub-cellular membranes where it acts as an intracellular Ca^{2+} release channel (Koulen et al. 2002). Interactions between PKD1 and PKD2 are driven by their cytoplasmic carboxyl-terminal regions (Hanaoka et al. 2000; Newby et al. 2002). PKD1–PKD2 interactions are critical to kidney architecture and function because complex-disrupting mutations in either partner lead to development of autosomal dominant polycystic kidney disease (ADPKD), which affects 1 in 1,000 individuals (Wilson 2004; Igarashi and Somlo 2002; Molland et al. 2010).

45.2.2 Polycystin-1 (TRPP1) with a C-type Lectin Domain

Polycystin-1 (PC-1) is a large transmembrane protein with an estimated molecular weight of ~500 kDa having 4303 amino acids (Hughes et al. 1995; Burn et al. 1995). The large extracellular N-terminal region contains several specific motifs including leucine-rich repeats (LRRs), C-type lectin domain, LDL-A region, multiple Ig-like domains (or PKD domains), REJ domain and GPS domain. It has 11 transmembrane domains, with a PLAT domain located in the first cytoplasmic loop and a small cytoplasmic tail with a G-protein-binding motif and coiled-coil region (Figs. 45.1a and 45.2). The 16 Ig-like domains are segmented such that the first Ig-like domain is localized between the LRRs and the C-type lectin domain, while the remaining 15 Ig-like domains are clustered together between LDL-A and REJ domains. This Ig-like domain cluster forms strong homophilic interactions that are important for cell-cell adhesion (Bycroft et al. 1999; Ibraghimov-Beskrovnaya et al. 2000; Streets et al. 2003). Polycystin is likely a multifunctional protein with important roles in cell-cell/matrix adhesion and ciliary functions (Hildebrandt and Otto 2005; Wilson 2004). Polycystin-1 undergoes partial cleavage at the GPS domain such that N-terminal and C-terminal polypeptides remain non-covalently linked (Qian et al.

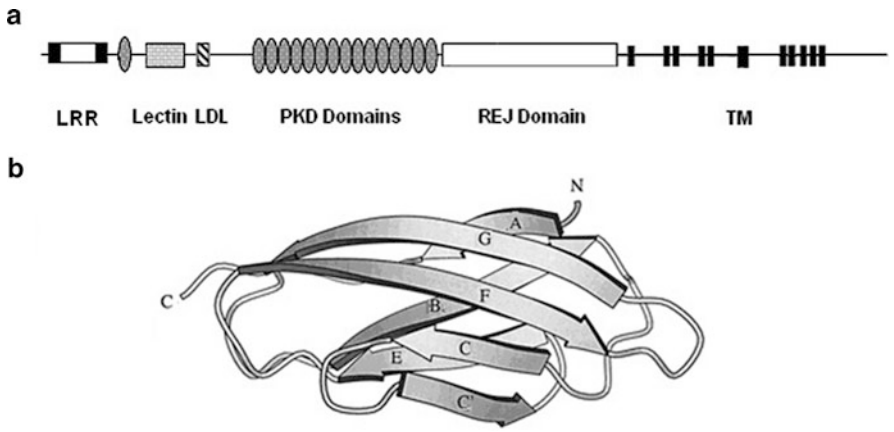

Fig. 45.1 (**a**) A schematic representation of the domains in polycystin-1. *LRR* leucine-rich repeat domain with flanking cysteine-rich regions, *Lectin* C-type lectin domain, *LDL* LDL-A module, *PKD* PKD (Ig-like) domains, *REJ domain* similar to sea urchin REJ protein, *TM* transmembrane domains. (**b**) PKD (Ig-like)-1 showing the elements of secondary structure. The β-strands are labeled (Reprinted with permission from Macmillan Publishers Ltd: EMBO J, Bycroft et al. ©1999)

2002; Wei et al. 2007). It is subsequently cleaved at the second site, which releases its C-terminal tail. The cytoplasmic tail of PC-1 enters the nucleus and regulates cell signaling events. This signaling function of PC-1 is regulated by PC-2 and may possibly be initiated by mechanical stimuli (Chauvet et al. 2004).

Analysis of the C-terminal cytosolic domain of human and mouse PC-1 has identified a number of conserved protein motifs, including a 20-amino-acid heterotrimeric G-protein activation sequence, suggesting that PC-1 may function as a heterotrimeric G-protein coupled receptor (Parnell et al. 1998). The *Xenopus* homologue of human *PKD1* (x*PKD1*) gene predicts the sequence of the putative protein, homologous to human PKD1 with a high level of expression in the kidney. A similar analysis in developing embryos and in an in vitro nephrogenic system suggests that *xPKD1* is associated with development of the amphibian pronephros (Burtey et al. 2005). The C-terminal intracellular segments of PC-1 have been extensively studied, mainly with respect to their putative involvement in cell signaling. Mutations in PC-1 result in ADPKD which is characterised by perturbation of transport resulting in fluid accumulation, cell proliferation and modification of the extracellular matrix (Weston et al. 2003). Cloned and expressed *PKD1* C-type lectin domain demonstrated that PC-1 may be involved in protein–carbohydrate interactions in vivo, and that Ca^{2+} is required for this interaction (Weston et al. 2001). Mutations in *PKD1* are implicated in human autosomal dominant polycystic disease.

Pletnev et al. (2007) made a model on a 3D structure and derived function of individual domains of PC-1. A three dimensional model of CTLD of PC-1 (sequence region 405–534) complexed with galactose and a Ca^{2+} was developed. The model suggests a αβ structural organization, which is composed of eight β strands and three α helices, and includes three disulfide bridges. It is consistent with the observed Ca^{2+} dependence of sugar binding to CLD and identifies the amino acid side chains (E^{499}, H^{501}, E^{506}, N^{518}, T^{519} and D^{520}) that are likely to bind the ligand (Pletnev et al. 2007). A coiled-coil domain within the C terminus of polycystin has been described to bind specifically to the C terminus of PKD2.

45.2.2.1 PKD (or Ig-like) Domains

The extracellular portion of PC-1 is modular in nature, and has a β sandwich-Ig-like protein module called PKD domain and comprises approximately 40% of the structure (Hughes et al. 1995). PC-1 consists of 16 copies of the PKD domain. Although the β-sandwich fold is common to a number of cell-surface modules, the PKD domain represents a distinct protein family. The tenth PKD domain of human and Fugu polycystin-1 showed extensive conservation of surface residues suggesting that this region could be a ligand-binding site. This structure will allow the likely effects of missense mutations in a large part of PKD1 gene to be determined (Bycroft et al. 1999) (Fig. 45.1b).The mechanical properties of PC-1 PKD domains (Forman et al. 2005; Qian et al. 2005) were first investigated for their importance in PKD. Atomic force microscopy experiments, applying force at the N and C termini of PKD domains, showed that PKD domains resist unfolding under significant force, a requirement for their function as mechanosensors (Forman et al. 2005; Qian et al. 2005). Hence, PC-1 was proposed to act as a mechanosensor, transducing fluid flow detected by the cilia of kidney epithelial cells into changes in intracellular calcium levels (Nauli et al. 2003). On the basis of predicted domain structure PC-1 seems to be involved in protein-protein and protein-carbohydrate interactions.

45.2.2.2 Amino Acid Polymorphism

Many disease-causing mutations have been characterized in *PKD1* gene, most of them resulting in premature protein termination. A few intragenic polymorphisms have been described that are also useful for linkage studies. A new diallelic polymorphism is described for amino acid residue 4058, Ala/Val4058, with allelic frequencies of 0.88 and 0.12, respectively, and a heterozygosity of 0.23, in the Greek and Greek-Cypriot populations. Interestingly, this polymorphism and Ala4091-A/G, which were described in Caucasians, were not detected in DNA from 44 Japanese. This is particularly important when allelic frequencies in a particular population are used for linkage analysis of families of different ethnic origin. Also, observation of the two polymorphisms together as haplotypes suggests that the Ala/Val4058 polymorphism occurred more recently than the establishment of the Ala4091-A/G polymorphism, and specifically on the G allele (Constantinides et al. 1997).

45.2.3 Polycystin-2 (TRPP2)

Polycystin-2 (or TRPP2) is a 968-amino acid containing protein of ~110 kDa with six transmembrane domains and cytoplasmic N- and C-terminal domains (Fig. 45.2) (Mochizuki et al. 1996). Polycystin-2 is thought to be a new member of the transient receptor potential (TRP) family of ion channels. It was shown to be a cation channel with some selectivity for Ca^{2+} (Gonzalez-Perrett et al. 2001) and functions in multiple subcellular locations including plasma membrane (Hanaoka et al. 2000; Babich et al. 2004), endoplasmic reticulum (Koulen et al. 2002) and the primary cilia (Nauli et al. 2003). Several domains present in N and C termini of PC-2 are responsible for PC-2's protein–protein interactions and Ca^{2+} sensitivity. At least two domains, one in each cytoplasmic tail, contribute to PC-2 oligomerization. Immediately distal to PC-2's last transmembrane domain is a functionally complex region of the C terminus that includes coiled-coil, EF-hand (helix-loop-helix), and ER retention domains. A calcium-binding EF hand domain begins upstream of and extends into the PC-1-interacting coiled-coil region (Mochizuki et al. 1996; Qian et al. 1997; Celić et al. 2008). The helix-loop-helix structure of the EF-hand binds Ca^{2+}, permitting the protein to sense or to buffer changes in Ca^{2+} (Gifford et al. 2007). The PC-2 EF-hand has a single Ca^{2+}-binding site with micromolar affinity (Celić et al. 2008). Slightly overlapping with both the coiled-coil and the EF-hand is the sequence that is required for maintaining PC-2's ER and Golgi localization (Cai et al. 1999). A naturally occurring truncation mutation that removes this C-terminal domain, and thus presumably abrogates all of its interactions and regulatory potential, is sufficient to cause ADPKD (Mochizuki et al. 1996).

Polycystin-2 (or TRPP2) has been implicated in various biological functions including cell proliferation, sperm fertilization, mating behaviour, mechanosensation and asymmetric gene expression. Polycystin-1 and -2 can function together as a complex as well as independently in a variety of subcellular compartments. Direct interaction between the cytoplasmic tails of the polycystins has been shown using yeast two-hybrid assay (Qian et al. 1997; Tsiokas et al. 1997). Being a calcium-activated channel PC-2 releases calcium from intracellular stores in response to local increases in calcium concentrations. The calcium-conducting pore of PC-2 is likely formed by the loop between the fifth and sixth transmembrane domains, with some involvement of the third transmembrane domain (Koulen et al. 2002). A missense mutation that perturbs this putative conducting pore (D511V) is causative of ADPKD (Koulen et al. 2002). PC2 also indirectly regulates cytoplasmic calcium levels through interactions with two major intracellular Ca^{2+} channels: the ryanodine receptor and the inositol 1,4,5-trisphosphate receptor (IP3R). The ryanodine receptor mediates calcium-induced calcium release, and PC-2 inhibits its function by binding the channel in its open state and decreasing its

conductance (Anyatonwu et al. 2007). PC-2 also modifies IP3-induced Ca^{2+} flux through direct binding between the PC-2C terminus and the IP3R (Li et al. 2005b, 2009).

45.2.3.1 Polycystin-L

Polycystin-L (PC-L), the third member of the polycystin family of proteins, functions as a Ca^{2+}-modulated nonselective cation channel when expressed in Xenopus oocytes. PC-L is predominantly expressed in adult mouse tissues and has a more restricted pattern of expression than either PC-1 or -2. In kidney, PC-L expression was first detected at E16, and levels increased into adulthood. Localization of PC-L was predominantly found in the apical region of the principal cells of inner medullary collecting ducts. PC-L was also found in discrete cell types of the retina, testis, liver, pancreas, heart, and spleen, but not in the lung. The expression pattern of PC-L suggests that it is unlikely to be a candidate gene for ADPKD (Basora et al. 2002). Results raise the possibility that PKD2L1 represents the third genetic locus that is responsible for PKD. However, its CTLD status remains to be investigated.

45.2.4 Interactions of Polycystins

PC-1 and PC-2 interact through their C-terminal cytoplasmic tails. This interaction results in an up-regulation of PC-1 but not PC-2. Furthermore, the cytoplasmic tail of PC-2 but not PC-1 formed homodimers through a coiled-coil domain distinct from the region required for interaction with PC-1. These interactions indicate that PC-1 and PC-2 may function through a common signaling pathway that is necessary for normal tubulogenesis and that PC-1 may require the presence of PC-2 for stable expression (Tsiokas et al. 1997). The intermediate filament (IF) protein vimentin is a strong PC-1-interacting partner. Cytokeratins K8 and K18 and desmin were also found to interact with PC-1. These interactions were mediated by coiled-coil motifs in PC-1 and IF proteins. Polycystin-1 may utilize this association for structural, storage, or signaling functions (Xu et al. 2001). Fibrocystin, a ~450 kDa protein, may form a complex with PC-2 to regulate calcium responses in kidney epithelia, but its exact role in normal and cystic epithelia is unknown (Wang et al. 2007).

A potential target for PC-1 signal transduction is the β catenin signal transduction pathway. This cytoplasmic protein is a key player in the regulation of cell polarity, proliferation, and morphogenesis, processes that are all affected in ADPKD. It was found that polycystin-1 interacts with the E-cadherin–catenin complex containing β catenin and suggested that polycystin-1 modulates signaling by β catenin. Several lines of evidence implicate β catenin in the pathogenesis of polycystic kidney disease. It appeared that aberrant β catenin signaling is a common feature of polycystic kidney diseases. Cytoplasmic β catenin interacts with members of the LEF/TCF family of transcription factors (van Adelsberg 2000).

45.2.5 Tissue and Sub-Cellular Distribution of Polycystins

Both proteins localize to primary cilia of renal epithelial cells, where they are implicated in mechanosensitive transduction signals (Yoder et al. 2002; Nauli et al. 2003). Polycystin 2/TRPP2 has been also documented at the plasma membrane (PM) and the ER—but it is still disputed whether it functions as an intracellular or a plasmalemmal channel. The finding that TRPP2 is retained in the ER of most cell systems has supported the view that TRPP2 might function as a reticular Ca^{2+}-release channel (Koulen et al. 2002). Conversely, TRPP2 has been shown to reside and act at the PM, notably in Madine–Darby canine kidney (MDCK) cells derived from cortical collecting ducts (Luo et al. 2003; Scheffers et al. 2002). These apparently incongruent views might be reconciled by the demonstration that subcellular transport and localization of TRPP2 are controlled by many interactions with adaptor proteins and enzymes (Köttgen et al. 2005; Streets et al. 2006; Geng et al. 2006). Such varied transport behaviour provides a mechanism for the dynamic regulation of TRPP2 channel density at the ER, PM and cilial localizations, and for different subcellular TRPP2 signaling functions. Polycystin is localized in membranes of renal and endothelial cells. When cultured cells made cell-cell contact, polycystin was localized to the lateral membranes of cells in contact (Ibraghimov-Beskrovnaya et al. 1997). Subcellular localization studies found PKD-1 to be a component of various cell junctional complexes and to be associated with the cytoskeleton (Xu et al. 2001). Scheffers et al. (2002) suggest that polycystin-2 can move freely in certain regions of the membrane where it probably functions as a channel, activated by, or in complex with, polycystin-1. PC-1 and PC-2 are functionally expressed in B-lymphoblastoid cells (LCLs), easily obtainable from ADPKD patients, to study PKD gene expression and function (Aguiari et al. 2004).

In fetal kidney, polycystin was localized to the plasma membranes of ureteric bud and comma and S-shaped bodies.

However, in more mature tubules in fetal kidney, in adult kidney, and in polycystic kidney, the majority of polycystin staining was intracellular. The temporal and spatial regulation of polycystin during renal development indicates that polycystin may play a role in nephrogenesis (van Adelsberg et al. 1997; van Adelsberg 1999a). Thus, the knowledge of the compartment-specific regulations of TRPP2 is of crucial importance for the understanding of its roles in health and disease (Giamarchi et al. 2006). The pattern of polycystin expression changed with gestational age in kidney. The widespread distribution of polycystin is consistent with the systemic nature of ADPKD and the role of epithelial cells in the disease (Weston et al. 2001).

45.3 Functions of Polycystin-1 and Polycystin-2

45.3.1 Polycystin-1 and Polycystin-2 Function Together

Polycystin-1 and -2 are thought to function together as part of a multiprotein membrane-spanning complex involved in cell-cell or cell-matrix interactions. Polycystin-1 and -2 interact to produce new calcium-permeable non-selective cation currents. Neither polycystin-1 nor -2 alone is capable of producing currents. Moreover, disease-associated mutant forms of either polycystin protein that are incapable of heterodimerization do not result in new channel activity. Thus, polycystin-1 and -2 co-assemble at the plasma membrane to produce a new channel and to regulate renal tubular morphology and function (Hanaoka et al. 2000). Polycystin-1 and -2 co-assembly can initiate signal transduction, leading to the activation of a number of downstream effectors, including heterotrimeric G-proteins, protein kinase C, mitogen-activated protein kinases, β-catenin, and the AP-1 transcription factor. In addition, PC-2 may function in mediating calcium flux.

The overlapping expression and localization patterns of polycystin-1 and -2 support their role as a complex in regulating multiple processes in tubular epithelia (Ong 2000). Both proteins are found in basolateral membranes and the primary cilium, where they may act together to regulate cellular adhesion and Ca^{2+} signaling. On the other hand, PC-2 is mainly expressed in ER, where it functions as a Ca^{2+} release channel (Koulen et al. 2002). In addition, PC-1 is highly expressed during development, with significant down-regulation of its expression in adult tissues. In contrast, expression of PC-2 seems to persist into adult life (Ong 2000). Experimental evidence from several groups has established an important role for polycystins in epithelial cell morphogenesis, including differentiation and maturation in vivo (Kim et al. 2000; Lu et al. 1997). Studies using MDCK cells demonstrated that expression of polycystin-1 at cell-cell junctions at controlled levels is critical for proper tubular differentiation (Bukanov et al. 2002). It has been shown that PC-1 is directly involved in intercellular adhesion *via* formation of strong homophilic interactions of its PKD (Ig-like) domains (Ibraghimov-Beskrovnaya et al. 2000). A direct role for Ig-like domains in cell-cell adhesion was demonstrated by specific perturbation of intercellular adhesion using antibodies against Ig-like domains in cell cultures (Ibraghimov-Beskrovnaya et al. 2000; Streets et al. 2003). Polycystin-1 was localized to the cell-cell adhesion complexes with adherens junctions and desmosomal junctions in epithelial cells of different origin (Bukanov et al. 2002; Huan and van Adelsberg 1999; Scheffers et al. 2000). Because alterations in PC-1-mediated adhesion may cause the abnormal epithelial cell phenotype observed in ADPKD cells, including dedifferentiation and loss of epithelial polarity, several studies examined cell-cell adhesion junctions in primary cells derived from ADPKD kidneys (Streets et al. 2003; Roitbak et al. 2004; Russo et al. 2005). Abnormal adherens and desmosomal junctions are found in ADPKD: intracellular junctions are devoid of desmosomal cadherins and associated proteins, which were sequestered to the cytoplasmic pools, and adherens junctions appeared disrupted, accompanied by a great reduction of E-cadherin expression and partial compensatory expression of N-cadherin (Roitbak et al. 2004) Streets et al. (2003) demonstrated that one of the primary functions of polycystin-1 is to mediate cell-cell adhesion in renal epithelial cells, probably via homophilic or heterophilic interactions of the PKD domains. Polycystin-1 localizes with desmosomal junctions (DJs) and adherens junctions (AJs). AJs and DJs are disrupted in ADPKD cells, while tight junctions (TJ) remain intact. In normal epithelial cells, PC-1 is found in a complex with talin (TAL), paxillin (PAX), vinculin (VINC), focal adhesion kinase (FAK), c-src (SRC), p130-cas (CAS), nephrocystin (NPH1) and tensin (TEN). In ADPKD cells, expression of FAK is lost from the focal adhesion complex (Ibraghimov-Beskrovnaya and Bukanov 2008; Chapin and Caplan 2010).

45.3.2 Cell-Cell and Cell-Matrix Adhesion

The *PKD* genes are required for normal fetal development. Consistent with its manifestations, PC-1 is widely expressed in both epithelial and nonepithelial tissues during embryological development. Mice with targeted mutations of either the *PKD1* or the *PKD2* genes die during embryogenesis. The observation, that loss of polycystin-1 or -2 function causes death during embryogenesis, suggests that *PKD1* and *PKD2*

might be part of a morphoregulatory pathway (van Adelsberg 1999b). The cystein-flanked leucine-rich repeats (LRR) of PC-1 act as mediators of the PC-1 interaction with the ECM. The observed suppression effect of the LRR on cell proliferation suggests a functional role of the LRR-mediated PC-1 involvement in cell-matrix and cell-cell interactions. These interactions may result in the enhanced cell proliferation that is a characteristic feature of ADPKD (Malhas et al. 2002; Chapin and Caplan 2010).

45.3.3 Role in Ciliary Signaling

The study of the polycystins has revealed some entirely novel insights into fundamental cell biology but these have not yet been satisfactorily integrated into a verified pathogenetic pathway for the development of ADPKD (Sutters 2006). The majority of epithelial cells along the nephron, except intercalated cells, possess a primary cilium, an organelle projecting from the cell's apical surface into the luminal space. Recent studies indicate that renal cilia have a sensory function. Many of the molecular players, which should help solve the mystery of how the renal cilium senses fluid flow, have been studied. Several proteins implicated in the pathogenesis of polycystic kidney disease localize to cilia. The role(s) of the polycystin signaling complex in mediating mechanosensory function by the primary cilium of renal epithelium as well as of the embryonic node have been reviewed (Nauli and Zhou 2004; Chapin and Caplan 2010). It is likely that the central pathogenetic pathway for cystogenesis stems from de-differentiation of tubular epithelial cells. Available evidence indicates that loss of polycystin activity leads to subtle derangements of cell calcium regulation through several possible pathways. Abnormal cell calcium homeostasis might then lead to altered differentiation in affected cells. The precise mechanism by which PC-1 functions, however, remains unclear. Polycystin-1 undergoes a proteolytic cleavage that releases its C-terminal tail (CTT), which enters the nucleus and initiates signaling processes. The cleavage occurs in vivo in association with alterations in mechanical stimuli. Polycystin-2 modulates the signaling properties of the PC-1 CTT.

Results show also a novel pathway by which PC-1 transmits messages directly to the nucleus (Chauvet et al. 2004). Low et al. (2006) showed that PC-1 tail interacts with the transcription factor STAT6 and the coactivator P100, and it stimulates STAT6-dependent gene expression. Under normal conditions, STAT6 localizes to primary cilia of renal epithelial cells. Cessation of apical fluid flow results in nuclear translocation of STAT6. Cyst-lining cells in ADPKD exhibit elevated levels of nuclear STAT6, P100, and the PC-1 tail. Exogenous expression of human PC-1 tail results in renal cyst formation in zebrafish embryos. This is a novel mechanism of cilia function in transduction of a mechanical signal to changes of gene expression involving PC-1 and shows that this pathway is inappropriately activated in ADPKD.

Primary Cilia of inv/inv Mouse Renal Epithelial Cells Sense Physiological Fluid Flow: Anomalous structure of primary cilia and/or impairment of increases in intracellular Ca^{2+} in response to fluid flow are thought to result in renal cyst formation in conditional kif3a knockout, Tg737 and pkd1/pkd2 mutant mice. The mutant inv/inv mouse develops multiple renal cysts like kif3a, Tg737 and pkd1/pkd2 mutants. Inv proteins have been shown to be localized in the renal primary cilia (Shiba et al. 2005).

Polycystins have been suggested to form mechanosensory transduction complexes involved in a variety of biological functions including sperm fertilization, mating behavior, and asymmetric gene expression in different species. Furthermore, their dysfunction is the cause of cyst formation in human kidney disease. The extracellular region of polycystin-1, which has a number of putative binding domains, may act as a mechanosensor. New evidence shows that a mechanosensitive signal, cilia bending, activates the PC-1-PC-2 channel complex. When working properly, this functional complex elicits a transient Ca^{2+} influx, which is coupled to the release of Ca^{2+} from intracellular stores (Cantiello 2003). Delmas (2004) focused on the pros and cons of their candidacy as mechanically gated channels and on recent findings that have significantly advanced our physiological insight. Nauli et al. (2006) proposed that calcium response to fluid-flow shear stress can be used as a read out of polycystin function and that loss of mechanosensation in the renal tubular epithelia is a feature of PKD cysts. Report supports a two-hit hypothesis as a mechanism of cystogenesis.

A large proportion of the extracellular region of polycystin-1 consists of β-sandwich PKD domains in tandem array. Using atomic force microscopy, it was shown that these domains, despite having a low thermodynamic stability, exhibit a remarkable mechanical strength, similar to that of Ig domains in the giant muscle protein titin. The simulations suggest that the basis for this mechanical stability is the formation of aforce-stabilised intermediate. Results suggest that these domains will remain folded under external force supporting the hypothesis that polycystin-1 could act as a mechanosensor, detecting changes in fluid flow in the kidney tubule (Forman et al. 2005). Both polycystins are localized to motile oviduct cilia and this localization is greatly increased upon ovulatory gonadotropic stimulation. It was suggested that PC-1 and -2 play an important role in granulosa cell differentiation and in development and maturation of ovarian follicles. In the oviduct both TRPV4 and polycystins could be important in relaying physiochemical

changes in the oviduct upon ovulation (Nauli et al. 2003; Teilmann et al. 2005).

45.3.4 Cilia and Cell Cycle

There is an intimate link between cilia and the cell cycle. The basal bodies/centrosomes of the cilia act as organizers of the mitotic spindle poles during cell division, directly connecting ciliogenesis with cell cycle regulation, and cilia are resorbed when cells enter the cell cycle. Because a number of cystoproteins causing PKD in humans and animals are expressed, at least partially, in cilia or the basal body of the cilia, polycystins and other cystoproteins may play an important role in connecting the mechanosensory function of the cilia to the centrosome and thus influence cell cycle control. Disruption of cystoproteins associated with cilia or basal bodies could, therefore, lead to dysregulation of the cell cycle and proliferation, resulting in cystic disease. Several lines of evidence support this hypothesis. Li et al. (2005b) showed that PC-2 regulates the cell cycle through direct interaction with Id2, a member of the helix-loop-helix (HLH) protein family that is known to regulate cell proliferation and differentiation. Id2 expression suppresses the induction of a cyclin-dependent kinase inhibitor, p21, by either PC-1 or PC-2. It was proposed that Id2 has a crucial role in cell-cycle regulation that is mediated by PC-1 and PC-2 (Chapin and Caplan 2010).

45.3.5 Polycystins and Sperm Physiology

Polycystins also play a significant role in sperm development and function. Drosophila PC-2 is associated with the head and tail of mature sperm. Targeted disruption of the PKD2 homologue results in nearly complete male sterility without disrupting spermatogenesis. Mutant sperm are motile but are unable to reach the female storage organs (seminal receptacles and spermathecae). The sea urchin PC-1-equivalent suPC-2 colocalizes with the PC-1 homolog REJ3 to plasma membrane over the acrosomal vesicle (Galindo et al. 2004; Kierszenbaum 2004). Like other PC-2 family members, suPC-2 is a six-pass transmembrane protein containing C-terminal cytoplasmic EF hand and coiled-coil domains. The location of suPC-2 suggests that it may function as a cation channel mediating the sperm acrosome reaction. The low cation selectivity of PC-2 channels would explain data indicating that Na^+ and Ca^{2+} may enter sea urchin sperm through same channel during the acrosome reaction (Neill et al. 2004). This localization also suggests that the suPC-2-REJ3 complex may function as a cation channel mediating acrosome reaction when sperm contact the jelly layer surrounding the egg at fertilization. Future studies leading to the identification of specific ligands for polycystins, including the signaling pathways, might define the puzzling relationship between renal tubular morphogenesis and sperm development and function.

45.4 Autosomal Dominant Polycystic Kidney Disease

45.4.1 Mutations in *PKD1* and *PKD2* and Association of Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is a common inherited nephropathy affecting over 1:1000 of worldwide population. It is a systemic condition with frequent hepatic and cardiovascular manifestations in addition to the progressive development of fluid-filled renal cysts that eventually result in loss of renal function in the majority of affected individuals. Mutations in either PC-1 or PC-2 account for the majority of autosomal dominant PKD. The cysts that grow in the kidney are the result of any number of mutations within the genes *PKD1* and *PKD2* that code for PC-1 and PC-2, respectively. Over 90 mutations have been discovered in *PKD1* alone, which lead to the disruption of proper function. These mutations have been found to be missense, nonsense, and frame-shift (Eo et al. 2002). The diagnosis of ADPKD is typically made using renal imaging despite the identification of mutations in *PKD1* and *PKD2* that account for virtually all cases. Most *PKD* gene mutations are loss of function and a 'two-hit' mechanism has been demonstrated underlying focal cyst formation. The protein products of the *PKD* genes, the polycystins, form a calcium-permeable ion channel complex that regulates the cell cycle and the function of the renal primary cilium. Abnormal cilial function is now thought to be the primary defect in several types of PKD including autosomal recessive polycystic kidney disease and represents a novel and exciting mechanism underlying a range of human diseases (Boucher and Sandford 2004; Chapin and Caplan 2010).

Russo et al. (2005) indicated that polycystin-1 is involved in cell proliferation and morphogenesis. Mutated PC-1 affects intercellular adhesion as shown by desmosomal junctions in primary cells derived from ADPKD cysts. While, primary epithelial cells from normal kidney showed co-localization of PC-1 and desmosomal proteins at cell-cell contacts, a striking difference was seen in ADPKD cells, where PC-1 and desmosomal proteins were lost from the intercellular junction membrane, despite unchanged protein expression levels. Results demonstrated that, in the absence of functional PC-1, desmosomal junctions cannot be properly assembled and remain sequestered in cytoplasmic compartments. Thus, PC-1 is crucial for formation of intercellular contacts. The abnormal expression of PC-1 causes disregulation of cellular

adhesion complexes leading to increased proliferation, loss of polarity and, ultimately cystogenesis.

45.4.2 Proliferation and Branching Morphogenesis in Kidney Epithelial Cells

Grimm et al. (2006) showed that the basal and EGF-stimulated rate of cell proliferation is higher in cells that do not express PC-2 versus those that do, indicating that PC-2 acts as a negative regulator of cell growth. In addition, cells not expressing PC-2 exhibited significantly more branching morphogenesis and multicellular tubule formation under basal and Hepatocyte GF-stimulated conditions than their PC-2-expressing counterparts, suggesting that PC-2 may also play an important role in the regulation of tubulogenesis. Cells expressing a channel mutant of PC-2 proliferated faster than those expressing the wild-type protein, but exhibited blunted tubule formation. Thus, the channel activity of PC-2 may be an important component of its regulatory machinery. Finally, PC-2 regulation of cell proliferation appears to be dependent on its ability to prevent phosphorylated extracellular-related kinase from entering the nucleus. These results indicate that PC-2 is necessary for the proper growth and differentiation of kidney epithelial cells (Grimm et al. 2006). Polycystin-2 is thought to function with PC-1, as part of a multiprotein complex involved in transducing Ca^{2+}-dependent information. Although its function as a Ca^{2+}-permeable cation channel is well established, its precise role in the plasma membrane, the endoplasmic reticulum and the cilium is controversial. Studies suggest that PC-2 (TRPP2) function is highly dependent on the subcellular compartment of expression, and is regulated by many interactions with adaptor proteins (Giamarchi et al. 2006).

Although the PKD genes were identified a decade ago, the pathway(s) leading from mutation to disease remain the subject of intense investigation. The pathogenesis of cyst formation is thought to involve increased cell proliferation, fluid accumulation, and basement membrane remodeling. It appears that cAMP metabolism is a central component of cyst formation, stimulating apical chloride secretion and driving the accumulation of cyst fluid. Evidence has shown that ADPKD cells also have an altered responsiveness to cAMP. In contrast to normal kidney cells whose cell proliferation is inhibited by cAMP, ADPKD cells are stimulated to proliferate. Thus, it is likely that an alteration in polycystin function transforms the normal cellular phenotype to one that responds to elevated cAMP by an increased rate of cell proliferation and that the enlarging cyst expands by an increased rate of cAMP-driven fluid secretion. Cyclic AMP and growth factors, including EGF, have complementary effects to accelerate the enlargement of ADPKD cysts, and thereby to contribute to the progression of the disease. This knowledge should facilitate the discovery of inhibitors of signal transduction cascades that can be used in the treatment of ADPKD (Calvet and Grantham 2001). Li et al. (2005) suggested that PC-2 and IP3R functionally interact and modulate intracellular Ca^{2+} signaling. Therefore, mutations in either PC-1 or PC-2 could result in the misregulation of intracellular Ca^{2+} signaling, which in turn could contribute to the pathology of ADPKD (Li et al. 2005).

Involvement of G-proteins was demonstrated by Delmas et al. (2004) who found that full-length PC-1 functions as a constitutive activator of $G_{i/o}$-type but not G_q-type G-proteins and modulates the activity of Ca^{2+} and K^+ channels via release of $G_{\beta\gamma}$ subunits. PC-1 lacking N-terminal 1,811 residues replicated the effects of full-length PC-1. Evidence indicates that full-length PC-1 acts as an untraditional G-protein-coupled receptor, activity of which is physically regulated by PC-2. Thus, it suggests that mutations in PC-1 or PC-2 that distort the polycystin complex would initiate abnormal G-protein signaling in ADPKD (Delmas et al. 2002). Regulation of intracellular Ca^{2+} mobilization has been associated with the functions of PC-1 and PC-2. PC-1 can activate the calcineurin/NFAT (nuclear factor of activated T-cells) signaling pathway (Puri et al. 2004). Puri et al. (2006) suggested a model in which PC-1 signaling leads to a sustained elevation of intracellular Ca^{2+} mediated by PC-1 activation of $G_{\alpha q}$ followed by PLC activation, release of Ca^{2+} from intracellular stores, and activation of store-operated Ca^{2+} entry, thus activating calcineurin and NFAT.

Endogenous Lectins as Drug Targets

46

Rajesh K. Gupta and Anita Gupta

46.1 Targeting of Mannose-6-Phosphate Receptors and Applications in Human Diseases

46.1.1 Lysosomal Storage Diseases

The lysosome is an intracytoplasmic acidic vacuole containing more than 60 hydrolytic enzymes for digestion of macromolecules, such as nucleic acids, proteins, lipids and complex carbohydrates. Expression of lysosomal enzyme activities is regulated by various intracellular environmental factors. Mutation of a gene coding for a lysosomal enzyme results in a specific genetic disease, often involving the central nervous system in children. Three groups of functional proteins are known at present for regulation of the expressed enzyme activity in lysosomes. Targeting of a newly synthesized protein is achieved by the mannose 6-phosphate receptor (M6PR) system (Chaps. 3–5), which was revealed in the course of I-cell disease research. Many lysosomal enzymes are excessively secreted in the extracellular compartment in the absence of this regulatory system in patients with this disease (Kornfeld and Sly 2001). Lysosomal enzymes are also components of cell type-specific compartments referred to as lysosome-related organelles which include melanosomes, lytic granules, MHC class II compartments, platelet-dense granules, and synaptic-like microvesicles. Lysosomal storage diseases (LSDs) are inherited metabolic disorders caused by deficient activity of a single lysosomal enzyme or other defects resulting in deficient catabolism of large substrates in lysosomes. There are more than 40 forms of inherited LSDs known to occur in humans, with an aggregate incidence estimated at 1 in 7,000 live births. Clinical signs result from the inability of lysosomes to degrade large substrates; because most lysosomal enzymes are ubiquitously expressed, a deficiency in a single enzyme can affect multiple organ systems. Thus LSDs are associated with high morbidity and mortality and represent a significant burden on patients and society. Because lysosomal enzymes are trafficked by M6PR mechanism, normal enzyme provided to deficient cells can be localized to the lysosome to reduce and prevent storage. However, many LSDs remain untreatable, and gene therapy holds the promise for effective therapy. Other therapies for some LSDs do exist, or are under evaluation, including heterologous bone marrow or cord blood transplantation, enzyme replacement therapy (ERT), and substrate reduction therapy, but these treatments are associated with significant concerns, including high morbidity and mortality, limited positive outcomes, incomplete response to therapy the cost (Haskins 2009), life-long therapy, and the cost (Haskins 2009). Moreover, proteins, vesicles, nano-particles or other polymers could be functionalized with mannose 6-phosphate or its analogues in order to be used as carriers of bioactive molecules for the treatments of different diseases (Gary-Bobo et al. 2007).

Transport of lysosomal enzymes is mediated by two M6PRs: a cation dependent (CD-MPR) and a cation independent receptor (CI-MPR) (see Chaps. 3–5 for structures and functions). In hepatocytes of MPR-deficient neonatal mice lysosomal storage occurs when both MPRs are lacking, whereas deficiency of CI-MPR only has no effect on the ultrastructure of the lysosomal system (Schellens et al. 2003). Some structural features have been shown to be crucial for the binding of M6P to CI-MPR. The hydroxyl group at 2-position of pyranose ring must be axial to allow a strong binding to the CI-MPR. The analogues synthesized to target CI-MPR must be isosteric to M6P to efficiently bind to the receptor. Moreover, a single negative charge is sufficient to allow the binding to the receptor while the phosphorus atom is not necessary to ensure recognition. However, the

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_46,

best ligands for CI-MPR contain two negative charges like in the malonate or phosphonate isosteric analogues of M6P.

46.1.2 Enzyme Replacement Therapy (ERT)

Enzyme replacement therapy (ERT) represents a major breakthrough in the treatment of LSDs, initially used for the treatment of Gaucher disease and now available for several other LSDs. For example ERT with recombinant human acid α-glucosidase (GAA) (rhGAA) is presently the only approach for the treatment of Pompe disease patients. To date, several studies have pointed to the role of a variety of structural and biochemical responses triggered by intracellular storage, which are considered to be responsible for the pathogenetic manifestation of LSDs. Abnormal intracellular trafficking of lipids and proteins may affect the function of membrane-bound proteins, such as receptors, and ligands. The CI-MPR is of particular interest as it is a key player in the internalization of exogenous enzymes, and for the possible consequences of deranged CI-MPR function on ERT efficacy. At the steady state, a fraction (~10%) of CI-MPR is located on cell surface, where it mediates the uptake of lysosomal enzymes. CI-MPR being an integral membrane glycoprotein follows a complex and finely regulated itinerary from the trans-Golgi network (TGN), where it binds newly synthesized lysosomal hydrolases, travels through the early endosomes towards the late endosomal compartments, and recycles back to the TGN. CI-MPR at the cell surface mediates the uptake of lysosomal enzymes, internalize in the early endocytic compartment and then recycles again to the plasma membrane through the endocytic recycling compartment (ERC). Some of these advances in LSDs therapies have been enumerated in sections to follow. However many of these studies are at experimental stages.

Pompe Disease (Glycogen Storage Disease Type II)

Pompe disease also called Glycogen storage disease type II (or acid maltase deficiency) is an autosomal recessive metabolic disorder which damages muscle and nerve cells throughout the body. It is caused by an accumulation of glycogen in the lysosome due to deficiency of the lysosomal acid α-glucosidase (GAA). The GAA enzyme is responsible for breaking down glycogen in the lysosome. In individuals afflicted with Pompe Disease, the GAA enzyme is either absent or present in a very low quantity and glycogen builds in the lysosome, resulting in symptoms associated with this disorder. The glycogen storage disease with a defect in lysosomal metabolism is the first glycogen storage disease to be identified, in 1932. The build-up of glycogen causes progressive muscle weakness (myopathy) throughout the body and affects various body tissues, particularly in the heart, skeletal muscles, liver and nervous system. There are four primary forms of Pompe Disease: The classic infantile form, the non-classic infantile, the juvenile form, and the adult form. The classic infantile form is the most severe. Pompe Disease is estimated to occur in about one in 40,000 births worldwide.

One of the major therapeutic applications of M6P derivatives could be the enzyme replacement therapy (ERT) for lysosomal diseases. To address the consequences of abnormalities of cellular morphology and function on CI-MPR subcellular localization, fibroblasts from Pompe disease patients with different genotypes and phenotypes have been studied. In these cells, which showed abnormalities of cellular morphology, CI-MPR is mislocalized and its availability at the plasma membrane is reduced. These abnormalities in CI-MPR distribution result in a less efficient uptake of rhGAA by Pompe disease fibroblasts. CI-MPR-mediated endocytosis of rhGAA is an important pathway by which the enzyme is delivered to the affected lysosomes of Pompe muscle cells. Hence, the generation of rhGAA containing high affinity ligands for the CI-MPR represents a strategy by which the potency of rhGAA and the clinical efficacy of enzyme replacement therapy for Pompe disease may be improved. To enhance the delivery of rhGAA to the affected muscles in Pompe disease, the carbohydrate moieties on the enzyme were remodelled to exhibit a high affinity ligand for CI-MPR. This was achieved by chemically conjugating on to rhGAA, a synthetic oligosaccharide ligand bearing M6P residues in the optimal configuration for binding the receptor (Zhu et al. 2004, 2005). This approach allowed to decrease the effective dose of enzyme and to treat either less accessible tissues, such as skeletal muscles, or tissues with a relatively low abundance of CI-MPR (Gary-Bobo et al. 2007).

The ERT for Pompe disease was recently approved in Europe, the U.S., Canada, and Japan using a recombinant human GAA (Myozyme, alglucosidase alfa) produced in CHO cells (CHO-GAA). The ERT with rhGAA is at present the only approved treatment for Pompe disease, in addition to supportive and physical therapies. However, ERT shows limited efficacy in some patients and does not completely correct the disease phenotype. Recently, an improved knowledge of Pompe disease pathophysiology has provided clues to explain the limitations of ERT. A mechanical effect of lysosomal inclusions on muscle contractility has been proposed as a key factor of disease resulting in a severe loss of contractility. In addition, it has been shown that secondary abnormalities of housekeeping cellular functions, such as autophagy, have an important role in the pathogenesis of cell damage in Pompe disease. Abnormalities of intracellular trafficking of vesicles and membrane-bound proteins, such as the CI-MPR, may be deleterious for the efficacy of ERT. Other approaches, also in a pre-clinical stage, include substrate reduction and gene therapy (Parenti and Andria 2011; McVie-Wylie et al. 2008).

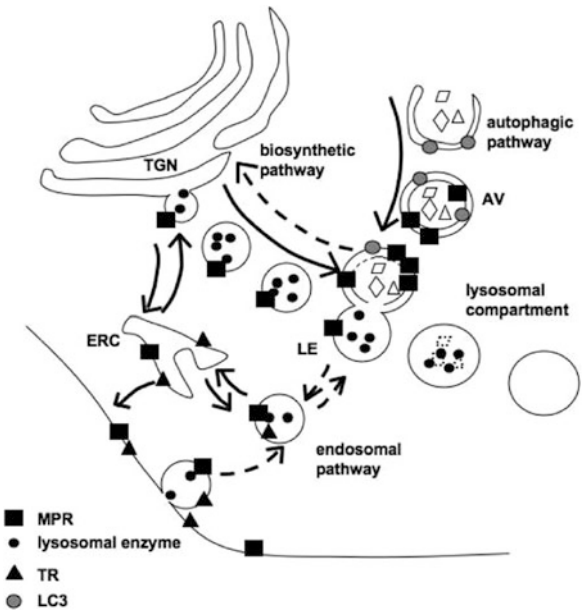

Fig. 46.1 Schematic representation of CI-MPR trafficking in the cells. CI-MPR follows different routes, including the biosynthetic pathway from the trans-Golgi network (*TGN*), where it binds and delivers newly synthesized lysosomal hydrolases to the late endosomal compartment. A fraction (~ 10%) of CI-MPR is located on the cell surface, where it mediates the uptake of lysosomal enzymes, is internalized in the endocytic pathway and recycles through the endocytic recycling compartment (*ERC*), again to the plasma membrane. Increased co-localization of CI-MPR with microtubule-associated protein 1 light chain 3 (*LC3*) in Pompe disease fibroblasts indicates that the CI-MPR in these cells is diverted from its normal routes and is sequestered in autophagosomes and autophagolysosomes. Since transferrin and transferring receptor trafficking is not affected in Pompe disease fibroblasts, it is likely that the disruption of CI-MPR trafficking occurs at the late endosomal compartment and in the retrograde route to the TGN (Cardone et al. 2008)

To investigate the mechanisms underlying the variable response to ERT, Cardone et al. (2008) studied cell morphology of Pompe disease fibroblasts, the distribution and trafficking of the CI-MPR that mediates rhGAA uptake, and rhGAA uptake itself. Immunofluorescence analysis showed abnormal intracellular distribution of CI-MPR in Pompe disease fibroblasts, increased co-localization with microtubule-associated protein 1 light chain 3 (LC3) and reduced availability of the receptor at the plasma membrane. The recycling of CI-MPR from the plasma membrane to the trans-Golgi network was also impaired. All these abnormalities were more prominent in severe and intermediate Pompe disease fibroblasts, correlating with disease severity. In severe and intermediate Pompe disease cells rhGAA uptake and processing were less efficient and correction of GAA activity was reduced. Results indicate a role for disrupted CI-MPR trafficking in the variable response to ERT in Pompe disease with implications for ERT efficacy and optimization of treatment protocols (Fig. 46.1).

Although ERT with acid α-glucosidase has become available for Pompe disease, the response of skeletal muscle, as opposed to the heart, has been attenuated. The poor response of skeletal muscle was attributed to the low abundance of the CI-MPR in skeletal muscle compared to heart. In CI-MPR-KO/GAA-KO (double KO) mice, the role of CI-MPR was emphasized by the lack of efficacy of ERT as demonstrated by markedly reduced biochemical correction of GAA deficiency and of glycogen accumulations in double KO mice, in comparison with the administration of the same doses in GAA-KO mice. Clenbuterol, a selective β_2-agonist, enhanced the CI-MPR expression in skeletal tissue and also increased efficacy from GAA therapy, thereby confirming the key role of CI-MPR with regard to ERT in Pompe disease. Biochemical correction improved in both muscle and non-muscle tissues, indicating that therapy could be similarly enhanced in other lysosomal storage disorders. In summary, enhanced CI-MPR expression might improve the efficacy of ERT in Pompe disease through enhancing receptor-mediated uptake of GAA (Koeberl et al. 2011).

Aspartylglycosaminuria

Aspartylglucosaminuria also called aspartylglycosaminuria (AGU), a severe lysosomal storage disease, is caused by the deficiency of the lysosomal glycosylasparaginase (GA), and accumulation of aspartylglucosamine (GlcNAc-Asn) in tissues. Aspartylglucosaminuria is caused by mutations in the gene encoding for a soluble aspartylglucosaminidase (AGA). Kyttälä et al. (1998) indicated that endocytotic capability of cultured telencephalic neurons for recombinant AGA was mediated by M6PRs. Human leukocyte glycosylasparaginase can correct the metabolic defect in Epstein-Barr virus (EBV)-transformed AGU lymphocytes rapidly and effectively by M6PR-mediated endocytosis or by contact-mediated cell-to-cell transfer from normal EBV-transformed lymphocytes, and that 2–7% of normal activity is sufficient to correct the GlcNAc-Asn metabolism in the cells. The combined evidence indicates that cell-to-cell transfer of GA plays a main role in enzyme replacement therapy of AGU by normal lymphocytes (Dunder and Mononen 2001).

Niemann-Pick Disease (NPD) Type-A, B and C

Acid sphingomyelinase (ASM), a member of the saposin-like protein family, is a lysosomal hydrolase that converts sphingomyelin to ceramide. Deficiency of ASM causes a variant form of Niemann-Pick disease. Progressive accumulation of lipid-laden macrophages is the hallmark of the ASM-deficient forms of Niemann-Pick disease (i.e. Types A and B NPD). Studies using receptor-specific ligands to inhibit enzyme uptake revealed that in normal cells rhASM was taken up by a combination of mannose receptor (MR) and M6PR,

respectively. Whereas in the ASM deficient (ASM-KO) cells the M6PR had a minimal role in rhASM uptake. Expression of M6PR mRNA was normal in the ASM-KO cells, although it was hypothesized that lipid accumulation in ASM-KO macrophages led to abnormalities in M6PR trafficking and/or degradation, resulting in reduced enzyme uptake. Consistent with this hypothesis, it was also found that, when rhASM was modified to expose terminal mannose residues and target mannose receptors, the uptake of this modified enzyme by ASM-KO cells was tenfold greater when compared with the "complex" type rhASM. These findings have important implications for NPD enzyme replacement therapy, particularly in the lung (Dhami and Schuchman 2004). Further studies suggest that ASM uses in part the M6P-R and Sortilin, a type I transmembrane glycoprotein that belongs to a family of receptor proteins, involved in lysosomal targeting (Ni and Morales 2006).

Niemann-Pick disease type C (NPC) is an autosomal recessive disorder that leads to massive accumulation of cholesterol and glycosphingolipids in late endosomes and lysosomes. NPC, caused by mutations in the *NPC1* gene or the *NPC2* gene, is characterized by the accumulation of unesterified cholesterol and other lipids in lysosomal compartment. NPC2 is a small lysosomal protein that is targeted to this compartment via a M6P-inhibitable pathway. Either of M6PRs alone is sufficient to transport NPC2 to the endo/lysosomal compartment, although M6PR-300 seems to be more efficient than M6PR-47. In the absence of both MPRs, NPC2 is secreted into the culture medium, and only a small amount of intracellular NPC2 can be detected, mainly in the ER. This leads to massive accumulation of unesterified cholesterol in the endo/lysosomal compartment of the MPR46/300-deficient fibroblasts, a phenotype similar to that of the NPC patient fibroblasts. The lysosomal targeting of NPC2 is strictly dependent on M6PRs in fibroblasts. In another concept, Rab9 is likely sequestered in an inactive form on Niemann-Pick type C membranes, as cation-dependent M6PRs were missorted to the lysosome for degradation, a process that was reversed by over-expression of Rab9. It seems that cholesterol contributes directly to the sequestration of Rab9 on Niemann-Pick type C cell membranes, which in turn, disrupts M6PR trafficking (Naureckiene et al. 2000; Ganley and Pfeffer 2006).

Mucolipidosis Type II and III

Mucolipidosis (ML) II and III are rare autosomal recessive inherited diseases characterized by deficiency of multiple lysosomal enzymes resulting in a generalized storage of macromolecules in lysosomes of cells of mesenchymal origin. The M6P lysosomal targeting signal on acid hydrolases is synthesized by the sequential action of uridine 5′-diphosphate-N-acetylglucosamine: lysosomal enzyme N-acetylglucosamine-1-phosphotransferase (GlcNAc-1-phosphotransferase) and GlcNAc-1-phosphodiester α-N-acetylglucosaminidase ("uncovering enzyme" or UCE). Mutations in the two genes that encode GlcNAc-1-phosphotransferase give rise to lysosomal storage diseases (ML type II and III). In ML II and ML III fibroblasts, most of the newly synthesized lysosomal enzymes are secreted into the medium instead of being targeted correctly to lysosomes. Studies indicate that phospholipases, like most other lysosomal enzymes in these diseases, are secreted into the blood instead of being targeted specifically to lysosomes. The M6PR pathway is needed for proper delivery of lysosomal phospholipases to lysosomes (Jansen et al. 1999). Boonen et al. (2009) demonstrated that UCE accounts for all the uncovering activity in the Golgi. In the absence of UCE, the weak binding of the acid hydrolases to the CI-MPR allows sufficient sorting to lysosomes to prevent the tissue abnormalities seen with GlcNAc-1-phosphotranferase deficiency (Boonen et al. 2009).

46.1.3 M6PR-Mediated Transport Across Blood-Brain Barrier

Enzyme replacement therapy has been used successfully in many lysosomal storage diseases. However, correction of brain storage has been limited by the inability of infused enzyme to cross the blood-brain barrier (BBB). Delivering therapeutic levels of lysosomal enzymes across the BBB is pivotal issue in treating CNS diseases, including the mucopolysaccharidoses. The newborn mouse is an exception because recombinant enzyme is delivered to neonatal brain after M6PR-mediated transcytosis. Access to this route is limited for 2 weeks of age, after which this transporter is lost with maturation.

Glial and Neuronal Cells Express CI-MPR

Enzyme replacement therapy for lysosomal storage disorders depends on efficient uptake of recombinant enzyme into the tissues of patients. This uptake is mediated by oligosaccharide receptors including the CI-MPR and the mannose receptor (MR). Studies on the uptake of recombinant α-(L)-iduronidase into glial and neuronal cells, produced by retrovirally transduced NIH3T3 fibroblasts indicate that: (1) neuronal and glial cells take up α-(L)-iduronidase released into the medium by retrovirally transduced fibroblasts expressing high levels of α-(L)-iduronidase; (2) both glial and neuronal cells express the CI-MPR responsible for lysosomal enzyme uptake; and (3) uptake of the lysosomal enzyme could be blocked by excess free M6P, but not glucose-6-phosphate. Thus, various brain cells take up α-(L)-iduronidase, possibly through a CI-MPR mediated pathway, and this uptake is higher in actively dividing or immature brain cells (Stewart et al. 1997).

GM2 Gangliosidosis

Intralysosomal stability of β-galactosidase is regulated by a multifunctional protein that interacts with two lysosomal enzymes, β-galactosidase and sialidase, and also exerts catalytic activities as carboxypeptidase, esterase and deamidase under various pH conditions. It is encoded by a gene on chromosome 20, and its mutation results in a neurodegenerative disease in children and adults (galactosialidosis). For digestion of lipid substrates, lysosomal enzymes need specific activator proteins as natural detergents for molecular interaction with these nonpolar compounds. Two different groups of proteins have been revealed. A protein encoded by a gene on chromosome 5 interacts with ganglioside GM2 and its asialo derivative, for their catalytic hydrolysis by β-hexosaminidase A. Another protein encoded by a gene on chromosome 10 is expressed as a precursor (prosaposin) which is then processed to four small proteins (saposins) with heterogeneous functions. They are essential for hydrolysis of sphingolipid substrates, and genetic deficiency of each protein results in various lipid storage diseases.

Sandhoff disease is an autosomal recessive lysosomal storage disease caused by a defect of the β-subunit gene (*HEXB*) associated with simultaneous deficiencies of β-hexosaminidase A (HexA; αβ) and B (HexB; ββ), and excessive accumulation of GM2 ganglioside (GM2) and oligosaccharides with N-acetylglucosamine (GlcNAc) residues at their non-reducing termini. From the neonatal brains of Sandhoff disease model mice (SD mice) produced by disruption of the murine Hex β-subunit gene allele ($Hexb^{-/-}$) recombinant Hex isozyme sub-units were found to be incorporated into the SD microglia via cell surface CI-MPR and mannose receptor to degrade the intracellularly accumulated GM2 and GlcNAc-oligosaccharides (Tsuji et al. 2005).

Tay-Sachs disease is a severe neurodegenerative disorder due to mutations in the *HEXA* gene coding for the α-chain of the αβ heterodimeric lysosomal enzyme β-hexosaminidase A (HexA). Guidotti et al. (1998) corrected HexA-deficient cells by *HEXA* gene transfer. Murine HexA-deficient fibroblasts derived from HexA-/- mice were transduced with the G.HEXA vector. Transduced cells overexpressed the α-chain, resulting in the synthesis of interspecific HexA (human α-chain/murine β-chain) and in a total correction of HexA deficiency. The α-chain was secreted in the culture medium and taken up by HexA-deficient cells via M6PR binding, allowing for the restoration of intracellular HexA activity in non-transduced cells.

To develop a novel enzyme replacement therapy for Tay-Sachs disease (TSD) and Sandhoff disease (SD), which are caused by deficiency of Hex A, Matsuoka et al. (2011) designed a genetically engineered *HEXB* encoding the chimeric human β-subunit containing partial amino acid sequence of the α-subunit and succeeded in producing the modified HexB by a CHO cell line stably expressing the chimeric HexB, which can degrade artificial anionic substrates and GM2 ganglioside in vitro, and also retain the wild-type (WT) HexB-like thermostability in presence of plasma. The modified HexB was efficiently incorporated via CI-MPR into fibroblasts derived from Tay-Sachs patients, and reduced the GM2 ganglioside accumulated in the cultured cells. The intracerebroventricular enzyme replacement therapy involving the modified HexB should be more effective for Tay-Sachs and Sandhoff than that utilizing the HexA, especially as a low-antigenic enzyme replacement therapy for Tay-Sachs patients who have endogenous WT HexB.

Mucopolysaccharidosis (MPS)

Recently, several studies showed that multiple infusions of high doses of enzyme partially cleared storage in adult brain. For example, the neonate uses the M6PR to transport phosphorylated β-glucuronidase (P- GUS) across the BBB. These results raised the question if correction of brain storage by repeated high doses of enzyme depends on M6P-mediated uptake or whether enzyme gains access to brain storage by another route when brain capillaries are exposed to prolonged, high levels of circulating enzyme (Grubb et al. 2008). Pharmacological manipulation with epinephrine restores functional transport of P-GUS across the adult BBB. The effect of epinephrine on the transport of P-GUS was ligand specific (Urayama et al. 2007).

The rat amniotic epithelial cells (AEC) over-express and secrete human β-glucuronidase (GUS) following transduction with an adenoviral vector encoding human GUS. The AEC were used as donor cells for cell-mediated gene therapy of CNS lesions in mice with mucopolysaccharidosis type VII (MPSVII), a lysosomal storage disorder caused by an inherited deficiency of GUS activity. After confirmation that the secreted GUS was taken up mainly via M6PRs in primary cultured neurons, the AECs were transplanted into the brains of adult MPSVII mice. Results suggest that intracerebral transplantation of genetically engineered AEC has therapeutic potential for the treatment of CNS lesions in lysosomal storage disorders (Kosuga et al. 2001).

The availability of both $MR^{+/+}$ and $MR^{-/-}$ mice led to study the effects of eliminating the MR on MR- and MPR-mediated plasma clearance and tissue distribution of infused phosphorylated (P) and nonphosphorylated (NP) forms of human β-glucuronidase. In $MR^{+/+}$ MPS VII mice, the MR clearance system predominated at doses up to 6.4 mg/kg P-GUS. Genetically eliminating the MR slowed plasma clearance of both P- and NP-GUS and enhanced the effectiveness of P-GUS in clearing storage in kidney, bone, and retina. Saturating the MR clearance system by high doses of enzyme also improved targeting to MPR-containing tissues

such as muscle, kidney, heart, and hepatocytes. Although ablating the MR clearance system genetically is not practical clinically, blocking the MR-mediated clearance system with high doses of enzyme is feasible. This approach delivers a larger fraction of enzyme to MPR-expressing tissues, thus enhancing the effectiveness of MPR-targeted ERT (Sly et al. 2006).

Mucopolysaccharidosis type VI (MPS VI) is an autosomal recessive disease caused by the deficiency of N-acetylgalactosamine 4-sulfatase (4S) leading to the lysosomal accumulation and urinary excretion of dermatan sulfate. MPS VI has also been described in the Siamese cat. Endocytosis of recombinant feline 4S (rf4S) by cultured feline MPS VI myoblasts was predominantly mediated by a M6PR and resulted in the correction of dermatan sulfate storage. The mutation causing feline MPS VI was identified as a base substitution at codon 476, altering a leucine codon to a proline (L476P) (Yogalingam et al. 1996). Differences in glycosylation of lysosomal enzymes can be an important factor in altering enzyme uptake by different cell types. In alternative approaches, carbohydrate modification variants may be useful for altering the distribution of exogenous enzyme in vivo (Fuller et al. 1998). Reports also suggest that muscle-mediated gene replacement therapy may be a viable method for achieving circulating levels of recombinant f4S (rf4S) in the MPS VI cat (Yogalingam et al. 1997).

Mucopolysaccharidosis Type IIIA (MPS IIIA) is a lysosomal storage disorder caused by a deficiency in the lysosomal enzyme sulfamidase, which is required for the degradation of heparan sulfate. The disease is characterized by neurological dysfunction but relatively mild somatic manifestations. In a naturally occurring mouse model to MPS IIIA, recombinant murine sulfamidase was able to correct the storage phenotype of MPS IIIA fibroblasts after endocytosis via M6PR (Bielicki et al. 1998; Gliddon et al. 2004; Urayama et al. 2008).

Mucopolysaccharidosis type IIIB (MPS-IIIB, Sanfilippo type B Syndrome) is a heterosomal, recessive lysosomal storage disorder resulting from a deficiency of α-N-acetylglucosaminidase (NAGLU). The use of secreted NAGLU in future enzyme and gene replacement therapy protocols will be with limited success due to its small degree of mannose-6-phosphorylation (Weber et al. 2001). Mucopolysaccharidosis type IIID or Sanfilippo D syndrome, a lysosomal storage disorder, is caused by the deficiency of N-acetylglucosamine-6-sulphatase (Glc6S). In addition to human patients, a Nubian goat with this disorder has been described. The r-caprine Glc6S was endocytosed by fibroblasts from patients with mucopolysaccharidosis type IIID via the M6PR-mediated pathway resulting in correction of the storage phenotype of these cells (Litjens et al. 1997). Mucopolysaccharidosis IVA (MPS IVA; Morquio A syndrome) is a lysosomal storage disorder caused by deficiency of N-acetylgalactosamine-6-sulfatase (GALNS), an enzyme that degrades keratan sulfate. The recombinant phosphorylated enzyme was dose-dependently taken up by M6PR thereby restoring enzyme activity in MPS IVA fibroblasts. Penetration of the therapeutic enzyme throughout poorly vascularized, but clinically relevant tissues, as well as macrophages and hepatocytes in wild-type mouse, supports development of rhGALNS as enzyme replacement therapy for MPS IVA (Dvorak-Ewell et al. 2010).

Palmitoyl-Protein Thioesterase (PPT) is a lysosomal long-chain fatty acyl hydrolase that removes fatty acyl groups from modified cysteine residues in proteins. Mutations in palmitoyl-protein thioesterase were found to cause the neurodegenerative disorder infantile neuronal ceroid lipofuscinosis, a disease characterized by accumulation of amorphous granular deposits in cortical neurons, leading to blindness, seizures, and brain death by the age of 3. The accumulation in cultured cells is reversed by the addition of recombinant palmitoyl-protein thioesterase that is competent for lysosomal uptake through M6PR (Lu et al. 1996). PPT expressed in COS-1 cells is recognized by M6PR and is routed to lysosome, but a substantial fraction of PPT is secreted. The PPT has a role outside the lysosomes in the brain and may be associated with synaptic functioning (Lehtovirta et al. 2001).

MPR as Target in MPS VII in Mice: Although ERT is an established method for treating lysosomal storage diseases, an alternative strategy to rectify lysosomal storage diseases depends on the interaction of a fragment of IGF2, with the IGF2 binding site on the IGF2/CI-MPR as tested in a murine mucopolysaccharidosis type VII (MPS VII) model. A chimeric protein containing a portion of mature human IGF2 fused to the C terminus of human β-glucuronidase was taken up by MPS VII fibroblasts in a M6P-independent manner. The tagged enzyme was delivered effectively to clinically significant tissues in MPS VII mice and effective in reversing the storage pathology. The peptide-based, glycosylation-independent lysosomal targeting system may enhance enzyme-replacement therapy for certain human lysosomal storage diseases (LeBowitz et al. 2004).

Lysosomal storage diseases may be treated by the transplantation of cells that secrete the enzyme which is deficient in patients. Secretion of lysosomal enzymes can be enhanced by reducing the MPR involved in the lysosomal sorting of newly synthesized lysosomal enzymes. Hammerhead ribozymes targeting the mRNA of murine CI-MPR cleave

RNA fragments efficiently and reduce the levels of murine MPR mRNA in transient transfection experiments. Thus, the reduction in MPR is sufficient to increase a lysosomal enzyme secretion (Yaghootfam and Gieselmann 2003).

46.1.4 Other Approaches using CI-MPR as Target

CI-MPR Binds and Internalizes Leukemia Inhibitory Factor: Leukemia inhibitory factor (LIF) is a multifunctional, highly glycosylated soluble protein belonging to the interleukin-6 (IL-6) subfamily of helical cytokines. LIF exerts an important role in neuronal, platelet and bone formation. Blanchard and co-workers have reported that glycosylated LIF and the macrophage-colony-stimulating factor were able to bind to CI-MPR in a M6P-sensitive manner (Blanchard et al. 1999). The M6P-containing cytokine LIF is rapidly internalized and degraded by cells expressing CI-MPR (Blanchard et al. 1999). Thus, CI-MPR is a candidate natural molecule, like other inhibitors of the IGF2 pathway, for the development of novel therapeutic strategies in treatment of haematopoietic disorders in which IL-6-type cytokines play a role, particularly multiple myeloma. CI-MPR can also bind and internalize renin and pro-renin (Admiraal et al. 1999). After internalization, pro-renin is swiftly activated by proteolytic cleavage (Saris et al. 2002). CI-MPR in myocytes may participate in the cardiac (pro)renin uptake by binding to the fraction of human (pro) renin, that is characterized by the presence of the M6P recognition marker (Saris et al. 2002).

Lysosomal Targeting for Cancer Therapy: CI-MPR has been reported to be a potential tumor suppressor in 70% of hepatocarcinomas and 15–30% of breast cancers (Hankins et al. 1996; Chappell et al. 1997; Oates et al. 1998). Moreover, over-expression of CI-MPR induced regression of tumors in mice and growth inhibition in cancer cells. These effects are probably due to the different functions of this receptor that indirectly controls cell growth: (1) internalization and degradation of various growth-promoting factors, such as IGF2 (Kiess et al. 1988), glycosylated LIF, and other M6P-containing cytokines, such as the macrophage colony-stimulating factor (Blanchard et al. 1999); (2) binding and uptake of granzyme B, an essential factor for T cell-mediated apoptosis (Motyka et al. 2000), and (3) regulation of secreted lysosomal enzymes that are responsible for extracellular matrix degradation and tumor dissemination. Attempts to target the acidic extracellular compartment of solid tumors have been performed by loading doxorubicin into pH-sensitive poly/PEG/folate micelles (Lee et al. 2005) or liposomes (Storm et al. 1987).

Inhibitors of PI3-Kinase Activity in Late Endocytic Pathway: Addition of wortmannin to normal rat kidney cells causes redistribution of the lysosomal type I integral membrane proteins Igp110 and Igp120 to a swollen vacuolar compartment. Wortmannin does not show gross morphological effect on TGN or lysosomes, or any effect on the delivery to the TGN of endocytosed antibodies against the type I membrane protein TGN38. The observed effects of wortmannin were due to inhibition of membrane traffic between CI-MPR-positive late endosomes and the TGN and to inhibition of membrane traffic between a novel Igp120-positive, CI-MPR-negative late endosomal compartment and lysosomes. The effects of wortmannin suggest a function for a PI3-kinase(s) in regulating membrane traffic in the late endocytic pathway (Reaves et al. 1996). 3-methyladenine (3-MA), a well-known inhibitor of autophagic sequestration, can also inhibit PI3-kinase activity, which is required for many processes in endosomal membrane trafficking. The treatment with 3-MA results in a specific redistribution of CI-MPR from the TGN to early/recycling endosomal compartments containing internalized transferrin. However, in contrast to wortmannin and LY294002, 3-MA did not cause the enlargement of late endosomal/lysosomal compartments. Hence, the effect of 3-MA is restricted to the retrieval of CI-MPR from early/recycling endosomes (Hirosako et al. 2004).

46.2 Cell Targeting Based on Mannan-Lectin Interactions

Carbohydrates exhibit properties of potential interest when developing drug-delivery mechanisms, such as specificity in their interaction with their receptors and the varied nature of potentially targetable receptors available. Macromolecular glycoconjugates, in particular, have shown some promise. Synthetic glycopolymers and glycoproteins have been used as carriers of covalently conjugated drugs, bearing carbohydrate ligands that provide delivery specificity. However, these systems commonly rely on endogenous mechanisms, such as lysosomal degradation, for release of the active drug, and so the unwanted release of the drug at sites other than the desired site of action is possible. Glycotargeting is being followed through two approaches: (1) relying on use of oligosaccharide moiety or (2) using the lectin as a component of the drug delivery system (Gao et al. 2007; Gupta et al. 2009; Minko 2004; Smart 2004). In the first approach, oligosaccharides or neoglycoconjugates form part of the drug delivery system, whereas, in the second approach using lectins towards glycotargeting, the principle is reversed of the first approach.

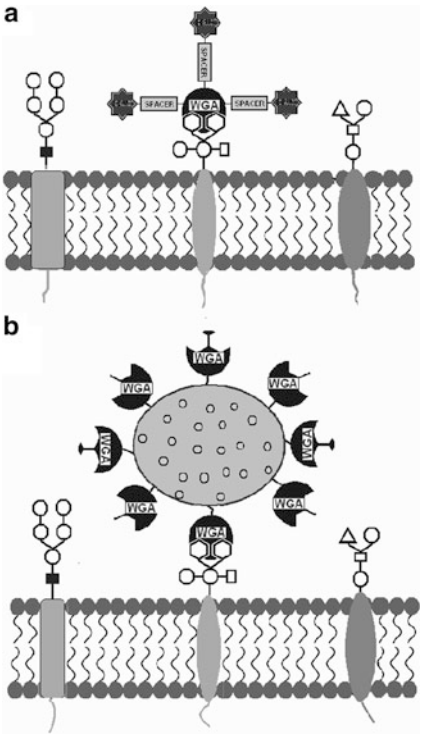

Fig. 46.2 Lectin-grafted formulations. (**a**) Lectin-grafted prodrug, (**b**) Lectin-grafted carrier system. Galactose, N-acetylgalactosamine, N-acetylglucosamine, Spacer, Fructose, Drug, Mannose

The delivery of therapeutic agents to, or via, the oral cavity is limited by the efficient removal mechanisms that exist in this area. The bio-recognition between lectinised drug delivery systems and glycosylated structures in the intestine can be exploited for improved peroral therapy. Lectins as proteins bind to specific sugar residues, and can interact with the glycoconjugates present on cell surfaces or salivary mucins. Endogenous lectins could also be used as points of attachment for carbohydrate-containing delivery systems. As lectins are multifunctional molecules, the possibility of using them is considered as a potential innovation for targeted and prolonged therapy within the oral cavity but considerations such as toxicity needs to be addressed before their routine use becomes a reality (Gao et al. 2007; Gupta et al. 2009; Minko 2004; Smart 2004).

The lectin-carbohydrate interaction can be made use of by the development of nanoparticles containing carbohydrate moieties that are directed to certain lectins (direct lectin targeting) as well as incorporating lectins into nanoparticles that are directed to cell surface carbohydrates (reverse lectin targeting) (Gabor et al. 2004) (Fig. 46.2). Treatment of glioblastoma multiforme (GBM), a primary malignant tumor of the brain, is one of the most challenging problems as no currently available treatment is curative. Surgery remains the basic treatment in which the bulk of the tumor is removed and the peripheral infiltrating part is the target of supplementary treatments. Many of the technologies based on nanotechnology can be applied in the improvement of drug delivery to GBM (Jain 2007).

46.2.1 Receptor-Mediated Uptake of Mannan-Coated Particles (Direct Targeting)

Cell surface-bound receptors represent suitable entry sites for delivery of macromolecules or supramolecular structures into cells by receptor-mediated endocytosis. Carrying the carbohydrate-tag, the drug delivery system can be recognized by the cells/tissues and internalised by endogenous lectins at the cell surface. Mammalian mannose/fucose/galactose specific cell surface receptors are expressed on macrophages and other antigen presenting cells such as dendritic cells (DCs) in skin and M-cells in intestine. Macrophages and DCs play an important role in host immune functions such as antigen presentation. Attempts have been made to modulate the function of macrophages for the treatment of genetic metabolic diseases. The mannose receptor (ManR) on macrophages mediates the internalization of a wide range of molecules or microorganisms in a pattern recognition manner (see Chaps. 15 and 35 for structure and functions of ManR). Therefore, it represents an attractive entry for specific drug, gene, or antigen delivery to macrophages and antigen-presenting DCs. Particles coated with carbohydrate ligands offer potential future in the site directed delivery of macromolecules and therapeutic drugs. Based on this principle delivery systems containing asialofetuin, galactose, mannose, or N-acetyl-galactosamine were developed and tested for endocytois by macrophages, DCs, and liver cells (Chiu et al. 1994). The use of carbohydrate-modified HPMA or liposomes gave improved results (Andre et al. 2000; Dasi et al. 2001). Liver or the colon, macrophages and mouse brain have been shown to be targeted by mannosylated liposomes (Man-liposome) (Umezawa and Eto 1988).

46.2.2 Polymeric Glyco-Conjugates as Carriers

Mannosylated Conjugates as Cell-Specific Carrier: Hepatic uptake characteristics of mannosylated bovine serum albumin (Man-BSA) were assessed as a liver-specific carrier system (Ogawara et al. 1999). The ^{111}In-Man18-BSA accumulated in the liver up to 70%; the endothelial cells and Kupffer cells contributed major fraction. These results provide useful information in designing drug targeting systems to the liver nonparenchymal cells via mannose receptors (Ogawara et al. 1999).

Mannosylpolyethylenimine (ManPEI) Conjugates: Presence of mannose receptors on DCs can be exploited for targeted gene transfer by employing mannosylpolyethylenimine (ManPEI) conjugates. Several ManPEI conjugates have been used for formation of ManPEI/DNA transfection complexes. Results demonstrated that DCs transfected with ManPEI/DNA complexes containing adenovirus particles are effective in activating T cells of T cell receptor transgenic mice in an antigen-specific fashion (Diebold et al. 1999).

Poly-(L-Lysine Citramide Imide): Commercially available quinic and shikimic acids appear as stable mannose bioisosteres, which should prove valuable tools for specific cell delivery (Grandjean et al. 2001). With the aim of promoting the targeting of macrophage mannose receptors and the internalization of the norfloxacin antibiotic, which is active against some intracellular bacteria, was coupled to a polymeric carrier, namely poly-(L-lysine citramide imide). This carrier, derived from two metabolites, citric acid and L-lysine, is known to be biocompatible and slowly degradable under slight acidic conditions. Prodrug macromolecules compete effectively with glucose oxidase and thus should be able to bring the drug up to the mannosyl receptor-bearing membranes of macrophages infected by intracellular bacteria (Gac et al. 2000).

Poly[N-p-Vinylbenzyl-O-β-Mannopyranosyl-(1-4)-D-Gluconamide (PV-Man): PV-Man is a polystyrene derivative that contains mannose moieties and interacts with ManR-carrying cell line. The PV-Man strongly binds to macrophage cells, probably due to a specific interaction mediated by ManRs on the cell membrane. Using a PV-Man glycopolymer, receptor-mediated gene transfer via ManR is another method for targeted gene delivery into macrophages (Park et al. 2005). Polymeric nanospheres (NS) with a polystyrene core and a glucosyloxyethyl methacrylate (GEMA) oligomer corona nanosphere proved to be a useful material for studying sugar-biomolecule recognition and offered a potential for using a multi-lectin nanoparticle array in glycoprotein mapping (Fromell et al. 2005; Serizawa et al. 2001).

Cyclodextrin Conjugates: A structure based saccharide-directed molecular delivery system through biological receptors was studied by Benito et al. (2004). The dendritic β-cyclodextrin (βCD) derivatives bearing multivalent mannosyl ligands were assessed for their binding efficiency towards the ConA and mammalian mannose/fucose specific cell surface receptor from macrophages. This new type of βCD-dendrimer construct showed high drug solubilization capability. A subtle change in the structure of the conjugate may have important consequences on receptor affinity (Benito et al. 2004).

McNicholas et al. (2007) synthesized amphiphilic β-cyclodextrins bearing hexylthio, dodecylthio, and hexadecylthio chains at the 6-positions and glycosylthiocarbamoyl-oligo(ethylene glycol) units at the 2-positions. The glycosyl residues (α-D-mannosyl and β-L-fucosyl) were intended for cell-targeting. These amphiphilic glycosylated cyclodextrins form vesicles in water. Hexylthio assemblies exhibited selective binding to Lens culinaris lectin. A bioeliminable amphiphilic poly(ethylene oxide)-b-poly(ε-caprolactone) (PEO-b-PCL) diblock copolymer end-capped by a mannose residue, synthesized by sequential controlled polymerization of ethylene oxide and epsilon-caprolactone, followed by the coupling of a reactive mannose derivative to the PEO chain end showed that these colloidal systems have great potential for drug targeting and vaccine delivery systems (Rieger et al. 2007).

Delivery of Antisense Oligonucleotides: Antisense oligonucleotides (ONs) are useful for selective inhibition of gene expression. However, their effective use is limited by inefficient cellular uptake and lack of cellular targeting. A drug targeting system which utilizes ManR-mediated endocytosis to enhance cellular uptake of ONs in alveolar macrophages (AMs), employs a molecular complex consisting of partially substituted mannosylated poly(L-lysine) (MPL), linked to ON. Upon recognition by the macrophage ManRs, the MPL was internalized by the receptor-mediated pathway, co-transporting the ON. The AMs treated with the MPL:ON complex exhibited a significant increase in ON uptake over free ON-treated controls. The ON uptake was shown to require the recognition of the mannose moiety since unmodified polylysine was much less effective in promoting ON uptake. Following cellular internalization, the ON largely accumulated in endocytic vesicles (Liang et al. 1996).

46.2.3 Mannosylated Liposomes in Gene Delivery

Mannosylated Liposomes: Introduction of ligands for cell-surface receptors into liposomes has been continuing to improve transfection efficiency: as far as macrophages are concerned (Simões et al. 1999). In earlier studies, liposomes were coated with macromolecular ligands such as transferrin, immunoglobulins and asialoglycoproteins. Direct respiratory delivery via inhalation of mannose modified liposomal carriers to alveolar macrophages is of great interest. The success of targeting systems to alveolar macrophages depends on internalization into these cells for pharmacological intervention. Mannose grafted liposome intercalated Benzyl derivative of an antibiotic MT81 (Bz2MT81) eliminated intracellular amastigotes of *Leishmania donovani* within splenic macrophages more

efficiently than the liposome intercalated Bz2MT81 or free Bz2MT81. Both Man-liposomes and Bz2MT81 appeared to be non-toxic to the host peritoneal macrophages. Liver and kidney function tests (SGPT, alkaline phosphatase, creatinine and urea in blood plasma) showed that the toxicity of Bz2MT81 was reduced up to normal level when mannose grafted liposomal Bz2MT81 were administered (Mitra et al. 2005).

Using cell receptors on the surface of mononuclear phagocyte cells, which are important hosts for HIV, stavudine-loaded Man-liposomal formulations have been developed for targeting HIV-infected cells. Using Con A as a model system for in-vitro ligand-binding capacity, Man-liposomes showed potential applications for the site-specific and ligand-directed delivery systems with better pharmacological activity (Garg et al. 2006). Perhaps, clustering of mannose residues on liposomal surfaces is important in determining the binding affinity of Man-liposomes with MBP and related to the mannose density of Man-liposomes (Terada et al. 2006; Wijagkanalan et al. 2008).

Mannosylated Cationic Liposomes: Several strategies have been developed to transfer genes directly into macrophages. In recent years, complexes of polylysine linked to ligands such as mannose (Ferkol et al. 1996; Erbacher et al. 1996) with DNA have been reported to enhance gene expression in macrophages. But, the transfection efficiency of many of these vectors is handicapped due to endosomal or lysosomal degradation. A promising nonviral gene delivery system developed involves cationic liposomes. Various kinds of cationic lipids have been synthesized and shown to be able to deliver genes into cells both in vitro and in vivo. DC-Chol liposomes have been used in gene therapy applications in clinical settings (Gao and Huang 1991; Nabel et al. 1993). A galactosylated cholesterol derivative in combination with dioleoylphosphatidylethanolamine (DOPE) efficiently transferred a plasmid DNA into human hepatoma cells (HepG2) via an asialoglycoprotein receptor-mediated mechanism (Kawakami et al. 1998). However, cationic liposomes do not exhibit any cell specificity in vivo. Kawakami et al. (2004) developed a low-molecular weight lipidic ligand, a mannosylated cholesterol derivative, cholesten-5-yloxy-N-(4-(1-imino-2-β-D-thiomannosylethyl)amino)butyl)-formamide (Man-C4-Chol), for gene delivery to hepatocytes and compared with other types of liposomes prepared with various molar ratios of Man-C4-Chol and particle size of about 200 nm for transfection assays in hepatocytes and mouse peritoneal macrophages (Kawakami et al. 2000).

The gene expression with Man-C4-Chol/DOPE (6:4) liposome/DNA complexes in the liver was observed preferentially in the non-parenchymal cells and was significantly reduced by predosing with Man-BSA. The gene expression in the liver was greater following intraportal injection. These results suggested that plasmid DNA complexed with Man-liposomes exhibits high transfection activity due to recognition by mannose receptors both in vitro and in vivo. Intravenous injection of DNAcationic liposome complexes resulted in gene expression in many tissues including the heart, lung, liver, kidney and spleen (Mahato et al. 1995) through participation of mannose receptors in liver Kuppfer and or endothelial cells. The splenic macrophages may also be targeted by this approach.

As far as the design of carriers for active targeting using receptor-mediated endocytosis was concerned, the density and stereochemistry of the ligand seemed to be important. It was demonstrated that galactosylated protein is recognized by liver cells in a manner directly related to the estimated surface density of the galactose residues. Similar strategy applies to Man-liposomes. The chemical structure and physicochemical characteristics of Man-C4-Chol seemed to satisfy the conditions for transfection in macrophages by offering a cationic charge and being recognized by the mannose structure on the liposomal surface.

Mannosylated-Emulsions: Carbohydrate grafted emulsions are one of the most promising cell-specific targeting systems for lipophilic drugs. Man-emulsions composed of soybean oil, EggPC and Man-C4-Chol with a ratio of 70:25:5 were significantly delivered to liver non-parenchymal cells (NPC) via mannose receptor-mediated mechanism after intravenous administration in mice and supported the design of pDNA/ligands-grafted cationic liposome complexes for cell-specific gene delivery (Kawakami et al. 2004). The in vitro study showed increased internalization of Man-5.0- and Man-7.5-emulsions and significant inhibition of uptake in the presence of mannan. The enhanced uptake of Man-emulsions was related to the increasing of Man-C4-Chol content. This suggested that the mannose density of Man-emulsions plays an important role in both cellular recognition and internalization via a mannose receptor-mediated mechanism (Yeeprae et al. 2006).

Wijagkanalan et al. (2008) demonstrated the efficient targeting to alveolar macrophages by the intratracheally administered Man-liposomes via ManR-mediated endocytosis in rats. The study involved Man-liposomes, with various ratio of mannosylated cholesterol derivatives, cholesten-5-yloxy-N-(4-((1-imino-2-D-thiomannosylethyl)-amino)alkyl)-formamide (Man-C4-Chol) and suggested that in vitro uptake of Man-liposomes occurs in a concentration-dependent manner. Through intratracheal route of administration of Man-7.5 and Man-5.0-liposomes, internalization was enhanced and selective to alveolar macrophages.

46.2.4 DC-Targeted Vaccines

A workshop on "Dendritic Cells: Biology and Therapeutic Applications," brought together basic and clinical research scientists to discuss the mechanisms underlying the control of immune responses and tolerance by DCs, as well as research in cancer immunotherapy based on DC vaccination (Ardavin et al. 2004).

Mannose Receptor Targeting Vaccine

DCs have a number of receptors for adsorptive uptake of antigens. Some are shared with other cells, such as Fcγ receptors, DEC-205, a type I membrane-integrated glycoprotein and the macrophage mannose receptor (MMR) (Chap. 35). Other receptors are more DC restricted, e.g., Langerin/CD207 (Chap. 35), DC-SIGN/CD209 (Chap. 36), asialoglycoprotein receptor or hepatic lectins (HL) (Chap. 33), and dendritic cell lectin (DLEC; also referred to as BDCA-2). Targeting antigens to endocytic receptors on professional APCs represents an attractive strategy to enhance the efficacy of vaccines. Such APC-targeted vaccines have the ability to guide exogenous protein antigens into vesicles that efficiently process the antigen for MHC class I and class II presentation. Efficient targeting not only requires high specificity for the receptor that is abundantly expressed on the surface of APCs, but also the ability to be rapidly internalised and loaded into compartments that contain elements of the antigen-processing machinery. The ManR and related C-type lectin receptors are especially designed to sample antigens, much like pattern recognition receptors, to integrate the innate with adaptive immune responses. A variety of approaches involving delivery of antigens to the ManR have demonstrated effective induction of potent cellular and humoral immune responses. ManR-targeted vaccines are likely to be most efficacious in vivo when combined with agents that elicit complementary activation signals. A better understanding of the mechanism associated with the induction of immune responses as a result of targeting antigens to the ManR, will be important in exploiting ManR-targeted vaccines not only for mounting immune defenses against cancer and infectious disease, but also for specific induction of tolerance in the treatment of autoimmune disease (Keler et al. 2004).

DEC-205 Mediated Cancer Immunotherapy

Anti α-DEC-205 antibodies target to the DEC-205 receptor that mediates antigen presentation to T cells by DC. DEC-205 is a mannose specific receptor, present on DC. One of the major functions of DEC-205 is to internalize the antigens and present to naïve T lymphocytes for development of T cell dependent immunity. To assess the potential of antigen targeting to DC, Bonifaz et al. (2004) incorporated ovalbumin into a mAb to the DEC-205 receptor, which is expressed on these cells in lymphoid tissues. A single low dose of antibody-conjugated ovalbumin initiated immunity from the naive $CD4^+$ and $CD8^+$ T cell repertoire. Unexpectedly, the αDEC-205 antigen conjugates targeted to DCs for long periods and ovalbumin peptide was presented on MHC class I. This was associated with stronger $CD8^+$ T cell-mediated immunity relative to other forms of antigen delivery, even when the latter was given at a 1,000 times higher doses. In parallel, the mice showed enhanced resistance to an established rapidly growing tumor and to viral infection at a mucosal site. By antibody-mediated antigen targeting via the DEC-205 receptor increased the efficiency of vaccination for T cell immunity, including systemic and mucosal resistance in disease models (Bonifaz et al. 2004; Mahnke et al. 2005). In preclinical studies, Badiee et al. (2007) prepared anti-human DEC-205 immunoliposomes (anti-hDEC-205 iLPSM) and compared their uptake by monocyte-derived DC and blood DC (BDC) with conventional liposomes (cLPSM). Confocal microscopy confirmed that the anti-hDEC-205 iLPSM were phagocytosed by DC and available for antigen processing. Thus, DEC-205 is one of effective targets for delivering liposomes to human DCs (Badiee et al. 2007).

Since, anti α-DEC-205 antibodies target to the DEC-205 receptor that mediates antigen presentation to T cells by DCs, these properties were exploited for immunization strategies by conjugating the melanoma antigen tyrosinase-related protein (TRP)-2 to α-DEC-205 antibodies and immunization of mice with these conjugates together with DC-activating oligonucleotides (CpG). Upon grafting of the melanoma cell line B16, α-DEC-TRP immunized mice were protected against tumor growth or showed substantially slow growth of implanted B16 cells into tumor bearing hosts. Approximately 70% of the animals were cured from existing tumors by treatment with α-DEC conjugates carrying two different melanoma antigens (TRP-2 and gp100). Thus, targeting of DCs in situ by antibody-antigen conjugates may be a novel approach to induce long-lasting antitumor immunity.

Mannan-Coated Nanoparticles in Vaccination: Genetic immunization using "naked" plasmid DNA (pDNA) has been used to elicit humoral and cellular immune responses. In search of a cell-targeted delivery system, cationic nanoparticles coated with pDNA for genetic immunization have been explored. Plasmid DNA-coated nanoparticles, especially with both an endosomolytic lipid and DC-targeting ligand, resulted in 16-fold increase in IgG titer and threefold release in Th1-type cytokine over "naked"

pDNA, indicating that the engineered pDNA-coated nanoparticles could enhance in vitro cell transfection and enhanced in vivo immune responses (Cui and Mumper 2002a). Furthermore, pDNA-coated nanoparticles, especially the mannan-coated pDNA-nanoparticles with DOPE, resulted in significant enhancement in both antigen-specific IgG titers and splenocyte proliferation over 'naked' pDNA alone (Cui and Mumper 2002b). The freeze-dried nanoparticles (prior to pDNA coating) showed potential application for cell-specific targeting of macrophages. Moreover, incubation of nanoparticles with ManR positive mouse macrophage cell line (J774E) showed that the uptake of mannan-coated nanoparticles by the cells was 50% higher than that of uncoated nanoparticles (Cui et al. 2003).

DC-SIGN-Mediated Targeting

Targeting DC surface proteins to deliver liposomes carrying antigens has demonstrated potential for eliciting antigen-specific immune responses. Myeloid dendritic cells (MyDCs) can serve as one of the major reservoirs for HIV-1. Using monocyte-derived MyDCs, Gieseler et al. (2004) presented the evidence for liposomal compound delivery to these cells by specifically addressing. DC-SIGN (CD209), a MyDC-associated C-type lectin implicated in the transmission of HIV-1 to T helper cells. The DC-SIGN was demonstrated as a superior target as compared with other MyDC markers (CD1a, CD4, CD45R0, and CD83). This study implied that liposomal targeting to DC-SIGN (CD209) and related C-type lectins may afford therapeutic intracellular drug delivery to MyDCs and other reservoir and nonreservoir cells susceptible to infection with HIV-1.

Since DCs are a central element in the development of antigen-specific immune responses, current DC-based vaccines are based on ex vivo-generated autologous DCs loaded with antigen prior to re-administration into patients. A more direct and less laborious strategy is to target antigens to DCs in vivo via specific surface receptors. Therefore, a humanized antibody, hD1V1G2/G4 (hD1), directed against the DC-SIGN was explored for its capacity to serve as a target receptor for vaccination purpose. hD1 was cross-linked to a model antigen, keyhole limpet hemocyanin (KLH). The chimeric antibody-protein complex (hD1-KLH) bound specifically to DC-SIGN and was rapidly internalized and translocated to the lysosomal compartment. Antibody-mediated targeting of antigen to DCs via DC-SIGN effectively induces antigen-specific naive as well as recall T-cell responses. This identifies DC-SIGN as a promising target molecule for DC-based vaccination strategies (Gupta et al. 2009; Tacken et al. 2005). Optimal HIV vaccines should elicit $CD8^+$ T cells specific for HIV proteins presented on MHC class I products, because these T cells contribute to host resistance to viruses. Based on humans, studies with highly polymorphic MHC products reveal that DCs and DEC-205 can cross-present several different peptides from a single protein. Because of the consistency in eliciting $CD8^+$ T cell responses these data support the testing of αDEC-205 fusion mAb as a protein-based vaccine (Bozzacco et al. 2007).

The efficacy of adenoviral (Ad) vectors can be enhanced through alterations in vector tropism such that DC-targeted transduction is achieved. The efficiency of DC transduction by Ad vectors retargeted to DC-specific DC-SIGN was studied and compared to that of Ad vectors retargeted through CD40 (Korokhov et al. 2005). A comparable and significant enhancement of gene transfer to monocyte derived DCs (MDDCs) was accomplished by means of an Ad vector harboring the Fc-binding domain of *S. aureus* protein A in combination with antibodies to DC-SIGN or to CD40 or with fused complexes of human Ig-Fc with their natural ligands, i.e., ICAM-3 or CD40L, respectively. Results demonstrated the usefulness of DC-SIGN as a DC-restricted targeting motif for Ad-mediated vaccination strategies.

Targeted Oral Vaccine Delivery to M Cells: A strategy for mucosal vaccination and drug delivery: In the intestine, the delivery of antigens across the epithelial barrier to the underlying lymphoid tissue is accomplished by M cells, a specialized epithelial cell type that occurs only in the lymphoid follicle-associated epithelium. Selective and efficient transport of antigen by M cells is considered an essential requirement for effective mucosal vaccines. Therefore, particulate antigen formulations are currently being developed to take advantage of the capacity of M cells to endocytose particles. Delivery may be achieved using synthetic particulate delivery vehicles including poly(DL-lactide-co-glycolide) microparticles and liposomes. M cell interaction of these delivery vehicles is highly variable, and is determined by the physical properties of both particles and M cells. Delivery may be enhanced by coating with reagents including appropriate lectins, microbial adhesins and immunoglobulins which selectively bind to M cell surfaces (Brayden 2001; Clark et al. 2001). In an alternative approach, antigens are coupled to or encapsulated in particulate synthetic carriers. To enhance binding and uptake of such nonviable vectors, ligands are being attached which direct the vaccine particle to receptors on the M cell surface. While binding and uptake of M cell-targeted latex particles and stable liposomes by mouse M cells has been shown using the mouse M cell-specific lectin, Ulex europaeus 1 (UEA-1), a direct relationship between M cell particle uptake and immune outcome was reported by Brayden (2001).

Since various lectins and lectin containing pathogens bind specifically to oligosaccharides including mannose on intestinal cells, exploiting this specificity, lectins have been

used as a ligand for targeted oral vaccine delivery to M cells (antigen-presenting cells) in follicle-associated epithelium. The antigen-sampling M cells offer a portal for absorption of colloidal and particulate delivery vehicles, including bacteria, viruses and inert microparticles. Consideration is also given to lectin-mediated targeting in non-intestinal sites and to the potential application of other bioadhesins to enhance M cell transport (Jepson et al. 2004). While ManR is found on lymphatic endothelial cells of small intestine, the intestinal serosa revealed a regular, dense, planar network of cells with prominent dendritic morphology within the external muscular layer and with increasing frequency along the length of the intestine (Flores-Langarica et al. 2005). The serosal-disposed layers show a significant fraction of DCs that express DEC-205, Langerin, CD14 and various other molecules. In vivo, these DCs responded to two microbial stimuli, systemic LPS and oral live bacteria, by up-regulating DEC-205, and Langerin within 12 h. This network of DCs, representing a unrecognized APC system in the intestine, needs to be explored for drug targeting and mucosal vaccination through ManR, DEC-205, and langerin present on intestinal cells (Flores-Langarica et al. 2005).

46.3 Asialoglycoprotein Receptor (ASGP-R) for Targeted Drug Delivery

46.3.1 Targeting Hepatocytes

Asialoglycoprotein receptor (ASGP-R) is predominantly expressed on the sinusoidal surface of mammalian hepatocytes and is responsible for the clearance of glycoproteins with desialylated galactose or acetylgalactosamine residues from the circulation by receptor-mediated endocytosis. The ASGP-R provides a unique means for the development of liver-specific carriers, such as liposomes, recombinant lipoproteins, and polymers for drug or gene delivery to the liver, especially to hepatocytes (Cawley et al. 1981; Wu et al. 1998) (Chap. 33). Another study used glycolipids containing a cluster galactoside moiety for targeting to ASGP-R. The liver uptake of the glycolipid-liposomes exceeds 80% compared to less than 10% for conventional liposomes after injection. The abundant receptors on the cells specifically recognize ligands with terminal galactose or N-acetylgalactosamine residues, and endocytose the ligands for an intracellular degradation process. The use of its natural ligand, i.e. asialofetuin, or synthetic ligands with galactosylated or lactosylated residues, such as galactosylated cholesterol, glycolipids, or galactosylated polymers has achieved significant targeting efficacy to the liver. There are several examples of successful targeted therapy for acute liver injury with asialofetuin-labeled and vitamin E-associated liposomes or with a caspase inhibitor loaded in sugar-carrying polymer particles, as well as for the delivery of an antiviral agent, 9-(2-phosphonylmethoxyethyl)adenine. Liposome-mediated gene delivery to the liver is still in its infancy due to difficulties in solving general issues, such as stability of liposome-DNA complexes in circulation, and lysosomal or endosomal degradation of plasmid DNA. Although, galactosylated polymers are promising for gene delivery, but require further studies to verify their potential applications (Wu et al. 2002).

Cationic liposomes and polymers have been accepted as effective non-viral vectors for gene delivery with low immunogenicity unlike viral vectors. Galactosylated liposomes and poly(amino acids) are selectively taken up by the ASGP-R-positive liver parenchymal cells in vitro and in vivo after intravenous injection. DNA-galactosylated cationic liposome complexes show higher DNA uptake and gene expression in the liver parenchymal cells in vitro than DNA complexes with bare cationic liposomes. In the in vitro gene transfer experiment, galactosylated liposome complexes are more efficient than DNA-galactosylated poly (amino acids) complexes but they have some difficulties in their biodistribution control. On the other hand, introduction of mannose residues to carriers resulted in specific delivery of genes to non-parenchymal liver cells (Hashida et al. 2001). Drugs conjugated with galactosyl-terminating macromolecules selectively enter hepatocytes after interaction of the carrier galactose residues with the ASGP-R present in large amounts and high affinity on hepatocytes. Within hepatocytes the conjugates are delivered to lysosomes where enzymes split the bond between the carrier and the drug, allowing the latter to become concentrated in the liver. The validity of this chemotherapeutic strategy has been endorsed by a clinical study (Fiume et al. 1997).

The results obtained reveal tremendous promise and offer enormous options to develop novel DNA based pharmaceuticals for liver disorders in near future. The ^{99m}Tc-labeled asialoglycoprotein analog, TcGSA (galactosyl-human serum albumin-diethylenetriamine - pentaacetic acid) has been applied to human hepatic receptor imaging. This method is unique and provides information that is totally independent of the ICG test or Child-Turcotte Score (Kokudo et al. 2003; Pathak et al. 2008).

The Specificity of ASGP-R for D-Galactose: The specificity of the receptor for D-galactose or D-mannose is accomplished by specific hydrogen bonding of the 3 and 4-hydroxyl groups with carboxylate and amide side-chains. Therefore, mutation of the amino acid sequence in the CRD results in a conversion of its specificity (Feinberg et al. 2000; Meier et al. 2000; Wu et al. 2002). The crystal structure provides a direct confirmation for the conversion of

the ligand-binding site of mannose-binding protein to an ASGP-R-like specificity (Meier et al. 2000). A number of functional mimics for the CRDs of these lectins have been developed by modification of the domain amino acid residues. The modified CRD displayed 40-fold preferential binding to N- acetylgalactosamine compared with galactose, making it a good functional mimic for ASGP-R (Feinberg et al. 2000). Mannose-labeling shifted the ratio to more non-parenchymal cell incorporation (the majority to Kupffer cells) (Feinberg et al. 2000). Therefore, alternative approaches are needed to target liposomes to hepatocytes via ASGP-R (Wu et al. 2002; Yamazaki et al. 2000).

46.4 Siglecs as Targets for Immunotherapy

46.4.1 Anti-CD33-Antibody-Based Therapy of Human Leukemia

Targeting CD33 (Siglec-3) or CD45 is currently exploited for immunotherapy of acute myeloid leukemia (AML). In normal myelopoiesis, expression of CD33 is restricted to advanced stages of differentiation, whereas primitive stem cells do not express CD33. Leukaemic stem cells in patients with $CD33^+$ AML express CD33 (Hauswirth et al. 2007). Antibody-targeted chemotherapy is a therapeutic strategy in cancer therapy that involves a monoclonal antibody specific for a tumor-associated antigen, covalently linked via a suitable linker to a potent cytotoxic agent. The restricted expression of several siglecs (Chaps. 16 and 17) to one or a few cell types makes them attractive targets for cell-directed therapies. The anti-CD33 (Siglec-3) antibody gemtuzumab (Mylotarg) is approved for treatment of acute myeloid leukemia, and antibodies targeting CD22 (Siglec-2) are currently in clinical trials for treatment of B cell non-Hodgkins lymphomas and autoimmune diseases. Since siglecs are endocytic receptors, they are very well suited for a 'Trojan horse' strategy, whereby therapeutic agents conjugated to an antibody, or multimeric glycan ligand, bind to the siglec and are efficiently carried into the cell. Although the rapid internalization of unmodified siglec antibodies reduces their utility for induction of antibody-dependent cellular cytotoxicity or complement-mediated cytotoxicity, antibody binding of Siglec-8, Siglec-9 and CD22 (Siglec-2) has been demonstrated to induce apoptosis of eosinophils, neutrophils and depletion of B cells, respectively. The properties of siglecs that make them attractive for cell-targeted therapies have been reviewed in Chaps. 16 and 17.

Gemtuzumab Ozogamicin (GO): Anti-CD33 antibodies have been used alone-and more effectively, attached to chemotherapy agents or radioisotopes-to treat those with AML (Nemecek and Matthews 2002). Antibody-targeted chemotherapy with gemtuzumab ozogamicin (GO) (CMA-676, a CD33-targeted immunoconjugate of N-acetyl-γ-calicheamicin dimethyl hydrazide [CalichDMH], a potent DNA-binding cytotoxic antitumor antibiotic) is a clinically validated therapeutic option for patients with AML. Calicheamicin is a cytotoxic natural product isolated from Micromonospora echinospora that is at least 1,000-fold more potent than conventional cytotoxic chemotherapeutics. Calicheamicin binds DNA and causes double-strand DNA breaks, leading to cell death. Gemtuzumab ozogamicin is the first clinically validated cytotoxic immunoconjugate in which a humanised anti-CD33 antibody is linked to a derivative of calicheamicin. A similar conjugate, inotuzumab ozogamicin, is being evaluated in Phase I clinical trials in patients with non-Hodgkin's lymphoma. GO is part of clinical practice for AML, but is frequently associated with severe side effects. A number of tumor-targeted immunoconjugates of calicheamicin are being explored preclinically at present for their therapeutic applications (Damle 2004).

Immunoconjugates of calicheamicin targeted against tumor-associated antigens exhibit tumor-specific cytotoxic effects and cause regression of established human tumor xenografts in nude mice. CD33-specific binding triggers internalization of GO and subsequent hydrolytic release of calicheamicin. The histone deacetylase inhibitor valproic acid potently augments gemtuzumab ozogamicin-induced apoptosis in AML cells. The synergistic proapoptotic activity of cotreatment of AML cells with VPA and GO indicates the potential value of this strategy for AML (Ten Cate et al. 2007). Simultaneous targeting of CD45 could improve GO cytotoxicity against AML cell lines and primary AML cells. Further study of this antibody combination for clinical use in AML is warranted (Walter et al. 2008).

Lintuzumab: Lintuzumab (HuM195) is an unconjugated humanized murine mAb directed against cell surface myelomonocytic CD33. The efficacy of lintuzumab in combination with induction chemotherapy has been compared with chemotherapy alone in adults with first relapsed or primary refractory AML. The percent CR plus CRp with MEC plus lintuzumab was 36% vs. 28% in patients treated with MEC alone. The overall median survival was 156 days and was not different in the two arms of the study. The addition of lintuzumab to salvage induction chemotherapy was safe, but did not result in significant improvement in

response rate or survival in patients with refractory/relapsed AML (Feldman et al. 2005).

46.4.2 CD22 Antibodies as Carrier of Drugs

The CD22 antigen is a viable target for therapeutic intervention for B-cell lymphomas. Several therapeutic anti-CD22 antibodies and an anti-CD22-based immunotoxin (HA22) are currently under investigation in clinical research. Coupling of anti-CD22 reagents with a nano-drug delivery vehicle is projected to significantly improve treatment efficacies. A mutant of the targeting segment of HA22 (a CD22 scFv), mut-HA22 conjugated to the surface of sonicated liposomes to generate immunoliposomes (mut-HA22-liposomes) may serve as promising carriers for targeted drug delivery to treat patients suffering from B-cell lymphoma (Loomis et al. 2010).

46.4.3 Immunogenic Peptides

Identification of immunogenic peptides for the generation of cytotoxic T lymphocytes (CTLs) may lead to the development of novel cellular therapies to treat disease relapse in AML patients. Bae et al. (2004) identified immunogeneic HLA-A2.1-specific CD33(65–73) peptide (AIISGDSPV) that was capable of inducing CTLs targeted to AML cells. The CD33-CTLs displayed HLA-A2.1-restricted cytotoxicity against both mononuclear cells from AML patients and the AML cell line. The peptide- was specific to CD33-CTLs that secreted IFN-γ in response to CD33(65–73) peptide stimulation. Alteration of native CD33(65–73) peptide at first amino acid residue from alanine (A) to tyrosine (Y) (YIISGDSPV) enhanced the HLA-A2.1 affinity/stability of the peptide and induced CTLs with increased cytotoxicity against AML cells. These results demonstrate the potential application of immunogenic HLA-A2.1-specific CD33 peptides in developing a cellular immunotherapy for treatment of AML patients (Bae et al. 2004). Bakker et al. (2004) selected a single chain Fv fragment that broadly reacted with AML samples and with myeloid cell lineages within peripheral blood. Expression cloning identified an antigen recognized as C-type lectin-like molecule-1 (CLL-1), and a transmembrane glycoprotein. CLL-1 showed variable expression in $CD34^+$ cells in chronic myelogenous leukemia and myelodysplastic syndrome but was absent in 12 of 13 cases of acute lymphoblastic leukemia. The AML reactivity combined with restricted expression on normal cells suggests CLL-1 as a novel potential target for AML treatment.

46.4.4 Blocking of CD33 Responses by SOCS3

CD33-related Siglecs 5–11 are inhibitory receptors that contain a membrane proximal ITIM, which can recruit SHP-1/2. The suppressor of cytokine signaling (SOCS) proteins, particularly SOCS1, are essential for regulating the inflammatory process. Gene-targeting studies revealed that SOCS play a nonredundant role in limiting the inflammatory response. SOCS expression is induced by cytokines, infective pathogen-associated molecular patterns, and other stimuli. They regulate cytokine signal transduction via a negative feedback loop. They are characterized by a phosphotyrosine binding SH2 domain and the SOCS box motif (Elliott and Johnston 2004; Krebs and Hilton 2001). SOCS3 binds phosphorylated ITIM of Siglec 7 and targets it for proteasomal-mediated degradation, suggesting that Siglec 7 is a SOCS target. SOCS3 can interact with a number of phosphorylated receptors and appears to potently inhibit JAKs in the presence of these receptors (Fujimoto and Naka 2003). Following ligation, the ECS E3 ligase is recruited by SOCS3 to target Siglec 7 for proteasomal degradation, and SOCS3 expression is decreased concomitantly. In addition, SOCS3 expression blocks Siglec 7-mediated inhibition of cytokine-induced proliferation. This may be a mechanism by which the inflammatory response is potentiated during infection (Orr et al. 2007a, b).

Yogalingam G, Litjens T, Bielicki J et al (1996) Feline mucopolysaccharidosis type VI. Characterization of recombinant N-acetylgalactosamine 4-sulfatase and identification of a mutation causing the disease. J Biol Chem 271:27259–27265

Zhu Y, Li X, Kyazike J et al (2004) Conjugation of mannose 6-phosphate-containing oligosaccharides to acid α-glucosidase improves the clearance of glycogen in pompe mice. J Biol Chem 279:50336–50341

Zhu Y, Li X, McVie-Wylie A et al (2005) Carbohydrate-remodelled acid α-glucosidase with higher affinity for the cation-independent mannose 6-phosphate receptor demonstrates improved delivery to muscles of Pompe mice. Biochem J 389:619–628

About the Author

Dr. Gupta is a former Professor and Chairman of the Department of Biophysics, Panjab University, Chandigarh, India. His primary areas of research are Molecular and Cell Biology, Enzymology and Protein Chemistry, and Radiation Biology. As a visiting researcher, he has worked at many institutions, including Northwestern University in Evanston, IL, the Center of Immunopathology and Experimental Immunology, INSERM, Paris and the Center of Cytogenetics and Immunogenetics, INSERM, Villejuif (France). He has been honored by Indian agencies as Emeritus Scientist by CSIR, Emeritus Professor by University Grants Commission (UGC), and Emeritus Medical Scientist by Indian Council of Medical Research (ICMR). Professor Gupta has made significant research contribution in scientific research and published 155 original research articles and reviews in Books and international journals of repute. He is the recipient of several awards and international fellowships including a WHO fellowship, the INSERM French Government fellowship, and the fellowship under Indo-French Exchange programme. Indian Council of Medical Research has honored him by conferring Swaran Kanta Dingley Oration Award of 1993 for his research contribution and extending knowledge in male reproduction. Dr. Gupta is the author of Proteomics of Spermatogenesis published by Springer (New York, USA) in 2005 and has contributed 34 reviews on the subject, as a single author. Associated with national and international scientific societies, he has chaired scientific sessions and delivered invited lectures at national and International conferences.

Professor G.S. Gupta holds master's degrees in Physical Chemistry and Biochemistry from Lucknow University, Lucknow, and a Ph.D. in Biophysics from Panjab University, Chandigarh (India).
