Angata et al. (2001a, 2004) identified *SIGLEC5**, a genomic segment adjacent to *SIGLEC5* gene in the Siglec gene cluster that showed extreme sequence identity with a part of *SIGLEC5* (Angata et al. 2004; Angata et al. 2001a). However, it was not clear if this genomic segment was a part of an active genetic element. It was evident that the genomic region downstream of *SIGLEC5** lacked sequences similar to the exon containing ITIM typically found in CD33rSiglecs, suggesting a possibility that the Siglec protein encoded by *SIGLEC5**, if any, may have a different signaling potential from that of Siglec-5, or any other human CD33rSiglecs. Patel et al. (1999) reported cloning of a leptin-binding protein of IgSF (OB-BP1/Siglec-6) and a cross-hybridizing clone (OB-BP2) that is identical to Siglec-5. Human tissues showed OB-BP2/Siglec-5 mRNA in peripheral blood leukocytes, lung, spleen, and placenta. Angata et al. (2006) proposed that Siglec-5 and Siglec-14 are paired inhibitory and activating receptors. It was also demonstrated that *SIGLEC14* and *SIGLEC5* have undergone concerted evolution via gene conversion in multiple primate species. Based on these results, the evolutionary dynamics behind the birth of Siglec-14 and its concerted evolution with Siglec-5 was suggested.

17.3.2 Siglec-5: An Inhibitory Receptor

Siglec-5 can recruit SHP-1 and SHP-2 after tyrosine phosphorylation and mediate inhibitory signaling, as measured by calcium flux and serotonin release after co-ligation with the activatory FcγRI. Surprisingly, however, mutagenesis studies showed that inhibition of serotonin release could still occur efficiently after a double tyrosine to alanine substitution, whereas suppression of Siglec-5-dependent adhesion required an intact tyrosine residue at the membrane proximal ITIM. A potential mechanism for tyrosine phosphorylation-independent inhibitory signaling was provided by results of in vitro phosphatase assays, which demonstrated low level activation of SHP-1 by the Siglec-5 cytoplasmic tail in the absence of tyrosine phosphorylation (Avril et al. 2005). Based on these findings, Siglec-5 can be classified as an inhibitory receptor with the potential to mediate SHP-1 and/or SHP-2-dependent signaling in the absence of tyrosine phosphorylation (Avril et al. 2005; Angata et al. 2006).

Siglec-5 was not expressed at significant levels by CD34+ progenitors either from bone marrow or mobilized peripheral blood. Siglec-5 expression remained absent or very low on cultured CD34+ cells, unlike CD33, which was present on almost all CD34+ cells by day 4. However, analysis of blasts from patients with AML revealed aberrant expression of Siglec-5 with CD34 in 50% of patients with CD34+ AML; 61% of AML cases were positive for Siglec-5 with an increased frequency in the French-American-British subtypes M3-5. All 13 acute lymphoblastic leukaemic (ALL) samples tested, were Siglec-5 negative (Virgo et al. 2003).

17.3.3 Siglec-5-Mediated Sialoglycan Recognition

The crystal structure of two N-terminal extracellular domains of human Siglec-5 and its complexes with two sialylated carbohydrates was determined. The native structure revealed an unusual conformation of the CC' ligand specificity loop and a unique interdomain disulfide bond (Fig. 17.2). The α(2,3)- and α(2,6)-sialyllactose complexed structures showed a conserved Sia recognition motif that involves both Arg124 and a portion of the G-strand in the V-set domain forming β-sheet-like hydrogen bonds with the glycerol side chain of the Sia. Only few protein contacts to the subterminal sugars are observed and mediated by the highly variable GG' linker and CC' loop. Structural observations provided mechanistic insights into linkage-dependent Siglec carbohydrate recognition and suggested that Siglec-5 and other CD33-related Siglec receptors are more promiscuous in sialoglycan recognition than previously understood (Zhuravleva et al. 2008)

Fig. 17.2 Ribbon diagram showing the native Siglec-5 structure with V-domain in magenta and C2-domain in blue. The disulfides are depicted with sticks. BC and C′D loops and the specificity-determining GG′ and CC′ regions are depicted in orange, cyan, green and yellow, respectively (Adapted by permission from Zhuravleva et al. 2008 © Elsevier)

17.4 Siglec-6

17.4.1 Cloning and Gene Organization of Siglec-6 (OB-BP1)

Siglec-6 was cloned independently by two groups: in one instance from a human placental library (Takei et al. 1997) and in another as a leptin-binding protein (Patel et al. 1999). While Takei et al. (1997) noted an alternately spliced form of obesity binding protein-1 (OB-BP1) (CD33L2) that is predicted to encode a soluble form of protein, Siglec-6 shows strong expression in human placental trophoblast and also at variable levels on human B cells (Patel et al. 1999). Placental trophoblast expression of Siglec-6 is a human-specific phenomenon, which is associated with presence of Siglec-6 ligands on cells of placental and endometrial (uterine epithelial) origin. There is a relationship between the tempo of Siglec-6 expression and the onset and progression of labor. Given the presence of inhibitory signaling motifs on the cytosolic tail of Siglec-6 and its leptin-binding ability, one can speculate about mechanistic connections to the unusually prolonged nature of the human birth process. Human siglec-6 (OB-BP1), like siglec-3 (CD33) recognize both Neu5Ac and Neu5Gc. Siglec-6 shows significant binding to sialyl-Tn (Neu5Acα2-6-GalNAc), a tumor marker associated with poor prognosis. Siglec-6 is an exception among siglecs in not requiring the glycerol side chain of sialic acid for recognition.

The complete cDNA contains an open reading frame of 1,326 nt encoding 442 amino acids and belongs to the IgSF. It is composed of three Ig-like domains; its high degree of similarity to CD33 (70% identity) in the first and second of these domains implies that the placenta-specific gene product is likely to be associated with cell-cell interaction. Northern-blot analysis revealed transcripts of four distinct sizes, 7.5 kb, 5.0 kb, 4.1 kb, and 2.0 kb, specifically in placenta. Consequently, this gene was termed CD33-antigen-like. An alternatively-spliced transcript encoding a 342-amino-acid peptide which lacked the transmembrane region and the cytoplasmic tail was also isolated. It was localized to human chromosome 19q13.3, where the CD33 gene is also located (Takei et al. 1997).

The leptin-binding protein of IgSF (OB-BP1/Siglec-6) along with OB-BP2/Siglec-5, and CD33/Siglec-3 constitute a unique related subgroup with a high level of overall amino acid identity. The cytoplasmic domains are not as highly conserved, but display motifs which are putative sites of tyrosine phosphorylation, including an ITIM and a motif found in SLAM and SLAM-like proteins. Human tissues showed high levels of OB-BP1 mRNA in placenta and moderate expression in spleen, peripheral blood leukocytes, and small intestine. OB-BP2/Siglec-5 mRNA was detected in peripheral blood leukocytes, lung, spleen, and placenta. OB-BP1 showed high expression in placental cyto- and syncytiotrophoblasts. While OB-BP1 exhibited tight binding ($K_D = 91$ nM), the other two showed weak binding with K_D values in 1–2 μM range. OB-BP1 specifically bound Neu5Acα2–6GalNAcα (sialyl-Tn) allowing its formal designation as Siglec-6. The OB-BP1/Siglec-6 as a Siglec may mediate cell-cell recognition events by interacting with sialylated glycoprotein ligands expressed on specific cell populations (Patel et al. 1999). OB-BP1 and 2 display no similarity to leptin receptor (Ob-R). In surface plasmon resonance studies, OB-BP1 bound leptin with a moderate affinity, while OB-BP2 and CD33 bound with low affinities. The three exhibited binding kinetics with relatively slow on and off rates, which differed significantly from typical receptor-cytokine kinetics in which both on and off rates are fast (Patel et al. 1999). If leptin is an endogenous ligand of OB-BP1, role in leptin physiology could be speculated. Patel et al. (1999) hypothesized that OB-BP1 regulates circulating levels of leptin or acts as a leptin carrier in blood via B cells.

17.4.2 Siglec-6 (OB-BP1) and Reproductive Functions

Siglec-6/OB-BP1 is expressed on immune cells of both humans and the closely related great apes. Placental trophoblast expression is human-specific, with little or no expression in ape placentae. Human placenta also expresses natural ligands for Siglec-6 (a mixture of glycoproteins carrying cognate sialylated targets), in areas adjacent to Siglec-6 expression. Ligands were also found in uterine endometrium and on cell lines of trophoblastic or endometrial origin. Thus, Siglec-6 was recruited to placental expression during human evolution, presumably to interact with sialylated ligands for specific negative signaling functions and/or to regulate leptin availability. The control of human labor is poorly understood, but involves multiple cues, including placental signaling. Human birthing is also prolonged in comparison to that in our closest evolutionary relatives, the great apes. Siglec-6 levels are generally low in placentae from elective surgical deliveries without known labor and the highest following completion of labor. It is speculated that the negative signaling potential of Siglec-6 was recruited to human-specific placental expression, to slow the tempo of human birth process. The leptin-binding ability of Siglec-6 is also consistent with this hypothesis, as leptin-deficient mice have increased parturition times (Brinkman-Van der Linden et al. 2007).

Preeclampsia (PE), which affects 4–8% of human pregnancies, causes significant maternal and neonatal morbidity and mortality. Within the basal plate, placental cytotrophoblasts (CTBs) encode proteins associated with PE and molecules like Siglec-6 and pappalysin-2, localized to invasive CTBs and syncytiotrophoblasts. Alterations in Siglec-6 have been reported in PE. Siglec-6 placental expression is unique to human, as is spontaneous PE (Winn et al. 2009).

17.5 Siglec-7 (p75/AIRM1)

17.5.1 Characterization

Siglec-7, the adhesion inhibitory receptor molecule 1 (p75/AIRM1), is a 75-kD surface glycoprotein that displays homology with the myeloid cell antigen CD33. In lymphoid cells, p75/AIRM1 is confined to NK cells and mediates inhibition of their cytolytic activity. p75/AIRM1 is also expressed by cells of the myelomonocytic cell lineage, in which it appears at a later stage as compared with CD33 (Vitale et al. 2001). The p75/AIRM1 gene is located on human chromosome 19 and encodes a member of the sialoadhesin family characterized by three Ig-like extracellular domains (one NH_2-terminal V-type and two C2-type) and a classical ITIM in the cytoplasmic portion. The highest amino acid sequence similarity has been found with the myeloid-specific CD33 molecule and the placental CD33L1 protein. Similar to other sialoadhesin molecules, p75/AIRM1 appears to mediate sialic acid-dependent ligand recognition (Nicoll et al. 1999; Angata and Varki 2000b).

Sugar-binding specificity of Siglec-7 expressed on CHO cells was characterized. Glyco-probes carrying unique oligosaccharide structures such as GD3 (NeuAc α2,8NeuAc α2,3Gal β 1,4Glc) and LSTb (Gal β1,3[NeuAc α 2,6]GlcNAc β1,3Gal β1,4Glc) oligosaccharides bound to Siglec-7 better than those carrying LSTc (NeuAc α2,6Gal β1,4GlcNAc β1,3Gal β1,4Glc) or GD1a (NeuAc α 2,3Gal β1,3GalNAc β1,4[NeuAc α2,3]Gal β1,4Glc) oligosaccharides. In contrast, Siglec-9, which is 84% identical to Siglec-7, did not bind to the GD3 and LSTb probes but did bind to the LSTc and GD1a probes. Substitution of a small region, Asn70-Lys75, of Siglec-7 with the equivalent region of Siglec-9 resulted in loss of Siglec-7-like binding specificity and acquisition of Siglec-9-like binding properties. In comparison, a Siglec-9-based chimera, which contains Asn70-Lys75 with additional amino acids derived from Siglec-7, exhibited Siglec-7-like specificity. These results with molecular modeling suggest that the C-C' loop in the sugar-binding domain plays a major role in determining the binding specificities of Siglecs-7 and -9 (Yamaji et al. 2002).

17.5.2 Cytoplasmic Domain of Siglec-7 (p75/AIRM1)

The cytoplasmic domain of Siglec-7 contains two signaling motifs: a membrane-proximal ITIM (Ile435-Gln-Tyr-Ala-Pro-Leu440) and a membrane-distal motif (Asn458-Glu-Tyr-Ser-Glu-Ile463). Upon pervanadate (PV) treatment, Siglec-7 recruited the protein tyrosine phosphatases Src homology-2 (SH2) domain-containing protein-tyrosine phosphatase-1 (SHP-1) and SHP-2 less efficiently than did other inhibitory receptors such as Siglec-9. Alignment of the amino acid sequences of the two Siglecs revealed only three amino acids difference in these motifs. These amino acids appeared to affect not only phosphatase recruitment but also the subsequent attenuation of Syk phosphorylation (Yamaji et al. 2005).

Siglec-7 shows a preference for α(2,8)-disialylated ligands and provides a structural template for studying the key interactions that drive this selectivity. The crystal

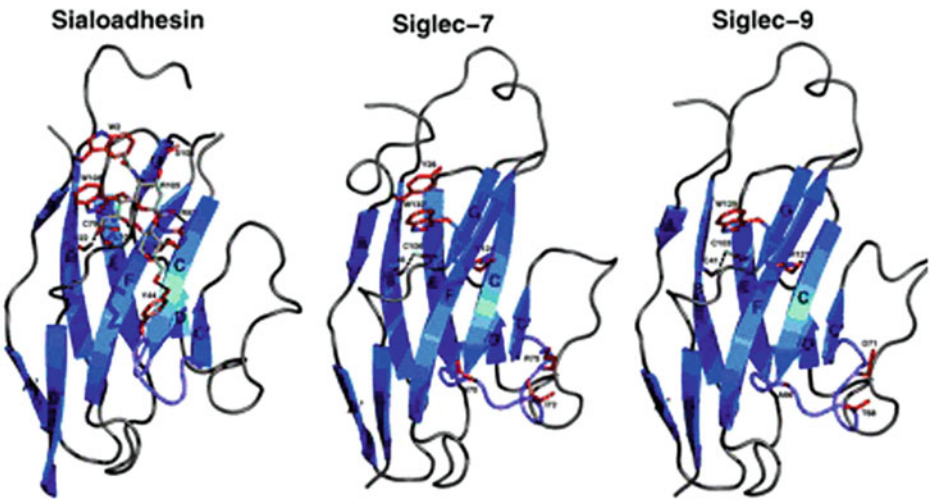

Fig. 17.3 *Comparison of sialoadhesin, Siglec-7, and Siglec-9 structures*. The crystal structures of sialoadhesin in complex with sialyllactose, the crystal structure of Siglec-7, and a model for Siglec-9 are shown in two representations. The ackbones are shown as *ribbons* with the side chains surrounding the ligand-binding site shown as *sticks* with *orange* carbons. The C-C' loop is *highlighted* in *magenta*. The two pyranose sugars from the sialyllactose ligand are shown as *sticks* with *green* carbons. Hydrogen bonds with the protein are shown as *black dotted lines*. For sialoadhesin, the two pyranose sugars of the ligand are shown in a *sticks* representation (Adapted by permission from Alphey et al. 2003 © The American Society for Biochemisty and Molecular Biology)

structure of the co-crystallized Siglec-7 with a synthetic oligosaccharide corresponding to the α(2,8)-disialylated ganglioside GT1b offers a first glimpse into how this important family of lectins binds the structurally diverse gangliosides. The complex structure revealed that the C-C' loop, a region implicated in previous studies as driving siglec specificity, undergoes a dramatic conformational shift, allowing it to interact with the underlying neutral glycan core of the ganglioside. Studies showed that binding of the ganglioside is driven by extensive hydrophobic contacts together with key polar interactions and that the binding site structure is complementary to preferred solution conformations of GT1b (Attrill et al. 2006a).

17.5.3 Crystallographic Analysis

The expression, crystallization and preliminary X-ray characterization of the Ig-V like domain of p75/AIRM1 have been reported. X-ray data were collected from a single crystal at 100 K at 1.45 A resolution showed that the crystal belongs to a primitive monoclinic space group, with unit-cell parameters a = 32.65, b = 49.72, c = 39.79 A, α = γ = 90, β = 113. The systematic absences indicate that the space group is P2(1). Assuming one molecule per asymmetric unit, V(M) (Matthews coefficient) was calculated to be 1.879 A^3 Da^{-1} and the solvent content was estimated to be 32.01%. The structure belongs to a different space group than Siglec-7 structure and was obtained using a bacterial expression system. The structure unveils the fine structural requirements adopted by a natural killer cell inhibitory receptor of the Siglec family in target-cell recognition and binding (Dimasi et al. 2004).

Alphey et al. (2003) described the high resolution structures of the N-terminal V-set Ig-like domain of Siglec-7 in two crystal forms. The latter crystal form reveals the full structure of this domain and allows us to speculate on the differential ligand binding properties displayed by members of the Siglec family. A fully ordered N-linked glycan is observed, tethered by tight interactions with symmetry-related protein molecules in the crystal. Comparison of the structure with that of sialoadhesin and a model of Siglec-9 shows that the unique preference of Siglec-7 for α(2,8)-linked disialic acid is likely to reside in the C-C' loop, which is variable in the Siglec family (Fig. 17.3). In the Siglec-7 structure, the ligand-binding pocket is occupied by a loop of a symmetry-related molecule, mimicking the interactions with sialic acid (Alphey et al. 2003).

17.5.4 Interactions of Siglec-7

Avril et al. (2006) examined the interaction of 10 siglecs with lipooligosaccharides (LOS) purified from four different *C. jejuni* isolates expressing GM1-like, GD1a-like, GD3-like, and GT1a-like oligosaccharides. Of all siglecs examined, only Siglec-7 exhibited specific, sialic acid-dependent interactions with *C. jejuni* LOS. Binding of Siglec-7 was also observed with

intact bacteria expressing these LOS structures. Specific binding of HS:19($GM1^+$ $GT1a^+$) bacteria was demonstrated with Siglec-7 expressed on transfected CHO cells and with peripheral blood leukocytes, among which HS:19($GM1^+$ $GT1a^+$) bacteria bound selectively to both NK cells and monocytes which naturally express Siglec-7. These results raise the possibility that, in addition to their role in generating autoimmune antibody responses, *C. jejuni* LOS could interact with Siglec-7 expressed by leukocytes, modulate the host-pathogen interaction, and contribute to the clinical outcome and the development of secondary complications such as Guillain-Barre syndrome (Avril et al. 2006).

In addition to their ability to recognize sialic acid residues, Siglec-7 and Siglec-9 display two conserved tyrosine-based motifs in their cytoplasmic region similar to those found in inhibitory receptors of the immune system. Siglecs-7 and -9 are able to inhibit the FcεRI-mediated serotonin release from RBL cells following co-crosslinking. In addition, under these conditions or after pervanadate treatment, Siglecs-7 and -9 associate with the Src homology region 2 domain-containing phosphatases (SHP), SHP-1 and SHP-2. Site-directed mutagenesis showed that the membrane-proximal tyrosine motif is essential for the inhibitory function of both Siglec-7 and -9, and is also required for tyrosine phosphory lation and recruitment of SHP-1 and SHP-2 phosphatases. The mutation of the membrane-proximal motif increased the sialic acid binding activity of Siglecs-7 and -9, suggesting the possibility that "inside-out" signaling may occur to regulate ligand binding (Angata et al. 2006). The crystal structure of siglec-7 in complex with a sialylated ligand, the ganglioside analogue DSLc4 [α(2,3)/α(2,6) disialyl lactotetraosyl 2-(trimethylsilyl)ethyl], allows for a detailed description of the binding site, required for structure-guided inhibitor design. Mutagenesis and binding assays demonstrated the key structural role for Lys131, a residue that changes conformation upon sialic acid binding. Differences between the binding sites of siglec family members were then exploited using α-methyl Neu5Ac (N-acetylneuraminic acid) as a basic scaffold. A co-crystal of siglec-7 in complex with the sialoside inhibitor, oxamido-Neu5Ac [methyl α-9-(amino-oxalyl-amino)-9-deoxy-Neu5Ac] and inhibition data for the sialosides gives clear leads for future inhibitor design (Attrill et al. 2006b).

17.5.5 Functions of Siglec-7

Negative Regulation of T Cell Receptor Signaling: Siglec-7 and Siglec-9 are capable of modulating T cell receptor (TCR) signaling in Jurkat T cells stably and transiently transfected with Siglec-7 or Siglec-9. Following either pervanadate stimulation or TCR engagement, both Siglecs exhibited increased tyrosine phosphorylation and recruitment of SHP-1. There was also a corresponding decreased transcriptional activity of nuclear factor of activated T cells (NFAT) as determined using a luciferase reporter gene. Like all siglecs, Siglec-7 and -9 recognize sialic acid-containing glycans of glycoproteins and glycolipids as ligands. Mutation of the conserved Arg in the ligand binding site of Siglec-7 (Arg^{124}) or Siglec-9 (Arg^{120}) resulted in reduced inhibitory function in the NFAT/luciferase transcription assay, suggesting that ligand binding is required for optimal inhibition of TCR signaling. The combined results demonstrate that both Siglec-7 and Siglec-9 are capable of negative regulation of TCR signaling and that ligand binding is required for optimal activity (Ikehara et al. 2004).

SOCS3 Targets Siglec 7 for Proteasomal Degradation: SOCS3 (Suppressor of Cytokine Signaling 3) is up-regulated during inflammation and competes with SHP-1/2 for binding to ITIM-like motifs on various cytokine receptors resulting in inhibition of signaling. Orr et al. (2007a) showed that SOCS3 binds the phosphorylated ITIM of Siglec 7 and targets it for proteasomal-mediated degradation suggesting that the Siglec 7 receptor is a SOCS target. In addition, SOCS3 expression blocks Siglec 7 mediated inhibition of cytokine-induced proliferation. It seems that SOCS target degrades simultaneously with the SOCS protein and that inhibitory receptors may be degraded in this way. This may be a mechanism by which the inflammatory response is potentiated during infection (Orr et al. 2007a).

17.6 Siglec-8

17.6.1 Characteristics and Cellular Specificity

Siglec-8 (SAF-2) is selectively expressed on human eosinophils, basophils, and mast cells, where it regulates their function and survival (Kikly et al. 2000; Floyd et al. 2000). SAF-2, identified by Kikly et al. (2000) was homologous with CD33 and siglec-5. SAF-2 is a 431-amino acid protein composed of 3 Ig domains with a 358-amino acid extracellular domain and a 47-amino acid tail. SAF-2 is useful in the detection and/or modulation of allergic cells (Bochner 2009; Aizawa et al. 2003). Siglec-8 was also found to be expressed on human mast cells and to a weak but consistent degree on human basophils (Kikly et al. 2000). Siglec-8 exists in 2 isoforms with identical extracellular and transmembrane sequences. A splice variant of Siglec-8, termed Siglec-8L, which contains an identical extracellular domain but a longer cytoplasmic tail possessing two ITIMs, was discovered from human genomic DNA (Bochner 2009; Foussias et al. 2001; Yousef et al. 2002). One isoform (Siglec-8) has a short cytoplasmic tail with no

known signaling sequences, while the other, Siglec-8 long form (Siglec-8L) has a longer cytoplasmic tail containing 2 -tyrosine-based signaling motifs (Foussias et al. 2000; Munday et al. 2001). The cytoplasmic region of Siglec-8L contains one consensus ITIM and a signaling lymphocyte activation molecule (SLAM)–like motif, suggesting that Siglec-8L may possess signal transduction activity (Crocker and Varki 2001a, b; Foussias et al. 2000; Munday et al. 2001). The highest levels of homology are found between Siglec-8 and Siglec-3 (49%), Siglec-5 (42%), and Siglec-7 (68%), with virtually all homology due to similarities in the extracellular and transmembrane regions. Siglec-8 is expressed not only on the surface of eosinophils but also on basophils and mast cells (Kikly et al. 2000), and the existence of both the Siglec-8 and Siglec-8L isoforms was verified in human eosinophils, basophils, and mast cells (Aizawa et al. 2002; Bochner 2009). Antibody cross-linking of Siglec-8 on human eosinophils induces caspase-dependent apoptosis in vitro (Nutku et al. 2003). Like Siglec-3 and Siglec-7 (p75/AIRM-1), ligation of Siglec-8 inhibits eosinophil survival. Cross-linking Siglec-8 with antibodies rapidly generated caspase-3–like activity and reduced eosinophil viability through induction of apoptosis. Siglec-8 activation may provide a useful therapeutic approach to reduce numbers of eosinophils in disease states where these cells are important (Nutku et al. 2008).

The siglec-8 gene mapped on chromosome 19q13.33-41, ~330 kb down-stream of Siglec-9 gene, is closely linked to genes encoding CD33, siglec-5, siglec-6, and siglec-7. It mediates sialic acid-dependent binding to human erythrocytes and to soluble sialoglycoconjugates (Floyd et al. 2000). Both Siglec-8 and Siglec8-L comprise of seven exons, of which the first five are identical, followed by marked differences in exon usage and mRNA splicing. The 499 amino acid protein encoded by the Siglec8-L open reading frame has a molecular weight of 54 kDa (Foussias et al. 2000) (Fig. 17.1).

17.6.2 Ligands for Siglec-8

Red blood cell rosettes are formed in presence of Siglec-8, and neuraminidase treatment alters rosette formation (Kikly et al. 2000; Floyd et al. 2000). Specific structures shown to bind Siglec-8 include forms of sialic acid that are linked α2–3 or α2–6 to Galβ1–4GlcNAc (Floyd et al. 2000). The binding of Siglec-8 is sialic acid-dependent. A Siglec-8-Ig chimeric protein revealed that of 172 glycan structures, ~40 structures were sialylated. Among these, avid binding was detected to a single defined glycan, NeuAcα2–3(6-*O*-sulfo)Galβ1–4[Fucα1–3]GlcNAc, also referred to as 6' sulphated sialyl Lewis X (6′-sulfo-sLe^x). Notably, neither unsulfated sLe^x (NeuAcα2–3Galβ1–4[Fucα1–3]GlcNAc), a known ligand for E-, P- and L-selectin nor an isomer with the sulfate on the 6-position of the GlcNAc residue (6-sulfo-sLe^x, NeuAcα2–3Galβ1–4[Fucα1–3](6-*O*-sulfo)GlcNAc) supported detectable binding. Whereas surfaces derivatized with sLe^x and 6-sulfo-sLe^x failed to support detectable Siglec-8 binding, 6′-sulfo-sLe^x supported significant binding with a K_D of 2.3 μM. Siglec-8 binds preferentially to the sLe^x structure bearing an additional sulfate ester on the galactose 6-hydroxyl (Bochner et al. 2005; Bochner 2009). Bochner et al. (2005) indicated that Siglec-8 is a highly specific lectin, binding preferentially to the sLe^x structure bearing an additional sulfate ester on the galactose 6-hydroxyl, namely NeuAcα2–3(6-*O*-sulfo)Galβ1–4[Fucα1–3]GlcNAc, also referred to in the literature as 6′-sulfo-sLe^x, which is a structure closely related to 6-sulfo-sLe^x, a candidate ligand for L-selectin. However, Blixt et al. (2003) suggested that Siglec-Ig chimeras showed a wide range of binding patterns with no clear binding preference for Siglec-8. Thus, Siglec-8 requires the presence of the sulphate on the sixth position of the galactose residue (Bochner 2009), though, the exact biochemical identity of natural tissue ligands for Siglec-8 remains unknown. Based on the occurrence of sulphated sLex-like structures made by airway cells, bronchial (and perhaps mononuclear cell) mucins have been suggested as candidate ligands for Siglec-F and Siglec-8 (Bochner 2009; Zhang et al. 2007).

17.6.3 Functions in Apoptosis

Recent work suggests that Siglecs are also empowered to transmit death signals, at least in myeloid cells. Strikingly, death induction by Siglecs is enhanced when cells are exposed to proinflammatory survival cytokines. Based on these insights, von Gunten and Simon (2006) hypothesized that at least some members of the Siglec family regulate immune responses via the activation of caspase-dependent and caspase-independent cell death pathways. Siglec-8 cross-linking with antibodies rapidly generated caspase-3-like activity and reduced eosinophil viability through induction of apoptosis. Siglec-8 crosslinking on eosinophils increased dissipation of mitochondrial membrane potential upstream of caspase activation. Inhibitors of mitochondrial respiratory chain components completely inhibited apoptosis. Additional experiments demonstrated that ROS was also essential for Siglec-8-mediated apoptosis and preceded Siglec-8-mediated mitochondrial dissipation (Nutku et al. 2003; 2005).

Based on structural homology alone, there was no clear mouse ortholog of Siglec-8. Therefore, using different strategies, it is now clear that Siglec-G is expressed on B lymphocytes (Hoffmann et al. 2007) while Siglec-F is most prominently expressed by mouse eosinophils (Angata et al. 2001a; Zhang et al. 2004; Tateno et al. 2005). This was somewhat unexpected based on sequence homology alone, because Siglec-F more closely resembles human Siglec-5,

which is not expressed by human eosinophils (Aizawa et al. 2003). Siglec-F is not expressed on mouse mast cells and instead is expressed on a wider range of cells including alveolar macrophages and at very low levels on T cells and neutrophils, none of which express Siglec-8 in human; and unlike Siglec-8, surface levels of Siglec-F on eosinophils and other cells increase during allergic inflammatory responses (Bochner 2009). Therefore, because of its preferential expression on eosinophils and preference for binding the same ligand, Siglec-F and Siglec-8 are best thought of as functionally convergent paralogs.

17.6.4 Siglec-8 in Alzheimer's Disease

Recent progress in pattern recognition receptors of monocytes and macrophages has revealed that Siglec family of receptors is an important recognition receptor for sialylated glycoproteins and glycolipids. Studies revealed that microglial cells contain only one type of Siglec receptors, Siglec-11, which mediates immunosuppressive signals and thus inhibits the function of other microglial pattern recognition receptors, such as TLRs, NLRs, and RAGE receptors. Salminen and Kaarniranta (2009) reviewed and indicated that aggregating amyloid plaques are masked in AD by sialylated glycoproteins and gangliosides. Sialylation and glycosylation of plaques, mimicking the cell surface glycocalyx, can activate the immunosuppressive Siglec-11 receptors, as well as hiding the neuritic plaques, allowing them to evade the immune surveillance of microglial cells. This kind of immune evasion can prevent the microglial cleansing process of aggregating amyloid plaques in AD.

17.7 Siglec-9

17.7.1 Characterization and Phylogenetic Analysis

The cDNA of human Siglec-9 encodes a type 1 transmembrane protein with three extracellular immunoglobulin-like domains and a cytosolic tail containing two tyrosines, one within a typical ITIM. The N-terminal V-set Ig domain has most amino acid residues typical of Siglecs. Expression of the full-length cDNA in COS cells induces sialic-acid dependent erythrocyte binding. A recombinant soluble form of the extracellular domain binds to α2-3 and α2-6-linked sialic acids. The carboxyl group and side chain of sialic acid are essential for recognition, and mutation of a critical arginine residue in domain 1 abrogates binding. The underlying glycan structure also affects binding, with Galβ1-4Glc[NAc] being preferred. Siglec-9 shows closest homology to Siglec-7 and both belong to a Siglec-3/CD33-related subset of Siglecs (with Siglecs-5, -6, and -8). The Siglec-9 gene is on chromosome 19q13.3-13.4, in a cluster with all Siglec-3/CD33-related Siglec genes, suggesting their origin by gene duplications. A homology search of the *Drosophila melanogaster* and *C.elegans* genomes suggests that Siglec expression may be limited to animals of deuterostome lineage, coincident with the appearance of the genes of the sialic acid biosynthetic pathway (Angata and Varki 2000a).

A full-length cDNA encoding Siglec-9, isolated from a dibutyryl cAMP-treated HL-60 cell cDNA library, is predicted to contain three extracellular Ig-like domains that comprise an N-terminal V-set domain and two C2-set domains, a transmembrane region and a cytoplasmic tail containing two putative tyrosine-based signaling motifs. Overall, Siglec-9 is approximately 80% identical in amino acid sequence to Siglec-7, suggesting that the genes encoding these two proteins arose relatively recently by gene duplication. Siglec-9 was found to be expressed by monocytes, neutrophils, and $CD16^+$, $CD56^-$ cells. Weaker expression was observed on app. 50% of B cells and NK cells and minor subsets of $CD8^+$ T cells and $CD4^+$ T cells (Zhang et al. 2000).

17.7.2 Functions of Siglec-9

17.7.2.1 Siglec-9 Transduces Apoptotic and Nonapoptotic Death Signals

In normal neutrophils, Siglec-9 ligation induces apoptosis. The increased Siglec-9-mediated death was mimicked in vitro by proinflammatory cytokines, such as GM-CSF, IFN-α, and IFN-γ, and was demonstrated to be caspase independent. Study suggested that apoptotic (ROS- and caspase-dependent) and nonapoptotic (ROS-dependent) death pathways are initiated in neutrophils via Siglec-9. The new insights have important implications for the pathogenesis, diagnosis, and treatment of inflammatory diseases such as sepsis and rheumatoid arthritis (von Gunten et al. 2005). Siglec-9, present on neutrophils is activated by intravenous (iv) administration of Ig during immuno-therapy, resulting in caspase-dependent and caspase-independent forms of cell death, resulting in neutropenia that is sometimes seen in association with iv-Ig therapy Neutrophil death was mediated by naturally occurring anti-Siglec-9 autoantibodies present in iv-Ig. Anti- Siglec-9 autoantibody-depleted iv-Ig failed to induce this caspase-independent neutrophil death. Results explain the cause of neutropenia that is seen in association with iv Ig therapy (von Gunten et al. 2006).

17.7.2.2 Bacterial Pathogen Lower Siglec-9 Innate Immune Response

Human neutrophil Siglec-9 recognizes host Sias as ""self,"" including *in cis* interactions with Sias on the neutrophil's own surface, thereby dampening unwanted neutrophil reactivity. Neutrophils presented with immobilized multimerized Sia α2-3Galβ1-4GlcNAc units engage them *in trans* via Siglec-9. The sialylated capsular polysaccharide of group B *Streptococcus* (GBS) also presents terminal Sia α2-3Galβ1-4GlcNAc units, and similarly engages neutrophil Siglec-9, dampening neutrophil responses in a Sia- and Siglec-9–dependent manner. GBS can impair neutrophil defense functions by coopting a host inhibitory receptor via sialoglycan molecular mimicry, a novel mechanism of bacterial immune evasion (Carlin et al. 2009). Experiments using a pan-caspase-inhibitor provided evidence for caspase-independent neutrophil death in Siglec-9 responders upon Siglec-9 ligation. Septic shock patients exhibit different ex vivo death responses of blood neutrophils after Siglec-9 ligation early in shock (von Gunten et al. 2009).

17.7.2.3 Siglec-9 Enhances IL-10 Production in Macrophages

Siglec-9 modulates cytokine production in macrophage cell line RAW264. Overexpression of siglec-9 in macrophage cell lines inhibited production of pro-inflammatory cytokines such as TNFα and enhanced the production of IL-10 in an ITIM-dependent manner in response to Toll-like receptor signaling (Ando et al. 2008). Cells expressing Siglec-9 produced low levels of TNF-α upon stimulation with LPS, peptidoglycan, unmethylated CpG DNA, and double-stranded RNA. On the other hand, IL-10 production was strongly enhanced in Siglec-9-expressing cells. Similar activity was also demonstrated by Siglec-5. However, the up-regulation of IL-10 as well as the down-regulation of TNF-α was abrogated when two tyrosine residues in the cytoplasmic tail of Siglec-9 were mutated to phenylalanine (Ando et al. 2008).

17.7.2.4 Siglec-9 is Expressed on Subsets of Acute Myeloid Leukemia Cells

Like Siglec-3, Siglec-9 is also expressed on subsets of AML and may provide additional therapeutic targets in the future (Biedermann et al. 2007). Siglec-9 was absent from normal bone marrow myeloid progenitors but present on monocytic precursors. Using primary AML cells or transfected rat basophilic leukemia cells, Siglec-9 mediated rapid endocytosis of anti-Siglec-9 mAb. Siglec-9 is not only a useful marker for certain subsets of AML, but also presents as a potential therapeutic target (Biedermann et al. 2007).

17.8 Siglec-10, -11, -12, and -16

17.8.1 Siglec-10

The full-length-Siglec-10 cDNA encodes a type 1 transmembrane protein containing four extracellular Ig-like domains, a transmembrane region, and a cytoplasmic tail with two ITIMs. The N-terminal V-set Ig domain has most of the amino acid residues typical of the Siglecs. Siglec-10 shows the closest homology to Siglec-5 and Siglec-3/CD33 and mapped to the same region, on chromosome 19q13.3. Various cells and cell lines including monocytes and dendritic cells express Siglec-10. Siglec-10 is an immune system-restricted membrane-bound protein that is highly expressed in peripheral blood leukocytes, spleen, and liver. The expressed protein was able to mediate sialic acid-dependent binding to human erythrocytes and soluble sialoglycoconjugates. Siglec-10 was detected on subsets of human leucocytes including eosinophils, monocytes and a minor population of NK-like cells. The molecular properties and expression pattern suggest that Siglec-10 may function as an inhibitory receptor within the innate immune system (Li et al. 2001; Munday et al. 2001). Genomic sequence of siglec-10 is localized within the cluster of genes on chromosome 19q13.3-4 that encodes other siglec family members. The extracellular domain of siglec-10 was capable of binding to peripheral blood leukocytes. The cytoplasmic tail of siglec-10 contains four tyrosines, two of which are embedded in ITIM-signaling motifs (Y^{597} and Y^{667}) and are likely involved in intracellular signaling. The ability of tyrosine kinases to phosphorylate the cytoplasmic tyrosines was evaluated by kinase assay using wild-type siglec-10 cytoplasmic domain and Y—>F mutants. The majority of the phosphorylation could be attributed to Y^{597} and Y^{667}. Further experiments with cell extracts suggest that SHP-1 interacts with Y^{667} and SHP-2 interacts with Y^{667} in addition to another tyrosine. Therefore siglec-10, as CD33, may be characterized as an inhibitory receptor (Whitney et al. 2001). A splice variant of Siglec-10, called Siglec-10Sv3 expresses in T- and B-cells. Moreover, another splicing form of Siglec-10, named Siglec-10Sv4, was also identified. One common characteristic of all Siglec-10 splice forms (except for Siglec-10Sv2) is their cytoplasmic tail with two ITIMs and one CD150-like sequence (Kitzig et al. 2002).

17.8.2 Siglec-11

As with others in this subgroup, the cytosolic domain of Siglec-11 is phosphorylated at tyrosine residue(s) upon

pervanadate treatment of cells and then recruits the protein-tyrosine phosphatases SHP-1 and SHP-2. However, Siglec-11 has several novel features relative to the other CD33/Siglec-3-related Siglecs. First, it binds specifically to α2-8-linked sialic acids. Second, unlike other CD33/Siglec-3-related Siglecs, Siglec-11 was not found on peripheral blood leukocytes. Instead, it was expressed on macrophages in various tissues, such as liver Kupffer cells. Third, it was also expressed on brain microglia, thus becoming the second Siglec to be found in the nervous system. Fourth, whereas the Siglec-11 gene is on human chromosome 19, it lies outside the previously described CD33/Siglec-3-related Siglec cluster on this chromosome. Fifth, analyses of genome data bases indicate that Siglec-11 has no mouse ortholog and that it is likely to be the last canonical human Siglec to be reported. Finally, although Siglec-11 showed marked sequence similarity to human Siglec-10 in its extracellular domain, the cytosolic tail appeard only distantly related. Analysis of genomic regions surrounding the Siglec-11 gene suggests that it is actually a chimeric molecule that arose from relatively recent gene duplication and recombination events, involving the extracellular domain of a closely related ancestral Siglec gene (which subsequently became a pseudogene) and a transmembrane and cytosolic tail derived from another ancestral Siglec (Angata et al. 2002b). Human Siglec-11 was expressed by tissue macrophages, including brain microglia (Angata et al. 2004). Comparisons with the chimpanzee genome indicate that human Siglec-11 emerged through human-specific gene conversion by an adjacent pseudogene. Conversion involved 5 cent untranslated sequences and the Sia-recognition domain. This human protein shows reduced binding relative to the ancestral form but recognizes oligosialic acids, which are enriched in the brain. Siglec-11 is expressed in human but not in chimpanzee brain microglia. Further studies will determine if this event was related to the evolution of Homo (Hayakawa et al. 2005).

17.8.3 Siglec 12

Analyses of genomic *SIGLEC* sequences across humans, chimpanzees, baboons, rats, and mice showed that CD33rSiglecs are evolving rapidly. This is particularly pronounced in the Sia-recognizing V-set domain, suggesting that this domain is under the greatest selection pressure. The human ortholog of Siglec-12 (formerly Siglec-L1) has an Arg Cys (R122C) substitution resulting in a protein unable to bind Sias (Angata et al. 2001). This protein is referred to as Siglec-XII in humans and differentially named as Siglec-12 in primates, where the Sia-binding arginine is present. The gene in both cases is referred to as *SIGLEC12*. Reversing this mutation *in vitro* restored Sia binding. The R122C mutation of the Siglec-XII protein is fixed in the human population, i.e. it occurred prior to the origin of modern humans. Additional mutations have since completely inactivated the *SIGLEC12* gene in some but not all humans. The chimpanzee Siglec-12 is fully functional and preferentially recognizes N-glycolylneuraminic acid, which is a common sialic acid in great apes and other mammals. Reintroducing the ancestral arginine into the human molecule regenerates the same properties. Thus, the single base pair mutation that replaced the arginine on human Siglec-L1 is likely to be evolutionarily related to the previously reported loss of N-glycolylneuraminic acid expression in the human lineage. The human genome contains several Siglec-like pseudogenes that have independent mutations that would have replaced the arginine residue required for optimal sialic acid recognition during human evolution (Angata et al, 2001). Unlike other CD33-rSiglecs that are primarily found on immune cells, Siglec-XII protein is expressed on some macrophages and also on various epithelial cell surfaces in humans and chimpanzees. *SIGLEC12* gene also expresses on certain human prostate epithelial carcinomas and carcinoma cell lines. This expression correlates with the presence of the non-frame-shifted, intact *SIGLEC12* allele. Polymorphic expression of Siglec-XII in humans thus has implications for prostate cancer biology and therapeutics (Mitra et al. 2011)

17.8.3.1 Siglec-like Gene (SLG)/S2V

Foussias et al. (2001) identified the complete genomic structure of Siglec-like gene (SLG), a putative member of Siglec-3-like subgroup of Siglecs, as well as two alternative splice variants. The SLG gene is localized 32.9 kb downstream of Siglec-8 on chromosome 19q13.4. The putative SLG-S and SLG-L proteins, of 477 and 595 amino acid residues, respectively, show extensive homology to many members of the Siglec-3-like subgroup. This homology is conserved in the extracellular Ig-like domains, as well as in the cytoplasmic tyrosine-based motifs. However, SLG-L protein contains two N-terminal V-set Ig-like domains, as opposed to SLG-S and other Siglec-3-like subgroup members which contain only one such domain. The SLG-S is highly expressed in spleen, small intestine and adrenal gland, while SLG-L exhibits high levels of expression in spleen, small intestine, and bone marrow (Foussias et al. 2001).

The Siglec-like gene which comprises of 11 exons, with 10 intervening introns, is localized 278 kb telomeric to Siglec-9 and 35 kb centromeric to Siglec-8 and on chromosome 19q13.4. The coding region consists of 2,094 bp, and

encodes for a putative 76.6 kDa protein. All Siglec-conserved structural features, including V-set domain, three C-set domains, transmembrane domain, ITIM and SLAM motifs, were found in this Siglec-like gene. Also, it has the conserved amino acids essential for sialic acid binding (Yousef et al. 2002). The cDNA of S2V Siglec encodes a type 1 transmembrane protein with four extracellular Ig-like domains and a cytoplasmic tail bearing a typical ITIM and an ITIM-like motif. A unique feature of S2V is the presence of two V-set Ig-like domains responsible for the binding to sialic acid, whereas all other known siglecs possess only one. S2V is predominantly expressed in macrophage. S2V is involved in the negative regulation of signaling in macrophage by functioning as an inhibitory receptor (Yu et al. 2001a).

17.8.4 Siglec-16

The lineages of *SIGLEC11* genes in human, rodent, dog, cow and non-human primates have undergone dynamic gene duplication and conversion, forming a potential inhibitory (Siglec-11)/activating (Siglec-16) receptor pair in chimpanzee and humans. A cDNA encoding human Siglec-16, classed as a pseudogene in databases (*SIGLECP16*), is expressed in various cell lines and tissues. A polymorphism screen for the two alleles (wild type and four-base pair deletion) of *SIGLEC16* found their frequencies to be 50% amongst the UK population. A search for donor sequences for Siglec-16 revealed a subfamily of activating Siglec with charged transmembrane domains predicted to associate with ITAM-encoding adaptor proteins (Cao et al. 2008). Using antisera specific to the cytoplasmic tail of Siglec-16, Cao et al. (2008) identified Siglec-16 expression in $CD14^+$ tissue macrophages and in normal human brain, cancerous oesophagus and lung. Although, most CD33rSiglecs have immune receptor tyrosine-based inhibitory motifs and signal negatively, novel DAP-12-coupled 'activating' CD33rSiglecs have been identified, such as siglec-14 and siglec-16, which are paired with the inhibitory receptors, siglec-5 and siglec-11, respectively (Cao and Crocker 2011). Siglec-16 was expressed at cell surface in the presence of DAP12, but not the FcRγ chain.

17.9 Mouse Siglecs

17.9.1 Evolution of Mouse and Human CD33-rSiglec Gene Clusters

Unlike most human Siglec-3 (hSiglec-3)-related Siglecs with promiscuous linkage specificity, mouse Siglec (mSiglec-F) shows a strong preference for α2–3-linked sialic acids. It is predominantly expressed in immature cells of the myelomonocytic lineage and in a subset of CD11b (Mac-1)-positive cells in some tissues. A comprehensive comparison of Siglecs between human and mouse genomes suggests that mouse genome contains eight Siglec genes, whereas the human genome contains 14 Siglec genes and a Siglec-like gene. Although a one-to-one orthologous correspondence between human and mouse Siglecs 1, 2, and 4 is confirmed, the Siglec-3-related Siglecs showed marked differences between human and mouse. Angata et al. (2001b) identified only four Siglec genes and two pseudogenes in the mouse chromosome 7 region syntenic to the Siglec-3-related gene cluster on human chromosome 19, which, in contrast, contains seven Siglec genes, a Siglec-like gene, and thirteen pseudogenes. Although analysis of gene maps and exon structures allows tentative assignments of mouse-human Siglec ortholog pairs, the possibility of unequal genetic recombination makes the assignments inconclusive. Current information suggests that mSiglec-F is likely a hSiglec-5 ortholog. The previously reported mSiglec-3/CD33 and mSiglec-E/MIS are likely orthologs of hSiglec-3 and hSiglec-9, respectively. The other Siglec-3-like gene in the cluster (mSiglec-G) is probably a hSiglec-10 ortholog. Another mouse gene (mSiglec-H), without an apparent human ortholog, lies outside of the cluster. Thus, although some duplications of Siglec-3-related genes predated separation of the primate and rodent lineages (about 80–100 million years ago), this gene cluster underwent extensive duplications in the primate lineage thereafter (Angata et al. 2001b).

17.9.2 Mouse CD33/Siglec-3

A cDNA for the putative mouse ortholog of hCD33 was cloned in 1994 (Tchilian et al. 1994). Similarities within the extracellular domain between hCD33 and mouse CD33 (mCD33; 62% identity in amino acid sequence) (Tchilian et al. 1994) and similar gene structure and chromosomal position relative to adjacent genes (Angata et al. 2001b) warrant its designation as the mouse ortholog of hCD33. However, the lack of sequence similarity in the cytosolic domains and difficulties in resolving phylogenetic relationships among the related Siglec molecules in humans and mice have raised questions about its functional equivalence to hCD33 (Angata et al. 2000, 2001a).

Differences with Human CD33: Although 16 human siglec proteins have been discovered, the mouse siglec family has fewer members (Yu et al. 2001b; Ulyanova et al. 2001): sialoadhesin, MAG, SMP, CD22, and CD33. Structurally, sialoadhesin, MAG, SMP, and CD22 are very similar in mice and humans. In contrast, human and mouse CD33, although

somewhat similar in their extracellular domains, are strikingly different in their transmembrane and cytoplasmic regions. Human CD33 contains two ITIM sequences in the cytoplasmic tail, whereas mouse CD33 does not. Characterization of several ITIM-containing human siglecs implies that there must be murine ITIM-containing siglecs. Ulyanova et al. (2001) described the molecular cloning and characterization of a murine ITIM-containing myeloid cell-restricted inhibitory siglec, MIS. None of the two Siglec-3-related Siglecs in mouse, i.e. mSiglec-3/CD33 (Tchilian et al. 1994) and mSiglec-E/MIS (Yu et al. 2001b) shows a clear one-to-one orthologous correspondence to hSiglecs (Angata and Varki 2000; Ulyanova et al. 2001). Although it is likely that these mSiglec-3-related Siglecs, as well as one reported by Dehal et al. (2001) are present in a similar gene cluster in mouse chromosome 7 (Dehal et al. 2001), there have been few reports of a comprehensive analysis of Siglec-3-related mouse Siglecs. Like hCD33, mCD33 is expressed on myeloid precursors in the bone marrow, albeit mostly in the more mature stages of the granulocytic lineage. Moreover, unlike hCD33, mCD33 in peripheral blood is primarily expressed on granulocytes. Also, unlike hCD33, mCD33 did not bind to α2-3- or α2-6-linked sialic acids on lactosamine units. Instead, it showed distinctive sialic acid-dependent binding only to the short O-linked glycans of certain mucins and weak binding to the sialyl-Tn epitope. Results indicate substantial species differences in CD33 expression patterns and ligand recognition and suggest functional degeneracy between mCD33 and the other CD33-related Siglec proteins expressed on cells of the myeloid lineage (Brinkman-Van der Linden et al. 2003).

17.9.3 Siglec-3-Related Siglecs in Mice

17.9.3.1 mSiglec-E

The mouse siglec E (mSiglec-E)- cDNA encodes a protein of 467 amino acids that contains three extracellular Ig-like domains, a transmembrane region and a cytoplasmic tail bearing two ITIMs. mSiglec-E is highly expressed in mouse spleen, which is rich in leucocytes. The ITIMs of mSiglec-E can recruit SHP-1 and SHP-2, two inhibitory regulators of immunoreceptor signal transduction. mSiglec-E, through cell-cell interactions, is probably involveed in haematopoietic cells and the immune system as an inhibitory receptor. In comparison with the known members, mSiglec-E exhibits a high degree of sequence similarity to both human siglec-7 and siglec-9. The gene encoding mSiglec-E is localized in the same chromosome as that encoding mouse CD33. Phylogenetically, though Yu et al. (2001a,b) did not show clear relation between mouse mSiglec-E with any human siglecs, Angata et al. (2001b) suggested that mSiglec-E is likely an ortholog of hSiglec-9.

17.9.3.2 mSiglec-F

Siglec-F is a CD33-rSiglec prominently expressed on mature circulating mouse eosinophils, and on some myeloid precursors in bone marrow (Zhang et al. 2004; Angata et al. 2001a). It has a binding preference for α2-3–linked Sias (Angata et al. 2001), with the best-known ligand being 6'sulfo-sialyl-Le^X (Tateno et al. 2005). Of interest, this structure is also the preferred ligand for human Siglec-8- (Bochner et al. 2005), a molecule also specifically expressed on human eosinophils (Floyd et al. 2000; Kikly et al. 2000). Although mouse Siglec-F is not the true ortholog of human Siglec-8 (Angata et al. 2001a), their marked similarities in expression patterns and ligand preferences suggest that they play equivalent roles.

The elevated eosinophil count in allergic conditions is well known as is a critical role for $CD4^+$ Th2 cells in regulating allergic inflammatory responses involving eosinophils. Zhang et al. (2007) investigated the biologic roles of Siglec-F in Siglec-F–null mice in an induced lung allergic response model. This model also mimics some other features of bronchial asthma in humans, such as IgE-mediated mast-cell activation and degranulation, airway inflammation and hyperreactivity, $CD4^+$ T-cell infiltration and cytokine production, goblet-cell hyperplasia, and mucus overproduction. Data with WT mice using this model suggested a negative feedback loop involving Siglec-F in controlling eosinophilic responses, a hypothesis confirmed by studies of Siglec-F–null mice. Zhang et al. (2007) studied in vivo functions of Siglec-F, expressed on mouse eosinophils, which are prominent in allergic processes. Induction of allergic lung inflammation in mice caused up-regulation of Siglec-F on blood and bone marrow eosinophils, accompanied by newly induced expression on some $CD4^+$ cells, as well as quantitative up-regulation of endogenous Siglec-F ligands in the lung tissue and airways. With the ITIM in the cytosolic tail of Siglec-F, Zhang et al. (2007) suggested a negative feedback loop, controlling allergic responses of eosinophils and helper T cells, via Siglec-F and Siglec-F ligands. Siglec-F–null mice, allergen-challenged null mice showed increased lung eosinophil infiltration, enhanced bone marrow and blood eosinophilia, delayed resolution of lung eosinophilia, and reduced peribronchial-cell apoptosis. Data supporting the proposed negative feedback role for Siglec-F, represent the in vivo demonstration of biologic functions for any CD33rSiglec, and predict a role for human Siglec-8 (the isofunctional paralog of mouse Siglec-F) in regulating the pathogenesis of human eosinophil-mediated disorders. This demonstration suggests an in vivo biologic role for a CD33rSiglec, and also potential role for CD33rSiglecs in regulating T-cell induction of eosinophilic responses. To search for a mouse Siglec (mSiglec) ortholog of Siglec-8 and other mouse Siglec paralogs, Aizawa et al. (2003) searched public database with cDNA sequences of human

Siglec-5 to -10 and identified two novel mSiglecs. One has significant sequence identity to human Siglec-5 and is a splice variant of mSiglec-F. The other has greatest sequence identity to human Siglec-10 (mSiglec-G). Both mSiglecs have extracellular Ig-like domains and intracellular tyrosine-based motifs. A expression of mSiglec-5 (or -F), -10, and -E mRNA was detected in purified mouse eosinophils, but analyses suggested that mSiglec-10 is probably most relevant to mouse eosinophils.

Mouse Siglec-F and Human Siglec-8 are Functionally Convergent Paralogs: Unlike most human hSiglec-3rSiglecs with promiscuous linkage specificity, mSiglec-F shows a strong preference for α2-3-linked sialic acids. It is predominantly expressed in immature cells of the myelomonocytic lineage and in a subset of CD11b (Mac-1)-positive cells in some tissues. The sialoside sequence 6'-sulfo-sLe^x (Neu5Ac α2-3 [6-SO4]Galβ1-4[Fuc α1-3]GlcNAc) is a preferred ligand for Siglec-F. The lectin activity of Siglec-F on mouse eosinophils was "masked" by endogenous cis ligands and could be unmasked by treatment with sialidase. Unmasked Siglec-F mediated mouse eosinophil binding and adhesion to multivalent 6'-sulfo-sLe^x structure. Although there is no clear-cut human ortholog of Siglec-F, Siglec-8 is encoded by a paralogous gene that is expressed selectively by human eosinophils and has been found to recognize 6'-sulfo-sLe^x. It seems that mouse Siglec-F and human Siglec-8 have undergone functional convergence during evolution and implicate a role for the interaction of these siglecs with their preferred 6'-sulfo-sLe^x ligand in eosinophil biology (Tateno et al. 2005).

Siglec-F showed efficient endocytosis of anti-Siglec antibody, and *Neisseria meningitidis* bearing sialylated glycans. Like CD22, endocytosis was dependent on ITIM and ITIM-like motifs. While endocytosis of CD22 was mediated by a clathrin-dependent mechanism and was sorted to early endosome and recycling compartments, Siglec-F endocytosis was directed to lysosomal compartments and was mediated by a mechanism that was independent of clathrin and dynamin. Like CD22, Siglec-F mediated endocytosis of anti-Siglec-F and sialoside ligands, a function requiring intact tyrosine-based motifs. In contrast, however, Siglec-F endocytosis was clathrin and dynamin independent, required ADP ribosylation factor 6, and trafficed to lysosomes (Tateno et al. 2007).

17.9.3.3 mSiglec-G

It is now well accepted that the innate immune system recognizes both damage (or danger)- and pathogen-associated molecular patterns (DAMP and PAMP, respectively) through pattern recognition receptors, such as Toll-like receptors (TLR) and/or Nod-like receptors (NLR). Less clear are whether and how the response to PAMP and DAMP are regulated differentially. The answers may reveal whether the primary goal of the immune system is to defend against infections or to alert the host of tissue injuries. As demonstrated the host response to DAMP is controlled by a DAMP-CD24-Siglec axis. CD24-Siglec G/10 pathway plays a key role in discriminating between DAMPs and PAMPs (Liu et al. 2009). Siglec-G is a recently identified protein with an inhibitory function restricted to a B-cell subset, the B1 cells and is an ortholog of Siglec-10. Siglec-G inhibits Ca2+ signaling specifically in these cells. In addition, it controls the cellular expansion and antibody secretion of B1 cell population (Hoffmann et al. 2007). Thus, both Siglecs, Siglec-G/Siglec-10 and CD22 modulate BCR signaling on different B-cell populations in a mutually exclusive fashion (Nitschke 2009).

17.9.3.4 mSiglec-H as an Endocytic Receptor

Siglec-H is a murine CD33-related endocytic receptor that lacks intrinsic tyrosine-based signaling motifs. Although Siglec-H has the typical structural features required for sialic acid binding, no evidence for carbohydrate recognition has been obtained. Siglec-H is expressed specifically on plasmacytoid dendritic cell (pDC) precursors in bone marrow, spleen, blood, and lymph nodes. It is also expressed in a subset of marginal zone macrophages in spleen and in medullary macrophages in lymph nodes. Siglec-H functions as an endocytic receptor and mediates efficient internalization of anti-Siglec-H Abs. Immunizing mice with ovalbumin-conjugated anti-Siglec-H Ab in presence of CpG generated antigen-specific CD8 T cells in vivo. Targeting Siglec-H may therefore be a useful way of delivering antigens to pDC precursors for cross-presentation (Zhang et al. 2006). Siglec-H depends on DAP12 for surface expression; and cross-linking with anti-siglec-H antibodies can selectively inhibit interferon-α production by pDCs following TLR9 (Toll-like receptor 9) ligation.

17.9.3.5 Myeloid Inhibitory Siglec in Mice

Myeloid inhibitory siglec (MIS) belongs to the family of sialic acid-binding Ig-like lectins. The full-length MIS cDNA from murine bone marrow cells is predicted to contain an extracellular region comprising three Ig-like domains (V-set amino-terminal domain followed by two C-set domains), a transmembrane domain and a cytoplasmic tail with two ITIM-like sequences. The closest relative of MIS in the siglec family is human siglec 8. Extracellular regions of these two siglecs share 47% identity at the amino acid level. Southern blot analysis suggests the presence of one MIS gene. MIS is expressed in the spleen, liver, heart, kidney, lung and testis tissues. Several isoforms of MIS protein exist due to the alternative splicing. In a human promonocyte cell line, MIS was able to bind Src homology 2-containing protein-tyrosine phosphatases, SHP-1 and SHP-2. This binding was mediated by the membrane-proximal ITIM of MIS. Moreover, MIS

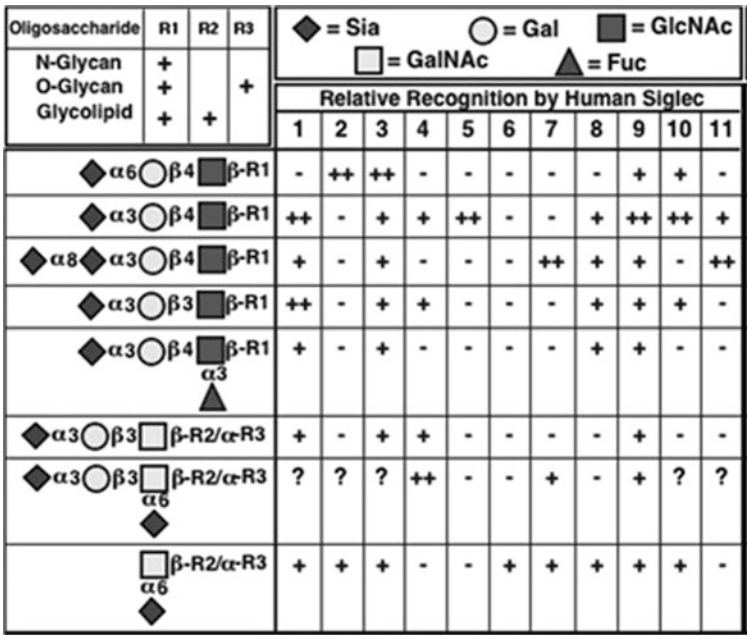

Fig. 17.4 *Glycan-binding specificities of human Siglecs.* With a few exceptions (CD22 and MAG), binding specificities of human Siglecs have varied significantly. In addition to assay formats and glycan linker issues, the density and arrangement of the ligands studied could be responsible for this variation. The most commonly reported specificities for the most commonly studied sialylated glycans are shown. Relative binding within studies of each Siglec is indicated as ++, strong binding; +, detectable binding; and –, very weak or undetectable binding. Not shown is the recently reported strong-binding preference of hSiglec-8 and mSiglec-F for 6′-sulfated-sialyl-Lewis x (sLex) and of hSiglec-9 for 6-sulfated-sLex. See text for the discussion (Reprinted with permission from Varki and Angata 2006 © Oxford University Press)

exerted an inhibitory effect on FcγRI receptor-induced calcium mobilization (Ulyanova et al. 2001).

17.10 Glycoconjugate Binding Specificities of Siglecs

Siglecs exhibit specificities for both the linkage and the nature of sialic acids in N-glycans, O-glycans and glycolipids. Many Siglecs recognize α2–3- and α2–6-linked sialic acids (Freeman et al. 1995; Brinkman-Van der Linden and Varki 2000), whereas others bind to other sialylated structures (Fig. 17.4). For example, Siglec-1 has been shown to bind the highly glycosylated surface protein CD43 (van den Berg et al. 2001), the epithelial mucin MUC-1 (Nath et al. 1999), and sialylated LPS of *Neisseria meningitidis* (Nm) (Jones et al. 2003). The Nm LPS sialylation can lead to increased bacterial susceptibility to phagocytic uptake, a phenomenon in direct contrast to earlier reported protective effects of LPS sialylation (Jones et al. 2003). Earlier studies of siglec specificities focused on α2-3- and α2-6-sialyllactos(amin)es and on one or two of the siglecs at a time. The binding of siglec-1, siglec-3 (CD33), siglec-4a (MAG), and siglec-5 to α2-3 sialyllactosamine is affected markedly by the presence of an α1-3-linked fucose. Studies revealed that: (1) while siglecs may not interfere with selectin-mediated recognition, fucosylation could negatively regulate siglec binding; (2) In contrast to earlier studies, siglec-3 prefers α2-6-sialyllactose; (3) siglec-5 binds α2-8-linked sialic acid, making it least specific for linkage recognition; (4) siglecs-2 (CD22), -3, -5, and -6 (obesity-binding protein-1) showed significant binding to sialyl-Tn (Neu5Acα2-6-GalNAc), a tumor marker associated with poor prognosis; (5) siglec-6 is an exception among siglecs in not requiring the glycerol side chain of sialic acid for recognition; (6) all siglecs require the carboxyl group of sialic acid for binding; (7) the presentation of sialyl-Tn epitope and/or more extended structures that include this motif may be important for optimal recognition by siglecs (Brinkman-Van der Linden and Varki 2001). Among a panel of glycans tested, Siglec-3 showed enhanced binding to a multivalent form of sialyl-Tn (NeuAcα2–6GalNAc) disaccharides (Brinkman-Van der Linden et al. 2003).

To determine if differences in glycan composition of siglec-5, siglec-7 and siglec-8 that may modify their function, Freeman et al. (2001) characterized N-linked oligosaccharide distribution in these three glycoproteins. The glycan pools from siglec-5 and siglec-7 contained a larger proportion of sialylated and core-fucosylated biantennary, triantennary and tetra-antennary oligosaccharides, whereas carbohydrate mixture released from siglec-8 is noticeably less sialylated and is

more abundant in 'high-mannose'-type glycans. Moreover, it was found that, in contrast to CD22 and CD33, mutating the conserved potentially N-linked glycosylation site in first domain has no effect on binding mediated by siglec-5 or siglec-7 (Freeman et al. 2001). Using recombinant chimeric soluble receptors, siglec-transfected cell lines and macrophages from wild-type and Sn-deficient mice, it was observed that sialylated but not non-sialylated variants of either genetic background were specifically recognized by Sn and siglec-5, whereas other siglecs examined were ineffective. In addition, macrophages expressing Sn, as well as transfectants expressing Sn or siglec-5, bound and phagocytosed sialylated bacteria in a siglec- and sialic acid-dependent manner.

Most mammalian cell surfaces display two major sialic acids (Sias), N-acetylneuraminic acid (Neu5Ac) and N-glycolylneuraminic acid (Neu5Gc). Humans lack Neu5Gc due to a mutation in CMP-Neu5Ac hydroxylase, which occurred after evolutionary divergence from great apes. Sonnenburg et al. (2004) described an apparent consequence of human Neu5Gc loss: domain-specific functional adaptation of Siglec-9. While recombinant human Siglec-9 showed recognition of both Neu5Ac and Neu5Gc, in striking contrast, chimpanzee and gorilla Siglec-9 strongly preferred binding Neu5Gc. Results also indicated that endogenous Sias (rather than surface Sias of bacterial pathogens) are the functional ligands of CD33rSiglecs and suggested that the endogenous Sia landscape is the major factor directing evolution of CD33rSiglec binding specificity. Findings suggested ongoing adaptive evolution specific to the Sia-binding domain, possibly of an episodic nature. Such domain-specific divergences should also be considered in upcoming comparisons of human and chimpanzee genomes (Sonnenburg et al. 2004; Varki and Crocker 2009). Recent work has also shown that engagement of neutrophil-expressed siglec-9 by certain strains of sialylated Group B streptococci can suppress killing responses, thereby providing experimental support for pathogen exploitation of host CD33rSiglecs (Cao and Crocker 2011).

Siglec-Mediated Cell Adhesion to Gangliosides: Binding specificities of MAG, SMP, and sialoadhesin were compared by measuring siglec-mediated cell adhesion to immobilized gangliosides. The α-series gangliosides displayed enhanced potency for MAG- and SMP-mediated cell adhesion, whereas sialoadhesin-mediated adhesion was comparable with α-series and non-α-series gangliosides. GD1α derivatives with modified sialic acids (7-, 8-, or 9-deoxy) or sulfate (instead of sialic acid) at the III(6)-position supported adhesion comparable with that of GD1α. A novel GT1aα analog with sulfates at two internal sites of sialylation (NeuAcα 2,3Galβ1,4GalNAc-6-sulfateβ1, 4Gal3-sulfateβ1, 4Glcβ1,1'ceramide) was the most potent siglec-binding structure. Compiled reports indicated that MAG and SMP display an extended structural specificity with a requirement for a terminal α2, 3-linked NeuAc and great enhancement by nearby precisely spaced anionic charges (Collins et al. 1999). Studies on the interaction of CD33 related-siglecs-5,-7,-8,-9,-10 with gangliosides GT1b, GQ1b, GD3, GM2, GM3 and GD1a revealed that Siglec-5 bound preferentially to GQ1b, but weakly to GT1b, whereas siglec-10 interacted only with GT1b ganglioside. Siglec-7 and siglec-9 displayed binding to gangliosides GD3, GQ1b and GT1b bearing a disialoside motif, though siglec-7 was more potent; besides, siglec-9 interacted also with GM3. Siglec-8 demonstrated low affinity to the gangliosides tested compared with other siglecs. Despite high structural similarity of CD33 related siglecs, they demonstrated different ganglioside selectivity, in particular to the Neu5Acα2-8Neu5Ac motif (Rapoport et al. 2003a). Siglec-7 binds to GD3 ganglioside, LSTb oligosaccharide, sialyl Le^a, and NeuAcα2–8NeuAc, whereas Siglec-9 preferentially binds GD1a ganglioside and LSTc oligosaccharide (Yamaji et al. 2002; Rapoport et al. 2003a; Miyazaki et al. 2004).

Sulfated Gangliosides, High-Affinity Ligands for Neural Siglecs, Inhibit NADase Activity of CD38: Three kinds of novel sulfated gangliosides structurally related to the Chol-1 (α-series) ganglioside GQ1bα were synthesized. These sulfated gangliosides were potent inhibitors of NADase activity of leukocyte cell surface antigen CD38. Among the synthetic gangliosides, GSC-338 (II(3)III(6)-disulfate of iso-GM1b) was surprisingly found to be the most potent structure in both the NADase inhibition and MAG-binding activity. The study indicated that the sulfated gangliosides are useful to study the recognition of the internal tandem sialic acid residues α2-3-linked to Gal(II(3)) as well as the siglec-dependent recognition including a terminal sialic acid residue (Hara-Yokoyama et al. 2003; Ito et al. 2003).

Binding of Soluble Siglecs with Sulfated Oligosaccharides: Soluble siglecs were studied with polyacrylamide glycoconjugates in which: (1) the Neu5Ac residue was substituted by a sulfate group (Su); (2) glycoconjugates contained both Su and Neu5Ac; (3) sialoglycoconjugates contained a tyrosine-O-sulfate residue. Sulfate derivatives of LacNAc did not bind siglecs-1, -4, -5, -6, -7, -8, -9, and -10; binding of 6'-O-Su-LacNAc to siglec-8 was stronger than binding of 3'SiaLacNAc. The relative affinity of 3'-O-Su-TF binding to siglecs-1, -4, and -8 was similar to that of 3'SiaTF. 3'-O-Su-Le(c) displayed two-fold weaker binding to siglec-1 and siglec-4 than 3'SiaLe(c). The interaction of soluble siglecs with sulfated oligosaccharides containing sialic acid showed that siglecs-1, -4, -5, -6, -7, -9, and -10 did not interact with

these compounds; binding of 6-O-Su-3'SiaLacNAc and 6-O-Su-3'SiaTF to siglec-8 was weaker than that of the corresponding sulfate-free sialoside probes. Siglec-8 displayed affinity to 6'-O-Su-LacNAc and 6'-O-Su-SiaLe^x, and defucosylation of the latter compound led to an increase in the binding. Sialoside probes containing tyrosine-O-sulfate residue did not display increased affinity to siglecs-1 and -5 compared with glycoconjugates containing only sialoside. Cell-bound siglecs-1, -5, -7, and -9 did not interact with 6-O-Su-3'SiaLacNAc, whereas the sulfate-free probe 3'SiaLacNAc demonstrated binding. In contrast, the presence of sulfate in 6-O-Su-6'SiaLacNAc did not affect binding of the sialoside probe to siglecs. 6'-O-Su-SiaLe^x displayed affinity to cell-bound siglecs-1 and -5; its isomer 6-O-Su-SiaLe^x bound more strongly to siglecs-1, -5, and -9 than SiaLe^x (Rapoport et al. 2006).

Potent Inhibitors of MAG: Ten of the known human siglecs or their murine orthologs were evaluated for their specificity for over 25 synthetic sialosides representing most of the major sequences terminating carbohydrate groups of glycoproteins and glycolipids. Each siglec was found to have a unique specificity for binding 16 different sialoside-streptavidin-alkaline phosphatase probes. Competitive inhibition studies revealed that Siglec-4 binds with 500–10,000-fold higher affinity to a series of mono- and di-sialylated derivatives of the O-linked T-antigen (Galβ1-3 GalNAc α OThr) as compared with α-methyl-NeuAc (Blixt et al. 2003).

Group B Streptococcal Capsular Sialic Acids Interact with Siglecs: Group B Streptococcus (GBS) is classified into nine serotypes that vary in capsular polysaccharide (CPS) architecture, but share the presence of terminal sialic acid (Sia) residue. The position and linkage of GBS Sia closely resembles that of cell surface glycans found abundantly on human cells. CD33-rSiglecs are expressed on host leukocytes that engage host Sia-capped glycans and send signals that dampen inflammatory gene activation. GBS evolved to display CPS Sia as a form of molecular mimicry limiting the activation of an effective innate immune response. Carlin et al. (2007) demonstrated that GBS of several serotypes interact in a Sia- and serotype-specific manner with certain human CD33-rSiglecs, including hSiglec-9 and hSiglec-5 expressed on neutrophils and monocytes. Modification of GBS CPS Sia by O-acetylation (OAc) has been recognized, and the degree of OAc can markedly impact the interaction between GBS and hSiglecs-5, -7, and -9. Thus, production of Sia-capped bacterial polysaccharide capsules that mimic human cell surface glycans in order to engage CD33-rSiglecs may be an example of bacterial mechanism of leukocyte manipulation (Carlin et al. 2007).

17.11 Functions of CD33-Related Siglecs

17.11.1 Endocytosis

Although it is assumed that CD33-related Siglecs have important roles in modulating leukocyte behavior, including inhibition of proliferation or cellular activation, modulation of cytokine secretion, and induction of apoptosis, their precise signaling functions remain unknown (Crocker et al. 2007; Crocker 2005; Varki and Angata 2006). Nevertheless, studies have demonstrated their interactions with various sialylated pathogens and suggested their potential importance in host defense and pathogenicity. For example, several pathogens, including *Neisseria meningitides*, Group B Streptococci, and *Campylobacter jejuni*, have been shown to bind to CD33-related Siglecs (Jones et al.; 11 2003; Avril et al. 2006; Carlin et al. 2007). Furthermore, there is increasing evidences that indicate endocytic capacities of human CD33-related Siglecs (Lock et al. 2004; Walter et al. 2005; Biedermann et al. 2007). This might be of physiological relevance for clearance of sialylated antigens and modulation of antigen presentation. Endocytosis of CD33 based immunotherapy results in cellular uptake of the drug (GO; Mylotarg^{TM}), which is cleaved intracellularly to release the toxic moiety (Linenberger 2005; Damle and Frost 2003). CD33 is present on tumor cells of 85–90% of adult and pediatric patients with acute myeloid leukemia (AML), and the therapeutic success of GO depends largely on its CD33-dependent uptake. Other CD33-related Siglecs, such as Siglec-8 for targeting eosinophils in allergic inflammation or other disease states, or Siglec-9 for treatment of AML or inflammatory diseases suggest are potential targets in clinical exploitation (Biedermann et al. 2007; Nutku et al. 2003; Von Gunten et al. 2005). The mechanisms underlying the endocytosis of CD33-related Siglecs remain elusive. Studies of CD33, Siglec-5, Siglec-F, and Siglec-9 have shown that they all endocytose slowly when bound to antibody. Also, CD33, Siglec-F, and Siglec-9 use their ITIMs for endocytosis (Walter et al. 2005; Biedermann et al. 2007; Tateno et al. 2007). However, it is not clear whether the ITIMs stimulate endocytosis when they are phosphorylated or when they are not phosphorylated. Walter et al. (2008b) identified proteins that bind to CD33 in an ITIM-dependent manner and assessed their importance for CD33 internalization in human myeloid cells by specific silencing of target genes through expression of siRNA.

It was shown that endocytosis is largely limited and determined by the intracellular domain while the extracellular and transmembrane domains play a minor role. Tyrosine phosphorylation, most likely through Src family kinases, increases uptake of CD33 depending on the integrity of two cytoplasmic ITIMs. Simultaneous depletion of protein tyrosine phosphatases (SHP1 and SHP2), which bound to phosphorylated CD33, increased internalization of CD33 slightly in some

cell lines, whereas depletion of spleen tyrosine kinase (Syk) had no effect, implied that SHP1 and SHP2 can dephosphorylate the ITIMs or mask binding of phosphorylated ITIMs to an endocytic adaptor. Studies indicated that restraint of CD33 internalization through intracellular domain is relieved partly when the ITIMs are phosphorylated and thus showed that Shp1 and Shp2 can modulate this process (Walter et al. 2008c). Walter et al. (2008b) indicated that phosphorylation-dependent ubiquitylation regulates cell surface expression and internalization, and thus possibly function, of CD33/Siglec-3, suggesting an important role of ubiquitin in endocytosis of ITIM-bearing inhibitory immunoreceptors.

17.11.2 Phagocytosis of Apoptotic Bodies

Elimination of apoptotic bodies is one of the important functions of macrophages. A specific apoptotic glycosylation pattern may play an assistant or even a causative role in phagocytosis of apoptotic bodies. Taking into account that siglecs, a mannose receptor and galectins expressed on macrophages could be involved in engulfment of apoptotic bodies, their potential expression on THP-1 cells was assessed by means of polyacrylamide glycoconjugates. A strong binding of cells occurred to siglec ligands (3'SiaLac, 6'SiaLac, [Neu5Acα2-8]2) and galectin ligands (LacNAc, GalNAcβ1 - 4GlcNAc, Galβ1 - 3GalNAcβ and asialoGM1), where as Galβ1 - 3GalNAcβ-terminated chains represented the apoptotic bodies; the other tested galectin ligands did not appear to be the target for THP-1 cells (Rapoport et al. 2003b).

Macrophage lectins were probed with neoglycoconjugates. Glyc-PAA-fluo where carbohydrate is linked to fluorescein-labeled polyacrylamide. The neoglycoconjugates containing a Neu5Acα2-3Gal fragment bound to macrophages isolated from blood of healthy donors. Besides, carbohydrate chains containing the same fragment were revealed on apoptotic bodies. Phagocytosis of apoptotic bodies by macrophages was inhibited with sialooligosaccharide ligands of siglec-5 and mAbs to siglec-5. Thus, siglec-5 expressed on macrophages could participate in phagocytosis of apoptotic bodies. In addition, siglecs of tumor-associated macrophages modify engulfment of apoptotic bodies. The phagocytic potency of macrophages isolated from blood of breast cancer patients was lower than engulfment ability of macrophages obtained from healthy donors. Staining of macrophages from blood of tumor patients was more intense than that of macrophages from healthy donors; phagocytosis of apoptotic bodies by tumor-associated macrophages was inhibited by carbohydrates that are known to be ligands for siglecs (Rapoport et al. 2005).

17.12 Siglecs as Targets for Immunotherapy

The restricted expression of several siglecs to one or a few cell types makes them attractive targets for cell-directed therapies. Anti-CD33 antibodies have been used alone-and more effectively, attached to chemotherapy agents or radioisotopes-to treat those with AML (Nemecek and Matthews 2002). The anti-CD33 (Siglec-3) antibody gemtuzumab (Mylotarg) is approved for treatment of acute myeloid leukemia (AML) and antibodies targeting CD22 (Siglec-2) are currently in clinical trials for treatment of B cell non-Hodgkins lymphomas and autoimmune diseases. O'Reilly and Paulson (2009) reviewed the properties of siglecs that make them attractive for cell-targeted therapies. In normal myelopoiesis, expression of CD33 is restricted to advanced stages of differentiation, whereas primitive stem cells do not express CD33. It was shown that leukaemic stem cells in patients with $CD33^+$ AML express CD33 (Hauswirth et al. 2007). Antibody-targeted chemotherapy is a therapeutic strategy in cancer therapy that involves a monoclonal antibody specific for a tumor-associated antigen, covalently linked via a suitable linker to a potent cytotoxic agent. Tumor-targeted delivery of a cytotoxic agent in the form of an immunoconjugate is expected to improve its antitumor activity and safety.

Antibody-targeted chemotherapy with gemtuzumab ozogamicin (GO) (CMA-676, a CD33-targeted immunoconjugate of N-acetyl-γ-calicheamicin dimethyl hydrazide [CalichDMH], a potent DNA-binding cytotoxic antitumor antibiotic) is a clinically validated therapeutic option for patients with AML. Calicheamicin is a cytotoxic natural product isolated from Micromonospora echinospora that is at least 1000-fold more potent than conventional cytotoxic chemotherapeutics. Gemtuzumab ozogamicin is indicated for the treatment of elderly patients with relapsed AML (Damle 2004).

Immunoconjugates of calicheamicin targeted against tumor-associated antigens exhibit tumour-specific cytotoxic effects and cause regression of established human tumor xenografts in nude mice. CD33-specific binding triggers internalization of GO and subsequent hydrolytic release of calicheamicin. Calicheamicin then translocates to the nucleus, where calicheamicin binds DNA in the minor groove and causes double-strand DNA breaks, leading to cell death. GO is part of clinical practice for AML, but is frequently associated with severe side effects. The histone deacetylase inhibitor valproic acid potently augments gemtuzumab ozogamicin-induced apoptosis in acute myeloid leukemic cells. The synergistic proapoptotic activity of cotreatment of AML cells with VPA and GO indicates the

potential value of this strategy for AML (Ten Cate et al. 2007). Finally, compared with either agent alone, antibody BC8 combined with GO resulted in marked tumor growth inhibition and superior survival rates of mice bearing human AML xenografts. Further study of this antibody combination for clinical use in AML is warranted (Walter et al. 2008a). Lintuzumab (HuM195) is an unconjugated humanized murine mAb directed against cell surface myelomonocytic CD33 (Feldman et al. 2005).

17.13 Molecular Diversity and Evolution of Siglec Family

The Siglecs can be divided into two groups: an evolutionarily conserved subgroup (Siglecs-1, -2, and -4) and a CD33/Siglec-3-related subgroup (Siglecs-3 and -5-13 in primates), which appear to be rapidly evolving (Varki et al. 2006). A human Siglec-like molecule (Siglec-L1) lacks a conserved arginine residue known to be essential for optimal sialic acid recognition by previously known Siglecs. Loss of the arginine from an ancestral molecule was caused by a single nucleotide substitution that occurred after the common ancestor of humans with the great apes but before the origin of modern humans. The chimpanzee Siglec-L1 ortholog remains fully functional and preferentially recognizes N-glycolylneuraminic acid, which is a common sialic acid in great apes and other mammals. Reintroducing the ancestral arginine into the human molecule regenerates the same properties. Thus, the single base pair mutation that replaced the arginine on human Siglec-L1 is likely to be evolutionarily related to the previously reported loss of N-glycolylneuraminic acid expression in the human lineage suggesting additional changes in the biology of sialic acids that may have taken place during human evolution (Angata et al. 2001b). Although a few Siglecs are well-conserved throughout vertebrate evolution and show similar binding preference regardless of the species of origin, most others, particularly the CD33-related subfamily of Siglecs, show marked inter-species differences in repertoire, sequence, and binding preference. The diversification of CD33-related Siglecs may be driven by direct competition against pathogens, and/or by necessity to catch up with the changing landscape of endogenous glycans, which may in turn be changing to escape exploitation by other pathogens (Angata 2006).

Comparison of different mammalian species has revealed differential and complex evolutionary paths for Siglec protein family, even within the primate lineage. The combination of microarray technology with the zebrafish model system can provide useful information on how genes are coordinated in a genetic network to control zebrafish embryogenesis and can help to identify novel genes that are important for organogenesis (Lo et al. 2003). Lehmann et al. (2004) investigated the occurrence of corresponding genes in bony fish. Interestingly, only unambiguous orthologs of mammalian siglec-4, a cell adhesion molecule expressed exclusively in the nervous system, could be identified in the genomes of fugu and zebrafish, whereas no obvious orthologs of the other mammalian siglecs were found. As in mammals, fish siglec-4 expression is restricted to nervous tissues. Expressed as recombinant protein, fish siglec-4 binds to sialic acids with a specificity similar to the mammalian orthologs. Relatively low sequence similarities in the cytoplasmic tail as well as an additional splice variant found in fish siglec-4 suggest alternative signaling pathways compared to mammalian species. Observations suggest that this siglec occurs at least in the nervous system of all vertebrates (Lehmann et al. 2004).

A comparison of the CD33rSiglec gene cluster in different mammalian species showed that it can be divided into subclusters, A and B. The two subclusters, inverted in relation to each other, each encodes a set of CD33rSiglec genes arranged head-to-tail. Two regions of strong correspondence provided evidence for a large-scale inverse duplication, encompassing the framework CEACAM-18 (CE18) and ATPBD3 (ATB3) genes that seeded the mammalian CD33rSiglec cluster. Phylogenetic analysis was consistent with the predicted inversion. Rodents appear to have undergone wholesale loss of CD33rSiglec genes after the inverse duplication. In contrast, CD33rSiglecs expanded in primates and many are now pseudogenes with features consistent with activating receptors. In contrast to mammals, the fish CD33rSiglecs clusters show no evidence of an inverse duplication. They display greater variation in cluster size and structure than mammals. The close arrangement of other Siglecs and CD33rSiglecs in fish is consistent with a common ancestral region for Siglecs. Expansion of mammalian CD33rSiglecs appears to have followed a large inverse duplication of a smaller primordial cluster over 180 million years ago, prior to eutherian/marsupial divergence. Inverse duplications in general could potentially have a stabilizing effect in maintaining the size and structure of large gene clusters, facilitating the rapid evolution of immune gene families (Cao et al. 2009).

A comprehensive comparative study of Siglecs between the human and mouse genomes suggests that the mouse genome contains eight Siglec genes, whereas the human genome contains 11 Siglec genes and a Siglec-like gene. Although a one-to-one orthologous correspondence between human and mouse Siglecs 1, 2, and 4 is confirmed, the Siglec-3-related Siglecs showed marked differences between human and mouse. Angata et al. (2001a) found only four Siglec genes and two pseudogenes in the mouse chromosome 7 region syntenic to the Siglec-3-related gene cluster on human chromosome 19, which, in contrast, contains seven Siglec genes, a Siglec-like gene, and thirteen pseudogenes. Although some duplications of Siglec-3-related genes predated separation of the primate and rodent

lineages (about 80–100 million years ago), this gene cluster underwent extensive duplications in the primate lineage thereafter (Angata et al. 2001a). A temporary lettered nomenclature for additional mouse Siglecs suggests that mSiglec-F is likely a hSiglec-5 ortholog and the previously reported mSiglec-3/CD33 and mSiglec-E/MIS are likely orthologs of hSiglec-3 and hSiglec-9, respectively. The other Siglec-3-like gene in the cluster (mSiglec-G) is probably a hSiglec-10 ortholog. Another mouse gene (mSiglec-H), without an apparent human ortholog, lies outside of the cluster. Thus, although some duplications of Siglec-3-related genes predated separation of the primate and rodent lineages (about 80–100 million years ago), this gene cluster underwent extensive duplications in the primate lineage thereafter (Angata et al. 2001a).

Humans are genetically very similar to "great apes", (chimpanzees, bonobos, gorillas and orangutans), our closest evolutionary relatives. The human T cells give much stronger proliferative responses to specific activation via the T cell receptor (TCR) than those from chimpanzees. Nonspecific activation using phytohemagglutinin was robust in chimpanzee T cells, indicating that the much lower response to TCR simulation is not due to any intrinsic inability to respond to an activating stimulus. CD33-related Siglecs are inhibitory signaling molecules expressed on most immune cells and are thought to down-regulate cellular activation pathways via cytosolic ITIMs. Among human immune cells, T lymphocytes are a striking exception, expressing little to none of these molecules. In stark contrast, T lymphocytes from chimpanzees as well as the other closely related "great apes" (bonobos, gorillas, and orangutans) express several CD33-related Siglecs on their surfaces. Thus, human-specific loss of T cell Siglec expression occurred after our last common ancestor with great apes, potentially resulting in an evolutionary difference with regard to inhibitory signaling. This was confirmed by studying Siglec-5, which is prominently expressed on chimpanzee lymphocytes, including CD4 T cells (Nguyen et al. 2006b).

Altheide et al. (2006) presented further evidence for accelerated evolution in Sia-binding domains of CD33-related Sia-recognizing Ig-like lectins. Other gene classes are more conserved, including those encoding the sialyltransferases that attach Sia residues to glycans. Despite this conservation, tissue sialylation patterns are shown to differ widely among these species, presumably because of rapid evolution of sialyltransferase expression patterns. Sia modifications on these glycopeptides also appear to be undergoing rapid evolution. This rapid evolution of the sialome presumably results from the ongoing need of organisms to evade microbial pathogens that use Sia residues as receptors. The rapid evolution of Sia-binding domains of the inhibitory CD33-related Sia-recognizing Ig-like lectins is likely to be a secondary consequence, as these inhibitory receptors presumably need to keep up with recognition of the rapidly evolving "self"-sialome.

Novel Super-Families of Lectins

Fibrinogen Type Lectins

18

Anita Gupta

18.1 Ficolins

Ficolins are one of the most important groups of proteins capable of recognizing pathogens, and they function in the innate immune defence as pathogen-associated molecular pattern recognition molecules (Bohlson et al. 2007; Thiel et al. 1997; Runza et al. 2008). Ficolins comprises of a collagen like domain at the N-terminus and a FBG (fibrinogen-like domain), which is the ligand-binding site, at the C-terminus, and they form trimer-based multimers that are N-terminally linked by disulfide bonds (Ohashi and Erickson 2004; Hummelshoj et al. 2007). Three human ficolins (L-, M and H -ficolins) have been characterized. The amino acid sequence homologies between L-ficolin and M-ficolin, and between H-ficolin and either L-ficolin or M-ficolin, are 80% and 48% respectively. These ficolins are associated with the mannose-binding lectin-associated serine protease, and the complexes activate the lectin complement pathway. Interestingly, ficolins collaborate with CRP (C-reactive protein), which is highly up-regulated during the acute-phase response, and the interaction stabilizes CRP binding to bacteria, resulting in the activation of the lectin complement pathway (Ng et al. 2007). In addition to humans, ficolins have been identified in different mammalian species including rodents and pigs, which have two related ficolin genes called A and B and α and β, respectively, orthologous to the human L- and M-ficolin genes, respectively (Endo et al. 2004). To date, H-ficolin has only been identified in humans where as the mouse and rat homologues of H-ficolin gene are pseudogenes, which accounts for the absence of the corresponding protein in rodents (Endo et al. 2004).

18.1.1 Ficolins versus Collectins

Collectins and ficolins bind to oligosaccharide structures on the surface of microorganisms, leading to the killing of bound microbes through complement activation and phagocytosis. The human collectins, which are oligomeric proteins composed of CRDs attached to collagenous regions, are structurally similar to ficolins (L-ficolin, M-ficolin, and H-ficolin). However, they make use of different CRD structures: C-type lectin domains for the collectins and fibrinogen-like domains for the ficolins. Collectins and ficolins bear no significant sequence homology except for the presence of collagen-like sequences over the N-terminal halves of the polypeptides that enable the assembly of these molecules into oligomeric structures. Collectins and ficolins both contain lectin activities within the C-terminal halves of their polypeptides, the C-type CRDs and fibrinogen β/γ (homology) (FBG) domain, respectively. These domains form trimeric clusters at the ends of the collagen triple helices emanating from a central hub, where the N-terminal ends of the polypeptides merge. The collectins and ficolins seem to have evolved to recognize the surface sugar codes of microbes and their binding, to the arrays of cell surface carbohydrate molecules, targets the microbe for subsequent clearance by phagocytic cells (Holmskov et al. 2003).

18.1.2 Characterization of Ficolins

Ficolins resemble collectins in structure, but their collagen-like stalks are followed by a domain homologous to the fibrinogen β and γ chains (Matsushita and Fujita 2001). While a collagen-like domain is found at the N-terminus, the fibrinogen-like domain (FD1), which is the sugar-binding site, is present at the C-terminus (Le et al. 1998; Teh et al. 2000). Ficolins are assembled from homotrimeric subunits comprising a collagen-like triple helix and a lectin-like domain—composed of three fibrinogen-like (FBG)-domains. Two cysteines at the N-terminal end of the polypeptide chains form interchain disulfide bonds that mediate assembly into higher oligomerization structures (Ohashi and Erickson 2004; Hummelshoj et al. 2007). Ficolins are structurally and functionally similar to MBL. Ficolins present in serum have

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_18, © Springer-Verlag Wien 2012

common binding specificity for N-acetylglucosamine (GlcNAc). MBL is also a collagenous lectin found in serum and specific for GlcNAc and mannose binding. Its domain organization is similar to that of ficolins, except that MBL has a CRD instead of a fibrinogen-like domain. Ficolin from monocytes is a polypeptide of ~ 42 kDa, which is similar in size to that of ficolin predicted from its cDNA-derived sequence and bound to *E. coli*. Protein(s) reactive with GlcNAc from porcine serum has M_r mainly 40 kDa and plays an important role(s) in innate immunity against microbial infection with Gram-positive and -negative bacteria (Nahid and Sugii 2006).

In humans, L-ficolin/P35 (or ficolin 2) and H-ficolin (or ficolin 3) are serum proteins, whereas M-ficolin (or ficolin 1) is a secretory protein produced by lung and blood cells (Matsushita et al. 1996; Sugimoto et al. 1998; Liu et al. 2005) and mainly expressed by the monocytic cell lineage (Matsushita et al. 1996; Sugimoto et al. 1998). In addition to humans, ficolins have been identified in different mammalian species including rodents and pigs (Ichijo et al. 1991; Fujimori et al. 1998), which have two related ficolin genes called A and B and α and β, respectively, orthologous to human L- and M-ficolin genes, respectively (Endo et al. 2004). Three human ficolins, ficolin-1 (M-ficolin), ficolin-2 (L-ficolin) and ficolin-3 (H-ficolin or Hakata antigen) are encoded by the *FCN1, FCN2* and *FCN3* genes, respectively. If MBL plays a role in innate immunity by acting as an opsonin and activating complement in association with MBL-associated serine protease (MASP) via lectin pathway, human serum ficolins, L-ficolin/P35 and H-ficolin (Hakata antigen), are also associated with MASPs and sMAP, a truncated protein of MASP-2, and activate complement. Thus, serum ficolins are structurally and functionally similar to MBL and have the capacity to activate the lectin pathway and have a role in innate Immunity (Matsushita and Fujita 2001; Krarup et al. 2004).

18.1.2.1 L-Ficolin (Ficolin-2)

L-ficolin (synonymous with ficolin-2 or Ficolin/P35) is synthesized in the liver and found in blood circulation (Matsushita et al. 1996). Adult plasma contains, on average, a level of L-ficolin that is threefold higher than found in cord blood, implying a protective role of this lectin. L-ficolin indeed binds to sugar structures via its FBG domains (Le et al. 1998) and, on binding to carbohydrates on bacteria, promotes clearance by phagocytosis (Matsushita et al. 1996). Like MBL, L-ficolin forms a complex with the MBL-associated proteases (MASPs) and binding of this complex to *Salmonella typhimurium* activated the complement system (Matsushita and Fujita 2001). L-ficolin binds to acetyl groups such as GlcNAc. This protein binds to clinically important bacteria, including *Salmonella typhimurium*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes* and *Streptococcus agalactiae* (Krarup et al. 2005; Lynch et al. 2004; Aoyagi et al. 2005). L-ficolin/P35 binds to an Ra chemotype strain of *S. typhimurium* (TV119) which has an exposed GlcNAc at the non-reducing termini of the polysaccharide, where as it did not bind to LT2, a smooth type strain of *S. typhimurium* with additional O-polysaccharides covering GlcNAc (Taira et al. 2000).

18.1.2.2 H-Ficolin (Ficolin-3)

H-ficolin (synonymous with ficolin-3 or Hakata antigen) was initially identified as a serum auto-antigen, recognized by antibodies in patients suffering from systemic lupus erythematosus and other autoimmune diseases (Sugimoto et al. 1998). It is synthesized in the liver by hepatocytes and bile duct epithelial cells and is secreted into both blood circulation and bile (Akaiwa et al. 1999). It is also synthesized by ciliated bronchial and Type II alveolar epithelial cells and is secreted into bronchus and the alveolar space (Akaiwa et al. 1999). H-ficolin is a lectin that binds to carbohydrate structures found on bacteria and may therefore play an important role in both systemic and mucosal immune defence systems (Endo et al. 2007; Dahl et al. 2001, 1997) Both H- and L-ficolins have also been shown to bind to carbohydrate structures found on Gram-negative bacteria. (Akaiwa et al. 1999; Le et al. 1998; Matsushita et al. 1996) Binding of L-ficolin to *S. typhimurium* directly opsonizes the bacteria for enhanced phagocytosis by polymorphonuclear leucocytes (PMNs) (Matsushita et al. 1996) and this is probably mediated by an L-ficolin receptor(s) on PMNs. H-ficolin shows affinity for GlcNAc, GalNAc and D-fucose, and binds to *S. typhimurium*, *Salmonella minnesota* and *Aerococcus viridans* (Sugimoto et al. 1998; Krarup et al. 2005). The finding that L-ficolin formed a functional complex with the MASPs that bound to *S. typhimurium* and subsequently activated the complement system, implied that L-ficolin could mediate killing and clearance of pathogens more effectively through complement activation and complement receptor-mediated phagocytosis (Matsushita et al. 2000). L ficolin and H-ficolin recognize surface structures on apoptotic cells and initiate the activation of lectin complement pathway (Kuraya et al. 2005). H-ficolin has only been identified in humans where as the mouse and rat homologues of H-ficolin gene are pseudogenes, which account for the absence of corresponding protein in rodents (Endo et al. 2004).

18.1.2.3 M-Ficolin (Ficolin-1)

M-ficolin was initially identified from the membrane fraction of pig uterus (Ichijo et al. 1993). Significant M-ficolin has been detected on U937 cells and on monocytes, but not on lymphocytes and granulocytes. Association with the surface of monocytes or U937 cells is apparently an intrinsic property of M-ficolin instead of that of monocytes or U937

cells. M-ficolin was shown to mediate U937 cell adhesion to the immobilized F(ab′)2 fragment of the anti-FBG antibody and therefore M-ficolin was linked to the cell cytoskeleton either directly or indirectly through its cytoskeleton-linked receptor(s). M-ficolin-mediated U937 cell adhesion may therefore be a novel pathway of monocyte emigration into extravascular tissues.

M-ficolin is synthesized in peripheral blood monocytes. Ficolin mRNA is synthesized by a human monocyte cells, and thus blood monocytes also normally synthesize human ficolin. Peripheral blood monocytes from adult human donors showed that ficolin mRNA is highly expressed in monocytes throughout the first 20 h of adhesion. The origin of ficolin from monocytes, together with its structural similarity to C1q and the collectins, raised the possibility that ficolin is another plasma protein capable of binding to surface structures of micro-organisms (Lu et al. 1996b). However, its expression is down-regulated during monocyte differentiation and its mRNA is not detectable in mature macrophages (Lu et al. 1996b). M-ficolin mRNA has been found to be abundant in peripheral blood monocytes, accounting for 0·44% of the total mRNA in the cells (Hashimoto et al. 1999b). However, M-ficolin mRNA is not detectable in monocyte-derived DCs and was detected only at a very low level in monocyte-derived macrophages in vitro (Hashimoto et al. 1999a, 1999b). M-ficolin expression is a marker of circulating monocytes and has been reported to be located in secretory granules in the cytoplasm of neutrophils, monocytes and type II alveolar epithelial cells in the lung (Liu et al. 2005). M-ficolin shows affinity for GlcNAc, GalNAc and sialic acid, and it binds to *Staph. aureus* through GlcNAc (Liu et al. 2005). M-ficolin binds weakly to *S. typhimurium*, but this binding is not inhibited by GlcNAc (Liu et al. 2005). In addition, the peptide Gly-Pro-Arg-Pro, which mimics the N-terminal sequence of the fibrin α-chain and inhibits fibrin polymerization, prevents binding of the M-ficolin FBG domain to GlcNAc. M-ficolin is expressed by blood monocytes and type II alveolar epithelial cells (Lu et al. 1996a; Theil et al. 2000; Liu et al. 2005; Frederiksen et al. 2005). Interestingly, M-ficolin expression is downregulated when monocytes mature into macrophages, but can be re-induced in mature macrophages when they are treated with bacterial products such as lipopolysaccharide (Frankenberger et al. 2008). M-ficolin, unlike L-ficolin and H-ficolin, was not considered to be a serum protein, but it was recently demonstrated that M-ficolin exists in human plasma and serum under normal conditions (Honore et al. 2008).

M-ficolin is highly homologous to L-ficolin at the amino-acid sequence level and also shows a marked preference for acetylated compounds (Frederiksen et al. 2005; Liu et al. 2005). H-ficolin, in contrast, is less closely related to L-ficolin and shows no binding affinity for acetylated derivatives. So far, it has been only reported to bind to Aerococcus viridans (Tsujimura et al. 2001; Krarup et al. 2005). M-ficolin also has lectin activity and, like L-ficolin (Le et al. 1998) it binds to GlcNAc via the FBG domain. As GlcNAc is a common carbohydrate moiety on Gram-negative bacteria, M-ficolin may also recognize these pathogens.

18.1.2.4 Veficolins

Cerberus rynchops (dog-faced water snake) belongs to Homalopsidae of Colubroidea (rear-fanged snakes). In addition to C-type lectins, the venom gland of *C. rynchops* contains two proteins that showed sequence homology to ficolin**.** These proteins were named as ryncolin 1 and ryncolin 2 (rynchops ficolin) and this new family of snake venom proteins as veficolins (venom ficolins). On the basis of its structural similarity to ficolin, it is speculated that ryncolins may induce platelet aggregation and/or initiate complement activation (OmPraba et al. 2010).

18.1.3 Ligands of Ficolins

Both H- and L-ficolins have also been shown to bind to carbohydrate structures found on Gram-negative bacteria (Akaiwa et al. 1999). L-ficolin binds to GlcNAc (Matsushita et al. 1996; Le et al. 1997, 1998) and N-acetyl-d-galactosamine (GalNAc) (Le et al. 1998). The binding ability is inhibited by acetylated compounds, indicating that this protein specifically recognizes acetyl groups (Krarup et al. 2004). L-ficolin activates the lectin pathway after binding to various capsulated bacteria (Matsushita et al. 1996; Lynch et al. 2004; Aoyagi et al. 2005). A binding specificity for GlcNAc was initially characterized by Matsushita et al. (1996, 2000), in agreement with the finding that L-ficolin recognizes lipoteichoic acid, a GlcNAc-containing cell wall component characteristic of Gram-positive bacteria (Lynch et al. 2004). Binding to a fungal 1,3-β-D-glucan preparation was later reported (Ma et al. 2004), whereas further investigations revealed specificity for N-acetylated carbohydrates and other non-carbohydrate acetylated compounds such as acetylcholine (Krarup et al. 2004). Where as M-ficolin was initially identified as a membrane-associated protein in pig uterus, based on its affinity for TGF-β1 (Ichijo et al. 1993), L-ficolin was shown to bind to corticosteroids (Edgar 1995), and both L- and M-ficolin were found to be elastin-binding proteins (Harumiya et al. 1995, 1996).

L-ficolin activates the lectin-complement pathway upon binding to lipoteichoic acid, a cell component found in all Gram-positive bacteria (Lynch et al. 2004). H-ficolin (ficolin-3), the primary structure of which is 48% identical to that of L-ficolin, binds to GlcNAc, GalNAc and d-fucose (Sugimoto et al. 1998). Unlike L-ficolin, the GlcNAc-binding activity of H-ficolin is not inhibited by acetyl compounds (Krarup et al. 2004). M-ficolin, the primary

structure of which is 80% and 48% identical to those of L-ficolin and H-ficolin, respectively (Sugimoto et al. 1998), binds to GlcNAc, GalNAc and sialic acid (Teh et al. 2000; Liu et al. 2005). This protein also recognizes acetyl groups, like L-ficolin (Frederiksen et al. 2005). Unlike the serum ficolins, M-ficolin has been detected on the surfaces of peripheral blood monocytes and promonocytic U937 cells (Lu et al. 1996a; Teh et al. 2000; Frederiksen et al. 2005). Gout et al. (2010) reported that L-ficolin preferentially recognized disulfated N-acetyllactosamine and tri- and tetrasaccharides containing terminal galactose or N-acetylglucosamine. Binding was sensitive to the position and orientation of the bond between N-acetyllactosamine and the adjacent carbohydrate. The crystal structure of the Y271F mutant fibrinogen domain showed that the mutation does not alter the structure of the ligand binding pocket. These analyses reveal ficolin ligands such as sulfated N-acetyllactosamine (L-ficolin) and gangliosides (M-ficolin) and provide precise insights into the sialic acid binding specificity of M-ficolin, emphasizing the essential role of Tyr^{271} in this respect.

18.1.4 X-ray Structures of M, L- and H-Ficolins

18.1.4.1 Homology to Tachylectin 5A

Several observations indicate that ficolins are not classical lectins and raise questions about their mechanism of action. To answer these questions at molecular level, the X-ray structures of their trimeric recognition domains, alone and in complex with various ligands, were solved to resolutions up to 1.95 and 1.7 Å, respectively. Both domains have three-lobed structures with clefts separating the distal parts of the protomers. Ca^{2+} ions are found at sites homologous to those described for *Tachypleus tridentatus* tachylectin-5A (TL5A), an invertebrate lectin (Kairies et al. 2001). Outer binding sites (S1) homologous to the GlcNAc-binding pocket of TL5A are present in ficolins but show different structures and specificities. In L-ficolin, three additional binding sites (S2–S4) surround the cleft (Garlatti et al. 2007a). The structures revealed that L-ficolin has evolved to be a versatile recognition protein able to recognize a variety of acetylated and carbohydrate targets through three different sites, suggesting that ficolins represent novel types of pattern recognition proteins. Results defined an unpredicted continuous recognition surface able to sense various acetylated and neutral carbohydrate markers in the context of extended polysaccharides such as 1,3-β-D-glucan, as found on microbial or apoptotic surfaces.

18.1.4.2 Domain Structures of M-Ficolin

The human M-ficolin FD1, which contains the ligand-binding site, was over-expressed in Pichia pastoris, purified and crystallized using the vapour-diffusion method at 293 K. The crystals belong to the monoclinic space group P21, with unit-cell parameters a = 55.16, b = 117.45, c = 55.19 Å, β = 99.88°, and contain three molecules per asymmetric unit (Tanio et al. 2006). To investigate the discrimination mechanism between self and non-self by ficolins, Tanio et al. (2007) determined the crystal structure of the human M-ficolin FD1 at 1.9A resolution. Although the FD1 monomer shares a common fold with the fibrinogen γ-fragment and tachylectin-5A, the Asp^{282}-Cys^{283} peptide bond, which is the predicted ligand-binding site on the C-terminal P domain, is a normal trans bond, unlike the cases of the other two proteins. The trimeric formation of FD1 results in the separation of the three P domains, and the spatial arrangement of the three predicted ligand-binding sites on the trimer is very similar to that of the trimeric collectin, indicating that such an arrangement is generally required for pathogen-recognition. The ligand binding study of FD1 in solution indicated that the recombinant protein binds to N-acetyl-d-glucosamine and the peptide Gly-Pro-Arg-Pro and suggested that the ligand-binding region exhibits a conformational equilibrium involving cis-trans isomerization of the Asp^{282}-Cys^{283} peptide bond. The crystal structure and the ligand binding study of FD1 provide an insight of the self- and non-self discrimination mechanism by ficolins (Tanio et al. 2007).

Since GlcNAc, the common ligand of ficolins from several species, is universally expressed on both pathogens and hosts, the discrimination mechanism between self (host) and nonself (pathogen) by ficolins is of particular interest. With regard to this, the trimer formation by the FD1 (M-ficolin FBG domain) is required to recognize pathogen surfaces with high ligand density. In addition, from structural and functional studies of M-ficolin FD1, Tanio et al. (2007) proposed that the ligand-binding region of FD1 exists in a conformational equilibrium between active and non-active states depending on three groups with a pK_a of 6.2, which are probably histidine residues, and suggested that the 2-state conformational equilibrium as well as the trimer formation contributes to the discrimination mechanism between self and non-self of FD1. The GlcNAc binding study of a series of single histidine mutants of FD1 demonstrated that His^{251}, His^{284} and His^{297} are required for the activity, and thus three histidines are the origins of pH dependency of FD1. The analyses of GlcNAc association and dissociation of FD1 provided evidence that FD1 always exchanges between the active and non-active states with the pH-dependent populations in solution. The biological roles of the histidine-regulated conformational equilibrium of M-ficolin are important in terms of self and non-self discrimination mechanism (Tanio and Kohno 2009).

The ligand-bound crystal structures of the CRD of M-ficolin, at high resolution provide the structural insights into its binding properties. Interaction with acetylated carbohydrates

differs from the one described for L-ficolin (Fig. 18.1). Garlatti et al. (2007b) also revealed the structural determinants for binding to sialylated compounds, a property restricted to human M-ficolin and its mouse counterpart, ficolin B. Comparison between the ligand-bound structures obtained at neutral pH and nonbinding conformations observed at pH 5.6 showed how the ligand binding site is dislocated at acidic pH. This means that the binding function of M-ficolin is subject to a pH-sensitive conformational switch. Considering that the homologous ficolin B is found in the lysosomes of activated macrophages (Runza et al. 2006), it is proposed that this switch can play a physiological role in such acidic compartments (Garlatti et al. 2007b).

The structure of human M-ficolin FD1 has been compared with the human fibrinogen γ fragment, tachylectin-5A, L-ficolin and H-ficolin. The overall structure of FD1 is similar to that of other proteins, although the peptide bond between Asp^{282} and Cys^{283}, which is in a predicted ligand-binding site, is a normal *trans* bond, unlike the cases of the other proteins. Analysis of the pH-dependent ligand-binding activity of FD1 in solution suggested that a conformational equilibrium between active and non-active forms in the ligand-binding region, involving cis-trans isomerization of the Asp^{282}-Cys^{283} peptide bond, contributes to the discrimination between self and non-self, and that the pK_a values of His^{284} are 6.1 and 6.3 in the active and non-active forms, respectively (Tanio et al. 2008).

18.1.4.3 Ligand-binding site of Ficolins

The crystal structures of human fibrinogen γ fragment (Pratt et al. 1997) and of the FD1 of *Tachypleus tridentatus* tachylectin-5A (TL5A), an invertebrate lectin (Kairies et al. 2001), have shown that the P domain contributes to ligand binding. In angiopoietin-2, the P domain of the FD1 relates to receptor binding (Barton et al. 2005). These findings suggest that the P domain of ficolins includes the sugar-binding site. Interestingly, although the sugars recognized by ficolins exist on the surface of the host cell, these proteins can discriminate between pathogens and the host cell. The crystal structures of ficolins, complexed with ligands, should clarify the molecular mechanism of the discrimination and advance drug design for general pathogens. The FReD (fibrinogen-related domain) of FIBCD1 (Fibrinogen C domain containing 1) forms noncovalent tetramers and that the acetyl-binding site of FReDs of FIBCD1 is homologous to that of tachylectin 5A and M-ficolin but not to the FReD of L-ficolin (Thomsen et al. 2010).

18.1.5 Functions of Ficolins

The lectin pathway of complement activation in humans is triggered through the action of MBL-associated serine protease-2 in response to recognition of neutral carbohydrates and other motifs present on microbial surfaces. This pathway is initiated by MBL, L-ficolin, H-ficolin, and M-ficolin (Matsushita and Fujita 2001; Liu et al. 2005; Frederiksen et al. 2005). MBL, through its C-type lectin domain, recognizes terminal carbohydrates, provided that their hydroxyl groups at positions C3 and C4 are in equatorial orientation (Weis et al. 1992).

Upon recognition of the infectious agent, the ficolins act through two distinct routes: initiate the lectin pathway of complement activation through attached mannose-binding lectin-associated serine proteases (MASPs), and a primitive opsonophagocytosis thus limiting the infection and concurrently orchestrating the subsequent adaptive clonal immune response. Ficolins are associated with the MASPs and the complexes activate the lectin-complement pathway (Fujita et al. 2004; Liu et al. 2005; Frederiksen et al. 2005) in response to recognition of neutral carbohydrates and N-acetyl groups on pathogens and damaged cells. This results from the ability of MBL and ficolins to associate with and trigger activation of MBL-associated serine protease (MASP)-2. Activated MASP-2 cleaves the complement proteins C2 and C4, thereby triggering the complement cascade (Thiel et al. 1997; Matsushita, et al. 2000). Three other MBL/ficolins-associated proteins have been described, the MASP-1 and MASP-3 proteases (Matsushita et al. 2002; Dahl, et al. 2001) and a truncated form of MASP-2 called MAp19 (19-kDa MBL-associated protein) or sMAp (Stover et al. 1999; Takahashi et al. 1999). MASP-3 has no known physiological substrates whereas MASP-1 cleaves with a low efficiency a few protein substrates, among which are fibrinogen and coagulation factor XIII (Krarup et al. 2008). It has been proposed that MASP-1 might contribute to the activation of the lectin pathway, though this issue is still controversial (Takahashi et al. 2008; Rossi et al. 2001).

Complement activation results in opsonization of microbes and apoptotic cells with C3-derived fragments, thus promoting their clearance through interaction with C3 receptors on phagocytes (Aoyagi et al. 2005; Kuraya et al. 2005). In addition, ficolins may themselves function as opsonins, as suggested by the ability of L-ficolin to enhance phagocytosis of *Salmonella typhimurium* by neutrophils (Matsushita et al. 1996) and the ability of L- and H-ficolins to increase adhesion/uptake of late apoptotic cells by macrophages (Jensen 2007; Honoré et al. 2007; Aoyagi et al. 2005; Kuraya et al. 2005).

The opsonizing effects of ficolins are exerted through receptors present on phagocytic cells that are likely common to other defense collagens such as C1q and the collectins. A likely candidate is the receptor for the collagenous domain of C1q (cC1qR) or calreticulin (Crt) (Stuart et al. 1997), which is thought to function in complex with the endocytic receptor CD91 (Ogden et al. 2001; Vandivier et al. 2002). This hypothesis is supported by studies showing that L- and

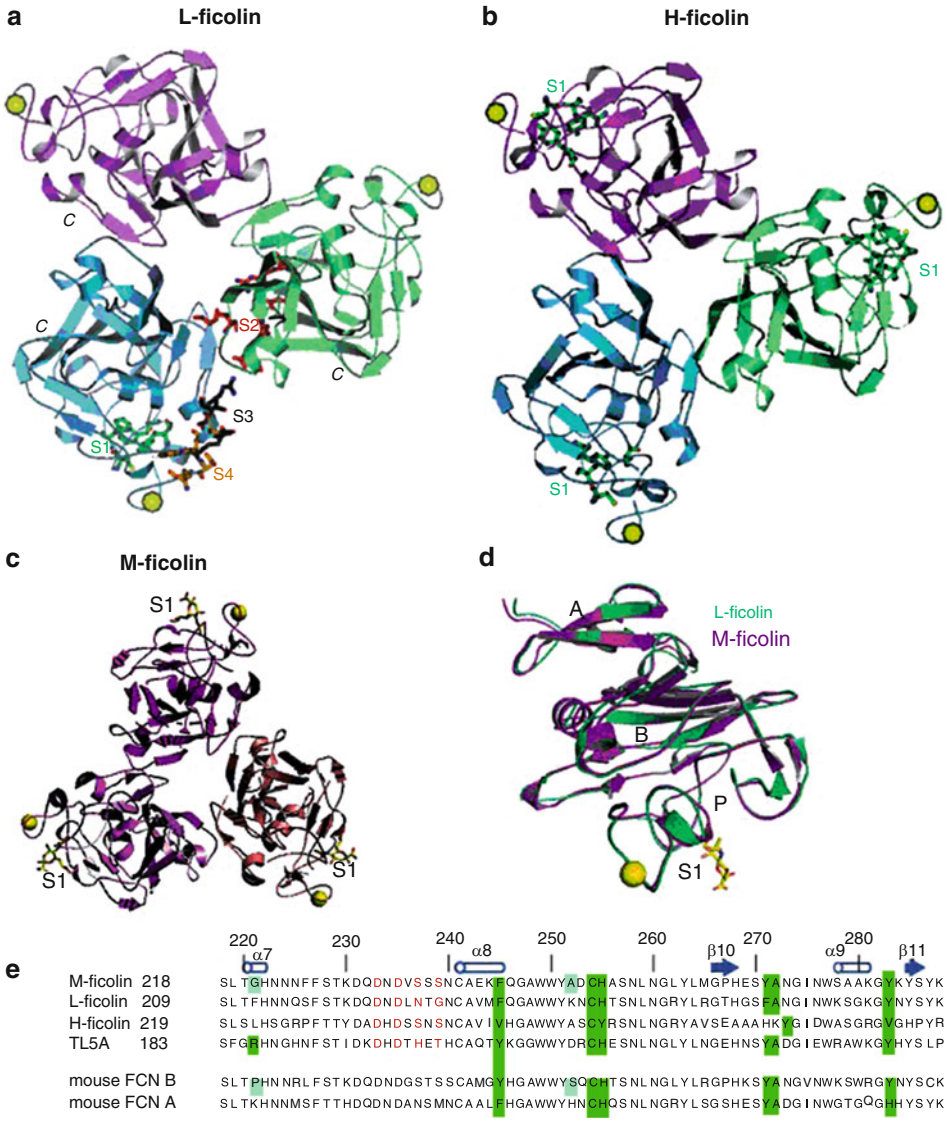

Fig. 18.1 *Homotrimeric structure of the recognition domains of human L-, H- and M-ficolins and location of their binding site(s)*: L-ficolin (**a**) and H-ficolin (**b**) structures seen from the target binding surface (*bottom* view). The side chains of the binding site residues are displayed as ball and sticks and colored *green* (S1), *red* (S2), *black* (S3), and *orange* (S4). To enhance clarity of the side view, only one of each representative binding sites is shown on the L-ficolin trimer. N and C indicate the N- and C-terminal ends of each protomer. Ca^{2+} ions are represented as golden spheres (Reprinted by permission from Macmillan Publishers Ltd: EMBO Journal, Garlatti. et al., © 2007a). (**c**) *Bottom* view of the homotrimeric structure of M-ficolin solved at neutral pH. Ca^{2+} ions are represented as golden spheres. The sialic acid ligand bound to site S1 is shown in a *yellow* ball and stick representation. (**d**) Superposition of the similar fibrinogen-like protomers of M-ficolin (*magenta*) and L-ficolin (*green*). Domains A, B, and P are labeled. (**e**) Sequence alignment of the P domains of human ficolins M, L, and H; mouse ficolins FCN B and FCN A; and TL5A. The residue numbering and the secondary structure elements apply to M-ficolin. Residues involved in the S1 binding site are colored green, and those involved in Ca^{2+} binding are colored red. Small residues allowing accommodation of sialic acid in site S1 are colored blue (Reprinted with permission from Garlatti et al. 2007b © American Society for Biochemistry and Molecular Biology)

H-ficolins bind to cC1qR/CRT (Kuraya et al. 2005) and that H-ficolin binding to Crt can be inhibited by MBL, suggesting that both proteins share a common binding site on CRT (Honoré et al. 2007). In addition, ficolins may themselves function as opsonins, as suggested by the ability of L-ficolin to enhance phagocytosis of *Salmonella typhimurium* by neutrophils and the ability of L- and H-ficolins to increase adhesion/uptake of late apoptotic cells by macrophages (Jensen et al. 2007; Honoré et al. 2007). The other putative function of monocyte surface M-ficolin was implicated by its affinity for GlcNAc, a common sugar structure on Gram-negative bacteria and other pathogens. M-ficolin might act

as a phagocytic receptor or adaptor on circulating monocytes for micro-organism recognition and may potentially mediate monocyte adhesion (Teh et al. 2000).

Studies have shown that MASP-2 binds to a short segment of the collagen-like domain of MBL. Recent studies revealed that Lys^{55} in the collagenous region of MBL is important for interaction with MASPs and CRT. On the other hand residues Lys^{57} of L-ficolin and Lys^{47} of H-ficolin are key components of the interaction with MASPs and CRT, providing strong indication that MBL and the ficolins share homologous binding sites for both types of proteins (Lacroix et al. 2009). Girija et al. (2007) showed that the MASP-2 binding site on rat ficolin-A is also located within the collagen-like domain and encompasses a conserved motif that is present in both MBLs and ficolins. Site-directed mutagenesis revealed that a lysine residue in the X position of the Gly-X-Y collagen repeat, Lys^{56} in ficolin-A, which is present in all ficolins and MBLs known to activate complement, is essential for MASP-2 binding. Similar binding sites and activation kinetics of MASP-2 suggest that complement activation by ficolins and MBLs follows analogous mechanisms.

18.1.5.1 The C3b Deposited by L-Ficolin/MBL forms Alternative Pathway C3 Convertase C3bBb

Serotype III group *B streptococci* (GBS) are the common cause of neonatal sepsis and meningitis. Although deficiency in maternal capsular polysaccharide (CPS)-specific IgG correlates with susceptibility of neonates to the GBS infection, serum deficient in CPS-specific IgG mediates significant opsonophagocytosis. The IgG-independent opsonophagocytosis requires activation of the complement pathway, a process requiring the presence of both Ca^{2+} and Mg^{2+}, and is significantly reduced by chelating Ca^{2+} with EGTA. The role of L-ficolin/mannose-binding lectin-associated serine protease (MASP) complexes in Ca^{2+}-dependent, Ab-independent opsonophagocytosis of serotype III GBS has been defined. The binding of L-ficolin/MASP complexes to the CPS generates C3 convertase C4b2a, which deposits C3b on GBS. The C3b deposited by this lectin pathway forms alternative pathway C3 convertase C3bBb whose activity is enhanced by CPS-specific IgG2, leading to an increased opsonophagocytic killing by further deposition of C3b on the GBS (Aoyagi et al. 2005).

18.1.6 Pathophysiology of Ficolins

Like invertebrate innate immune reactions, the human PGN and 1, 3-β-D-D-glucan recognition proteins function as complement-activating lectins. The counterparts of these proteins from human serum are MBL and L-ficolin. The specific microbial cell component-coupled columns demonstrated that MBL and L-ficolin bind to PGN and 1, 3-β-D-D-glucan, respectively. MBL and L-ficolin were associated with MBL-associated serine proteases-1 and -2 (MASPs) and small MBL-associated protein. The binding of purified MBL/MASP and L-ficolin/MASP complexes to PGN and 1, 3-β-D-glucan, respectively, resulted in the activation of the lectin-complement pathway (Ma et al. 2004; Matsushita and Fujita 2001). A lot of reports showed that dysfunction or abnormal expressions of ficolins may play crucial roles in the pathogenesis of human diseases including: (1) infectious and inflammatory diseases, e.g., recurrent respiratory infections; (2) apoptosis, and autoimmune disease; (3) systemic lupus erythematosus; (4) IgA nephropathy; (5) clinical syndrome of preeclampsia; (6) other diseases associated factor e.g. C-reactive protein. Zhang and Ali (2008) reviewed the structures, functions, and clinical implications of ficolins and summarized the reports on the roles of ficolins in human diseases. Precise identification of ficolins functions will provide novel insight in the pathogenesis of these diseases and may provide novel innate immune therapeutic options to treat disease progression.

In clinical studies, like MBL, no absolute levels of deficiency have yet been defined. In more than 300 children with recurrent respiratory tract infections no correlation has been observed between L-ficolin levels and severity of disease (Atkinson et al. 2004). An association with MBL deficiency in the same patient cohort had already been reported (Cedzynski et al. 2004). In this study, low levels of L-ficolin were more common in patients than in controls and most common in patients with co-existing atopic disorders, suggesting a role for L-ficolin in protection from microorganisms complicating allergic disease. Polymorphisms in the ficolins have been identified, although their clinical significance is as yet unknown (Dommett et al. 2006).

18.2 Tachylectins

18.2.1 Horseshoe Crab Tachylectins

Tachylectin-related proteins belong to fibrinogen type lectins and function in innate immunity of various animals, from ancient sponges to vertebrates. The specific recognition by horseshoe crab tachylectins with a propeller-like fold or a propeller-like oligomeric arrangement is reinforced by the short distance between the individual binding sites that interact with pathogen-associated molecular patterns (PAMPs). There is virtually no conformational change in the main or side chains of tachylectins upon binding with the ligands. This low structural flexibility of the propeller structures must be very important for specific interaction with PAMPs. While MBL and ficolins trigger complement activation through the

lectin pathway in the form of opsonins, tachylectins have no effector collagenous domains and no lectin-associated serine proteases found in the mammalian lectins. Furthermore, no complement-like proteins have been found in horseshoe crabs, except for α_2-macroglobulin. The mystery of the molecular mechanism of the scavenging pathway of pathogens in horseshoe crabs is to be solved (Kawabata and Tsuda 2002).

Kawabata and Iwanaga (1999) purified five types of tachylectins from circulating hemocytes and hemolymph plasma of the Japanese horseshoe crab, *Tachypleus tridentatus*. Tachylectin-1 interacts with Gram-negative bacteria probably through 2-keto-3-deoxyoctonate, one of the constituents of LPS. Tachylectin-1 also binds to polysaccharides such as agarose and dextran with broad specificity. Tachylectin-2 binds to D-GlcNAc or D-GalNAc and recognizes staphylococcal lipoteichoic acids and LPS from several Gram-negative bacteria. In contrast, tachylectins-3 and -4 specifically bind to S-type LPS from several Gram-negative bacteria through a certain sugar moiety on the O-specific polysaccharides (O-antigens). Tachylectin-5 identified in hemolymph plasma has the strongest bacterial agglutinating activity in the five types of tachylectins, and exhibits broad specificity against acetyl group-containing substances. Thus, the innate immune system of horseshoe crab may recognize invading pathogens through a combinatorial method using lectins with different specificities against carbohydrates exposed on pathogens. An encounter of these lectins derived from hemocytes and hemolymph plasma at injured sites, in response to the stimulation of LPS, suggests that they serve synergistically to accomplish an effective host defense against invading microbes and foreign substances (Kawabata and Iwanaga 1999). The structure of tachylectin-2, the first example of a fivefold symmetric β-propeller protein, sheds light on the role played by this lectin in horseshoe crab host defense (Rini and Lobsanov 1999).

18.2.1.1 Tachylectin 5A and 5B

Gokudan et al. (1999) characterized tachylectins 5A and 5B (TLs-5). TLs-5 agglutinated all types of human erythrocytes and Gram-positive and Gram-negative bacteria. TLs-5 specifically recognizes acetyl group-containing substances including noncarbohydrates; the acetyl group is required and is sufficient for recognition. TLs-5 enhanced the antimicrobial activity of a horseshoe crab-derived big defensin. cDNA sequences of TLs-5 indicated that they consist of a short N-terminal Cys-containing segment and a C-terminal fibrinogen-like domain with the highest sequence identity (51%) to that of mammalian ficolins. TLs-5, however, lack the collagenous domain found in a kind of "bouquet arrangement" of ficolins and collectins. Electron microscopy revealed that TLs-5 form two- to four-bladed propeller structures. Kairies et al. (2001) reported the crystal structure of TL5A, a lectin from hemolymph plasma of T. tridentatus. TL5A shares not only a common fold but also related functional sites with γ fragment of mammalian fibrinogen (Fig. 18.2). A fibrinogen-related lectin, named Dorin M, from the hemolymph plasma of soft tick, Ornithodoros moubata, is produced in the tick hemocytes. Dorin M is also expressed in salivary glands and has a fibrinogen-like domain. It exhibits similarity with tachylectins 5A and 5B from a horseshoe crab, Tachypleus tridentatus. In addition, Dorin M is closely related to tachylectins-5 (Rego et al. 2006).

18.2.2 X-ray Structure

TL5A is an ellipsoidal molecule (overall dimensions ~34 × 36 × 53 $Å^3$), subdivided into three distinct but interacting domains (Fig. 18.2 a and b). The N-terminal domain A (residues Asp^{45}–Trp^{89}) comprises two short helices and a small two-stranded antiparallel β-sheet. The N-terminal helix (α1) is diagonally twisted and anchored through a disulfide bond (Cys^{49}–Cys^{80}) to the second strand of β-sheet (β2). The second, short helix β2 connects strand β1 with strand β2. Structural elements N-terminal of Asp^{45} could not be resolved because of poorly defined electron density. Cysteine residues Cys^6 and Cys^{170} were expected to be involved in lectin homodimerization. However, electron density revealed Cys^{170} to be present in the free -SH form. In addition, chemical-labeling experiments also showed that Cys^6 and Cys^{170} are present in the free SH forms in native TL5A. The two disulfide bridges, Cys^{49}–Cys^{80} and Cys^{206} Cys^{219}, were confirmed by sequence analysis of peptides derived from TL5A (Kairies et al. 2001). The central and larger domain B (residues Thr^{90}–Ala^{180} and Pro^{253}–Phe^{264}) is clamped through domains A and P and predominantly made up by a twisted seven-stranded antiparallel β-sheet (strands β3–β7, β9 and β12). Helices β4 and β5 within this domain can be interpreted as a single helix divided by a loop, which participates with a small antiparallel two-stranded β-sheet (β4, β5) to the main seven-stranded β-sheet. The central strand β12 (residues Gln^{254}–Pro^{261}) extends the C terminus of domain P back to domain B, bringing both polypeptide termini in close proximity. The C-terminal domain P (residues Gly^{181}–Leu^{252}) possesses only a few short elements of regular secondary structure, and comprises two major functional sites within TL5A: the Ca^{2+}-binding site and the nearby acetyl group-binding pocket (Fig. 18.2b). The Ca^{2+} ion is bound in a loop region located ~11 Å away from the adjacent ligand binding site, coordinated by seven oxygen ligands in a pentagonal bipyramidal manner. Both carboxylate oxygen atoms of Asp^{198}, the main chain carbonyl oxygens of His^{202} and Thr^{204}, and

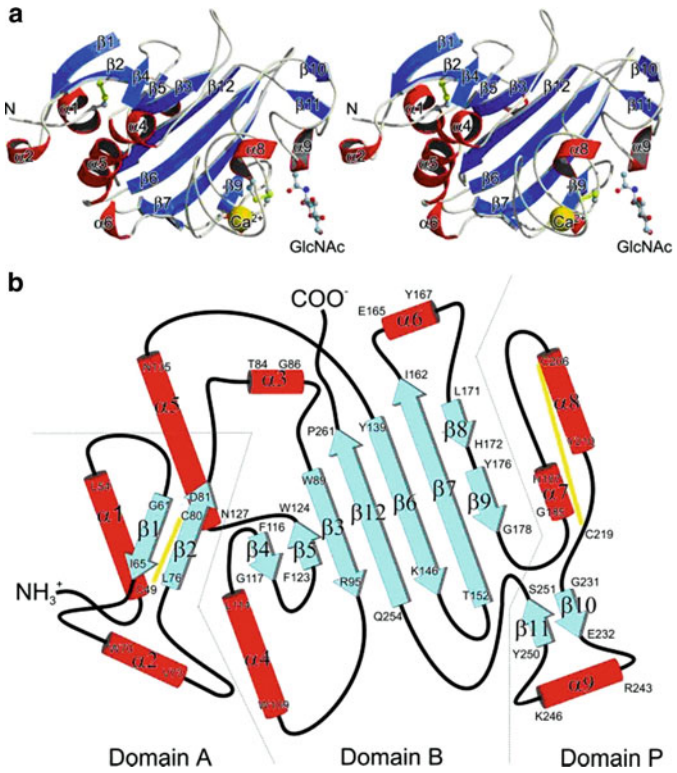

Fig. 18.2 *Crystal structure of TL5A from the Japanese horseshoe crab T. tridentatus*. (**a**) Stereo view of the TL5A ribbon plot. GlcNAc is represented by a ball-and-stick model and the Ca^{2+} ion is represented by a golden sphere. Disulfide bridges are colored yellow. (**b**) Topology diagram showing the arrangement of secondary-structure elements in TL5A. Disulfide bridges are indicated by yellow lines. Domains named in analogy to γ-fibrinogen fragment (Yee et al. 1997) (Reprinted with permission from Kairies et al. 2001© National Academy of Sciences USA)

one water molecule (WAT 40) form the pentagonal base, whereas WAT61 and the side chain oxygen atom OD1 (Asp^{200}) occupy the vertices of the bipyramide (Kairies et al. 2001).

19.1 Glycoside Hydrolase Family 18 Proteins in Mammals

19.1.1 Chitinases

Chitinases (EC.3.2.1.14) hydrolyze the β-1,4-linkages in chitin, an abundant N-acetylglucosamine (GlcNAc) polysaccharide that is a structural component of protective biological matrices of invertebrate such as insect exoskeletons and fungal cell walls. Chitinases cleave chitin and contain the conserved sequence motif DXXDXDXE, in which the glutamate is the catalytic residue. Chitinases are found in species including archaea, bacteria, fungi, plants, and animals. On the basis of sequence homologies, chitinases fall into two groups: families 18 and 19 of glycosyl hydrolases. Members of family 18 employ a substrate-assisted reaction mechanism (van Aalten et al. 2001), whereas those of family 19 adopt a fold-and-reaction mechanism similar to that of lysozyme (Monzingo et al. 1996), suggesting that these families evolved independently to deal with chitin. The glycoside hydrolase 18 (GH18) family of chitinases is an ancient gene family widely expressed in archea, prokaryotes and eukaryotes. Since chitin is an important structural component of pathogens like fungi as well as a constituent of the mammalian diet, a dual function for mammalian chitinases in innate immunity and food digestion has been envisioned (Suzuki et al. 2002; Boot et al. 2005a). Indeed, for human chitotriosidase, an enzyme predominantly expressed by phagocytes, a fungistatic effect has been demonstrated (van Eijk et al. 2005; Brunner et al. 2008). Several studies have tried to link a common chitotriosidase deficiency to susceptibility for infection by chitin-containing parasites (Bussink et al. 2006). The physiological function of the second mammalian chitinase, acidic mammalian chitinase (AMCase), has attracted considerable attention due to a report linking the protein to the pathophysiology of asthma (Zhu et al. 2004a).

19.2 Chitinase-Like Lectins: Chi-Lectins

In addition to active chitinases, highly homologous mammalian proteins lacking enzymatic activity due to substitution of active-site catalytic residues have been identified. Despite their lack of enzymatic activity, these proteins have retained active-site carbohydrate binding and hence have been named chi-lectins (Renkema et al. 1998; Houston et al. 2003; Bussink et al. 2006). Like the active chitinases, chi-lectins belong to family 18 of glycosyl hydrolases, consisting of a 39-kDa catalytic domain having a TIM-barrel structure, one of the most versatile folds in nature (Sun et al. 2001; Fusetti et al. 2003; Houston et al. 2003). In contrast to both chitinases, chi-lectins lack the conserved additional chitin-binding domain (Boot et al. 2001). Despite the detailed knowledge regarding structure, insight into the exact physiological function of the various chi-lectins is limited (Bussink et al. 2006). Similar to chitotriosidase and AMCase, chi-lectins are secreted locally or into the circulation and hence Chi-lectins play a significant role in inflammatory conditions. For example, human cartilage GP39 (HC-gp39/YKL-40/CHI3L1), a protein expressed by chondrocytes and phagocytes, has been implicated in arthritis, tissue remodeling, fibrosis, and cancer (Johansen 2006). Similarly, the human chi-lectin YKL-39 (CHI3L2) and the murine Ym1 (CHI3L3/ECF-L) have been associated with the pathogenesis of arthritis (Tsuruha et al. 2002) and allergic airway inflammation, respectively (Ward et al. 2001; Homer et al. 2006). Investigation of family 18 glycosyl hydrolases has revealed that active chitinases and chi-lectins are widespread and conserved in the mammalian kingdom. An ancient gene duplication first allowed the specialization of two active chitinases, chitotriosidase and AMCase, and subsequent gene duplications followed by loss-of-enzymatic-function mutations, have led to the evolution of a broad spectrum of chi-lectins in mammals.

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_19, © Springer-Verlag Wien 2012

Chitin is not found in vertebrates, but vertebrates do possess a small number of closely-related active chitinases. In mammals these are represented primarily by AMCase and chitotriosidase, both of which appear to have roles in the immune system. Eukaryotes also possess di-N-acetylchitobiase, a lysosomal enzyme involved in the degradation of N-linked glycoproteins, which is distantly related to AMCase and chitotriosidase. In mammals, but not other vertebrates, there are non-enzymatic chitinase-like proteins very similar to AMCase and chitotriosidase, such as YKL-40. Preservation of the hydrophobic substrate binding cleft, and consequently of high affinity binding to chito-oligosaccharides, has been demonstrated in some of these proteins, which have been termed chitinase-like lectins or Chi-lectins. Stabilin-1 interacting chitinase-like protein (SI-CLP, CHID1) is a non-enzymatic protein of unknown function which is distantly related to other mammalian glycoside hydrolase family 18 proteins and is conserved in eukaryotes.

19.3 YKL-40 [Chitinase 3-Like Protein 1 (CHI3L1)]

19.3.1 The Protein

Johansen and associates identified a protein secreted in vitro by the human osteosarcoma cell line MG63 and named it 'YKL-40' based on its three NH2-terminal amino acids tyrosine (Y), lysine (K), and leucine (L) and its molecular weight of 40 kDa (Johansen et al. 1992). Chitinase 3-like protein 1 or YKL-40 contains a single polypeptide chain of 383 amino acids. The complete amino acid and cDNA sequence of human YKL-40 was deduced by Hakala et al. (1993). The sequence of YKL-40 from several other mammals is known. Amino acid sequence of YKL-40 suggested that YKL-40 belongs to the glycosyl hydrolase family 18. YKL-40 shares significant amino acid sequence homology to bacterial chitinases and to six "mammalian chitinase–like proteins": oviduct-specific glycoprotein, chitotriosidase, YKL-39, TSA 1902, inducible silicotic bronchoalveolar lavage protein-p58 also named acidic mammalian chitinase, and mouse Ym1 also named eosinophil chemotactic cytokine (Boot et al. 2005b; Johansen et al. 2006). Interestingly, *Drosophila melanogaster* secretes several proteins, DS47 and imaginal disc growth factors, with sequence homology to YKL-40 (Kawamura et al. 1999).

The gene for human CHI3L1 is located on chromosome 1q31–q32, and consists of 10 exons and spans about 8 kb of genomic DNA (Rehli et al. 1997). The genes of all other human mammalian chitinase–like proteins identified are also located on chromosome 1. The transcriptional regulation of YKL-40 during human macrophage differentiation has been described. There are probably two independent transcription start sites and the promoter sequence that contains binding sites for several known factors and specific binding of nuclear PU.1, Sp1, Sp3, USF, AML-1, and C/EBP proteins (Rehli et al. 2003). The Sp1-family transcription factors seem to have a predominating role in controlling YKL-40 promoter activity.

19.3.2 Cell Distribution and Regulation

CHI3L1 is expressed by a variety of cell types including synovial cells, chondrocytes and smooth muscle cells, neutrophils, macrophages, fibroblast-like synovial cells, chondrocytes, and hepatic stellate cells. The expression of CHI3L1 is totally absent in monocytes (Rehli et al. 1997) and marginally expressed in monocyte-derived dendritic cells (Krause et al. 1996), but is strongly induced during the late stages of human macrophage differentiation. Rehli et al. (1997) demonstrated that promoter elements (in particular, the proximal -377 base pairs of the CHI3L1 promoter region) control the expression of CHI3L1 in the macrophage. CHI3L1 is also expressed in neutrophils (Volck et al. 1998), chondrocytes (Hakala et al. 1993), fibroblast-like synoviocytes (De Ceuninck et al. 2001), vascular smooth muscle cells, vascular endothelial cells (Malinda et al. 1999), ductal epithelial cells (Qin et al. 2007), hepatic stellate cells (Johansen 2006), and colonic epithelial cells (Mizoguchi 2006). In physiological concentrations CHI3L1 tends to promote proliferation of these cell types.

In U87, hypoxia and ionizing radiation induced a significant increase in YKL-40 after 24–48 h. The hypoxic induction of YKL-40 was independent of HIF1. Etoposide, ceramide, serum depletion and confluence led to elevated YKL-40. Inhibition of p53 augmented the YKL-40 expression indicating that YKL-40 is attenuated by p53. In contrast, both basic fibroblast growth factor and tumor necrosing factor-α repressed YKL-40. Diverse types of stress resulted in YKL-40 elevation, which strongly supports an involvement of YKL-40 in the malignant phenotype as a cellular survival factor in an adverse microenvironment (Junker et al. 2005a, b).

CHI3L1 is related to several other mammalian chitinase-like proteins (CLPs): chitotriosidase, YKL-39, Ym1, AMCase, oviduct-specific glycoprotein,, human cartilage glycoprotein 39 (HC-gp39) and stabilin-1-interacting (SI)-CLP. These mammalian chitinase-like proteins possess a conserved sequence motif (DXXDXDXE) on strand 4, and catalytic activity in these chitinases is mediated by the glutamic acid (E), which protonates the glycosidic bond with chitin (van Aalten et al. 2001). AMCase and chitotriosidase have catalytic activity but CHI3L1, YKL-39, Ym1, oviductin, SI-CLP do not have this activity (Kzhyshkowska et al. 2006). Due to substitution of an

essential glutamic acid residue to leucine, CHI3L1 loses chitinase activity, but still can bind to chitin and chito-oligosaccharides with high affinity through a preserved hydrophobic substrate binding cleft (Kawada et al. 2007). SI-CLP is upregulated by IL-4 as well as by glucocorticoids. This feature of SI-CLP makes it an attractive candidate for the examination of individual sensitivity of patients to glucocorticoid treatment and prediction of side effects of glucocorticoid therapy

Exposure to antigens containing chitin- or chitin-like structures sometimes induces strong T helper type-I. responses in mammals which may be associated with the induction of mammalian chitinases

19.3.3 Ligands of YKL-40

YKL-40 binds chitin of different lengths in a similar fashion as with other family 18 chitinases, but has no chitinase activity (Hakala et al. 1993; Renkema et al. 1998). The amino acids essential for the catalytic activity in chitinases are three acidic residues Asp, Glu, and Asp. The corresponding residues in human YKL-40 are Asp^{115}, Leu^{119}, and Asp^{186}. The recombinant chitin-binding domain binds to chitin, but not to glucan, xylan, or mannan and the binding of the recombinant chitin-binding domain to chitin was inhibited by N-acetylglucosamine, di-N-acetylchitobiose, and hyaluronan, but not by N-acetylgalactosamine or chondroitin. Furthermore, the recombinant domain interacts specifically with hyaluronan and hybrid-type N-linked oligosaccharide chains on glycoproteins, and that the oligosaccharide-binding characteristics are similar to those of wheat germ agglutinin, a lectin that binds to chitin (Ujita et al. 2003). YKL-40 binds specifically to collagen triple helices and regulates cleavage and fibril formation. Furthermore, Bigg et al., have reported an ability of YKL-40 to bind to collagen type 1, 2 and 3 (Bigg et al. 2006). YKL-40 binds chitin and chito oligosaccharides using 9 GlcNAc-binding subsites. The short chito-oligosaccharides which prime hyaluronic acid synthesis and are retained at reducing ends of hyaluronic acid molecules in mammals are suggested carbohydrate ligands for YKL-40; hyaluronic acid is associated with similar processes to YKL-40. Heparan sulphate, found on proteoglycans, is also a potential ligand and cell surface receptor for YKL-40 (Fusetti et al. 2003; Houston et al. 2003). The putative heparin-binding site is GRRDKQH (residues 143–149) (Fusetti et al. 2003). YKL-40 has therefore been defined as a CLP or chitinase-like lectin (Chi-lectin). YKL-39 is a protein of unknown function closely related to YKL-40 and present in humans and other primates.

YKL-40 is a glycoprotein in which most of the glucosamine is incorporated into N-linked complex oligosaccharides (De Ceuninck et al. 1998). Two possible sites of glycosylation are found in YKL-40, but only the NH2-terminal is glycosylated with two units of N-acetylglucosamine through β(1–4) linkage. Binding of either short or long oligosaccharides to human YKL-40 is possible, and the presence of two distinct binding sites with selective affinity for long and short oligosaccharides suggests that YKL-40 could function by cross-linking two targets. Glycosylation is a unique feature of the YKL-40 structure as the residue corresponding to Arg^{84} does not exist in chitinases and is mutated to Pro in other mammalian chitinase–like proteins. YKL-40 also binds heparin and amino acid sequence analysis reveals that YKL-40 contains one heparin binding motif (GRRDKQH at position 143–149) and two potential hyaluronan binding sites on the external face of the folded protein (Fusetti et al. 2003; Malinda et al. 1999). The putative heparin-binding site is located in a surface loop. It has been suggested that heparan sulfate is a more likely ligand of YKL-40, and unsulfated fragments of heparan sulfate can be accommodated in the binding groove of YKL-40 (Fusetti et al. 2003).

19.3.4 The Crystal Structure of YKL-40

Family 18 chitinases have catalytic domains of triosephosphate isomerase (TIM barrel) fold with a conserved DxDxE motif (Vaaje-Kolstad et al. 2004) and catalyze the hydrolytic reaction by substrate-assisted mechanism (Fig. 19.1a) (Terwisscha van Scheltinga et al. 1996; van Aalten et al. 2001), whereas family 19 chitinases have high percentage of α-helices and adopt the single displacement catalytic mechanism (Hoell et al. 2006). The crystallographic structures of human YKL-40 (Fusetti et al. 2003; Houston et al. 2003) and goat YKL-40 (Mohanty et al. 2003) display the typical fold of family 18 glycosyl hydrolases (Henrissat and Davies 1997). The structure is divided into two globular domains: a big core domain which consists of a $(\beta/\alpha)_8$ domain structure with a TIM barrel fold, and a small α/β domain, composed of five antiparallel β-strands and one α-helix, inserted in the loop between strand β7 and helix α7. This gives the active site of YKL-40 a groove-like character (Fig. 19.1b and Fig. 19.2). The TIM barrel domain consisting an $(\alpha/\beta)_8$-barrel fold has been found in many different proteins, most of which are enzymes. The TIM barrel domains share low sequence identity and have a diverse range of functions. The specific enzyme activity is determined by the eight loops at the carboxyl end of β-strands. In some TIM barrels, an additional loop

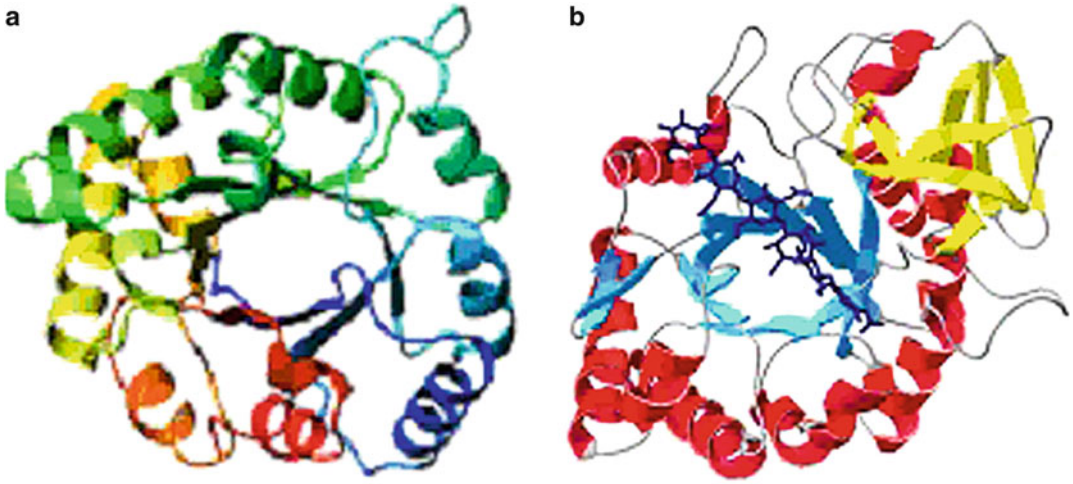

Fig. 19.1 (**a**) Top view of a triosephosphateisomerase (TIM) barrel (PDB code: 8TIM), colored from *blue* (N-terminus) to *red* (C-terminus). (**b**) Structure of human YKL-40 with bound GlcNAc oligomer. β-strands are colored as described in Fig. 19.1a. The GlcNAc oligomer is shown in *dark blue* (PDB code: 1HJW)

from a second domain approaches the active site of the TIM domain and participates in binding and catalysis (Li and Greene 2010).

Mammary Gland Protein-40 (MGP40): X-ray structure of chitolectin, mammary gland protein (MGP-40), is consistent with the $(\beta/\alpha)_8$ barrel topology of the Family 18 glycosidase proteins (Houston et al. 2003; Sun et al. 2001; van Aalten et al. 2001; Varela et al. 2002). MGP40 is an Asn-linked glycoprotein itself. The single disaccharide is covalently linked to the protein (at Asn^{39}) and forms hydrogen bonds with Arg^{84} and Ile^{40}, influencing the backbone conformation of loop Val^{75}-Phe^{85}, which in turn alters the disposition of Trp^{78}. Since Trp^{78} is an essential member of the binding site, the altered positioning of the site leads to constriction of the binding site, thereby leading to the inability of the MGP40 to bind sugar. Therefore, the oligosaccharides cannot bind to the putative binding site. Finally, Arg^{84}, which is hydrogen-bonded to the covalently bond sugar, is conserved in this particular class of chitolectins. The active chitinases in the Family 18 group which bind and cleave sugars possess a Pro in place of Arg^{84}, which in turn leads to inability of hydrogen bonding to the covalent linked sugar. Subsequently, there is a "relaxed" backbone conformation of the Val^{75}-Phe^{85} loop in the Family 18 chitinases and thereby no constriction of the binding site (Mohanty et al. 2003).

Human Cartilage Glycoprotein-39 (HUMGP39): The X-ray crystal structures of another chitolectin HumGP39 has been reported independently by two different groups (Houston et al. 2003; Fusetti et al. 2003). These structures are also consistent with $(\beta/\alpha)8$ barrel topology. The HumGP39 protein structures show a disaccharide covalently linked to it at $Asn^{19.}$ However, these structures depict in addition an oligosaccharide bound in the active site. Crystal structures of this protein show complexes with di, tri, tetra, penta and hexasaccharide bound at the active site. Based on these studies, it appears that the chitolectin group of proteins from Family 18 can bind chitin oligosaccharides. In comparison to MGP40 and HumGP39, the active site of glycosidases shows a difference of a glutamic acid, an essential acid/base residue for chitin cleavage and replaced with leucine or glutamine in chito-lectins.

The primary sequences of MGP40 and HumGP39 are highly identical (83 % identity). It was observed that since Arg^{84} is conserved between the two proteins, it is not the cause for the lack of oligosaccharide binding in MGP40 (Mohanty et al. 2003). Haq et al. (2007) compared the aromatic residues in both the proteins, focusing on Trp and Tyr residues present in the floor of the binding groove that are likely to interact strongly with the sugar molecules. Haq et al. (2007) suggested that MGP40 is capable of binding oligo-saccharides contrary to the conclusion of Mohanty

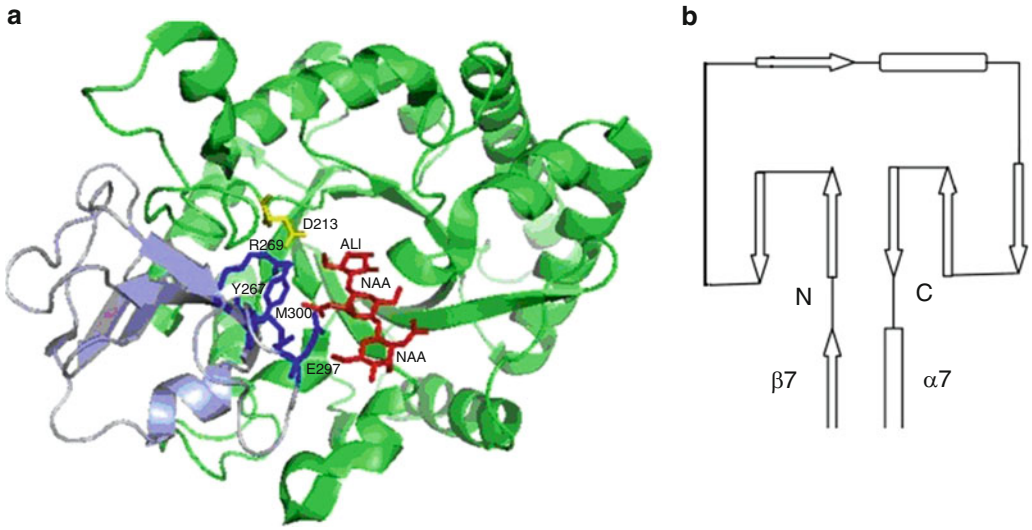

Fig. 19.2 *Structural analysis of Chitinase insertion domain (CID)*: (**a**) Ribbon model of human chitotriosidase (PDB: 1HKM) in complex with the substrate (NAA-NAA-ALI), showing the TIM barrel and CID. The helices and strands on the TIM barrel are coloured in *green* and those on the CID are coloured in *light blue*. Some residues (Tyr^{267}, Arg^{269}, Glu^{297}, and Met^{300}) in *blue* on the CID and Asp^{213} in *yellow* on the TIM barrel interact with the substrate in *red*. (**b**) Schematic representation of the CID between β7 and α7 on the TIM barrel, which is composed of two anti-parallel β-strands followed by one β-strand, one short α-helix, and lastly three anti-parallel β-strands. The arrows indicate β-strands and the rectangles are α-helices. The lines stand for the loops connecting α-helices or β-strands (Reprinted from Li and Greene 2010 © PLoS One)

et al. (2003) and that the conformation of residues 209–213 is not altered upon ligand binding as proposed by Mohanty et al. (2003). Based on the two HumGP39 structures, it was inferred that there are two distinct binding sites; a distal site for trisaccharides and the main site for tetra- and larger saccharides. It was proposed that the Trp in the +1 position functions as a "gate" to the main binding site that is in the "pinched" conformation when the oligosaccharide is not bound and is in the "stacked" conformation while interacting with the oligosaccharide.

Chitinase Insertion Domain (CID): While catalytic domain in chitinase activity has been studied extensively, the function of the chitinase insertion domain is least understood. For example, human chitotriosidase (PDB code: 1HKM), as a family 18 chitinase in the subfamily A, has a TIM domain and a chitinase insertion domain (CID), which is a module inserted into the TIM barrel (Fig. 19.2). Therefore the presence or absence of the insertion domain appears to be subfamily specific (Suzuki et al. 1999; Li and Greene 2010). Chitinase insertion domain sequences include four experimentally determined structures and span five kingdoms. The role of conserved residues was explored by conducting a structural analysis of a number of holo-enzymes. Hydrogen bonding and van der Waals calculations revealed a distinct subset of four conserved residues constituting two sequence motifs that interact with oligosaccharides. The other conserved residues may be key to the structure, folding, and stability of this domain. Sequence and structural studies of the chitinase insertion domains conducted within the framework of evolution identified four conserved residues which clearly interact with the substrates. Evolutionary studies propose a link between the appearance of chitinase insertion domain and the function of family 18 chitinases in the subfamily A (Li and Greene 2010).

19.4 Human Cartilage 39-KDA Glycoprotein (or YKL-39)/(CHI3L2)

The homologous human cartilage 39-kDa glycoprotein (HC gp-39) from articular cartilage chondrocytes primary culture has the N-terminal sequence YKL, which was termed YKL-19. The cDNA of HC gp-39 contained an open reading frame coding for a 383-amino acid long peptide which contains regions displaying significant homology with a group of bacterial and fungal chitinases and a similar enzyme found in the nematode, Brugia malayi. In addition significant homologies were observed with three mammalian secretory proteins, suggesting that a related protein family exists in mammals. The human protein does not possess any glycosidic activity against chitinase substrates. The mRNA of HC gp-39 is present in human articular chondrocytes as well is in liver, but undetectable in muscle tissues, lung, pancreas, mononuclear cells, or fibroblasts. Neither the protein nor mRNA for HC gp-39 was detectable in normal newborn or adult human articular cartilage obtained at surgery, while mRNA for HC gp-39 was detectable both in synovial specimens and in cartilage obtained from patients with rheumatoid arthritis (Hakala

et al. 1993; Renkema et al. 1998). One major site of synthesis of HC gp-39is the involuting mammary gland upon cessation of lactation (Morrison and Leder 1994). The 1434-nt sequence of YKL-39 cDNA predicts a 385-residue initial translation product and a 364-residue mature YKL-19. The amino acid sequence of YKL-39 is most closely related to YKL-40, followed by macrophage chitotriosidase, oviductal glycoprotein, and macrophage YM-1. These proteins share significant sequence identity with bacterial chitinases and have the probable structure of an $(\alpha\beta)_8$ barrel. The YKL-39 lacks the active site glutamate, which is essential for the activity of chitinases, and as expected has no chitinase activity. The highest level of YKL-39 mRNA expression is seen in chondrocytes, followed by synoviocytes, lung, and heart. YKL-39 accounts for 4 % of the protein in chondrocyte-conditioned medium, prostromelysin accounts for 17 %, and YKL-40 accounts for 33 %. In contrast to YKL-40, YKL-39 is not a glycoprotein and does not bind to heparin.

HC gp-39 and chitotriosidase are expressed in lipid-laden macrophages accumulated in various organs during Gaucher disease. In addition, these proteins can be induced with distinct kinetics in cultured macrophages. Studies depict remarkable phenotypic variation among macrophages present in the atherosclerotic lesion. Furthermore, chitotriosidase enzyme activity was shown to be elevated up to 55-fold in extracts of atherosclerotic tissue. Although a function for chitotriosidase and HC gp-39 has not been identified, it was hypothesized that these proteins play a role in cell migration and tissue remodeling during atherogenesis (Boot et al. 1999). However, little is known about the distribution of HC-gp39 and its role in fetal development (Ling and Recklies 2004).

19.5 Ym1 and Ym2: Murine Proteins

19.5.1 The Protein

Ym1 (or CH13L3) and Ym2 (or CH13L4) are murine chi-lectins, which are produced by macrophages, dendritic cells and mast cells. Ym1 is a murine protein secreted in large quantities by peritoneal macrophages upon nematode infection and is a marker for alternatively activated macrophages, which exert anti-inflammatory effects and promote wound healing, as well as combating parasitic infections. It is a single chain polypeptide (45 kDa) with a strong tendency to crystallize at its isoelectric point (pI 5.7). Upon nematode infection, murine peritoneal macrophages synthesize and secrete Ym1 protein, which is a functional marker for alternatively activated macrophages in T_{H2}-mediated inflammatory responses. Ym1 shares significant structural similarity to the family 18 chitinases. The function of Ym1 is not known, and there is conflicting evidence regarding both chitinase activity (weak or absent) and sugar-binding activity. SPR studies suggested that Ym1 exhibits calcium-independent binding at low pH to glucosamine (GlcN) and galactosamine (GalN), and especially to oligomers of these sugars, including heparin, but not to the unsubstituted or N-acetylated sugar. Treatment of macrophages and mast cells in vitro with IL-4 induced expression of Ym1 and Ym2 mRNA (HogenEsch et al. 2006). While Ym2 mRNA expression increased 976-fold, the mRNA of Ym1 increased 24-fold in the skin of cpdm/cpdm mice. Macrophages, dendritic cells and mast cells are cellular sources of Ym1 and Ym2 proteins. Eosinophils and neutrophils did not contain detectable concentrations of these proteins (Boot et al. 2005b; HogenEsch et al. 2006). Ym2 is another murine protein of unknown function closely related to Ym1. The Ym1 gene is mapped to a central region of mouse chromosome 3 (in the region syntenic to human chromosome 1p13) and that of another murine chitinase-like gene, Brp39, to a central region of mouse chromosome 1 (in the region syntenic to human chromosome 1q31).

Ym1 and Ym2 (Ym1/2) are induced by IL-4 in mouse bone marrow-derived mast cells and highly induced in bronchoalveolar lavage fluid (BALF) and the lung. Ym1/2 expression was completely inhibited by dexamethasone (Dex) in BALF and weakly inhibited in the lung. Although Dex pretreatment inhibited the Ym1/2 expression level in an animal model, it did not reduce IL-4 induction of Ym1/2 expression in primary cultured macrophages. It had no inhibitory effect on the phosphorylation level of STAT6 in macrophages. The inhibitory effect of Dex on Ym1/2 protein expression in the murine model of asthma does not involve the STAT6 signaling pathway (Lee et al. 2008).

Oral infections of mice with *Trichinella spiralis* induce activation of peritoneal exudate cells to transiently express and secrete Ym1. Co-expression of Ym1 with Mac-1 and scavenger receptor pinpoints macrophages as its main producer. A single open reading frame of 398 amino acids with a leader peptide (21 residues) typical of secretory protein has been deduced. Ym1 exhibits binding specificity to saccharides with a free amine group, such as GlcN, GalN, or GlcN polymers, but it does not bind to other saccharides. The interaction is pH-dependent but Ca^{2+} and Mg^{2+} ion-independent. The binding avidity of Ym1 to GlcN oligosaccharides was enhanced due to the clustering effect. Specific binding of Ym1 to heparin suggests that heparin/heparan sulfate may be its physiological ligand in vivo during inflammation and/or tissue remodeling. Although it shares 30 % homology with microbial chitinases, no chitinase activity was found associated with Ym1 (Chang et al. 2001).

Crystals discovered within the aged lung at the sites of chronic inflammation in a mouse model of chronic

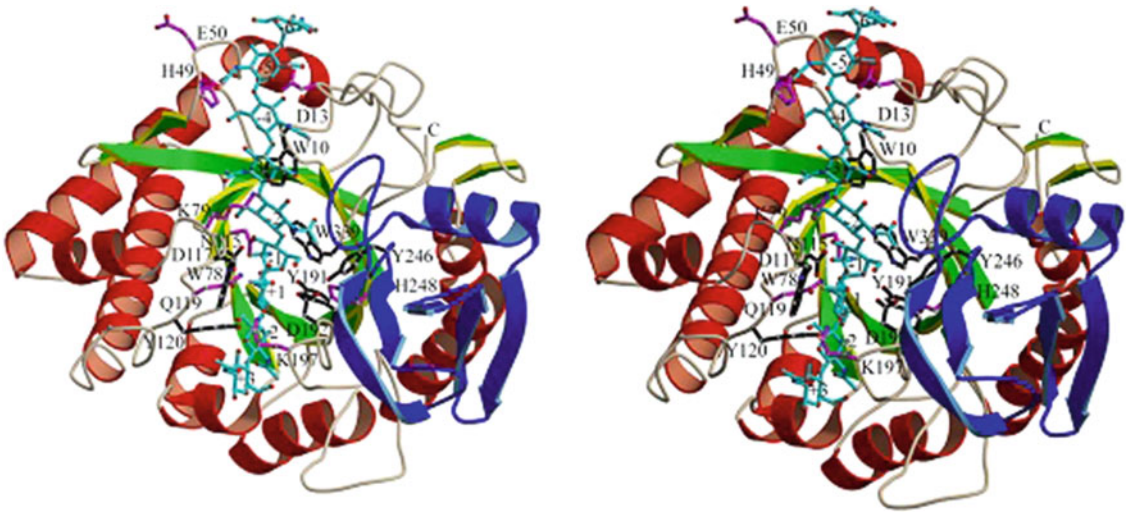

Fig. 19.3 Stereo view of the refined Ym1 structure with a model of N-acetylglucosamine$_9$ (NAG9). The NAG9 model was generated through superposition of the hCGP39–NAG8 complex, the SmChiA–NAG8 complex, and the SmChiB–NAG5 complex. The NAG9 model is labeled with the − 6 to +3 sugar-binding subsites and is shown as a stick drawing with cyan carbons. Helices in the TIM-barrel domain are colored in *red*, strands in *green*, and the additional α + β domain in *blue*. The conserved carbohydrate-interacting residues are shown in *magenta*, where non-conserved residues are shown in *black* (Reprinted with permission from Tsai et al. 2004 © Elsevier)

granulomatous disease, were identified as the chitinase-like protein Ym1. Ym1, found as a neutrophil granule protein, had weak β-N-acetylglucosaminidase activity, indicating that it might contribute to the digestion of glycosaminoglycans. Crystal formation is likely to be a function of excess neutrophil turnover at sites of inflammation in the chronic granulomatous disease mouse. Failure to remove subcutaneous Ym1 crystals injected into knockout mice indicates that a failure of digestion may also contribute to crystallization (Harbord et al. 2002).

19.5.2 Crystal Structure of Ym1

Co-crystallization and soaking experiments with various glucosamine or N-acetylglucosamine oligomers yield only the uncomplexed Ym1. The refined Ym1 structure at 1.31A resolution clearly displays a water cluster forming an extensive hydrogen bond network with the "active-site" residues (Fig. 19.3). This water cluster contributes notable electron density to lower resolution maps and this might have misled and given rise to a previous proposal for a monoglucosamine-binding site for Ym1. But crystals of Ym1 complexed with GlcN or GlcNAc polymers could not be obtained. A structural comparison of family 18 glycosidase like proteins reveals a lack of several conserved residues in Ym1, and illustrates the versatility of the divergent active sites. Therefore, Ym1 may lack N-acetylglucosamine-binding affinity, and this suggests that a new direction should be taken to unravel the function of Ym1 (Tsai et al. 2004).

Mouse Breast Regression Protein 39: Mouse breast regression protein 39 (BRP-39; CHI3l1) and its human homologue YKL-40 are chitinase-like proteins that lack chitinase activity. The biological properties of BRP-39/YKL-40 have only been rudimentarily defined. BRP-39$^{-/-}$ mice have markedly diminished antigen-induced T_{H2} responses and that epithelial YKL-40 rescued the T_{H2} responses in these animals. Mechanistic investigations demonstrated that BRP-39 and YKL-40 play an essential role in antigen sensitization and immunoglobulin E induction, stimulate dendritic cell accumulation and activation, and induce alternative macrophage activation. These proteins also inhibit inflammatory cell apoptosis/cell death while inhibiting Fas expression, activating protein kinase B/AKT, and inducing Faim 3. These proteins may prove therapeutic targets in T_{H2}- and macrophage-mediated disorders.

19.5.3 Oviductin

The high-molecular-weight oviductins, consisting of the amino-terminal 39-kDa catalytic domain followed by a heavily glycosylated serine/threonine-rich domain, are secreted by nonciliated oviductal epithelial cells and have been shown to play a role in fertilization and early embryo development (Buhi 2002). Among glycoside hydrolase family 18 proteins, it has a unique O-glycosylated mucin-like region following the chitinase-like domain. Carbohydrate binding has yet to be investigated in oviductin. The deduced amino acid sequence of an estrogen-dependent sheep oviductal glycoprotein (Mr 90,000–116,000) revealed the

presence of several potential sites for glycan substitution on a protein backbone of Mr 66,500, and identity with chitinases. The oviductal glycoprotein contained N-acetylgalactosamine, N-acetylglucosamine, galactose, fucose, and sialic acid both in α2,3 and α2,6 linkages, typical of sialomucins. The oviductal glycoprotein was resistant to digestion with O-glycanase alone and chondroitinase ABC, with the latter indicating that it was not a proteoglycan. Results suggest that the secreted glycoprotein contains saccharide residues typical of sialomucins, and despite primary amino acid sequence identity, the oviductal glycoprotein does not share an enzymatic relationship with chitinases (DeSouza and Murray 1995).

19.6 Functions of CHI3L1 (YKL-40)

Although CHI3L1 was first identified in 1993 (Hakala et al. 1993), its biological function has been largely undetermined. CHI3L1 possesses a functional carbohydrate-binding motif which allows binding with a polymer or oligomer of GlcNAc, but CHI3L1 lacks enzymatic activity entirely. It is not yet known to have a specific receptor. Expression of YKL-40 appears to be induced by a change in the extracellular matrix environment, and is thought to have a role in development, tissue remodelling and inflammation. However, its pattern of expression is associated with pathogenic processes related to inflammation, extracellular tissue remodeling, fibrosis and solid carcinomas. It is assumed that YKL-40 plays a role in cancer cell proliferation, survival, invasiveness and in the regulation of cell-matrix interactions. YKL-40 is suggested as a marker associated with a poorer clinical outcome in genetically defined subgroups of different tumors (Kazakova and Sarafian 2009; Lee et al. 2011).

19.6.1 Role in Remodeling of Extracellular Matrix and Defense Mechanisms

Mammalian chitinase-like proteins have a postulated role in remodeling of extracellular matrix and defense mechanisms against chitin-containing pathogens. The expression of these proteins is increased in parasitic infections and allergic airway disease. YKL-40 has been indicated as a biomarker of sepsis (Hattori et al. 2009). YKL-40 is a growth factor for fibroblasts and has an anti-catabolic effect preserving extracellular matrix during tissue remodeling (Ling and Recklies 2004). YKL-40 stimulates migration and adhesion of endothelial cells and vascular smooth muscle cells (VSMCs), suggesting a role in angiogenesis (Malinda et al. 1999; Nishikawa and Millis 2003), and may play a role in regulating response of cancer cells to hypoxia (Saidi et al. 2008).

19.6.2 Growth Stimulating Effect

Since CHI3L regulates the growth of imaginal disc cells in *D.melanogaster,* it has been predicted that CHI3L1 can have a growth stimulating effect (Kawamura et al. 1999). Growth stimulating effects of CHI3L1 have been demonstrated on connective tissue cells (Recklies et al. 2002) and on endothelial cells (Malinda et al. 1999). CHI3L1 also stimulates angiogenesis and reorganization of vascular endothelial cells (Malinda et al. 1999). Insulin-like growth factor-1 works synergistically with CHI3L1 to enhance the response of human synovial cells isolated from patients with osteoarthritis (Recklies et al. 2002). In addition, CHI3L1 also promotes the activation of 2 major signaling pathways associated with mitogenesis and cell survival: MAPK (mitogen-activated protein kinase) pathways and PI-3 K (phosphoinositide 3-kinase)-mediated pathways in fibroblast cells. The purified human CHI3L1 efficiently phosphorylates MAPK p42/p44 in human synovial cells, fibroblasts, articular chondrocytes (Recklies et al. 2002) and human colonic epithelial cells (Eurich et al. 2009) in a dose-dependent manner. It has been suggested that G-protein-regulated MAPK networks are involved in the action of most non-nuclear oncogenes and subsequent carcinogenesis and tumor progression (Pearson et al. 2001). The networks are involved in the activation of MAPK p42/p44 which may enhance the carcinogenic change of epithelial cells during upregulated CHI3L1 expression under inflammatory conditions (Eurich et al. 2009).

19.7 Chi-Lectins As Markers of Pathogenesis

19.7.1 A Marker of Inflammation

The CHI3L1 plays a role in the pathological conditions leading to arthritis and tissue fibrosis (Recklies et al. 2002). Increased circulating levels of CHI3L1 have been reported in the serum of patients with several inflammatory conditions including IBD (Crohn's disease (CD) and ulcerative colitis (UC) (Vind et al. 2003), asthma (Chupp et al. 2007; Ober et al. 2008) and liver cirrhosis (Johansen et al. 1997). Serum CHI3L1 is rarely detectable in healthy individuals (Vind et al. 2003), and therefore CHI3L1 has been proposed as a useful marker for indicating inflammatory activity and poor clinical prognosis for IBD (Vind et al. 2003). CHI3L1 is strongly expressed by macrophages in the synovial membrane of patients with rheumatoid arthritis (RA) and a polarized IFNγ-mediated proinflammatory Th1-type immune response has been observed in half the patients with RA. CHI3L1 seems to be the cross-tolerance inducing protein in chronic arthritis which effectively downregulates the pathogenic immune responses. It is possible that nasal administration of

CHI3L1 represents an attractive approach for suppressing the clinical manifestation of chronic types of inflammation as well as autoimmune diseases.

Human cartilage GP39 (HC-gp39) has been implicated in arthritis, inflammatory bowel disease, tissue remodeling, fibrosis, and cancer (Hakala et al. 1993; Recklies et al. 2002; Johansen 2006). Prominent sites of HC-gp39 production are degenerate articular cartilage and inflamed or hyperplastic synovium, fibrotic liver tissue and gliomas, where a correlation of HC-gp39 production with malignancy has been reported. The presence of HC-gp39 at sites of inflammation has been described in several studies (Hormigo et al. 2006; Johansen et al. 1999a, 1999b), and the use of serum levels of this protein as a disease marker for the progression of joint erosion has been proposed. Cintin et al. (2002) have reported that serum levels of HC-gp39 correlate negatively with survival in patients with colorectal carcinomas; a similar correlation has been suggested for patients with breast carcinomas (Johansen et al. 1995). Similarly, the human chi-lectin YKL-39 (CHI3L2) and the murine Ym1 (CHI3L3/ECF-L) have been associated with the pathogenesis of arthritis (Tsuruha et al. 2002) and allergic airway inflammation, respectively (Chang et al. 2001; Ward et al. 2001; Homer et al. 2006).

Acidic mammalian chitinase (AMCase) and murine lectin Ym1 are upregulated in Th2-environment, and enzymatic activity of AMCase contributes to asthma pathogenesis. Chitotriosidase and YKL-40 reflect the macrophage activation in atherosclerotic plaques. Serum level of YKL-40 is a diagnostic and prognostic marker for numerous types of solid tumors. YKL-39 is a marker for the activation of chondrocytes and the progression of the osteoarthritis in human. The genetic contribution of YKL-40 gene to atopic susceptibility strongly suggests that the g.-247C/T polymorphism in the CHI3L1 promoter region is associated with the risk of atopy (Sohn and Wu 2009).

Expression in Osteoarthritis: Among numerous substances increasingly proposed for diagnostic purposes, very few may be considered as true disease markers in osteoarthritis (OA); COMP, antigenic keratin sulphate, hyaluronic acid, YKL-40, type III collagen N-propeptide and urinary glucosyl-galactosyl pyridinoline seem to be the most promising (Punzi et al. 2005). The presence of YKL-40 in cartilage and synovium in OA patients correlates with histopathological changes and may reflect local disease activity. In addition, the levels of YKL-40 in serum and synovial fluid also seem to correlate with disease severity. The functional role of YKL-40 is not yet clear, but its production as part of the inflammatory response in articular chondrocytes may modulate the cellular response to proinflammatory cytokines, acting to limit connective tissue degradation. Further elucidation of its roles and relationships may enable YKL-40 to act as a useful biomarker in the development of therapies for OA (Huang and Wu 2009).

Biomarkers for Asthma: Ober and Chupp (2009) provided an overview of genetic basis of asthma and immune-mediated diseases with polymorphisms in the genes encoding these proteins, CHIT1, CHI3L1, and CHIA, respectively. Polymorphisms in the CHIT1, CHIA, and CHI3L1 genes influence chitotriosidase enzyme activity, acid mammalian chitinase activity, and YKL-40 levels, respectively. Regulatory SNPs in CHI3L1 have been also associated with asthma, atopy, and immune-mediated diseases, and nonsynonymous SNPs in CHIA were associated with asthma. No CHIT1 polymorphisms, including a common nonfunctional 24-bp duplication allele, have been associated with asthma. These genes represent novel asthma susceptibility genes. Additional studies of this gene in populations of diverse ancestries are warranted (Ober et al. 2009). There is ample evidence to support an association of acidic mammalian chitinase (AMC) and YKL-40 with allergic bronchial asthma in patients. Recent studies in a mouse asthma model revealed that anti-inflammatory drugs like corticosteroid and cysteinyl leukotriene receptor antagonist were able to suppress elevated pulmonary levels of mammalian chitinases. Taken together, mammalian chitinases and chitinase-like proteins may be useful as biomarkers for asthma (Shuhui et al. 2009). Assessments of YKL-40 may allow physicians to more accurately diagnose and predict the course of asthma and thereby allow therapy to be appropriately tailored for a given patient (Hartl et al. 2009)

An overview of the chitinase and chitinase-like proteins, has been related to the genetic studies of asthma and immune-mediated diseases with polymorphisms in the genes encoding these proteins, CHIT1, CHI3L1, and CHIA, respectively. Polymorphisms in the genes of these proteins influence chitotriosidase enzyme activity, acid mammalian chitinase activity, and YKL-40 levels, respectively. Regulatory SNPs in CHI3L1 were also associated with asthma, atopy, and immune-mediated diseases, and nonsynonymous SNPs in CHIA were associated with asthma. No CHIT1 polymorphisms, including a common nonfunctional 24-bp duplication allele, have been associated with asthma. These genes represent novel asthma susceptibility genes (Ober and Chupp 2009).

Cardiovascular Diseases: Several inflammatory cytokines are involved in vascular inflammation resulting in endothelial dysfunction which is the earliest event in the atherosclerotic process leading to manifest cardiovascular disease. Human cartilage glycoprotein-39 (YKL-40) is secreted into

circulation by macrophages, neutrophils, chondrocytes, vascular smooth muscle cells and cancer cells. The YKL-40 is a serum biomarker in diseases with fibrosis, inflammation and tissue remodelling. In contrast to C-reactive protein (CRP) produced in the liver in response to inflammation, YKL-40 is produced by lipid-laden macrophages inside the vessel wall. YKL-40 is an inflammatory glycoprotein involved in endothelial dysfunction by promoting chemotaxis, cell attachment and migration, reorganization and tissue remodeling as a response to endothelial damage. YKL-40 protein expression is seen in macrophages and smooth muscle cells in atherosclerotic plaques with the highest expression seen in macrophages in the early lesion of atherosclerosis. Several studies demonstrate that elevated serum YKL-levels are independently associated with the presence and extent of coronary artery disease and even higher YKL-40 levels are documented in patients with myocardial infarction. Moreover, elevated serum YKL-40 levels have also been found to be associated with all-cause as well as cardiovascular mortality. YKL-40 levels are elevated both in patients with type-1 and type-2 diabetes, known to be at high risk for the development of cardiovascular diseases, when compared to non-diabetic persons.

Atherosclerotic plaque macrophages express YKL-40, particularly macrophages that have infiltrated deeper into the lesion, and the highest YKL-40 mRNA expression is found in macrophages in early atherosclerotic lesion (Boot et al. 1999). Studies have suggested that high serum YKL-40 levels could be a prognostic biomarker of short survival. This is demonstrated in 80-year-old people and in patients with *Streptococcus pneumoniae* bacteraemia, and local or metastatic cancer (Johansen et al. 2009; Kastrup et al. 2009). Serum YKL-40 levels are elevated in patients with acute myocardial infarction (MI) ((Nøjgaard et al. 2008; Wang et al. 2008) and stable coronary artery disease (CAD),and associated with the number of diseased vessels assessed by coronary angiography. Elevated serum YKL-40 is a risk factor for acute coronary syndrome and death in patients with stable CAD (Kastrup et al. 2009).

The serum YKL-40 was increased in chronic heart failure (CHF), and YKL-40 detected high risk patients for adverse outcomes in CHF (Bilim et al. 2010; Johansen et al. 2010). The YKL-40 is elevated and associated with mortality in patients with stable coronary artery disease (CAD). The influence of statin treatment and lipid status has been studied on serum YKL-40 and Hs-CRP in patients with stable CAD. HsCRP, but not YKL-40, is associated with the cholesterol levels in statin treated patients. In general population, elevated plasma YKL-40 levels are associated with increased risk of ischemic stroke and ischemic cerebrovascular disease, independent of plasma CRP levels (Kjaergaard et al. 2010), indicating that YKL-40 could be a superior prognostic biomarker in patients with stable CAD, since it is independent of changes in cholesterol levels in both statin and non-statin treated patients (Mygind et al. 2011).

A positive association between elevated circulating YKL-40 levels and increasing levels of albumin-uria has been described in patients with type 1 diabetes indicating a role of YKL-40 in the progressing vascular damage resulting in microvascular disease. YKL-40 has been related to endothelial dysfunction, atherosclerosis, cardiovascular disease and diabetes and offers future perspectives in research (Catalán et al. 2011; Rathcke et al. 2009; Rathcke and Vestergaard 2009; Mathiasen et al. 2010). However, Plasma YKL-40 was identified as an obesity-independent marker of type 2 diabetes related to fasting plasma glucose and plasma IL-6 levels (Nielsen et al. 2008).

Neurological Diseases: Elevated levels of CHI3L1 (YKL-40) have been observed in the cerebrospinal fluid (CSF) of human and non-human primates with lentiviral encephalitis. Immunohistochemistry showed that CHI3L1 was associated with astrocytes. It was demonstrated that CHI3L1 is induced in astrocytes in a variety of neurological diseases but that it is most abundantly associated with astrocytes in regions of inflammatory cells (Bonneh-Barkay et al. 2010; Gaidamashvili et al. 2004; Nigro et al. 2005). Disease-modifying therapies for Alzheimer's disease (AD) would be most effective during the preclinical stage before significant neuronal loss occurs. Data demonstrate that YKL-40 is elevated in AD and, together with Aβ42, has potential prognostic utility as a biomarker for preclinical AD (Craig-Schapiro et al. 2010).

Respiratory Disorders: The exaggerated expression of YKL-40, the human homolog of BRP-39, has been reported in chronic obstructive pulmonary disease (COPD). We hypothesized and confirmed that BRP-39/YKL-40 plays an important role in the pathogenesis of cigarette smoke (CS)-induced emphysema. Studies demonstrate a regulatory role of BRP-39/YKL-40 in CS-induced inflammation and emphysematous destruction. Studies also highlight that maintaining the physiologic levels of YKL-40 in the lung will be therapeutically important to prevent excessive inflammatory responses or emphysematous alveolar destruction (Matsuura et al. 2011). Idiopathic pulmonary fibrosis (IPF) is a progressive interstitial lung disease that is hallmarked by fibrosis, inflammation and tissue remodelling. The -329 A/G polymorphism was associated with serum and BALF YKL-40 levels in IPF patients. High serum and BALF YKL-40 levels are associated with poor survival in IPF patients and could be useful prognostic markers for survival in IPF (Korthagen et al. 2011).

19.7.2 CHI3L1 as Biomarker in Solid Tumors

CHI3L1 or YKL-40 is expressed and secreted by several types of solid tumors including glioblastoma, colon cancer, breast cancer and malignant melanoma (Table 19.1). Although the exact function of CHI3L1 in inflammation and cancer is largely unknown, CHI3L1 plays a pivotal role in exacerbating the inflammatory processes and in promoting angiogenesis and remodeling of the extracellular matrix. CHI3L1 may be highly involved in the chronic engagement of inflammation which potentiates development of epithelial tumorigenesis presumably by activating the mitogen-activated protein kinase and the protein kinase B signaling pathways. Anti-CHI3L1 antibodies or pan-chitinase inhibitors may have the potential to suppress CHI3L1-mediated chronic inflammation and the subsequent carcinogenic change in epithelial cells (Eurich et al. 2009).

Clinical studies with different types of advanced tumors suggest that serum levels of CHI3L1 may be a new biomarker in cancer. In many cases, serum CHI3L1 provides independent information of survival. The highest serum CHI3L1 is detected in patients with advanced cancer and with the poorest prognosis. However, serum CHI3L1 cannot be used as a single screening test for cancer (Johansen et al. 2006). When evaluated with other prognostic factors of survival after recurrence of breast cancer, serum CHI3L1and serum LDH were the most significant independent factors. It was suggested that serum CHI3L1 may be of value in the follow-up of patients with breast cancer and in evaluating potential metastatic spread. CHI3L1 expression is strongly elevated in serum and biopsy material from glioblastomas patients. Though, the elevated plasma CHI3L1 is a biomarker of poor prognosis in cancer patients, but in general population, elevated plasma CHI3L1 predicts increased risk of gastrointestinal cancer and decreased survival after any cancer diagnosis (Johansen et al. 2009).

It has been strongly hypothesized that CHI3L1 plays a pivotal role as a growth stimulating factor for solid tumors or has a suppressive/protective effect in the apoptotic processes of cancer cells (Johansen et al. 2006) and inflammatory cells (Lee et al. 2009). In addition to CHI3L1 expression in a wide variety of human solid tumors, elevated levels of CHI3L1 in serum and/or plasma have been detected in patients with different types of solid tumors. Therefore, it is reasonable to predict that the serum level of CHI3L1 can be a reliable marker of progression of certain kinds of tumors and of a "bad prognosis" in patients with certain types of malignant tumors (Johansen et al. 2006).

The CHI3L1 can be used as a tumor marker for ovarian cancer (Høgdall et al. 2009), small cell lung cancer (Johansen et al. 2004), metastatic breast cancer (Johansen et al. 2009, 2010), and metastatic prostate cancer (Brasso et al. 2006). In addition, CHI3L1 is one of the most significant prognosis markers for cervical adenocarcinoma (Mitsuhashi et al. 2009), recurrent breast cancer (Johansen et al. 1995) and metastatic breast cancer (Jensen et al. 2003), as well as advanced stages of breast cancer (Coskun et al. 2007). Interestingly, the CHI3L1 serum level could be a useful and sensitive biomarker for recurrence in locally advanced breast carcinoma (Coskun et al. 2007), ovarian carcinoma (Gronlund et al. 2006), endometrial cancer (Diefenbach et al. 2007), squamous cell carcinoma of the head and neck (Roslind et al. 2007, 2008), metastatic prostate cancer or melanoma (Johansen et al. 2007; Schmidt et al. 2006), Hodgkin's lymphoma (Biggar et al. 2008) and colon cancer. Johansen and colleagues suggest that CHI3L1 may be used as a sensitive predictor of any cancer (Johansen

Table 19.1 *Expression of CHI3L1 (or YKL40) in solid tumors* (Eurich et al. 2009; Johansen et al. 2006)

et al. 2009; Qin et al. 2007). They categorized patients into 5 distinct levels according to the amount of plasma CHI3L1 detected by ELISA, and found that participants with the highest level of plasma CHI3L1 had a median survival rate of only 1 year after the cancer diagnosis (Johansen et al. 2009). In contrast, the patients with the lowest level of plasma CHI3L1 had a survival rate of more than 4 years. Although the variation of CHI3L1 serum levels in healthy subjects in this study was relatively small, subsequent measurements would be required to determine cancer risk since the serum level of CHI3L1 could also be elevated in patients with other inflammatory diseases or autoimmune disorders (Johansen et al. 2008; van Aalten et al. 2001). From the results, it has been highly predicted that serum CHI3L1 levels seem to be a potential and promising biomarker for malignant tumors.

It is believed that IBD is a risk factor of cancer development based on the severity of the disease course. As previously reported, serum CHI3L1 concentration is elevated in patients with IBD (Vind et al. 2003) and primary colorectal cancer (Cintin et al. 2002). People with CD have a 5.6-fold increased risk of developing colon cancer; therefore screening for colon cancer by colonoscopy is strongly recommended for patients who have had CD for several years (Collins et al. 2006). Inflammation was recently recognized as an important factor in the pathogenesis of malignant tumors (Bromberg and Wang 2009).

Eurich et al. (2009) reviewed some examples of inflammation-mediated carcinogenesis and diseases which express CHI3L1 during the course of inflammation and the subsequent tumorigenesis. CHI3L1 protects cancer cells from undergoing apoptosis and also has an effect on extracellular tissue remodeling by binding specifically with collagen types I, II, and III (Bigg et al. 2006). Studies indicate that CHI3L1 is strongly associated with cell survival and cell migration during the drastic tissue remodeling processes by interacting with extracellular matrix components (Ling and Recklies 2004). The canonical (Wnt/β-catenin) pathway is known to play a crucial role in UC-related tumor progression (van Dekken et al. 2007). Reports strongly suggest that CHI3L1 may have a direct but not a secondary role for inflammation-associated tumorigenesis by continuously activating the Wnt/β-catenin canonical signaling pathway in CECs. As demonstrated, CHI3L1 expression is enhanced by proinflammatory cytokine interleukin-6 (De Ceuninck et al. 1998; Mizoguchi 2006), which also has a critical tumor-promoting effect during early colitis-associated cancer tumorigenesis (Grivennikov et al. 2009). The chitin-binding motif (CBM) of CHI3L1 is specifically associated with the CHI3L1-mediated activation of the Akt-signaling in CEC by transfecting the CBM-mutant CHI3L1 vectors in SW480 CECs. Downstream, CHI3L1 enhanced the secretion of IL-8 and TNFα in a dose-dependent manner. The 325 through 339 amino-acids in CBM are crucial for the biological function of CHI3L1 and is a critical region for the activation of Akt, IL-8 production, and for a specific cellular localization of CHI3L1. The activation may be associated with the development of chronic colitis (Chen et al. 2011).

19.7.3 Chitinase 3-Like-1 Protein (CHI3L1) or YKL-40 in Clinical Practice

Anti-Inflammatory Role of CHI3L1 (YKL-40): Chitinase 3-like-1 gene is significantly upregulated in inflamed colon of the dextran sulfate sodium-induced colitis model. CHI3L1 is mainly expressed in colonic epithelial cells and macrophages in the inflamed colon of dextran sulfate sodium-induced colitis. The CHI3L1 possesses an ability to enhance the adhesion and internalization of intracellular bacteria into colonic epithelial cells. In vivo neutralization of CHI3L1 significantly suppressed the development of dextran sulfate sodium-induced colitis by decreasing the bacterial adhesion and invasion into colonic epithelial cells. The CHI3L1 inhibited cellular responses to the inflammatory cytokines IL-1 and TNF-α. Stimulation of human skin fibroblasts or articular chondrocytes with IL-1 or TNF-α in presence of CHI3L1 resulted in a marked reduction of both p38 mitogen-activated protein kinase and stress-activated protein kinase/Jun N-terminal kinase phosphorylation, whereas nuclear translocation of NF-kB proceeded unimpeded. HC-gp39 suppressed the cytokine-induced secretion of MMP1, MMP3 and MMP13, as well as secretion of the chemokine IL-8 (Ling and Recklies 2004). Kawada et al. (2007) provided insight into the physiological role of mammalian chitinases in host/microbial interactions and suggested that inhibition of chitinase activity can be a novel therapeutic strategy of allergic and inflammatory disorder (Kawada et al. 2007). Unexpected roles have been identified for CHI3L1 in intestinal inflammation. While galectin-1 contributes to the suppression of intestinal inflammation by the induction of effector T cell apoptosis, in contrast, galectin-4 is involved in the exacerbation of this inflammation by specifically stimulating intestinal $CD4^+$ T cells to produce IL-6. CHI3L1 enhances the host/microbial interaction that leads to the exacerbation of intestinal inflammation (Mizoguchi and Mizoguchi 2007).

CHI3L1 plays a unique role during the development of intestinal inflammation, the protein is induced in both colonic lamina propria macrophages and CECs during the course of intestinal inflammation in experimental colitis models as well as in patients with IBD (Mizoguchi 2006). It has been suggested that a genetic defect against intracellular bacterial infection is strongly associated with the development of CD. CHI3L1 molecule particularly enhances the adhesion of chitin-binding protein-expressing bacteria to CECs through

the conserved amino-acid residues (Kawada et al. 2008). Therefore, overexpression of CHI3L1 may be strongly associated with the intracellular bacterial adhesion and invasion on/into CECs in CD patients (Xavier and Podolsky 2007). In contrast, in an aseptic condition such as bronchial asthma, epithelium-expressing CHI3L1 seems to play a regulatory role by rescuing Th2-type immune responses (Lee et al. 2009). Further studies are required to understand the exact role of epithelium-expressing CHI3L1 in inflammatory conditions.

CHI3L1 was recently introduced into clinical practice, yet its application is still restricted (Kazakova and Sarafian 2009). CHI3L1 may participate in the innate immune response as it is regarded as an acute phase protein, since its plasma concentration is increased in inflammatory diseases (Chupp et al. 2007; Kronborg et al. 2002; Johansen 2006; Rathcke et al. 2006). The CHI3L1/YKL-40 is induced specifically during the course of inflammation in such disorders as inflammatory bowel disease, hepatitis and asthma and has been found to be either the cause or a biomarker for asthma. When the asthma subjects were stratified, serum CHI3L1 levels in the exacerbation group were higher than those in the stable and control groups (Chupp et al. 2007; Fontana et al. 2010). The CHI3L1 gene is abnormally expressed in the hippocampus of subjects with schizophrenia and may be involved in the cellular response to various environmental events that are reported to increase the risk of schizophrenia. The functional variants at the CHI3L1 locus influence the genetic risk of schizophrenia. CHI3L1 is a potential schizophrenia-susceptibility gene and suggest that the genes involved in the biological response to adverse environmental conditions are likely to play roles in the predisposition to schizophrenia (Zhao et al. 2007).

19.8 Evolution of Mammalian Chitinases (-Like) of GH18 Family

Homologous lectins to chitinases of the glycosyl hydrolase family 18 have been isolated from plants. Insects utilize multiple family 18 chitinolytic enzymes and also non-enzymatic chitinase-like proteins for degrading/remodeling/binding to chitin in different insect anatomical extracellular structures, such as the cuticle, peritrophic membrane, trachea and mouth parts during insect development, and possibly for other roles including chitin synthesis. Drosophila protein database revealed the presence of 18 chitinase-like proteins. Among these, seven are novel chitinase-like proteins that contain four signature amino acid sequences of chitinases, including both acidic and hydrophobic amino acid residues critical for enzyme activity (Zhu et al. 2004a). *D. melanogaster* imaginal disc growth factor proteins stimulate cell proliferation in common with mammalian chitinase-like protein YKL-40, but are only distantly related to mammalian glycoside hydrolase family 18 proteins, displaying around 25 % sequence identity. Chitinases may also affect gut physiology through their involvement in peritrophic membrane turnover. The chitinase from larvae of tomato moth (Lacanobia oleracea) shows 75–80 % identity with other Lepidopteran chitinases. L. oleracea chitinase caused chronic effects when fed, causing reductions in larval growth and food consumption by 60 % (Fitches et al. 2004). A chitinase-like protein from oyster, Clp1, which binds chitin and exhibits similar functional properties to YKL-40, has been described.

Gene duplication and loss according to a birth-and-death model of evolution is a feature of the evolutionary history of the GH18 family. Mammals are not known to synthesize chitin or metabolize it as a nutrient, yet the human genome encodes eight GH18 family members. Some GH18 proteins lack an essential catalytic glutamic acid and are likely to act as lectins rather than as enzymes. Both types of proteins widely occur in mammals although these organisms lack endogenous chitin. Molecular phylogenetic analyses suggest that both active chitinases (chitotriosidase and AMCase) result from an early gene duplication event. Further duplication events, followed by mutations leading to loss of chitinase activity, allowed evolution of chi-lectins. The homologous genes encoding chitinase (-like) proteins are clustered in two distinct loci that display a high degree of synteny among mammals. Despite the shared chromosomal location and high homology, individual genes have evolved independently. Orthologs are more closely related than paralogues, and calculated substitution rate ratios indicate that protein-coding sequences underwent purifying selection. Substantial gene specialization has occurred in time, allowing for tissue-specific expression of pH optimized chitinases and chi-lectins (Bussink et al. 2007). Bussink et al. (2007) reported that several family 18 chitinase-like proteins are present only in certain lineages of mammals, exemplifying evolutionary events in the chitinase protein family (Bussink et al. 2007).

The current human GH18 family likely originated from ancient genes present at the time of the bilaterian expansion (~550 M years). The family expanded in the chitinous protostomes *C. elegans* and *D. melanogaster*, declined in early deuterostomes as chitin synthesis disappeared, and expanded again in late deuterostomes with a significant increase in gene number after the avian/mammalian split. This comprehensive genomic study of animal GH18 proteins reveals three major phylogenetic groups in the family: chitobiases, chitinases/chitolectins, and stabilin-1 interacting chitolectins. Only the chitinase/chitolectin group is associated with expansion in late deuterostomes. Finding that the human GH18 gene family is closely linked to the human MHC paralogon on chromosome 1, together with the recent association of GH18 chitinase activity with Th2 cell inflammation, suggests that its late expansion could be related to an

emerging interface of innate and adaptive immunity during early vertebrate history (Funkhouser and Aronson 2007).

Novel Groups of Fuco-Lectins and Intlectins

20

Rajesh K. Gupta and G.S. Gupta

20.1 F-type Lectins (Fuco-Lectins)

A novel lectin family "F-type" constituted by a large number of proteins exhibit greater multiples of F-type motif, either tandemly arrayed or in mosaic combinations with other domains, including a putative transmembrane receptor that suggests an extensive functional diversification of this lectin family. F-type domains are found in proteins from a range of organisms from bacteria to vertebrates, but exhibit patchy distribution across different phylogenetic taxa suggesting that F-type lectin genes have been selectively lost even between closely related lineages, and making it difficult to trace the ancestry of the F-type domain. F-type lectins were first characterized in eels, which are teleost fish. Teleost fish species commonly have a number of F-type lectins (containing multiple tandem F-type domains) resulting from gene duplication events that have occurred independently in different teleost fish lineages. The F-type domain has clearly gained functional value in fish, whereas the fate of F-type domains in higher vertebrates is not clear, rather it has become defunct. While the functions of many F-type lectins have not yet been characterized, a pathogen-recognition role has been established for F-type lectin-like proteins in both invertebrates (e.g. the horseshoe crab *Tachypleus tridentatus*) and vertebrates (e.g. the Japanese eel *Anguilla japonica*). The F-type lectin fold from *Anguilla anguilla* agglutinin (AAA) (Bianchet et al. 2002) is widely distributed in proteins from horseshoe crabs to amphibians, with some representatives proposed to play a role in immunity (Honda et al. 2000; Saito et al. 1997). Although AAA and the rat MBL specifically recognize terminal L-fucose, they do so through differing binding interactions (Ng et al. 1996), which illustrate convergent functional properties among unrelated lectin families. Interestingly, the F-type fold is also shared with several proteins of distinct functional properties, including C-terminal domain of blood coagulation factors V and VIII, C-terminal domain of bacterial sialidases, N-terminal domain of fungal galactose oxidase, a human ubiquitin ligase subunit APC10/DOC1, a domain of single-strand DNA repair protein XRCC1, the b1 domain of neuropilin, and yeast allantoicase (Odom and Vasta 2006) pointing towards an ancient origin for F-type fold. The structural analogy of these seemingly unrelated proteins is indicative of the archaic origin of this lectin fold. Proteins from fish and amphibians with a range of domain organizations contain F-type domains, most of which are likely to bind fucose based on the conservation of key residues. The single-domain F-type lectins found in eels, which represent an early branch of teleost fish, are generally not found in modern teleosts, having been replaced by tandem two-domain proteins in species including striped bass (*Morone saxatilis*), zebrafish (*Danio rerio*), pufferfish (*Tetraodon nigroviridans* and *Fugu rubripes*) and stickleback (*Gasterosteus aculeatus*). In two-domain F-type lectins, both domains feature the fucose and Ca^{2+}-binding residues, but the N-terminal domain lacks one inter-strand disulfide bond, and the C-terminal domain lacks the adjacent cysteines in loop 4, which may affect sugar binding. In four-domain tandem F-type lectins, which are exclusive to trout species (e.g. *Oncorhynchus mykiss*), the first and second domains lack the adjacent cysteines, and the second domain has strikingly lost all three residues from His/Arg/Arg triad, suggesting that fucose binding has been lost in this domain.

20.1.1 F-type Lectins in Mammalian Vertebrates

20.1.1.1 Characterization

The fate of F-type domains in higher vertebrates is not clear. Two genes encoding three-domain F-type proteins are predicted in the genome of the opossum (*Monodelphis domestica*), an early-branching mammal. The genes are present in tandem within a genomic region that is absent in placental mammals and in birds, but which in *Xenopus tropicalis* contains a gene encoding a three-domain F-type lectin ~40 % identical to the opossum sequences. In humans

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_20, © Springer-Verlag Wien 2012

this region would lie within chromosome 12, between the conserved genes *Wbp11* and *Foxj2*. Some remnants of F-type lectin genes are evident in this region of human genome. Human macrophages express a membrane lectin, or sugar-specific receptor, which specifically mediates the binding and endocytosis of mannose- and fucose-terminated glycoproteins and is involved in the phagocytosis of pathogens (Leu et al. 1985). A similar lectin activity was sought on cultured human DC (Avraméas et al. 1996).

A lectin with a high affinity for fucose residues has been purified from rat liver. The rat hepatic fucose binding protein (FBP) contains two polypeptide subunits with M_r of 88 kDa and 77 kDa. Peptide maps of the subunits, however, showed that they are structurally very similar but distinct from other rat hepatic lectins (Lehrman et al. 1986). The hepatic FBP has a high affinity for Fuc-BSA and galactosyl-BSA but a low affinity for N-acetylglucosaminyl-BSA. In contrast, the mannose/N-acetylglucosamine lectin binds N-acetylglucosaminyl-BSA and Fuc-BSA but not galactosyl-BSA (Lehrman and Hill 1986). The interaction between a rat alveolar macrophage lectin (M_r of 180 kDa) and its ligands is dependent on Ca^{2+} over a optimal pH range. The apparent K_D for fucosyl bovine serum albumin is 20.4×10^{-10} M. D-Mannose, L-fucose, and N-acetyl-D-glucosamine were the most effective inhibitors, and D-galactose was the least. The lectin isolated from alveolar macrophages is widely distributed in other rat tissues. Hepatocytes are devoid of this lectin, but hepatic Kupffer cells and endothelial cells contain significant amounts (Haltiwanger and Hill 1986). Of all rat tissues examined, only liver contained the fucose-binding lectin, whereas both liver and blood serum contained the mannose/N-acetylglucosamine lectin. The fucose-binding lectin was neither responsible for the uptake nor more than one lectin was acting. With the identification of another lectin (Mr = 180 kDa) only two lectins appeared to be involved. The hepatic mannose/N-acetylglucosamine lectin had a higher affinity for L-fucosyl-bovine serum albumin than the majority of the lectin in hepatocytes. This lectin, called the high affinity form, showed K_D of 2.3×10^9 for L-fucosyl-bovine serum albumin compared to 3.5×10^8 for the normal form. The two forms, however, had identical molecular weights (32 kDa) under reducing and nonreducing conditions and produced identical peptide maps after protease digestion (Haltiwanger et al. 1986).

20.1.1.2 Fucose Binding Proteins/Lectins in Fertilization

Bolwell et al. (1979) suggested that fertilization in *Fucus serratus* is based on an association between fucosyl- and mannosyl-containing ligands on the egg surface and specific carbohydrate-binding receptors on the sperm surface like *Fucus serratus,* the fucose-binding proteins (FBP) have been identified in mammamlian spermatozoa. In boar spermatozoa, during ionophore induced early stage acrosome reaction (AR), the FBP is first localized at the border between equatorial segment and anterior acrosome. With the propagation of AR the FBP was dramatically expressed and visible over the entire surface of acrosome and equatorial segment. Results suggested that FBP is responsible for the specific binding of the ghost-sperm unit to the zona pellucida (Friess et al. 1987). Oviductal sperm in cattle (Bos Taurus) revealed a prominent FBP of 16.5 kDa, which was labeled over live uncapacitated sperm acrosome, while capacitated sperm did not. The presence of a Le^a-binding protein with an apparent mass of 16.5 kDA appeared to originate from seminal plasma (Ignotz et al. 2001).

20.2 F-type Lectins in Fish and Amphibians

20.2.1 Anguilla Anguilla Agglutinin (AAA)

The fucose-binding lectins are secretory proteins and exhibit only weak similarities to frog pentraxin, horseshoe crab tachylectin-4, and fly fw protein. There are at least seven closely related members whose messages are abundantly expressed in liver and in significant levels in gill and intestine. The serum fucolectins are derived from liver. The message levels were increased by lipopolysaccharide, suggesting a role for fucolectins in host defense. Eel fucolectins have a SDS-resistant tetrameric structure consisting of two disulfide-linked dimers (Honda et al. 2000). Eel serum lectins have been useful as anti-H hemagglutinins and also in lectin histochemistry as fucose-binding lectins (fucolectins). This domain of unknown function has been identified in Japanese eel (Anguilla japonica) fucolectins and at least one frog pentraxin. The AAA acts as a defensive agent, recognizes blood group fucosylated oligosaccharides including A, B, H and Lewis B-type antigens, but does not recognize Lewis A antigen. AAA has low affinity for monovalent haptens.

20.2.1.1 AAA: A Homotrimer with Three Fucose Binding Sites

AAA is a non-covalent homotrimer in which all three fucose binding sites are oriented in the same direction. This arrangement resembles that of the C-type CRDs in mannose binding protein and may confer high affinity for pathogen surfaces displaying repetitive arrays of oligosaccharide ligands. The AAA F-type CRD has a β-barrel structure, with one three-stranded β-sheet and one five-stranded sheet, connected by two disulfide bonds. One end of the barrel features five loop regions (here termed loops 1–5) that form a ring enclosing the site of fucose binding, which is a positively-charged hollow (Fig. 20.1). A Ca^{2+} ion is bound within a sub-domain that largely lacks regular

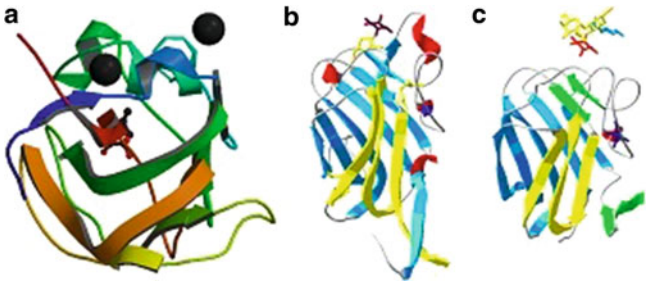

Fig. 20.1 (**a**) Structure of Anguilla anguilla agglutinin asymmetric unit (PDB ID 1 K12); (**b**) Fucose Binding lectin with bound fucose: β-strands in three-stranded sheet are colored *yellow* and those in the five-stranded sheet are colored *blue*. 310 helices are colored *red*. The fucose ligand is shown in *purple* and the Ca^{2+} ion in *blue* (PDB ID: 1 K12); (**c**) Structure of F-type domain 1 from *S. pnemoniae* SP2159 with bound blood group A tetrasaccharide. B-strands in the three-stranded sheet are colored *yellow*, those in the five-stranded sheet are colored *blue*, and those in other sub-structures are colored *green*. The 310 helix is colored red. Ca^{2+} is shown in *blue*. The ligand is colored by monosaccharide: *yellow*, Gal/GalNac; *blue*, Glc; *red*, Fuc (PDB ID: 2J1U)

secondary structure, and stabilization of tertiary or quaternary structure by Ca^{2+} may enhance sugar binding activity in AAA and other F-type lectins. Within the positively-charged hollow, side chains from a triad of residues characteristic of fucose binding make hydrogen bonds to the 3-OH, 4-OH and ring oxygen of fucose. In AAA these residues—a histidine in loop 3 and two arginine residues in loop 4—are present in the fucose binding sequence motif **H**. . .**R**GDCCGE**R**, which is found in other F-type domains in more general form **H**. . .**R**XDXXXX(**R**/**K**), where the gap between **H** and **R** is around 26 residues. Carbon atoms C1 and C2 of the fucose ring make van der Waals contacts with the adjacent disulfide-bonded cysteine residues in loop 4 (**H**. . .**R**GDCCGE**R**), and the methyl group (C6) is accommodated in a hydrophobic pocket formed by side chains from loops 1 and 2. Other monosaccharide ligands (e.g. 3-O-methyl-D-galactose, 3-O-methyl-D-fucose) are bound through the same set of interactions. Oligosaccharide ligands, which include the blood group antigens H and Le^a, interact with AAA primarily through the terminal fucose, but non-terminal saccharide residues also interact with a subset of the residues involved in fucose binding as well as additional residues from loop regions 1, 2 and 4. In the seven fucolectins from the Japanese eel (*Anguilla japonica*), various combinations of residue substitutions in loops 1 and 2 open up the methyl binding pocket and/or allow for polar interactions, which may adjust the oligosaccharide binding specificities of these lectins and tune them to recognize different pathogens. Non-eel F-type domains have a shorter loop 1, which may remove some interaction with oligosaccharide ligands and broaden oligosaccharide specificity.

20.2.1.2 Glycans Interacting AAA

AAA is suggested to be associated with innate immunity by recognizing disease-associated cell surface glycans such as bacterial LPSs, and has been widely used as a reagent in hematology and glycobiology. Among the glycans tested, AAA reacted well with nearly all human blood group A_h (GalNAcα1 → 3[L Fucα1 → 2]Gal), B_h (Galα1 → 3[L Fucα1 → 2]Gal), (H LFucα1 → 2Gal) and Le^b (Fucα1 → 2 Galβ1 → 3[Fucα1 → 4]GlcNAc) active glycoproteins (gps), but not with blood group Le^a (Galβ1 → 3[Fucα1 → 4] GlcNAc) substances, suggesting that residues and optimal density of α1-2 linked LFuc to Gal at the non-reducing end of glycoprotein ligands are essential for lectin-carbohydrate interactions. Blood group precursors, Galβ1-3GalNAc (T), GalNAcα1-Ser/Thr (Tn) containing glycoproteins and *N*-linked plasma gps, gave only negligible affinity. Among the mammalian glycotopes tested, A_h, B_h and H determinants were the best, being about 5 to 6.7 times more active than LFuc, but were weaker than *p*-nitrophenylαFuc indicating that hydrophobic environment surrounding the LFuc moiety enhance the reactivity. The hierarchy of potency of oligo- and mono-saccharides can be ranked as follows: *p*-nitrophenyl-αFuc > A_h, B_h and H > LFuc > LFucα1 → 2 Galβ1 → 4Glc (2′-FL) and Galβ1 → 4[L Fucα1 → 3]Glc (3′-FL), while LNDFH I (Le^b hexa-), Le^a, Le^x (Galβ1 → 4 [Fucα1 → 3]GlcNAc), and LDFT (gluco-analogue of Le^y) were inactive. From the present observations, it can be concluded that the combining site of AAA should be a small cavity-type capable of recognizing mainly H/crypto H and of binding to specific polyvalent ABH and Le^b glycotopes (Wu et al. 2004).

20.2.1.3 Comparison of AAA with MBL and UEA-1

MBL from eel serum has a M_r of ~246 kDa and is composed of identical subunits of ~24 kDa, two of each were always covalently linked. AAA, a FBL from eel serum, had a M_r of about 121 kDa and consisted four subunits of 30 kDa, which was made of two identical subunits of 15 kDa. Upon isoelectric focusing MBL displays four bands ranging from pH 4.8 to 5.2. FBL shows 17–20 bands between pH 5.5 and 6.2. Hemagglutination activity of MBL was inhibited only by mannan, whereas FBL activity was inhibited by several glycosubstances. MBL and FBL activity was constant between pH 4–5 and 10. Temperatures above 55º C totally destroyed MBL activity whereas FBL activity remained constant up to 75 º C (Gercken and Renwrantz 1994).

The binding site of AAA has been compared with related fucose-specific lectin from *Ulex europaeus* (UEA-I). Both AAA and lectin from *Ulex europaeus* (UEA-I) recognize Fuc α1-2Gal β-HSA. In addition, AAA cross-reacts

with neoglycolipids bearing lacto-N-fucopentaose (LNFP) I [H type 1] and II [Le^a], and lactodifucotetraose (LDFT) as glycans. UEA-I, on the other hand, binds to a LDFT-derived neoglycolipid but not to the other neoglycolipids tested. According to these results, AAA reacts with fucosylated type 1 chain antigens, whereas UEA-I binds only to the α1-2-fucosylated LDFT-derived neoglycolipid. AAA showed a broad reaction in the superficial pyloric mucosa from secretors and non-secretors, but AAA reactivity was more pronounced in Le(a^+b^-) individuals. On the other hand, UEA-I stained the superficial pyloric mucosa only from secretor individuals. Both reacted with most human carcinomas of different origin (Baldus et al. 1996).

20.2.2 FBP from European Seabass

A Binary Tandem Domain F-Lectin from Striped Bass (Morone Saxatilis): The FBP32 is a recently-characterized two-domain F-type lectin from striped bass, which is expressed abundantly in liver, and to a minor extent in other tissues. FBP32 is present in serum and up-regulated by inflammatory challenge. Gene duplication has produced at least one FBP32 paralogue (the more widely expressed FBP32II) in striped bass, while multiple two-domain F-type lectins are present in other fish species as a result of independent gene duplications. FBP32 binds specifically, in a Ca^{2+}-independent manner, to terminal fucose, but does not share the specificity of AAA for the H and Le^a antigens. FBP32 is monomeric and the presence of two F-type domains within one polypeptide may serve to increase ligand binding affinity, as an alternative mechanism to the oligomerization seen in AAA. Odom and Vasta (2006) described the molecular characterization of a unique L-Fuc-binding lectin from serum of striped bass (*Morone saxatilis*) that not only shares the CRD motif of AAA but possesses two similar yet distinct CRDs in the polypeptide subunit. In contrast with the N-terminal CRD, which presents the highest similarity to the AAA CRD, the C-terminus-CRD presents unique features. Among F-type tandem lectins, MS-FBP32 and other tandem binary homologues appear unique in that although their N-terminal domain shows close similarity to the fucose recognition domain of the eel agglutinin, their C-terminal domain exhibits changes that potentially could confer a distinct specificity for fucosylated ligands. In contrast with the amniotes, in which F-type lectins appear conspicuously absent, the widespread gene duplication in teleost fish suggests these F-type lectins acquired increasing evolutionary value within this taxon.

The crystal structure of the complex of MS-FBP32 with L-fucose shows a cylindrical 81-A-long and 60-A-wide trimer divided into two globular halves: one containing N-terminal CRDs (N-CRDs) and the other containing C-terminal CRDs (C-CRDs). The resulting binding surfaces at the opposite ends of the cylindrical trimer have the potential to cross-link cell surface or humoral carbohydrate ligands. The N-CRDs and C-CRDs of MS-FBP32 exhibit significant structural differences, suggesting that they recognize different glycans. Analysis of the carbohydrate binding sites provides the structural basis for the observed specificity of MS-FBP32 for simple carbohydrates and suggests that the N-CRD recognizes more complex fucosylated oligosaccharides and with a relatively higher avidity than the C-CRD. Modeling of MS-FBP32 complexed with fucosylated glycans that are widely distributed in nature suggests that the binary tandem CRD F-type lectins functions as opsonins by cross-linking "non-self" carbohydrate ligands and "self" carbohydrate ligands, such as sugar structures displayed by microbial pathogens and glycans on the surface of phagocytic cells from the host (Bianchet et al. 2010) (Fig. 20.2).

A lectin specific for fucose and galactose from serum of *Dicentrarchus labrax* showed hemagglutinating activity (HA) against rabbit erythrocytes. The HA was calcium-independent and comprised of two components, but only 34 kDa component (DLL2) showed activity against rabbit erythrocytes. The HA is a dimeric structure stabilized by disulfide bonds. The Ca^{2+}-independent fucose-binding specificity, a significant amino acid sequence homology of the N-terminal end, and cross-reaction of eel fucolectin with antibodies to DLL2 suggested that this lectin belongs to fucolectin family (Cammarata et al. 2001).

20.2.3 Other F-type Lectins in Fish

A F-type lectin (DlFBL) has been isolated from sea bass (Dicentrarchus labrax) serum. DlFBL exhibits two tandemly arranged CRDs that display F-type sequence motif. DlFBL is specifically expressed and localized in hepatocytes and intestinal cells. Exposure of formalin-killed *E. coli* to DlFBL enhanced their phagocytosis by D. labrax peritoneal macrophages relative to the unexposed controls, suggesting that DlFBL may function as an opsonin in plasma and intestinal mucus (Salerno et al. 2009).

A fucose-binding lectin, designated SauFBP32, was purified from the serum of the *gilt head bream Sparus* with subunit M_r of 35 and 30 kDa under reducing and non-reducing conditions, respectively. The native lectin is a monomer under the selected experimental conditions and agglutinated rabbit erythrocytes (Cammarata et al. 2007). A 23 kDa L-fucose-binding lectin from serum of Nile tilapia (*Oreochromis niloticusL.*), designated as TFBP, was isolated by Argayosa and Lee (2009). The fucose-binding proteins were detected in the soluble protein extracts from the gills, gut, head kidneys, liver, serum and spleen using a fucose-binding protein. The fucose-binding lectin from gill

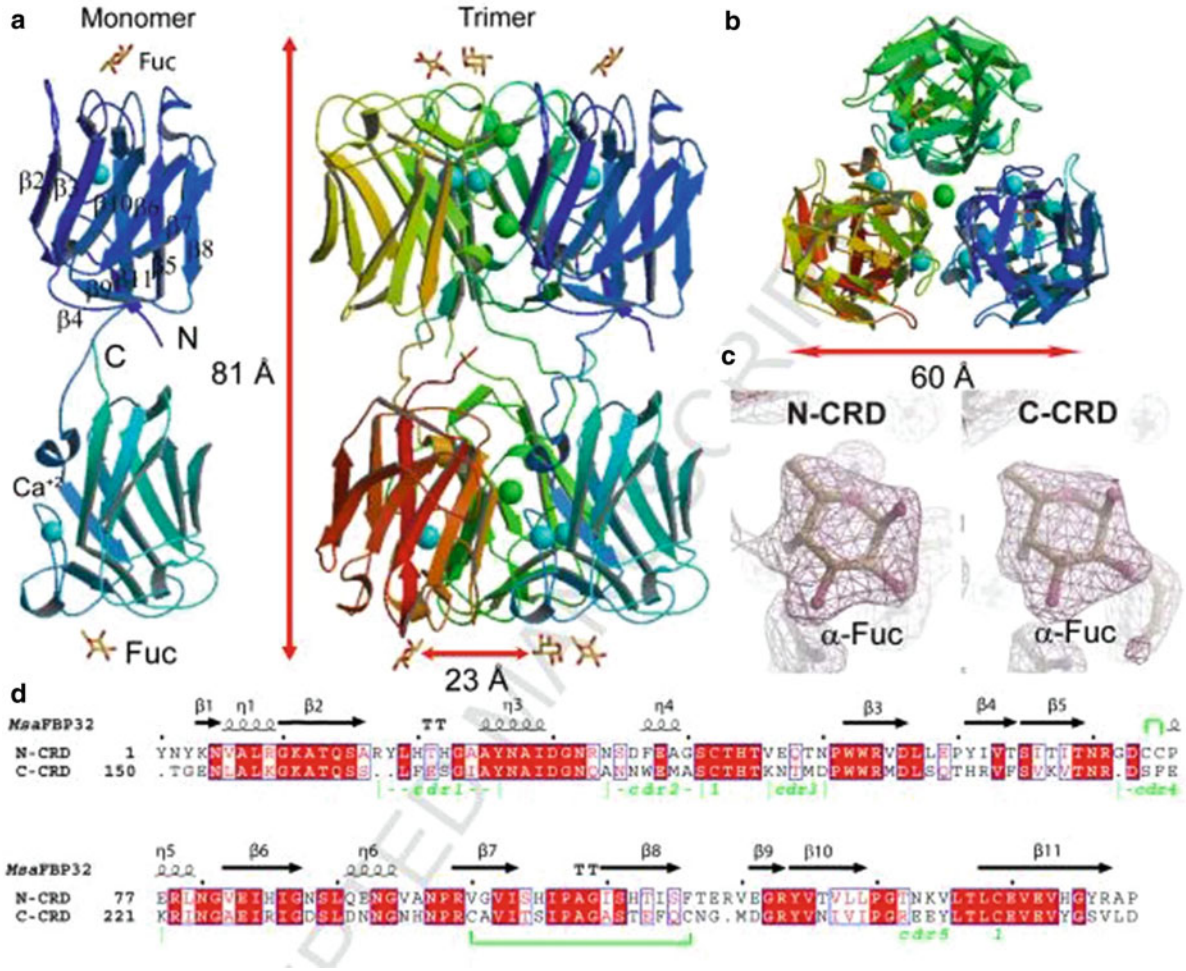

Fig. 20.2 *Structure of* MS*FPB32:* (**a**) View of MSFPB32 asymmetric unit of the crystal (trimer) and of an isolated monomer. (**b**) top view of the ASU trimer (N-CRD side). Monomers are colored with different hues. L-Fucose atoms are colored *yellow* for carbon atoms, and *red* for oxygen atoms. Ca^{+2} ions are colored *cyan* and Cl^{-} ions are colored *green*. (**c**) 2mFo-DFc sigmaA-weigthed electronic density at the CRDs binding sites. The *magenta* map is contoured at 0.35 e/Å^3. (**d**) Sequence alignment of the two MSFPB32 CRDs resulting in a 48.6 % and a 51 % of identity for the N- and the C-CRD respectively. The first line indicates the observed secondary structure elements of each CRD. Coils indicate 3–10 helices, T indicates turns and arrows indicate β-sheets strands. *Red* solid boxes over the sequences indicate identity and boxed *red* characters indicate amino acids with similar polarity. The last line shows the positions of the different CRDs. Disulfide bridges are indicated either by number "1" under the connected cysteines or a green line between them when they are within one CRD (Printed with permission from Bianchet et al. 2010 © Elsevier)

of bighead carp (*Aristichthys nobilis*) designated GANL had a M_r of 37 kDa under reducing conditions. GANL is a homomultimeric glycoprotein with a native molecular mass of 220 kDa and a carbohydrate content of ~13.4 %. The purified lectin only agglutinated rabbit native erythrocytes, and did not require Ca^{2+}. Its activity was inhibited by only fucose. GANL contains a high proportion of Asp, Glu, Leu, Val, and Lys. The 10 residues of N-terminal region were AGEQGGQCSA. GANL agglutinates and inhibits the growth of *Vibrio harveyi* but has no antifungal activity (Pan et al. 2010).

20.2.4 F-Type Lectins in Amphibians

Xenopus species possess proteins containing F-type domains in copies of 1 (*X laevis* X-epilectin), 2 (*X tropicalis* II-FBPL), 3 (*X tropicalis* III-FBPL) or 4 (*X laevis* II-FBPL), as well as 5 F-type domains in combination with a pentraxin domain (*X laevis* PXN-FBPL). *Xenopus* F-type domains sometimes lack fucose-binding His residue and/or a small number of Ca^{2+}-binding residues. A posterior epidermal marker, X-epilectin in *X. laevis* gene encodes for a fucolectin, which specifically binds fucose residues. The expression of this gene is switched on during gastrulation

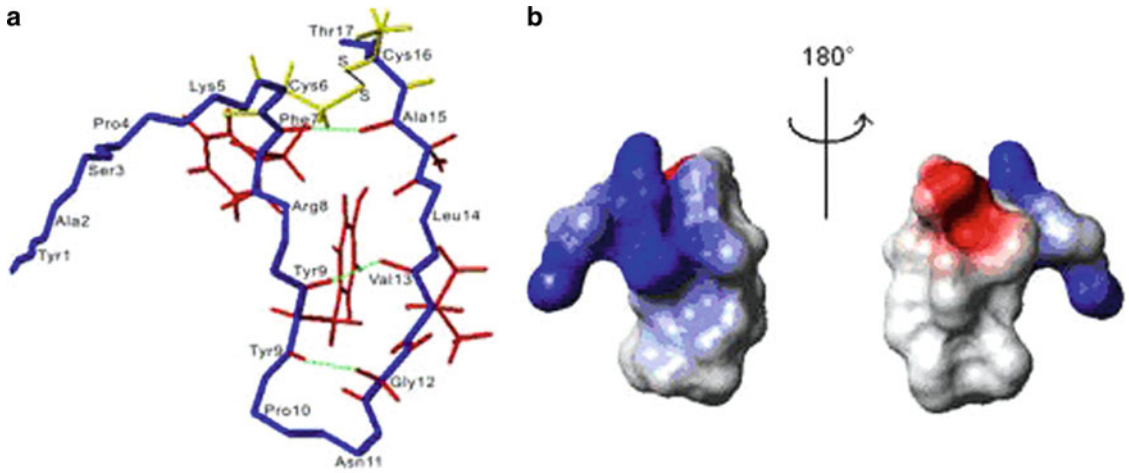

Fig. 20.3 The solution structure of odorranalectin. Backbone, side-chains of residues 4–16 and side-chains of residues 1–3, 4 were shown in *blue*, *red* and *green*, respectively. (**a**) The mean structure calculated from the 20 lowest-energy structures which highlighted three hydrogen bonds (*green broken lines*) and one disulfide bonds (*black solid line*). (**b**) Electrostatic surface of odorranalectin. Positively charged region and negatively charged region were shown in *blue* and *red*, respectively (Adapted from Li et al. 2008)

and up-regulated during neurula stages and found expressed ubiquitously throughout the epidermis. In adult, X-epilectin is mainly expressed in intestinal components, kidney, spinal cord and skin. Change of fate of animal caps into cement gland or dorsal mesoderm induces a down-regulation of X-epilectin expression in explants treated respectively with ammonium chloride and activin A. X-epilectin expression is down-regulated by Noggin and tBR, an effect which is inhibited by BMP4 over-expression, suggesting X-epilectin expression is mediated by BMP signaling pathway (Massé et al. 2004).

A lectin-like peptide named odorranalectin was identified from skin secretions of *Odorrana grahami*. The lectin was composed of 17 aa with a sequence of YASPKCFRY-PNGVLACT. L-fucose could specifically inhibit the haemagglutination induced by this lectin. In mice, odorranalectin mainly conjugated to liver, spleen and lung. The cyclic peptide of odorranalectin in solution NMR adopts a β-turn conformation stabilized by one intramolecular disulfide bond between Cys6-Cys16 and three hydrogen bonds between Phe7-Ala15, Tyr9-Val13, Tyr9-Gly12 (Fig. 20.3). NMR titration and mutant analysis showed that residues K5, C6, F7, C16 and T17 on odorranalectin consist of binding site of L-fucose. The structure of odorranalectin in bound form is more stable than in free form. Smaller peptides which can mimic the function of lectins are promising candidates for drug targeting (Li et al. 2008).

20.3 F-type Lectins in Invertebrates

20.3.1 Tachylectin-4

The F-type domain is found in a range of invertebrate species, often within lineage-specific protein contexts. Sugar binding has been demonstrated in an F-type lectin from the Japanese horseshoe crab *Tachypleus tridentatus*. Like many invertebrates, the horseshoe crabs hemolymph fluid, containing solutes and hemocytes, bathes the internal organs. The horseshoe crab hemocytes are a single type of granular cell, which mounts an innate immune response upon recognition of bacterial LPS. Tachylectin-4 from horseshoe crab hemocyte has Ca^{2+} dependendent hemagglutinating activity against human A-type erythrocytes and was more potent than hemocyte lectin with an affinity to *N*-acetylglucosamine, tachylectin-2. The tachylectin-4 is an oligomeric glycoprotein of 470 kDa, composed of subunits of 30 and 320.5 kDa. The activity was inhibited by L-Fucose, *N*-acetylneuraminic acid and bacterial S-type LPS but not by R-type LPS lacking O-antigen. Colitose (3-deoxy-L-fucose), a unique sugar present in the O-antigen of *E. coli* O111:B4 with structural similarity to L-fucose, is the most probable candidate for a specific ligand of tachylectin-4. The ORF of 1344-bp cDNA coding for tachylectin-4 coded for the mature protein with 232 amino acids. Tachylectin-4 is homologous to the

NH2-terminal domain with unknown functions of *Xenopus laevis* pentraxin 20.

20.3.2 F-type Lectins from *Drosophila melanogaster*

Furrowed and CG9095 from *Drosophila melanogaster* contain single F-type domains within an architecture that also includes a C-type lectin-like domain and a number of complement control repeats. These proteins, which have homologs in other insects (e.g. bee and mosquito) are the only F-type proteins which have transmembrane domains. Signaling by these receptors is influenced by O-fucosylation, but the F-type domains in the receptors do not contain complete His/Arg/Arg triads (the C-type lectin-like domain in these receptors is also unlikely to bind sugar). It has been stated that F-type domains are not present in the nematode worm *Caenorhabditis elegans*, but a highly divergent F-type domain, which is very unlikely to bind fucose, is present in the CG9095 orthologue, C54G4.4. The divergence of F-type domains between CG9095 proteins in different species is suggestive of a non-sugar-binding function of the F-type domain in these receptors.

20.3.3 F -Type Lectins in Sea Urchin

In the sea urchin *Strongylocentrotus purpuratus*, a single F-type domain is present in complex protein architectures, as well as in a simple single-domain fucolectin. The complex proteins include CRL, which is involved in the complement system, and a protein containing a CCP and an EGF domain, both of which have very similar F-type domains, and a protein containing scavenger receptor Cys-rich, Kringle and other domains. F-type domains in the sea urchin are distinctive due to a number of insertions and the absence of fucose-binding His residue and adjacent cysteines. The sea urchin lectin from *Toxopneustes pileolus* is galactose and fucose specific. Incubation of rat peritoneal mast cells with this lectin in presence of CaCl2 inhibited the histamine release induced by GlcNAc-specific *Datura stramonium* agglutinin (DSA). It is suggested that the lectin binds to D^{+}-Gal residues of DSA to interfere with mast cell activation induced by DSA, a glycoprotein with arabinose and Gal residues (Suzuki-Nishimura et al. 2001). Discoidin I and discoidin II are N-acetylgalactosamine (GalNAc)-binding proteins from *Dictyostelium discoideum*. They consist of two domains: an N-terminal discoidin domain and a C-terminal H-type lectin domain. The N-terminal discoidin domain presents a structural similarity to F-type lectins such as eel agglutinin, where an amphiphilic binding pocket suggests possible carbohydrate-binding activity (Mathieu et al. 2010).

20.3.4 Bindin in Invertebrate Sperm

In free-spawning, invertebrate's sperm–egg incompatibility is a barrier to mating between species, and divergence of gamete recognition proteins (GRPs) can result in reproductive isolation. Bindin is a major protein for species-specific recognition between sperm and congenetic egg during fertilization in many free-spawning marine invertebrates. Bindins have identical 24-residue signal peptides and conserved 97-residue N-terminal sequences, and they differ in mass because of the presence of between 1 and 5 tandemly repeated 134-residue fucose-binding lectin (F-lectin) domains. Oyster bindin is a single copy gene, but F-lectin repeat number and sequence are variable within and between individuals. Eight residues in F-lectin fucose-binding groove are subject to positive diversifying selection, indicating a history of adaptive evolution at lectin's active site. There is one intron in middle of each F-lectin repeat, and recombination in this intron creates many combinations of repeat halves. Alternative splicing creates many additional size and sequence variants of the repeat array. Males contain full-length bindin cDNAs of 5 possible sizes, but only one or two protein mass forms exist in each individual. Sequence analysis indicates that positive selection, alternative splicing, and recombination can create thousands of bindin variants within *C. gigas*. The extreme sequence variation in F-lectin sequence of oyster bindin within-species is a novel finding (Springer et al. 2008). The full-length bindin cDNA from oyster *Crassostrea angulata* comprises 1,049 bp with a 771-bp ORF encoding 257 amino acids. The deduced amino acid sequence contained a putative signal peptide of 24 amino acids. The length of the bindin genomic DNA was 8,508 bp containing four exons and three introns. Three haplotypes of F-lectin repeat were detected from seven sequences of F-lectin repeat of six male oysters. Intron-4 may play an important role in recombination. The amount of intraspecific polymorphism in male GRPs may be a consequence of the relative efficiency of local (molecular recognition) and global (electrical, cortical, and physical) polyspermy blocks that operate during fertilization (Moy et al. 2008; Wu et al. 2010).

20.4 F-type Lectins in Plants

The fucose binding proteins extracted from Lotus tetragonolobus seeds consists of two distinct classes of components which correspond to tetrameric glycoproteins of 118–120 kDa with potent temperature dependent

hemagglutinating activity and a highly aggregated dimeric component of 58 kDa with macrophage activating properties (Leu et al. 1980). Immobilized fucose-binding lectin Lotus tetragonolobus agglutinin (LTA1), also known as lotus lectin LTA is effective in isolating glycans containing the Le^x antigen and is useful in analyzing specific fucosylation of glycoconjugates (Yan et al. 1997). A well ordered, two-dimensional lattice is formed from fucose-specific isolectin A from Lotus tetragonolobus cross-linked with difucosyllacto-N-neohexaose, an oligosaccharide possessing the Le^x determinant, which is an oncofetal antigen. Using the symmetry and dimensions of the lattice and its appearance in filtered electron micrographs, molecular models were used to determine the orientation of the lectin in the lattice, and to define the range of lectin-oligosaccharide interactions consistent with the structural data (Cheng et al. 1998). Detailed discussion on plant lectins is beyond scope of this book.

20.5 F-type Lectins in Bacteria

The F-type domain is found in a diverse type of bacterial species, in a variety of architectural contexts. Bacterial F-type domains frequently conserve the fucose binding motif, but they do not include disulfide bonds. Mutagenesis experiments have suggested that genes encoding putative glycoside hydrolases are necessary for full virulence of gram positive *S. pneumonia* in a murine lung model of pneumonia. One such gene (SP2159) of *S. pneumoniae* TIGR4 is "fucolectin-related protein" but here called SpGH98. This gene is part of a fucose utilization operon that is conserved among three sequenced strains of *S. pneumoniae*. This protein is a 1038-amino acid protein of which the ~600 amino acid N-terminal region shows amino acid sequence identity with family glycoside hydrolase 98 (GH98). Following GH98 catalytic module is a triplet of modules (Fig. 20.4) which have ~ 50–60 % identity with one another and ~25 % amino acid sequence identity to AAA (Bianchet et al. 2006). This protein contains a C-terminal triplet of fucose binding modules that have significant amino acid sequence identity with the Anguilla anguilla fucolectin. Boraston et al. (2006) dissected the modular structure of SpGH98 by heterologous production of two single modules (SpX-1 and SpX-3), a tandem construct (SpX-20.2) and the triplet (SpX-20.2.3). Functional studies of these fucose binding modules reveal binding to fucosylated oligosaccharides and suggest the importance of multivalent binding. The crystal structures of ligand bound forms of one fucose binding module uncovered the molecular basis of fucose, ABH blood group antigen, and LeY antigen binding. These studies, extended by fluorescence microscopy, showed specific binding to mouse lung tissue

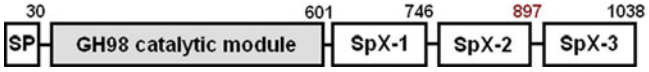

Fig. 20.4 Modular arrangement of SpGH98. The number above the box shows the number of amino acid residue that defines the module boundaries. SP denotes the signal peptide (Boraston et al. 2006)

and defined a new family of carbohydrate binding modules (CBM) now classified as family 47 (Boraston et al. 2006).

Among other Gram-positive bacteria, an F-type domain is found in a protein from *Solibacter usitatus* Ellin6076, combined with a number of bacterial immunoglobulin-like domains and FG-GAP repeats. A lectin is associated with the bacterial cell surface of Rhizobium lupini strain LL13 with a Mr ~19,000. This protein specifically aggregated L-Fuc-BSA-coated microspheres (Wisniewski et al. 1994). Among Gram-negative purple bacteria, an F-type domain follows the structurally similar coagulation factor V/VIII domain in a protein from Saccharophagus degradans 2–40, an organism which degrades a range of polysaccharide substrates, whereas in *Acidiphilium cryptum* JF-5 an F-type domain is present at the C-terminus of the fucolectin tachylectin-4 pentraxin-1 protein, and in Gluconobacter oxydans 621 H F-type domains are present in the proteins GOX0967 and GOX0982. Among bacteria of the planctomycetes phylum, an F-type domain is present at the centre of a large protein that is a periplamic component of a sugar transport system in *Blastopirellula marina* DSM 3645, and a more distantly related domain is present in a probable cytochrome c precursor (NPβ868124) in *Rhodopirellula baltica* SH 20.

PA-IIL is a fucose-binding lectin from *Pseudomonas aeruginosa* that is closely related to the virulence factors of the bacterium and has high affinity for the monosaccharide ligand. Structural studies revealed a new carbohydrate-binding mode with direct involvement of two calcium ions (Mitchell et al. 2002). The crystal structure of the tetrameric PA-IIL in complex with fucose and calcium allowed a proposal which suggested hydrogen-bond network in the binding site. Computational methods indicated that extensive delocalization of charges between the calcium ions, the side chains of the protein-binding site and the carbohydrate ligand is responsible for the high enthalpy of binding and therefore for the unusually high affinity observed for this unique mode of carbohydrate recognition (Mitchell et al. 2005). Mutagenesis of amino acids forming the specificity binding loop allowed identification of one amino acid that is crucial for definition of lectin sugar preference. Altering specificity loop amino acids causes changes in saccharide-binding preferences of lectins derived from PA-IIL, via creation or blocking possible binding interactions (Adam et al. 2007).

The fucose-specific lectin LecB is implicated in tissue binding and biofilm formation by the opportunistic pathogen

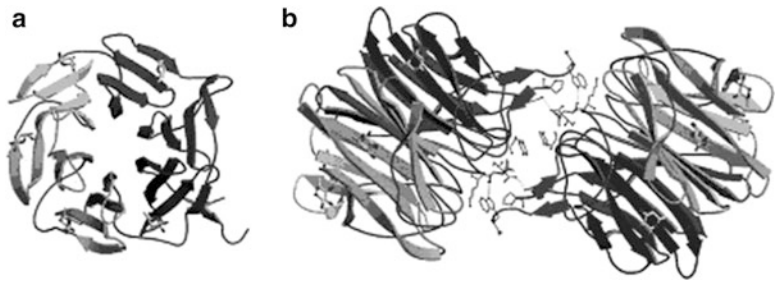

Fig. 20.5 (**a**) Ribbon diagram of monomer A of AAL complexed with fucose shown as sticks. (**b**) Dimer of AAL with stick representation of the amino acids involved in the interaction of monomers (Adapted with permission from Wimmerova et al. 2003 © The American Society for Biochemistry and Molecular Biology)

Pseudomonas aeruginosa, which causes severe respiratory tract infections mainly in immuno-compromised patients or cancer patients undergoing chemotherapy (Kolomiets et al. 2009). The plant pathogen *Ralstonia solanacearum*, which causes lethal wilt in many agricultural crops, produces a potent L-fucose-binding lectin (RSL: subunit Mr 9.9 kDa) exhibiting sugar specificity similar to that of PA-IIL of the human aggressive opportunistic pathogen *Pseudomonas aeruginosa* (Sudakevitz et al. 2002). The properties of the first lectin are related to fungal lectins. The second one, RS-IIL (subunit Mr 120.6 kDa) is a tetrameric lectin with high sequence similarity to fucose-binding lectin PA-IIL of *Pseudomonas aeruginosa*. RS-IIL recognizes fucose but displays much higher affinity to mannose and fructose, which is opposite to the preference spectrum of PA-IIL (Sudakevitz et al. 2004).

20.6 Fuco-Lectins in Fungi

20.6.1 Fuco-Lectin from Aleuria Aurantia (AAL)

A fucose-binding lectin was purified from fruiting bodies of *Aleuria aurantia*, **a** widespread ascomycete fungus. The lectin combines the terminal fucose in the carbohydrate chain. AAL shows sugar-binding specificity for L-fucose. Recombinant form of AAL is a fucose-binding lectin composed of two identical 312 aa subunits (Kochibe and Furukawa 1980). Each subunit contains five binding sites for fucose. One of the binding sites in rAAL had unusually high affinities towards fucose and fucose-containing oligosaccharides with K_D values in the nM range. (Olausson et al. 2008). Isolectin A from *Lotus tetragonolobus* (LTL-A), and AAL were found to be specific for fucose residues. While α-L-Fuc-(1,3)-β-D-GlcNAc and Lewis^x (Le^X) bound to both lectins, sialyl-Lewis^x (sLe^X) bound to AAA only. AAA bound to the ligands more tightly. Binding strength for both lectins decreased from α-L-Fuc-(1,3)-β-D-GlcNAc to Le^X and was lowest for sLe^X. STD NMR experiments suggest that only the L-fucose residues are in intimate contact with the protein (Haselhorst et al. 2001).

AAL: Overall Fold and Organization: The crystal structure of the lectin complexed with fucose revealed that each monomer consists of a six-bladed β-propeller fold and of a small antiparallel two-stranded β-sheet that plays a role in dimerization. Five fucose residues were located in binding pockets between the adjacent propeller blades (Fig. 20.5a) (Paoli 2001). The global shape is a short cylinder, or tore, with an approximate diameter of 45 Å and a height of 35 Å. In the β-propeller fold, each consecutive β-sheet has its first strand (number 1) lining the central cavity of the protein and the last one (number 4) most exposed to solvent at the cylinder surface. Loops connecting the strands within each module are rather short, with the exception of blade III (amino acids 108–162) that displays longer loops. The consecutive blades are connected by long segments that run from the outside of the protein to the central tunnel. AAL has been described as a dimer in solution and also confirmed as a dimer in crystal. The two monomers are very similar, and superimposition of their backbones gives an r.m.s. value of 0.26 Å. A pseudo-2-fold axis of symmetry generates this dimer in the crystal (Fig. 20.5b). The small domain created by the antiparallel association of the N-terminal and C-terminal peptides plays a key role in the dimerization, additional contact being mediated by four loops (those interconnecting blades I and II and blades II and III and the loops between strands β_2-I and β_3-I and between strands β_2-II and β_3-II). Hydrophobic contacts involve the C terminus Trp^{312} from each monomer with Lys^{83} from the other. In addition, tyrosine residue, Tyr^6, interacts via aromatic ring stacking with its counterpart on the other monomer through 2-fold axis. Four main hydrogen bonds are also established between the side chains of Asp^{263} and Ser^{283} and between the Trp^{312} nitrogen side chain and backbone carbonyl backbone of Leu^{59}. Several amino acids at the N and C termini of

the peptide chains protrude from the base of the β-propeller cylinder, associating in a small anti-parallel two-stranded β-sheet that forms a separated domain. The inner cavity of AAL has a tunnel shape with a diameter of about 8 Å in its middle part and almost closed off on the N terminus side of the first inner β-strands. This cavity has a strong hydrophobic character, being formed mostly by the conserved alanine residues of the first strands of each propeller blade. The core is filled with a set of about 50 water molecules forming a well ordered hydrogen bond network.

Due to repeats in the amino acid sequence, there are strong similarities between the sites. Oxygen atoms O-3, O-4, and O-5 of fucose are involved in hydrogen bonds with side chains of amino acids conserved in all repeats, whereas O-1 and O-2 interact with a large number of water molecules. The nonpolar face of each fucose residue is stacked against the aromatic ring of a Trp or Tyr amino acid, and the methyl group is located in a highly hydrophobic pocket. Depending on the precise binding site geometry, the alpha- or beta-anomer of the fucose ligand is observed bound in the crystal. Experiments conducted on a series of oligosaccharides confirmed the broad specificity of the lectin, with a slight preference for alphaFuc1-2Gal disaccharide. This multivalent carbohydrate recognition fold is a new prototype of lectins that is proposed to be involved in the host recognition strategy of several pathogenic organisms including not only the *Aspergillus* but also the phytopathogenic bacterium *Ralstonia solanacearum* (Wimmerova et al. 2003).

20.7 Intelectins

20.7.1 Intelectin-1 (Endothelial Lectin HL-1/ Lactoferrin Receptor or *Xenopus* Oocyte Lectin)

The murine gene encoding Intelectin (ITLN) was identified by Komiya et al. (1998) and was renamed Intelectin-1 (ITLN-1), following the isolation of Intelectin-2 by Lee et al. (2001). Murine intelectin-1 was called as HL-1 (Endothelial lectin HL-1) and suggested it to be a human homolog of *Xenopus* oocyte lectin XL-35. The protein has been identified independently as Omentin of adipose tissue. The protein is structurally identical to the intestinal receptor for lactoferrin (Wrackmeyer et al. 2006). The cDNA was cloned by Suzuki et al. (2001) and called LFR [Lactoferrin (LF) receptor (R)].

The mature human intelectin-1 (hITLN-1) is a secretory glycoprotein consisting of 295 amino acids and *N*-linked oligosaccharides, and its basic structural unit is a 120-kDa homotrimer in which 40-kDa polypeptides are bridged by disulfide bonds. The *hITNL* gene was split into 8 exons on chromosome 1q21.3. The hITNL showed high levels of homology with mouse intelectin, *Xenopus laevis* cortical granule lectin/oocyte lectin, lamprey serum lectin, and ascidian galactose-specific lectin. These homologues commonly contained no CRD, which is a characteristic of C-type lectins, although some of them have been reported as Ca^{2+}-dependent lectins. Recombinant hITNL revealed affinities to D-pentoses and a D-galactofuranosyl residue in presence of Ca^{2+}, and recognized bacterial arabinogalactan of *Nocardia* containing D-galactofuranosyl residues. These results suggested that hITNL is a galactofuranose binding lectin that plays a role in the recognition of bacterial- specific components in the host, and is not a member of C-type lectin family (Tsuji et al. 2001).

Galactofuranosyl residues, which are not found on mammalian tissues, are recognized as dominant immunogens (Daffe et al. 1993; Leitao et al. 2003). The hITLN-1 is expected to recognize not only *N. rubra* (Daffe et al. 1993), but also *Aspergillus fumigatus* (Leitao et al. 2003), *Mycobacterium tuberculosis* (Pedersen and Turco 2003), *Streptococcus oralis* (Abeygunawardana et al. 1991), *Leishmania major*, and *Trypanosoma cruzi* (Suzuki et al. 1997), all of which contain galactofuranosyl residues in cell walls. Some observations indicate that hITLN-1 and mouse intelectin-1 (mITLN-1) may play an immunological role against selected microorganisms or foreign antigens (Pemberton et al. 2004a, 2004b; Datta et al. 2005; Kuperman et al. 2005; Wali et al. 2005). Since intelectin homologues are generally oligomeric (Abe et al. 1999; Suzuki et al. 2001; Tsuji et al. 2001; Nagata 2005), this structure may influence their function.

Most mammalian ITLNs have 10 conserved Cys residues but two of these are not found in the N-terminal regions of mouse and rat ITLNs. The recombinant hITLN-1 is a trimer, disulfide-linked through Cys-31 and Cys-48, and N-glycosylated at Asn-163. Despite 84.9 % amino acid identity to hITLN-1, recombinant and intestinal mITLN-1 are unglycosylated 30-kDa monomers. Elution profiles of recombinant hITLN-1, as well as recombinant and intestinal mITLN-1 indicated that the two intelectins have different saccharide-binding specificities. Despite 84.9 % amino acid identity between these two proteins, the oligomeric structure and carbohydrate-recognition specificity of mITLN-1 differ from those of hITLN-1 (Tsuji et al. 2007). In mammals, the galactose-binding C-type lectins, a macrophage lectin or asialoglycoprotein receptors, bind to asialoglycoproteins. However, the binding affinity of hITNL-1 to asialoglycoproteins was weak (Tsuji et al. 2001). This was thought to be because the galactosyl residues of asialoglycoproteins are galactopyranosides although hITNL has affinity to the galactofuranosyl residue.

The hITLN-1 mRNA level increases in airway epithelial cells from individuals with asthma (Kuperman et al. 2005). A high percentage of malignant pleural mesothelioma show

up-regulated expression of hITLN-1 (Wali et al. 2005). A marked induction in Intelectin gene expression was observed among human primary mesothelial cells as a consequence of crocidolite asbestos exposure and simian virus 40 infection. However, expression of hITNL-1 is decreased in human airway epithelium of smokers compared to nonsmokers (Carolan et al. 2008). Others have shown that infection with *T. spiralis* (Pemberton et al. 2004a, 2004b) or *Trichuris muris* (Datta et al. 2005) induced mITLN-1 and mITLN-2 mRNA expression. These observations and the galactofuranose binding by hITLN-1 and mITLN-1 suggest that ITLN homologues may have an immunoregulatory role in host defense. For instance, the serum ITLN homologue of ascidian (galactose-specific lectin) functions as an opsonin (Abe et al. 1999). However, Voehringer et al. (2007) indicated no significant modification of immune responses or clearance of microorganisms in mITLN transgenic mice. Although hITLN-1 is a soluble intestinal protein (Tsuji et al. 2001), hITLN-1 is also a glycosylphosphatidylinositol-anchored intestinal lactoferrin receptor (Suzuki et al. 2001), HL-1 of vascular endothelial cells (Lee et al. 2001), or omentin of adipose tissue (Schäffler et al. 2005) and human visceral fat (Tsuji et al. 2007). However, the physiological function of mITLN-1 may differ from that of hITLN-1. It was reported that swine ITLN, which is expected to be oligomeric, is associated with lipid rafts on the enterocyte brush border (Wrackmeyer et al. 2006). It is possible that hITLN-1 is similarly located. Additional investigation will be required to further establish the physiological function of ITLN-1 in both humans and mice.

Human hITLN-1 mRNA is expressed in heart, small intestine, colon, and thymus and exclusively localized in endothelial cells (Lee et al. 2001). Primary cultures of human aortic endothelial cells are positive for HL-1 expression, but several other human cell types are not. The brush border membrane is organized in stable glycolipid-based lipid raft microdomains, and like divalent lectin galectin-4, intelectin was enriched in microvillar "superrafts", i.e., membranes that resist solubilization with Triton X-100 at 37º C. Wrackmeyer et al. (2006) reported that trimeric Intelectin serves as an organizer and stabilizer of the brush border membrane, preventing loss of digestive enzymes to the gut lumen and protecting the glycolipid microdomains from pathogens.

Intelectin is expressed in Paneth and goblet cells of small intestine and serves a protective role in the innate immune response to parasite infection (Komiya et al. 1998; Peebles 2010; Wrackmeyer et al. 2006). Secretory granules of lysozyme-positive Paneth cells in the bottom of crypts as well as goblet cells along crypt-villus axis were intensively labeled with intelectin antibodies, but quantitatively, the major site of intelectin deposition was the enterocyte brush border. Tsuji et al. (2009) found that human intelectin-1 is a serum protein and binds to *Mycobacterium bovis* bacillus Calmette-Guérin (BCG). Human ITLN-1-binding to BCG was inhibited by Ca^{2+}-depletion, galactofuranosyl disaccharide, ribose, or xylose, and was dependent on the trimeric structure of human ITLN-1. Human ITLN-1-transfected cells express ITLN-1 on the cell surface and secrete it in the culture supernatant. Study indicates that intelectin is a host defense lectin that assists phagocytic clearance of microorganisms.

As the *X. laevis* oocyte lectin, a homologue of hITNL, has been shown to participate in the formation of fertilization envelope that blocks sperm entry, hITNL may also participate in fertilization. However, hITNL was also expressed on various tissues other than oocytes, and it has been demonstrated that the other homologues are also present in various tissues (Komiya et al. 1998; Abe et al. 1999). Thus, hITNL and its homologues may not only participate in the formation of fertilization envelope but also have other physiological functions.

The hITLN is plentifully expressed in heart. Since *viridans streptococci* invading blood attack heart and cause subacute infectious endocarditis, and since the surface polysaccharide of *Streptococcus oralis* contains galactofuranosyl residues (Abeygunawardana et al. 1991), hITNL may function in heart as a defense protein against these pathogens (Komiya et al. 1998).

20.7.2 Intelectin-2 (HL-2) and Intelectin-3

Intelectin-2 shows 91 % sequence homology with Intelectin, later named Intlectin-1 (Pemberton et al. 2004). Intelectin-2 also called HL-2 (Endothelial lectin HL-2) was identified as the human homologue of *Xenopus* oocyte lectin XL-35 (Lee et al. 2001). The Intelectin-2 gene is absent from C57BL/10 genome but present in genome of BALB/c mice. The protein is expressed by intestinal goblet cells, and its expression is up-regulated after infection with the nematode parasite *Trichinella spiralis*. BALB/c mice, which express Intelectin-2 are resistant to this nematode, whereas C57BL/10 mice, which do not express Intelectin-2 are susceptible to *Trichinella spiralis* infection. The deduced amino acid sequence of each homologue of HL-1 and HL-2 is about 60 % identical and 80 % similar to that of XL35, and none of these sequences contains the C-type lectin motif, although it is known that XL35 requires calcium for ligand binding.

Sheep Intlectins: Intelectin 2 (sITLN2) from sheep abomasal mucosa shared 76–83 % homology with other mammalian intelectins. Expression of sheep abomasal ITLN2 mRNA was up-regulated on post-challenge of worm-free sheep with *Teladorsagia circumcincta*. Infection with *T. circumcincta* was also associated with increased levels of abomasal transcripts encoding sheep mast cell

protease-1, ovine galectin-14 and IL4, which indicated a Th2 type response. The amino acid sequences of sheep sITLN1 and sITLN3 share 86 % and 91 % homology with sheep sITLN2 respectively. While sITLN1 and sITLN3 transcripts are expressed ubiquitously in most of the normal sheep tissues, sITLN2 transcript was restricted to the abomasal mucosa in normal sheep tissues. The three sITLN were absent in unchallenged naïve lambs but induced in abomasal mucosa following challenge of both *Teladorsagia circumcincta* and *Dictyocaulus filaria* natural infection suggesting that intelectins may play an important role in mucosal response to nematode infections in ruminants (French et al. 2009).

Intelectins are capable of binding bacteria via galactofuranose residues and function as intestinal receptors for the antimicrobial glycoprotein lactoferrin (Lf). Lf binds strongly to enterohemorrhagic *E. coli* (EHEC) and the Lf receptor expressed in terminal rectum, the site of predilection of EHEC in cattle. Bovine intelectins (bITLN1 and bITLN2) were expressed in abomasum and rectum, but expression appeared minimal in the jejunum. There was significantly higher expression of bITLN2 in terminal rather than proximal rectum. Thus two bovine ITLNs are expressed along with Lf in the gastrointestinal tract, where they may interact with microbial pathogens (Blease et al. 2009).

20.7.3 Intelectins in Fish

Lin et al. (2009) characterized seven zebrafish intelectins (zINTLs) and made comparative analysis of intelectins from various species. zINTL1-3 are highly expressed in one or several adult tissues. zINTL4-7, however, were expressed at quite low levels both in adults and various development stages. Of the seven zINTLs, zINTL3 was expressed predominantly in the liver and highly up-regulated upon infection, suggesting its important roles in immunity. Based on the characterization of intelectin members in various species it was indicated that intelectin family may be a deuterostome specific gene family; and their expression patterns, quaternary structures and glycosylations vary considerably among various species, though their sequences are highly conserved. Moreover, these varied features have evolved multiple times independently in different species, resulting in species-specific protein structures and expression patterns (Lin et al. 2009). Rainbow trout plasma Intelectin exhibited calcium-dependent binding to N-acetylglucosamine (GlcNAc) and mannose conjugated Toyopearl Amino 650 M matrices. The lectin appeared at ~37 kDa and ~ 72 kDa bands. Similar analysis of plasma revealed a single 72 kDa band under reducing conditions. MALDI-TOF MS demonstrated five, ~37 kDa isoforms (pI 5.3–6.1). A 975 bp cDNA sequence encoded a 325 amino acid secretory protein with homology to human and murine intelectins, which bind bacterial components and were induced during parasitic infections. Rainbow trout IntL was detected ubiquitously in many tissues. Rainbow trout IntL plays a role in innate immune defense against bacterial and chitinous microbial organisms (Russell et al. 2008).

Two types of IntL genes have been identified from catfish. The genomic structure and organization of IntL2 were similar to those of the mammalian species and of zebrafish and grass carp, but orthologies could not be established with mammalian IntL genes. The IntL genes are highly conserved through evolution. Sequence analysis also indicated the presence of the fibrinogen-related domain in the catfish IntL genes. Phylogenetic analysis suggested the presence of at least two prototypes of IntL genes in teleosts, but only one in mammals. The catfish IntL1 gene is widely expressed in various tissues, whereas the channel catfish IntL2 gene was mainly expressed in the liver. While the catfish IntL1 is constitutively expressed, the catfish IntL2 was drastically induced by i.p. injection of *Edwardsiella ictaluri* and/or iron dextran. While IntL1 was expressed in all leukocyte cell lines, no expression of IntL2 was detected in any of the leukocyte cell lines, suggesting that the up-regulated channel catfish IntL2 expression after bacterial infection may be a consequence of the initial immune response, and/or a downstream immune response rather than a part of the primary immune responses (Takano et al. 2008).

20.7.4 Eglectin (XL35) or Frog Oocyte Cortical Granule Lectins

Xenopus Laevis Egg Cortical Granule: *Xenopus laevis* egg cortical granule, calcium-dependent, galactosyl-specific lectin participates in forming the fertilization layer of the egg envelope and functions in establishing a block to polyspermy. This oligomeric lectin is released extracellularly at fertilization and binds to its polyvalent glycoprotein ligand that is cross-linked in the jelly coat layer surrounding the oocyte. The lectin is expressed again at gastrulation and may function as well in cell–cell or cell–matrix adhesion events in the embryo (Outenreath et al. 1988; Lee et al. 1997). A cDNA encoding XL35 was isolated from a *Xenopus* oocyte cDNA library (Lee et al. 1997). The amino acid sequence it encodes did not display the C-type lectin motif, although it does require calcium for binding. The cDNAs encoding two human homologues of the *Xenopus* oocyte lectin, XL35, were isolated from a small intestine cDNA library and termed HL-1 and HL-2. The deduced amino acid sequence of each homologue is about 60 % identical and 80 % similar to that of XL35, and none of these sequences contains the C-type lectin motif, although XL35 requires calcium for ligand binding. HL-1 transcripts

are present at relatively high levels in heart, small intestine, colon, thymus, ovary, and testis. HL-2 transcripts, by contrast, are expressed only in small intestine (Lee et al. 2001).

The translated cDNA for the cortical granule lectin had a signal peptide, a structural sequence of 298 amino acids, a molecular weight of 32.7 kDa, contained consensus sequence sites for N-glycosylation and a fibrinogen domain. The lectin cDNA expressed during early stages of oogenesis and 2/3 of the lectin was associated with the extracellular perivitelline space and the egg/embryo fertilization envelope. Lectin mRNA levels were from 100- to 1000-fold greater in ovary than in other adult tissues. The lectin did not have sequence homology to any known lectin families but had 41–88 % amino acid identity with nine translated cDNA sequences from an ascidian, lamprey, frog, mouse, and human. Based on the conserved carbohydrate binding and structural properties, it was named as eglectin (Chang et al. 2004).

Several nucleic acid sequences that predict proteins homologous to XL35 have been reported in frog, human, mouse, lamprey, trout, ascidian worm. These proteins also showed high degrees of amino acid sequence homology to a common fibrinogen-like motif that may involve carbohydrate binding. Several independent studies on these lectins strongly suggest that the lectins are expressed and stored in specialized vesicles that may be released upon infection by pathogens. In addition, some family members have been shown to bind to oligosaccharides from bacterial pathogens. Therefore, this family of lectins likely participates in pathogen surveillance as part of the innate immune system. These were named as homologues of XL35 (Lee et al. 2004).

Xenopus Embryonic Epidermal Lectin (XEEL): The *Xenopus laevis* embryonic epidermal lectin (XEEL) belong to the group of mammalian intelectins, frog oocyte cortical granule lectins, and plasma lectins in lower vertebrates and ascidians. A cDNA from a *Xenopus laevis* embryo library encodes a predicted translation product of 342 amino acids containing a signal sequence for secretion. The predicted protein has 62–70 % amino acid identity with the *Xenopus* oocyte cortical granule lectin (XCGL), the mouse intelectin, the human HL-1/intelectin and HL-2. Onset of gene expression occurs by gastrulation and the transcripts localize in non-ciliated epidermal cells all over the tail bud embryos. The designated XEEL is secreted from the embryonic epidermis (Nagata et al. 2003).

XCL-1: Ishino et al. (2007) isolated a 35-kDa Ca^{2+}-dependent lectin (XCL-1) from adult *Xenopus* serum. Although XCL-1 gene was not induced in the regenerating tails, Ishino et al. (2007) isolated a cDNA for an XCL-1-related protein (XCL-2). In contrast to the XCL-1 gene, XCL-2 gene expression was significantly increased in the regenerating tails, suggesting its role in tail regeneration. Although both XCL-1 and XCL-2 belong to *Xenopus* lectin family (X-lectins), XCL-1 and XCL-2 exhibit distinct developmental gene expression from two other known X-lectin members, both of which are expressed in the embryonic stage, whereas the XCL-1 and XCL-2 genes are predominantly expressed in the adult and middle/late tadpole stages, respectively, suggesting multiple functions of X-lectins. A gene for a humoral C-type lectin family is transiently expressed in the regenerating legs of the American cockroach (Arai et al. 1998). It suggests that the induction of a gene in regenerating organs is conserved among insects and vertebrates.

Annexins (Lipocortins)

21

G.S. Gupta

21.1 Annexins

21.1.1 Characteristics of Annexins

The annexins or lipocortins are a multigene family of proteins that bind to acidic phospholipids and biological membranes in a Ca^{2+}-dependent manner (Gerke and Moss 2002; Gerke et al. 2005; Raynal and Pollard 1994; Swairjo and Seaton 1994). Annexins are ubiquitous and characterized by an ability to bind to anionic phospholipids at membrane surfaces in response to elevated Ca^{2+}. Annexins are amphipathic and distinct from soluble and integral membrane proteins, but share features of both (Kojima et al. 1994; Brisson et al. 1991). Annexins have molecular weights ranging between 30 and 40 kDa (only annexin 6 is 66 kDa) and possess striking structural features. The characteristic annexin structural motif is a 70-amino-acid repeat, called the annexin repeat. Four annexin repeats packed into an α-helical disk are contained within the C-terminal polypeptide core (Gerke and Moss 2002). While all annexins share this core region, aminoterminal domains of annexins are diverse in sequence and length (ranging from 11 to 196) on each annexin member. It is this diversity of N-terminal amino-acid sequence that gives the individual annexins their functional differences and biological activities and appears to differentiate the cellular function and location (Gerke and Moss 2002; Gerke et al. 2005; Raynal and Pollard 1994). Cysteine 198 is relatively conserved in annexins, and three of four cysteines (198, 242, and 315) in annexin A4 are conserved in annexin A3. Phospholipids are suggested to bind via hydrophilic head groups to annexins, and the phospholipid-binding region is proposed to be localized on the convex surface side where calcium-binding sites are located in the crystal structure of annexin 5 (Huber et al. 1990). The calcium- and phospholipid-binding sites are located in the carboxy terminal domains. Some of the annexins bind to glycosaminoglycans (GAGs) in a Ca^{2+}- dependent manner. While annexin 2 has specific and high-affinity heparin-binding activity (Kassam et al. 1997), annexin A4 binds to heparin, heparan sulfate and chondroitin sulfate (CS) columns in a Ca^{2+}- dependent manner, annexin 5 to heparin and heparan sulfate columns in a Ca^{2+}-dependent manner and annexin 6 to heparin and heparan sulfate columns in a Ca^{2+}-independent manner and to CS columns in a Ca^{2+}-dependent manner (Ishitsuka et al. 1998) (see Table 21.1). Reports suggest that some annexin species may function as recognition elements for L-α-dipalmitoylphosphatidylethanolamine (PE)-derivatized GAGs under some conditions. The crystal structure of several of the annexins has been reported (Favier-Perron et al. 1996; Luecke et al. 1995; Swairjo et al. 1995). It has been established that the annexins are composed of two distinct sides. The convex side faces the biological membrane and contains the Ca^{2+}- and phospholipid-binding sites. The concave side faces the cytosol and contains the N and C termini. Although the annexins have been studied mostly as calcium-dependent phospholipid-binding proteins mediating membrane-membrane and membrane-cytoskeleton interactions, annexins A4, A5 and A6 bind also to carbohydrate structures suggesting that these annexin possess lectin-like domains.

Annexins bind to phosphatidylserine, phosphatidylethanolamine, and phosphatidylinositol, which are present in the inner leaflet or cytosolic surface of plasma membrane and hardly appear on cell surface, in contrast to phosphatidylcholin and sphingomyelin, which are major components of the outer leaflet of plasma membrane. However, latter are not recognized by annexins. Annexins also bind to organelle membranes such as the Golgi apparatus. This binding can be reversed by the removal of calcium, freeing the annexin from the phospholipid membrane. However, the functional significance of their reversible membrane-binding ability remains unknown in many annexins, although in some it is thought to be important for vesicle aggregation and membrane organization (Liemann and Huber 1997; Rand 2000; Rescher and Gerke 2004; Lim and Pervaiz 2007). Although all annexins share this binding property, there is variation in calcium sensitivity and phospholipid specificity between

ANXA7	Sorcin, galectin
ANXA8	None known
ANXA9	None known
ANXA10	None known
ANXA11	Programmed cell death 6 (PDCD6), sorcin
ANXA13	Neural precursor cell expressed, developmentally down-regulated 4 (NEDD4)

individual annexins. For example, within one cell there can be differences in the distribution of annexins, with annexin A1 having an endosomal localisation, A2 to be found in cytosol and A4 being associated with the plasma membrane (Liemann and Huber 1997). Furthermore annexins are exported from cytosol to the outside of cells across the plasma membrane by unknown mechanisms. Although annexins lack hydrophobic signal peptides, secretion and expression on cell surface experienced by some annexins are e6dent in some cell types.

Like galectins, certain members of annexin family can be found both inside and outside cells. In particular, annexins A1, A2, A4, A5, and A11 can be found in the nucleus. This localization is consistent with the findings that annexin A1 possesses unwinding and annealing activities of a helicase and that annexin A2 is associated with a primer recognition complex that enhances the activity of DNA polymerase α. Despite these efforts and accomplishments, however, there is little e6dence or information on an endogenous carbohydrate ligand for these lectins that show nuclear and/or cytoplasmic localization (Wang et al. 2004).

21.1.2 Classification and Nomenclature

Annexins are expressed in a wide range of organisms such as higher plants, slime molds, metazoans, insects, birds, and mammals. Studies of the amino acid sequence of the annexins have established the homology of these proteins. Over 20 types have been found in all eukaryotic kingdoms as well as plants and animals. There are 12 human annexin subfamilies (A1–A11 and A13) that have been found to have various intra- and extracellular roles in a range of cellular processes (Gerke and Moss 2002; Gerke et al. 2005). The annexins are classified into five groups (A–E), and within each of these groups, individual annexins are identified numerically. Annexins in group A are human annexins, with group B referring to animal annexins without human orthologs, group C to fungi and moulds, group D to plants and group E to protists (Liemann and Huber 1997; Rand 2000; Hayes and Moss 2004; Rescher and Gerke 2004; Lim and Pervaiz 2007). At least one of the members can be found expressed in nearly every eukaryotic cell types. Almost all cells produce several kinds of annexins simultaniously and the expression levels are rather high. Why do they need annexins in plenty? It may be helpful in defining the question that the task of annexins is not a unique and annexins have to interact with various ligands both outside and inside of cells to act for multiple roles (Ponnampalam and Rogers 2006).

By definition, an annexin protein must be capable of binding in a Ca^{2+}-dependent manner to negatively charged phospholipids and has to contain a conserved structural element the so-called annexin repeat, a segment of some 70 amino acid residues. Molecular structures obtained for a number of annexins over the past decade helped to extend the similarities to the three-dimensional level. Moreover, they defined a hitherto unknown structural fold, the conserved annexin domain, which is built of four annexin repeats packed into a highly α-helical disk, and which now is considered to be a general membrane binding module. The annexin family has grown steadily in 1990s, and with the turn of the century, more than 160 unique annexin proteins have been discovered in more than 65 different species ranging from fungi and protists to plants and higher vertebrates (Fig. 21.1) (Morgan and Fernandez 1997; Morgan et al. 1999). For a detailed discussion of annexin properties, their structural organization, and intracellular as well as tissue distribution, the interested reader is referred to previous review (Gerke and Moss 2002).

The vertebrate A family includes the 13 annexins that make the family in mammals, but the number of annexins may vary in other classes of vertebrates as genes have been gained and lost. Ancient polyploidization events in bony fish, and more recent genome duplications in pseudotetraploid frogs (Xenopus), have duplicated many of the annexin genes. Thus, annexin A1 has undergone two successive duplications to yield up to four copies in some fish, amphibians and birds. Mammalian ANXA6 is a compound gene, probably derived from the fusion of duplicated ANXA5 and ANXA10 genes in early vertebrate evolution. Annexins A7, A8 and A10 have not yet been detected in fish, although genes similar to annexin A7 have been found in earlier-diverging species such as the sea urchin, the earthworm and

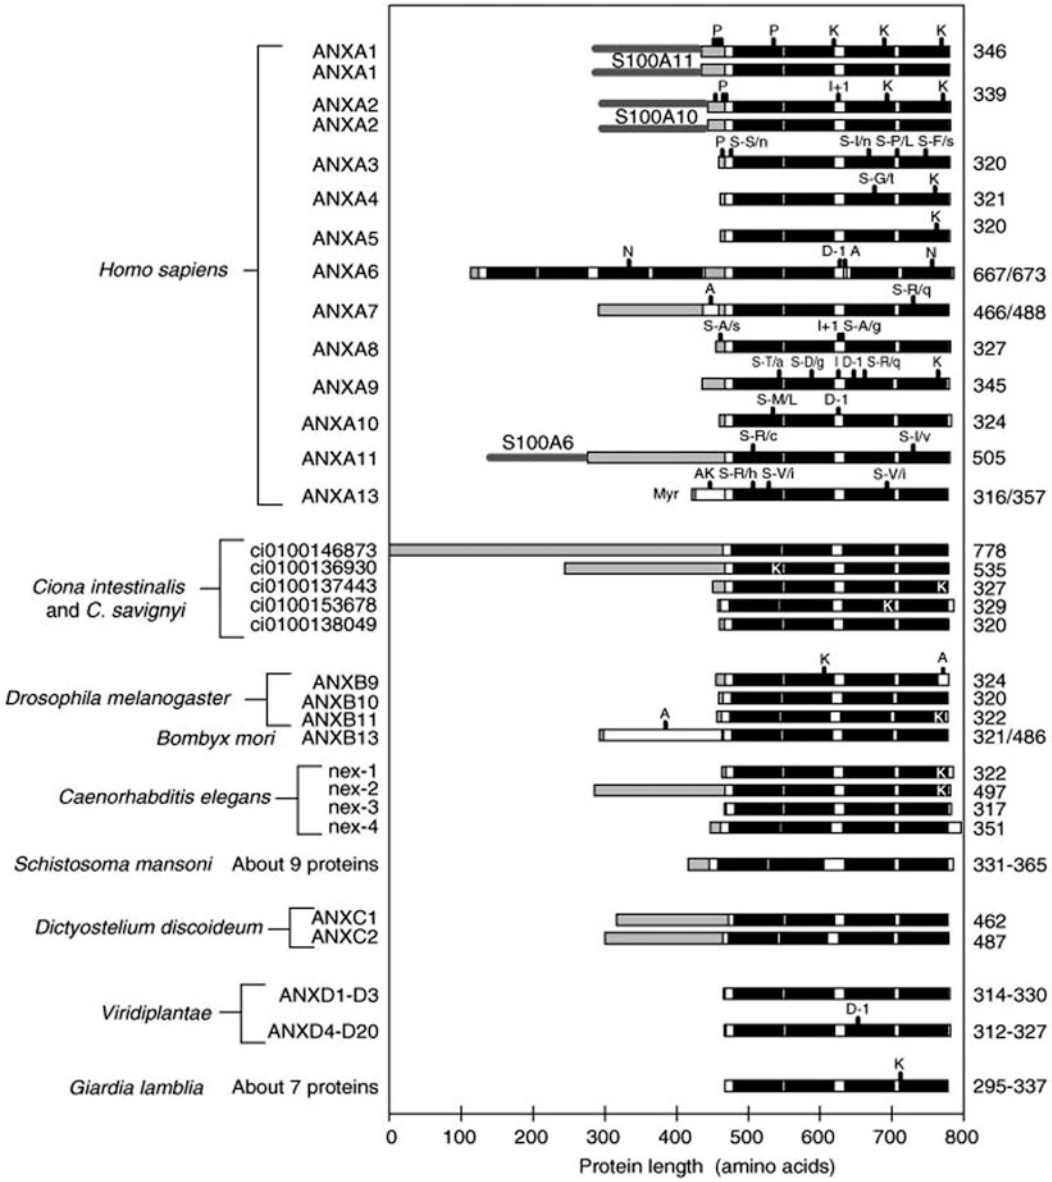

Fig. 21.1 Domain organization of representative annexin proteins: orthologs of the 12 human annexins shown in other vertebrates have the same structures, with strict conservation of the four repeats in the core region (*black*) and variation in length and sequence in the amino-terminal regions (*shaded*). Human ANXA1 and ANXA2 are shown as dimers, with the member of the S100 protein family that they interact with. Domain structures for other model organisms are derived from public data made available by the relevant genome-sequencing projects. Features: *S100Ax* sites for attachment of the indicated member of the S100 family of calcium-binding proteins, *P* known phosphorylation sites, *K*, KGD synapomorphy (a conserved, inherited characteristic of proteins), *I* codon insertions (+x denotes the number of codons inserted), *S-A/b* nonsynonymous coding polymorphisms (SNPs) with the amino acid in the major variant (*A*) and that in the minor variant (*b*), *N* putative nucleotide-binding sites, *D* codon deletions (−x denotes the number of codons deleted), *A* alternatively spliced exons, *Myr* myristoylation. The total length of each protein is indicated on the *right* (Printed from Moss and Morgan, Genome Biol. 5: 219 © 2004)

Hydra. The reasons for the tendency of annexin genes (or their chromosomal regions) to duplicate, their successful preservation, and the extent to which they contribute to vertebrate complexity are as yet unknown. The 12 human annexin genes range in size from 15 kb (*ANXA9*) to 96 kb (*ANXA10*) and are dispersed throughout the genome on chromosomes 1, 2, 4, 5, 8, 9, 10 and 15. Annexin genes from other vertebrates may vary slightly in size and chromosomal linkage, but orthologs are grossly similar in their sequence and splicing patterns (Moss and Morgan 2004).

21.1.3 Annexins in Tissues

Annexins are expressed in a wide range of organisms such as higher plants, slime molds, metazoans, insects, birds,

and mammals. The expression level and tissue distribution of annexins span a broad range, from abundant and ubiquitous (annexins A1, A2, A4, A5, A6, A7, A11) to selective (such as annexin A3 in neutrophils and annexin A8 in the placenta and skin) or restrictive (such as annexin A9 in the tongue, annexin A10 in the stomach and annexin A13 in the small intestine). Annexin A1, A2, A3, A4, A5 and A6 are present in cardiac tissue. Annexin A5 is present in both cardiomyocytes and non-myocytal cells of the heart. Annexin A5 mRNA levels were highest in the fibroblast-like cells, followed by the endothelial cells, and a weak signal in the cardiomyocytes (Jans et al. 1995; Matteo and Moravec 2000). Porcine heart expresses annexins A5 and A6 in large amounts, and annexins A3 and A4 in much smaller amount. Annexins A5 and A6 are involved in the regulation of membrane-related processes (Pula et al. 1990). Annexins play a role in the regulation of Ca^{2+} pumps and exchangers on the sarcolemma, and are altered in some cardiac disease states. The plasma membrane of the heart muscle cell and its underlying cytoskeleton are vitally important to the function of the heart. Two major annexin A6 binding proteins were identified as actin and annexin A6 itself. Annexin A6 bound to itself both in the presence and in the absence of calcium ions. Annexin A6 bound preferentially not only to the N terminal fragment (domains I-4, residues 1–352) but also to C-terminal fragments corresponding to domains V + VI and domains VII + VIII (Locate et al. 2008). During embryonic delopment, annexins 1, 2 and 4 have been identified in murine CNS with distinct patterns of temporal and spatial expression. Annexin A4 is the first annexin to be expressed on embryonic day E9.5 while annexin 1A is the last to be expressed (E21.5) (Hamre et al. 1995).

Annexin A1 is expressed by small sensory neurons of rat dorsal root ganglia (DRG), by most neurons of the spinal cord (SC), and by ependymal cells lining the central canal. Annexin A2 is expressed by most sensory neurons of the DRG but is primarily expressed in the SC by glial cells. Annexin A3 is expressed by most sensory neurons, regardless of size, by endothelial cells lining the blood vessels, and by the perineurium. In the SC, annexin A3 is primarily expressed by astrocytes. In the DRG and the SC, annexin A4 is primarily expressed by glial cells and at lower levels by neurons. In the DRG, annexin A5 is expressed in relatively high concentrations in small sensory neurons in contrast to the SC, where it is expressed mainly by ependymal cells and by small-diameter axons located in the superficial laminae of the dorsal horn areas. Annexin A6 is differentially expressed by sensory neurons of the DRG, being more concentrated in small neurons. In the SC, annexin 6 has the most striking distribution and concentrated subjacent to the plasma membrane of motor neurons and their processes. The differential localization pattern of annexins in cells of the SC and DRG could reflect their individual biological roles in Ca^{2+}-signal transduction within the CNS (Naciff et al. 1996). Annexin A3 is implicated in the microglial response to motor nerve injury. It is induced after hypoglossal nerve injury in rat, specifically in activated (axotomy-stimulated) microglia. A3 was the most prominent among annixins expressed in microglia. Results suggested that Annexin 3 may be a Ca^{2+}-dependent mediator between phospholipids and F-actin in microglia stimulated by peripheral nerve injury (Konishi et al. 2006).

21.1.4 Functions of Annexins

Annexins are generally cytosolic proteins, with pools of both a soluble form and a form stably or reversibly associated with components of the cytoskeleton or proteins that mediate interactions between the cell and the extracellular matrix (matricellular proteins). Although the broad themes in terms of cellular function have been uncovered, but the precise role of these proteins is unclear (Gerke and Moss 2002; Hill et al. 2008). Because of the ability of annexins to bind to and "annex" or aggregate membrane surfaces, they appear to participate in Ca^{2+}-regulated membrane dynamics. Thus they have been shown to be involved in exocytosis (Creutz 1992; Gerke and Moss 2002), membrane domain organization and ion channel activity regulation (Hill et al. 2008).

Some annexins such as A1 and A2, have been found in the nucleus (Tomas and Moss 2003; Eberhard et al. 2001) and in certain instances, annexins may be expressed at the cell surface, despite the absence of any secretory signal peptide; for example, annexin A1 translocates from the cytosol to the cell surface following exposure of cells to glucocorticoids (Solito et al. 1994), and annexin A2 is constitutively expressed at the surface of vascular endothelial cells where it functions in the regulation of blood clotting (Brownstein et al. 2001). The A5 and A6 knockout mice have subtler phenotypes and need further investigation (Brachvogel et al. 2003), and two independently derived A7 null mutant mouse strains are either embryonic lethal (Srivastava et al. 1999) or show changes in calcium homeostasis (Herr et al. 2001). The diversity of phenotype in the annexin knockout mice is consistent with these proteins having largely independent functions. Roles for annexins that have been established from studies using cultured cells are not always reflected in phenotypic abnormalities in the corresponding knockout mice, suggesting that functional redundancy may, in some instances, obscure the full range of functions of these multifunctional proteins. In mice that lack an overt phenotype, there is now the opportunity to test molecular theories of annexin function, such as the proposed calcium channel activity of A5.

The annexins have a wide range of biological functions related to their phospholipid/membrane-binding properties (Crompton et al. 1988), such as inhibition of coagulation, interactions with membranous and cytoskeletal elements, vesicular transport and exocytosis and endocytosis. Shifts in subcellular locations (from the cytosol to membrane) are observed on some intracellular annexins, suggesting the active movement of annexins corresponding to dynamic lipid vesicle transport. Since, the expression of some annexins depends on rate of cellular proliferation (Schlaepfer and Haigler 1990), it has been proposed that the cellular level of the annexins might be critical for the regulation of cell growth. However, this hypothesis has been questioned. Results show that cellular expression of annexins plays a general role in cell growth and support the concept that post-transcriptional mechanisms may control levels of annexin 1 and 7 (Raynal et al. 1997). They are anti-inflammatory proteins that inhibit phospholipase A2 activity in vitro by sequestering the substrate phospholipids from phospholipase A2 (Blackwell et al. 1980). Furthermore, the annexins exhibit anti-coagulant activity (Tait et al. 1989), calcium channel activity (Rojas et al. 1990), and cyclic phosphate phosphohydrolase activity (Ross et al. 1990). They function in the membrane fusion process, exocytosis, endocytosis, membrane-cytoskeleton interactions (Gerke et al. 2005) and regulation of calcium-dependent anion current activation (Chan et al. 1994).

Some annexins are capable of calcium-independent binding and several have roles in vesicle aggregation. Annexins A1, A2 and A11 function in cooperation with other calcium-binding proteins to form complexes while annexins A1, A2 and A5 interact with cytoskeletal proteins. Many annexins are involved in exocytic and endocytic pathways and some have roles in ion channel regulation (Gerke and Moss 2002). Extracellularly, annexin A1 has a role in controlling the inflammatory response while annexin A2 is present on the external surface of endothelial cells, where it may act as a receptor for ligands, including plasminogen and tissue plasminogen activator. Extracellular annexin A5 is thought to be involved in the anticoagulation process (Rand 2000; Hayes and Moss 2004) (see also Table 21.1).

21.2 Annexin Family Proteins and Lectin Activity

After being exported outside the cells, some annexins have been shown to function as receptors for extracellular proteins. There exists evidence that shows that annexins interact with glycoconjugates. Annexin A4 was first identified as a lectin binding to carbohydrate moieties of sialoglycoproteins and glycosaminoglycans in the presence of calcium; afterwards annexin 5 and 6 and some other annexins exhibited similar lectin activity. The localization sites of annexin A4 in major expression tissues, the kidney and pancreas, and the result of in vitro binding assay of several glycoconjugates suggest that annexin A4 is involved in the formation of apical sorting (secretory) vesicles due to the interaction with some GPI-anchored glycoproteins and proteoglycans. Exocrine-type neurotrophic activity is found in annexin 5 and involvement of some annexins in cell-adhesion (or inhibition of cell-adhesion) has been found. Future studies should aim at identifying endogenous glycoconjugate ligands recognized by annexins in a variety of cases and investigating the carbohydrate recognition mechanism. While annexin A4 binds glycosaminoglycans (GAGs) in a calcium-dependent manner (Kojima et al. 1996), annexin A5 bound to heparin and heparan sulfate column but not to chondroitin sulfate column. Annexin A5 binds to collagen and annexin A2 binds to tissue plasminogen activator, tenascin and heparin. Moreover, Annexin A6 was adsorbed to heparin and heparan sulfate columns in a calcium-independent manner and to chondroitin sulfate columns in a calcium-dependent manner. Binding of annexins to a wide variety of other proteins is also known (Moss and Morgan 2004) (Table 21.1). Thus, annexins A2, A4, A5, and A6 have different GAG binding properties and function as recognition elements for GAGs in extracellular space (Ishitsuka et al. 1998). Many annexins have posttranslational modifications, such as phosphorylation and myristoylation. Such modifications and surface remodeling of individual members presumably account for much of the subfamily specificity in annexin interactions (Moss and Morgan 2004).

21.3 Annexin A2 (p36)

Annexin A2/(p36) contains three distinct functional regions, the N-terminal region, the C-terminal region, and the core region. The core region of p36 contains Ca^{2+}- and phospholipid-binding sites, whereas C-terminal region contains 14-3-3 homology domain and the plasminogen-binding domain. The N terminus of annexin A2 (p36) contains two important regulatory domains, the L and P domains. The L domain consists of the first 14 residues of the N terminus that contains a high affinity binding site for the p11 protein. The P domain of p36 contains the phosphorylation sites for protein kinase C (Ser^{25}) and pp60src (Tyr23). The N-terminal L and P domains play regulatory roles; activation of the phosphorylation sites of annexin A2 tetramer results in an increase in the $A_{1/2(Ca2+)}$ for chromaffin granule aggregation and F-actin binding, whereas binding of the p11 subunit decreases the $A_{1/2(Ca2+)}$ for these activities. Annexin A2 is a receptor for the alternatively spliced segment of fibronectin type III domains in tenascin-C (Chung and Erickson 1994; Chung et al. 1996; Ling et al.

2004) and for plasminogen and tissue plasminogen activator (Hajjar et al. 1994).

21.3.1 Annexin 2 Tetramer (A2t)

Annexin A2 often co-expresses with another protein, p11 (S100A10), forming an (annexin A2)$_2$-(S100A10)$_2$ heterotetramer (Annexin 2 tetramer (A2t)). Monomeric and tetrameric annexin A2 share many of the same binding properties, e.g. the abilities to bind Ca^{2+}, phospholipid membranes, and certain GAGs (including heparin and heparan sulfate), albeit typically with some modification in affinity. The p11 component alone, despite belonging to the E-F hand family of Ca^{2+}-binding proteins, does not bind Ca^{2+} nor does it bind phospholipids or GAG. The association between annexin A2 and p11 does not require Ca^{2+} and utilizes the concave annexin molecular surface (reviewed in Shao et al. 2006).

Interaction of A2t with Heparin: The heterotetrameric complex formed by the binding of p11 to p36 (A2t) is the predominant form in most cells (Kassam et al. 1997). Interactions of heparin with Ca^{2+}- and A2t have been studied. A2t has been shown to be present at both the cytosolic and extracellular surfaces of the plasma membrane of many cells (Waisman 1995). Extracellular A2t has been proposed to function as a cell adhesion factor (Tressler and Nicolson 1992; Tressler et al. 1993), a receptor for plasminogen and tissue plasminogen activator (Cesarman et al. 1994), and a receptor for tenascin-C (Chung and Erickson 1994; Hajjar et al. 1994; Hubaishy et al. 1995). It is possible that heparin might be involved in the regulation of the interaction of A2t with these ligands. In the absence of Ca^{2+}, heparin induces a more moderate change in the conformation of A2t. Of interest was the heparin-induced increase in the β-sheet from ~21% to 27% and decrease in unordered structure from 22% to 18%. Hubaishy et al. (1995) reported that A2t bound to a heparin affinity column and that the phosphorylation of A2t on tyrosine residues blocked the heparin-binding activity of the protein. The study on interaction of A2t with heparin identified A2t as a specific, high affinity heparin-binding protein. Furthermore, the Ca^{2+}-dependent binding of heparin to A2t causes a dramatic conformational change in the protein. The p36 subunit of A2t contains a Cardin-Weintraub glycosaminoglycan recognition site (Cardin and Weintraub 1989) and that a peptide to this region of A2t binds heparin.

The interaction of A2t with heparin was also shown to be inhibited by tyrosine phosphorylation of A2t (Hubaishy et al. 1995). Since the role that heparin binding plays in the structure or function of A2t is unknown, the current study was aimed at the characterization of the interaction of heparin with A2t. Analysis of the CD spectra of A2t showed that the binding of heparin to A2t resulted in a profound change in the conformation of A2t. We also found that in the absence of Ca^{2+}, a small change in the conformation of A2t occurred upon heparin binding. It was also observed that A2t formed a large complex with heparin. A2t bound heparin with an apparent K_D of 32 ± 6 nM and a stoichiometry of 11 ± 0.9 mol of A2t/mol of heparin. A2t does not bind to disaccharides of heparin, but does bind to 3-kDa heparin that contains ~10 monosaccharides. The binding of ~11 molecules of A2t to a single 17-kDa heparin strand that contains ~50 monosaccharide units suggests that A2t requires ~4–5 monosaccharide units for binding.

Several consensus sequences have been identified among members of the heparin-binding family of proteins. For example, the heparin-binding sequence of the C-terminal region of fibronectin has been identified as WQPPRARI. The p36 subunit of A2t contains a Cardin-Weintraub heparin-binding consensus sequence. Furthermore, a peptide to this region of p36 subunit of A2t (300LKIRSEFKK-KYGKSLYY316) undergoes a conformational change upon heparin binding. These results therefore suggest that residues 300–316 of the p36 subunit of A2t are involved in heparin binding (Kassam et al. 1997).

Fucoidan, a sulfated fucopolysaccharide, mimics the fucosylated glycans of glycoproteins and has been used as a probe for investigating the role of membrane polysaccharides in cell − cell adhesion. A2t is bound to fucoidan with an apparent K_D of 1.24 ± 0.69 nM; the binding of fucoidan to A2t was Ca^{2+}-independent. Furthermore, in the presence but not the absence of Ca^{2+}, the binding of fucoidan to A2t decreased the α-helical content from 32% to 7%. A peptide corresponding to a region of the p36 subunit of A2t, F (306) − S(313), which contains a sequence for heparin binding, was shown to undergo a conformational change upon fucoidan binding. This suggests that heparin and fucoidan bound to this region of A2t. Thus, the binding of A2t to the carbohydrate conjugates of certain membrane glycoproteins have profound effects on the structure and biological activity of A2t (Sandra et al. 2000).

Ca^{2+}-dependent binding of A2t to heparin caused a large decrease in the α-helical content of A2t from ~44% to 31%, a small decrease in the β-sheet content from ~27% to 24%, and an increase in the unordered structure from 20% to 29%. The binding of heparin also decreased the Ca^{2+} concentration required for a half-maximal conformational change in A2t from 360 to 84 μM. Data suggests that in the presence of Ca^{2+}, heparin induces a large conformational change in A2t, resulting in a substantial change in the conformation of the protein. However, heparin can also interact with A2t in the absence of Ca^{2+} and, to a much smaller degree, affect the conformation of the protein (Kassam et al. 1997). A2t

appears to be a unique member of the heparin-binding proteins because A2t can discriminate between heparin and heparan sulfate ligands.

21.3.2 Crystal Analysis of Sugar-Annexin 2 Complex

Identification of annexin A2 as a heparin-binding protein (Kassam et al. 1997) raised the possibility that this protein-GAG interaction may participate in the regulation of thrombotic processes. To characterize the heparin-annexin A2 interaction and to determine the basis for its Ca^{2+} dependence, crystallographic studies were carried out on human annexin A2 in complex with heparin-derived oligosaccharides of varying lengths. Binding measurements in solution were also performed using surface plasmon resonance (SPR) (Shao et al. 2006). Crystallographic analysis revealed that the common heparin-binding site is situated at the convex face of domain IV of annexin A2. At this site, annexin A2 binds up to five sugar residues from the nonreducing end of the oligosaccharide. Unlike most heparin-binding consensus patterns, heparin binding at this site does not rely on arrays of basic residues; instead, main-chain and side-chain nitrogen atoms and two calcium ions play important roles in the binding. Especially significant is a novel calcium-binding site that forms upon heparin binding. Two sugar residues of the heparin derivatives provide oxygen ligands for this calcium ion. Comparison of all four structures shows that heparin binding does not elicit a significant conformational change in annexin A2. The combined data with surface plasmon resonance measurements provide a clear basis for the calcium dependence of heparin binding to annexin A2 (Shao et al. 2006).

21.3.3 Functions of Annexin A2

Dual Action of Annexin 2 Tetramer and Arachidonic Acid: Annexin 2 has been implicated in membrane fusion during the exocytosis of lamellar bodies from alveolar epithelial type II cells. Immunodepletion of Annexin 2 from type II cell cytosol reduced its fusion activity. The A2t induced the fusion of lamellar bodies with the plasma membrane in a dose-dependent manner. This fusion is Ca^{2+}-dependent and is highly specific to A2t because other annexins (1 and 2 monomer, 3, 4, 5, and 6) were unable to induce the fusion. The fusion between lamellar bodies with the plasma membrane is driven by the synergistic action of A2t and arachidonic acid (Chattopadhyay et al. 2003).

In an earlier report, though annexins 1–4 mediated liposome aggregation in the presence of 1 mM Ca^{2+}, only A2 tetramer had aggregation activity at 10 μM Ca^{2+}, where as A5 and A6 had negligible aggregation activity at Ca^{2+} concentrations up to 1 mM Ca^{2+}. Of six purified annexins (A1–A6) tested for their ability to reconstitute secretion from permeabilized cells, only Annexin A2 was effective. Annexin A2 was not involved in the exocytosis of lamellar bodies (Liu et al. 1996; Blanchard et al. 1996). The neuroblastoma cells are known to express annexins and confirmed in cell membrane. Following stimulated release of noradrenaline by K^+ depolarisation or by treatment with the ionophore A23187, results favoured for a general role in calcium signaling at discrete intracellular locations by annexins 2 and 5. The results did not support the specific involvement for Annexin 2 in membrane fusion at sites of vesicle exocytosis (Blanchard et al. 1996).

Antiphospholipid (aPL) antibodies recognize receptor-bound β2 glycoprotein I (β2GPI) on target cells, and induce an intracellular signaling and a procoagulant/proinflammatory phenotype that leads to thrombosis. Evidence indicates that annexin A2 binds β2GPI on target cells. Romay-Penabad et al. (2009) studied the effects of human aPL antibodies in A2-deficient ($A2^{-/-}$) mice. After IgG-APS (antiphospholipid syndrome) or 4C5 injections and vascular injury, mean thrombus size was significantly smaller and tissue factor activity was significantly less in $A2^{-/-}$ mice compared with $A2^{+/+}$ mice. The expression of VCAM-1 induced by IgG-APS or 4C5 in explanted $A2^{-/-}$ aorta was also significantly reduced compared with $A2^{+/+}$ mice. It was suggested that annexin A2 mediates the pathogenic effects of aPL antibodies in vivo and in vitro APS.

Soluble A2t activates human monocyte-derived macrophages (MDM), resulting in secretion of inflammatory mediators and enhanced phagocytosis. The modulation of macrophage function by A2t is mediated through TLR4, suggesting an important role for this stress-sensitive protein in the detection of danger to the host, whether from injury or invasion (Swisher et al. 2010). Up-regulation of annexin A2 in differentiated retinal pigment epithelial (RPE) cells may be required for development of phagocytic capability. Law et al. (2009) showed that annexin A2 is highly enriched on newly formed phagosomes in RPE cells and that siRNA-mediated depletion of annexin A2 results in impairment of photoreceptor outer segments (POS) internalization. Findings provide direct evidence that annexin A2 is necessary for the normal circadian phagocytosis of POS by RPE cells.

21.4 Annexin A4 (p33/41)

21.4.1 General Characteristics

Annexin A4 (also called endonexin, protein II, chromobindin 4, placental anticoagulant protein II, and PP4-X) is one of a family of proteins that interact with

phospholipids in the presence of calcium. Annexin A4 is a 36-kDa protein that can aggregate on the inner leaflet of cellular membranes. It has additional unique property of recognizing carbohydrates. Calcium-dependent phospholipid binding activities are common and characteristic properties of the annexin family proteins. Phospholipids are suggested to bind via hydrophilic head groups to annexins, and the phospholipid-binding region is proposed to be localized on the convex surface side where calcium-binding sites are located in the crystal structure of annexin A5. Annexin A4 has been proposed to be involved in exocytosis and in the coagulation process. These functions are related to the ability of the annexins to bind to acidic phospholipids. Annexin A4 strongly binds to either lipid at acidic pH. At neutral pH only weak binding to phosphatidic acid (PA) and no binding to phosphatidylserine (PS) occurs. But addition of Ca^{2+} leads to a strong binding to the lipids also at neutral pH. Binding of annexin A4 induces dehydration of the vesicle surface (Zschörnig et al. 2007). Annexin A4 shares 50–60% sequence homology to annexin 5 and was shown to bind heparin, but the binding of heparin to this protein was inhibited by a variety of carbohydrates including glucose, N-acetylneuraminic acid, heparan sulfate, and chondroitin sulfate (Kojima et al. 1996). In contrast, heparan sulfate or other glycosaminoglycans do not induce a conformational change in A2t (Becker et al. 1990).

Gene trap disruption of the first intron revealed that there were in fact three splice variants of annexin A4 with differing tissue expression (Li et al. 2003). The knockout animal lacked the major transcript, annexin A4a, which has a broad tissue distribution. However, two further transcripts, designated annexin A4b and Annexin A4c, were unaffected by the intron disruption in this region. Annexin A4b was shown to be expressed only in the digestive tract and annexin A4c exhibited a restricted expression pattern within solitary chemosensory cells. In nonstratified epithelia, they extend from the basement membrane to the lumen and appear to perform paracrine/endocrine functions (Li et al. 2003).

Annexin A4 is localized in the apical cytoplasmic region of pancreatic acinar cells where zymogen granules are concentrated. Since it is the major component of the zymogen granule membrane, the glycosylphosphatidylinositol-anchored glycoprotein GP-2 was suggested to play a role in apical sorting and secretion of zymogens. The major carbohydrate structures of porcine GP-2 were trisialo-triantennary and tetrasialo-tetra-antennary complex-type oligosaccharides. Annexin IV interacts with GP-2 in the presence of calcium and it recognizes the terminal sialic acid residues linked through α2-3 linkages to the carbohydrate of GP-2. Thus, GP-2 is an endogenous ligand of annexin IV in the exocrine pancreas (Tsujii-Hayashi et al. 2002).

21.4.2 Tissue Distribution

Annexin A4 is found at high levels in secretory epithelia in the lung, intestine, stomach, trachea, and kidney. It is thought to be a marker for polarized epithelial cells. Although the biological roles for annexin A4 remain largely unclear, it has been implicated in the regulation of calcium-activated epithelial chloride channels (Chan et al. 1994) and shown to have anti-inflammatory properties (Katoh 2000; Gotoh et al. 2005). Annexin A4 has also been shown to play a role in kidney organogenesis in *Xenopus laevis*, where ablation of the gene product results in abnormal development of pronephric tubules (Seville et al. 2002). Hill et al. (2003) showed that Annexin A4 can regulate passive membrane permeability to water and protons and can alter physical properties of the membranes by associating with them (Ponnampalam and Rogers 2006). Hill et al. (2008) demonstrated that the major transcript of annexin A4, annexin A4a, is present in the superficial and transitional epithelium of the bladder, where it is expressed throughout the urothelium. Umbrella cells have large numbers of unique elongated vesicles underlying the apical membrane. These "fusiform vesicles" are thought to play a key role in the bladder's ability to stretch by providing a large amount of membrane available for exocytosis and endocytosis. This allows umbrella cells to increase their apical surface area in response to filling and then to decrease it upon emptying (Hill et al. 2008). Given the biophysical properties and urothelial expression of annexin A4, it was hypothesized that this annexin could be important to the integrity or the regulation of bladder permeability barrier.

Bladder filling has been shown to activate a complex set of mechano-sensitive responses in umbrella cells, including ATP release and purinergic receptor-dependent membrane trafficking (Wang et al. 2005). Hydrostatically induced stretch has been shown to raise intracellular Ca^{2+} in the urothelium; furthermore, blocking Ca^{2+} release from intracellular stores inhibited exocytosis (Wang et al. 2005). Given the known membrane-organizing ability of annexins and sensitivity to $Ca^{2+,}$ annexin A4 might play a specific role in umbrella cell membrane trafficking (reviewed in Hill et al. 2008).

It was demonstrated in wild-type bladders that stretch induces a redistribution of annexin A4 within basal and intermediate cells to the cellular periphery. A genetically modified mouse model in which the protein is not expressed in renal epithelia (Li et al. 2003) revealed no alterations in normal bladder function or morphology in the annexin $A4a^{-/-}$ animals, suggesting that the role of annexin A4 in the bladder does not include barrier function or stretch-regulated intracellular trafficking. $Anx4^{-/-}$ mouse model shows no protein in the urothelium where as wild-type umbrella cells showed uniform cytoplasmic staining and

some association with the nuclear membrane. It was indicated that loss of anaxin A4 from the urothelium does not affect barrier function, membrane trafficking, or normal bladder-voiding behavior (Hill et al. 2008).

Microarray studies of human endometrium have shown that Annexin A4 mRNA is significantly up-regulated during the secretory phase of the menstrual cycle compared with the proliferative phase (Kao et al. 2002; Riesewijk et al. 2003; Ponnampalam et al. 2004; Mirkin et al. 2005). Anx4 mRNA is up-regulated during mid-secretory (MS) and late-secretory (LS) phases compared with proliferative phases during the menstrual cycle. Anx4 was localized to glandular and luminal epithelium and was present in high levels throughout the menstrual cycle except during early-secretory (ES) phase, when it was significantly reduced. Results suggest that, in proliferative explants, progesterone significantly increased the Anx4 mRNA and protein after 48 h in culture. Estrogen did not have any significant effects. Anx4 transcription and translation are regulated by progesterone and suggests that Anx4 may be important in regulating ion and water transport across the endometrial epithelium (Ponnampalam and Rogers 2006).

21.4.3 Characterization

Soluble monomers of annexin A4 trimerize in the cytoplasm bind to the membrane and then assemble into higher order structures at the membrane interface creating a crystallization cascade in 2D across a large cross-sectional area of membrane (Zanotti et al. 1998). In vitro cross-linking studies demonstrate that trimer, hexamer and higher aggregates of annexin form in the presence of Ca^{2+} and phospholipid-containing vesicles (Concha et al. 1992). Annexin A4 has a short amino-terminal of 12 amino acids, which is susceptible to phosphorylation by protein kinase C. Phosphorylation by protein kinase C causes the release of the N-terminal of annexin A4 and inhibits annexin A4's ability to aggregate on the membrane (Kaetzel et al. 2001). Annexin A4 has also been found in the cytoplasm (Zimmermann et al. 2004) and nucleus (Raynal et al. 1996), and it can be secreted (Masuda et al. 2004). Intranuclear annexin A4 has been shown to translocate to the cytoplasm because of an increase in intracellular calcium (Mohiti et al. 1995; Barwise and Walker 1996; Raynal et al. 1996), and during Fas-induced cell death (Gerner et al. 2000), however, the functional role of nuclear annexin A4 is currently not well known (reviewed in Ponnampalam and Rogers 2006).

Annexin (A4) possesses four repeat domains with one Ca^{2+}-binding site (CBS) in each domain. A4 binds the Na^+ ion in CBSs. One structure (1.58 A) bound Na^+ ion in CBS I, whereas another structure (1.35 A) bound the Na^+ ion in CBS II and CBS III. The Cα atoms of CBS III largely moved by coordination of Na^+ ion. In the Cα atoms of CBS I, however, little change resulted from Na^+-coordination. Only the side chain of Glu71 was moved by Na^+-coordination in CBS I. These results indicate that Annexin A4 binds not only Ca^{2+} but also Na^+ ion in CBS (Butsushita et al. 2009).

21.4.4 Pathophysiology

Annexins have been implicated in tumor progression. There is significant increase in expression in annexins A1, A2, A4 and A11 in primary tumors compared with normal colon. Expression of annexins A2, A4 and A11 was related with increasing tumor stage (Duncan et al. 2008). Annexin A4 is elevated in ovarian CCC tumors and is associated with chemoresistance in cultured ovarian cancer cells. Results demonstrate that Annexin A4 confers chemoresistance in ovarian cancer cells in part by enhancing drug efflux (Kim et al. 2009).

The presence of antiphospholipid (aPL) antibodies increases the risk for recurrent miscarriage (RM). Annexins bind to anionic phospholipids (PLs) preventing clotting on vascular phospholipid surfaces. Plasma levels of annexin 5 are significantly higher at the beginning of pregnancy, at the sixth and eighth week of pregnancy in women with aPL antibodies compared with those without aPL antibodies, where as there were no significant differences in plasma annexin A4 levels between women with and without aPL antibodies. These antibodies could displace annexin from anionic phospholipid surfaces of syncytiotrophoblasts (STBs) and hereby promote coagulation activation (Ulander et al. 2007).

Annexins have well characterized anti-inflammatory properties and Lipoxin A4 (Annexin A4) has been shown to exert protective effects in stomach. Suppression of aspirin-triggered lipoxin synthesis, through co-administration of a selective COX-2 inhibitor, results in a significant exacerbation of gastric injury. The gastroprotective effects of lipoxin A4 appear to be receptor mediated, and attributable to suppress leukocyte adherence to the vascular endothelium and to elevate gastroduodenal blood flow, and mediated via lipoxin-induced nitric oxide generation (Wallace et al. 2005).

21.4.5 Doublet p33/41 Protein

Ca^{2+}-dependent carbohydrate-binding proteins from bovine kidney under nonreducing conditions form doublet protein bands corresponding to 33 kDa (p33) and 41 kDa (p41) where as under reducing conditions, a single protein band (p33) was observed. The p33/41 is a lectin which binds to

sialoglycoproteins and glycosaminoglycans in a calcium-dependent manner. Amino acid sequences of p33/41 are highly homologous to those of calcium/phospholipid-binding annexin protein, annexin 4 (endonexin) especially in the consensus sequences. The p33/41 exhibited calcium/phospholipid-binding activity similar to annexin 4 (Kojima et al. 1994). The p33/41 cDNA encodes a protein of 319 amino acids with a molecular mass of 35,769 Da. The deduced amino acid sequence was identical to that of bovine annexin 4 except for one amino acid substitution. The recombinant protein revealed that p41 is a dimer of p33 cross-linked at Cys-198 via a disulfide bond. The recombinant protein bound to columns of heparin and fetuin glycopeptides in a calcium dependent manner and to phospholipid vesicles composed of phosphatidylserine (PS)/phosphatidylcholine (PC), phosphatidylethanolamine (PE)/PC or phosphatidylinositol (PI)/PC. Thus, p33/41 binds two types of ligands via different sites and that phospholipids modulate the carbohydrate binding activity of p33/21. The p33/41 does not contain any of the consensus sequences conserved in the CRDs of any animal lectins. Furthermore, consensus heparin-binding motifs (such as BXBXBXXXXB), identified glycosaminoglycan-binding sequences, or basic amino acid clusters capable of binding to acidic polysaccharides through simple ionic interaction were not observed within the primary sequence of p33/41, that suggested that p33/41 may contain a unique CRD. The p33/41 is highly concentrated in the apical plasma membrane of the epithelial cells in the renal proximal tubules, and integrated into the renal brush border membrane. Heparin does not compete with phospholipids in the binding to p33/21.

Chen et al. (1993) reported three-dimensional models of annexins (1, 2, 3, 5 and 7) constructed by homology modeling using the crystal structure of annexin 5 as a template, and showed that cysteines 198, 242, and 315 in the annexin 3 model do not appear to be exposed on the protein surface. A conformational change to expose cysteine 198 to the outside and to allow it to form an intermolecular disulfide bridge appears to occur upon dimer formation of annexin A4.

21.5 Annexin A5/Annexin V

Annexin A5/Annexin V is a protein of unknown biological function that undergoes Ca^{2+}-dependent binding to phospholipids located on the cytosolic face of the plasma membrane. Annexin 5 has been isolated as placental anticoagulant protein I, inhibitor of blood coagulation, vascular anticoagulant-α, endonexin II, lipocortin 5, placental protein 4, and anchorin CII. The function of the protein is unknown. However, based on in vitro experiments, annexin A5 has been proposed to play a role in the inhibition of blood coagulation by competing for phosphatidylserine binding sites with prothrombin and also to inhibit the activity of phospholipase A1. Annexin 5 is a Ca^{2+}-dependent membrane-binding protein that forms voltage-dependent Ca^{2+} channels in phospholipid bilayers and is structurally and functionally characterized. Data indicate that key amino acid residues act as selectivity filters and voltage sensors, thereby regulating the permeability of the channel pore to ions (Demange et al. 1994).

21.5.1 Gene Encoding Human Annexin A5

Characterization of three genomic clones for human annexin 5 revealed that annexin 5 spans at least 29 kb of the human genome and contains 13 exons ranging in length from 44 to 513 bp and 12 introns from 232 to 8 kb. The absence of a typical tata box and the presence of high G + C content and Sp1-binding sites in its promoter characterize it as a 'housekeeping' gene and account for its broad pattern of expression. Potential binding sites for Cis-regulatory elements identified in 5′-upstream region of annexin 5 are consistent with its known regulation by oncogenic and growth-related stimuli. Annexin 5, like its chick homologue, differs from the genes encoding annexins I, II and III in features of its promoter and in the size of its exons 1, 2 and 3 in ways that may impart individuality to its regulation and function (Fernández et al. 1994). The human gene encoding annexin 5 was localized to 4q26-q28. This localization overlaps but differs slightly from the previous assignment of annexin 5 to 4q28-q32 (Tait et al. 1991).

21.5.2 Interactions of Annexin A5

Annexin A5 is a collagen binding protein of the annexin family associated with plasma membranes of chondrocytes, osteoblasts, and many other cells. As a major constituent of cartilage-derived matrix vesicles it has been shown to bind to native type II and X collagen. In accordance with this observation, annexin A5 is localized in the extracellular matrix of calcifying cartilage in the fetal human growth plate, and that it was restricted to the chondrocyte surface in proliferating and resting cartilage. Furthermore, annexin A5 not only binds to native type II and X collagen, but also to chondrocalcin, the carboxy-terminal extension of type II procollagen, in a calcium-independent manner (Table 21.1). Pepsin digestion of type II collagen results in loss of annexin A5 binding. This confirms a notion that the telopeptide region of type II collagen carries annexin A5 binding sites (Kirsch and Pfaffle 1992; Rahman et al. 1997).

Collagen/Annexin A5 Interactions Regulate Chondrocyte Mineralization: Physiological mineralization in growth plate cartilage is highly regulated and restricted to terminally differentiated chondrocytes. Extracellular matrix components (collagens) of growth plate cartilage are directly involved in regulating the mineralization process. Findings showed that types II and X collagen interact with cell surface-expressed annexin A5. These interactions lead to stimulate annexin A5-mediated Ca^{2+} influx resulting in an increased $[Ca^{2+}]i$, and ultimately increased alkaline phosphatase activity and mineralization of growth plate chondrocytes. Thus, the interactions between collagen and annexin A5 regulate mineralization of growth plate cartilage. Because annexin A5 is up-regulated during pathological mineralization events of articular cartilage, it is possible that these interactions also regulate pathological mineralization (Kim and Kirsch 2008).

Annexin A5 Associates with the IFN-γ Receptor and Regulates IFN-γ Signaling: Many of the biological activities of IFN- γ are mediated through the IFN-γR3-linked Jak-Stat1α pathway. However, regulation of IFN-γ signaling is not fully understood, and not all responses to IFN-γ are Stat1α dependent. Annexin A5 is a putative IFN-γR binding protein. Through an inducible association with the R2 subunit of the IFN-γR, annexin A5 modulates cellular responses to IFN- γ by modulating signaling through the Jak-Stat1 pathway (Leon et al. 2006). Annexin A5 is a specific high-affinity inhibitor of PKC-mediated phosphorylation of annexin 1 and myosin light chain kinase substrates. It appears that inhibition occurred by direct interaction between annexin A5 and PKC (Schlaepfer et al. 1992). Annexin A5 has been shown to interact with kinase insert domain receptor and integrin β5 (Marina et al. 2003; Wen et al. 1999).

21.5.3 Molecular Structure of Annexin A5

Each annexin is composed of two principal domains: the divergent NH2-terminal "head" and the conserved COOH-terminal protein core. The latter harbors the Ca^{2+} and membrane binding sites and is responsible for mediating the canonical membrane binding properties. An annexin core comprises four (in annexin A6 eight) segments of internal and interannexin homology that are easily identified in a linear sequence alignment (Gerke and Moss 2002). It forms a highly α-helical and tightly packed disk with a slight curvature and two principle sides. The more convex side contains novel types of Ca^{2+} binding sites, the so-called type II and type III sites (Weng et al. 1993), and faces the membrane when an annexin is associated peripherally with phospholipids. The more concave side points away from the membrane and thus appears accessible for interactions with the NH2-terminal domain and/or possibly cytoplasmic binding partners (Fig. 21.2).

The first structure for an annexin core was solved by Huber et al. (1990) for annexin A5. More than ten crystal structures for annexin cores have been described showing a remarkable conservation of the overall three-dimensional fold (Huber et al. 1990; Liemann and Lewit-Bentley 1995; Swairjo and Seaton 1994). Human annexin A5 (PP4) has been analysed by crystallography. Two crystal forms of human annexin A5 have been refined at 2.3 A and 2.0 A resolution to R-values of 0.184 and 0.174, respectively, applying very tight stereochemical restraints with deviations from ideal geometry of 0.01 A and 2°. The polypeptide chain of 320 amino acid residues is folded into a planar cyclic arrangement of four repeats. The repeats have similar structures of five α-helical segments wound into a right-handed compact superhelix. Three calcium ion sites in repeats I, II and IV and two lanthanum ion sites in repeat I have been found in the R3 crystals. They are located at the convex face of the molecule opposite the N terminus. Repeat III has a different conformation at this site and no calcium bound. The calcium sites are similar to the phospholipase A2 calcium-binding site, suggesting analogy also in phospholipid interaction. The center of the molecule is formed by a channel of polar charged residues, which also harbors a chain of ordered water molecules conserved in the different crystal forms. Comparison with amino acid sequences of other annexins shows a high degree of similarity between them. Long insertions are found only at the N termini. Most conserved are the residues forming the metal-binding sites and the polar channel. Annexins A5 and A7 form voltage-gated calcium ion channels when bound to membranes in vitro (Huber et al. 1992).

The molecule has dimensions of 64 × 40 × 30 A3 and is folded into four domains of similar structure. Each domain consists of five α-helices wound into a right-handed superhelix yielding a globular structure of ~18 Å diameter. The domains have hydrophobic cores whose amino acid sequences are conserved between the domains and within the annexin family of proteins. The four domains are folded into an almost planar array by tight (hydrophobic) pair-wise packing of domains II and III and I and IV to generate modules (II–III) and (I–IV), respectively. The assembly is symmetric with three parallel approximate diads relating II to III, I to IV and the module (II–III) to (I–IV), respectively. The latter diad marks a channel through the centre of the molecule coated with charged amino acid residues. The protein has structural features of channel forming membrane proteins and a polar surface characteristic of soluble proteins. It is a member of the third class of amphipathic proteins different from soluble and membrane proteins (Huber et al. 1990; Voges et al. 1995).

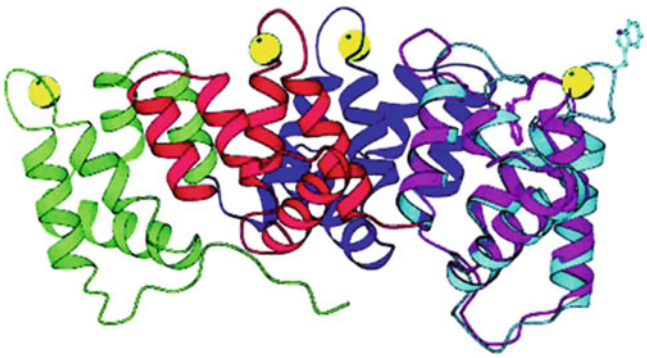

Fig. 21.2 Crystal structure of human annexin A5. The ribbon drawing illustrates the highly α-helical folding of the protein core that forms a slightly curved disk. Different colors were chosen to highlight the four annexin repeats that are given in *green* (repeat I), *blue* (repeat II), *red* (repeat III), and *violet*/*cyan* (repeat IV). The NH2-terminal domain appears unstructured and extends along the concave side of the molecule (*green*). The high and low Ca^{2+} forms are shown in a superposition revealing the conformational change in repeat III, which leads to an exposure of Trp-187 (*violet* for the low and *cyan* for the high Ca^{2+} form). Bound Ca^{2+} are depicted as *yellow spheres* (Printed with permission from Liemann and Lewit-Bentley 1995 © Elsevier)

Annexin 5 is known to form doublet bands exhibiting an apparent difference of 4 kDa on SDS-PAGE. Unlike annexin A4, the annexin 5 isoforms are not sensitive to reducing agents and occur as a result of only two amino acid substitutions between the isoforms (Learmonth et al. 1992; Bianchi et al. 1992). Emerging evidences suggest that both annexin 1 and annexin 5 can bind to many types of cell surfaces, and the identification of annexins as new receptors of tissue plasminogen activator in human endothelial cells (Hajjar et al. 1994) and of influenza virus in cultured cells (Otto et al. 1994) implies functional expression of annexins on the cell surface. Annexin 5, also identified as a collagen-type II binding protein (anchorin CII), was shown to be secreted and present in plasma, amniotic fluid, and post-culture medium (Kirsch and Pfaffle 1992).

21.5.4 Annexin A5-Mediated Pathogenic Mechanisms

Antiphospholipid syndrome: Annexin A5 forms a shield around negatively-charged phospholipid molecules. Without the shield, there is an increased quantity of phospholipid molecules on cell membranes, speeding up coagulation reactions and causing the blood-clotting characteristic of the antiphospholipid antibody syndrome. Antibodies directed against annexin A5 are the cause of a syndrome called the antiphospholipid syndrome. Annexin A5 binds to phospholipid bilayers, forming two-dimensional crystals that block the phospholipids from availability for coagulation enzyme reactions. Antiphospholipid (aPL) antibodies cause gaps in the ordered crystallization of Annexin A5 which expose phospholipids and thereby accelerate blood coagulation reactions. Recently, hydroxychloroquine, a synthetic antimalarial drug, could reverse this antibody-mediated process. In another translational application, Annexin A5 resistance may identify a subset of aPL syndrome patients for whom this is a mechanism for pregnancy losses and thrombosis. The elucidation of aPL-mediated mechanisms for thrombosis and pregnancy complications may open new paths towards addressing this disorder with targeted treatments and mechanistic assays (Rand et al. 2010).

Annexin A5 in prevention of atherothrombosis in SLE: It is becoming evident that atherosclerosis is an inflammatory disease, which is modulated autoimmunity in animal models. An interesting example of how autoimmune reactions can influence atherosclerosis and consequences thereafter is systemic lupus erythematosus (SLE)-associated cardiovascular disease (CVD). Antithrombotic effect exerted by Annexin A5 is thought to be mediated mainly by forming a mechanical shield over phospholipids (PLs) reducing availability of PLs for coagulation reactions. It may be hypothesized that Annexin A5 can be effective as a treatment to prevent plaque rupture and atherothrombosis not only in SLE, but also in the general population prone to CVD (Cederholm and Frostegård 2007).

21.5.5 A Novel Assay for Apoptosis

Annexin A5 is used as a probe in the annexin A5 affinity assay to detect cells that have expressed phosphatidylserine on the cell surface, a feature found in apoptosis as well as other forms of cell death (Koopman et al. 1994; Wen et al. 1999). Platelets also expose phosphatidylserine on their surface when activated, which serves as binding site for various coagulation factors. In early stages of apoptosis changes occur at the cell surface, which have remained difficult to recognize. One of these plasma membrane alterations is the translocation of phosphatidylserine (PS) from the inner side of the plasma membrane to the outer layer, by which PS becomes exposed at the external surface of the cell. Annexin A5 can be used as a sensitive probe for PS exposure upon the cell membrane. Translocation of PS to the external cell surface is not unique to apoptosis, but occurs also during cell necrosis. The difference between these two forms of cell death is that during the initial stages of apoptosis the cell membrane remains intact, while at the very moment that necrosis occurs the cell membrane looses its integrity and becomes leaky. Therefore the measurement of Annexin A5 binding to the cell surface as

indicative for apoptosis has to be performed in conjunction with a dye exclusion test to establish integrity of the cell membrane. In comparison with other tests the Annexin A5 assay is sensitive and easy to perform. The Annexin A5 assay permits measurements of the kinetics of apoptotic death in relation to the cell cycle (Vermes et al. 1995).

21.5.6 Calcium-Induced Relocation of Annexins 4 and 5 in the Human Cells

Cultured human DCs, human osteoblasts and the osteosarcoma cell line MG-63 express annexins A1, A2, A4, A5 and A6. The bulk of these annexins is intracellular express. During endocytosis by DCs, there was a redistribution of annexin A5 which was found to colocalize with vesicles (Larsson et al. 1995). In non-confluent cells, annexin A4and annexin A5 are strongly present throughout the nucleus and are also present in the cytoplasm. On elevation of the intracellular calcium with the ionomycin, the intranuclear pools of annexin A4 and annexin A5 cells showed relocation to the nuclear membrane within seconds. Results support a role for annexins at cellular membranes in response to elevation of cytosolic calcium levels (Mohiti et al. 1995; Raynal et al. 1996). Studies are consistent with the role for annexins in mediating the calcium signal at the plasma membrane and within the nuclei of fibroblasts (Barwise and Walker 1996).

21.6 Annexin A6 (Annexin VI)

21.6.1 Structure

Annexin A6 participates in the formation of a reversible, membrane-cytoskeleton complex in smooth muscle cells through association of protein kinase C (Babiychuk et al. 1999; Schmitz-Peiffer et al. 1998). In contrast to other annexins which have a structural motif of four repeats in the central core region, annexin A6 has eight repeats (Raynal and Pollard 1994). Analysis of the crystal structure of annexin A6 also indicated that it is uniquely organized into two lobes, the N-terminal half (from repeat one to four) and the C-terminal half (from repeat five to eight) of the molecule (Kawasaki et al. 1996; Benz et al. 1996), and each lobe has convex and concave sides and a hydrophilic pore surrounded by the four repeats that might be involved in GAG interactions. Bovine brain annexin A6 is bound to chondroitin sulfate in a Ca^{2+}-dependent manner (Ishitsuka et al. 1998). Furthermore, exon 21 was alternatively spliced, giving rise to two annexin 6 isoforms that differ with respect to a six amino-acid insertion at the starting site of repeat seven (Smith et al. 1994). Results suggest that both lobes of annexin A6, the N- and C-terminal halves of the molecule, are necessary for specific attachment of the annexin-6-expressing cells to CS chains. Calcium-free recombinant human annexin A6 consists of two similar halves closely resembling annexin A1 connected by an alpha-helical segment and arranged perpendicular to each other. The calcium and membrane binding sites assigned by structural homology are therefore not located in the same plane. Analysis of the membrane-bound form of annexin A6 by electron microscopy shows the two halves of the molecule coplanar with the membrane, but oriented differently to the crystal structure, suggesting a flexible arrangement. Ion channel activity has been found for annexin 6 and the half molecules by electrophysiological experiments (Benz et al. 1996).

21.6.2 Functions

Though annexin A6 is a cytoplasmic protein, it functions as a receptor for CS chains. Some reports have described the extracellular expression of annexins on the outer plasma membrane (Kirsch and Pfaffle 1992; Yeatman et al. 1993; Chung and Erickson 1994; Tressler et al. 1994). Since, a significant amount of annexin A6 is exposed on the external cell surface membrane, it is likely that annexin A6 functions as a receptor for CS chains and is involved in the anti-adhesive activity of CS proteoglycans.

During cell-substratum adhesion, cells undergo attachment, spreading and form stress fibers and focal adhesion; these are sequential steps requiring different molecular mechanisms (Sage and Bornstein 1991; Murphy-Ullrich 1995; Murphy-Ullrich 2001). Chondroitin sulfate (CS) proteoglycan PG-M/versican has an inhibitory effect on cell-substratum adhesion. CS chains are needed for this activity, and the immobilization of CS chains on substrata is essential (Yamagata et al. 1989). Takagi et al. (2002) isolated a 68 kDa protein as a candidate receptor for CS chains and identified that protein as annexin 6. Moreover, taking advantage of A431 cells that do not express annexin A6 and transfecting them with exogenous annexin A6, it was demonstrated that annexin 6 is directly involved in the attachment of cells to CS chains and is expressed on cell surfaces. Taken together, it was concluded that annexin A6 is a receptor for CS chains or that it, at least, binds to CS on the cell surface in the presence of Ca^{2+}.

Annexins A2 and A6, which contain KFERQ-like sequences, are degraded more rapidly in response to serum withdrawal, while annexins A5 and A11, without such sequences are degraded at the same rate in the presence and absence of serum. Using isolated lysosomes, only the annexins containing KFERQ-like sequences are degraded by chaperone mediated-autophagy. These results provide evidence for the importance of KFERQ motifs in substrates of chaperone-mediated autophagy (Cuervo et al. 2000).

C-Type Lectins: Collectins

C-Type Lectins Family

22

Anita Gupta and G.S. Gupta

22.1 C-Type Lectins Family

22.1.1 The C-Type Lectins (CLEC)

Historically the C-Type lectins (CLEC) or C-type lectin receptors (CLR) form a family of Ca^{2+} dependent carbohydrate binding proteins which have a common sequence motif of 115–130 amino acid residues, referred to as the carbohydrate recognition domain (CRD). The C-type designation is from their requirement for calcium for binding. The C-type lectin superfamily is a large group of proteins which is characterized as having at least one carbohydrate recognition domain (CRD), which has been found in more than 1,000 proteins, and it represents a ligand-binding motif that is not necessarily restricted to binding sugars (Drickamer 1999). Proteins that contain C-type lectin domains have a diverse range of functions including cell-cell adhesion, immune response to pathogens and apoptosis. However, many C-type lectins actually lack calcium- and carbohydrate-binding elements and thereby have been termed C-type lectin-like proteins. The CRD has four cysteines that are perfectly conserved and involved in two disulfide bonds. The CRD has been found in various kinds of proteins such as hepatic asialoglycoprotein receptor, lymphocyte IgE receptor, mannose binding protein, selectins (Drickamer 1999; Lasky et al. 1989; Zeng and Weigel 1996) and proteoglycan core protein. Their functions include complement activation, endocytosis, cell recognition, defense mechanism, and morphogenesis (Drickamer 1999; Weis et al. 1998). Many evolutionarily related sequences belonging to the C-type lectins do not show overall sequence similarity. However, they have been classified on the basis of four cysteine residues, being involved in disulfide bridging, which are the trademark of this domain type. The framework surrounding this domain type can be very different from its C-terminal location in the collectins. The monomeric and membrane bound selectins have an N-terminal C-type lectin domain that mediates adhesion between certain cell types through carbohydrate binding. Other proteins, such as phospholipase A2 receptor and the macrophage mannose receptor, contain multiple copies of C-type lectin domains within a single polypeptide. Proteins possessing C-type lectin-like domain (CTLD) type are not necessarily lectins. Type II antifreeze protein present in some arctic fish and the mammalian pancreatic stone protein bind to and inhibit the growth of ice and calcium carbonate crystals, respectively (Håkansson and Reid 2000) and hence are not exactly CLEC but form a part of CTLD.

C-type lectins are either produced as transmembrane proteins or secreted as soluble proteins. Examples of soluble C-type lectins include members of the collectins family, such as the lung surfactant proteins A (SP-A) and SP-D (Wintergest et al. 1989), which are secreted at the luminal surface of pulmonary epithelial cells, and the mannose-binding protein (MBP), a collectin present in the plasma (Kawasaki et al. 1983). Transmembrane C-type lectins can be divided into two groups, depending on the orientation of their amino (N)-terminus. These are type I and type II C-type lectins depending on their N-terminus pointing outwards or inwards into the cytoplasm of the cell respectively. Examples of transmembrane C-type lectins are the selectins (Ley and Kansas 2004), the mannose receptor (MMR) family (East and Isacke 2002), and the dendritic cell-specific ICAM-3 grabbing non-integrin (DC-SIGN) (Geijtenbeek et al. 2002).

22.1.2 C-Type Lectin Like Domain (CLRD/CTLD)

Use of terms of "C-type lectin", "C-type lectin domain" (CLRD), "C-type lectin-like domain" (also abbreviated as CLRD), often used interchangeably and use of CRD in the literature, have been clarified by Zelensky and Gready (2005). With the large number of CLR sequences and structures now available, studies indicate that the implications of the CRD domain are broad and vary widely in function. In metazoans, most proteins with a CLR are not lectins. Moreover, proteins use the C-type lectin fold to bind other proteins, lipids, inorganic molecules (e.g., Ca_2CO_3), or

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,

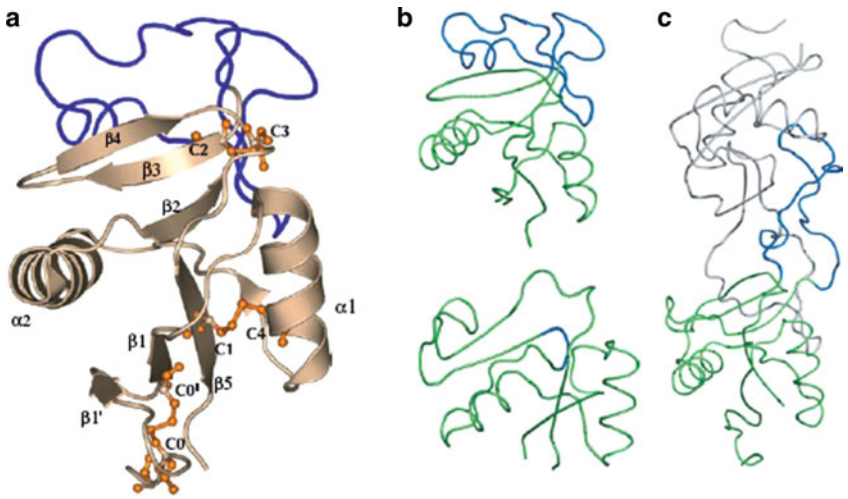

Fig. 22.1 CTLD structure. (**a**) Cartoon representation of a typical CTLD structure (PDB 1K9I). The long loop region is shown in *blue*. Cystine bridges are shown as *orange sticks*. The cystine bridge specific for long form CTLDs (C0-C0') is also shown. (**b**), (**c**), and (**d**): **Variation of the long loop region structure**. Three common forms of the CTLD long loop region are shown. Panels (B: PDB 1K9I) and (C: PDB 1UUH) show canonical CTLDs in which long loop region is tightly packed (**b**) or flipped out to form a domain-swapping dimer (D: PDB 1C3A). A compact CTLD from human CD44 Link domain is shown in panel (**c**). The core domain and long loop region are colored *green and blue*, respectively (Reviewed by Zelensky and Gready 2005)

even ice (e.g., the antifreeze glycoproteins). An increasing number of studies show that "atypical" C-type lectin-like proteins are involved in regulatory processes pertaining to various aspects of the immune system. Examples include the NK cell inhibitory receptor Ly49A, a C-type lectin-like protein, which is shown to complex with the MHC class I ligand (Correa and Raulet 1995), and the C-type lectin-like protein mast cell function-associated antigen which is involved in the inhibition of IgE-Fc γRI mediated degranulation of mast cell granules (Guthmann et al. 1995). Yet glycan binding by C-type lectins is always Ca^{2+}-dependent because of specific amino acid residues that coordinate Ca^{2+} and bind the hydroxyl groups of sugars (Cummings and McEver 2009). To resolve the contradiction, a more general term C-type lectin like domain (CLRD) was introduced to distinguish a group of Ca^{2+}-independent carbohydrate-binding animal proteins from the Ca^{2+}-dependent C-type of animal lectins (CLR/CLEC). The usage of this term is however, somewhat ambiguous, as it is used both as a general name for the group of domains with sequence similarity to C-type lectin CRDs (regardless of the carbohydrate-binding properties), and as a name of the subset of such domains that do not bind carbohydrates, with the subset that does bind carbohydrates being called C-type CRDs. Also both 'C-type CRD' and 'C-type lectin domain' terms are still being used in relation to the C-type lectin homologues that do not bind carbohydrate, and the group of proteins containing the domain is still often called the 'C-type lectin family' or 'C-type lectins', although most of them are not in fact lectins. The abbreviation CRD is used in a more general meaning of 'carbohydrate-recognition domain', which encompasses domains from different lectin groups. Occasionally CRD is also used to designate the short amino-acid motifs (i.e. amino-acid domain) within CLRDs that directly interact with Ca^{2+} and carbohydrate (Zelensky and Gready 2005). In this book authors will use the term C-type lectin domain or C-type lectin-like domain (CTLD/CLRD) interchangeably in its broadest definition to refer to protein domains that are homologous to the CRDs of the C-type lectins, or which have structure resembling the structure of the prototypic C-type lectin CRD or as used by different researchers in their work. More over, due to contradictions (Zelensky and Gready 2005) and uncertainties which may arise in future studies our sequence of chapters is not based on structure databases as in the SCOP; instead chapters are linked more to cell functions or cell biology.

22.1.3 The CLRD Fold

The CLRD fold has a double-loop structure (Fig. 22.1a). The overall domain is a loop, with its N- and C-terminal β strands (β1, β5) coming close together to form an antiparallel β-sheet. The second loop, which is called the long loop region, lies within the domain; it enters and exits the core domain at the same location. Four cysteines (C1–C4), which are the most conserved CLRD residues, form disulfide bridges at the bases of the loops: C1 and C4 link β5 and α1 (the whole domain loop) and C2 and C3 link β3 and β5 (the long loop region). The rest of the chain forms two flanking α helices (α1 and α2) and the second ('top') β-sheet, formed by strands β2, β3 and β1. The long loop region is involved in

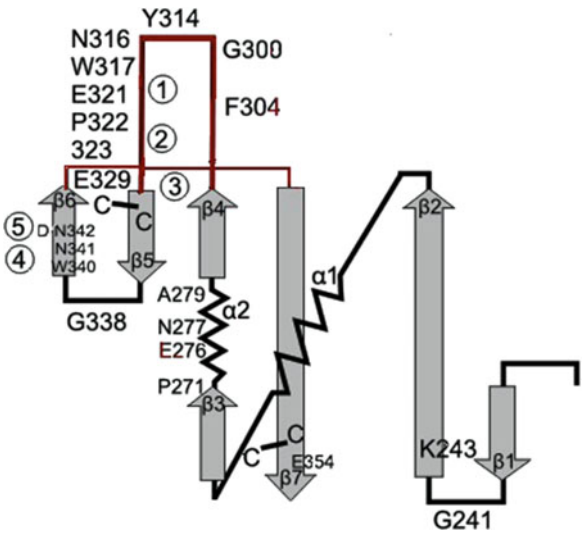

Fig. 22.2 Two-dimensional representation of the C-type lectin fold. The β-strands and α-helices have been numbered β1–β7 and α1–α2, respectively. Secondary structure elements comprise the following residues: (SP-D numbering); α1, 254–264; α2, 273–288; β1, 236–240; β2, 243–253; β3, 267–269; β4, 291–297; β5, 331–335; β6, 339–343; β7, 347–355. The amino acids that are coordinated to the carbohydrate binding calcium ion are denoted with *encircled numbers 1–5*. The conserved residues are indicated with their amino acid one letter symbol. The second calcium ligand is normally an asparagine but is an arginine or alanine in the SP-A sequences. The fifth calcium ligand is an aspartic acid residue in all sequences except dog SP-A, where it is an asparagine (Adapted by permission from Håkansson and Reid 2000 © John Wiley and Sons)

Ca^{2+}-dependent carbohydrate binding, and in domain-swapping dimerization of some CLRDs (Fig. 22.1a), which occurs via a unique mechanism (Mizuno et al. 1997; Feinberg et al. 2000; Mizuno et al. 2001; Hirotsu et al. 2001; Liu and Eisenberg 2002). As suggsted, the CLRD structure is mainly composed of two antiparallel β-sheets; one of these is four-stranded and the other five stranded. The four-stranded β-sheet is found at the N-terminal part of the domain and is flanked by two helices. In trimeric collectins, this sheet is interacting with the α-helical coiled-coil. The five-stranded β-sheet is rather distorted and more remotely located away from the trimer center. This β-sheet, together with some of the loop structure, makes up the carbohydrate binding ligand site. Two of the β-strands (β2 and β7) are relatively long and participate in both sheets. One of the disulfide bridges anchors helix α1 to strand β7 of the four-stranded β-sheet, the other ties together the two most peripheral strands (β5 and β6) of the five-stranded β-sheet. Since the calcium binding amino acid ligands are found at or close to these two strands, this disulfide bridge probably plays an important role in stabilizing the structure around the functional carbohydrate binding site (Fig. 22.2). For conserved positions involved in CLRD fold maintenance and their structural roles readers are referred elsewhere (Zelensky and Gready 2003). In addition to four conserved cysteines, one other sequence feature and the highly conserved 'WIGL' motif is located on the β2 strand and serves as a useful landmark for sequence analysis.

The crystal structure of the CRD of a rat mannose-binding protein, determined as the holmium-(Ho^{3+}) substituted complex by multi-wavelength anomalous dispersion (MAD) phasing, reveals an unusual fold consisting of two distinct regions, one of which contains extensive nonregular secondary structure stabilized by two holmium ions. The structure explains the conservation of 32 residues in all C-type CRDs, suggesting that the fold seen is common to these domains (Weis et al. 1991). Structurally, CLRDs can be divided into two groups: canonical CLRDs having a long loop region, and compact CLRDs that lack it. The second group includes Link or protein tandem repeat (PTR) domains (Brissett and Perkins 1996; Kohda et al. 1996) and bacterial CLRDs (Hamburger et al. 1999; Kelly et al. 1999). Link domain or PTR is a special variety of CLRD, which lacks the long loop region. The major function of Link domains is binding hyaluronan. Although proteins containing it have different domain architecture, their number is small, and they have not been divided into subgroups. Group I CLRDcps contain both canonical and Link-type CLRDs. Other Link-domain containing proteins have four types of domain architecture. Domain composition of Link proteins is similar to that of the N-terminal part of Group I (lecticans). Another family usually included in the CLRD superfamily is that of endostatin (Hohenester et al. 1998). However, endostatin fold is not a suitable example of a CLRD and hence not to be considered further.

The 3D structure of the lectin domain is known to atomic resolution from X-ray analyses of rat and human mannan-binding protein fragments (Weis et al. 1991; Sheriff et al. 1994; Weis and Drickamer 1994), a human lung surfactant protein D fragment (Håkansson et al. 1999), a human E-selectin fragment (Graves et al. 1994), pancreatic stone protein (Bertrand et al. 1996), tetranectin (Nielsen et al. 1997), snake venom factor IX0X binding protein (Mizuno et al. 1997), tunicate C-type lectin (Poget et al. 1999), and from an NMR study of sea raven antifreeze protein (Gronwald et al. 1998). The fold of the C-type lectin domain in some the C-type lectins is shown in Fig. 22.3.

22.1.3.1 Naming of Secondary Structure Elements

Although the CTLD fold is well conserved among its known representatives, there is no general agreement on the numbering of CTLD secondary structural elements in the literature. The secondary structure element numbering scheme in first solved CTLD structure (rat MBP-A by Weis et al. 1991) included five strands, two helices and four loops. However, this description turned out to be insufficient, as MBP lacks some secondary structure elements that are present in long-form CTLD structures, while other small strands were not defined. Other reports describing the structures of CTLDs that have a different number of secondary structure

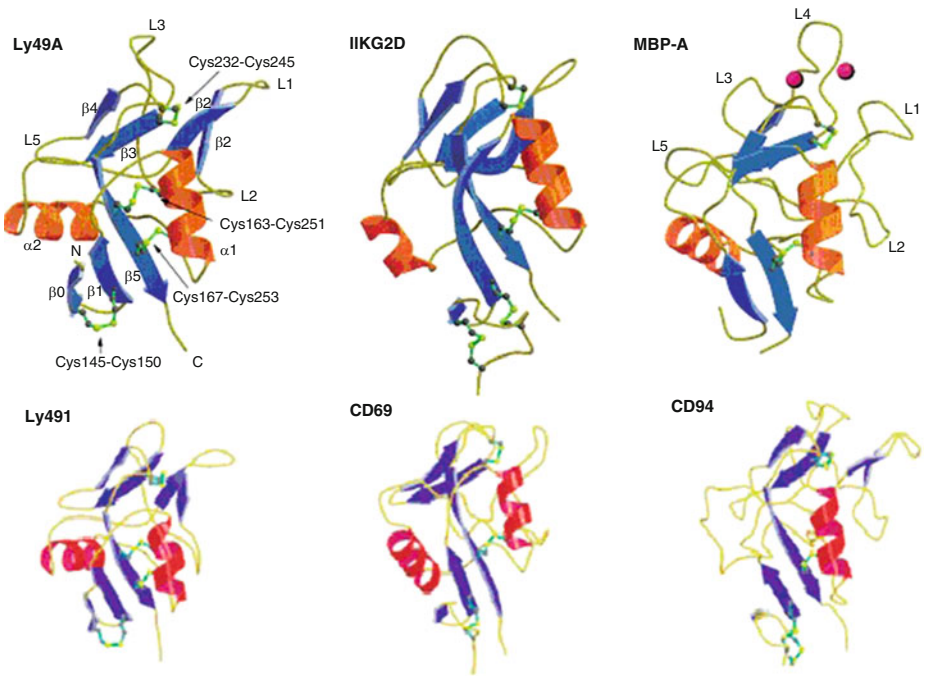

Fig. 22.3 Anatomy of some of the C-type lectin-like domains. Ribbon diagrams of Ly49A (PDB: ID 1QO3) (Tormo et al. 1999), Ly49I (1JA3) (Dimasi et al. 2002), NKG2D (1HQ8) (Wolan et al. 2001), MBP-A (1BCH) (Weis et al. 1991), CD94 (1B6E) (Boyington et al. 1999) and CD69 (1FM5) (Natarajan et al. 2000). The secondary structural elements are colored as follows: β strands *blue*, α-helices *red*, and loop regions *gold*. The disulphide bonds are shown in *green* as ball-and-stick representation. The Ca^{2+} ions bound to MBP-A are drawn as *magenta spheres* (Reviewed in Natarajan et al. 2002)

elements than MBP-A either introduced their own numbering: β strands 1–6 in asialoglycoprotein receptor (ASGPR) by Meier et al. (2000); six β strands in Link module, with labeling not consistent with ASGPR or MBP-A (Kohda et al. 1996); β1–β7 in NKG2D (Wolan et al. 2001); β1–β8 in EMBP (Swaminathan et al. 2001), or extended the secondary structure element naming scheme used for MBP-A (Ly49A secondary structure element numbering is consistent with that in MBP-A) (Tormo et al. 1999).

22.1.3.2 Ca^{2+}-Binding Sites in CLRD/CTLD

Four Ca^{2+}-binding sites recur in CTLD structures from different groups (Chap. 1). The site occupancy depends on the particular CTLD sequence and on the crystallization conditions; in different known structures zero, one, two or three sites are occupied. Sites 1, 2 and 3 are located in the upper lobe of the structure, while site 4 is involved in salt bridge formation between α2 and the β1/β5 sheet. Sites 1 and 2 were observed in the structure of rat MBP-A complexed with holmium, which was the first CTLD structure determined. Site 3 was first observed in the MBP-A complex with Ca^{2+} and oligomannose asparaginyl-oligosaccharide. It is located very close to site 1 and all the side chains coordinating Ca^{2+} in site 3 are involved in site 1 formation. Since biochemical data indicate that MBP-A binds only two calcium atoms (Loeb and Drickamer 1988), Ca^{2+}-binding site 3 is considered a crystallographic artifact. However, in many CTLD structures where site 1 is occupied, a metal ion is also found in site 3; examples include the structures of DC-SIGN and DC-SIGNR (Feinberg et al. 2001), invertebrate C-type lectin CEL-I (Sugawara et al. 2004), lung surfactant protein D (Hakansson et al. 1999) and the CTLD of rat aggrecan (Lundell et al. 2004). It is interesting to note that molecular dynamics simulations of the MBP-A/mannose complex suggested that Ca^{2+} binding site 3 is involved in the binding interaction (Harte and Bajorath 1994; Zelensky and Gready 2005). Residues with carbonyl side chains involved in Ca^{2+} coordination in site 2 form two characteristic motifs in the CTLD sequence, and together with the calcium atom are directly involved in monosaccharide binding. Despite their spatial proximity, from the evolutionary and structural points of view Ca^{2+}-binding sites 1 and 2 should be considered as independent. Crystallographic studies of rat MBP-A CTLD crystallized at a low metal ion concentration (0.325 mM Ho^{3+} instead of 20 mM as used to obtain the CTLD complexed with mannose) have shown that site 1 has higher affinity for Ca^{2+} as it remains occupied and Ca^{2+}-coordination geometry is retained while site 2 loses its metal ion (Ng et al. 1998). Unlike many other functions of the CTLD, Ca^{2+}-dependent carbohydrate binding is found across the whole phylogenetic distribution of the family, from sponges to human, and thus is likely to be the ancestral function (Weis and Drickamer 1996).

22.1.4 Ligand Binding

CTLDs selectively bind a wide variety of ligands. As the superfamily name suggests, carbohydrates are primary ligands for CTLDs and the binding is Ca^{2+}-dependent (Weis and Drickamer 1996). However, the fold has been shown to specifically bind proteins (Natarajan et al. 2002), lipids (Sano et al. 1998) and inorganic compounds including $CaCO_3$ and ice. In several cases the domain is multivalent and may bind both protein and sugar (Zelensky and Gready 2005). Carbohydrate binding is, however, a fundamental function of the superfamily and the best studied one. The first characterized vertebrate CTLDs were Ca^{2+}-dependent lectins, and most of the functionally characterized CTLDs from lower organisms were isolated because of their sugar-binding activity. Although as the number of CTLD sequences grows it becomes clearer that the majority of them do not possess lectin properties, CTLDs are still regarded as a lectin family (Zelensky and Gready 2004).

Four Link protein-encoding genes have been identified in mammals, each physically linked with one of the lectican genes; this suggests that lecticans and Link proteins are of a common evolutionary origin (Spicer et al. 2003). Link proteins and lecticans are also functionally associated: cartilage Link proteins bind both aggrecan and hyaluronan stabilizing the proteoglycan/glycosaminoglycan network (Faltz et al. 1979). CD44 and its recently identified close homologue Lyve-1 are type I transmembrane molecules and cell surface receptors for hyaluronan (Banerji et al. 1999). Tumor necrosis factor-inducible protein (TSG-6) is a soluble protein with a CUB and a Link domain (Lee et al. 1992; Wisniewski and Vilcek 1997). The structure of the latter in free and hyaluronan-bound states has been determined by NMR (Blundell et al. 2003). Stabilin-1 and -2 (also known as FEEL-1/-2) (Tamura et al. 2003; Adachi and Tsujimoto 2002) are scavenger receptors which have the capacity to internalize conventional scavenger ligands such as low density lipoprotein, bacteria and advanced glycation end products. Unlike Stabilin-2, Stabilin-1 does not bind hyaluronan or other glycosaminoglycan (Prevo et al. 2004).

22.1.5 C-Type Lectin-Like Domains in Model Organisms

An important approach to understanding the roles of mammalian carbohydrate-binding proteins is to examine the functions of orthologs in simpler organisms. Because of the advanced state of the developmental, genetic and genomic study of *Caenorhabditis elegans* and *Drosophila melanogaster*, these organisms are particularly attractive models. Homologs of six classes of lectins have been identified using methods of sequence comparisons combined with knowledge of how these proteins interact with glycan ligands.

With regard to C-type lectin-like domains, relative to genome size there are far more CTLDs in the model invertebrates than in mammals. However, the *C elegans* and *Drosophila* proteins that contain CTLDs are quite distinct from the mammalian proteins that contain CTLDs. These differences are evident in the sequences of the CTLDs and the domain organization of the proteins in which they are found. Only a small subset of invertebrate CTLDs contain the constellation of amino acid residues that form Ca^{2+} and sugar-binding sites in mammalian C-type carbohydrate-recognition domains (Drickamer and Dodd 1999; Dodd and Drickamer 2001).

22.1.5.1 Evolution of the C-Type Lectin-Like Domain

The CTLDs of higher eukaryotes are protein modules originally identified as carbohydrate-recognition domains (CRDs) in a family of Ca^{2+}-dependent animal lectins. Less closely related but still definitely homologous CTLDs have been identified in a variety of proteins that do not appear to have carbohydrate-binding activity. All of the domains in the CTLD group show distinct evidence of sequence similarity and are thus believed to have descended from a common ancestor by a process of divergent evolution.

22.2 Classification of CLRD/CTLD-Containing Proteins

The C-type lectin superfamily is a large group of proteins that are characterized by the presence of one or more CLRDs. They can be divided into 17 subgroups based on additional non-lectin domains and gene structure, the two independent sets of criteria. The two approaches give essentially the same results, indicating that members of each group are derived from a common ancestor, which had already acquired the domain architecture that is characteristic of the group. Initially classified into seven subgroups (I to VII) based on the order of various protein domains in each protein: (I) Lecticans or hyalectans, (II) asialoglycoprotein receptors, (III) collectins, (IV) selectins, (V) NK cell receptors, (VI) endocytic receptors, and (VII) lectins as product of regenerating genes (*Reg*) (Drickamer 1993; McGreal et al. 2004). This classification was subsequently updated in 2002, leading to seven additional groups (VIII to XIV) (Drickamer and Fadden 2002) based on structural organization. A further

three subgroups were added (XV to XVII) by Zelensky and Gready (2005). More than 100 different proteins encoded in the human genome contain the CTLD. Most of these groups have a single CTLD, but the macrophage mannose receptor (group VI) has eight CTLDs. The domain architecture of the CTLDcps in different groups is shown in Fig. 22.4. The monomeric and membrane bound selectins have an N-terminal C-type lectin domain that mediates adhesion between certain cell types through carbohydrate binding. Groups VII (REG), IX (tetranectin), XI (attractin), XIII (DGCR2; DiGeorge syndrome critical region gene 2), XV (BIMLEC), and XVII (CBCP) have no known glycan ligands. The section of animal lectins genomics resource includes information on the structure and function of proteins in each group, as well as annotated sequence alignments, and a comprehensive database for all human and mouse CTLD-containing proteins (Table 22.1).

Despite the presence of a highly conserved domain, C-type lectins are functionally diverse and have been implicated in various processes including cell adhesion, tissue integration and remodeling, platelet activation, complement activation, pathogen recognition, endocytosis (Table 22.1). From a functional perspective, we know most about collectins, endocytic receptors, myeloid lectins, and selectins, and these groups are discussed in detail in chapters to follow. However, proteins possessing CTLDs type are not necessarily lectins.

22.3 Disulfide Bonds in Lectins and Secondary Structure

22.3.1 Arrangement of Disulfide Bonds in CTLDs

Drickamer and Dodd (1999) summarized positions of six different disulfide bonds in CTLDs (Fig. 22.5). Chemical evidence for the presence of each of these bonds, except number 4, has been provided in at least one CTLD (Fuhlendorff et al. 1987; Usami et al. 1993). The positions of disulfide bonds designated 1, 2, and 3 have been demonstrated by x-ray crystallography as well (Weis et al. 1991; Nielsen et al. 1997), while homology modeling of CTLDs containing disulfide bonds 5 and 7 shows that they could readily be accommodated into the C-type lectin fold. The patterns of cysteine residues in the CTLDs from *C. elegans* are consistent with the presence of disulfide bonds in each of the arrangements shown in Fig. 22.5 except for bond type 4. No additional pairs of cysteine residues within the CTLDs are consistently evident for any of the subgroups, indicating that the cysteine residues are mostly involved in disulfide bonds of the types already characterized in vertebrate homologues.

CTLDs lacking one of a pair of cysteine residues almost invariably also lack the cysteine side chain to which the first residue would be linked. Like the CTLDs from other organisms, those from *C.elegans* each contain a subset of the possible disulfide bonds. CTLDs in a given subgroup generally show the same disulfide bonds, although a few domains contain extra unique pairs of cysteine residues that might form disulfides. Thus, the similarity in disulfide bond structure in each subgroup reflects the overall similarity in sequence of the CTLDs (Drickamer and Dodd 1999). CEL-I from the sea cucumber, *Cucumaria echinata* is composed of two identical subunits held by a single disulfide bond. A subunit of CEL-I is composed of 140 amino acid residues. Two intrachain (Cys3–Cys14 and Cys31–Cys135) and one interchain (Cys36) disulfide bonds were also identified from an analysis of the cystine-containing peptides obtained from the intact protein (Hatakeyama et al. 2002; Yamanishi et al. 2007).

22.3.2 Functional Role of Disulfides in CTLD of Vertebrates

Single cysteine residues appear in several of these groups at positions 7 and 8 as well as at a unique position 9. The turn between β-strands 3 and 4 is exposed on the surface of the domain, so it is expected that cysteine residues at position 9 would be accessible for formation of disulfide bonds. It is possible that such bonds could form with other cysteine residues within the same polypeptide but outside the CTLDs. However, no likely pairing partner is evident for any of these residues, suggesting that they are more likely to form interchain disulfide bonds. Homo- and hetero-dimer formation through cysteine residues at positions 7 and 8 has been particularly well documented in snake venom proteins containing CTLDs (Usami et al. 1993). The botrocetin, which promotes platelet agglutination in the presence of von Willebrand factor, from venom of the snake Bothrops jararaca is a heterodimer composed of the α subunit and the β subunit held together by a disulfide bond. Seven disulfide bonds link half-cystine residues 2–13, 30–128, and 103–120 of the α subunit; 2–13, 30–121, and 98–113 of the β subunit; and 80 of the α subunit to 75 of the β subunit. In terms of amino acid sequence and disulfide bond location, two-chain botrocetin is homologous to echinoidin (a sea urchin lectin) and other C-type lectins (Usami et al. 1993). The disulfide bond pattern of Trimeresurus stejnegeri lectin (TSL), a member of the C-type lectin family, showed four intrachain disulfide bonds: Cys3–Cys14, Cys31–Cys131, Cys38–Cys133 and Cys106–Cys123, and two interchain linkages, Cys2–Cys2 and Cys86–Cys86 (Zeng et al. 2001). The antifreeze polypeptide (AFP) from the sea raven, Hemitripterus americanus, a member of the cystine-rich class of blood antifreeze proteins,

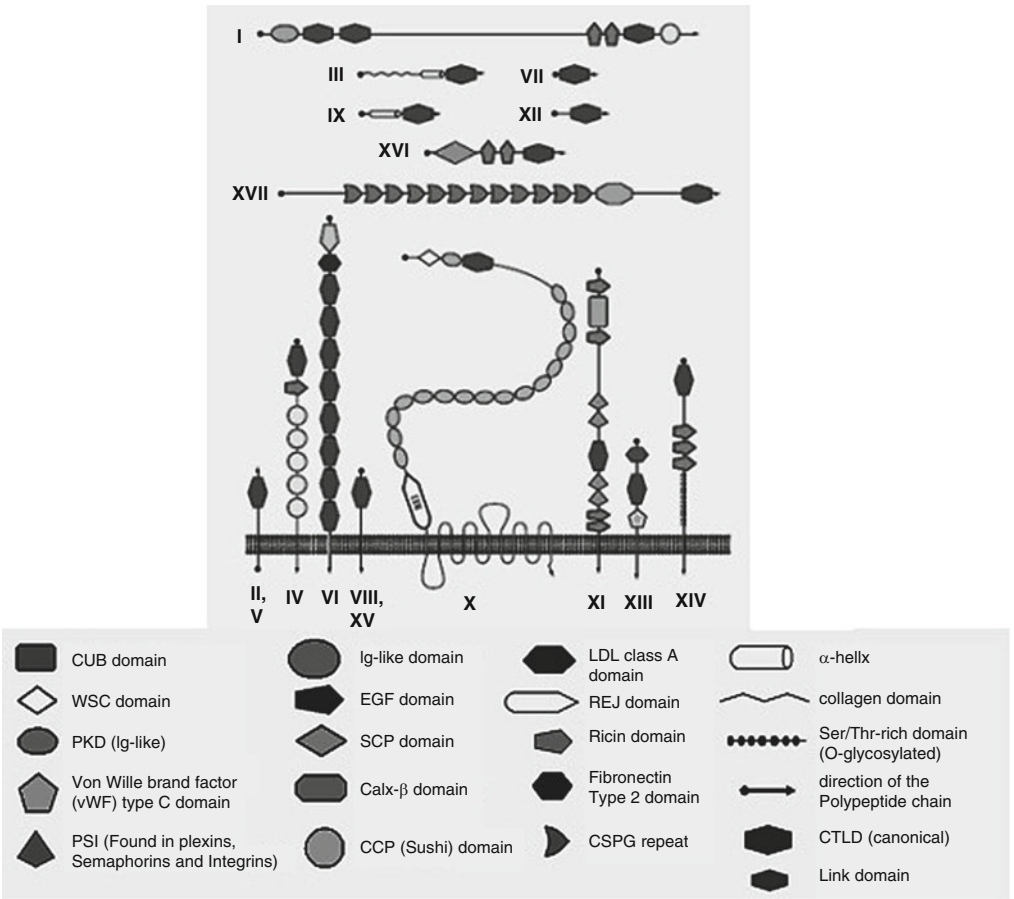

Fig. 22.4 **Domain architecture of vertebrate CTLD**, with mammalian homologues, from different groups. Group numbers are indicated next to the domain charts. *I* lecticans, *II* the ASGR group, *III* collectins, *IV* selectins, *V* NK receptors, *VI* the macrophage mannose receptor group, *VII* REG proteins, *VIII* the chondrolectin group, *IX* the tetranectin group, *X* polycystin 1, *XI* attractin, *XII* EMBP, *XIII* DGCR2, *XIV* the thrombomodulin group, *XV* Bimlec, *XVI* SEEC, *XVII* CBCP (Adapted with permission from Zelensky and Gready 2005 © John Wiley and Sons)

contains 129 residues with 10 half-cystine residues and all 10 half-cystine residues appeared to be involved in disulfide bond formation. The disulfide bonds are linked at Cys7 to Cys18, Cys35 to Cys125, and Cys89 to Cys122. Similarities in covalent structure suggest that the sea raven AFP, pancreatic stone protein, and several lectin-binding proteins comprise a family of proteins which may possess a common fold (Ng and Hew 1992).

Functional rat or human asialoglycoprotein receptors (ASGP-Rs), the galactose-specific C-type lectins, are hetero-oligomeric integral membrane glycoproteins. Rat ASGP-R contains three subunits, designated rat hepatic lectins (RHL) 1, 2, and 3; human ASGP-R contains two subunits, HHL1 and HHL2. Both receptors are covalently modified by fatty acylation (Zeng et al. 1996). Unfolded forms of the HHL2 subunit of the human ASGP-Rs are degraded in the ER, whereas folded forms of the protein can mature to the cell surface (Wikström and Lodish 1993). Deacylation ofASGP-Rs with hydroxylamine results in the spontaneous formation of dimers through reversible disulfide bonds, indicating that deacylation concomitantly generates free thiol groups. Results also show that Cys57 within the transmembrane domain of HHL1 is not normally palmitoylated. Thus, Cys35 in RHL1, Cys54 in RHL2 and RHL3, and Cys36 in HHL1 are fatty acylated, where as Cys57 in HHL1 and probably Cys56 in RHL1 are not palmitoylated (Zeng et al. 1996). Eosinophil granule major basic protein 2 (MBP2 or major basic protein homolog) is a paralog of major basic protein (MBP1) and, similar to MBP1, is cytotoxic and cytostimulatory in vitro. MBP2, a small protein of 13.4 kDa molecular weight, contains ten cysteine residues. Mass spectrometry shows two cystine disulfide linkages (Cys20–Cys115 and Cys92–Cys107) and six cysteine residues with free sulfhydryl groups (Cys2, Cys23, Cys42, Cys43, Cys68, and Cys96). MBP2, similar to MBP1, has conserved motifs in common with C-type

Table 22.1 Classification of C-type lectins with associated domains

Group	Name	Associated domains
I	Lecticans (Hyalectans)	EGF, Sushi, Ig and Link domains
II	Asialoglycoprotein and DC receptors	None
III	Collectins	None
IV	Selectins	Sushi and EGF domains
V	NK – cell receptors	None
VI	Multi-CTLD endocytic receptors	FnII and Ricin domains
VII	Reg group of lectins	None
VIII	Chondrolectin, Layilin	None
IX	Tetranectin	None
X	Polycystin	WSC, REJ, PKD domains
XI	Attractin	PSI, EGF and CUB domains
XII	Eosinophil major basic protein (EMBP)	None
XIII	DGCR2	None
XIV	Thrombomodulin	EGF domains
XV	Bimlec	None
XVI	SEEC	SCP and EGF domains
XVII	CBCP/Frem1/QBRICK	CSPG repeats and CalX-β domains

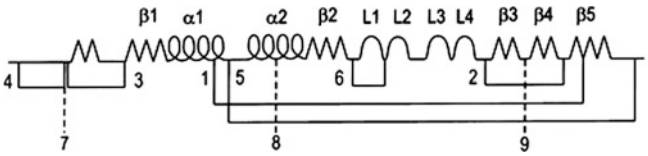

Fig. 22.5 Disulfide bonds in CTLDs. Secondary structure shared by most CTLDs is summarized, with *coils* representing α-helices, *jagged lines* denoting β-strands and loops shown as *curved segments*. The number of these elements corresponds to the secondary structure organisation of rat serum mannose-binding protein (Weis et al. 1991). Potential disulfide bonds within the CTLD are numbered 1 through 6 and cysteines that participate in interchain disulfide bonds are numbered 7 through 9 (Adapted with permission from Drickamer and Dodd 1999 © Oxford University Press)

lectins. The disulfide bond locations are conserved among human MBP1, MBP2 and C-type lectins (Wagner et al. 2007).

The biological functions of rat surfactant protein-A (SP-A), an oligomer composed of 18 polypeptide subunits are dependent on intact disulfide bonds. Reducible and collagenase-reversible covalent linkages of as many as six or more subunits in the molecule indicate the presence of at least two NH2-terminal interchain disulfide bonds. However, the reported primary structure of rat SP-A predicts that only Cys6 in this region is available for interchain disulfide formation. Direct evidence for a second disulfide bridge was obtained by analyses of a set of three mutant SP-As with telescoping deletions from the reported NH2-terminus. Two of the truncated recombinant proteins formed reducible dimers despite deletion of the domain containing Cys6. A novel post translational modification results in naturally occurring cysteinyl isoforms of rat SP-A which are essential for multimer formation (Elhalwagi et al. 1997). Pulmonary SP-D is assembled predominantly as dodecamers consisting of four homotrimeric subunits each. Association of these subunits is stabilized by interchain disulfide bonds involving two conserved amino-terminal cysteine residues (Cys-15 and Cys-20). Mutant recombinant rat SP-D lacking these residues (RrSP-Dser15/20) is secreted in cell culture as trimeric subunits rather than as dodecamers. Disulfide cross-linked SP-D oligomers are required for the regulation of surfactant phospholipid homeostasis and the prevention of emphysema and foamy macrophages in vivo (Zhang et al. 2001).

22.4 Collectins

22.4.1 Collectins: A Group of Collagenous Type of Lectins

Collectins are a small family of secreted oligomeric glycoproteins that contain in common an NH2-terminal collagen-like domain and a COOH-terminal lectin (carbohydrate binding) domain (collagenous + lectin domains = collectin), and found in both lung and serum. The name collectin is derived from the words "collagen" and "lectin." Collectins are C-type lectins that contain a collagen-like domain and usually assemble in large oligomeric complexes containing 9–27 subunits. They belong to C-type lectins family and have an important function in innate immunity, recognizing and binding to microorganisms via sugar arrays on the microbial surface. To date, nine different collectins have been identified: mannan-binding lectin (MBL), surfactant protein A (SP-A), surfactant protein D (SP-D), collectin liver 1 (CL-L1), collectin placenta 1 (CL-P1), conglutinin, collectin of 43 kDa (CL-43) and collectin of 46 kDa (CL-46), and collectin from kidney (CL-K1). The collectins MBP, conglutinin, CL-43, CL-46, CL-K1, SP-A, and SP-D are soluble, whereas CL-L1 and CL-P1 are membrane proteins. Some collectins, such as MBP and SP-A, organize into a "bouquet," and others, such as bovine conglutinin and SP-D, organize into a "cruciform" shape. One of the best-studied serum collectins is MBP (Chaps. 23–25).

Collectins: Mannan-Binding Protein as a Model Lectin

23

Anita Gupta

23.1 Collectins

A group of collagenous type of lectins: Collectins are a small family of secreted oligomeric glycoproteins that contain in common an NH2-terminal collagen-like domain and a COOH-terminal lectin (carbohydrate binding) domain (collagenous + lectin domains = collectin), and found in both lung and serum. The name collectin is derived from the words "collagen" and "lectin." Collectins are C-type lectins that contain a collagen-like domain and usually assemble in large oligomeric complexes containing 9–27 subunits. They belong to C-type lectins family and have an important function in innate immunity, recognizing and binding to microorganisms via sugar arrays on the microbial surface. To date, nine different collectins have been identified: mannan-binding lectin (MBL), surfactant protein A (SP-A), surfactant protein D (SP-D), collectin liver 1 (CL-L1), collectin placenta 1 (CL-P1), conglutinin, collectin of 43 kDa (CL-43) and collectin of 46 kDa (CL-46), and collectin from kidney (CL-K1). The collectins MBP, conglutinin, CL-43, CL-46, CL-K1, SP-A, and SP-D are soluble, whereas CL-L1 and CL-P1 are membrane proteins. Some collectins, such as MBP and SP-A, organize into a "bouquet," and others, such as bovine conglutinin and SP-D, organize into a "cruciform" shape. One of the best-studied serum collectins is MBP. Bovine CL-43 is structurally one of the simplest collectins, consisting of only three polypeptides, each of which contains a terminal CTLD. Rats have two serum MBPs designated A and C, sometimes called mannan-binding proteins. Humans appear to have only a single MBP corresponding to the rat MBP-A. The collectins can be classed into two distinct group, with MBP and SP-A being hexamers and SP-D, conglutinin and collectin-43 (CL-43) being tetramers, with proteins in the latter group also having significantly larger dimensions with respect to the length of their collagen-like 'stalks'. The structural and functional relationships of this group of collectins have been reviewed (Håkansson and Reid 2000; Hansen and Holmskov 2002; and others).

Each polypeptide chain in collectins consists of four regions: a relatively short N-terminal region, a collagen like region, an α-helical coiled-coil, and a C-terminal lectin domain. With the exception of the N-terminal region, these regions or domain types are also found in molecules other than collectins (Fig. 22.1). The presence of a collagen like region in these molecules imposes a trimeric structure. This is a prerequisite for their proper function; the carbohydrate affinity of a single collectin carbohydrate recognition domain (CRD) is weak but the trimeric organization permits a trivalent and hence stronger interaction between collectin and carbohydrate-containing target surface. In most of the collectins, these trimers are further assembled into larger entities, which enables them to cross-link several target particles and perhaps also to interact simultaneously with target and with host cells (Håkansson and Reid 2000).

Lung surfactant protein D (SP-D) and bovine conglutinin are X-shaped molecules consisting of four trimers extending pairwise from the hub with the lectin domains at the tip of the collagenous arms (Crouch et al. 1994). These dodecamers have been shown to associate further into even larger complexes, with an increased capacity to aggregate bacteria. Surfactant protein A (SP-A) is the major protein component of lung surfactant complex and exhibits a reduced and denatured molecular mass of 35 kDa in humans. SP-A has been shown to have a flower-bouquet-like octadecameric structure similar to that of complement C1q. SP-A interacts with lipids and specifically binds to dipalmitoylphosphatidylcholine (DPPC). Lung SP-A (Voss et al. 1988) and most mannan binding proteins form bouquet-like complexes with up to six trimers. The degree of oligomerization differs between the different proteins, but may also vary within the molecular population of a single preparation. Only the larger complexes, i.e., pentamers or hexamers, give a full biological

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_23, © Springer-Verlag Wien 2012

response in terms of macrophage stimulation and complement activation. Comparisons of hybrid peptide chains of rat MBP-A and MBP-C and site-directed mutagenesis led to the conclusion that oligomerization depends on the N-terminal region and that the most N-terminal of its cysteines (Cys6) is indispensable for the formation of oligomers of trimers. The other two cysteines (Cys13 and Cys18) are involved in intratrimer disulfide bridge formation (Wallis and Drickamer 1999). There are a several reviews, which described the biological, physiological, and functional properties of the collectins (Håkansson and Reid 2000; Weis and Drickamer 1996; Lu 1997; Crouch 1998). Håkansson and Reid, (2000) focussed on the structural aspects of the mannan-binding proteins and the lung surfactant proteins.

23.1.1 N-Terminal Region

The N-terminal region of collectins is defined as the segment N-terminal to the first collagenous triple-helix residue. This relatively cysteine-rich region stabilizes the trimers through disulfide bridging (Crouch et al. 1994; Holmskov et al. 1995) and links them together in the collectin oligomers. There seems to be no overall homology between the collectins in this part of the molecule. The only general trend (to which canine SP-A, Rhesus monkey MBP-C, and CL-L1 do not conform) seems to be two cysteine residues separated in sequence by 4–5 amino acids, and perhaps also that the amino acid preceding the second of these cysteines is hydrophobic in most of the collectins. Most of the other amino acids separating these two cysteine residues are relatively hydrophobic in MBP and SP-D but hydrophilic in SP-A. The collectins can nonetheless be divided into different groups with related N-terminal regions. The N-terminal sequences of SP-D, conglutinin, and collectin-43 are clearly related and of similar length, i.e., 25–28 amino acids, and include two cysteine residues. The N-terminal region of SP-A is much shorter and, due to variation in signal peptidase cleavage, is not homogenous; there are two isoforms with seven or ten residues containing one or two cysteines, respectively (Elhalwagi et al. 1997). The third group consists of mannan-binding proteins A and C, which have distinct, yet related, N-terminal regions, each approximately 20 amino acids long. The hepatic forms rat MBP-C and mouse MBP-C have only two cysteines while the other mannan-binding proteins have three, although the sequence of rhesus monkey MBP-C deviates from the similarity displayed by the other sequences. Human MBP has three cysteines despite its closer evolutionary relationship to rat MBP-C and forms larger oligomers in serum than it does in the liver (Kurata et al. 1994). The fourth group, so far represented only by human CL-1, has a much longer N-terminal sequence with only one cysteine.

23.1.2 Collagenous Region

Information on collagen structure is mainly derived from fiber diffraction studies (Beck and Brodsky 1998), and the crystallographic structures of model compounds (Kramer et al. 1998, 1999). A collagen structure can be recognized from the amino acid sequence with its characteristic Gly-X-Y repetitive pattern, where X and Y can be any amino acid but are frequently prolines or hydroxyprolines. Each of the three chains forms a left-handed polyproline II like helix and then chains are coiled around each other in a right-handed manner with the glycine residues in the interior of the superhelix. Interchain hydrogen bonds between N-H groups of glycine and the C_5O groups of the amino acid in X position stabilize the structure. On account of this and absence of intrachain hydrogen bonds, the collagen helix can exist as a trimer. The helical parameters are sequence dependent and differ between imino acid rich and amino acid rich regions (Kramer et al. 1999). The collagen triple helix is surrounded by water molecules that interact with most polar groups, which are exposed to the solvent, either by their side chains or carbonyl groups. Accordingly, the triple helix in the collectins is rich in charged amino acids. The triple helix is most stable due to its high tensile strength, stability, and relative resistance to proteolysis. In addition, a triple helical region can also mediate binding interactions with other macromolecules as shown for C1q and the macrophage scavenger receptor. The collagenous region in MBP contains a binding site for its associated serine proteases (MASP-1 and MASP-2) through which the complement cascade of reactions is triggered (Thiel et al. 1997).

Collectins bind to their macrophage receptor through the collagenous region (Malhotra et al. 1993). The length of collagenous region differs between the collagens; the X- shaped SP-D and bovine collectin have the longest triple-helical regions, and SP-A and MBP the shortest. Most of the collectin prolines in Y position are hydroxylated. Hydroxylated and glycosylated lysines have been demonstrated in SP-D, MBP, collectin 43 and conglutinin (Håkansson and Reid 2000). SP-A oligomerizes as an octadecamer, which forms a flower bouquet-like structure. The collagen-like domain of human SP-A consists of 23 Gly-X-Y repeats with an interruption near the midpoint of this domain. This interruption causes a kink, but its role remains largely unknown. In SP-A, there appears to be a kink in the collagenous rod in this part of the helix, as judged by electron microscopy. The collagen triple helices aggregate laterally at their N-terminal ends, but there is no evidence for covalent crosslinking. At the site of the Gly-X-Y interruption, the helices make a 60° bend and diverge (Voss et al. 1988) in a manner familiar from studies on the C1q structure (Lu et al. 1993). Oligomerization of MBP-A is in part promoted by the N-terminal part of its collagenous region (Wallis and Drickamer 1999), but this region is not indispensable for SP-A oligomer formation (McCormack et al. 1997).

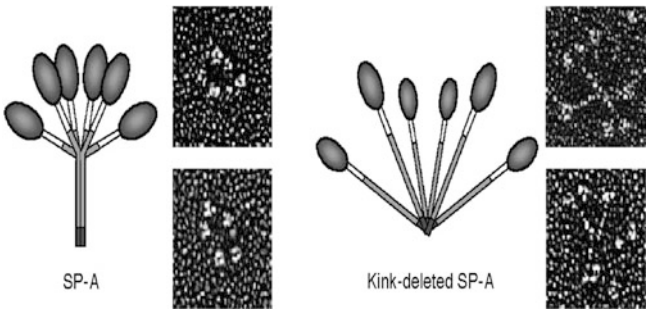

Fig. 23.1 Interruption of Gly-X-Y repeats in the SP-A is critical for the formation of a flower bouquet-like octadecamer (Adapted by permission from Uemura et al. 2006 © American Chemical Society)

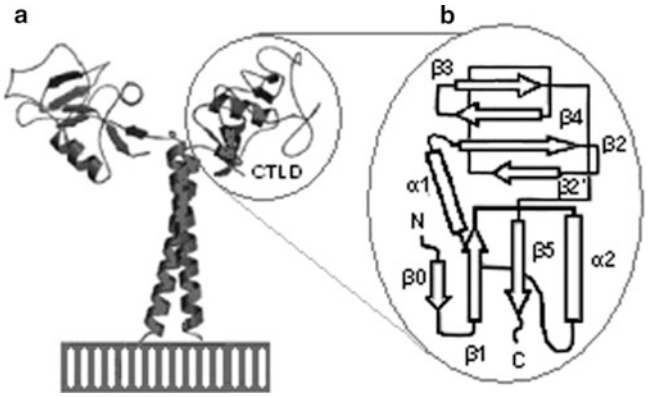

Fig. 23.2 (**a**) **Ribbon representation of the maltose-binding protein (MBP-A;** PDB ID: 1KMB), a CTLD family prototype. (**b**) The topology diagram of CTLD receptor family. This secondary structure organization is well conserved in all known CTLD of identified three-dimensional. In diagrams, *C* and *N* represent the carboxyl- and N-terminus ends of the protein, respectively. For simplicity, the Ca^{2+} ions in the MBP-A ribbon representation are omitted (Adapted by permission from Sawicki et al. 2001© John Wiley and Sons)

To define the importance of the kink region of SP-A, two mutated proteins were constructed to disrupt the interruption of Gly-X-Y repeats. Results indicate that the interruption of Gly-X-Y repeats in the SP-A molecule is critical for the formation of a flower bouquet-like octadecamer and contributes to SP-A's capacity to aggregate phospholipid liposomes (Uemura et al. 2006; Fig. 23.1).

23.1.3 C-Type Lectin Domain

MBP-A is a prototype member of Ca^{2+} dependent lectin in CTLD family (Fig. 23.2a). Collectins have a common sequence motif of 115–130 amino acid residues as carbohydrate recognition domain (CRD) and has been described in Chap. 22. Despite the diversity of ligand recognized by CTLD, members of this family exhibit a highly conserved structure (Fig. 23.2b). The core structure consists of two α-helixes (α1 and β2) and two anti-parallel β-sheets formed by β strands (β0, β1, and β5) and (β2, β2', β3, and β4). The secondary structure elements composing the CTLD core region are conserved among the determined structure (Sawicki et al. 2001), whereas considerable variation is observed in the sequence and structure of the loops connecting the secondary structure elements. It has been demonstrated that the sequence and structure variability of these loops confer ligand specificity (Torgersen et al. 1998).

A comparison of the amino acid sequences of 22 different extracellular collectins yields 18 conserved amino acids in addition to the four cysteines. Perhaps most important from a structural point of view is a hydrophobic cluster containing the conserved residues Phe^{304}, Tyr^{314}, Trp^{317}, Pro^{322}, Trp^{340}, in addition to the semi-conserved Val^{332}. They hold together the carbohydrate binding region consisting of strand β6 and the stretch between the two strands β4 and β5. Trp^{340} is also hydrogen bonded to the conserved Asn^{277} of helix α2. Asn^{277} is in turn hydrogen bonded to the main-chain carbonyl group of Gly^{338}, as is the conserved residue Asn^{316}. Glycine 338 appears to play a key role in the loop structure preceding the β6 strand. Its main-chain conformation is not compatible with the presence of a side chain, which is also true for the other two conserved glycines, Gly^{241} and Gly^{309}, and for most of the nonconserved SP-D glycines as well. Glu^{276}, Asn^{277}, and Ala^{279} are on the nonexposed side of helix α2, which is preceded by the conserved Pro^{271}. Asn^{277}, as mentioned, is hydrogen bonded to both Gly^{338} and Trp^{340}, and Glu^{276} is hydrogen bonded to the main-chain amino group of the nonconserved. Studies indicate a slower evolutionary pace in and around the β5 and β6 strands, i.e., the carbohydrate binding site. In addition to the carbohydrate binding calcium ion, two more calcium ions have been found in crystallographic studies of MBP and SP-D (Weis et al. 1998; Weis and Drickamer 1994; Håkansson et al. 1999). One of these is found 8 Å away from the carbohydrate binding calcium and is complexed by three aspartic acid and one glutamic acid residues. These residues are either conserved or only conservatively replaced in MBPs, SP-D, conglutinin, and Cl-43, but not in SP-A (Håkansson and Reid 2000; Weis and Drickamer 1994).

The electrostatic potential along the surface of collectins displays a large positively charged area within the cavity between the three lectin domains. This surface charge can be observed both for the mannan-binding proteins and SP-D, but is not present on the C-type lectins that are not collectins, e.g., in tetranectin or on the surface of E-selectin. In SP-D,

this charge results from the presence of nonconserved lysine residues. The charged area may be involved in interactions with negative charges on the surface of its targets, e.g., LPS moiety of microbial carbohydrates or the phospholipids of the pulmonary surfactant. The calcium ions in these proteins do influence the surface charge, and the apo protein is characterized by large negatively charged areas on the central and peripheral parts of the lectin domains. Thus, the calcium ions might have a functional role other than carbohydrate binding, e.g., they may maintain a certain electrostatic potential pattern on the surface of the molecule. In this context, it is interesting to note that SP-D was found to bind to its putative receptor gp340 in a manner that was calcium dependent but not inhibited by the presence of maltose (Holmskov et al. 1997; Håkansson and Reid 2000).

The C-type lectin domains in collectins are attached to collagen regions via α-coiled neck regions. Collectins form trimers that may assemble into larger oligomers. Each polypeptide chain consists of four regions: a relatively short N-terminal region, a collagen like region, an α-helical coiled-coil, and the lectin domain. Primary structure data are available for many proteins, while the most important features of the collagen-like region can be derived from its homology with collagen. Carbohydrate binding has been structurally characterized in several complexes between MBP and carbohydrate and between SP-D and carbohydrate; all indicate that the major interaction between carbohydrate and collectin is the binding of two adjacent carbohydrate hydroxyl groups to a collectin calcium ion. In addition, these hydroxyl groups form hydrogen bond to some of the calcium amino acid ligands. While each collectin trimer contains three such carbohydrate binding sites, deviation from overall threefold-symmetry has been demonstrated for SP-D, which may influence its binding properties. The protein surface between the three binding sites is positively charged in both MBP and SP-D (Crouch 1998; Håkansson and Reid 2000).

23.1.4 Comparative Genetics of Collagenous Lectins

MBLs and ficolins (FCNs) are structurally related to C1q, but activate the lectin complement pathway via interaction with MBL-associated serine proteases (MASPs). MBLs, FCNs, and other collagenous lectins also bind to some host macromolecules and contribute to their removal. While there is evidence that some lectins and the lectin complement pathway are conserved in vertebrates, many differences in collagenous lectins have been observed among humans, rodents, and other vertebrates. For example, humans have only one MBL but three FCNs, whereas most other species express two FCNs and two MBLs. Bovidae express CG and other SP-D-related collectins that are not found in monogastric species. Some dysfunctions of human MBL are due to single nucleotide polymorphisms (SNPs) that affect its expression or structure and thereby increase susceptibility to some infections. Collagenous lectins have well-established roles in innate immunity to various microorganisms. So it is possible that some lectin genotypes or induced phenotypes influence resistance to some infectious or inflammatory diseases in animals (Lillie et al. 2005).

23.1.5 Generalized Functions of Collectins

While MBL and SP-D interact with mannose, glucose, L-fucose, ManNAc, GlcNAc as their ligands, SP-A has affinity for glucose, mannose, maltose, and inositol (Kerrigan and Brown 2009). The collectins function in "innate" immunity and act before the induction of an antibody-mediated response. Collectins stimulate in vitro phagocytosis by recognizing surface glycans on pathogens, they promote chemotaxis, and they stimulate the production of cytokines and reactive oxygen species by immune cells. Lung surfactant lipids have the ability to suppress a number of immune cell functions such as proliferation, and this suppression of the immune response is further augmented by SP-A. Although SP-A and SP-D were originally found in the lung, they are also expressed in the intestine. Their function is to enhance adhesion and phagocytosis of microorganisms by agglutination and opsonization. The genes for MBL, SP-A and SP-D have been mapped to human chromosome 10, with at least two expressed SP-A genes (SP-AI and SP-AII) forming a cluster with an SP-A pseudogene. Somatic cell hybrid mapping places the human SP-A and SP-D genes at 10q22-q23 while MBL is localised at 10q21. The close evolutionary relationship between the collectins is further emphasized by a common pattern of exons in their genomic structures and the presence of a gene cluster on chromosome 10 in humans that contains the genes known for the human collectins. Studies on the structure/function relationships within the collectins could provide insight into the properties of a growing number of proteins also containing collagenous regions such as C1q, the hibernation protein, the α- and β-ficolins, as well as the membrane acetylcholinesterase and macrophage scavenger receptor.

All defense collagens (C1q, SP-A, MBL) have shown a qualitatively and quantitatively similar enhancement of monocyte phagocytosis of targets that are suboptimally opsonized with IgG or CR type 1 ligands, C4b and C3b (Wright 2005). The six amino acid sequence required for this functional stimulation has been identified within the collagen-like domain (Arora et al. 2001). This rapid enhancement of

phagocytic activity is triggered when the defense collagen is bound to the particle to be ingested. Interaction of C1q with its cell-surface receptor on neutrophils induces the activation of respiratory burst. However, this action did not occur with MBP and SP-A, proteins that also contain collagen-like domains (Goodman and Tenner 1992). Interaction of C1q with its cell-surface receptor on neutrophils induces the activation of respiratory burst. This action did not occur with MBP and SP-A, proteins that also contain collagen-like domains (Goodman and Tenner 1992).

23.2 Human Mannan-Binding Protein

Mannose-binding lectin (MBL) is a Group III C-type lectin belonging to the collectins (Holmskov et al. 2003), which are a group of soluble oligomeric proteins containing collagenous regions and CTLDs. MBL is secreted into the blood stream as a large multimeric complex and is primarily produced by the liver, although other sites of production, such as the intestine, have been proposed (Uemura et al. 2002). Ca^{2+}-dependent MBLs belong to the family of animal lectins isolated from the liver and serum of rabbits, humans and rodents. Mannan-binding protein was discovered as a rabbit lectin binding to mannan (Kawasaki et al. 1978). Later the term mannose-binding protein (MBP) was introduced, unfortunately implying a more selective reactivity than is characteristic for this protein. The burst of investigations on MBP deficiency in serum (MBL) and susceptibility to infectious diseases was roused by the seminal demonstration of low MBL levels in children deficient in opsonizing activity and suffering from unexplained sensitivity to infections (Super et al. 1989). Initially, investigations of causal relationship between MBL and disease susceptibility relied on quantification of MBL in serum or plasma (or in some cases, of opsonizing activity). However, the finding of genetic influence on the MBL level opened up for determining the MBL status by genotyping (Holmskov et al. 2003; Kerrigan and Brown 2009; Nuytinck and Shapiro 2004; Worthley et al. 2006).

Sheriff et al. (1994) confirmed that human MBP is a hexamer of trimers with each subunit consisting of an amino-terminal region rich in cysteine, 19 collagen repeats, a 'neck', and a carbohydrate recognition domain that requires calcium to bind ligand. A 148-residue peptide, consisting of the 'neck' and CRDs forms trimers in solution and in crystals. The structure of this trimeric peptide has been determined in two different crystal forms. The 'neck' forms a triple α-helical coiled-coil. Each α-helix interacts with a neighbouring carbohydrate recognition domain. The spatial arrangement of the carbohydrate recognition domains suggests how MBP trimers form the basic recognition unit for branched oligosaccharides on microorganisms (Sheriff et al. 1994) (Fig. 23.3).

23.2.1 Characterization of Serum MBL

23.2.1.1 The Protein

Serum MBL contains both a collagen-like domain and a carbohydrate-recognition domain (CRD). The overall polypeptide structure of MBL is similar to that of the other collectins (SP-A, SP-D, conglutinin, CL-43, liver collectin 1, and CL-46). It includes a short, cysteine-rich N-terminal stretch (aa 1–21), a collagen like region (aa 22–81) with one interruption (aa 43–44) that causes the collagen-like structure to bend, a neck region (aa 82–115), and a carbohydrate recognition domain (aa 116–228) (Drickamer and Taylor 1993). This domain confers the carbohydrate specificity of MBL and is stabilized by two disulfide bonds. Due to collagen-like domain, MBL forms homotrimers, designated the MBL subunit. The collagen-like structure is stabilized by the presence of hydroxyprolines and glycosylated hydroxylysines (Ma et al. 1997). The subunit structures assemble from C to N terminus. The neck region initiates the folding (Childs et al. 1990), and the collagen-like region zips toward the N terminus, creating trimeric subunits. The structure is finally stabilized by intrasubunit disulfide bonds in the N-terminal region (Hansen and Holmskov 1998). The oligomer structure of MBL is similar to the structure of C1q, the primary component of the classical pathway of complement (Ikeda et al. 1987), where the bouquet- like forms arise from the formation of intersubunit disulfide bonds in the N-terminal region (Hoppe and Reid 1994). The elucidation of the structure of MBL is

complicated by the fact that the polypeptide chain of MBL is very heterogeneous. In addition to several post-translational modifications, there are three well documented mutations in the collagen-like region (Garred et al. 1992; Lipscombe et al. 1992; Madsen et al. 1994). These mutations all lead to amino acid substitutions, which distort the collagen-like region and inhibit the correct formation of the oligomer forms of MBL. In addition to the heterogeneity of the polypeptide chain, promoter polymorphisms (Madsen et al. 1995) result in highly variable amounts of MBL in the blood.

Human MBP is a homooligomer composed of 32-kDa subunits. Each subunit has an NH_2-terminal region containing cysteines involved in interchain disulfide bond formation, a collagen-like domain containing hydroxyproline and hydroxylysine, a neck region, and a carbohydrate-recognition domain with an amino acid sequence highly homologous to other Ca^{2+}-dependent lectins. Three subunits form a structural unit, and an intact MBP consists of two to six structural units. The carbohydrate-recognition domain is specific for mannooligosaccharide structures on pathogenic organisms, whereas the collagen-like domain is believed to be responsible for interactions with other effector proteins involved in host defense. Cattle possess three serum C-type lectins capable of recognizing mannan in a calcium-dependent manner (Srinivasan et al. 1999).

23.2.1.2 Two Major Forms of MBL in Human Serum

MBP is mainly synthesized in the liver and occurs naturally in two forms, serum MBP (S-MBP) and intracellular MBP (I-MBP). S-MBP activates complement in association with MBP-associated serine proteases via the lectin pathway. The first precise analysis of the major human MBL oligomers was performed by Teillet et al. (2005). Two major MBL forms are present in human serum with mass values of 228,098 + 170 Da (MBL-I) and 304,899 + 229 Da (MBL-II) for the native proteins, whereas reduction of both species yielded a single chain with an average mass of 25,340 + 18 Da. This demonstrates that MBL-I and -II contain 9 and 12 disulfide-linked chains, respectively, and therefore are trimers and tetramers of the structural unit. As shown by surface plasmon resonance spectroscopy, trimeric and tetrameric MBL bound to immobilized mannose-BSA and N-acetylglucosamine-BSA with comparable K_D values (2.2 and 0.55 nM and 1.2 and 0.96 nM, respectively). However, tetrameric MBL exhibited significantly higher maximal binding capacity and lower dissociation rate constants for both carbohydrates. As shown by gel filtration, both MBL species formed 1:2 complexes with MASP-3 or MAp19. The oligomerization state of MBL has a direct effect on its carbohydrate-binding properties, but no influence on the interaction with the MASPs (Teillet et al. 2005). The serum MBP shares similarity with mammalian and chicken hepatic lectins in primary structure of carbohydrate-recognition domain, as well as in the ligand-binding mode: a high affinity (K_D ~ nM) is generated by clustering of approximately 30 terminal target sugar residues on a macromolecule, such as bovine serum albumin, although the individual monosaccharides have low affinity (K_D 0.1–1 mM). On the other hand, MBP does not manifest any significant affinity enhancement toward small, di- and trivalent ligands, in contrast to the hepatic lectins whose affinity toward divalent ligands of comparable structures increased from 100- to 1,000-fold. Such differences may be explained on the basis of different subunit organization between the hepatic lectins and MBP (Lee et al. 1992). Inhibition assays suggested that rat serum MBP has a small binding site which is probably of the trough-type. The 3- and 4-OH of the target sugar are indispensable, while the 6-OH is not required. These characteristics are shared by the rat hepatic lectin and chicken hepatic lectin, both of which are C-type lectins containing carbohydrate-recognition domains highly homologous to that of MBP. Apparently, the related primary structures of these lectins give rise to similar gross architecture of their binding sites, despite the fact that each exhibits different sugar binding specificities (Lee et al. 1991).

23.2.1.3 Intracellular MBP (I-MBP)

The I-MBP shows distinct accumulation in cytoplasmic granules, and is predominantly localized in the endoplasmic reticulum (ER) and involved in COPII vesicle-mediated ER-to-Golgi transport. However, the subcellular localization of either a mutant (C236S/C244S) I-MBP, which lacks carbohydrate-binding activity, or the wild-type I-MBP in tunicamycin-treated cells shows an equally diffuse cytoplasmic distribution, suggesting that the unique accumulation of I-MBP in the ER and COPII vesicles is mediated by an N-glycan-lectin interaction. The binding of I-MBP with glycoprotein intermediates occurs in the ER, which is carbohydrate- and pH-dependent, and is affected by glucose-trimmed high-mannose-type oligosaccharides. These results indicated that I-MBP may function as a cargo transport lectin facilitating ER-to-Golgi traffic in glycoprotein quality control (Nonaka et al. 2007).

23.2.1.4 Ligands for MBL

Among the cells tested, only lymphocytes from thymus of BALB/c mice express endogenous ligands for MBL on their surface, while those from bone marrow, spleen, mesenteric lymph nodes and peripheral blood all being negative. Interestingly, among the thymocytes, only the immature thymocytes with $CD4^+CD8^+CD3$ low phenotype expressed the MBL ligands, which decreased on cell maturation. The major cell surface glycoprotein bearing MBL ligands was identified as CD45RO, which is a transmembrane protein with tyrosine phosphatase activity. The MBL ligands on

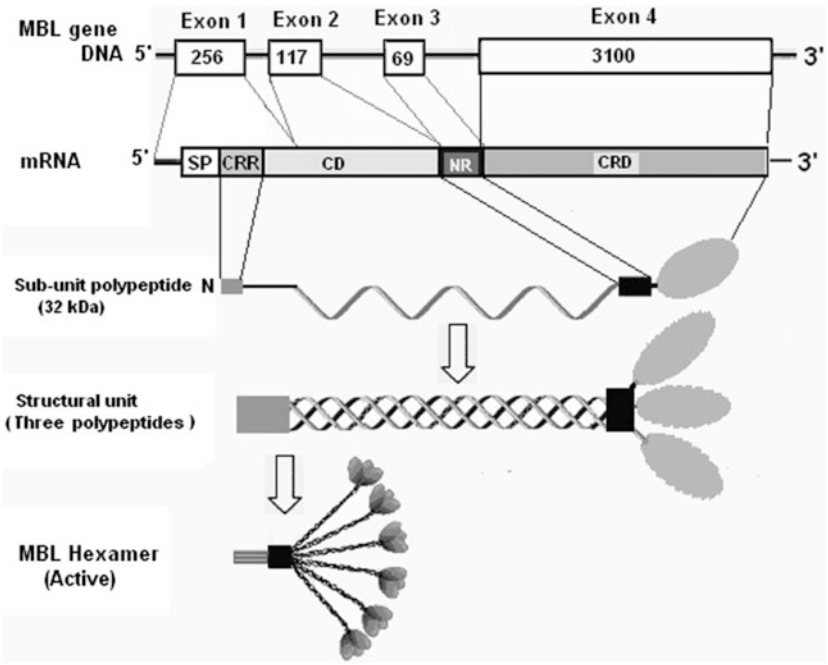

Fig. 23.4 The human MBL gene with the corresponding mRNA and protein domains. The lengths of the four exons and three introns are indicated by the number of base pairs in the box of the figure. The mRNA encodes for the various protein domains shown as signal peptide (*SP*), cysteine rich region (*CRR*), collagen domain (*CD*), neck region (*NR*) (coiled-coil), and carbohydrate recognition domain (*CRD*) in the figure. The peptides self associates into a homo- trimer (structural subunit). Each peptide contains a lectin domain (*gray*) to bind the specific, microbial carbohydrate motifs. Functional MBL circulates in higher-order multimers: (tetramers, pentamers and hexamers)

thymic CD45 contain high mannose type or hybrid type N-linked oligosaccharides (Uemura et al. 1996).

The MBL recognizes a wide array of pathogens independently of specific antibody, and initiates the lectin pathway of complement activation. The MBL binds to neutral carbohydrates on microbial surfaces and recognises carbohydrates such as mannose, glucose, L-fucose, N-acetyl-mannosamine (ManNAc), and N-acetyl-glucosamine (GlcNAc). Oligomerisation of MBL enables high avidity binding to repetitive carbohydrate ligands, such as those present on a variety of microbial surfaces, including *E. coli*, *Klebisella aerogenes*, *Neisseria meningitides*, *Staphylococcus aureus*, *S. pneumonia*, *A. fumigatus and C. albicans* (Kerrigan and Brown 2009; Ng et al. 2002) and Trichinella spirali (Gruden-Movsesijan et al. 2003).

23.2.2 Gene Structure of MBP

The MBP molecule comprises a signal peptide, a cysteine-rich domain, a collagen-like domain, a 'neck' region and a carbohydrate-binding domain. Each domain is encoded by a separate exon. The NH2 terminus of human MBP is rich in cysteines that mediate interchain disulphide bonds and stabilize the second collagen-like region. This is followed by a short intervening region, and the carbohydrate recognition domain is found in the COOH-terminal region. The genomic organization (Fig. 23.4) lends support to the hypothesis that the gene arose during evolution by a process of exon shuffling. Several consensus sequences that may be involved in controlling the expression of human serum MBP have been identified in the promoter region of the gene. The consensus sequences are consistent with the suggestion that this mammalian serum lectin is regulated as an acute-phase protein synthesized by the liver (Taylor et al. 1989). Analysis of the human MBP gene reveals that the coding region is interrupted by three introns, and all four exons appear to encode a distinct domain of the protein. It appears that the human MBP gene has evolved by recombination of an ancestral nonfibrillar collagen gene with a gene that encodes carbohydrate recognition, and is therefore similar to the human surfactant SP-A gene and the rat MBP gene. The gene for MBP is located on the long arm of chromosome 10 at 10q11.2-q21, a region that is included in the assignment for the gene for multiple endocrine neoplasia type 2A (Sastry et al. 1989; Schuffenecker 1991). In order to elucidate the mechanism underlying the wide intra- and interracial variety in MBP level in serum, Naito et al. (1999) studied the transcriptional regulation of human MBP. The 5′ RACE analysis of Hep G2 RNA indicated the presence of an exon, designated as "exon 0," upstream of exon 1 and thus, two MBP mRNAs with different sizes of 5′-noncoding regions were detected: the longer transcript starting at exon 0 and the shorter one at exon 1. Promoter analysis revealed that the transcript starting from exon 1 predominates over the one that starts from exon 0. The NH2-terminal residue of rat liver MBP, glutamic acid, is preceded by a predominantly hydrophobic stretch of 18 amino acids, which was assumed

to be a signal peptide. Near the NH2-terminal, there was a collagen-like domain, which consisted of 19 repeats of the sequence Gly-X-Y. Here, X and Y were frequently proline and lysine. Three proline and lysine residues were hydroxylated, and one of the latter appeared to link to galactose. Computer analysis of several lectins for sequence homology suggested that the COOH-terminal quarter of the MBP is associated with the calcium binding as well as carbohydrate recognition (Oka et al. 1987) (Fig. 23.4).

23.2.2.1 Evolutionary Relationship to the Asialoglycoprotein Receptor

cDNAs encoding MBP-A from rat liver is encoded by four exons separated by three introns. The NH2-terminal, collagen-like portion of the protein is encoded by the first two exons. These exons resemble the exons found in the genes for nonfibrillar collagens in that the intron which divides them is inserted between the first two bases of a glycine codon and the exons do not have the 54- or 108-bp lengths characteristic of fibrillar collagen genes. The carbohydrate-binding portion of MBP-A is encoded by the remaining two exons. This portion of the protein is homologous to the CRD of the hepatic asialoglycoprotein receptor, which is encoded by four exons. It appears that the three COOH-terminal exons of the asialoglycoprotein receptor gene have been fused into a single exon in the MBP-A gene. The organization of the MBP-A gene is very similar to the arrangement of the gene encoding the highly homologous pulmonary surfactant apoprotein, although one of the intron positions is shifted by a single amino acid (Drickamer and McCreary 1987).

23.2.2.2 MBL Genotypes and MBL Levels

Low serum concentrations of MBP are associated with three independent mutations in codons 52, 54, and 57 (Turner 2003) of exon 1, resulting in amino acid replacement of Arg-52 to Cys, Gly-54 to Asp, and Gly-57 to Glu, respectively, all of which occurred in the collagen-like domain. These replacements appear to inhibit oligomerization of the structural unit of the molecule and consequently abolish the ability to initiate complement activation without impairing the original lectin-binding specificity to oligosaccharide ligands. Information from increasing literature suggests that MBL deficiency, which mainly results from the three relatively common single point mutations in exon 1 of the gene, predisposes both to infection by extracellular pathogens and to autoimmune disease. In addition, the protein also modulates disease severity, at least in part through a complex, dose-dependent influence on cytokine production. The mechanisms and signaling pathways involved in such processes remain to be elucidated (Jack et al. 2001). The prevalence of mutations in the MBL gene is about 10%, but in Africa South of Sahara it is as high as 30% (Juul-Madsen et al. 2003).

MBL2 coding alleles associated with low blood levels are present in up to 40% of Caucasoids, with up to 8% having genotypes associated with profound reduction in circulating MBL levels. Low-producing MBL2 variants and low MBL levels are associated with increased susceptibility to and severity of a variety of infective illnesses, particularly when immunity is already compromised – for example, in infants and young children, patients with cystic fibrosis, and after chemotherapy and transplantation. These observations suggest that administration of recombinant or purified MBL may be of benefit in clinical settings where MBL deficiency is associated with a high burden of infection (Worthley et al. 2005).

23.2.3 Regulation of MBP Gene

Suppression by Glucocorticoid: In order to elucidate the mechanism underlying the wide intra- and interracial variety in MBP level in serum, Naito et al. (1999) studied the transcriptional regulation of human MBP. In addition, a hepatocyto-specific nuclear factor, (HNF)-3, which controls the expression of hepatocyte specific genes, up-regulates the transcription of human MBP from exon 1, while a glucocorticoid, which is known to up-regulate acute phase proteins, markedly suppresses MBP transcription. In addition, polymorphism also occurs in the promoter region at two positions (Madsen et al. 1995). Functional promoter analysis indicated that three haplotype variants as to these positions, HY, LY, and LX, exhibit high, medium and low promoter activity, respectively (Naito et al. 1999).

Upregulation by Interleukins: The MBP mRNA expression in human hepatoma cell line HuH-7 is increased by IL-6, dexamethasone, and heat shock, decreased by IL-1, and unaffected by IFNγ, TNFα and TGFβ. The binding of IL-2 to its receptor (IL-2Rβ) induces IL-2Rβ phosphorylation by the tyrosine kinase associated with the T-cell receptor (TCR) complex. This mechanism is due to the putative lectin activity of IL-2 (Cebo et al. 2002), which is a calcium-independent lectin specific for oligomannosidic N-glycans with five and six mannose residues. This lectin activity is preserved after binding of IL-2 to IL-2Rβ. IL-2 behaves as a bifunctional molecule that associates IL-2Rβ with specific glycoprotein ligands of the TCR complex including a glycosylated form of CD3 (Zanetta et al. 1996). Thus, the action of cytokines appears to be mediated by specific transcription factors.

Effect of Growth Hormone: Studies in animals and humans indicate that growth hormone (GH) and insulin-like growth factor-I (IGF-I) modulate immune function. In normal patients, GH therapy increases the level of MBL, and the treatment of acromegalics with pegvisomant decreases the levels of MBL. The effect on MBL was thought to be due to a specific action of GH, since IGF-I treatment did not affect MBL level. However, GH or hormone replacement therapy (HRT) in Turner syndrome (TS) influences the serum levels of MBL and other proteins participating in the innate immune defense such as surfactant protein D (SP-D) and vitamin D binding protein (DBP). The treatment with GH significantly increases MBL and SP-D levels in TS patients, while HRT marginally decreased DBP. Whether the present findings suggest a link between the endocrine and the immune system needs further examination (Gravholt et al. 2004).

Thyroid Hormone Regulates MBL Levels: Studies have indicated the existence of causal links between the endocrine and immune systems and cardiovascular disease. In all hyperthyroid patients, MBL levels are increased – median (range), 1,886 ng/ml before treatment and decreased to 954 ng/ml from normal levels of 1,081 ng/ml after treatment. Administration of thyroid hormones to healthy persons induced mild hyperthyroidism and increased MBL levels significantly to 1,714 ng/ml. Since MBL is part of the inflammatory complement system, the modulation by thyroid hormone, of complement activation may play a role in the pathogenesis of a number of key components of thyroid diseases (Riis et al. 2005).

23.2.4 Structure-Function Relations

MBL has an oligomeric structure (400–700 kDa), built of subunits that contain three identical peptide chains of 32 kDa each. Although MBL can form several oligomeric forms, there are indications that dimers and trimers are not biologically active and at least a tetramer form is needed for activation of complement. MBL in the blood is complexed with another protein, a serine protease called MASP-2 (MBL-associated serine protease). The crystal structure of the CRD of a rat mannose-binding protein, determined as the holmium-substituted complex, reveals an unusual fold consisting of two distinct regions, one of which contains extensive nonregular secondary structure stabilized by two holmium ions. The structure explains the conservation of 32 residues in all C-type carbohydrate-recognition domains, suggesting that the fold seen is common to these domains (Weis et al. 1991, 1998).

The basic structural unit is a triple helix of MBL peptides, which aggregate into complement-fixing higher-order structures (tetramers, pentamers and hexamers). MBP forms a trimeric helical structure via interactions of the collagenous tails that are stabilized by disulfide bonds in the cysteine-rich amino terminal region. These trimers aggregate to generate three or six trimers in a "bouquet" organization (Fig. 23.1). Each CRD in the trimer is separated by approximately 53 Å, which is critical to the function of the lectin. This is because each individual CRD has a relatively low affinity and low specificity for glycan ligands and can bind to glycans rich in *N*-acetylglucosamine, *N*-acetylmannosamine, fucose, and glucose. The spacing between CRDs provides regulation and enhances the potential interactions with extended mannan-containing glycoconjugates, especially those on bacteria, yeast, and parasites. Weis and Drickamer (1999) determined crystal structure at 1.8 A Bragg spacings of a trimeric fragment of MBP-A, containing the CRD and the neck domain that links the carboxy-terminal CRD to the collagen-like portion of the intact molecule. The neck consists of a parallel triple-stranded coiled coil of α-helices linked by four residues to the CRD (Chang et al. 1994). The isolated neck peptide does not form stable helices in aqueous solution. The carbohydrate-binding sites lie at the distal end of the trimer and are separated from each other by 53 A. The carbohydrate-binding sites in MBP-A are too far apart for a single trimer to bind multivalently to a typical mammalian high-mannose oligosaccharide. Thus MBPs can recognize pathogens selectively by binding avidly only to the widely spaced, repetitive sugar arrays on pathogenic cell surfaces. Sequence alignments revealed that other C-type lectins might have a similar oligomeric structure, but differences in their detailed organization will have an important role in determining their interactions with oligosaccharides.

Phagocytic Interaction Site on MBL: The phagocytic activity induced by MBL and other molecules that contain a collagen-like region contiguous with a pattern recognition domain is mediated by C1qR(P). The specific interaction site was identified through two mutants, one of which has five GXY triplets deleted below the kink region of MBL and the other one having only two of the GXY triplets deleted below the kink. These mutants, which failed to enhance phagocytosis, suggested the importance of a specific sequence GEKGEP in stimulating phagocytic activity. Similar sequences were detected in other defense collagens, implicating the consensus motif GE(K/Q/R)GEP as critical in mediating the enhancement of phagocytosis through C1qR(P) (Arora et al. 2001).

MASP-Binding Sites in MBP: Mutations in the collagen-like domain of serum MBP interfere with the ability of the protein to initiate complement fixation through MASPs. Studies with truncated and modified MBPs and synthetic peptides demonstrated that MASPs bind on the C-terminal side of the

hinge region formed by an interruption in the Gly-X-Y repeat pattern of the collagen-like domain. The binding sites for MASP-2 and for MASP-1 and -3 overlap but are not identical. The two most common naturally occurring mutations in MBP result in substitution of acidic amino acids for glycine residues in Gly-X-Y triplets on the N-terminal side of the hinge. Studies showed that the triple helical structure of the collagen-like domain is largely intact in the mutant proteins, but it is more easily unfolded than in wild-type MBP. Thus, the effect of the mutations is to destabilize the collagen-like domain, indirectly disrupting the binding sites for MASPs (Wallis et al. 2004).

23.2.5 Functions of MBL

23.2.5.1 Functions as an Opsonin

MBL has also been proposed to function directly as an opsonin by binding to carbohydrates on pathogens and then interacting with MBL receptors on phagocytic cells, promoting microbial uptake and stimulating immune responses (Fig. 23.5). This was described by Kuhlman et al. who observed that binding of MBL to *Salmonella montevideo* resulted in an MBL-dependent uptake by monocytes (Kuhlman et al. 1989). Thus MBL can interact directly with receptor(s) on the surface of monocytes and several potential MBL receptors have been proposed, although their likelihood is debated in the literature. Calreticulin has emerged as the main candidate, but further studies are required to confirm its interaction with MBL and its role in the phagocytosis of pathogens. Ip et al. (2008) has shown that MBL modifies cytokine responses through cooperation with TLR2/6 in the phagosome. Although the stimulation of the inflammatory response was not caused by enhanced phagocytosis, bacterial engulfment was required. This study demonstrates the importance of phagocytosis in providing the appropriate cellular environment to facilitate cooperation between molecules.

MBL has the capacity to modify the efficiency of uptake and the expression of other phagocytic receptors. Activation of the complement system via MBL-associated serine proteases (MASPs) (Kerrigan and Brown 2009; Dahl et al. 2001; Stover et al. 1999; Thiel et al. 1997), results in deposition of complement on the microbial surface that can lead to uptake via complement receptors (Neth et al. 2002). However, inhibition of bacterial growth associated with the MBL-MASP activation of complement has also been observed, without any enhancement of phagocytosis (Ip and Lau 2004). This indicates that the specific responses induced by MBL may be dependent on the nature of the microbial target. MBL can also influence expression of other PRRs, as demonstrated by the ability of MBL to augment the uptake of *S. aureus* through the up-regulation of scavenger receptor A (SR-A) (Ono et al. 2006) (Fig. 23.5).

Recognition of Pathogens: MBL has a major protective effect through activation of the complement system via MBL-associated serine proteases (MASPs). This can cause the lysis of Gram-negative bacteria and also opsonize a wide spectrum of potential pathogens for phagocytosis. MBL may also influence phagocytosis in the absence of complement activation through an interaction with one or more collectin receptors. This may also be the basis for a direct effect of the protein on inflammatory responses. MBL forms individual complexes with MBL-associated serine proteases (MASP)-1, -2, -3 and a truncated form of MASP-2 (MAp19) and triggers the lectin pathway of complement through MASP-2 activation. MBL, like C1q, is a six-headed molecule that forms a complex with two protease zymogens, which in the case of the MBL complex are MASP-1 and MASP-2. MASP-1 and MASP-2 are closely homologous to C1r and C1s, and all four enzymes are likely to have evolved from gene duplication of a common precursor. When the MBL complex binds to a pathogen surface, MASP-1 and MASP-2 are activated to cleave C4 and C2. Thus the MBL pathway initiates complement activation in the same way as the classical pathway, forming a C3 convertase from C2b bound to C4b. Humans deficient in MBL experience a substantial increase in infections during early childhood, indicating the importance of the MBL pathway for host defense.

The Mannan-Binding Lectin Pathway Is Homologous to the Classical Pathway: MBP has been shown to have complement-dependent bactericidal activity; for example, *Escherichia coli* strains *K12* and *B*, which have exposed *N*-acetylglucosamine and L-glycero-D-mannoheptose, respectively, are killed by MBP with the help of complement. MBP serves as a direct opsonin and mediates binding and uptake of bacteria that express a mannose-rich O-polysaccharide by monocytes and neutrophils. MBP functions as a β-inhibitor of the influenza virus and protects cells from HIV infection by binding to gp120, a high mannose-type oligosaccharide-containing envelope glycoprotein on HIV. MBL can alter the function of microbial structures, such as gp120 of HIV, to prevent infection. In addition, the α-mannosidase inhibitor 1-deoxymannojirimycin-treated baby hamster kidney (BHK) cells, which have high mannose-type oligosaccharide exposed on their surfaces, can be killed by MBP with the help of complement. MBP activates complement through interactions with complement subcomponents C1r/C1s or two novel C1r/C1s-like serine proteases, MBP-associated serine proteases (MASP-1 and MASP-2). The MBP-mediated complement activation is named the MBP pathway. The protein may also interact with the components of other cascade systems such as the clotting system, which will have a role in microbial pathogenesis. An understanding of these basic mechanisms will be vital if we are to use purified or recombinant MBL in therapeutic applications (Jack et al. 2001).

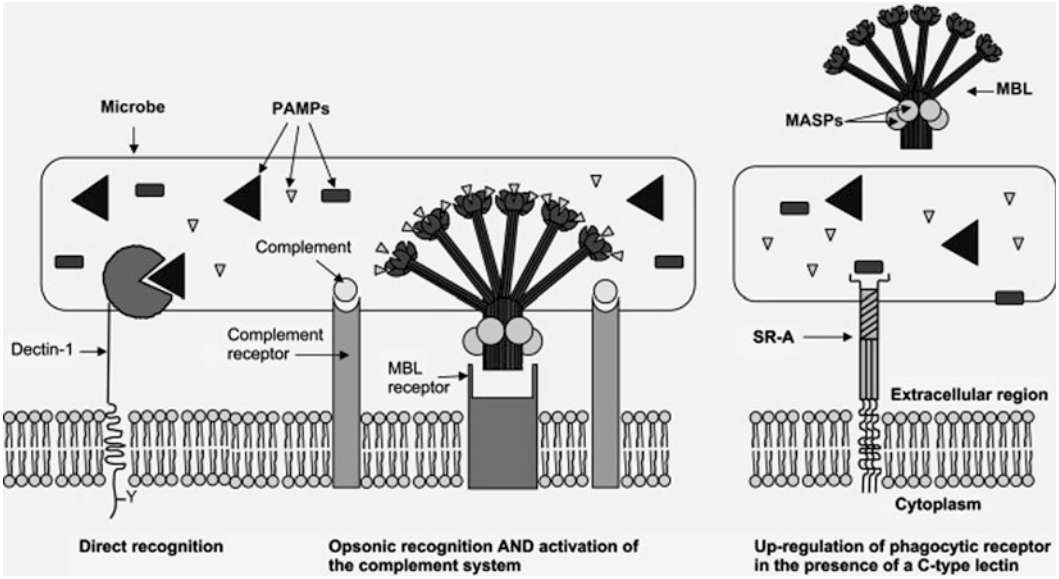

Fig. 23.5 Direct recognition, opsonisation, complement activation and receptor up-regulation by C-type lectins. Phagocytic C-type lectins can directly recognise PAMPs on the surface of microbes and mediate phagocytosis (e.g. Dectin-1). Alternatively, soluble C-type lectins can interact directly with pathogens to promote opsonisation of the microbe (e.g. MBL) which can subsequently be phagocytosed via specific receptors. In addition, some C-type lectins can activate complement leading to its deposition on the microbial surface and phagocytosis mediated by complement receptors (e.g. MBL associated MASPS are activated on binding to pathogens which in turn cleave complement components and activate the complement system). Finally, C-type lectins can cause up-regulation of other phagocytic receptors, independently of their binding to the microbe [e.g. MBL up-regulation of scavenger receptor A (*SR-A*)] (Adapted with permission from Kerrigan and Brown 2009 © Elsevier)

The MBL binds through multiple lectin domains to the repeating sugar arrays that decorate many microbial surfaces, and is then able to activate the complement system through a MBL-associated protease-2. For selected Gram-negative organisms, such as *Salmonella* and *Neisseria*, the relative roles of lipopolysaccharide (LPS) structure and capsule are important in binding; the LPS is of major importance. Studies on clinically relevant organisms showed that MBL binding leads to activation of purified C4, suggesting that the bound lectin is capable of initiating opsonophagocytosis and/or bacterial lysis.

Normal mammalian cells such as circulating blood cells are usually covered with complex oligosaccharides terminated with sialic acids and do not bind MBP. On the other hand, malignant transformations or viral infections modify the oligosaccharide structures on cell surfaces, and some tumor tissues have been shown to bind to MBP. Ma et al. (1999) showed that MBP recognizes and binds specifically to oligosaccharide ligands expressed on the surfaces of a human colorectal carcinoma. Interestingly, the recombinant vaccinia virus carrying human MBP gene was demonstrated to possess a potent growth-inhibiting activity against human colorectal carcinoma cells transplanted in nude mice and a significant prolongation of life span of tumor-bearing mice. Unexpectedly, the mutant MBP, which had essentially no complement-activating activity, was nearly as active as wild-type MBP. These results indicated that MBP has a cytotoxic activity, which was termed as MBP-dependent cell-mediated cytotoxicity (MDCC).

23.2.5.2 Functions in Antibody-Independent Pathway of Complement System

The complement system comprises a complex array of enzymes and non-enzymatic proteins that is essential for the operation of innate as well as the adaptive immune defense. The complement system is activated in three ways: by the classical pathway which is initiated by antibody-antigen complexes, by the alternative pathway initiated by certain structures on microbial surfaces, and by an antibody-independent pathway that is initiated by the binding of mannan-binding lectin to carbohydrates. The MBL is structurally related to the complement C1 subcomponent, C1q, and seems to activate the complement system through an associated serine protease known as MASP-1 or p100, which is similar to C1r and C1s of the classical pathway. The MBL binds to specific carbohydrate structures

found on the surface of a range of microorganisms, including bacteria, yeasts, parasitic protozoa and viruses, and exhibits antimicrobial activity by killing that is mediated by the terminal, lytic complement components or by promoting phagocytosis. The level of MBL in blood plasma is genetically determined, and deficiency is associated with frequent infections in childhood, and possibly also in adults. A new MBL-associated serine protease (MASP-2) which shows a striking homology with the reported MASP-1 and the two C1q-associated serine proteases C1r and C1s has also been identified. Thus complement activation through MBL, like the classical pathway, involves two serine proteases and may antedate the development of the specific immune system of vertebrates (Thiel et al. 1997).

IgA, an important mediator of mucosal immunity, activates the complement system via the lectin pathway. Results indicate a dose-dependent binding of MBL to polymeric, but not monomeric IgA coated in microtiter plates. This interaction involves the carbohydrate recognition domain of MBL. MBL binding to IgA results in complement activation, which is proposed to lead to a synergistic action of MBL and IgA in antimicrobial defense. These results may explain glomerular complement deposition in IgA nephropathy (Roos et al. 2001).

23.2.5.3 Modulation of Associated Serine Proteases

MBP neutralizes invading microorganisms by binding to cell surface carbohydrates and activating MBP-associated serine proteases-1, -2, and -3 (MASPs). MASP-2 subsequently cleaves complement components C2 and C4 to activate the complement cascade. The MBP modulates MASP-2 activity in two ways. First, MBP stimulates MASP-2 auto-activation by increasing the rate of autocatalysis when MBP.MASP-2- complexes bind to a glycan-coated surface. Second, MBP occludes accessory C4-binding sites on MASP-2 until activation occurs. Once these sites become exposed, MASP-2 binds to C4 while separate structural changes create a functional catalytic site able to cleave C23. Only activated MASP-2 binds to C2, suggesting that this substrate interacts only near the catalytic site and not at accessory sites. MASP-1 cleaves C2 almost as efficiently as MASP-2 does, but it does not cleave C23. Thus MASP-1 probably enhances complement activation triggered by MBP.MASP-2 complexes, but it cannot initiate activation itself (Chen and Wallis 2004). MASP-1 probably enhances complement activation triggered by MBP. MASP-2 complexes, but it cannot initiate activation itself.

In the human lectin pathway, MASP-1 and MASP-2 are involved in the proteolysis of C4, C2 and C3. The human MBL-MASP complex contains a new 22 kDa protein [small MBL-associated protein (sMAP)] bound to MASP-1. The nucleotide sequence of sMAP cDNA revealed that it is a truncated form of MASP-2, consisting of the first two domains (i.e. the first internal repeat and the EGF-like domain) with four different C-terminal amino acids. sMAP mRNAs are expressed in liver by alternative polyadenylation of the MASP-2 gene, in which a sMAP-specific exon containing an in-frame stop codon and a polyadenylation signal is used. The involvement of sMAP in the MBL-MASP complex suggests that the activation mechanism of the lectin pathway is more complicated than that of the classical pathway (Takahashi et al. 1999).

23.2.5.4 Ra-Reactive Factor: A Complex of MBL and the Serine Protease

The Ra-reactive factor (RaRF) is a complement dependent antimicrobial factor that reacts with numerous microorganisms such as viruses, bacteria, fungi and protozoa. The RaRF consists of a complement-activating component (CRaRF) called P 100 component (MASP) and a polysaccharide-binding (mannose-binding) component (Matsushita et al. 1992). The cDNA for RaRF-P100 from the human liver contains an ORF of 2,097 nt encoding a protein of 699 aa residues in the cloned cDNA of 4,489 nt. This protein exhibits 87.4% amino acid homology with mouse P100, and 36.4% and 37.1% homologies with that of the C1r and C1s subcomponents of human complement, respectively. The P100, together with the C1r and C1s, forms a unique protein family having the same module/domain constitution (Takada et al. 1993; Takayama et al. 1999).

The polysaccharide-binding component of RaRF consists of two different 28-kDa polypeptides, P28a and P28b. Partial amino acid sequences of P28a and P28b indicated that these polypeptides are similar to MBP-C and MBP-A (liver and serum MBP respectively) (Drickamer et al. 1986; Oka et al. 1987). The primary structures of P28a and P28b deduced from cDNAs are homologous to one another. They have three domains, a short NH2-terminal domain, a collagen-like domain, and a domain homologous to regions of some carbohydrate-binding proteins, as in rat MBPs. The P28a and P28b polypeptides are the products of two unique mouse genes which are expressed in hepatic cells (Kuge et al. 1992).

23.3 MBP/MBL from Other Species

23.3.1 Rodents

Rat liver MBP contains two distinct but homologous polypeptides. Each polypeptide consists of three regions: (a) an NH2-terminal segment of 18–19 amino acids which is rich in cysteine and appears to be involved in the formation of interchain disulfide bonds which stabilize dimeric and trimeric forms of the protein, (b) a collagen-like domain consisting of 18–20 repeats of the sequence Gly-X-Y and containing 4-hydroxyproline residues in several of the Y

positions, and (c) a COOH-terminal carbohydrate-binding domain of 148–150 amino acids. The sequences of the COOH-terminal domains are highly homologous to the sequence of the COOH-terminal carbohydrate-recognition portion of the chicken liver receptor for N-acetylglucosamine-terminated glycoproteins and the rat liver asialoglycoprotein receptor. Each protein is preceded by a cleaved, NH2-terminal signal sequence, consistent with the finding that this protein is found in serum as well as in the liver. The entire structure of the mannose-binding proteins is homologous to dog pulmonary surfactant apoprotein (Drickamer et al. 1986). Rat liver MBP is specific for mannose and N-acetylglucosamine and is encoded by two species of mRNA of 1.4 and 3.5 kb respectively. The sequence of the open reading frame of 3.5 kb mRNA was completely identical to that of the 1.4 kb mRNA. Each mRNA species arises from one gene, with the differences in size most easily being accounted for by differential utilization of the polyadenylation sites of one transcript (Wada et al. 1990).

Mouse *Mbl1* and *Mbl2* have five and six exons, respectively. The structure of the mouse Mbl genes is similar to that of the rat and human MBP genes and shows homology to the other collectin genes, with the entire carbohydrate recognition domain being encoded in a single exon and all introns being in phase 1. The MBP encoded by mouse Mbl1 with three cysteines in the first coding exon, like the rat Mbl1 and human MBL, is capable of a higher degree of multimerization and has apparent ability to fix complement in the absence of antibody or C1q. However, the structural features of other exons, that is, the larger size of collagen domain region in the first coding exon (64 bp in Mbl2 vs 46 bp in Mbl1) and the smaller size of the exon encoding the trimerization domain (69 bp in Mbl2 vs 75 bp in Mbl1) revealed that the single human MBL gene is closely related to rodent Mbl2 rather than rodent Mbl1. In contrast to the evolution of bovine surfactant protein-D – which duplicated in bovidae after divergence from humans, MBP gene most likely duplicated prior to human-rodent divergence, and that the human homolog to *Mbl1* was perhaps lost during evolution (Sastry et al. 1995). The deduced amino acid sequence of the mouse MBP, as with rat and the human forms, have an NH2 terminus that is rich in cysteine, which stabilizes a collagen α-helix followed by a carboxyl- terminal carbohydrate binding domain. Though, the mouse MBP-A mRNA, as with the human, is induced like the acute phase reactant serum amyloid P protein, yet the expression of mouse MBP-C mRNA is not regulated above its low baseline level. The expression of both MBP-A and -C mRNA is restricted to the liver under basal and stress conditions (Sastry et al. 1991).

23.3.2 Primates MBL

The nucleotide and amino-acidic sequences of MBL2 among primates are highly homologous, underlining the importance of this molecule in the defense system against pathogen invasions. In particular, in the collagen-like domain that confers the characteristic structure to MBL2 protein, the identity among primates is really high. In the carbohydrate recognition domain, primates' group-specific amino-acidic mutations did not result in changes of the structure or function of this MBL2 domain. Results indicate that MBL2 is well conserved in agreement with its important role in the immune system. However, same 'plasticity' of the MBL2 human gene was not observed in non-human primates, where a frequency of more than 1% of nucleotide variations was described in the coding and promoter regions (Verga Falzacappa et al. 2004).

A bovine cDNA encodes a protein of 249 aa residues with a signal peptide of 19 aa. This MBP has the ability to activate complement and expressed only in liver. The bovine MBP is likely to be a homologous to human MBP and bears homology to rat and mouse MBP-C which are localized in liver cells rather than to rat and mouse MBP-A found in serum (Kawai et al. 1997). C-type lectins in alligator liver, termed alligator hepatic lectin (AHL) is specific for mannose/L-fucose and contained equal amounts of 21- and 23-kDa bands on SDS (Lee et al. 1994).

23.4 Similarity Between C1Q and Collectins/Defense Collagens

23.4.1 Structural Similarities

The C1q is the first component of classical pathway of complement activation that links the adaptive humoral immune response to the complement system by binding to antibodies complexed with antigens. C1q can, however, also bind directly to the surface of certain pathogens and thus trigger complement activation in the absence of antibody. Collectins family of macromolecules is characterized by a conserved, collagen-like region of repeating Gly-X-Y triplets contiguous with a non-collagen-like sequence. The structural similarity between the collectins and C1q has been demonstrated: They all contain multiple polypeptides which are organised into subunits containing triple-helical stalks throughout their collagen-like regions and globular 'heads' in C-terminal regions. Four, or six, of these structures are associated via distinct, short, N-terminal regions to form oligomeric

molecules seen in electron microscope. The overall structural similarity between C1q and collectins, however, does not extend to similarity in amino acid sequences over the C-terminal regions. The C-terminal regions of C1q, unlike those of collectins, do not contain conserved residues found in CRDs present in C-type lectins. Instead, C1q has a high degree of homology to collagen sequences (Type VIII and X) and this is consistent with the fact that, unlike collectins, C1q binds to protein motifs in IgG, or IgM, rather than to carbohydrate structures. Also, despite showing interruptions in their collagen-like regions, collectins do not always display a 'bend' in their collagen-like 'stalks' similar to that which is seen in C1q. Therefore, C1q may be more closely related to collagens than to collectins.

23.4.2 Functional Similarities

The C1q and MBL function to eliminate invading microorganisms by activating the classical pathway (C1q) or the lectin pathway (MBL and ficolin) (Ma et al. 2004) of the complement system by transmitting a signal from the recognition domains of the globular heads to their collagen-like domains, which autoactivates their associated serine proteases ($C1r_2s_2$ or mannan-binding lectin-associated serine proteases (Sim and Tsiftsoglou 2004).

Defense collagens modulate the cytokine expression, specifically by monocyte cytokine production by phagocyte cells under conditions in which phagocytosis is enhanced. Under conditions in which phagocytosis is enhanced, C1q and MBL modulate cytokine production and contribute signals to human peripheral blood mononuclear cells, leading to the suppression of LPS-induced pro-inflammatory cytokines, IL-1α and IL-1β, and an increase in the secretion of cytokines IL-10, IL-1 receptor antagonist, monocyte chemoattractant protein-1, and IL-6. Thus, defense collagen-mediated suppression of a pro-inflammatory response may be an important step in the avoidance of autoimmunity during the clearance of apoptotic cells (Fraser et al. 2006). Understanding the mechanisms involved in defense collagen and other soluble pattern recognition receptor modulation of the immune response may provide important novel insights into therapeutic targets for infectious and/or autoimmune diseases and additionally may identify avenues for more effective vaccine design (Fraser and Tenner 2008; Paidassi et al. 2007).

It is proposed that C1q, MBL, and other opsonins prevent autoimmunity and maintain self-tolerance by supporting the efficient clearance of apoptotic material, as well as by actively modulating phagocyte function. In absence of danger, defense collagens appear to recognise and remove apoptotic cells (Nauta et al. 2003). C1q and MBL have been shown to bind directly to apoptotic cell surfaces and apoptotic cell blebs via their globular heads (Navratil et al. 2001). Interaction of the collagen-like tails with the phagocyte surface triggers apoptotic cell ingestion via macropinocytosis (Ogden et al. 2001). Indeed, deficiencies and/or knock-out mouse studies have highlighted critical roles for C1q, SP-D, and MBL and other soluble pattern recognition receptors in the clearance of apoptotic bodies and protection from autoimmune diseases along with mediating protection from specific infections (Botto et al. 1998; Gabriaud et al. 2003; Stuart et al. 2005), in which mice exhibit impaired clearance of apoptotic cells. Deficiency of C1q is a risk factor for the development of autoimmunity in humans and mice (Botto and Walport 2002; Mitchell et al. 2002; Miura-Shimura et al. 2002).

23.4.3 Receptors for Defense Collagens

A number of putative MBL-binding proteins/receptors have been proposed including cC1qR/Crt (Klickstein et al. 1997), C1qRp (Tenner et al. 1995; Stuart et al. 1997) and CR1 (Ghiran et al. 2000). However, it is unclear whether MBL is acting as a direct opsonin or is merely enhancing other complement pathways and/or antibody-mediated phagocytosis. Membrane receptors for the soluble 'defense collagens' – naturally occurring chimeric molecules that contain a recognition domain contiguous with a collagen-like triple helical domain and play a role in protecting the host from pathogens entering the blood, lung and other tissues – have been isolated and are being characterized. These receptors are key to understanding the mechanisms by which defense collagens influence cellular responses in clearance of cellular debris or to initiate the responses that lead to the destruction of microbial pathogens.

Pulmonary SP-A: Forms and Functions

24

Anita Gupta and Rajesh K. Gupta

24.1 Pulmonary Surfactant Proteins

24.1.1 Pulmonary Surfactant

Pulmonary surfactant is a complex mixture of lipids and proteins, and is synthesized and secreted by alveolar type II epithelial cells and bronchiolar Clara cells. It acts to keep alveoli from collapsing during the expiratory phase of the respiratory cycle. After its secretion, lung surfactant forms a lattice structure on the alveolar surface, known as tubular myelin. Surfactant proteins (SP)-A, B, C and D make up to 10% of the total surfactant. SP-B and SP-C are relatively small hydrophobic proteins, and are involved in the reduction of surface-tension at the air-liquid interface. SP-A and SP-D, on the other hand, are large oligomeric, hydrophilic proteins that belong to the collagenous Ca^{2+}- dependent C-type lectin family (known as "Collectins"), and play an important role in host defense and in the recycling and transport of lung surfactant. There is increasing evidence that surfactant-associated proteins A and -D (SP-A and SP-D, respectively) contribute to the host defense against inhaled microorganisms. Based on their ability to recognize pathogens and to regulate the host defense, SP-A and SP-D have been recently categorized as "Secretory Pathogen Recognition Receptors". In nut-shell, the four lung-specific surfactant-associated proteins: SP-A, SP-B, SP-C, and SP-D serve a number of different roles, including enhancement of surface-active properties of surfactant glycerophospholipids, surfactant phospholipid reutilization, and immune defense within the alveolus. The basic structures of SP-A and SP-D include a triple-helical collagen region and a C-terminal homotrimeric lectin or CRD. The trimeric CRDs can recognize carbohydrate or charge patterns on microbes, allergens and dying cells, while the collagen region can interact with receptor molecules present on a variety of immune cells in order to initiate clearance mechanisms. Gene knock-out mice models of lung hypersensitivity and infection, and functional characterization of cell surface receptors have revealed the diverse roles of SP-A and SP-D in control of lung inflammation (Kishore et al. 2005)

24.1.2 Pulmonary Surfactant Protein A

24.1.2.1 Intracellular and Intraalveolar Localization

Although SP-A is secreted by type II pneumocytes as a component of pulmonary surfactant, its secretion pathway as well as its subcellular localization in the human lung are uncertain. In adult human lungs, only type II pneumocytes could be identified as SP-A positive cells within the parenchymal region. SP-A was localized mainly in small vesicles and multivesicular bodies close to the apical plasma membrane. Only few lamellar bodies were weakly labeled at their outer membranes. The strongest SP-A activity was found over tubular myelin figures. Labeling for SP-A was also found in close association with the surface film and unilamellar vesicles. Results supported that SP-A is mainly secreted into the alveolar space via an alternative pathway that largely bypasses the lamellar bodies. After secretion, the outer membranes of unwinding lamellar bodies become enriched with SP-A when tubular myelin formation is initiated. SP-A may also be involved in the transition of tubular myelin into the surface film (Ochs et al. 2002). Immunogold labeling showed that SP-A occurs predominantly at the corners of the tubular myelin lattice. Being an integral component of the lamellar body, peripheral compartment and secreted surfactant membranes support the concept that lysozyme may participate in the structural organization of lung surfactant (Haller et al. 1992).

24.1.2.2 Lamellar Bodies

Lamellar bodies of identical periodicity and ultrastructural geometry are present in lung (type II pneumocytes), serosal mesothelium (peritoneum, pleura, and pericardium), and

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_24,

joints (type A and type B synoviocytes) (Dobbie 1996). SP-A was detected in the cytoplasm of type II cells as asymmetrically distributed punctate fluorescent bodies that resembled lamellar bodies. Most of the SP-A was located within bodies of the type II cell. Although, lamellar bodies are enriched in SP-A, yet it is insufficient for structural transformation to tubular myelin and surface film formation in vitro. SP-A is secreted from type II cells primarily by a pathway separate from lamellar bodies. Surfactant secretion by lung type II cells occurs when lamellar bodies fuse with plasma membrane and surfactant is released into alveolar lumen. The fetal lung secretes significant quantities of surfactant during late gestation to initiate respiration at birth. A pathway of extracellular routing of SP-A prior to its accumulation in lamellar bodies in cultured type II cells has been suggested (Jain et al. 2005).

24.2 Structural Properties of SP-A

24.2.1 Human SP-A: Domain Structure

SP-A, the major surfactant protein, is a C-type lectin that activates macrophages in the lung alveolus and plays an important role in immune defense. SP-A is synthesized primarily by type II pneumonocytes and is developmentally regulated in fetal lung in concert with surfactant glycerophospholipid synthesis (Boggaram and Mendelson 1988). In humans and baboons, SP-A is encoded by two highly similar genes, *SP-A1* and *SP-A2* (Katyal et al. 1992; McCormick et al. 1994), whereas, in rabbits (Chen et al. 1992), rats (Fisher et al. 1987; Smith et al. 1995) and mice (Korfhagen et al. 1996), SP-A is encoded by a single-copy gene. Genomic analysis of human cellular DNA with SP-A cDNA demonstrated the presence of multiple hybridizing fragments that are not accounted for by available SP-A gene sequences. The functional SP-A gene is present in human chromosome 10. The functional SP-A gene and the pseudogene are syntenic (Korfhagen et al. 1996).

The lung and serum SP-A and SP-D are assembled as oligomers of trimeric subunits. Each subunit consists of four major domains: a short cysteine-containing NH_2-terminal cross-linking domain (N); a triple helical collagen domain of variable length; a trimeric coiled-coil linking domain (L; also referred to as the neck); and a carboxyl-terminal, C-type lectin CRD (Fig. 24.1a, b). Interactions between the amino-terminal domains of SP-D subunits have been shown to be stabilized by interchain disulfide bonds (Brown-Augsburger et al. 1996; Crouch et al. 1994), and similar mechanisms stabilize the oligomerization of SP-A and most other collectins. The primary protein component of human SP-A is a 32 kDa glycoprotein. A cDNA clone encoding for rat pulmonary SP-A encodes the sequence of 56 amino acids at the N-terminus. Isolated rat alveolar type II cells contain two species of mRNA for this protein (Fisher et al. 1987). Structural details of SP-D have been discussed in Chap. 25.

The primary structure of mature SP-A is conserved among different mammals with some differences. It consists of four structural domains: (1) an NH_2-terminal segment involved in intermolecular disulfide bond formation; (2) a collagen-like domain characterized by 23 Gly-*X*-*Y* repeats with an interruption near the midpoint of the domain; (3) α-helical coiled-coil domain, which constitutes the neck region between the collagen and the globular domain; and (4) a COOH-terminal globular domain involved in phospholipid binding and in Ca^{2+}-dependent binding of oligosaccharides (McCormack 1998; Head et al. 2003). SP-A is modified after translation (cleavage of the signal peptide, proline hydroxylation, and Asn^{187}-linked glycosylation). Unlike SP-As from other mammalian species, baboon and human SP-As consist of two polypeptide chains, SP-A1 and SP-A2. The major differences between mature SP-A1 and SP-A2 are in the collagen domain. Electron micrographs show that SP-A like MBP assembles as six trimers arrayed in parallel and in register, resembling a bouquet of tulips (Voss et al. 1988), whereas SP-D is cruciform, formed by radial arrangements of four trimers (Crouch et al. 1994) (Fig. 24.1a, b). Properties of SP-A are dependent on the presence of calcium. Each SP-A monomer binds two to three calcium ions in conditions chosen as similar to those found in the alveolar lumen. The higher affinity site for calcium is located in the non-collagenous carboxy-terminal end of SP-A that contains a CRD homologous to other C-type lectins. The binding of calcium to this region of SP-A causes a conformational change (Haagsman et al. 1990; Sohma et al. 1993).

24.2.1.1 SP-A is Assembled as Large Oligomer

Larger aggregates of SP-A are formed by means of disulfide bond formation within a short N-terminal segment containing two cysteine residues. More variability in the degree of oligomerization was observed with recombinant human SP-A than with natural canine SP-A. Collagenase digestion suggested that the full assembly of protein subunits was dependent on an intact collagen-like domain. Cysteines in noncollagen domain of SP-A form intrachain bonds between residues 135–226 and 204–224. The CD spectra of both recombinant and natural SP-A were consistent with the presence of a collagen-like triple helix. As determined by the change in ellipticity at 205 nm, thermal transition temperatures of canine, natural human, and recombinant SP-A were 51.5°C, 52.3°C, and 42.0°C, respectively (Haagsman et al. 1989). SP-A exists as fully assembled complexes with 18 polypeptide chains, but it is also consistently found in smaller oligomeric forms. This is true for both the water- and lipid-soluble fractions of SP-A. Hydroxyproline residues are present in SP-A in a region

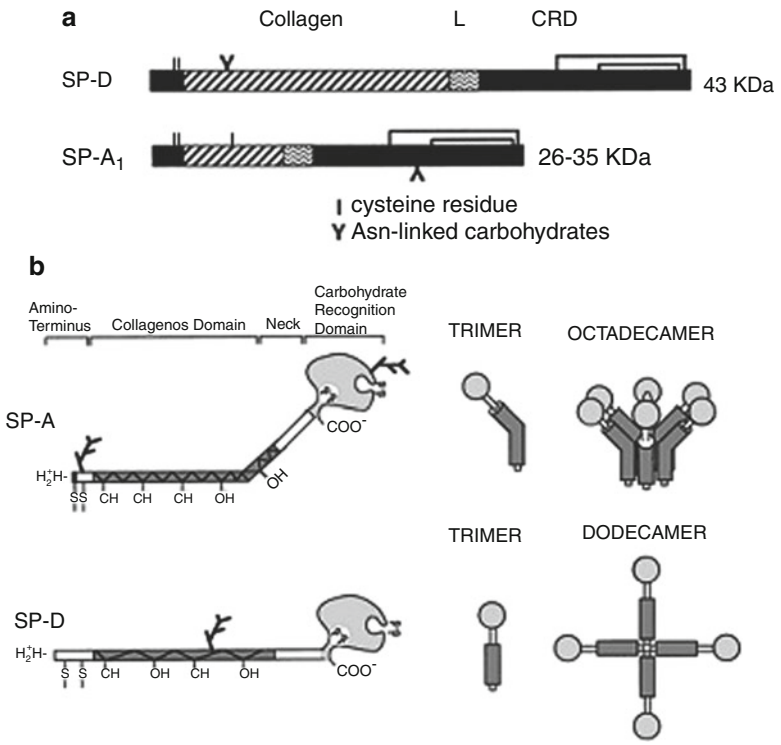

Fig. 24.1 Structural organization of SP-A and SP-D. (**a**) Each subunit of SP-A and SP-D consists of four major domains: a short cysteine-containing NH_2-terminal cross-linking domain (*N*); a triple helical collagen domain of variable length; a trimeric coiled-coil linking domain (*L*; also referred to as the neck); and a carboxyl-terminal, C-type lectin carbohydrate recognition domain (*CRD*) Differences in monomer size result from differences in the length of the collagen domain (*diagonal lines*). The Asn-linked oligosaccharide in SP-D is located in the collagen domain, whereas the Asn-linked sugar in human SP-A is located within the CRD (Crouch 1998). (**b**) Monomers form trimers that, in turn, form higher ordered oligomers of 18 (6 × 3) units for SP-A and 12 (4 × 3) units for SP-D. Molecules are not drawn to scale. SP-D is significantly larger than SP-A (Wright 1997) (Adapted with permission from Mason et al. 1998 © The American Physiological Society)

with a collagen-like sequence. SP-A treated with tunicamycin to block N-glycosylation and with 2,2-dipyridyl to inhibit the hydroxylation of proline residues suggests that hydroxylation of proline residues is required for perfect oligomerization of SP-A and for thermal stability in interaction with lipid (García-Verdugo et al. 2003; McCormack 1998; Palaniyar et al. 2001).

24.2.1.2 The Collagen-Like Domain of Human SP-A

A collagen-like domain of human SP-A consists of 23 Gly-X-Y repeats with an interruption near the midpoint of this domain. McCormack et al. (1999) suggested that : (1) SP-A trimerization does not require the collagen-like region or interchain disulfide linkage; (2) the N-terminal portion of collagen-like domain in SP-A is required for specific inhibition of surfactant secretion but not for binding to liposomes or for enhanced uptake of phospholipids into type II cells; (3) N-terminal interchain disulfide linkage in SP-A can functionally replace the N-terminal segment for lipid binding, receptor binding, and enhancement of lipid uptake, and (4) the N-terminal segment is required for the association of trimeric subunits into higher oligomers, for phospholipid aggregation, and for specific inhibition of surfactant secretion and cannot be replaced by disulfide linkage alone for these activities. To define the function of the kink region of SP-A, two mutated proteins were constructed to disrupt the interruption of Gly-X-Y repeats: SP-ADEL, which lacks the Pro47-Cys48-Pro49-Pro50 sequence at the interruption, and SP-AINS, in which two glycines were introduced to insert Gly-X-Y repeats (Gly-Pro47-Cys48-Gly-Pro49-Pro50). EM revealed that both mutants form octadecamers that lack a bend in the collagenous domain. The interruption of Gly-X-Y repeats in the SP-A molecule is critical for the formation of a flower bouquet-like octadecamer and contributes to SP-A's capacity to aggregate phospholipid liposomes (Uemura et al. 2006). The C-terminal non-collagenous domain of SP-A is essential for its correct folding and assembly, as judged by the secretion of various deletion mutants expressed in COS cells. Results suggest that three prefolded non-collagenous domains register and act as a nucleation center for the folding of the collagenous triple helix which

proceeds in a zipper-like fashion towards the N-terminus (Spissinger et al. 1991).

The mutant SP-A1(δAVC,C6S) was thermally less stable for collagen structure with increased susceptibility to trypsin degradation. The supratrimeric assembly of human SP-A is essential for collagen triple helix stability at physiological temperatures, protection against proteases, protein self-association, and SP-A-induced ligand aggregation. The supratrimeric assembly is not essential for the binding of SP-A to ligands and anti-inflammatory effects of SP-A (Sánchez-Barbero et al. 2005, 2007).

24.2.2 Structural Biology of Rat SP-A

24.2.2.1 Chemical Modification of SP-A Alters Binding Affinity to Alveolar Type II Cells

Alkylation of SP-A with excess of iodoacetamide yielded forms of SP-A that did not inhibit surfactant lipid secretion and did not compete with ^{125}I-SP-A for cell surface binding. Kuroki et al. (1988b) concluded that: (1) cell surface binding activity of rat SP-A is directly related to its capacity to inhibit surfactant lipid secretion; (2) the lectin activity of SP-A against mannose ligands does not appear to be essential for cell surface binding; (3) the human SP-A derived from individuals with alveolar proteinosis exhibits different binding characteristics from rat SP-A.

24.2.2.2 Amino Terminal Processing of SP-A Results in Cysteinyl Isoforms

Triple-helix formation from three polypeptide chains requires previous trimerization of COOH-terminal globular domains by a trimeric α-helical coiled-coil (Head et al. 2003; McCormack et al. 1997a; Elhalwagi et al. 1997). Octadecamers appear to be formed by lateral association of the NH_2-terminal half of six triple-helical stems, forming a microfibrillar end piece stabilized by disulfide bonds at the NH_2-terminal region (Head et al. 2003) (Fig. 24.2). In rat SP-A two cysteine residues are involved in multimer formation: a cysteine in the 6 position of the NH_2-terminal segment (McCormack et al. 1997b) and another cysteine in the position −1, which is the last position of the signal peptide, one amino acid before the NH_2 terminus (Elhalwagi et al. 1997). Human SP-A, as well as rhSP-A1 and rhSP-A2 also have considerable NH_2-terminal heterogeneity, in which about 50–75% of human SP-A molecules contain Cys^{-1} isoforms (Elhalwagi et al. 1997; Wang et al. 2004; Garcia-Verdugo et al. 2003). In human SP-A1, four cysteine residues are potentially involved in the arrangement of the disulfide bonding: two cysteine residues in the NH_2-terminal segment (Cys^{-1} and Cys^{6}), another in the middle of the collagen-like sequence within the Pro-Cys-Pro-Pro interruption (Cys^{48}), and a fourth cysteine at position 65 (Cys^{65}) in the collagen domain near the neck. Cys^{65} is substituted by Arg^{65} in the human SP-A2 polypeptide chain (Floros and Hoover 1998). The biological functions of rat SP-A are dependent on intact disulfide bonds. Reducible and collagenase-reversible covalent linkages of as many as six or more subunits in the molecule indicate the presence of at least two NH2-terminal interchain disulfide bonds. Primary structure of rat SP-A predicts that only Cys^{6} in this region is available for interchain disulfide formation. However, direct evidence for a second disulfide bridge was obtained by analyses of a set of mutant SP-As with deletions from the reported NH2-terminus. Thus, a post- translational modification results in naturally occurring rat SP-A cysteinyl isoforms, which are essential for multimer formation (Elhalwagi et al. 1997)

The role of the intermolecular bond at Cys^{6} and the collagen-like domain (Gly8-Pro80) in the interactions of SP-A with phospholipids and alveolar type II cells were investigated using mutant forms of protein. McCormack et al. (1997b) suggested that: (1) the Cys^{6} interchain disulfide bond of SP-A is required for aggregation of liposomes and for potent inhibition of surfactant secretion. (2) The collagen-like region is required for competition with ^{125}I-SP-A for receptor occupancy and specific inhibition of surfactant secretion in the presence of competing sugars. (3) Both the NH2-terminal disulfide and the collagen-like region are required to enhance the association of phospholipid vesicles with type II cells Yet, Zhang et al. (1998) suggested that neither Cys^{-1}-dependent multimerization nor the longer SP-A isoform is absolutely required for oligomeric association of trimeric SP-A subunits, SP-A/phospholipid interactions, or the regulation of surfactant secretion or uptake from type II cells by rat SP-A.

24.2.2.3 Glu^{195} and Arg^{197} Are Essential for Receptor Binding

The binding of SP-A to its high affinity receptor on alveolar type II cells is thought to be dependent on a CRD, while the interaction with lipids is attributed to the hydrophobic neck region of the molecule. To explore the role of the CRD in the interactions of SP-A with type II cells and lipids, McCormack et al. (1994) introduced mutations into the cDNA to encode for the substitutions Glu^{195}—>Gln and Arg^{197}—>Asp (SP-Ahyp, Gln^{195},Asp^{197}) and expressed the mutant protein in insect cells. Wild type SP-A produced in insect cells does not contain hydroxyproline (SP-Ahyp), but like rat SP-A it binds to carbohydrate affinity columns, lipids, and the SP-A receptor and is a potent inhibitor of the secretion of surfactant from type II cells. Study indicated that the binding of SP-A to its receptor and the inhibition of surfactant secretion are critically dependent on the carbohydrate binding specificity of CRD. Furthermore, phospholipid aggregation and augmentation of phospholipid uptake into

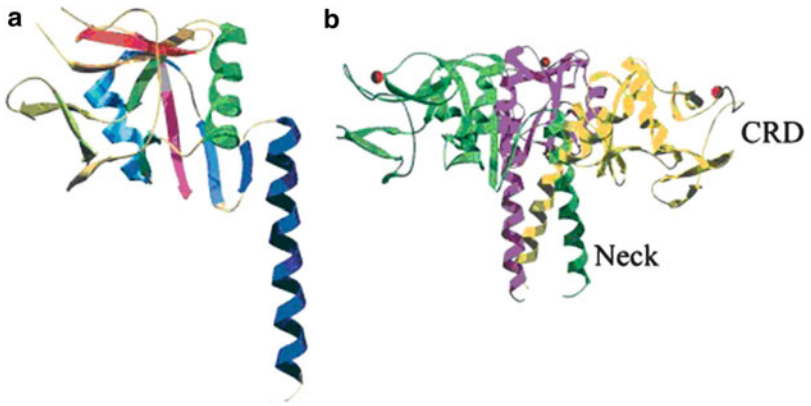

Fig. 24.2 Structure of CRD and neck domain (Δ1–80/N187S) of rat SP-A. A recombinant rat SP-A containing only the amphipathic linking domain and the CRD and lacking the consensus for asparagine-linked glycosylation (ΔN1-P80,N187S) was synthesized in insect cells using baculovirus vectors and purified on affinity column. (**a**) Ribbon diagram of (Δ1–80/N187S) monomer with secondary structure. (**b**) the (Δ1–80/N187S) trimer with each monomer colored differently and calcium ions in primary site are shown as *red spheres* (Adapted by permission from Head et al. 2003 © The American Society for Biochemistry and Molecular Biology)

type II cells are mediated by the C-terminal region of SP-A by a mechanism that is distinct from phospholipid binding.

Rat serum MBP-A is structurally analogous to SP-A and functionally equivalent to SP-A. MBP-A does not possess the ability to interact with lipids and type II cells. Honma et al. (1997) investigated the SP-A region involved in binding lipids and interacting with type II cells by using chimeric proteins with MBP-A. The binding of chimeras to DPPC and GalCer with activity comparable to recombinant SP-A suggested that MBP-A region of Glu185-Ala221 could functionally replace the homologous SP-A region of Glu195-Phe228 without loss of interaction with lipids and type II cells (Honma et al. 1997).

24.2.3 3-D Structure of SP-A Trimer

The crystal structure of the trimeric CRD and neck domain of SP-A was solved to 2.1-A resolution. The crystal structure was derived from a fragment, which encompasses the extended, helical neck region (residues 81–108) and the globular CRD (residues 111–228) of the SP-A monomer. The fragment forms a stable non-covalent trimer in solution (McCormack et al. 1999). The secondary structure of the CRD includes three α-helices and 11 short (3–7 residues) strands of β-sheet (Fig. 24.2b). The overall fold of the CRD in SP-A is similar to that of SP-D and MBP. The main structural differences are restricted to the region that includes surface loops and calcium binding sites. The neck region consists of a single amphipathic α-helix (residues 84–108) culminating in a reverse turn (residues 108–111) that leads into the first β-sheet of the CRD domain. The neck regions of three monomers are intertwined around a three-fold rotational symmetry axis to form the coiled-coil trimer (Fig. 24.2b). The trimer is held together primarily by means of hydrophobic face of the amphipathic helix from the neck of each monomer. This hydrophobic face is composed of side chains of Leu^{87}, Leu^{91}, Ile^{94}, Ile^{98}, Thr^{101}, Met^{102}, and Leu^{105}. The reverse turn is situated around the three-fold symmetry axis such that the polar side chains of Gln^{108} and Ser^{110} form H-bonds with their counterparts in the other two monomers (Fig. 24.2a). Three intermolecular salt bridges linking Glu^{90} and Lys^{95} of adjacent monomers provide additional stabilization. Intramolecular contacts between the neck and CRD are minimal in the SP-A monomer.

In the SP-A trimer, the interface between domains does not have the appearance of a freely mobile hinge region as it does in the monomer. Major contacts between the two domains are primarily intermolecular and mostly hydrophilic. In one such contact, the carboxylate group of the C terminus, Phe^{228}, of one monomer forms a salt bridge and an H-bond with the side chains of neck residues His^{96} and Gln^{100}, respectively, of another monomer. All three residues are invariant in mammalian SP-A sequences. The neck and CRD domains are oriented nearly perpendicularly to each other in SP-A, in contrast to both SP-D and MBP, where the interdomain angles are greater (i.e. "T" versus "Y" shapes, respectively).

Two metal binding sites were identified, one in the highly conserved lectin site and the other 8.5 A away. The interdomain CRD-neck angle is significantly less in SP-A than in SP-D, and MBL. This conformational difference may endow the SP-A trimer with a more extensive hydrophobic surface capable of binding lipophilic membrane components. The appearance of this surface suggests a putative binding region for membrane-derived SP-A ligands such as phosphatidylcholine and lipid A, the endotoxic lipid component of

bacterial lipopolysaccharide that mediates the potentially lethal effects of Gram-negative bacterial infection (Head et al. 2003).

Three-dimensional (3D) structure of SP-A in association with a lipid ligand (DPPC: egg phosphatidylcholine lipid monolayers) was determined using single particle electron crystallography and computational 3D reconstruction in combination with molecular modeling. TEM showed that SP-A subunits readily formed trimers and interacted with lipid monolayers, exclusively via the globular domains. The plane of the putative lipid-protein interface was relatively flat and perpendicular to the hydrophobic neck region; the cleft region in the middle of the trimer had no apparent charge clusters. Amino acid residues that were known to affect lipid interactions, Glu^{195} and Arg^{197}, were located at the protein-lipid interface. The molecular model indicated that the hydrophobic neck region of the SP-A did not interact with lipid monolayers but was instead involved in intratrimeric subunit interactions. The glycosylation site of SP-A was located at the side of each subunit, suggesting that the covalently linked carbohydrate moiety probably occupies the spaces between the adjacent globular domains, a location that would not sterically interfere with ligand binding (Palaniyar et al. 2000).

24.2.4 Bovine SP-A

24.2.4.1 Self-Aggregation of SP-A Depends on Ca^{2+} and Other Factors

Bovine SP-A forms extended fibers in the presence of calcium. On phosphatidylcholine or especially DPPC monolayers, SP-A at roughly 0.005 mg/ml formed large numbers of fibers and elaborate fibrous networks. The weak protein-protein interactions amongst free SP-As could be stabilized by phospholipids. In the presence of glycolipid GM1-ganglioside, SP-A's globular headgroup regions appeared enlarged and only small non-fibrous clusters were observed (Palaniyar et al. 1998b).

The importance of cations, particularly calcium, on SP-A function is well known and self-aggregation of bovine SP-A is Ca^{2+}-dependent. The concentration Ca^{2+} needed for half-maximal self-association ($K_{aCa}{}^{2+}$) depended on the presence of salts. Ca^{2+}-dependent SP-A aggregates formed in absence of NaCl are structurally different from those formed in its presence. Self-aggregation of SP-A can be pH and temperature-dependent and influenced by the presence of salts, which reduced the extent of self-association of the protein (Ruano et al. 2000). The CD spectra of bovine SP-A at various pH values indicated that α-helical content progressively decreased and that of β-sheet increased as the pH was reduced (Ruano et al. 1998). The quaternary organisation of bovine SP-A is altered by the presence of cations, especially calcium and sodium. There is a transition concentration, unique for each cation, at which a conformational switch occurs. The fact that the transition concentrations of cations are within physiological range suggests that cation-mediated conformational changes of SP-A could be operative in vivo (Ridsdale et al. 1999). The domains of SP-A that mediate lipid binding have been mapped. It was demonstrated that (1) lipid binding and pH-dependent liposome aggregation are mediated by CRD of SP-A, (2) distinct but overlapping domains within the CRD are required for pH- and Ca^{2+}-dependent liposome aggregation, and (3) conserved acidic and polar residues of the carbohydrate binding site of SP-A are essential for interactions with type II cells (McCormack et al. 1997c).

24.2.4.2 Substitution of His^{197} Creates Specific Lipid Uptake Defects

Mutagenesis of Glu^{195} and Arg^{197} of SP-A has implicated both residues as critical participants in the interaction of the molecule with alveolar type II cells and phospholipids. Substitution of Ala, Lys, His, Asp, and Asn for Arg at position 197 in SP-A action revealed that Ala^{197} retained complete activity in the SP-A functions and hence Arg^{197} is not essential for SP-A function. The Lys^{197} mutation displayed all functions of the wild type protein but exhibited a twofold increase in lipid uptake activity. The His^{197} mutation displayed all SP-A functions studied except for lipid uptake. The His^{197} mutation clearly demonstrated that lipid aggregation alone by SP-A is insufficient to promote lipid uptake by type II cells. Thus, specific interactions between type II cells and SP-A are involved in the phospholipid uptake processes (Pattanajitvilai et al. 1998)

Formation of Folds and Vesicles by DPPC Monolayers: Depositing DPPC organic solvent solutions in excess at an air:buffer interface led to the formation of elongated structures which could be imaged by TEM. The structures appeared to be DPPC folds protruding into the sol. The structures were frequently ordered with respect to one another, suggesting that they arose during lateral compression due to excess DPPC and are characteristic of a type of monolayer collapse phase. The elongated folds are unstable and can resolve by forming vesicles. Fold formation occurred at defined lipid concentrations above which more vesicles were observed. SP-A did not influence fold or vesicle formation but bound to the edges of these structures preferentially. It suggested that DPPC monolayers can form bilayers spontaneously in the absence of surfactant apoproteins, other proteins or agents (Ridsdale et al. 2001).

The temperature dependence of 2,850 cm^{-1} phospholipid acyl chain CH2 symmetric stretching frequencies in infra red (IR) spectrum showed a broad, reversible, melting event

from about 15°C to 40°C in both the lipid extract and the native surfactant. The SP-A from bovine lung lavage was reconstituted into a binary lipid mixture of acyl chain perdeuterated DPPC-d62/DPPG (85:15 w/w) at a ratio approximating to that in surfactant. High levels of SP-A induced an ordering of the phospholipids, as shown by an increase in the transition temperature of DPPC-d62 compared to the lipid model. In contrast, a mixture of the other surfactant proteins induced a progressive disordering of the phospholipids and disruption of the cooperativity of the melting event (Reilly et al. 1989).

Structural Changes in SP-A Induced by Cations Reorient the Protein on Lipid Bilayers: Cations influence the interaction of bovine SP-A with phospholipid vesicles made of DPPC and unsaturated phosphatidylcholine (PC) (Gurel et al. 2001). The SP-A octadecamers exist in an "opened-bouquet" conformation in the absence of cations and interact with lipid membranes via one or two globular headgroups. Calcium-induced structural changes in SP-A resulted into the formation of a clearly identifiable stem in a "closed-bouquet" conformation. This change, in turn, results in all of SP-A's globular headgroups interacting with the lipid membrane surface and with the stem pointing away from the membrane surface. These results give direct evidence that the headgroups of SP-A (comprising CRDs), and not the stem (comprising the amino-terminus and collagen-like region), interact with lipid bilayers. Study supported models of tubular myelin in which headgroups, not the tails, interacted with lipid walls of the lattice (Palaniyar et al. 1998a).

24.2.4.3 Formation of Membrane Lattice Structures with SP-A

Tubular myelin (TM), the pulmonary surfactant membranous structure contains elongated tubes that form square lattices. Atomic force microscopy (AFM) imaging of the unstained sections containing TM indicated a highly heterogeneous surface topography with height variations ranging from 10 to 100 nm. In tapping-mode AFM, tubular myelin was seen as hemispherical protrusions of 30–70 nm in diameter, with vertical dimensions of 5–8 nm. This study suggests detection of 3-D nanotubes present in low abundance in a biological macromolecular complex (Nag et al. 1999).

Under TEM dipalmitoylphosphatidyl choline-egg phosphatidyl- choline (1:1 wt/wt) bilayers formed corrugations, folds, and predominantly 47-nm-square latticelike structures. SP-A specifically interacted with these lipid bilayers and folds. Other proteolipid structures could act as intermediates for reorganizing lipids and SP-As. Such a reorganization could result to the localization of SP-A in the lattice corners and could explain, in part, the formation of TM-like structures in vivo (Palaniyar et al. 1999).

Surfactant Lipid Peroxidation Damages SP-A and Inhibits Interactions with Phospholipid Vesicles: Lipid peroxidation (LPO) affects the function of SP-A. Exposure of SP-A to LPO is associated with an increase in the level of SP-A-associated carbonyl moieties and a marked reduction in SP-A-mediated aggregation of liposomes. LPO initiated by an azo-compound resulted in enhanced protein oxidation and inhibited SP-A-mediated liposome aggregation. Exposure of SP-A to LPO resulted in oxidative modification and functional inactivation of SP-A by phospholipid radicals (Kuzmenko et al. 2004). At the same time, pulmonary SP-A inhibits the lipid peroxidation stimulated by linoleic acid hydroperoxide of rat lung mitochondria and microsomes. Under similar conditions, BSA was unable to inhibit lipid peroxidation stimulated by LHP, indicating that the effect is specific to SP-A (Terrasa et al. 2005).

24.2.5 SP-A in Other Species

Canine surfactant SP-A sediments with a sedimentation coefficient of 14 S, giving a Mr of about 700 kDa. The hydrodynamic data can be approximated as a prolate ellipsoid having an axial ratio of about 20. SP-A aggregates into a complex of 18 monomers, which may form six triple-helices. The shape of the complex is considerably more globular than collagen and is not consistent with end-to-end binding of the helices to form fibrous structures. Canine SP-A contains a domain of 24 repeating triplets of Gly-X-Y, similar to that found in collagens. SP-A forms a collagen-like triple helix when in solution. The CD of protein demonstrated a relatively large negative ellipticity at 205 nm, with a negative shoulder ranging from 215 to 230 nm. There was no positive ellipticity, and the spectrum was not characteristic of collagen. Trypsin hydrolysis resulted in a fragment with peak negative ellipticity at about 200 nm, without the negative shoulder. Further hydrolysis of this fragment with pepsin resulted in a CD spectrum similar to that of collagen. The spectrum of the collagen-like fragment was reversibly sensitive to heating to 50°C, and was irreversibly lost after treatment with bacterial collagenase (King et al. 1989).

A full-length cDNA to guinea pig pulmonary SP-A consists of 1,839 bp and is highly conserved at both nucleotide and amino acid sequence levels with those from other species. As expected, guinea pig SP-A mRNA is abundantly expressed in adolescent lung tissue and is undetectable in nonpulmonary tissues. SP-A mRNA expression is confined to cells of the alveolar epithelium with no expression in the bronchiolar epithelial cells, whereas SP-B mRNA is expressed in both alveolar and bronchiolar epithelial cell populations. This distinct expression pattern suggests that

the guinea pig lung will be a useful model in which to study expression of transcription factors implicated in the regulation of SP genes (van Eijk et al. 2001; Yuan et al. 1997). The complete cDNAs for ovine SP-A consists of 1,901 bp and encodes a protein of 248 amino acids (Pietschmann and Pison 2000). SP-A is present in pulmonary tissues of horses. The equine SP-A predicted from a cDNA of 747 bp consists of 248 amino acids, showing highest homology with SP-A from sheep (85.01%). The genomic DNA of equine SP-A, as in other species, includes three introns. There was no indication for the existence of two different SP-A genes (Hospes et al. 2002).

24.3 Cell Surface Receptors for SP-A

Different receptors have been identified on cells that work as receptors for SP-A or SP-D. In human monocytes the antibacterial activity of SP-A is mediated by a receptor for SP-A. A receptor with a high degree of specificity has been suggested for SP-A on alveolar macrophages (AMΦs). Chen et al. (1996) showed that secretagogues stimulates surfactant uptake through recruitment of SP-A receptors to the type II cell surface. Alveolar type II cells express a high affinity receptor for pulmonary SP-A, and the interaction of SP-A with these cells leads to inhibition of surfactant lipid secretion. The binding of SP-A to type II cells required Ca^{2+} and exhibited high-affinity for AMΦs (Kuroki et al. 1988a). The cell membrane receptor for SP-A regulates secretion of alveolar type II cells by negative feedback. Because TGF-β also inhibits Ca^{2+} fluxes, SP-A and TGF-β could be representative of a group of physiologic regulators that act by modulating intracellular Ca signaling (Strayer et al. 1999).

C1qR for Phagocytosis (C1qRp) (or CD93): The 126-kDa polypeptide is a functional common receptor or component of the receptor that mediates the enhancement of phagocytosis. Expression of this receptor is limited to cells of myeloid origin, platelets and endothelial cells, consistent with a relatively selective function. The amino acid sequence for C1qRp indicates that this surface glycoprotein receptor is a type I membrane protein of 631 amino acid containing a region homologous to C-type lectin CRDs, 5 EGF-like domains, a single transmembrane domain and a 47 amino acid intracellular domain. C1qRp cross-linked directly by monoclonal anti-C1qRp or engaged as a result of cell surface ligation of SP-A, as well as C1q and MBL, enhances phagocytosis (Nepomuceno et al. 1999; Tenner 1998). Ligation of human monocytes with immobilized R3, a IgM mAb recognizing C1qRp, also triggers enhanced phagocytic capacity of these cells in absence of ligand, verifying the direct involvement of this polypeptide in the regulation of phagocytosis. A distinct C1q receptor that triggers superoxide in polymorphonuclear leukocytes has been functionally characterized and designated as C1qRO2^{-}. Thus, there are at least two C1q receptor/receptor complexes (C1qRp and C1qRO2^{-}), each triggering distinct cellular responses, that can be expressed on the same, as well as on different, cell types (Tenner 1998) (see Chap. 41).

The C1q receptor (C1qR), identified from U937 cells and human tonsil lymphocytes, interacts with the C1q, mannose-binding protein, conglutinin and lung SP-A (Malhotra et al. 1990). This C1qR is an acidic glycoprotein, which exists as a dimer of Mr 115,000 in soluble form under non-denaturing conditions. The interaction of SP-A with U937 cells was found to up-regulate the surface expression of C1qR and to trigger the expression of an intracellular pool of C1qR (Malhotra et al. 1992). The collagen triple helix in Clq, MBP and SP-A, a cluster of similar charged residues has been suggested to be associated with receptor binding. A similar region of charge density occurs close to the N-terminus of conglutinin (Malhotra et al. 1993). SP-A binds to both *S. aureus* and monocytes and mediates the phagocytosis of the bacteria by these cells. Results demonstrate that C1qR mediates the phagocytosis of SP-A-opsonized *S. aureus* by monocytes (Geertsma et al. 1994).

SP-A Receptor 210 (SP-R210): Both type II cells and macrophages express a 210-kDa SP-A-binding protein, which was purified from U937 macrophage membranes and rat lung membranes. The 210-kDa protein was functional cell-surface receptor on type II cells, and the macrophage SP-A receptor is involved in SP-A-mediated clearance of pathogens (Chroneos et al. 1996; Yang et al. 2005). However, bovine AMΦs expose binding sites that are specific to SP-A, and depend on Ca^{2+} and on mannose residues. Two receptor proteins bound SP-A in a Ca^{2+}-dependent manner: one comprised of a 40-kDa protein showing mannose dependency and second of a 210-kDa protein, showing no mannose sensitivity (Plaga et al. 1998).

Glycoprotein-340: A Member of Scavenger Receptor Superfamily: A glycoprotein (Mr 340 kDa, gp-340) was purified from human bronchioalveolar lung washings from a patient with alveolar proteinosis. The gp-340 was found to bind to lung SP-D and also SP-A. Its molecular mass was 340 kDa in reduced state and decreased to 290 kDa in unreduced state. Binding between gp-340 and SP-D and

SP-A required the presence of calcium, and was not inhibited by maltose. Binding between gp-340 and SP-D is a protein-protein interaction rather than a lectin-carbohydrate interaction and that the binding to gp-340 takes place via carbohydrate recognition domain CRD of SP-D (Holmskov et al. 1997). Glycoprotein-340 interacts directly with pathogenic microorganisms and induces their aggregation, suggesting its role in innate immunity. Differential regulation of gp-340 in epithelial cell lines by phorbol myristate acetate indicates that gp-340 s involvement in mucosal defense and growth of epithelial cells may vary at different body locations and during different stages of epithelial differentiation (Kang et al. 2002)

SP-A Specific Receptor (SPAR): A pulmonary protein of ~30 kDa binds SP-A. The cDNAs encoding this protein were identified in human (4.1-kb) and porcine (1.8-kb) lung expression libraries. Both cDNAs encode similar ~32-kDa proteins that bind SP-A. The human and porcine SP-A recognition (SP-A specific receptor; SPAR) proteins resemble each other, as well as other cell membrane receptors. Their projected structures are consistent with cell membrane receptors. SPAR transcripts are expressed primarily in lung. SPAR-producing cells resemble the alveolar cells expressing SP-B and SP-C transcripts in appearance, location, and distribution (Strayer et al. 1993)

SP-A increases intracellular $[Ca^{2+}]_i$. Increased SP-A concentrations lead to a higher percentage of responding cells. SP-A also leads to a dose-dependent and transient generation of IP3. Secretagogue-induced secretion is inhibited by SP-A, which binds to SPAR on the surface of type II cells. The mechanism of SP-A-activated SPAR signaling involves PI3K, since PI3K inhibitor LY294002 rescued surfactant secretion from inhibition by SP-A. Thus, SP-A signals to regulate surfactant secretion through SPAR, via pathways that involve tyrosine phosphorylation, include insulin receptor substrate-1 (IRS-1), an upstream activator of PI3K, and entail activation of PI3K. This activation leads to inhibition of secretagogue-induced secretion of pulmonary surfactant (White and Strayer 2000).

24.4 Interactions of SP-A

24.4.1 Protein-Protein Interactions

SP-A has been involved in the physiology of reproduction. Consistent with the activation of ERK-1/2 and COX-2-induced by SP-A in myometrial cells, there are two major proteins recognized by SP-A in these cells. One of these SP-A targets is intermediate filament (IF) desmin. SP-A recognizes especially its rod domain, which is known to play an important role during the assembly of desmin into filaments. SP-A is colocalized with desmin filaments in myometrial cells. Interestingly, vimentin, the IF characteristic of leukocytes, is one of the major proteins recognized by SP-A in protein extracts of U937 cells. The ability of SP-A to interact with desmin and vimentin, and to prevent polymerization of desmin monomers, shed light on unexpected and wider biological roles of this collectin (Garcia-Verdugo et al. 2008a; Tanfin 2008).

Schlosser et al. (2006) described the molecular interaction between the extracellular matrix protein microfibril-associated protein 4 (MFAP4) and SP-A. MFAP4 is a collagen-binding molecule containing a C-terminal fibrinogen-like domain and a N-terminal located integrin-binding motif and interacts with SP-A via the collagen region in vitro. MFAP4 and SP-A are colocated in different lung compartments indicating that the interaction may be operative in vivo (Schlosser et al. 2006). The SP-A binds to sTLR4 and MD-2 and the reaction is Ca^{2+}-dependent. The direct interaction between SP-A and TLR4/MD-2 suggests the importance of supratrimeric oligomerization in the immunomodulatory function of SP-A (Yamada et al. 2006). The α1-antitrypsin and SP-A are major lung defense proteins. SP-A can bind α1-antitrypsin. The CRD of SP-A appeared to be a major determinant of interaction, by recognizing α1-antitrypsin carbohydrate chains. However, binding of SP-A carbohydrate chains to the α1-antitrypsin amino acid backbone and interaction between carbohydrates of both proteins was also possible (Gorrini et al. 2005). At least three different proteins from bovine lung soluble fraction bind to SP-A in a Ca^{2+}-dependent manner. The main protein with molecular mass of 32 kDa was identified as annexin IV. The lung annexin IV augmented the $Ca2^{+}$-induced aggregation of lung lamellar bodies from rats. The SP-A binds annexin IV through protein-protein interaction, although, both proteins are phospholipid-binding proteins (Sohma et al. 1995). Among several polypeptides, the 200-kDa major polypeptide reacted with SP-A on ligand blots. This polypeptide corresponded completely with nonmuscle (cellular) myosin heavy chain. A smaller polypeptide of 135 kD also binds SP-A and appears to be a proteolytic fragment of the 200 kD peptide (Michelis et al. 1994).

Kresch and Christian (1998) isolated two SP-A specific binding proteins from type II cells with M_r of 86 and >200 kDa under nonreducing conditions, but dissociated into proteins with M_r of 65, 55, and 50 kDa. The 86-kDa protein is a glycoprotein with ~30% of its mass as carbohydrate. A protein band of 63 kDa under reduced conditions was identified as rat homolog of human type II transmembrane protein p63 (CKAP4/ERGIC-63/CLIMP-63) (Kresch and Christian 1998). The p63 closely interacts with SP-A and may play a role in trafficking or the biological function

of SP-A (Gupta et al. 2006). EM confirmed endoplasmic reticulum and plasma membrane localization of P63 in type II cells with prominent labeling of microvilli (Bates et al. 2008).

The SP-A and SP-D bind transmembrane inhibitory regulatory protein α (SIRPα) through their globular heads to initiate a signaling pathway that blocks proinflammatory mediator production. In contrast, their collagenous tails stimulate proinflammatory mediator production through binding to calreticulin/CD91. Together a model is implied in which SP-A and SP-D help maintain a non/anti-inflammatory lung environment by stimulating SIRPα on resident cells through their globular heads. However, interaction of these heads with PAMPs on foreign organisms or damaged cells and presentation of collagenous tails in an aggregated state to calreticulin/CD91 stimulates phagocytosis and proinflammatory responses (Gardai et al. 2003).

24.4.2 Protein-Carbohydrate Interactions

Haurum et al. (1993) studied the influence of carbohydrates on the binding of SP-A, MBP and conglutinin to mannan. The order of inhibiting potency on the binding of SP-A was: N-acetylmannosamine > L-fucose, maltose > glucose > mannose. These results were independent of the source or method of extraction of SP-A, and generally consistent with earlier studies that examined binding to various saccharide-substituted supports (Haagsman et al. 1987). However, they are in obvious disagreement with a study that characterized the binding of dog SP-A to various neoglycoproteins, glycolipids, and neoglycolipids (Childs et al. 1992). Notably, the latter studies demonstrated a preferential recognition of galactose and an inability to compete with free monosaccharides. Although residues corresponding to Glu^{185} and Asn^{187} are found in essentially all members of the mannose binding subgroup, SP-A has a substitution in the position corresponding to Asn^{187} (Arg in dog and rat and Ala in human). Drickamer has suggested that this correlates with the capacity of SP-A to bind to a variety of sugars with comparatively weak affinity (Drickamer 1992). In any case, mutagenesis of corresponding residues in the putative carbohydrate binding site of SP-A (Glu^{195} to Gln and Arg^{197} to Asp) reversed the preference from mannose to galactose in affinity chromatography assays using mannose- and galactose-substituted supports (McCormack 1998). Deletion of the consensus sequences for N-linked glycosylation showed no obvious effect on lectin activity (McCormack 1998). Human SP-A has been shown to bind to lactosylceramide (Childs et al. 1992), galactosylceramide, and gangliotriaosylceramide (Kuroki et al. 1992). The optimal binding conditions were drastically different for three receptors (lactosylceramide, galactosylceramide, and gangliotetraosylceramide). At pH 24.4 and at 5 mM Ca concentration the binding affinity of SP-A followed the order: galactosylceramide > lactosylceramide > gangliotetraosylceramide (Hynsjö et al. 1995).

Collectins bind DNA from a variety of origins, including bacteria, mice, and synthetic oligonucleo- tides. Pentoses, such as arabinose, ribose, and deoxyribose, inhibit the interaction between SP-D and mannan, one of the well-studied hexose ligands for SP-D and d-forms of the pentoses are better competitors than the l-forms (Palaniyar et al. 2004).

24.4.3 SP-A Binding with Lipids

SP-A exhibits high affinity binding interactions with lipid as well as carbohydrate ligands. SP-A binds specifically to DPPC, the most abundant phospholipid species in surfactant (Kuroki and Akino 1991), whereas SP-D binds to the minor surfactant component phosphatidylinositol (Ogasawara et al. 1992; Persson et al. 1992). Both bind to the lipopolysaccharide moieties that decorate bacterial surfaces; SP-A recognizes the lipid A component of lipopolysaccharide (Kalina et al. 1995), whereas SP-D binds to the core oligosaccharide and *O*-oligosaccharides (Sahly et al. 2002). Electron micrographs and other data indicate that the globular CRD and collagen-like domains in both surfactant proteins are oriented proximal and distal, respectively, to the membrane surface (Palaniyar et al. 1998, 2002).

SP-A Specifically Binds DPPC: Although a monolayer of DPPC, the major component of pulmonary surfactant, is thought to be responsible for the reduction of surface tension at the air-liquid interface of the alveolus, the participation of unsaturated and anionic phospholipids and the three surfactant-associated proteins is suggested in the generation and maintenance of this surface-active monolayer. Pulmonary SP-A enhances the surface activity of lipid extract surfactant and reverses inhibition by blood proteins in vitro (Cockshutt et al. 1990). SP-A interacts strongly with a mixture of surfactant-like phospholipids. Although SP-A binds phosphatidylcholine and Sphingomyelin, it showed very strong binding to DPPC, it did not bind to phosphatidylglycerol (PG), phosphatidyl- inositol, phosphatidylethanolamine, and phosphatidylserine. SP-A also exhibited strong binding to distearoylphosphatidyl-choline, but weak binding to dimyristoyl-, 1-palmitoyl-2-linoleoyl, and dilinoleoyl-phosphatidylcholine. Thus, it indicates that (1) SP-A specifically and strongly binds DPPC, (2) SP-A binds the nonpolar group of phospholipids, (3) the second positioned palmitate is involved in DPPC binding, and (4) the specificities of polar groups of dipalmitoylglycerophospholipids also appear to be important for SP-A binding, (5) the phospholipid binding activity of SP-A is dependent upon calcium ions and the integrity of the collagenous domain of SP-A, but not on the

oligosaccharide moiety of SP-A. SP-A may play an important role in the regulation of recycling and intra- and extracellular movement of DPPC (Kuroki and Akino 1991; Yu and Possmayer 1998). Yu et al. (1999) suggested the importance of CRD and N-terminal dependent oligomerization in SP-A-phospholipid associations.

Binding of SP-A to Glycolipids: The SP-A binds to galactosylceramide and asialo-GM2, and that both saccharide and ceramide moieties in the glycolipid molecule are important for the binding of SP-A to glycolipids (Kuroki et al. 1992). Though, ^{125}I-SP-A bound to galactosylceramide and asialo-GM2, but failed to exhibit significant binding to GM1, GM2, asialo-GM1, sulfatide, and Forssman antigen. The study of ^{125}I-SP-A binding to glycolipids coated onto microtiter wells also revealed that SP-A bound to galactosylceramide and asialo-GM2. SP-A bound to galactosylceramides with non-hydroxy or hydroxy fatty acids, but showed no binding to either glucosylceramide or galactosylsphingosine. Results provide evidence for binding specificity for proteins that have Ca^{2+}-dependent CRDs and raise the possibility that glycosphingolipids are endogenous ligands for SP-A (Childs et al. 1992).

Interaction with Phospholipid Liposomes: Ca^{2+} ions induce an active conformation in SP-A, which rapidly binds to liposomes and mediates their aggregation. SP-A/liposome interaction shows $K_D = 5$ μM for interaction between SP-A and DPPC liposomes. With POPC, the complex formation proceeds at half the rate, leading to a lower final equilibrium level of SP-A- DPPC interaction. Distearoylphosphatidylcholine (DSPC) shows a stronger interaction than DPPC. Among phospholipid headgroups, phosphatidyl inositol (PI) and sphingomyelin (SM) interact comparable to DPPC, while less interaction is seen with phosphatidylethanolamine (PE) or with phosphatidylglycerol (PG). Thus both headgroup and fatty acid composition determine SP-A phospholipid interaction. However, the protein does not exhibit high specificity for either the polar or the apolar moiety of phospholipids (Meyboom et al. 1999).

Whereas SP-A binds to DPPC and galactosylceramide (GalCer), MBP-A binds phosphatidylinositol (PI). SP-A also interacts with alveolar type II cells. Specific monoclonal antibodies inhibit the interactions between SP-A and lipids or alveolar type II cells. The amino acid residues 174–194 of SP-A and the corresponding region of MBP-A are critical for SP-A-type II cell interaction and Ca^{2+}-dependent lipid binding of collectins (Chiba et al. 1999; Tsunezawa et al. 1998).

Intermolecular Cross-Links Mediate Aggregation of Phospholipid Vesicles by SP-A: SP-A plays a central role in the organization of phospholipid bilayers in the alveolar air space. SP-A in lung lavage exists in oligomeric forms (N = 6, 12, 18 . . .) mediated by collagen-like triple helices and intermolecular disulfide bonds. These protein-protein interactions, involving the amino-terminal domain of SP-A, facilitate the alignment of surfactant lipid bilayers into unique tubular myelin structures. Accelerated aggregation of unilamellar vesicles required SP-A and 3 mM free calcium. The initial rate of aggregation was proportional to the concentration of canine SP-A over lipid:protein molar ratios ranging from 200:1 to 5,000:1. Data demonstrate the importance of the quaternary structure (triple helix and intermolecular disulfide bond) of SP-A for the aggregation of unilamellar phospholipid vesicles (Ross et al. 1991).

SP-A is thought to influence the surface properties of surfactant lipids and regulate the turnover of extracellular surfactant through interaction with a specific cell-surface receptor. SP-A induces a rapid Ca^{2+}-dependent aggregation of phospholipid vesicles and mediated by Ca^{2+}-induced interactions between carbohydrate-binding domains and oligosaccharide moieties of SP-A. This mechanism of membrane interactions may be relevant to the formation of the membrane lattice of tubular myelin, an extracellular form of surfactant (Haagsman et al. 1991)

24.5 Functions of SP-A

24.5.1 Surfactant Components in Surface Film Formation

Pulmonary surfactant is a mixture of phospholipids and proteins that lines the distal airways and stabilizes the gas-exchanging alveolar units of the lung. Surfactant membranes are decorated with SP-A, one of the four known surfactant proteins. The main function of surfactant is to reduce the surface tension at the air/liquid interface in the lung. This is achieved by forming a surface film that consists of a monolayer which is highly enriched in dipalmitoylphosphatidylcholine and bilayer lipid/protein structures closely attached to it. The molecular mechanisms of film formation and of film adaptation to surface changes during breathing in order to remain a low surface tension at the interface are unknown. The results of several model systems give indications for the role of the surfactant proteins and lipids in these processes. Veldhuizen and Haagsman (2000) described and compared the model systems that are used for this purpose and the progress that has been made. Despite some conflicting results using different techniques, workers concluded that surfactant protein B (SP-B) plays the major role in adsorption of new material into the interface during inspiration. SP-C's main functions are to exclude non-DPPC lipids from the interface during expiration and to attach the bilayer structures to the

lipid monolayer. The SP-A appears to promote most of SP-B's functions. Veldhuizen and Haagsman (2000) described a model proposing that SP-A and SP-B create DPPC enriched domains which can readily be adsorbed to create a DPPC-rich monolayer at the interface. Further enrichment in DPPC is achieved by selective desorption of non-DPPC lipids during repetitive breathing cycles. Reports that SP-A is required for the formation of tubular myelin (Korfhagen et al. 1996) and other large surfactant aggregates (Veldhuizen et al. 1996) and for the preservation of low surface tensions in presence of serum protein inhibitors (Cockshutt et al. 1990) suggest that the protein serves multiple roles in surfactant function.

24.5.2 Recognition and Clearance of Pathogens

SP-A interacts with viruses, bacteria and fungi. Furthermore, SP-A binds to various other inhaled glycoconjugates. SP-A receptors on phagocytic cells have been described that are important to ensure rapid pathogen clearance. This innate defence system of the lung is particularly important during infections in young children when the acquired immune system has not yet become fully established. Also in later life SP-A could be very important to prevent the lungs from infections by pathogens not previously encountered. Lung collectins, SP-A and SP-D have a relatively high affinity for oligosaccharides. This is an important determinant of self/non–self recognition, because most carbohydrates in animals are monosaccharides. Therefore, SP-A and SP-D enhance microbial phagocytosis by innate immune cells, such as macrophages and neutrophils, by opsonizing and aggregating bacteria and viruses, by acting as an activation ligand, and by upregulating the expression of immune cell surface receptors that recognize microbes. In addition, SP-A and SP-D also promote apoptotic cell uptake by innate immune cells and regulate cytokine and free radical production in a context-dependent manner. As an example, SP-A inhibits LPS-stimulated nitric oxide (NO) production by alveolar macrophages isolated from normal lungs, but promotes NO production in macrophages that have been activated by IFN-γ (Stamme et al. 2000). Both proteins possess direct bactericidal activity against bacteria and fungi through unknown mechanisms (Wu et al. 2003) (Table 24.1). In addition, SP-A may limit the inflammatory response in the lungs, thus preventing damage to the delicate lung epithelia. Evidences suggest that SP-A may modulate the allergic response to various glycosylated inhaled antigens. The presence of SP-A (and SP-D) in other organs indicates that these collectins may have a general role in mucosal immunity (Haagsman 1998; Tino and Wright 1998).

Table 24.1 Immune functions of SP-A and SP-D (Adapted by permission from Kishore et al. 2005 © Springer)

1. Endotoxin clearance and regulation of LPS-induced inflammation
2. Recognition, agglutination and phagocytosis of viral, bacterial and fungal pathogens[$]
3. Macrophage and neutrophil activation and chemotaxis
4. Microbial growth inhibition
5. Non-specific defense molecules in tears, saliva and body secretions against pathogens
6. Reduced viral infectivity
7. Protection against intrauterine infection and inflammatory reactions
8. Modulation of inflammation
9. Recognition and clearance of apoptotic and necrotic cells
10. Anti-proliferative effects on B and T lymphocytes
11. Pattern recognition of glycoprotein allergens
12. Inhibition of IgE-allergen cross-linking
13. Suppression of histamine release from basophils and mast cells
14. Modulation of Th cytokine profile
15. Modulation of maturation and antigen presentation by dendritic cells

Functions of SP-A and SP-D as collectins: SP-A and SP-D bind to and opsonize viruses, bacteria, allergens, and apoptotic cells. SP-A and SP-D enhance microbial phagocytosis by aggregating bacteria and viruses. SP-A and SP-D also possess direct bactericidal effects and potentially bind to a variety of receptors to modulate immune cell cytokine and inflammatory mediator expression (Wright 2005)

Although, the absence of SP-A changed the structure and in vitro properties of surfactant, the in vivo function of surfactant in SP-A$^{-/-}$ mice was not changed under the conditions of experiments. In the absence of SP-A, the structure of pulmonary surfactant large aggregates is altered, tubular myelin is absent, and SP-A is no longer available to contribute to the formation of the typical lattice-like structure. However, the surface tension–reducing function of surfactant appeared unaffected, suggesting that SP-A does not appear to play a primary role in surfactant homeostasis. Although the mice were able to survive with no apparent pathology in a sterile environment, and respond similarly to wild-type (WT) mice in exercised or hyperoxic conditions (Ikegami et al. 1998, 2000), their pulmonary immune responses are insufficient during immune challenge. *SP-D*–null mice have a more complex phenotype. Even in the absence of pathogens, the *SP-D*–null mice display advancing alveolar proteinosis and increased lipid pools, indicating that SP-D has a role in surfactant homeostasis. Metalloproteinases were also elevated in their lungs, which developed an emphysema-like phenotype. *SP-A*– and *SP-D*–null mice were more susceptible to bacterial and viral infections and LPS-mediated inflammation, confirming roles for SP-A and SP-D in modulating immune responses in the lung (Wright 2005) (Table 24.1).

SP-A facilitates phagocytosis by opsonizing bacteria, fungi and viruses, stimulates the oxidative burst by

phagocytes and modulates pro-inflammatory cytokine production by phagocytic cells. Pulmonary surfactant also exhibits immunomodulatory functions and plays a key role in host defense against infection. For example, surfactant lipids suppress a variety of immune cell functions, most notably lymphocyte proliferation. Both SP-A and SP-D improve phagocytosis of pathogens by polymorphonuclear neutrophils (Hartshorn et al. 1998). SP-A can also provide a link between innate and adaptive immune responses by promoting differentiation and chemotaxis of dendritic cells. The SP-A-deficient gene-targeted mouse is susceptible to lung infection with multiple organisms (LeVine et al. 1997). One view that reconciles these apparently divergent functions of SP-A is that its high affinity for surfactant membranes is a mechanism for concentrating the protein at the front lines of defense against inhaled pathogens (Hawgood and Poulain 2001; McCormack and Whitsett 2002). In addition, SP-A and SP-D each modifies the in vivo response to instilled endotoxin, leading to decreased lung injury and reduced inflammatory cell recruitment (Borron et al. 2000; Greene et al. 1999). The SP-A-mediated interaction of lipids with type II cell plasma membrane may contribute, in part, to the lipid uptake process by type II cells (Kuroki et al. 1996).

24.5.3 SP-A: As a Component of Complement System in Lung

There is a functional complement system present in the lung that helps in removal of pathogens. Complement proteins of alternative and classical pathways of complement have been observed in bronchoalveolar lavage fluids (BALF) from healthy volunteers (Watford et al. 2000). Because of structural and functional similarities between C1q and pulmonary SP-A, SP-A may interact with and regulate proteins of complement system. The SP-A binds directly to C1q, though only weakly to intact C1. The binding of SP-A to C1q prevents the association of C1q with C1r and C1s, and therefore the formation of active C1 complex required for classical pathway activation through a common binding site for C1r and C1s or Clq. Furthermore, SP-A blocked the ability of C1q to restore classical pathway activity in C1q-depleted serum. Thus, SP-A may down-regulate complement activity through its association with C1q and may serve a protective role in lung by preventing C1q-mediated complement activation and inflammation along the delicate alveolar epithelium (Tenner et al. 1989; Watford et al. 2001).

24.5.4 Modulation of Adaptive Immune Responses by SPs

Increasing evidence shows that SP-A and SP-D modulate the functions of adaptive immune cells, DCs and T cells. DCs form a tightly meshed network within the upper airways, parenchyma, and alveolar airspace, and are ideally positioned to sample inhaled antigens (Lipscomb and Masten 2002). DC density increases upon inflammatory stimuli, particularly in the lower airways as a result of recruited myeloid DC precursors (Jahnsen et al. 2001). Although SP-A and SP-D both bind to DCs in a calcium-dependent manner, they have differential effects on DC function. For example, SP-D enhances antigen uptake and presentation by bone marrow–derived DCs, but SP-A inhibits DC maturation and phagocytic and chemotactic function in vitro (Brinker et al. 2001, 2003). Also, SP-A and SP-D inhibit T-cell proliferation via two mechanisms: an IL-2–dependent mechanism observed with accessory cell–dependent T cell mitogens and specific Ag, as well as an IL-2–independent mechanism of suppression that potentially involves attenuation of calcium signaling (Borron et al. 1998a). Moreover, SP-A–mediated inhibition of T cell proliferation might partially result from TGF-ß present in the SP-A preparations (Kunzmann et al. 2006). In contrast to the results, obtained using bone marrow–derived DCs, SP-D was found to decrease antigen presentation by DCs isolated from the mouse lung during both resting and inflammatory conditions (Hansen et al. 2007). A role for SP-D in regulating T-cell responses in vivo is demonstrated in a study by Fisher et al. (2002) showing that *SP-D*–null mice have an accumulation of $CD4^+$ and $CD8^+$ T cells expressing activation markers CD69 and CD25 in the perivascular and peribronchial regions of the lung. Thus, studies suggest that surfactant may be a critical regulator of organ-specific immune regulation in the lung, and that the hyporesponsive immunologic environment of the lung is, in part, facilitated by the actions of SP-A and SP-D in an effort to thwart inflammatory cascades that could potentially damage the lung and impair gas exchange. SP-A regulates the differentiation of immature DCs into potent T cell stimulators. Studies demonstrate that SP-A participates in the adaptive immune response by modulating important immune functions of DCs (Brinker et al. 2003).

SP-A Inhibits Human Lymphocyte Proliferation and IL-2 Production: Studies suggest that purified SP-A suppress both PHA and anti-CD-3 activated proliferation of human peripheral blood and tonsillar mononuclear cells in a dose-

dependent manner at concentrations as low as 50 pM. In contrast, ConA-stimulated PBMC proliferation was slightly augmented by the addition of SP-A. The inhibition of PHA-stimulated proliferation by SP-A was accompanied by corresponding decline in IL-2 concentration. The in vitro inhibitory effect of SP-A was not blocked by C1q. The effect was not mediated by CRD of SP-A, but a 36-amino acid Arg-Gly-Asp (RGD) motif-containing span of collagen-like domain was responsible for the inhibition of T cell proliferation (Borron et al. 1998b).

In addition to SP-A, SP-D could also reduce the incorporation of ^{3}H-thymidine into PBMC in a dose-dependent manner. A recombinant peptide composed of neck and CRD of SP-D [SP-D(N/CRD)] was also suppressive for lymphocyte proliferation. Inhibitory effect of both SP-A and SP-D on histamine release in the early phase of allergen provocation and suppressing lymphocyte proliferation in the late phase of bronchial inflammation suggest that SP-A and SP-D may be protective against the pathogenesis of asthma (Wang et al. 1998). These experiments emphasize a potential role for SP-A in dampening lymphocyte responses to exogenous stimuli.

TGF-β1 and SP-A Influence Immune-Suppressive Properties of SP-A on CD4^{+} T Lymphocytes: SP-A and TGF-β1 have been shown to modulate the functions of different immune cells and specifically to inhibit T lymphocyte proliferation. Recombinant human SP-A1 suppressed T lymphocyte proliferation and IL-2 mRNA expression. The effect of rSP-A1m was mediated through TGF-βRII and could be antagonized by anti-TGF-β1 neutralizing antibodies and sTGF-βRII. The association between SP-A and latent TGF-β1 provides a possible mechanism that regulate TGF-β1-mediated inflammation and fibrosis reactions in lung but also leads to possible misinterpretation of immune-modulator functions of SP-A. Monitoring of SP-A preparations for possible TGF-β1 is essential (Kunzmann et al. 2006).

SP-A Differentially Regulates IFN-γ- and LPS-Induced Nitrite Production by Rat AMΦ: The role of SP-A and SP-D in regulating production of free radicals and cytokines is controversial. Haddad et al. (1994) suggest that peroxynitrite, but not .NO or superoxide and hydrogen peroxide, in concentrations likely to be encountered in vivo, caused nitrotyrosine formation and decreased the ability of SP-A to aggregate lipids.

The state and mechanism of activation of the immune cell influence its response to SP-A. SP-A inhibited production of NO and iNOS in rat AMΦs stimulated with smooth LPS, which did not significantly bind SP-A, or rough LPS, which avidly bound SP-A. In contrast, SP-A enhanced production of NO and iNOS in cells stimulated with IFN-γ or INF-γ plus LPS. Neither SP-A nor SP-D affected baseline NO production, and SP-D did not significantly affect production of NO in cells stimulated with either LPS or IFN-γ. These results suggest that SP-A contributes to the lung inflammatory response by exerting differential effects on the response of immune cells, depending on their state and mechanism of activation (Stamme et al. 2000).

SP-A$^{-/-}$ mice produced significantly more TNF-α and NO than SP-A$^{+/+}$ mice after intratracheal administration of LPS. Human SP-A to SP-A$^{-/-}$ mice restored regulation of TNF-α and NO production to that of SP-A$^{+/+}$ mice without affecting other markers of lung injury. Neither binding of LPS by SP-A, nor enhanced LPS clearance were the primary means of inhibition. It seems that SP-A acts directly on immune cells to suppress LPS-induced inflammation and that the endogenous or exogenous SP-A inhibits pulmonary LPS-induced cytokine and NO production in vivo (Borron et al. 2000). SP-A suppresses NO production by activated AMΦs by inhibiting TNF-α secretion and NF-kB activation (Hussain et al. 2003). SP-A also modulates NO production by AMΦ in vitro but results are contrasting. In AMΦ and type II cells, iNOS is known to generate NO, which is upregulated by SP-A of different origin in a concentration – dependent manner, whereas type II cells were unresponsive to SP-A. The increase in NO production was associated with elevation in expression of iNOS. Results indicated that SP-A is the agonist and not a contaminating LPS (Blau et al. 1997).

SP-A Modulates Production of Cytokines: SP-A enhances concanavalin A-induced proliferation and levels of TNF-α, IL-1 α, 1β, and IL-6 by human peripheral blood mononuclear cells. A similar enhancement of TNF-α release by SP-A was observed by rat peripheral blood cells, splenocytes, and alveolar macrophages. In combinations of SP-A with surfactant lipids, the enhanced levels of TNF-α resulting from SP-A treatment decreased as the lipids increased. At higher relative concentrations of SP-A, the lipids had little or no effect. SP-A also enhanced the production of IgA, IgG, and IgM by rat splenocytes. These data demonstrate that SP-A is capable of modulating immune cell function in lung by regulating cytokine production and Ig secretion (Kremlev et al. 1997; Huang et al. 2002).

SP-A Exhibits Inhibitory Effect on Eosinophils IL-8-Production: Eosinophils are one of the important sources of cytokines such as IL-8 at the site of allergic inflammation. Pulmonary SP-A plays a potential role in modifying inflammation and the immune function. SP-A could modify IL-8 production and release by eosinophils stimulated with ionomycin. The regulating effect of SP-A on eosinophil cytokine generation was verified. SP-A inhibits the secretion of IL-8 in a dose-dependent fashion. SP-A attenuated the production and release of IL-8 by eosinophils in a

concentration-dependent manner. Thus, SP-A may have the potential to modify allergic inflammation by inhibiting the release and production of IL-8 by eosinophils (Cheng et al. 1998, 2000).

SP-A Inhibits Lavage-Induced Surfactant Secretion in Newborn Rabbits: Various agents stimulate the secretion of lung surfactant from alveolar type II cells by increasing intracellular Ca^{2+}, c-AMP, or diacylglycerol. In vivo and in vitro experiments with granular pneumocytes suggest that SP-A inhibits secretion of pulmonary surfactant (Corbet et al. 1992). Stilbene disulfonic acids are potent but reversible inhibitors of lung surfactant secretion (Chander and Sen 1993). While searching the role of C-terminal domain of SP-A in binding to type II cells and regulation of phospholipid secretion, Murata et al. (1993) demonstrated that the non-collagenous, C-terminal, domain of SP-A is responsible for the protein's inhibitory effect on lipid secretion and its binding to type II cells.

24.5.5 SP-A Stimulates Chemotaxis of AMΦ and Neutrophils

Besides accelerating pathogen clearance by pulmonary phagocytes, SP-A also stimulates alveolar macrophage chemotaxis and directed actin polymerization. Moreover, SP-A also stimulates neutrophil chemotaxis and supports a role in regulating neutrophil migration in pulmonary tissue (Schagat et al. 2003). The stimulatory effect of surfactant on macrophage migration was mediated and stimulated by SP-A. Heat treatment or reduction and alkylation of SP-A reduced its stimulatory effect. The SP-A stimulates migration primarily by enhancing chemotaxis (directed movement) rather than chemokinesis (random movement). The interaction of SP-A with macrophages may be mediated partly by the collagen-like domain of SP-A (Wright and Youmans 1993).

24.5.6 SP-A Inhibits sPLA2 and Regulates Surfactant Phospholipid Break-Down

Secretory type IIA phospholipase A2 (sPLA2-IIA) is one of the key enzymes that may potentially play a role in the pathogenesis of inflammatory diseases because its presence is observed in sera of patients with bacterial infection and in the airspaces of animals with endotoxin-induced acute lung injury (Arbibe et al. 1997). Lyso-phospholipids are generated from surfactant mediated by type-II PLA2. Lyso-phospholipids exert a major injurious effect on lung cell membranes during ARDS. This hydrolysis was inhibited by SP-A through a direct and selective protein-protein interaction between SP-A and sPLA2-II (Arbibe et al. 1998). The absence of SP-A exacerbates the susceptibility of surfactant to degradation by $sPLA_2$-IIA. SP-A inhibits Ca^{2+}-independent acidic PLA2 of rat lung homogenate or isolated lamellar bodies but does not affect Ca^{2+}-dependent alkaline enzyme. Thus, inhibition of sPLA2 activity by SP-A may be a protective mechanism by maintaining surfactant integrity during lung injury (Arbibe et al. 1998; Chabot et al. 2003a; Fisher et al. 1994). SP-A and DOPG/PG play a role in the surfactant-mediated inhibition of sPLA2-IIA expression in AMΦs and that this inhibition occurs via a downregulation of NF-kB activation (Wu et al. 2003). Peroxiredoxin 6 (Prdx6), a protein with both GSH peroxidase and PLA_2 activities, degrades internalized DPPC of lung surfactant. The PLA_2 activity is inhibited by SP-A. A direct interaction between SP-A and Prdx6 may be a mechanism for regulation of the PLA_2 activity of Prdx6 by SP-A (Wu et al. 2006).

24.5.7 SP-A Helps in Increased Clearance of Alveolar DPPC

SP-A is necessary for lungs to respond to hyperventilation or secretagogues with increased ^{3}H-DPPC uptake. SP-A improves the surfactant activity of lipid extracts by enhancing the rate of adsorption and/or spreading of phospholipid at the air/liquid interface resulting in the formation of a stable lipid monolayer at lower bulk concentrations of either phospholipid or calcium (Chung et al. 1989). The surfactant phospholipids are mainly phosphatidylcholine and phosphatidylglycerol species, but analysis has shown that dipalmitoylphosphatidyl choline (DPPC) and dioleylphosphatidylglycerol (DOPG), in particular, play a major role in maintaining the biophysical properties of the surfactant film (Hawgood and Poulain 2001). SP-A enhances the uptake of liposomes containing DPPC, 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC), or 1,2-dihexadecyl-sn-glycero-3-phosphocholine (DPPC-ether) by alveolar type II cells (Tsuzuki et al. 1993). SP-A also modulates the PLA_2-mediated degradation of internalized DPPC (Jain et al. 2003). Pulmonary SP-A binds the lipids DPPC and galactosylceramide and induces aggregation of phospholipid vesicles.

The SP-A also inhibits lipid secretion and enhances the uptake of phospholipid by alveolar type II cells. Kuroki et al. (1994) suggested that the CRD is essential for the SP-A functions of lipid binding, liposome aggregation, the inhibitory effect on lipid secretion, and the augmentation of lipid uptake by type II cells, and these activities are largely attributable to amino acid residues within the steric inhibitory footprint of antibody, 1D6, bound to the small disulfide loop region. The neck domain of SP-A may also be involved

in the process of SP-A-mediated uptake of phospholipids by alveolar type II cells.

In vitro studies have revealed that the surface activity of oxidized surfactant was impaired and that this effect could be overcome by SP-A. Mechanically ventilated, surfactant-deficient rats were administered either bovine lipid extract surfactant (BLES) or in vitro oxidized BLES. Instillation of an in vitro oxidized surfactant caused an inferior physiological response in a surfactant-deficient rat (Bailey et al. 2004). Both C-reactive protein (CRP) and SP-A affect the surface activity of bovine lipid extract surfactant (BLES), a clinically applied modified natural surfactant. Although SP-A and CRP both bind PC, there is a difference in the manner in which they interact with surface films (Nag et al. 2004).

Isolated perfused rat lung showed that both clathrin- and actin-mediated pathways are responsible for endocytosis of dipalmitoylphosphatidylcholine (DPPC)-labeled liposomes by granular pneumocytes in the intact lung. Further studies may strengthen for a major role of receptor-mediated endocytosis of DPPC by granular pneumocytes, a process critically dependent on SP-A (Lang et al. 2008).

24.5.8 Protection of Type II Pneumocytes from Apoptosis

Activation of SPAR by SP-A binding initiates a signal through pathways that involve tyrosine phosphorylation, include IRS-1, and entail activation of PI3K. In other cell types, cytokines that activate the PI3K signaling pathway promote cell survival. SP-A affects apoptosis as measured by DNA laddering, and other techniques. The protective effects of SP-A were abrogated by inhibition of either tyrosine-specific protein kinase activity or PI3K (White et al. 2001). Analysis of anti-apoptotic signaling species downstream of IRS-1 showed activation of PKB/Akt but not of MAPK. Phosphorylation of IkB was minimally affected by SP-A. However, FKHR was rapidly phosphorylated in response to SP-A and its DNA-binding activity was significantly reduced. Since FKHR is pro-apoptotic, this may play an important role in signaling the anti-apoptotic effects of SP-A. Therefore, survival-enhancing signaling activated by SP-A include SPAR through IRS-1, PI3K, PKB/Akt, and FKHR (White and Strayer 2002).

SP-A and SP-D are potent modulators of macrophage function and may suppress clearance of apoptotic cells through activation of the transmembrane receptor signal inhibitory regulatory protein alpha (SIRPα). Gardai et al. (2003) provided evidence that SP-A and SP-D act in a dual manner to enhance or suppress inflammatory mediator production depending on binding orientation. In this concept, a model is implied in which SP-A and SP-D help maintain a non/anti-inflammatory lung environment by stimulating SIRPα on resident cells through their globular heads (Janssen et al. 2008).

24.5.9 Anti-inflammatory Role of SP-A

SP-A Modulates the Cellular Response to Smooth and Rough LPSs by Interaction with CD14: Lung SP-A modulates cellular inflammatory responses by their direct interactions with pattern-recognition receptors (PRRs) and has been implicated in the regulation of pulmonary host defense. Pathogen derived components such as LPS, peptidoglycan (PGN) or zymosan are potent stimulators of inflammation. SP-A binds to rough forms but not to smooth forms of LPS. SP-A interacts with CD14 on AMΦ and inhibits the binding of smooth LPS to CD14 and reduces TNF-α expression induced by smooth LPS (Sano et al. 1999). In this interaction, SP-A associates with LPS via lipid A moiety of rough LPS and involved in the anti-bacterial defences of the lung. The direct interaction of SP-A with CD14 constitutes a likely mechanism by which SP-A modulates LPS-elicited cellular responses (Sano et al. 1999; Stamme et al. 2002). Studies show that the direct interaction of SP-A with TLR2 alters PGN-induced cell signaling and that SP-A modulates inflammatory responses against the bacterial components by interactions with PRRs (Murakami et al. 2002; Crowther et al. 2004). SP-A also down-regulates TLR2-mediated signaling and TNF-α secretion stimulated by zymosan. This supports an important role of SP-A in controlling pulmonary inflammation caused by microbial pathogens (Sato et al. 2003). NF-kB activation and TNF-α expression induced by PGN or zymosan were significantly inhibited in presence of SP-A. AMΦs are prototypical alternatively activated macrophages, with limited production of reactive oxygen intermediates (ROI) in response to stimuli (Weissbach et al. 1994). Crowther et al. (2004) support an anti-inflammatory role for SP-A in pulmonary homeostasis by inhibiting MΦ production of ROI through a reduction in NADPH oxidase activity. SP-A has been shown to stimulate the phagocytosis of apoptotic neutrophils (PMNs) and anti-inflammatory cytokine release by inflammatory AMΦs. Furthermore, SP-A enhances TGF-β 1 release from both AMΦ populations (Reidy and Wright 2003).

However, Alcorn and Wright (2004) suggested that SP-A inhibits inflammatory cytokine production in a CD14-independent manner and also by mechanisms independent of LPS signaling pathway (Alcorn and Wright 2004). SP-A inhibited LPS-induced mRNA levels for TNF-α, IL-1α, and IL-1β as well as NF-kB DNA binding activity. Significantly, SP-A also diminished ultra pure LPS-stimulated TNF-α produced by wild-type and CD14-null mouse alveolar macrophages. Additionally, SP-A inhibited TNF-α stimulated by PMA in both wild-type and TLR4-mutant

macrophages. Salez et al. (2001) highlighted the inhibitory role of SP-A in the anti-inflammatory activity of macrophages through inhibition of IL-10 production.

SP-A Regulates Surfactant Phospholipid Clearance After LPS-Induced Injury In Vivo: SP-A plays a role in surfactant homeostasis after acute lung injury. In bacterial LPS- induced injury into the lungs surfactant phospholipid levels were increased 1.6-fold in injured SP-$A^{-/-}$ animals, although injury did not alter ^{3}H-choline or ^{14}C-palmitate incorporation into dipalmitoylphosphatidylcholine (DPPC), suggesting no change in surfactant synthesis/secretion after injury. SP-A may play a role in regulating clearance of surfactant phospholipids after acute lung injury (Quintero et al. 2002). As SP-A inhibits LPS-induced in vitro IL-10 formation by bone marrow-derived macrophages, Chabot et al. (2003b) demonstrated an in vivo inhibitory role of SP-A on anti-inflammatory activity of mononuclear phagocytes, through inhibition of IL-10 production.

SP-A Regulates TNF-α Production: SP-A inhibited the LPS-induced TNF-α response of both interstitial (iMΦ) and alveolar human MΦ (AMΦ), as well as IL-1 response in iMΦ. Studies lend a credit to a physiological function of SP-A in regulating alveolar host defense and inflammation by suggesting a fundamental role of this protein in limiting excessive proinflammatory cytokine release in AMΦ during ARDS (Arias-Diaz et al. 2000; McIntosh et al. 1996). Surfactant lipids inhibit cytokine production by immune cells, and SP-A stimulates it. The increases in TNF-α mRNA and protein induced by SP-A were inhibited by surfactant lipids. SP-A exerts its action, at least in part, via activation of NF-kB. Moreover, the NF-kB inhibitors blocked SP-A-dependent increases in TNF-α mRNA levels. Observations suggest a mechanism by which SP-A plays a role in induced inflammation in the lung. The SP-A-induced increase in TNF-α levels differ among SP-A variants and appear to be affected by SP-A genotype and if SP-A is derived from one or both genes (Wang et al. 2000). Further more, different serotypes of LPS respond to SP-A differently on regulation of inflammatory cytokines in vitro (Song and Phelps 2000a, b).

SP-A Up-Regulates Activity of ManR and TLRs Expression by MΦs: SP-A selectively enhances ManR expression on human monocyte-derived macrophages. SP-A up-regulation of ManR activity provides a mechanism for enhanced phagocytosis of microbes by AMΦs, thereby enhancing lung host defense against extracellular pathogens (Beharka et al. 2002). Not only SP-A, but other lung collectins also enhance the uptake of *S. pneumoniae* or *M. avium* by AMΦs. The direct interaction of lung collectins with MΦs resulted in increased cell surface expression of scavenger receptor A or mannose receptor, which are responsible for phagocytosis. A more complete understanding of the molecular mechanism is required (Sano et al. 2006).

Henning et al. (2008) reported the SP-A-induced transcriptional and posttranslational regulation of TLR2 and TLR4 expression during the differentiation of primary human monocytes into MΦs. Despite SP-A's ability to up-regulate TLR2 expression on human MΦs, it dampens TLR2 and TLR4 signaling in these cells. SP-A decreases the phosphorylation of IkBα, a key regulator of NF-kB activity, and nuclear translocation of p65 which result in diminished TNF-α secretion in response to TLR ligands. SP-A also reduces the phosphorylation of TLR signaling proteins upstream of NF-kB, including members of the MAPK family. Finally, SP-A decreases the phosphorylation of Akt, a major cell regulator of NF-kB and potentially MAPKs. These data identify a critical role for SP-A in modulating the lung inflammatory response by regulating MΦ TLR activity (Henning et al. 2008). Molecular mechanisms related to the immunostimulatory activity of SP-A using MΦs from C3H/HeJ mice, which carry an inactivating mutation in the TLR-4 gene, and TLR-4-transfected CHO cells, suggest that SP-A-induced activation of NF-kB signaling pathway and up-regulation of cytokine synthesis such as TNF-α and IL-10 are critically dependent on TLR-4 functional complex. These findings support the concept that TLR-4 signals in response to both foreign pathogens and endogenous host mediators (Guillot et al. 2002).

SP-A Increases MMP-9 Production by THP-1 Cells: MMP-9 from alveolar MΦs is a major source of elastolytic activity in lung. SP-A may regulate MMP-9 expression. SP-A induced the expression of MMP-9 in THP-1 cells and peripheral blood mononuclear cells. It is believed that SP-A action is mediated through TLR-2. These observations suggest the presence of a locally controlled mechanism by which MMP-9 levels may be regulated in alveolar AΦs. Perhaps, SP-A influences the protease/antiprotease balance in lungs of patients with changes in surfactant constituents favoring an abnormal breakdown of extracellular matrix components (Vazquez et al. 2003). However, $Mmp9^{-/-}/Spd^{-/-}$ and $Mmp12^{-/-}/Spd^{-/-}$ mice developed air space enlargement similar to $Spd^{-/-}$ mice, supporting the concept that increased expression of each metalloproteinase seen in $Spd^{-/-}$ lungs is not major cause of emphysema (Zhang et al. 2006).

SP-A Provides Immunoprotection in Neonatal Mice: SP-A acts as an autocrine cytokine: it binds its receptor and specifically regulates transcription of surfactant proteins and other genes. SP-A null pups, reared on corn dust bedding had significant mortality The exogenous SP-A delivered by mouth to newborn SP-A null pups with SP-A

null mothers improved newborn survival in the corn dust environment. The lack of SP-D did not affect newborn survival, while SP-A produced by either the mother or the pup or oral exogenous SP-A significantly reduced newborn mortality associated with environmentally induced infection in newborns (George et al. 2008). The beneficial role of surfactant in improving oxygenation has already been established in clinical trials, whereas the immunomodulating effects are promising but remain to be elucidated (Kneyber et al. 2005).

24.6 Reactive Oxygen and Nitrogen-Induced Lung Injury

A pathway for the generation of potential oxidants with the reactivity of hydroxyl radical without the need for metal catalysis has been described. In response to various inflammatory stimuli, lung endothelial, alveolar, and airway epithelial cells, as well as activated AMΦ, produce both .NO and superoxide anion radicals (O_2^-). .NO regulates pulmonary vascular and airway tone and plays an important role in lung host defense against various bacteria. However, .NO may be cytotoxic by inhibiting critical enzymes such as mitochondrial aconitase and ribonucleotide reductase, by S-nitrosolation of thiol groups, or by binding to their iron-sulfur centers. In addition, .NO reacts with O_2^- at a near diffusion-limited rate to form the strong oxidant peroxynitrite ($ONOO^-$), which can nitrate and oxidize key amino acids in various lung proteins such as SP-A, and inhibit their functions. The presence of $ONOO^-$ in the lungs of patients with ARDS has been demonstrated. Various studies have shown that inhalation or intratracheal instillation of various respirable mineral dusts or asbestos fibers increased levels of inducible NOS mRNA. Zhu et al. (1998) reviewed the evidence for the upregulation of .NO in the lungs of animals exposed to mineral particulates and assess the contribution of reactive nitrogen species in the pathogenesis of the resultant lung injury (Zhu et al. 1998).

24.6.1 Decreased Ability of Nitrated SP-A to Aggregate Surfactant Lipids

The .NO can modify oxidant stress by limiting superoxide (O_2^-)-mediated injury. However, the product of .NO reaction with O_2^-, peroxynitrite ($ONOO^-$), is a potent oxidizing and nitrating agent. At high concentrations, .NO inhibit O_2-induced lipid peroxidation. However, ONOO., formed by reaction of .NO and O_2^-, nitrates SP-A leading to decreased ability to aggregate lipids and bind mannose (Zhu et al. 1998). Depending on the pH, tetranitromethane (TNM) acts either as a nitrating (pH $>$ or $=$ 24.4) or an oxidizing agent (pH $<$ or $=$ 6). SP-A, treated with TNM at pH 6, 24.4, 8, or 10, was tested for its ability to aggregate lipids. Treatment of SP-A with 0.5 mM TNM decreased its ability to aggregate lipids by 30% at pH 24.4, and 90% at pH 8, but had no effect on disulfide-dependent oligomeric state of SP-A. In contrast, SP-A exposed to 1 mM TNM at pH 6 had background levels of nitrotyrosine and exhibited normal lipid aggregation properties. It appeared that tyrosine nitration selectively inhibits the SP-A-mediated lipid aggregation without affecting its ability to bind lipids (Haddad et al. 1996). Sequencing of nitrated peptides demonstrated that the nitration was equally distributed on Tyr164 and Tyr1624. Nitrated SP-A exhibited decreased ability to aggregate surfactant lipids in the presence of Ca^{2+} (Greis et al. 1996). Peroxynitrite, produced by activated AMΦs, can nitrate SP-A and that CO_2 increased nitration by enhancing enzymatic nitric oxide production (Zhu et al. 2000).

Nitrated SP-A Does Not Enhance Adherence of *P. carinii* to Alveolar MΦs: Nitration of SP-A alters its ability to bind to mannose-containing saccharides on *P. carinii*. Human SP-A nitrated by ONOO– or tetranitromethane decreases its binding to *P.* carinii by increasing its dissociation constant from 24.8×10^{-9} to 1.6×10^{-8} or 2.4×10^{-8} M, respectively, without significantly affecting the number of binding sites. Furthermore, ONOO – nitrated SP-A failed to mediate the adherence and phagocytosis of *P. carinii* to rat AM as compared with normal SP-A. Binding of SP-A to rat AMΦs was not altered by nitration. These results indicate that nitration of SP-A interferes with its ability to serve as a ligand for *P. carinii* adherence to AMΦs at the site of the SP-A molecule (Zhu et al. 1998). Nitration of SP-A impairs its host- defense properties. Pulmonary edema fluid from patients with ALI has significantly higher levels of nitrite (NO_2^-) + nitrate (NO_3^-) compared with pulmonary edema fluid from patients with hydrostatic pulmonary edema. Nitrated pulmonary SP-A was also detected in the edema fluid of patients with ALI. This study indicated that reactive oxygen-nitrogen species may play a role in the pathogenesis of human ALI (Zhu et al. 2001).

24.7 Non-Pulmonary SP-A

24.7.1 SP-A in Epithelial Cells of Small and Large Intestine

Although, lung is the major source of surfactant proteins, SP-A expression has been reported in extra-pulmonary tissues. Several lines of evidence indicate that pulmonary and gastrointestinal epithelium produce closely related surface-active materials. Small intestine and colon express SP-A

constitutively (Rubio et al. 1995). Both SP-A genes, SP-A1 and SP-A2 genes, are expressed in human small and large intestine. The size of intestinal SP-A mRNA is the same as that in human lung (Lin et al. 2001). SP-A mRNA transcripts are readily amplified from the trachea, prostate, pancreas, intestine and thymus. SP-A sequences derived from lung and thymus mRNA revealed the presence of both SP-A1 and SP-A2, whereas only SP-A2 expression was found in the trachea and prostate (Madsen et al. 2003a). The middle ear protein has the same epitope as human lung SP-A. SP-A is also expressed in pig Eustachian tube. The secreted antimicrobial molecules of the tubotympanum include lysozyme, lactoferrin, beta defensins, and the SP-A, SP-D. Defects in the expression or regulation of these molecules may also be the major risk factor for otitis media (Lim et al. 2000). Human vaginal mucosa and vaginal lavage fluid show presence of SP-A protein and its transcripts. Transcripts of SP-A were identified in vaginal wall, derived from SP-A genes, SP-A1 and SP-A2.

24.7.2 SP-A in Female Genital Tract and During Pregnancy

SP-A1 is found in female genital tract. Evidence suggests that SP-A is produced in a squamous epithelium, namely the vaginal mucosa, and has a localization that would allow it to contribute to both the innate and adaptive immune response. In vagina, as in lung, SP-A is an essential component of the host-defence system (MacNeill et al. 2004). The bronchiolar 16 kD Clara cell secretory protein (CC16) and the alveolar SP-A are secreted in the amniotic fluid, where they reflect the growth and the maturity of the fetal lung (Cho et al. 1999). There is compelling evidence to suggest that the fetus signals the initiation of labor by secretion into amniotic fluid of major lung SP-A. SP-A protein has been demonstrated in human chorioamniotic membranes. Parturition at term, gestational age and chorioamnionitis in preterm delivery are associated with changes in the expression of SP-A in the chorioamniotic membranes (Han et al. 2007). The maternal smoking during pregnancy does not alter secretory functions of the epithelium of the distal airways and the alveoli at term (Hermans et al. 2001, 2003).

Exogenous administration of SP-A into mouse amniotic fluid at 15 dpc caused preterm labor. SP-A activated amniotic fluid macrophages in vitro to produce NF-kB and IL-1beta. These macrophages, which are of fetal origin, migrate to the pregnant uterus causing an inflammatory response and increase uterine NF-kB activity. It is suggested that the increase in NF-kB within the maternal uterus both directly increases expression of genes that promote uterine contractility and negatively impacts the capacity of the PR to maintain uterine quiescence, contributing to the onset of labor. Findings, therefore, indicate that SP-A secreted into amniotic fluid/the maturing fetal lung serves as a hormone of parturition (Condon et al. 2004; Mendelson and Condon 2005). It was proposed that IL-1 from extrapulmonary sources induces the SPs in premature lung and is responsible for decreased risk of RDS in intra-amniotic infection (Väyrynen et al. 2002). However, Sun et al. (2006) suggested that SP-A can be synthesized locally in human fetal membranes, which can be induced by glucocorticoids. SP-A appeared to induce PGE2 synthesis in chorionic trophoblasts via induced expression of cyclooxygenase type 2. Levels of SP-A and SP-B, in Amniotic fluid, change during human parturition. Whereas SP-A was detected in all amniotic fluid samples SP-B was detected in 24.1% of mid-trimester samples and in samples at term. The median amniotic fluid concentrations of SP-A and SP-B were significantly higher in women at term than in women in the mid-trimester, and decreases during spontaneous human parturition at term (Garcia-Verdugo et al. 2008a).

Human myometrial cells express functional SP-A1 binding sites and respond to SP-A1 to initiate activation of signaling related to human parturition. SP-A1 is not produced in rat uterus, but detected transiently in rat myometrium at the end (Days 19 and 21) of gestation, but not postpartum. SP-A1 binds myometrium through its collagenlike domain and rapidly activated MAPK1/3 in myometrial cells. Bacterial LPS, known to trigger uterine contractions and preterm birth, also activated MAPK1/3. Results provide the evidence for inhibitory cross talk between SP-A1 and LPS signals, and new insight into the mechanisms of normal and preterm parturition (Garcia-Verdugo et al. 2007, 2008b). Various microorganisms colonize this area and may cause intrauterine infection or trigger preterm labor.

Surfactant Protein-D

25

Rajesh K. Gupta and Anita Gupta

The collectins can be classed into two distinct group, with MBP and SP-A being hexamers and SP-D, conglutinin and collectin-43 (CL-43) being tetramers, with proteins in the latter group also having significantly larger dimensions with respect to the length of their collagen-like 'stalks' (Lu et al. 1993). MBP, lung SP-D, conglutinin, CL-43 and CL-46 are important components of innate immune defence system. They all bind complex glycoconjugates on microorganisms thereby inhibiting infection, enhancing the clearance by phagocytes and modulating the immune response. In addition, SP-D inhibits the generation of radical oxygen species or the propagation of lipid peroxidation. Knock-out mice deficient in SP-D have a disturbed homeostasis of pulmonary surfactant and suffer from oxidative stress leading to pulmonary inflammation upon microbial challenge. Moreover, both SP-D and SP-A (Chap. 24) have been shown to enhance oxygen radical production by alveolar macrophages. The structural and functional relationships of this group of collectins have been reviewd (Hansen and Holmskov 2002; Jinhua et al. 2003).

25.1 Pulmonary Surfactant Protein-D (SP-D)

Surfactant proteins, SP-A and SP-D contribute significantly to surfactant homeostasis and pulmonary immunity. Their basic structures include a triple-helical collagen region and a C-terminal homotrimeric lectin or CRD. The trimeric CRDs can recognize carbohydrate or charge patterns on microbes, allergens and dying cells, while the collagen region can interact with receptor molecules present on a variety of immune cells in order to initiate clearance mechanisms. Gene knock-out mice models of lung hypersensitivity and infection, and functional characterization of cell surface receptors have revealed the diverse roles of SP-A and SP-D in control of lung inflammation. A model based on studies with the calreticulin-CD91 complex as a receptor for SP-A and SP-D has suggested an anti-inflammatory role for SP-A and SP-D in naïve lungs which would help minimise the potential damage that continual low level exposure to pathogens, allergens and apoptosis can cause. However, when lungs are overwhelmed with exogenous insults, SP-A and SP-D can assume pro-inflammatory roles in order to complement pulmonary innate and adaptive immunity. The structural and functional aspects of SP-A and SP-D emphasize on their roles in controlling pulmonary infection, allergy and inflammation (Kishore et al. 2006)

Lung SP-D can directly interact with carbohydrate residues on pulmonary pathogens and allergens, stimulate immune cells, and manipulate cytokine and chemokine profiles during the immune response in lungs. Therapeutic administration of rfhSP-D, a recombinant homotrimeric fragment of human SP-D comprising the alpha-helical coiled-coil neck plus three CRDs, protects mice against lung allergy and infection caused by the fungal pathogen *Aspergillus fumigatus*. Curcumin inhibits inflammatory response reducing significantly all histopathological parameters in different pulmonary aspiration models. Curcumin is a potential therapeutic agent in acute lung injury (Guzel et al. 2009).

The lung is the main site of synthesis for SP-D, but transcripts were readily amplified from trachea, brain, testis, salivary gland, heart, prostate gland, kidney, and pancreas. Minor sites of synthesis were uterus, small intestine, placenta, mammary gland, and stomach. The sequence of SP-D derived from parotid gland mRNA was identical with that of pulmonary SP-D. SP-D immunoreactivity was found in alveolar type II cells, Clara cells, on and within alveolar macrophages, in epithelial cells of large and small ducts of the parotid gland, sweat glands, and lachrymal glands, in epithelial cells of the gall bladder and intrahepatic bile ducts, and in exocrine pancreatic ducts. SP-D was also present in epithelial cells of the skin, esophagus, small intestine, and urinary tract, as well as in the collecting ducts of the kidney. SP-D is present in mucosal lined surfaces throughout the human body, including the male reproductive tract and not

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_25,

restricted to a subset of cells in the lung. The localization and functions of SP-D indicated that this collectin is the counterpart in the innate immune system of IgA in the adaptive immune system (Madsen et al. 2000). The extra-pulmonary expression of SP-A and SP-D indicates the systemic roles of these proteins. SP-D is localized in the cytoplasm of a subpopulation of bronchiolar epithelial cells as well as type II cells. Anti-SP-D selectively decorated secretory compartments of nonciliated bronchiolar cells (Clara cells) with strong and specific labeling of apical electron-dense secretory granules. Studies provide evidence that SP-D is a secretory product of nonciliated bronchiolar cells. It was suggested that Clara cell-derived SP-D is a component of bronchiolar lining material, consistent with the hypothesis that SP-D contributes to surfactant metabolism and/or host defense within small airways (Crouch et al. 1992).

Alveolar Type II cells bind and recycle SP-D in vitro to lamellar bodies: Alveolar type II cells secrete, internalize, and recycle pulmonary surfactant complex that increases alveolar compliance and participates in pulmonary host defense. SP-D has been described as a modulator of surfactant homeostasis. Mice lacking SP-D accumulate surfactant in their alveoli and type II cell lamellar bodies, organelles adapted for recycling and secretion of surfactant. However, SP-D binding did not alter type II cell surfactant lipid uptake. Thus, type II cells bind and recycle SP-D in vitro to lamellar bodies, but SP-D may not directly modulate surfactant uptake by type II cells (Herbein and Wright 2001).

25.1.1 Human Pulmonary SP-D

25.1.1.1 Human Pulmonary SP-D Protein

Human pulmonary SP-D was identified in lung lavage by its similarity to rat SP-D in both its molecular mass and its Ca^{2+}-dependent-binding affinity for maltose. On SDS/PAGE human SP-D behaved as a single band of 150 kDa in non-reducing and 43 kDa band in reducing conditions. The presence of a high concentration of glycine (22%), hydroxyproline and hydroxylysine in the amino acid composition of human SP-D pointed towards its collagen-like structure. Human SP-D has a similar carbohydrate-binding specificity to rat SP-D, but differed from that of other lectins, such as conglutinin. Amino acid sequence analysis showed the presence of collagen-like Gly-Xaa-Yaa triplets in human SP-D. The derived amino acid sequence indicated that mature SP-D polypeptide chain is 355 residues long, having a short non-collagen-like N-terminal section of 25 residues, followed by a collagen-like region of 177 residues and a C-terminal C-type lectin domain of 153 residues. The human SP-D and bovine serum conglutinin showed 66% identity despite their marked differences in carbohydrate specificity (Lu et al. 1993). SP-D differs in its quaternary structure from SP-A and other members of the family, such as C1q, in that it forms large multimers held together by N-terminal domain, rather than aligning the triple helix domains in traditional "bunch of flowers" arrangement. SP-D is an oligomeric complex of four set of homotrimers. Purified trimeric and multimeric SP-D represent separate and only partly interconvertible molecular populations with distinct biochemical properties (Soerense et al. 2009).

25.1.1.2 Genomic Organization of Human SP-D

SP-D gene sequences spann > 11 kb on long arm of chromosome 25. Genomic sequencing revealed that signal peptide/amino-terminal domain, the CRD, and the linking sequence between the collagen domain, and CRD are each encoded by a single exon, as seen for SP-A and MBP-C. However, sequencing also demonstrated a unique intron-exon structure for collagen domain which is encoded on five exons, including four tandem exons of 117 bp. The latter exons show marked conservation in the predicted distribution of hydrophilic amino acids, consistent with tandem replication of this collagen gene sequence during evolution (Crouch et al. 1993). Human SP-D gene (*Sftp4 or Sftpd*) was assigned to chromosome 25. A regional mapping panel for five loci was mapped to 10q. S*ftp4*, the SP-A gene (*Sftp1*/*Sftpa*), and the microsatellite D10S109 were placed in the interval 10q22–q23. In situ hybridization of metaphase chromosomes using genomic probes gave selective labeling of 10q22.2–23.1 (Crouch et al. 1993; Kölble et al. 1993).

Rust et al. (1996) described the characterization of a human genomic fragment (H5E7) that encodes entirety of first translated exon (Exon 2), Intron 1, a short transcribed untranslated sequence (Exon 1; 39 bp), and approximately 4 kb of sequence upstream from transcription initiation site. The start site comprises of a putative TATA box (CATAAATA) of ~30 bp upstream of the start site. Complete sequencing of a HS-1674 fragment encoding approximately 1.7 kb of sequence 5′ to TATA demonstrated multiple potential cis-regulatory elements including half-site glucocorticoid response elements (GRE), a canonical AP-1 consensus, several AP-1 like sequences, E-box sequences, NF-IL-6 and PEA3 motifs, and putative interferon response elements. Studies support the hypothesis that the effects of glucocorticoids on SP-D production in vivo are regulated at level of transcription.

While SP-D is the product of a single gene whereas SP-A is the product of two highly homologous genes SP-A1 and SP-A2. The relative location and orientation of each of the SP-A and SP-D genomic sequences have been characterized. Characterization of two overlapping genomic clones revealed that SP-A pseudogene lies in a reverse orientation

15 kb away from the 5′ side of SP-A1. Both SP-A2 and SP-D are on the 5′ side of SP-A1 at approximate distances of 40 and 120 kb, respectively. The SP-A and SP-D loci were also oriented relative to centromere, with overall order being: centromere-SP-D-SP-A2-pseudogene-SP-A1- telomere (Hoover and Floros 1998). Several single nucleotide polymorphisms (SNP) have been identified in the SP-A1, SP-A2 and SP-D genes (Pantelidis et al. 2003).

25.1.1.3 Transcriptional Regulation of SP-D Promotor

Proximal Promoter of SP-D Gene: Because AP-1 proteins regulate cellular responses to diverse environmental stimuli, He et al. (2000) hypothesized that conserved AP-1 motif (at -109) and flanking sequences in human SP-D promoter contribute to the regulation of SP-D expression. Davé et al. (2004) identified the role of nuclear factor of activated T cells (NFATs) in regulation of murine SP-D gene (*Sftpd*) transcription. Components of calcineurin/NFAT pathway were identified in respiratory epithelial cells of the lung that potentially augment rapid assembly of a multiprotein transcription complex on *Sftpd* promoter inducing SP-D expression via direct interaction with TTF-1 in lung epithelial cells

CCAAT/Enhancer-Binding Proteins (C/EBP): CCAAT/enhancer-binding proteins (C/EBP) constitute a family of transcription factors that are involved in regulation of proliferation and differentiation in several cell types. In epithelial lung cells the C/EBPα isoform seems to play a role in the regulation of SPs and Clara cell specific protein (CCSP). In vitro results suggest that C/EBPδ alone is not related to the maintenance of proteins involved in differentiation (Låg et al. 2000). It was hypothesized that conserved C/EBP motifs in the near-distal and proximal promoters contribute to the regulation of SP-D expression by C/EBPs. Five SP-D motifs (-432, -340, -319, -140, and -90) homologous to C/EBP consensus sequence specifically bound to C/EBPs in gel shift assays, and four of the five sites (-432, -340, -319, and -90) efficiently competed for binding of C/EBPα, C/EBPβ, or C/EBPδ to consensus oligomers. The conserved AP-1 element at -109 was required for maximal promoter activity, but not for transactivation of SS698 by C/EBPs. Thus, interactions among C/EBP elements in near-distal promoter can modulate promoter activity of SP-D (He and Crouch 2002).

Retinoblastoma Protein Activates C/EBP-Mediated Transcription of SP-D: The retinoblastoma protein (RB) through histone deacetylase (HDAC) plays a critical role in cell cycle regulation. RB is also involved in activation of expression of a number of tissue specific- and differentiation-related genes and stimulates the expression of a differentiation-related gene, SP-D in lungs. RB specifically stimulated the activity of human SP-D gene promoter. Activation by RB was mediated through a NF-IL6 (C/EBPβ) binding motif in the human SP-D promoter, and this sequence specifically bound to C/EBPα, C/EBPβ, and C/EBPδ. Furthermore, the complexes containing RB and C/EBP proteins directly interacted with C-EBP binding site on DNA. Thus, RB plays a direct role in C/EBP-dependent transcriptional regulation of human SP-D expression (Charles et al. 2001).

25.1.2 Rat Lung SP-D

Ontogeny of Surfactant Apoprotein D, SP-D in Rat Lung: In rat lungs SP-A increased during late gestation and reached its maximum on day 1 of neonate, and then gradually declined until at least day 5. SP-D content during early gestation was less than 10 ng/mg protein until day 18, but on day 19 there was a fourfold increase in SP-D (compared to that on day 18). It increased twice between day 21 and the day of birth, when it reached the adult level of 250 ng/mg protein, which is about one fourth that of the adult level of SP-A. Unlike SP-A there seemed to be no decrease in SP-D content after birth. SP-D is regulated developmentally as with other components of surfactant. In contrast to humans, rat lungs are immature at birth. Alveolarization starts on postnatal day 4. Studies support the concept that postnatal alveolarization in rat lungs is associated with significant increases in the SP-B content in lb and volume fraction of lb in type II pneumocytes. The postnatal compartment-specific distribution of SP-A, precursors of SP-C and SP-D does not change (Schmiedl et al. 2005).

Rat SP-D Protein: Rat SP-D was SP-D, purified from the supernatant of rat bronchoalveolar lavage fluids, and delipidated form does not exhibit interaction with lipids in the same fashion as SP-A. SP-D consists of three regions: an NH2-terminal segment of 25 amino acids, a collagen-like domain consisting of 59 Gly-X-Y repeats, and a COOH-terminal carbohydrate recognition domain of 153 amino acids. There are six cysteine residues present in rat SP-D: two in NH2-terminal noncollagenous segment and four in COOH-terminal carbohydrate-binding domain. The collagenous domain contains one possible N-glycosylation site. The protein is preceded by a cleaved, NH2-terminal signal peptide. Rat SP-D is encoded by a 1.3-kb mRNA which is abundant in lung and highly enriched in alveolar type II cells. Extensive homology exists between rat SP-D and bovine conglutinin (Shimizu et al. 1992; Lim et al. 1993; Ogasawara et al. 1991).

In electron microscopy, rat SP-D is made of four identical rod-like arms (46 nm in length), each with an 8–9-nm

diameter globular terminal expansion. The arms, which are similar in diameter to the type I collagen helix (~4 nm), emanate from central "hub" in two pairs that closely parallel each other for their first 10 nm. This structure is consistent with hydrodynamic studies that predict a highly asymmetric and extended molecule (f/f0 = 3.26) with a large Stokes radius of 18 nm. Pepsin digestion gave glycosylated, trimeric collagenous fragments. Trimeric subunits containing intact triple helical domains were also liberated from SP-D dodecamers by sulfhydryl reduction under non-denaturing conditions. Digestion of rSP-D with bacterial collagenase generated a COOH-terminal carbohydrate binding fragment and a smaller peptide (~12 kDa, unreduced) that contains interchain disulfide bonds. Higher orders of multimerization with as many as eight molecules associated at the hub were also identified. Rat SP-D molecules are assembled as tetramers of trimeric subunits (12 mers). Dodecamers can participate in higher orders of molecular assembly involving interactions of NH_2-terminal peptide domains. Interactions between amino-terminal domains of trimers are stabilized by interchain disulfide bonds. SP-D molecules can associate to form complex multimolecular assemblies (Crouch et al. 1994b).

Studies demonstrated that a single genetically distinct chain type can account for various and complex molecular assemblies of SP-D (Crouch et al. 1994a). The SP-D forms large multimers held together by N-terminal domain, rather than aligning the triple helix domains in traditional "bunch of flowers" arrangement. The two cysteine residues within hydrophobic NH_2-terminus are critical for multimer assembly and have been proposed to be involved in stabilizing disulfide bonds. These cysteins exist within reduced state in dodecameric SP-D and form a specific target for S-nitrosylation both in vitro and by endogenous, pulmonary derived NO within a rodent acute lung injury model (Crouch et al. 1994a; Guo et al. 2008).

25.1.3 Mouse SP-D

The Protein: A cDNA deduced sequence predicts a 19-amino acid signal sequence, a 25-amino acid long NH_2-terminus with two cysteines, followed by an uninterrupted collagen domain with 59 Gly-X-Y repeats. Next, a short "neck" domain of 28 amino acids, with a potential to form trimeric alpha-helical coiled coil is found ending in a COOH-terminal 125-amino acid CRD. The mature mouse SP-D protein of 355 amino acids shows strong homology to rat (92% identity), human (76%), and bovine (72%) SP-D amino acid sequences. The mouse SP-D gene is expressed predominantly in lung and also in heart, stomach, and kidney but not in brain. In contrast, mouse SP-A mRNA expression was found to be restricted to lung. Histochemically, SP-A and SP-D mRNA were detected in a significant number of non-pulmonary tissues but proteins have a more limited distribution. SP-D protein was detected in lung, uterus, ovary, and lacrimal gland, whereas SP-A protein was detected only in lung (Akiyama et al. 2002). Mouse SP-D gene (*Sftp4*) has been localized to chromosome 14 (to a region syntenic to human chromosome 10), closely linked to genes for *Mbl1*, and SP-A (*Sftp1*) (Motwani et al. 1995).

Genomic Organization of Mouse Lung SP-D Gene: The mouse SP-D gene (*Sftpd*), which spans eight exons over 14 kb of sequence and shows an overall organization similar to other collectin genes. The complete 5′ untranslated region of mRNA is encoded by a single exon. Analysis of 3.5 kb of 5′ flanking nucleotide sequence for *Sftpd* reveals positional conservation of a number of transcription factor binding sites when compared with human SP-D gene and bovine conglutinin gene (Lim et al. 2003). The single copy SP-D-like gene is present in mammals, birds, and amphibians but is absent in fish. An atypical, rodent-specific, long terminal repeat of retroviral origin containing a minisatellite that has become inserted in *Sftpd* is described. Three new polymorphic microsatellites are also described, one of which is just 160 bp upstream of *Sftpd*. This microsatellite was used to map the gene to central region of chromosome 14. Fine-scale mapping indicates that it lies in a 5.64-centimorgan area between D14Mit45 and D14Mit60 (Lawson et al. 1999).

The Collectin Gene Locus: Three of four known mouse collectin genes have been mapped to chromosome 14. To characterize spatial relationship of these genes, one large clone hybridized to both SP-A and SP-D cDNAs was found to contain sequences from one of the mouse *Mbl1*. The SP-A, *Mbl1*, and SP-D genes reside contiguously within a 55-kb region. The SP-A and *Mbl1* genes are in same 5′–3′ orientation and 16 kb apart. The SP-D gene is in opposite orientation to two other collectin genes, 13 kb away from 3′ end of the *Mbl1* gene. The size (13 kb) and organization of mouse gene was similar to that of human SP-D. Exon I is untranslated. The second exon is a hybrid exon that contains signal for initiation of translation, signal peptide, N-terminal domain, and first seven collagen triplets of collagen-like domain of the protein. Four short exons (III to VI) encode collagen-like domain of protein, and exons VII and VIII, the linking and the CRDs, respectively (Akiyama et al. 1999).

Developmental Expression: SP-D mRNA and protein were readily detected in alveolar type II and nonciliated bronchiolar epithelial cells of lung, as well as in cells of the tracheal epithelium and tracheal submucosal glands of the adult mouse. However, SP-A mRNA or protein was not detected in murine trachea. Expression of murine SP-D mRNA was first detected on Ed 16 of gestation in pregnant mice, and this

increased dramatically before birth and during the immediate postnatal period. The developmental expression of murine SP-A mRNA paralleled that of SP-D except that there was a small decrease in mRNA on postnatal Ed 5. Thus, SP-D is synthesized not only in the lung but also in submucosal glands of trachea (Wong et al. 1996).

25.1.4 Bovine SP-D

Gjerstorff et al. (2004) characterized the gene encoding bovine SP-D and its proximal promoter. Cloning and sequencing of the bSP-D gene, including the complete 5′-untranslated sequence, reveal that the gene comprises nine exons spanning ~ 25.5 kb and resembling bovine conglutinin gene. The gene localizes to the same locus as conglutinin gene on Bos taurus chromosome 28 at position q1.8, which also includes the genes for CL-43 and CL-46. Several potential cis-regulatory elements, similar to elements known to regulate transcription of human SP-D, were identified in the 5′-upstream sequence. Bovine SP-D is heavily expressed in lung and the trachea, but also in segments of gastrointestinal tract, mammary glands and salivary glands. By genotyping two potential polymorphisms leading to variations in amino acid composition of CRD (242 Glu/Val and 268 Ala/Gly) have been assigned.

Human and bovine SP-D from late amniotic fluid and BAL gave a Mr of a trimeric subunit in the range 115–125 kDa for human SP-D and 110–123 kDa for bovine SP-D. A single polypeptide chain was determined at 37–41 and 36–40 kDa for human and bovine species respectively. Primary structures, determined by MS and Edman degradation, showed heterogeneity in SP-D, caused mainly by high number of post-translational modifications in the collagen-like region. Proline and lysine residues were partly hydroxylated and lysine residues were further O-glycosylated with disaccharide galactose-glucose. A partly occupied N-linked glycosylation site was characterized in human SP-D. The carbohydrate was determined as a complex type bi-antennary structure, with a small content of mono-antennary and tri-antennary structures. No sialic acid residues were present on the glycan, but some had an attached fucose and/or an N-acetylglucosamine residue linked to the core. Bovine SP-D was having a similar structure (Leth-Larsen et al. 1999).

25.1.5 Porcine Lung SP-D

The complete cDNA sequence of porcine SP-D, including the 5′ and 3′ untranslated regions, was determined from two overlapping clones. Three unique features were revealed from porcine sequence in comparison to SP-D from other species, making porcine SP-D an intriguing species addition to the collectin family. The collagen region contains an extra cysteine residue, which may have important structural consequences. The other two differences, a potential glycosylation site and an insertion of three amino acids lie in the loop regions of CRD, close to carbohydrate binding region and thus may have functional implications. The genes for SP-D (*Sftpd*) and SP-A (*Sftpa*) also co-localized to a region of porcine chromosome 14 band 14q25—>q26 that is syntenic with human and murine collectin loci (van Eijk et al. 2000, 2001).

The porcine SP-D appeared as a band of ~ 53 kDa in reduced state and ~138 kDa in unreduced state (Soerensen et al. 2005a). The monomeric porcine SP-D (50–53 kDa) is larger than that of SP-D from humans (43 kDa). Carbohydrate moiety is a highly heterogeneous, complex type oligosaccharide which is sialylated. The heterogeneity of oligosaccharide sialylation results in existence of many differently charged porcine SP-D isoforms. The removal of carbohydrate moiety reduces the inhibitory effect of porcine SP-D on IAV haemagglutination. Ultrastructural analysis showed the presence of both dodecameric and higher order oligomeric complexes of SP-D (van Eijk et al. 2000, 2002). Porcine tissues showed SP-D predominantly present in Clara cells and serous cells of bronchial submucosal glands, and to a lesser extent in alveolar type II cells, epithelial cells of intestinal glands (crypts of Lieberkuhn) in duodenum, jejunum and ileum and serous cells of dorsolateral lacrimal gland (Soerensen et al. 2005b). SP-A and D are expressed in the porcine Eustachian tube (ET) originating from upper airways and were present in epithelial cells of ET (Paananen et al. 2001). Porcine SP-D is an important reagent for use in existing porcine animal models for human lung infections.

25.2 Interactions of SP-D

The SP-A and SP-D bind carbohydrates, lipids, and nucleic acids with a broad-spectrum specificity and initiate phagocytosis of inhaled pathogens as well as apoptotic cells. Investigations on gene-deficient and conditional overexpressed mice indicated that lung SP-A and SP-D directly modulate innate immune cell function and T-cell-dependent inflammatory events and have a unique, dual-function capacity to induce pathogen elimination and control proinflammatory mechanisms (Botas et al. 1998; Haczku 2008).

25.2.1 Interactions with Carbohydrates

SP-D showed specific calcium-dependent binding to alpha-D-glucosidophenyl isothiocyanate-BSA and maltosyl-BSA, but negligible binding to beta-D-glucosidophenyl

isothiocyanate-BSA or unconjugated BSA. The most efficient inhibitors of SP-D binding were alpha-glucosyl-containing saccharides (e.g. isomaltose, maltose, malotriose). Studies demonstrate that SP-D is a calcium dependent lectin-like protein and that the association of SP-D with surfactant is mediated by carbohydrate-dependent interactions with specificity for alpha-glucosyl residues. Crystallographic studies of trimeric human SP-D neck + CRD domains have shown that maltose, a preferred saccharide ligand, binds to calcium via the vicinal 3- and 4-OH groups of the non-reducing glucose, previously designated calcium ion 1 and glucose 1 (Glc1), respectively (Shrive et al. 2003).

Oligo and Polysaccharide Recognition by SP-D: SP-D binding to *Aspergillus fumigatus* is strongly inhibited by a soluble β-(1—>6)-linked but not by a soluble β-(1—>3)-linked glucosyl homopolysaccharide (pustulan and laminarin, respectively), suggesting that SP-D recognizes only certain polysaccharide configurations. Docking studies predict that α/β-(1—>2)-, α-(1—>4)-, and α/β-(1—>6)-linked but not α/β-(1—>3)-linked glucosyl trisaccharides can be bound by their internal glucosyl residues and that binding also occurs through interactions of the protein with the 2- and 3-equatorial OH groups on the glucosyl ring. Given the sequence and structural similarity between SP-D and other C-type lectins, many of the predicted interactions should be applicable to this protein family (Allen et al. 2001).

SP-D binds to various synthetic fucosylated oligosaccharides. Fucα1-3GalNAc and Fuc α1-3GlcNAc elements show strong binding to SP-D. Fucosylated glycoconjugates are present at the surface of *Schistosoma mansoni*, a parasitic worm that transiently resides in lung during development. In line with this observation, SP-D was found to bind to larval stages of *S. manson* and may interact with multicellular lung pathogens (van de Wetering et al. 2004). The SP-A and SP-D bind gram-positive bacteria through lipoteichoic acid (LTA) and peptidoglycan, components of cell wall of gram-positive bacteria. The CRD is responsible for this binding (van de Wetering et al. 2001).

Interaction with LPS: Both SP-A and SP-D bind bacterial lipopolysaccharide (LPS). Wang et al. (2008a) demonstrated specific binding between CRD and heptoses in the core region of LPS. The geometry suggested that all three CRDs are simultaneously bound to LPS under conditions that support Ca^{2+}-mediated interaction. Mutant trimeric recombinant neck + CRDs (NCRDs) of SP-D is known to bind with rough LPS (R-LPS). Crystallographic analysis of hNCRD demonstrated a novel binding orientation for LD-heptose, involving hydroxyl groups of side chain. Similar binding was observed for a synthetic α1—>3-linked heptose disaccharide corresponding to heptoses I and II of inner core region in many LPS. 7-O-Carbamoyl-l,D-heptose and D-glycero-α-D-manno-heptose were bound via ring hydroxyl groups. Interactions with side chain of inner core heptoses provide a potential mechanism for recognition of diverse types of LPS by SP-D (Wang et al. 2008b). SPD binds to human α2-macroglobulin, that protects the collectin from proteolytic degradation by elastase (Craig-Barnes et al. 2010).

SP-D Binds MD-2 (lymphocyte antigen 96) and TLRs Through CRD: SP-A interacts with MD-2 and alters LPS signaling. SP-D modulates LPS-elicited inflammatory cell responses. Ligand blot analysis revealed that SP-D bound to N-glycopeptidase F-treated sMD-2. In addition, the biotinylated SP-D pulled down the mutant sMD-2 with Asn (26) —>Ala and Asn (114) —>Ala substitutions, which lacks the consensus for N-glycosylation. Results demonstrated that SP-D directly interacts with MD-2 through CRD (Nie et al. 2008).

Human SP-D exhibits specific binding, through its CRD, to extracellular domains of rTLR-2 and TLR-4 by a mechanism different from its binding to PI and LPS (Ohya et al. 2006). SP-D bound to a complex of soluble forms of TLR4 and MD-2 with high affinity and down-regulates TNF-α secretion and NF-kB activation elicited by rough and smooth LPS, in alveolar macrophages and TLR4/MD-2-transfected HEK293 cells. Study demonstrates that SP-D down-regulates LPS-elicited inflammatory responses by altering LPS binding to its receptors and reveals the importance of correct oligomeric structure of the protein in this process (Yamazoe et al. 2008).

Binding with Glycoprotein-340: A glycoprotein (Mr 340 kDa, gp-340) from human bronchioalveolar lung washings from a patient with alveolar proteinosis was found to bind to lung SP-D. Like gp-340, CRP-ductin binds human SP-D in a calcium-dependent manner. CRP-ductin also showed calcium-dependent binding to both gram-positive and -negative bacteria (Holmskov et al. 1997).

Interactions with Decorin and Biglycan and Other Proteoglycans: Decorin and biglycan are closely related abundant extracellular matrix proteoglycans that bind to C1q and MBL. The human decorin, a SP-D-binding protein, from amniotic fluid co-purifies with SP-D. SP-D and decorin interact with each other (K_D = 4 nM) by two mechanisms: (1) the CRD of SP-D binds, in a calcium dependent-manner, to sulfated N-acetyl galactosamine moiety of the glycosaminoglycan chain and (2) C1q, a complement protein that is known to interact with decorin core protein via its collagen-like region, partially blocks the interaction between decorin and native SP-D. It is suggested that decorin core protein binds the collagen-like region of SP-D and CRDs of SP-D interact with dermatan sulfate moiety of decorin via lectin activity (Nadesalingam et al. 2003).

Other members of collectin family, including collectin-43 and conglutinin also bind to decorin and biglycan. Thus, decorin and biglycan act as inhibitors of activation of complement cascade and pro-inflammatory cytokine production mediated by C1q. These proteoglycans are likely to down-regulate proinflammatory effects mediated by C1q (Groeneveld et al. 2005).

25.2.2 Binding with Nucleic Acids

Collectins can bind nucleic acid, which is a pentameric sugar-based anionic polymer. SP-D and MBL bind to both DNA and RNA effectively. SP-D also enhances the uptake of DNA by human monocytic cells. Therefore, nucleic acids can act as ligands for collectins (Palaniyar et al. 2003b). Pentoses, such as arabinose, ribose, and deoxyribose, inhibit the interaction between SP-D and mannan, one of the well-studied hexose ligands for SP-D; biologically relevant D-forms of the pentoses are better competitors than the L-forms. SP-D binds apoptotic cells through DNA present on these cells. SP-D binds and aggregates mouse alveolar macrophage DNA effectively. Alveolar macrophages of SP-D$^{-/-}$ mice contained more nicked DNA than those of SP-A$^{-/-}$ and wild type mice. Results also suggested that CRDs of SP-D may recognize DNA present on apoptotic cells. Therefore, cell-surface DNA could be a ligand for recognition of apoptotic cells by collectins and may have important biological implications, such as the alleviation of DNA-mediated tissue inflammation (Palaniyar et al. 2003a)

SP-D enhances the uptake of Cy3-labeled fragments of DNA and DNA-coated beads by U937 human monocytic cells, in vitro. Analysis of DNA uptake by alveolar macrophages shows that SP-D, but not SP-A deficiency results in reduced clearance of DNA, ex vivo. Additionally, both SP-A- and SP-D-deficient mice accumulate anti-DNA Abs in sera in an age-dependent manner. Thus, SP-A and SP-D may reduce the generation of anti-DNA autoantibody, which may be explained in part by defective clearance of DNA from lungs in absence of these proteins. These findings establish two new roles for these innate immune proteins and that SP-D enhances efficient pinocytosis and phagocytosis of DNA by macrophages and minimizes anti-DNA Ab generation (Palaniyar et al. 2005).

25.2.3 Interactions with Lipids

Surfactant proteins interact with phospholipids and are believed to play important roles in alveolar spaces. Pulmonary SP-D binds glycosylated lipids such as phosphatidylinositol (PI) and glucosylceramide (GlcCer). The major known surfactant-associated ligand for lung SP-D is PI. SP-D binds to PI in various phospholipids or a fraction containing phospholipids. Interaction of SP-D with PI is dependent on calcium and inhibited by competing saccharides. SP-D binds with similar efficiency to liposomes (Ogasawara et al. 1992; Persson et al. 1992). On TLC plates, SP-D bound exclusively to GlcCer, whereas it failed to bind to GalCer, GM1, GM2, asialo-GM1, asialo-GM2, sulfatide, Forssman antigen, ceramide dihexoside, ceramide trihexoside, globoside, paragloboside or ceramide. SP-D bound to ceramide monohexoside in glycolipids isolated from rat lung and bronchoalveolar lavage fluids of rats (Kuroki et al. 1992). PI interaction, at least in part, involves the carbohydrate moiety. Results suggest that: (1) carbohydrate binding specificity of SP-D (Glu-321—>Gln and Asn-323—>Asp) was changed from a mannose-glucose type to a galactose type; (2) the GlcCer binding property of SP-D is closely related to its sugar binding activity; and (3) the PI binding activity is not completely dependent on its carbohydrate binding specificity (Ogasawara and Voelker 1995a). SP-D counteracts the inhibitory effect of SP-A on phospholipid secretion by alveolar type II cells. Native SP-D alters SP-A activity in type II cells through interaction with it via SP-D-associated lipids (Kuroki et al. 1991).

SP-D binds specifically to saturated, unsaturated, and hydroxylated fatty acids (FA). Maximal binding to FA was dependent on calcium, and was localized to neck and CRD region in recombinant trimeric neck + CRDs. Saccharide ligands showed complex, dose-dependent effects on FA binding, and FAs showed dose- and physical state-dependent effects on the binding of SP-D to mannan (DeSilva et al. 2003).

Trimeric neck-carbohydrate recognition domains (NCRDs) of rat and human SP-D exhibited dose-dependent, calcium-dependent, and inositol-sensitive binding to solid-phase PI and to multilamellar PI liposomes. Studies directly implicate the CRD in PI binding and reveal unexpected species differences in PI recognition that can be largely attributed to the side chain of residue 343. In addition, oligomerization of trimeric subunits is an important determinant of recognition of PI by human SP-D (Crouch et al. 2007, 2009).

25.3 Structure: Function Relations of Lung SP-D

25.3.1 Role of NH_2 Domain and Collagenous Region

SP-A and SP-D possess similar structures in mammalian C-type lectin superfamily. Both proteins are composed of four characteristic domains which are: (1) an NH_2-terminal domain involved in interchain disulfide formation (denoted

A1 domain for SP-A or D1 for SP-D); (2) a collagenous domain (denoted A2 or D2); (3) a neck domain (denoted A3 or D3); and (4) a CRD (denoted A4 or D4). A collagen domain deletion mutant (CDM) of SP-D and a second variant lacking both the amino-terminal region and collagen-like domain were generated and collagenase-resistant fragment (CRF) was purified. Studies on CDM and CRF demonstrated that collagen-like domain is required for dodecamer but not covalent trimer formation of SP-D and plays an important, but not essential, role in the interaction of SP-D with phosphatidylinositol (PI) and glucosylceramide (GlcCer). Removal of amino-terminal domain of SP-D along with collagen-like domain diminished PI binding and effectively eliminated GlcCer binding (Ogasawara and Voelker 1995b). Amino-terminal domains of SP-A and SP-D are critical for surfactant phospholipid interactions and surfactant homeostasis, respectively.

To further assess the importance of N-terminal domains of SP-D/SP-A in surfactant structure and function, a chimeric SP-D/SP-A gene was constructed by substituting nucleotides encoding amino acids Asn-1-Ala7 of rat SP-A with the corresponding N-terminal sequences from rat SP-D, Ala1-Asn25. Studies indicated that N terminus of SP-D: (1) can functionally replace the N terminus of SP-A for lipid aggregation and tubular myelin formation, but not for surface tension lowering properties of SP-A, and (2) is not sufficient to reverse the structural and metabolic pulmonary defects in SP-D$^{-/-}$ mouse (Palaniyar et al. 2002).

25.3.2 Role of NH2-Terminal Cysteines in Collagen Helix Formation

The NH2-terminal sequence of each monomer in SP-D contains two conserved cysteine residues. The SP-D is preferentially secreted as dodecamers consisting of four collagenous trimers cross-linked by disulfide bonds. Although mutants with serine substituted for Cys15 and Cys20 (RrSP-Dser15/20) are secreted as trimeric subunits, proteins with single cysteine substitutions were retained in the cell. Studies suggest that the most important and rate-limiting step for the secretion of SP-D involves the association of cross-linked trimeric subunits to form dodecamers stabilized by specific inter-subunit disulfide cross-links. Interference with collagen helix formation prevents secretion by interfering with efficient disulfide cross-linking of the NH2-terminal domain (Brown-Augsburger et al. 1996a). The two conserved cysteine residues participate in interchain disulfide bonds formation. Substitution of serine for Cys15 and Cys 20 in recombinant rat SP-D (RrSP-Dser15/20) bound to the hemagglutinin of influenza A virus. However, it failed to aggregate virus and did not enhance the binding of influenza A to neutrophils (PMN), augment PMN respiratory burst, or protect PMNs from deactivation. It indicates that amino-terminal disulfides are required to stabilize dodecamers, and support the hypothesis that the oligomerization of trimeric subunits contributes to the anti-microbial properties of SP-D (Brown-Augsburger et al. 1996b; Crouch et al. 2005).

25.3.3 D4 (CRD) Domain in Phospholipid Interaction

As discussed earlier that SP-A specifically binds to DPPC, the major lipid component of surfactant, and can regulate the secretion and recycling of this lipid by alveolar type II cells. SP-D binds to PI and glucosylceramide (GlcCer). The D3 (neck) plus D4 (CRD) domains of SP-D play a role in lipid binding and that CRD domain is essential for PI binding. Furthermore, the A3 domain of SP-A cannot account for all the lipid binding activity of this protein. The results implicate the A4 domain of SP-A as an important structural domain in lipid aggregation phenomena (Ogasawara et al. 1994). Saitoh et al. (2000) showed that (1) SP-A region Leu-219-Phe-228 is required for liposome aggregation and interaction with alveolar type II cells, (2) SP-A region Cys-204-Cys-218 is required for DPPC binding, (3) the SP-D region Cys-331-Phe-355 is essential for minimal PI binding, and (4) the epitope for mAb 1D6 is located at the region contiguous to SP-A region Leu-219-Phe-228. Analysis of chemotactic properties of trimeric CRD demonstrated that CRD was chemotactic for neutrophils (polymorphonuclear leukocytes). The chemotactic activity was abolished by maltose, which did not suppress the chemotactic response to fMLP (Cai et al. 1999).

The recombinant structure, containing three CRDs, was comparable to native SP-D in terms of carbohydrate binding specificity, binding to LPSs of Gram-negative bacteria, and interaction with phospholipids. The CRD of SP-D, without the neck region peptide that was also expressed, showed a very weak affinity for LPSs and phospholipids. The α-helical neck region on its own showed affinity for phospholipids and thus might contribute to the binding of SP-D to these structures. These results show the importance of the neck region as a trimerizing agent in bringing together three CRDs and suggest that multivalency is important in the strong binding of SP-D to carbohydrate targets (Kishore et al. 1996).

Zhang et al. (2001a) provided evidence that amino-terminal heptad repeats of the neck domain are necessary for intracellular, trimeric association of SP-D monomers and for the assembly and secretion of functional dodecamers (Zhang et al. 2001b). A recombinant homotrimer, composed of the α-helical neck region of human surfactant protein D and C1q B chain globular domain, was an inhibitor of classical complement pathway (Kishore et al. 2001).

25.3.4 A Three Stranded α-Helical Bundle at Nucleation Site of Collagen Triple-Helix Formation

A short stretch of 35 amino acids comprising a structural motif is responsible for tight parallel association and trimerization of three identical polypeptide chains of lung SP-D, which contains both collagen regions and C-type lectin domains. This 'neck-region' is located at nucleation site at which collagenous sequences fold into a staggered triple-helix to consist of a triple-stranded parallel α-helical bundle in a non-staggered, and extremely strong, non-covalent association. This type of association between three polypeptide chains may represent a common structural feature immediately following C-terminal end of triple-helical region of collagenous proteins (Hoppe et al. 1994).

The SP-D is assembled predominantly as dodecamers consisting of four homotrimeric subunits each. Trimerization of SP-D monomers is required for high affinity saccharide binding, and the oligomerization of trimers is required for many of its functions. A peptide containing α-helical neck region can spontaneously trimerize in vitro. Håkansson et al. (1999) determined the crystal structure of a trimeric fragment of hSP-D at 2.3 A resolution. The structure comprises an α-helical coiled-coil and three carbohydrate-recognition domains (CRDs). A deviation from symmetry was found in the projection of a single tyrosine side chain into the centre of coiled-coil; the asymmetry of this residue influences orientation of one of the adjacent CRDs. The cleft between the three CRDs presents a large positively charged surface. The fold of CRD of hSP-D is similar to that of MBP, but its orientation relative to α-helical coiled-coil region differs somewhat to that seen in MBP structure. The novel central packing of tyrosine side chain within the coiled-coil and the resulting asymmetric orientation of CRDs has unexpected functional implications. The positively charged surface might facilitate binding to negatively charged structures, such as LPS (Håkansson et al. 1999).

Association of trimeric subunits is stabilized by interchain disulfide bonds involving two conserved amino-terminal cysteine residues (Cys-15 and Cys-20). Mutant recombinant rat SP-D lacking these residues (RrSP-Dser15/20) is secreted in cell culture as trimeric subunits rather than as dodecamers. Activity of SP-D in lungs is dependent on oligomeric structure. In transgenic mice that express mutant RrSP-Dser15/20 showed that the activity of lung SP-D in vivo is dependent on oligomeric structure. Disulfide cross-linked SP-D oligomers are required for regulation of surfactant phospholipid homeostasis and prevention of emphysema and foamy macrophages in vivo (Zhang et al. 2001a; McAlinden et al. 2002).

The solution structure of a 64-residue peptide encompassing the coiled-coil domain of human SP-D confirmed that the domain forms a triple-helical parallel coiled coil. Symmetry-ADR (ambiguous distance restraint) structure calculations demonstrated that leucine zipper region of SP-D is an autonomously folded domain and agreed with X-ray crystal structure, differing mainly at a single residue, Tyr248. This residue is completely symmetric in solution structure, and markedly asymmetric in crystalline phase. This difference may be functionally important, as it affects orientation of antigenic surface presented by SP-D (Kovacs et al. 2002).

25.3.5 Ligand Binding Amino Acids

Arg343 in SP-D Discriminates Between Glucose and N-acetylglucosamine Ligands: SP-D binds glucose (Glc) stronger than N-acetylglucosamine (GlcNAc). Structural superimposition of hSP-D with MBP-C complexed with GlcNAc revealed steric clashes between the ligand and the side chain of Arg343 in hSP-D. Computational model of Arg343—>Val (R343V) mutant hSP-D demonstrated that Arg343 is critical for hSP-D recognition specificity and plays a key role in defining ligand specificity differences between MBP and SP-D. Additionally, the number of binding orientations contributes to monosaccharide binding affinity (Allen et al. 2004). Asp325, in addition to Arg343, is other important determinant of ligand selectivity, recognition, and binding; and that differences in crystal contact interfaces exert, through Asp325, significant influence on preferred binding modes (Shrive et al. 2009).

Contributions of Phenylalanine-335 to Ligand Recognition: A trimeric fusion protein encoding the human neck + CRD bound to aromatic glycoside p-nitrophenyl-α-D-maltoside with a higher affinity than maltose. Maltotriose, which has the same linkage pattern as the maltoside, bound with intermediate affinity. Substitution of leucine Phe-335 decreased affinities for maltoside and maltotriose without altering affinity for maltose or glucose, and substitution of tyrosine or tryptophan for leucine restored binding to maltotriose and maltoside. Crouch et al. (2006a) indicated that Phe-335, which is evolutionarily conserved in all known SP-Ds, plays important role in SP-D function. The ligand binding of homologous human, rat, and mouse trimeric neck + CRD fusion proteins, each with identical N-terminal tags remote from ligand-binding surface was compared. The ligand recognition by human SP-D involves a complex interplay between saccharide presentation, valency of trimeric subunits, and species-specific residues that flank primary carbohydrate binding site (Crouch et al. 2006b).

25.3.6 Ligand Binding and Immune Cell-Recognition

Crystallographic studies of trimeric human SP-D neck +CRD domains have shown that maltose, a preferred saccharide

ligand, binds to calcium via the vicinal 3- and 4-OH groups of the non-reducing glucose, previously designated calcium ion 1 and glucose 1 (Glc1), respectively (Shrive et al. 2003). These interactions are further stabilized by hydrogen bonding of Glc1 to amino acid side chains that also coordinate with calcium ion 1. The crystal structures of maltose-bound rfhSP-D (recombinant homotrimeric fragment of human SP-D comprising α-helical coiled-coil neck plus three CRDs) at 1.4A, and of rfhSP-D at 1.6A provided insights on the mode of carbohydrate recognition and fine details of SP-D binding to allergens/antigens or whole pathogens, and details on engagement of effector cells and molecules of humoral immunity. A calcium ion, located on trimeric axis in a pore at the bottom of funnel formed by the three CRDs and close to neck-CRD interface, is coordinated by a triad of glutamate residues which are, to some extent, neutralised by their interactions with a triad of exposed lysine residues in the funnel. The spatial relationship between neck and CRDs is maintained internally by these lysine residues, and externally by a glutamine, which forms a pair of hydrogen-bonds within an external cleft at each neck-CRD interface. Structural links between central pore and cleft suggested a possible effector mechanism for immune cell surface receptor binding in presence of bound, extended LPS and phospholipid ligands. The structural requirements for such an effector mechanism, involving both the trimeric framework for multivalent ligand binding and recognition sites formed from more than one subunit, are present in both native hSP-D and rfhSP-D, providing a possible explanation for significant biological activity of rfhSP-D (Shrive et al. 2003).

25.4 Regulation of Sp-D by Various Factors

25.4.1 Glucocorticoids

Surfactant proteins are known to be regulated by glucocorticoids. Lung explants from fetuses depend on hydrocortisone for their growth. The addition of hydrocortisone resulted in increase in SP-D mRNA expression (Gonzales et al. 2001; Shannon et al. 2001). The accelerated lung maturation accompanying glucocorticoid exposure in utero is associated with a precocious increase in SP-D gene transcription and protein production by pulmonary epithelial cells (Mariencheck and Crouch 1994). Glucocorticoid treatment in vivo of fetal, neonatal and adult rats for short durations exhibits stimulatory effect on contents of lung SP-D. Human lung is under developmental and glucocorticoid regulation occurring at a pre-translational level. SP-D is not influenced by inflammatory mediators that regulate SP-A, suggesting that these two proteins are not coordinately regulated in response to lung infection (Dulkerian et al. 1996). Early postnatal use of Dex in infants with respiratory distress syndrome (RDS) was shown to improve pulmonary status and to allow early weaning off mechanical ventilation. Early use of Dex can improve pulmonary status and also increase SP-A and SP-D levels in tracheal fluid in premature infants with RDS (Wang et al. 1996).

25.4.2 1α,25-Dihydroxyvitamin D3

The active form of 1α,25-dihydroxyvitamin D_3 [1,25 $(OH)_2D_3$], has been shown to stimulate lung maturity, alveolar type II cell differentiation and fetal lung development. In fetal rat lung, 1,25$(OH)_2D_3$ increases the synthesis and secretion of surfactant lipids and accelerates the appearance of the morphological features of alveolar type II cells (Marin et al. 1993). It was stated that a natural metabolite of 1,25 $(OH)_2D_3$ increases surfactant phospholipid and SP-B mRNA and protein synthesis in human NCI-H441 cells (Rehan et al. 2002; Phokela et al. 2005). Phokela et al. (2005) suggest that regulation of surfactant protein gene expression in human lung and type II cells by 1,25$(OH)_2D_3$ is not coordinated where as 1,25$(OH)_2D_3$ decreases SP-A mRNA and protein levels in both fetal lung tissue and type II cells.

25.4.3 Growth Factors

Keratinocyte growth factor (KGF, FGF-7) is a potent mitogen of pulmonary bronchial and alveolar epithelial cells. Airway epithelial cells (AEC) proliferate in response to KGF. KGF instillation resulted in epithelial cell hyperplasia in rats and the mRNA levels for SP-A, SP-B, and SP-D were increased in whole lung tissue on days 1 and 2 after KGF treatment (Yano et al. 2000). In presence of KGF, rat serum mRNAs for surfactant proteins were maintained at high levels. Secretion of SP-A and SP-D was found to be independent of phospholipid secretion (Mason et al. 2002). Clara cells also responded to human KGF in vivo by proliferation as well as by changes in protein expression, whereas no significant response was observed in pulmonary neuroendocrine cells (Fehrenbach et al. 2002; Shannon et al. 2001). Growth hormone significantly increases MBL and SP-D levels in Turner Syndrome. A link between endocrine and immune system with clinical consequences needs to be studied (Gravholt et al. 2004). VEGF is an autocrine proliferation and maturation factor for developing alveolar type II cells. But VEGF does not change the transcriptional level of SP-A, SP-C, and SP-D though it increases SP-B. The effects of VEGF isoform on type II

cells are likely to be exerted indirectly through reciprocal paracrine interactions involving other lung cell types (Raoul et al. 2004). Pretreatment therapy by recombinant human VEGF (rhVEGF) decreased RSV disease in perinatal lamb respiratory syncytial virus (RSV) model (Meyerholz et al. 2007). Increased expression of SP-D mRNA at 6 and 24 h and decreased expression of SP-A mRNA at 12 h were observed after treatment with all-trans retinoic acid (RA) (Grubor et al. 2006).

25.5 SP-D in Human Fetal and Newborns Lungs

The SP-D was not detected in fetuses at 8–19 weeks gestation. At 21 weeks gestation, SP-D was weakly localized, in some cases (5/9), in the epithelial lining of both bronchioles and terminal airways. In contrast at 21 weeks gestation, SP-A was more markedly detected in the epithelial lining of both bronchioles and terminal airways in all cases but not detected in bronchioles and terminal airways at 8–19 weeks gestation. The production of SP-D in fetal human lungs begins in bronchiolar and terminal epithelium from about 21 weeks of gestation (Mori et al. 2002). Stahlman et al. (2002) detected SP-D on airway surfaces by 10 weeks' gestation and indicated that SP-D is secreted onto luminal surfaces by epithelial cells lining ducts of many organs, where it likely plays a role in innate host defense. The SP-D concentrations in umbilical cord blood and capillary blood are highly variable and depend on several perinatal conditions. In preterm infants, significant changes occur in collectin umbilical cord blood concentrations and pulmonary SP-D levels. Further studies are needed to elucidate the effect of respiratory distress and infection on SP-D concentrations (Dahl et al. 2006; Hilgendorff et al. 2005).

Serum SP-D and MBL levels are significantly low in preterms between 28 and 32 week gestational age (GA) compared to term infants and positively correlated with history of antenatal corticosteroids and chorioamnionitis. The SP-D levels in tracheal aspirates (TA) were increased in preterm infants between 28 and 32 week GA with respiratory distress syndrome compared to control subjects in contrast to extremely immature infants <28 week GA suffering from respiratory distress syndrome (RDS). SP-D concentrations in umbilical cord blood and capillary blood in premature infants are twice as high as in mature infants and depend on several perinatal conditions. High SP-D levels in umbilical cord blood and capillary blood on day 1 were found to be related to increased risk of RDS and infections (Dahl et al. 2006).

25.6 Non-Pulmonary SP-D

25.6.1 Human Skin and Nasal Mucosa

The SP-D has been detected in basal layers of normal human skin. It is more abundant in the stratum spinosum of lesional psoriatic and atopic skin due to more cells producing molecule rather than up-regulation of production in single cells of diseased skin (Hohwy et al. 2006). The surface tension of SP-deficient artificial sebum is (a) lowered by skin-extracted SP-B and (b) further reduced to a level comparable to normal sebum by additional presence of skin-extracted SP-A and SP-D, consistent with their surface tension-lowering capabilities in lung (Mo et al. 2007). SP-A2, SP-B, and SP-D mRNAs were expressed normal human nasal epithelial (NHNE) cells and human nasal mucosa and localized in ciliated cells of the surface epithelium and serous acini of submucosal glands (Kim et al. 2007; Woodworth et al. 2006, 2007).

25.6.2 Digestive Tract, Mesentery, and Other Organs

The fact that surfactant-like materials composed of phospholipids are secreted by a number of other organs prompted several groups to search for SP expression in these organs also. The SP-D occurs in gastric mucosa at the luminal surface and within gastric pits of mucus-secreting cells. The hydrophilic proteins SP-A and SP-D and their transcripts have been found in a number of tissues, including gastric and intestinal mucosae, mesothelial tissues (mesentery, peritoneum, and pleura), synovial cells, Eustachian tube and sinus, and possibly in salivary glands, pancreas, and urinary tract. SP-D is expressed in mucus-secreting cells of gastric mucosa. SP-D protein and mRNA were not detected in the duodenum and remainder of the gastrointestinal tract (Herias et al. 2007). It is possible that SP-D may participate in the regulation of secretion or assembly of gastric acid barrier. Alternatively, SP-D may participate in gastric mucosal host defense (Fisher and Mason 1995). By contrast, the hydrophobic proteins SP-B and SP-C actually appear to be expressed in lung epithelium only. The expression of SP-A and SP-D appears as a general feature of organs exposed to pathogens because they present an interface with the external milieu. Although this function has been investigated in lung only through the gene-targeting approach, increased expression of SP-A in the infected middle ear and of SP-D in the *Helicobacter*-infected

antrum argues for such a function also in other organs. In organs that are not exposed to external pathogens, their role is likely to exert anti-inflammatory and immunomodulatory functions, as suggested by increased SP-A immunoreactivity in rheumatoid disease. SP-A and SP-B have been found in association with phospholipids in the lung of all air-breathing vertebrates, including the most primitive forms represented by lungfish, which implies that the surfactant system had a single evolutionary origin. Immunochemical proximity of the proteins among vertebrates indicates considerable conservation during evolution. Infection with the gastroduodenal pathogen *Helicobacter pylori* up-regulates expression of SP-D in human patients with gastritis, and its influence on colonization has been demonstrated in a *Helicobacter* SP-D-deficient (SP-$D^{-/-}$) mouse model. SP-D binds and agglutinates *H. pylori* cells in a lectin-specific manner, and has been shown to bind *H. pylori* lipopolysaccharide. Furthermore, evidence indicates that *H. pylori* varies LPS O-chain structure to evade SP-D binding which is speculated aids persistence of this chronic infection (Bourbon and Chailley-Heu 2001; Moran et al. 2005). To explore the similarity between lung and peritoneal surfactants, Chailley-Heu et al. (1997) suggested that mesothelial cells also produce SP-A and SP-D, although they are of embryonic origin (mesodermal) and are different from those of lung and digestive tract (endodermal) that secrete these surfactants. Porcine SP-D bound to solid-phase mannan in a Ca^{2+}-dependent manner with a saccharide specificity similar to rat and human SP-D. Whereas SP-D and SP-A are abundant in the peripheral lung, their presence in sputum derived from the larger airways is variable and their carbohydrate binding capacity is lost. Sputum sol fraction and LPS inhibited the binding of the collectins to carbohydrate in the presence of calcium (Griese et al. 2001).

Bands for SP-A were detected in human Eustachian tube (ET) (SP-A, 34 kDa) and in kidney extracts, and for SP-D (43 kDa) in Eustachian tube and in kidney extracts (SP-D, 86 kDa), and for SP-B (8 kDa) in human ET and organ of Corti extracts. Dysfunction of local mucosal immunity in ET may predispose infants to recurrent otitis media. The protein was found in the granules of microvillar epithelial cells. SP-A and SP-D may be important for antibody-independent protection of the middle ear against infections (Kankavi 2003; Paananen et al. 2001).

25.6.3 Male Reproductive Tract

SP-A and SP-D have been identified in testis and epididymis. The presence of SP-A, SP-D and components of molecular weight 34 and 43 kDa have been detected in human spermatozoa. SP-A is localized in mid-piece, the tail, and sometimes at equatorial region of spermatozoa (Kankavi et al. 2008). SP-D mRNA and protein are present throughout the mouse male reproductive tract, including the prostate. Castration increases prostate SP-D mRNA levels. SP-D protects the human prostate from infection by pathogens. The SP-D inhibits infection of prostate epithelial cells by *Chlamydia trachomatis* in an in vitro infection assay. The SP-D binds to C. *trachomatis* via its carboxy-terminal lectin domains. SP-D protein levels are increased at sites of inflammation in prostate, suggesting SP-D may also contribute more generally to inflammatory regulation in prostate (Oberley et al. 2005). Results suggest that infection and androgens regulate SP-D in the prostate (Oberley et al. 2007b).

Surfactant proteins in the stallion reproductive tract contribute to immune surveillance and to active barrier defense mechanism (Kankavi et al. 2007). SP-A and SP-D are present in the mare genital tract, vulva, vagina, ovarium, uterus and tuba uterina. The SPs are present not only in just lamellar bodies associated with lung, but also in genital system of mare (Kankavi et al. 2007). SP-D protein was localized in the apical portion of the reproductive epithelial cells. One of the functions of the SP-D protein may be to protect cervical epithelial cells from infection by C. *trachomatis*. *Chlamydia muridarum* infection caused an increase in the SP-D protein content of reproductive tract epithelial cells. Data were suggestive that SP-D may play a role in innate immunity in the female reproductive tract in vivo (Oberley et al. 2004, 2007a).

25.6.4 Female Genital Tract

The SP-D is present in the female genital tract, the placenta and in amniotic fluid. In the placenta, SP-D was seen in all villous and extravillous trophoblast subpopulations. Endometrial presence of SP-D in non-pregnant women varied according to stage of the menstrual cycle and was up-regulated towards the secretory phase. Endometrial SP-D may prevent intrauterine infection at the time of implantation and during pregnancy (Leth-Larsen et al. 2004). Findings suggest that SP-A and SP-D interact with chlamydial pathogens and enhance their phagocytosis into macrophages. *Chlamydia muridarum* infection increases SP-D protein content of reproductive tract epithelial cells, suggestiing that SP-D plays a role in innate immunity in the female reproductive tract in vivo (Oberley et al. 2004, 2007).

Amniotic Fluid: MBP, SP-A and SP-D are present in amniotic fluid and localize on the surface of amniotic epithelium. MBP levels in amniotic fluid were found to increase sharply from about 32 weeks of gestation. Both SP-A and SP-D were detected in amniotic fluid as early as 26 weeks gestation and, SP-A levels rose sharply from 32 weeks towards term. By

contrast, SP-D levels rose only moderately. Collecins appear to play a role in antibody-independent recognition and clearance of pathogens in amniotic cavity, towards term (Malhotra et al. 1994; Miyamura et al. 1994b). The production of SP-D is increased shortly prior to birth, and the increases in total lung SP-D and SP-D mRNA are temporally correlated with SP-D secretion and the appearance of SP-D in amniotic fluid.

Intra-Amniotic Endotoxin Accelerates Lung Maturation: Intra-amniotic LPS and cytokines may decrease RDS and increase chronic lung disease in the newborn. Intrauterine exposure to LPS increases surfactant protein expression and improves lung stability and aeration in preterm animals (Bry and Lappalainen 2001). Intra-amniotic endotoxin from *E. coli* 055:B5 induces lung maturation within 6 days in fetal sheep of 125 days gestational age. SP-A, SP-B, and SP-C mRNAs were maximally induced at 2 days. SP-D mRNA was increased fourfold at 1 day and remained at peak levels for up to 7 days. The alveolar pool of SP-B was significantly increased between 4 and 7 days in conjunction with conversion to the fully processed active airway peptide. All SPs were significantly elevated in the BAL fluid by 7 days (Bachurski et al. 2001). IL-1 and glucocorticoid affect the expression of SP-A, -B, and –C in lung explants from rabbit fetuses. The study revealed beneficial additive effects of glucocorticoid and cytokine on lung surfactant (Vayrynen et al. 2004).

25.7 Functions of Lung SP-D

25.7.1 Innate Immunity

Surfactant is a complex of lipids and proteins that reduces surface tension at the air/liquid interface of the lung and regulates immune cell function. Surfactant immune function is primarily attributed to two proteins: SP-A and SP-D. It has been known for several years that surfactant lipids suppress a variety of immune cell functions, most notably lymphocyte proliferation, which, conversely, is augmented by SP-A. Thus surfactant lipids and proteins may be counterregulatory, and changes in lipid-to-protein ratios may be important in regulating the immune status of the lung. That these ratios change in disease states is clear, but it is not known whether the alterations are a cause or an effect. Studies with mice in which the SP-A and SP-D genes have been ablated are helping to clarify the role of surfactant in immune function (Kingma and Whitsett 2006)

The SP-A and SP-D bind carbohydrates, lipids, and nucleic acids with a broad-spectrum specificity and initiate phagocytosis of inhaled pathogens as well as apoptotic cells. Investigations on gene-deficient and conditional overexpressed mice indicated that lung SP-A and SP-D directly modulate innate immune cell function and T-cell-dependent inflammatory events and have a unique, dual-function capacity to induce pathogen elimination and control proinflammatory mechanisms. Surfactant protein-D participates in innate response to inhaled microorganisms and organic antigens, and contributes to immune and inflammatory regulation within lung. Porcine SP-D promotes uptake of pathogenic bacteria by epithelial cells. This reflects a scavenger function for SP-D in intestine, which enables the host to generate a more rapid response to infectious bacteria. SP-D binds to surface glycoconjugates expressed by a wide variety of microorganisms, and to oligosaccharides associated with the surface of various complex organic antigens. After binding of SP-D to microbial surface effector mechanisms such as agglutination, neutralizing or opsonization of microorganisms for phagocytosis are initiated. SP-D also specifically interacts with glycoconjugates and other molecules expressed on the surface of macrophages, neutrophils, and lymphocytes. Presence and activity of SP-D in porcine coronary endothelial cells depend on PI3K/Akt, Erk and nitric oxide and decrease after multiple passaging. They suggest a protective role of SP-D in these cells (Lee et al. 2009). In addition, SP-D binds to specific surfactant-associated lipids and can influence the organization of lipid mixtures containing phosphatidylinositol in vitro. SP-D-deficient transgenic mice show abnormal accumulations of surfactant lipids, and respond abnormally to challenge with respiratory viruses and bacterial lipopolysaccharides. The phenotype of macrophages isolated from lungs of SP-D-deficient mice is altered. SP-D stimulates chemotaxis of phagocytes and once bound to the phagocytes, the production of oxygen radicals can be induced. Circumstantial evidence indicates that abnormal oxidant metabolism and/or increased metalloproteinase expression contributes to the development of emphysema. The expression of SP-D is increased in response to many forms of lung injury, and deficient accumulation of appropriately oligomerized SP-D might contribute to the pathogenesis of a variety of human lung diseases (Crouch 2000; Hogenkamp et al. 2007; Reid 1998; Wright 2004; Awasthi et al. 2001) (Figs. 25.1, 25.2, 25.3).

25.7.2 Effects on Alveolar Macrophages

SP-D opsonizes pathogens and enhances their phagocytosis by alveolar macrophages and neutrophils. SP-D was found to bind alveolar Type II cells, Clara cells, and alveolar macrophages. In Type II cells abundant binding was

observed in the endoplasmic reticulum, whereas Golgi complex and multivesicular bodies were labeled to a limited extent. Anti-surfactant SP-A and SP-D showed both SP-A and SP-D in same granules (Kuan et al. 1994). Both SP-D and SP-A have been shown to enhance oxygen radical production by alveolar macrophages. SP-D binds specifically to alveolar macrophages and the receptor involved is different from that of C1q (Miyamura et al. 2004a). SP-D can bind to specific surfactant phospholipids and to glycoconjugates associated with the surface of various microorganisms, consistent with possible roles in surfactant metabolism and pulmonary host defense. Administration of a truncated 60-kDa fragment of human rSP-D reduces the number of apoptotic and necrotic alveolar macrophages and partially corrects the lipid accumulation in SP-D-deficient mice. The same SP-D fragment binds preferentially to apoptotic and necrotic alveolar macrophages in vitro, that suggests that SP-D contributes to immune homeostasis in lung by recognizing and promoting removal of necrotic and apoptotic cells (Clark et al. 2002, 2003) (Fig. 25.3). Findings indicate that collagen domain of SP-D is not required for assembly of disulfide-stabilized oligomers or the innate immune response to viral pathogens. However, collagen domain of SP-D is required for regulation of pulmonary macrophage activation, airspace remodeling, and surfactant lipid homeostasis (Kingma et al. 2006). Surfactant protein D regulates the cell surface expression of alveolar macrophage β2-integrins (Senft et al. 2007).

Opsonization of Gram-Negative Bacteria Independent of Macrophages: SP-A and SP-D bind LPS, opsonize microorganisms, and enhance the clearance of lung pathogens. The pulmonary clearance of *E. coli K12* was reduced in SP-A-null mice and was increased in SP-D-overexpressing mice. Purified SP-A and SP-D inhibited bacterial synthetic functions of several, but not all, strains of *E. coli, Klebsiella pneumoniae,* and *E. aerogenes*. In general, rough *E. coli* strains were more susceptible than smooth strains, and collectin-mediated growth inhibition was partially blocked by coincubation with rough LPS vesicles. Data indicate that SP-A and SP-D are antimicrobial proteins that directly inhibit proliferation of Gram-negative bacteria in a macrophage- and aggregation-independent manner by increasing the permeability of the microbial cell membrane (Wu et al. 2003).

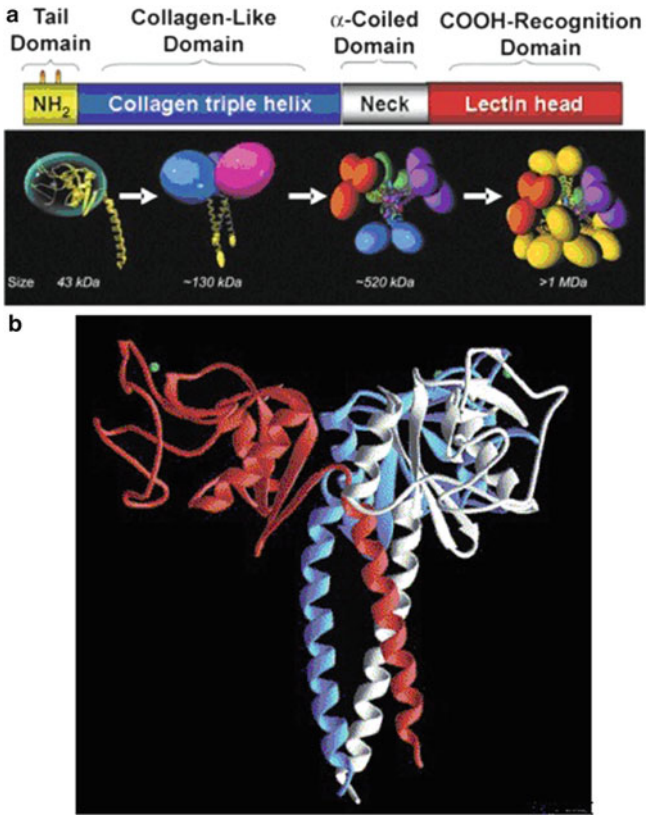

Fig. 25.1 SP-D structure: (*Upper Panel*) **A model of SP-D structure**. The SP-D monomer (43 kDa) consists of a carbohydrate recognition domain which forms the globular head structure. This domain is connected to the collagen-like helical tail domain by a short, 30–amino acid, neck domain. At the end of the tail domain is the amino terminus in which cysteines 15 and 20 are positioned (shown as *yellow* projections). (*Central panel*) Stylized representation of SP-D multimer assembly (note tail domains are shown *shortened* for ease of visualization). The head and neck domains drive the aggregation of the SP-D monomer to form a trimer of ~130 kDa. These trimers associate to form a dodecamer (~520 kDa). The forces holding this dodecamer together are unclear, although there is a dependency upon the amino-terminal cysteines as mutant lacking these cysteines do not form dodecamers. These dodecamers can assemble to a multimer of greater than 1 MDa. It is unclear whether the dodecamer is an essential intermediate in multimer formation. It should be noted that neither the trimer nor the dodecamer are globular proteins, due to the presence of the long collagen tail and thus under native conditions will behave as molecules with greater molecular radius (Adapted from Guo et al. PLoS Biol. 2008; 6: e266). (*Lower Panel*) *Ribbon diagram* shows the overall main chain structure of human lung surfactant protein SP-D. Each monomer is shown in a different colour and calcium ions are depicted as *green spheres* (Adapted with permission from Håkansson et al. 1999 © Elsevier)

25.7.3 Functions of Neutrophils

Calcium-Dependent Neutrophil Uptake of Bacteria: Because neutrophils (PMN) and monocytes are recruited into the airspaces in association with many types of infection or lung injury, Crouch et al. examined the interactions of these cells with SP-D. Natural or recombinant rat SP-D showed dose-dependent effects on human PMN and monocyte migration. Studies established that SP-D can bind to specific sites on neutrophils and monocytes involving saccharide binding domains of SP-D (Crouch et al. 1995). The SP-A and SP-D increased calcium-dependent neutrophil uptake of *E. coli, S. pneumoniae,* and *S. aureus*. Collectins

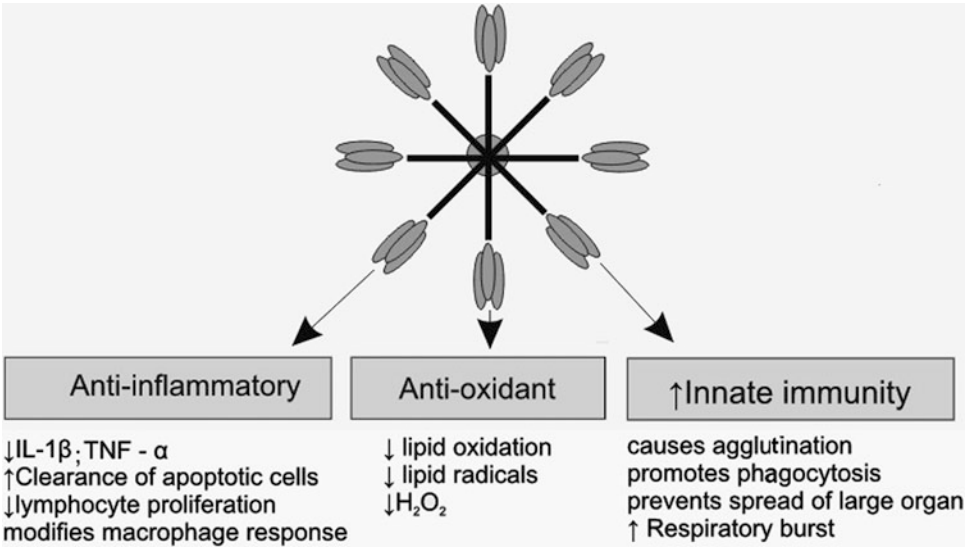

Fig. 25.2 The potential actions of surfactant protein D that may be beneficial in protecting lungs from COPD. SP-D is illustrated as a dodecamer (containing 12 monomeric chains of the carbohydrate recognition domains). SP-D has anti-inflammatory properties by attenuating the expression of pro-inflammatory cytokines such as interleukin (*IL*)-1β, 6, 8 and tumor necrosis factor-α and reducing lymphocyte accumulation in the perivascular tissues in the lungs. SP-D reduces lipid peroxidation and generation of hydrogen peroxide in vivo. SP-D also plays an important role in the innate immunity by promoting phagocytosis and agglutination of pathogens and recruiting neutrophils into lung tissues during active infections (see text for details)

enhanced bacterial uptake occurred through a mechanism that involved both bacterial aggregation and direct actions on neutrophils. The degree of multimerization of SP-D preparations was a critical determinant of both aggregating activity and potency in enhancing bacterial uptake. Results provided evidence that surfactant collectins may promote neutrophil-mediated clearance of bacteria in the lung independently of opsonizing antibody (Hartshorn et al. 1998, 2002).

Neutrophil Serine Proteinases Inactivate SP-D: Because SP-D specifically interacts with neutrophils that infiltrate the lung in response to acute inflammation and infection, the neutrophil-derived serine proteinases (NSPs): neutrophil elastase, proteinase-3, and cathepsin G degrade SP-D. All three human NSPs specifically cleaved recombinant rat and natural human SP-D dodecamers in a time- and dose-dependent manner at the sites of inflammation with potential deleterious effects on its biological functions (Hirche et al. 2004; Griese et al. 2003). However, excess NSPs in lungs play a central role in pathology of inflammatory pulmonary disease. The serpinb1, an efficient inhibitor of the three NSPs, preserves cell and molecular components responsible for host defense against *P. aeruginosa*. The regulation of pulmonary innate immunity by serpinb1 is nonredundant and is required to protect two key components, the neutrophil and SP-D, from NSP damage during host response to infection (Benarafa et al. 2007).

25.7.4 Protective Role in Allergy and Infection

SP-A and SP-D modulate allergic reactions, and resolution of inflammation. SP-A and SP-D can interact with receptor molecules present on immune cells leading to enhanced microbial clearance and modulation of inflammation. SP-A and SP-D also modulate the functions of cells of the adaptive immune system including DCs and T cells. SP-D has multiple functions in innate immunity in lung. The generation of SP-D knock-out mice has revealed a central role for this protein in the control of lung inflammation. Accumulating evidence in mouse models of infection and inflammation indicates that truncated recombinant forms of SP-D are biologically active in vivo. Clark and Reid (2002) addressed structural requirements for recognised activities of SP-D in vitro and in vivo, with emphasis on evidence arising from studies with transgenic mice and mouse models of inflammatory lung disease. The potential of truncated recombinant forms of surfactant protein D as novel therapy for infectious and inflammatory disease is discussed. Constitutive absence of SP-D in mice is associated with lung inflammation, alteration in surfactant lipid homeostasis, and increased oxidative-nitrative stress. The extracellular pool size of SP-D fluctuates significantly during acute inflammation. Clearance of SP-D into lung tissue is increased during inflammation and that tissue-associated neutrophils significantly contribute to this process. Studies using murine models of allergy and infection have raised the

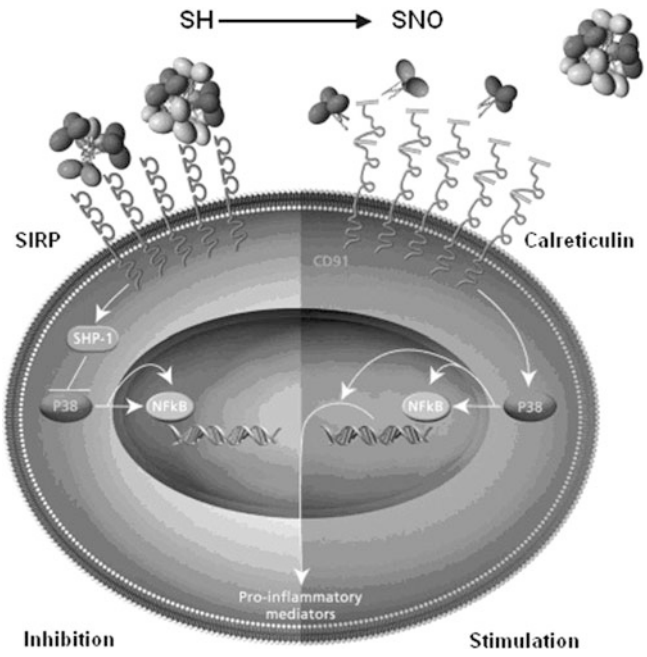

Fig. 25.3 A model of the pro- and anti-inflammatory functions of SP-D: Under non-inflammatory conditions, SP-D remains in large multimeric or dodecameric forms in which the tail domains remain buried. The head domains bind to SIRP-1α and activate the kinase SHP-1. SHP-1 activation inhibits p38 activations, potentially resulting in the blockaged of NF-κB action and the inhibition of infammatory function. Under inflammatory conditions the production of NO leads to the formation of SNO-SP-D and the disruption of the multimeric structure. The tail domains now become exposed and bind to calreticulin. This results in p38 phosphorylation via CD91, potentially leading to NF-κB activation and the production of pro-inflammatory mediators. Presumably other actions which result in disruption of SP-D multimeric structure may also be pro-inflammatory (Adapted from Guo et al. PLoS Biol. 2008; 6: e266)

possibility that recombinant forms of SP-A and SP-D may have therapeutic potential in controlling pulmonary infection, inflammation, and allergies in humans (Haczku 2008).

Using an opportunistic fungal pathogen *Aspergillus fumigatus* (Afu), Kishor et al. (2002) studied the role of SP-A and SP-D in the host immunity. Afu causes a systemic infection via lungs, called invasive aspergillosis (IPA) in immunocompromised subjects. In immunocompetent subjects, it can cause an allergic disorder, called allergic bronchopulmonary aspergillosis (ABPA). Therapeutic administration of these proteins in a murine model of IPA can rescue mice from death. Treating mice, having ABPA, can suppress IgE levels, eosinophilia, pulmonary cellular infiltration and cause a marked shift from a pathogenic Th2 to a protective Th1 cytokine profile. These results highlight the potential of SP-A, SP-D and their recombinant forms, as novel therapeutics for lung allergy and infection (Brandt et al. 2008; Kishor et al. 2002).

Susceptibility of SP-A or SP-D Genetically Deficient Mice: Madan et al. (2005) examined the susceptibility of SP-A (AKO) or SP-D gene-deficient (DKO) mice to Afu allergen challenge. Both AKO and DKO mice showed intrinsic hypereosinophilia and several-fold increase in levels of IL-5 and IL-13, and lowering of IFN-γ to IL-4 ratio in the lungs, suggesting a Th2 bias of immune response. The AKO and DKO mice showed distinct immune responses to Afu sensitization. Intranasal treatment with SP-D or rhSP-D (a recombinant fragment of SP-D) was effective in rescuing Afu-sensitized DKO mice, while SP-A-treated Afu-sensitized AKO mice showed several-fold elevated levels of IL-13 and IL-5, resulting in increased pulmonary eosinophilia and damaged lung tissue. These studies suggest a role for SP-A and SP-D in offering resistance to pulmonary allergenic challenge. Fungi have been implicated in pathogenesis of chronic rhinosinusitis (CRS) with eosinophilic mucus (EMCRS). SP-D is expressed in nasal mucosa and is up-regulated in vitro in response to fungal allergens. SP-D offers a potential therapy for treatment of CRS (Ooi et al. 2007).

Regulation of Chemotaxis and Degranulation of Human Eosinophils: Alveolar macrophages express receptors specific for SP-A and SP-D and provide insight into potential roles of collectins in recruitment and maturation of mononuclear phagocytes in lung (Tino and Wright 1999). SP-D markedly inhibited chemotaxis of eosinophils triggered by eotaxin, a major tissue-derived CC-chemokine. In addition, degranulation of ECP in response to Ca^{2+} ionophore, immobilized IgG and serum from allergic patients was inhibited by SP-D. Data support the concept of an anti-inflammatory function of SP-D in the lung of patients with allergic diseases (von Bredow et al. 2006).

Surfactant Proteins and Lipids as Modulators of Inflammation: SP-A binds with *Mycoplasma pneumoniae* with high affinity and enhances inflammatory response of human and rat macrophages. The interaction of SP-A with bacteria involved phospholipids as major ligand. The SP-A reactive lipid consisted of several disaturated molecular species of phosphatidylglycerol (PtdGro). The disaturated PtdGro failed to alter the anti-inflammatory action of SP-A, but could modify the host response to LPS. These findings reveal that both the lipids and proteins of pulmonary surfactant play a role in regulating the host response to invading microorganisms (Chiba et al. 2006) (Fig. 25.3).

Exogenous surfactants and surfactant phospholipids without SP-A and SP-D inhibit secretion of pro-inflammatory cytokines and NO in NR8383 AMφ. The inhibitory effects of surfactant on oxygen radical and LPS-induced NO formation may result from mechanisms of low cell signaling. The anti-inflammatory activity of surfactant products used in the treatment of neonatal

respiratory distress syndrome (RDS) may depend upon the specific preparation used (Kerecman et al. 2008). SP-D would protect against acute lung injury from hyperoxia in vivo. Local expression of SP-D protects against hyperoxic lung injury through modulation of proinflammatory cytokines and antioxidant enzymatic scavenger systems (Jain et al. 2008). Murine models of pulmonary hypersensitivity suggest that SP-D may be a potent anti-allergic protein.

Anti-inflammatory Protein in Human Coronary Artery SMCs: Immunoreactive SP-D protein is present in smooth muscle cells (SMCs) and endothelial cells. SP-D was also detected in human coronary artery SMCs (HCASMCs). Treatment of HCASMCs with endotoxin (LPS) stimulated the release of IL-8, a proinflammatory cytokine. This release was inhibited >70% by recombinant SP-D. It is stated that SP-D in human coronary arteries functions as an anti-inflammatory protein in HCASMCs (Snyder et al. 2008).

25.7.5 Adaptive Immune Responses

SP-A and SP-D are part of innate immune system and regulate the functions of other innate immune cells, such as macrophages. They also modulate the adaptive immune response by interacting with antigen-presenting cells and T cells, thereby linking innate and adaptive immunity. Emerging studies suggest that SP-A and SP-D function to modulate the immunologic environment of the lung so as to protect the host and, at the same time, modulate an overzealous inflammatory response that could potentially damage the lung and impair gas exchange. Numerous polymorphisms of SPs have been identified that may potentially possess differential functional abilities and may act via different receptors to ultimately alter the susceptibility to or severity of lung diseases (Pastva et al. 2007; Haley et al. 2002).

Nadesalingam et al. (2005) showed that SP-D binds various classes of Igs, including IgG, IgM, IgE and secretory IgA, but not serum IgA. SP-D recognizes IgG, aggregates IgG-coated beads and enhances their phagocytosis by murine macrophage RAW 264.7 cells. Therefore, SP-D effectively interlinks innate and adaptive immune systems (Nadesalingam et al. 2005). IL-4 selectively up-regulates SP-D expression in type II alveolar rat epithelial cell cultures. Since SP-D has a potent anti-inflammatory function, this mechanism may be part of a negative feedback loop providing a regulatory link between adaptive and innate immunity during allergic inflammation (Cao et al. 2004).

SP-A and D Suppress $CD3^+/CD4^+$ Cell Function: SP-A and SP-D inhibit lymphocyte proliferation in presence of accessory cells. SP-A and SP-D directly suppress Th cell function. Both proteins inhibited $CD3^+/CD4^+$ lymphocyte proliferation induced by PMA and ionomycin in an IL-2-independent manner. Both proteins decreased the number of cells entering the S and mitotic phases of the cell cycle. Inhibition of T cell proliferation by SP-A and SP-D occurs via two mechanisms, an IL-2-dependent mechanism observed with accessory cell-dependent T cell mitogens and specific Ag, as well as an IL-2-independent mechanism of suppression that potentially involves attenuation of $[Ca^2]_I$ (Borron et al. 2002).

SP-D Enhances Bacterial Antigen Presentation by DCs SP-D interacts with DCs to enhance uptake and presentation of bacterial antigens. It binds to immature DCs in a dose-, carbohydrate-, and calcium-dependent manner, whereas its binding to mature DCs is reduced. SP-D also binds to *E. coli HB101* and enhances its association with DCs. In addition, SP-D enhances antigen presentation of an ovalbumin fusion protein to ovalbumin-specific MHC class II T cell hybridomas. Studies demonstrate that SP-D augments antigen presentation by DCs and suggest that innate immune molecules such as SP-D may help initiate an adaptive immune response for the purpose of resolving an infection (Brinker et al. 2001, 2002).

As DC function varies depending on the tissue of origin, studies were extended to APCs isolated from mouse lung. Though the SP-D binds specifically to lung CD11c-positive cells, results show that SP-D increases the opsonization of pathogens, but decreases the antigen presentation by lung DCs, and thereby, potentially dampens the activation of T cells and an adaptive immune response against bacterial antigens—during both steady-state conditions and inflammation (Hansen et al. 2007)

The SP-D shares target cells with the proinflammatory cytokine TNF-α, an important autocrine stimulator of DCs and macrophages in the airways. TNF-α can contribute to enhanced SP-D production in the lung indirectly through inducing IL-13. The SP-D, on the other hand, can antagonize the proinflammatory effects of TNF-α on macrophages and DCs, at least partly, by inhibiting production of this cytokine (Hortobágyi et al. 2008). Soerensen et al. (2005b) showed that porcine SP-D (pSP-D) expression in lung surfactant is induced by bacterial infection by an aerogenous route rather than by a haematogenous route and that the protein interacts specifically with alveolar macrophages and with DCs in microbial-induced in bronchus-associated lymphoid tissue (BALT). The purpose of the interaction between pSP-D and DCs in BALT remains unclear, but pSP-D could represent a link between the innate and adaptive immune system, facilitating the bacterial antigen presentation by DCs in BALT.

Lymphocyte Activation in Lungs of SP-D Null Mice: In vitro evidence suggests that SP-D may suppress local T cell responses. In vivo, the SP-D deficient mice ($SP\text{-}D^{-/-}$) showed

marked T cell activation in the lungs, as reflected by an increased percentage of both $CD4^+$ and $CD8^+$ T cells expressing CD69 and CD25. CD4 lymphocytes and the fraction expressing CD69 was also increased in BAL. Increases in CD69-positive CD8 lymphocytes was not significant. Among proinflammatory cytokines, the expression of IL-12 and IL-6 was increased in the lungs of $SP\text{-}D^{-/-}$ mice. The lack of local pulmonary production of SP-D may lead to a state of persistent T cell activation, possibly in response to exogenous antigens (Fisher et al. 2002).

25.7.6 Apoptosis

Emerging results indicate that collectins are able to bind self-derived ligands in the form of apoptotic cells and regulate inflammatory responses. Stuart et al. (2006) discussed the understanding of the process of collectin recognition of dying and damaged cells and its implications for autoimmune and inflammatory diseases. The SP-A, SP-D, and C1q all enhance apoptotic cell ingestion by resident murine and human alveolar macrophages in vitro. However, only SP-D altered apoptotic cell clearance from the naive murine lung, suggesting that SP-D plays a particularly important role in vivo. Similar to C1q and MBL, SP-A and SP-D bind apoptotic cells in a localized, patchy pattern and drive apoptotic cell ingestion by phagocytes through a mechanism dependent on calreticulin and CD91 (Vandivier et al. 2002). SP-A binds to and enhances macrophage uptake of other nonself particles, specifically apoptotic polymorphonuclear neutrophils (PMNs). PMNs are recruited into the lungs during inflammation, but as inflammation is resolved, PMNs undergo apoptosis and are phagocytosed by *MΦ*s. SP-A enhances phagocytosis via an opsonization-dependent mechanism and binds apoptotic cells. Data suggest that SP-A and SP-D facilitate the resolution of inflammation by accelerating apoptotic PMN clearance (Schagat et al. 2001) and that SP-D influences innate host defense by regulating sCD14 in a process mediated by MMP-9 and MMP-12 (Senft et al. 2005).

25.7.7 Other Effects of SP-D

Enhanced Pulmonary Lipoidosis: Targeted disruption of SP-D gene caused a marked pulmonary lipoidosis characterized by increased alveolar lung phospholipids, demonstrating a unexpected role for SP-D in surfactant homeostasis. Pulmonary-specific expression of SP-D corrects pulmonary lipid accumulation in SP-D gene-targeted mice (Fisher et al. 2000). SP-D deficient mice have three to four times more surfactant lipids in air spaces and lung tissue than control mice. Relative to saturated phosphatidylcholine (Sat PC), SP-A and SP-C were decreased in alveolar surfactant and the large-aggregate surfactant fraction in SP-D deficienct mice. SP-D deficiency results in multiple abnormalities in surfactant forms and metabolism that cannot be attributed to a single mechanism (Ikegami et al. 2000). Development of dementia, including Alzheimer's disease (AD), is associated with lipid dysregulation and inflammation. As SP-D has multiple effects in lipid homeostasis and inflammation, the correlation between SP-D concentrations and development of dementia as well as to augmented mortality has been indicated (Nybo et al. 2007).

Body Mass Index: Reports have demonstrated that body mass index (BMI; kg/m^2) is influenced by genes in common with SP-D. In Danish twins, serum SP-D was significantly and inversely associated with weight and waist circumference in men and to BMI in both genders. The $SP\text{-}D^{-/-}$ mice and wild-type mice gained significantly increased weight, with 90 mg/week on normal chow and significantly increased fat in $SP\text{-}D^{-/-}$ male mice. It suggests that there is an association between low levels or absent SP-D and obesity (Sorensen et al. 2006b). Racial differences in SP-D expression exist since median plasma SP-D in Chinese population was approximately two times lower than the median serum SP-D previously measured in a Danish population using same immuno-assay. The inverse association between serum SP-D and BMI found in Chinese population is related to obesity in similar ways in Chinese and Danes (Zhao et al. 2007).

25.8 Oxidative Stress and Hyperoxia

Contributor to the Protection of Lung from Oxidative Stresses: The surfactant lining is exposed to highest ambient oxygen tension of any internal interface and encounters a variety of oxidizing toxicants including ozone and trace metals contained within the 10 kl of air that is respired daily. The pathophysiological consequences of surfactant oxidation in humans and animals include airspace collapse, reduced lung compliance, and impaired gas exchange. In many instances, normal surfactant inhibits many immune cell functions including proliferation resulting from various stimuli and production of reactive oxidative species, inflammatory mediators, and some cell surface markers. The predominant surfactant lipids appear to be responsible for these suppressive effects. Conversely, surfactant proteins SP-A and SP-D stimulate many aspects of immune cell behavior. The SP-A and SP-D directly protect surfactant phospholipids and macrophages from oxidative damage. Both proteins block accumulation of thiobarbituric acid-reactive substances and conjugated dienes during copper-

induced oxidation of surfactant lipids or LDL particles by a mechanism that does not involve metal chelation or oxidative modification of proteins. Low density lipoprotein oxidation is instantaneously arrested upon SP-A or SP-D addition, suggesting direct interference with free radical formation or propagation. The antioxidant activity of SP-A is located to the carboxyl-terminal domain of the protein, which, like SP-D, contains a C-type lectin CRD. Thus, the SP-A and SP-D, which are ubiquitous among air breathing organisms, contribute to the protection of lung from oxidative stresses due to atmospheric or supplemental oxygen, air pollutants, and lung inflammation (Bridges et al. 2000; Phelps 2001).

To evaluate the effects of O3 exposure in mouse strains with genetically different expression levels of SP-D Kierstein et al. (2006) exposed Balb/c, C57BL/6 and SP-D knockout mice to O3 or air. Ozone-exposed Balb/c mice demonstrated significantly enhanced acute inflammatory changes and higher levels of SP-D and released more IL-10 and IL-6 in BAL. IL-6 contributes to the up-regulation of SP-D after acute O3 exposure; elevation of SP-D in the lung is associated with resolution of inflammation. Absence or low levels of SP-D predispose to enhanced inflammatory changes following acute oxidative stress.

Permeabilization of Bacteria by SPs: Studies suggest that SP-A and SP-D have a direct effect on growth and viability of Gram-negative bacteria, *Mycoplasma pneumoniae and Histoplasma capsulatum*. Permeability assays indicate membrane permeabilization by BAL fluid of mice that were sufficient or deficient in surfactant proteins, of rough and smooth LPS-containing membranes, and of genetically altered bacteria. The permeabilizing activity of concentrated BAL material from SP-$A^{+/+}$ mice was substantially greater than that from SP-$A^{-/-}$ animals, and was sensitive to hyperoxic exposure. Reports suggest that pulmonary collectins directly permeabilize bacteria in an LPS-dependent and rough LPS-specific manner. Oxidative damage blocks the permeabilizing activity of alveolar lining fluid and purified proteins (McCormack 2006).

Effect of Hyperoxia: The mRNA level of SP has been reported to be increased in lungs of animals exposed to hyperoxia. Relative amounts of SP-A, SP-B, and SP-D mRNA expression in congenital diaphragmatic hernia (CDH) lung were significantly decreased compared to controls at birth. The inability of O_2 to increase SP mRNA expression in hypoplastic CDH lung suggests that the hypoplastic lung is not responsive to increased oxygenation for the synthesis of SP (Shima et al. 2000). The hypoplastic lung in CDH has both a quantitative and qualitative reduction in surfactant. Aderibigbe et al. (1999) evaluated early effects of hyperoxia (95% O_2) on expression of SP-D in adult male rat lung. Hyperoxia had differential effects on SP-D abundance in alveolar epithelial and bronchiolar epithelial cells, and therefore may influence the availability of SP-D to bind microbial pathogens in airways depending on cell type and location. Alternatively, absence of SP-D aggravates hyperoxia-induced injury. This was tested in SP-D-deficient (SP-$D^{-/-}$) and wild-type (SP-$D^{+/+}$) mice which were exposed to 80% or 21% oxygen. Paradoxically, SP-$D^{-/-}$ mice had 100% survival during 14 days of hyperoxia, vs. 30% in SP-$D^{+/+}$. Perhaps, resistance of SP-D-deficient mice to hyperoxia reflects homeostatic changes in SP-$D^{-/-}$ phenotype involving both phospholipid and SP-B-mediated induced resistance of surfactant to inactivation as well as changes in immunomodulatory BAL cytokine profile (Jain et al. 2007).

Environmental Influences on SP-D Genes: Genetic risk for respiratory distress in infancy has been recognized with increasing frequency in neonatal intensive care units. Examples of genetic variations known to be associated with or cause respiratory distress in infancy have been reviewed (Cole et al. 2001). Serum SP-D levels in children are genetically determined. A SNP located in NH_2-terminal region ($Met^{11}Thr$) of mature protein is significantly associated with the serum SP-D levels. In a classic twin study, the serum SP-D levels increased with male sex, age, and smoking status. The intraclass correlation was higher for monozygotic (MZ) twin pairs than for dizygotic (DZ) twin pairs. Multivariate analysis of MZ and DZ covariance matrixes showed significant genetic correlation among serum SP-D and metabolic variables (Sørensen et al. 2006a). Like MBL**,** structural as wells as promoter variants linked to disease states are known for SP-D. In children MZ and DZ like-sexed twin pairs aged 6–9 years, intraclass correlations were significantly higher in MZ than in DZ twins, indicating substantial genetic influence on both MBL and SP-D levels (Husby et al. 2002).

C-Type Lectins: Selectins

L-Selectin (CD62L) and Its Ligands

26

G.S. Gupta

26.1 Cell Adhesion Molecules

Cell adhesion molecules are glycoproteins expressed on the cell surface and play an important role in inflammatory as well as neoplastic diseases. There are four main groups: the integrin family, the immunoglobulin superfamily, selectins, and cadherins. The integrin family has eight subfamilies, designated as β1 through β8. The most widely studied subfamilies are β1 (CD29, very late activation [VLA] members), β2 (leukocyte integrins such as CD11a/CD18, CD11b/CD18, CD11c/CD18, and αd β2), β3 (CD61, cytoadhesions), and β7 (α4 β7 and αE β7). The immunoglobulin superfamily includes leukocyte function antigen-2 (LFA-2 or CD2), leukocyte function antigen-3 (LFA-3 or CD58), intercellular adhesion molecules (ICAMs), vascular adhesion molecule-1 (VCAM-1), platelet-endothelial cell adhesion molecule-1 (PE-CAM-1), and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). The selectin family includes L-selectin (CD62L), P-selectin (CD62P), and E-selectin (CD62E). Cadherins are major cell-cell adhesion molecules and include epithelial (E), placental (P), and neural (N) subclasses. The binding sites (ligands/receptors) are different for each of these cell adhesion molecules (e.g., ICAM binds to CD11/CD18; VCAM-1 binds to VLA-4). The specific cell adhesion molecules and their ligands that may be involved in pathologic conditions and potential therapeutic strategies by modulating the expression of these molecules have been discussed (Elangbam et al. 1997). The main classes of adhesion molecule involved in lymphocyte interactions are the selectins, the integrins, members of the Ig superfamily, and some mucinlike molecules. Most adhesion molecules play fairly broad roles in the generation of immune responses. The three selectins act in concert with other cell adhesion molecules (e.g., intracellular adhesion molecule (ICAM-1), vascular cell adhesion molecule- 1 (VCAM-1), and leukocyte integrins (Springer 1990; Shimizu et al. 1992) to effect adhesive interactions of leukocytes, platelets, and endothelial cells. Hence selectins which belong to C-type lectins family are reviewed in Chaps. 26–28

26.1.1 Selectins

The selectin family of lectins consists of three closely related cell-surface molecules with differential expression by leukocytes (L-selectin), platelets (P-selectin), and vascular endothelium (E- and P-selectin). Structural identity of a selectins resides in its unique domain composition (Fig. 26.1). E-, P-, and L-selectin are >60% identical in their NH2 terminus of 120 amino acids, which represent the lectin domain (Siegelman et al. 1989; Lasky et al. 1989; Johnston et al. 1989; Bevilacqua et al. 1989; Camerini et al. 1989; Tedder et al. 1989). The ligands (counter structures) of selectins are sialylated and fucosylated carbohydrate molecules which, in most cases, decorate mucin-like glycoprotein membrane receptors. Their common structure consists of an N-terminal Ca^{2+}-dependent lectin-type domain, an epidermal growth factor (EGF)-like domain, multiple short consensus repeat (SCR) domains similar to those found in complement regulatory proteins, a transmembrane region, and a short cytoplasmic C-terminal domain. Together this arrangement results in an elongated structure which projects from the cell surface, ideal for initiating interactions with circulating leucocytes**.** The lectin domain forms the main ligand binding site, interacting with a carbohydrate determinant typified by fucosylated, sialylated, and usually sulphated glycans such as sialyl Lewis X (s-Le^X). The EGF domain may also play a role in ligand recognition. The multiple SCR domains (two for L-selectin, six for

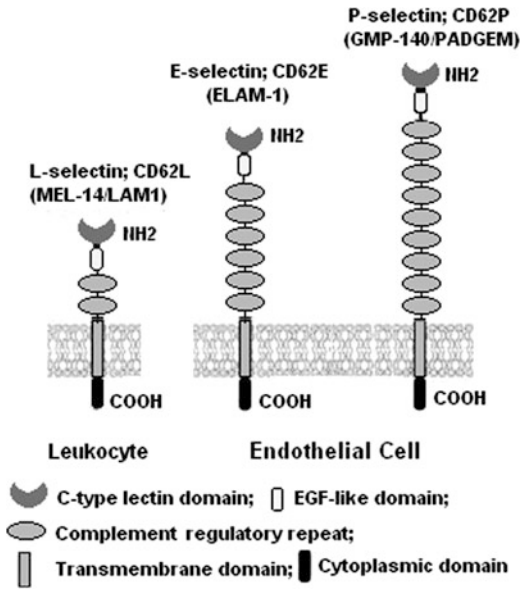

Fig. 26.1 Domain composition of the three known human selectins. The extracellular portion of each selectin contains an amino terminal domain homologous to C-type lectins and an adjacent epidermal growth factor-like domain. The single EGF element that is found in each selectin is followed by a varying number of repetitive elements, each ~ 60 amino acids long, which resemble protein motives found in complement regulatory proteins and a transmembrane sequence. A short cytoplasmic sequence is at the carboxyl terminus of each selectin. The number of amino acids present in the mature proteins as deduced from the cDNA sequences are: L-selectin, 385; P-selectin, 789; and E-selectin, 589

E-selectin, and nine for P-selectin) probably act as spacer elements, ensuring optimum positioning of the lectin and EGF domains for ligand interaction. The EGF repeats have comparable sequence similarity. Each complement regulatory-like module is 60 amino acids in length and contains six cysteinyl residues capable of disulfide bond formation. This feature distinguishes the selectin modules from those found in complement binding proteins, such as complement receptors 1and 2, which contain four cysteines (Hourcade et al. 1989).

The selectins cell-surface receptors play a key role in the initial adhesive interaction between leukocytes and endothelial cells at sites of inflammation (Fig. 26.2). Activation of endothelial cells (EC) with different stimuli induces the expression of E- and P-selectins, and other adhesion molecules (ICAM-1, VCAM-1), involved in their interaction with circulating cells. Lymphocytes home to peripheral lymph nodes (PLNs) via high endothelial venules (HEVs) in the subcortex and incrementally larger collecting venules in the medulla. HEVs express ligands for L-selectin, which mediates lymphocyte rolling.

26.2 Leukocyte-Endothelial Cell Adhesion Molecule 1 (LECAM-1) (L-Selectin/CD62L or LAM-1)

26.2.1 Leukocyte-Endothelial Cell Adhesion Molecule 1 in Humans

Lymphocyte trafficking is a fundamental aspect of the immune system that allows B and T lymphocytes with diverse antigen recognition specificities to be exposed to various antigenic stimuli in spatially distinct regions of an organism. A lymphocyte adhesion molecule that is involved with this trafficking phenomenon has been termed the homing receptor. The Leukocyte-endothelial cell adhesion molecule 1 (LECAM-1) (L-selectin/MEL-14) or leukocyte adhesion molecule-1 (LAM-1, TQ1, Leu-8), a cell surface component, expressed by human lymphocytes, neutrophils, monocytes, and their precursors, is the member of the selectin family of cellular adhesion/homing receptors which play important roles in leukocyte-endothelial cell interactions. LECAM-1 mediates leukocyte rolling and leukocyte adhesion to endothelium at sites of inflammation. The migration of naive T cells into lymphoid tissues is mediated by the chemokine SLC (secondary lymphoid tissue chemokine), which is expressed by the high vascular endothelium, stromal cells, and dendritic cells in lymphoid tissue, and binds to the CCR7 chemokine receptor on naive T cells. In addition, L-selectin mediates the binding of lymphocytes to HEV of PLN, which is an essential process in lymphocyte recirculation and hence also known as PLN homing receptor. Metabolic studies revealed that thymocytes synthesize markedly less L-selectin than do thoracic duct lymphocytes (TDL) or LN lymphocytes. However, Northern blot studies indicated that thymocytes possess more L-selectin RNA than do TDL. These results provide evidence that post-transcriptional events contribute to regulation of L-selectin expression in thymocytes.

26.2.1.1 Lymphocyte-Associated Molecule (LAM-1) and L-Selectin Are Homologous

A cDNA encoding a human lymphocyte cell surface molecule named lymphocyte-associated molecule (LAM-1) composed of multiple distinct domains, one domain homologous with animal lectins was identified by Tedder et al. (1989). This cDNA clone hybridized with RNAs found in B cell lines and T lymphocytes, but not with RNA from other cell types. The amino acid sequence of LAM-1 is 77% homologous with the sequence of the mouse lymphocyte homing receptor, suggesting that LAM-1 may function in human lymphocyte adhesion. The LAM-1 gene is located on chromosome 1q23–25, as is another member of this adhesion family, suggesting that this new family

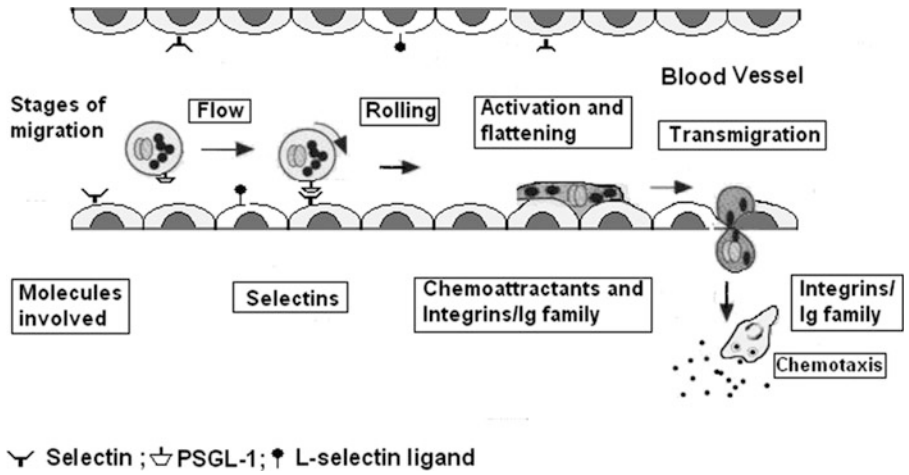

Fig. 26.2 Schematic outline of the stages involved in leucocyte migration through post-capillary venular endothelium. Leucocytes flowing in the vein become tethered to the vessel wall, a step mediated largely by the selectin family of adhesion receptors. The leucocytes then roll along the vessel wall until they come into contact with a chemoattractant and become activated. Activation leads to engagement of members of the integrin family of receptors binding to immunoglobulin (Ig) family adhesion receptors on the endothelium. This causes them to become more firmly attached, stop rolling, flatten on the surface of the endothelial cell, and transmigrate

of proteins may be encoded by a cluster of "adhesion protein" loci. The human homologue of murine peripheral lymph node-specific receptor is highly homologous to the murine receptor in overall sequence that may be involved with human lymphocyte homing. The extracellular region of the human receptor contained an NH2-terminally located carbohydrate binding domain followed by an EGF-like domain and a domain containing two repeats of a complement binding protein/motif (CRP). Interestingly, the human receptor showed a high degree of sequence homology to endothelial cell adhesion molecule ELAM (Bowen et al. 1989; Camerini et al. 1989). Genomic analysis of human DNA suggests a low-copy gene under high-stringent conditions. The nucleotide sequence predicts a mature protein of 334 amino acids, identical in length to mouse lymph node homing receptor core protein (mLHR) (Siegelman and Weissman 1989). The cDNA encoding baboon L-selectin predicts a protein of 372-aa, which is 95% identical to that of human L-selectin (Tsurushita et al. 1996). The carbohydrate binding domain is apparently involved in the adhesive interaction between murine lymphocytes and PLN endothelium. The lectin and EGF-like regions are the most homologous, while CRP domains are less conserved between species. The two CRP units in hLHRc are distinct from those in mLHRc in that they are homologous to one another rather than identical, suggesting strong pressure for maintenance of two repeats in this molecule (Siegelman and Weissman 1989).

26.2.2 Gene Structure of L-Selectin

The leukocyte adhesion molecule-1 (LAM-1) or L-selectin gene expressed by human lymphocytes, neutrophils, monocytes, and their precursors spans greater than 30 kbp of DNA and is composed of at least 10 exons. The 5′ end of LAM-1 mRNA revealed a single initiation region for transcription. Exons II through X contain translated sequences; exon II encodes the translation initiation codon; exon III, the leader peptide; IV, the lectin-like domain; V, the epidermal growth factor-like domain; VI and VII, the short consensus repeat units; exon VIII, the transmembrane region; exon IX encodes seven amino acids containing a potential phosphorylation site; and exon X encodes the five remaining amino acids of the cytoplasmic tail and the long 3′ untranslated region. Sequences of *Lam-1* cDNA clones and protein expressed by neutrophils are identical to cDNA sequences and the protein expressed by lymphocytes. Therefore, the usage of exons II through X results in the generation of a single major LAM-1 protein product expressed by lymphocytes and neutrophils (Ord et al. 1990; Watson et al. 1990).

26.2.3 Murine PLN Homing Receptor/mLHR3

Characterization of the cDNAs encoding the murine lymphocyte homing receptor (mLHR) has revealed mosaic structure containing three well-known protein motifs: a

C-type lectin domain, an epidermal growth factor-like domain, and two exact copies of a short consensus repeat sequence homologous to those found in a family of complement regulatory proteins (CRP), in addition to a signal sequence, a transmembrane anchor, and a short cytoplasmic tail. The receptor molecule is potentially highly glycosylated, and contains an apparent transmembrane region. Analysis of mRNA transcripts reveals a predominantly lymphoid distribution in direct relation to the cell surface expression of the MEL-14 determinant, and the cDNA clone is shown to confer the MEL-14 epitope in heterologous cells. These features, including ubiquitination, embodied in this single receptor molecule form the basis for numerous approaches to the study of cell-cell interactions (Lasky et al. 1989; Siegelman et al. 1989). Characterization of genomic clones encoding mLHR gene revealed a high degree of correlation between various structure/function motifs and exons that specify them. Comparison of the exons encoding the two identical copies of the complement regulatory motif revealed that short intronic regions 5′ and 3′ of these exactly repeated exons are also identical. The mLHR core peptide locus is localized to chromosome 1, the portion syntenic with chromosome 1 in man. The gene on chromosome 1 is very near to a site that contains the genes for the family of complement regulatory proteins which encode short consensus repeats similar to those found in the homing receptor (Dowbenko et al. 1991; Siegelman et al. 1990).

The partial sequencing of a rat cDNA revealed a putative peptide of 372 aa, including a signal peptide of 38 aa. The protein has three tandem domains: a lectin domain, an EGF-like domain and two repeats of complement regulatory proteins (CRP domain). The lectin binding domain has 93.2% and 81.4% and the EGF-like domain has 85.3% and 76.5% aa identity with those of mouse and human, respectively. In the CRP repeat domain, the amino acid identity was 72.6% between human and rat and 71.8% between mouse and rat. The main transcript is of about 3 kb in peripheral blood mononuclear cells (PBMC), spleen and thymus. Sackstein et al. (1995) identified the complete coding sequence of 105-bp 5′-untranslated region and a 359-bp 3′-untranslated region. Expression studies gave evidence that cDNA represented rat L-selectin. The cDNA encoding rabbit L-Selectin encodes a peptide of 377 aa, including a signal peptide of 38 amino acids. Sequence analysis demonstrated extensive homology with L-Selectins from other species (Qian et al. 2001). The bovine L-selectin is predicted amino acid sequence with an overall high identity to that of human and murine L-selectin. However, the cytoplasmic tail of bovine L-selectin showed little similarity to that of human and murine L-selectin (Bosworth et al. 1993).

26.3 Functions of L-Selectin

The selectin family of adhesion molecules (E-, P- and L-selectins) is involved in leukocyte recruitment to the sites of inflammation and tissue damage. In contrast to most other adhesion molecules, selectin function is restricted to leukocyte interactions with vascular endothelium. Multiple studies indicate that the selectins mediate neutrophil, monocyte, and lymphocyte rolling along the venular wall. The generation of selectin-deficient mice has confirmed these findings and provided further insight into how the overlapping functions of these receptors regulate inflammatory processes. These proteins also play a critical part in the subsequent interactions of lymphocytes with antigen-presenting cells and later with their target cells (da Costa Martins et al. 2004). L-selectin dimerization enhances tether formation to properly spaced ligand. Ezrin-radixin-moesin proteins are required for microvillar positioning of L-selectin and that this is important both for leukocyte tethering and L-selectin shedding (Ivetic and Ridley 2004; Ivetic et al. 2004). L-selectin is involved not only in leukocyte tethering and rolling, but also in leukocyte activation.

26.3.1 Lymphocyte Homing and Leukocyte Rolling and Migration

Selectins participate in leukocyte homing to particular tissues, and can be expressed either on leukocytes (L-selectin, CD62L) or on vascular endothelium (Fig. 26.2). L-Selectin is expressed on naive T cells and guides their exit from blood into peripheral lymphoid tissues. The interaction between L-selectin and the vascular addressins is responsible for the specific homing of naive T cells to lymphoid organs but does not, on its own, enable the cell to cross the endothelial barrier into the lymphoid tissue. Studies have shown that inhibition of selectin function can ameliorate a range of inflammatory processes, offering the possibility that antagonists of selectin function may be useful in the treatment of inflammatory lung diseases such as asthma (Symon and Wardlaw 1996). Experiments on L-sel$^{-/-}$ mice showed that L-sel$^{-/-}$ leukocytes were severely impaired in their ability to respond to a directional cue. These findings indicate that L-selectin is important in

enabling leukocytes to respond effectively to chemotactic stimuli in inflamed tissues (Hickey et al. 2000). L- selectin, ICAM-1, and both β1- and β-integrins seem to function synergistically to mediate optimal leukocyte rolling and entry into tissues, which is essential for the generation of effective inflammatory responses in vivo (Steeber et al. 1999; Diacovo et al. 2005). Lymphocyte homing and leukocyte rolling and migration are impaired in L-Sel$^{-/-}$ mice. Whether L-selectin-mediated rolling can promote leukocyte adhesion in vivo independent of P- and E-selectin, Jung et al. (1998) concluded that L-selectin can mediate rolling that results in sufficient leukocyte recruitment to account for the robust inflammatory response seen in E^{-}/P^{-} mice at later times.

There are numerous in vitro studies that demonstrate that engagement of L-selectin leads to the activation of several signaling pathways potentially contributing to subsequent adhesion, emigration, or even migration through the interstitium. Ligation of L-selectin through conserved regions within the lectin domain activates signal transduction pathways and integrin function in human, mouse, and rat leukocytes (Steeber et al. 1997). L-selectin signal transduction requires protein kinase Cα, ι, and θ binding (Kilian et al. 2004). This actually induces cellular events in vivo.

L-Selectin-Mediated Lymphocyte Rolling Is Regulated by Endothelial Chemokines: CXCR2- and E-selectin-induced neutrophils arrest during inflammation in vivo (Smith et al. 2004). L-selectin mobilized intracellular CXCR4 significantly increases surface CXCR4 stimulation and inhibited SDF-1 induced CXCR4 internalization (Ding et al. 2003). Engagement of both CD4 and CXCR4 is required for HIV-induced shedding of L-selectin on primary resting CD4^{+} T cells (Wang et al. 2004).

Intracellular Mechanisms of L-Selectin Induced Capping: Capping of surface receptors is an ubiquitous mechanism but least understood. Junge et al. (1999) demonstrated that L-selectin triggering results in receptor capping of the L-selectin molecules in lymphocytes. This process involves intracellular signaling molecules. L-Selectin capping seems to be independent on activation of p56lck-kinase, but requires the neutral sphingomyelinase, small G proteins and the cytoskeleton. Capping of L-selectin upon stimulation might play an important role in the very early phase of lymphocyte trafficking.

26.3.2 Immune Responses

The mouse strains, deficient in selectin leukocyte adhesion receptors, have been very informative in finding the roles of cell adhesion molecules in leukocyte-endothelium interaction and produced some surprises.

26.3.2.1 Impaired Primary T Cell Responses in L-Sel$^{-/-}$ mice

L-selectin-deficient mice show impaired leukocyte recruitment into inflammatory sites and impaired primary T cell responses. L-selectin-deficient mice are defective in cutaneous delayed-type hypersensitivity (DTH) responses when tested after conventional intervals of immunization (4d). L-selectin plays an important role in the generation of primary T cell responses but may not be essential for humoral and memory T cell responses (Tedder et al. 1995). Lymphocyte migration in L-selectin-deficient mice is due to altered subset migration and aging of the immune system (Steeber et al. 1996). Circulating lymphocyte numbers or subpopulations were not altered in young L-Sel$^{-/-}$ mice, but circulating monocyte numbers were increased nearly threefold. In contrast, older L-Sel$^{-/-}$ mice had disproportionate increases of both naive and memory CD4^{+} T cells present within spleen and blood. Results and the finding that memory lymphocytes in wild-type mice expressed L-selectin demonstrated a requirement for L-selectin in the regulation of memory lymphocyte migration. Therefore, L-selectin-dependent pathways of lymphocyte migration are important for the normal migration of both naive and memory lymphocytes (Steeber et al. 1996). Selectin deficient mice show impaired development of mucosal immunity in the gut-associated lymphoreticular tissue (Csencsits and Pascual 2002; Pascual et al. 2001; Csencsits and Pascual 2002). Using allogeneic skin graft rejection as a model of cutaneous inflammation, L-Sel$^{-/-}$ mice rejected both primary and secondary allogeneic skin grafts significantly more slowly than L-selectin$^{+/+}$ littermates. The delayed rejection of skin grafts by L-Sel$^{-/-}$ mice reflects impaired migration of effector cells into the graft rather than delayed or impaired generation of a CTL response (Tang et al. 1997).

Perhaps L-selectin is required on effector cells for local interactions in the CNS to cause myelin damage in experimental allergic encephalomyelitis as implied by the expression of ICAM-1, VCAM-1, L-selectin, and leukosialin in mouse CNS during the induction and remission stages of experimental allergic encephalomyelitis (Dopp et al. 1994; Grewal et al. 2001).

26.3.2.2 Humoral Immune Responses in L-Sel$^{-/-}$ mice

The altered distribution of lymphocyte subpopulations in L-Sel$^{-/-}$ mice resulted in significantly elevated serum IgM and IgG1 levels and augmented humoral immune responses to T cell-independent and T cell-dependent Ags following i.p. immunization. By contrast, s.c. immunization of L-selectin-deficient mice with a T cell-dependent Ag resulted in serum IgM responses that were lower when compared with wild-type littermates on d 7, while IgG responses were absent. Most serum Ig responses were normal by d 14 and secondary responses were higher in L-selectin-deficient

mice. These results indicate that lymphocyte migration plays an important role in the initiation of humoral responses and demonstrate complementary and overlapping roles for the spleen and other peripheral lymphoid tissues in the generation of immune responses (Steeber et al. 1996).

26.3.2.3 CD62L$^+$ Sub-Population of Regulatory T Cells Protect from Lethal Acute GVHD

The CD4$^+$CD25$^+$ T_{reg} cells are important in the regulation of immune responses in allogeneic bone marrow (BM) and solid organ transplantation. T_{reg} cells are recognized for their critical role in induction and maintenance of self-tolerance and prevention of autoimmunity. Reports indicate that L-Sel^{hi} T_{regs} interfere with the activation and expansion of GVHD effector T cells in secondary lymphoid organs early after BM transplantation. Ermann et al. (2005) examined the differential effect of CD62L$^+$ and CD25$^-$ subsets of CD4$^+$CD25$^+$ T_{reg} cells on aGVHD-related mortality. Both subpopulations showed the characteristic features of CD4$^+$CD25$^+$ T_{reg} cells in vitro and did not induce acute GVHD in vivo. However, in cotransfer with donor CD4$^+$CD25$^-$ T cells, only the CD62L$^+$ subset of CD4$^+$CD25$^+$ T_{reg} cells prevented severe tissue damage to the colon and protected recipients from lethal aGVHD (Ermann et al. 2005).

26.3.2.4 Human CD62L$^-$ Memory T Cells Are Less Responsive to Alloantigen

Human memory (CD45RO+) CD4+ T cells can be distinguished into two subpopulations on the basis of expression of the lymph node homing receptor, L-selectin. Human L-selectin-positive memory T-helper (Th) cells promote the maturation of IgG- and IgA-producing cells by naive B cells. Results suggest that the human L-selectin-negative and -positive subpopulations of human memory CD4$^+$ T cells contain Th1-like and Th2-like cytokine-producing cells, respectively (Kanegane et al. 1996). Memory T cells (CD62L$^-$) represent a population of T cells that have previously encountered pathogens and may contain fewer T cells capable of recognizing neoantigens including recipient alloantigen (aAg). Human naive (CD62L$^+$) or memory (CD62L$^-$) T cells have different capacities to respond to aAg (Foster et al. 2004). Physical fitness affects immune responses to a psychological but not a physical stressor (Hong et al. 2004).

26.3.2.5 Structural Requirements for Release of L-selectin

The cytoplasmic domain of L-selectin regulates leukocyte adhesion to endothelium independent of ligand recognition, by controlling cytoskeletal interactions and/or receptor avidity (Kansas et al. 1993). This was suggested by the strong amino acid sequence conservation of the cytoplasmic domain of L-selectin between humans and mice. L-selectin mediates leukocyte rolling on vascular endothelium at sites of inflammation and lymphocyte migration to PLN. L-selectin is rapidly shed from the cell surface after leukocyte activation by a proteolytic mechanism that cleaves the receptor in a membrane proximal extracellular region. The release of L-selectin is likely to be regulated by the generation of an appropriate tertiary conformation within the membrane-proximal region of the receptor, which allows recognition by a membrane-bound endoprotease with relaxed sequence specificity that cleaves the receptor at a specific distance from the plasma membrane. Studies suggest a generalized protein-processing pathway involved in the endoproteolytic release of specific transmembrane proteins which harbor widely differing primary sequences at/or neighboring their cleavage sites (Chen et al. 1995).

Effect of shedding of L-selectin: L-selectin shedding does not regulate constitutive T cell trafficking but controls the migration pathways of antigen-activated T lymphocytes. In other words, L-selectin shedding from antigen-activated T cells prevents re-entry into peripheral lymph nodes (Galkina et al. 2003). Expression of the L-selectin can be rapidly down-modulated by regulated proteolysis at a membrane-proximal site. Evidence suggested that the L-selectin secretase activity might involve a cell surface, zinc-dependent metalloprotease and might be related to the activity involved in processing of membrane-bound TNF-α (Feehan et al. 1996). In addition, the cytoplasmic domain of L-selectin may regulate shedding by a mechanism in which bound calmodulin may operate as a negative effector (Matala et al. 2001). Studies show that TNF-α-converting enzyme (TACE) is involved in the shedding of L-selectin by NSAIDS in human neutrophils (Gomez-Gaviro et al. 2002).

Role of Circulating L-Selectin: Leukocyte activation along inflamed vascular endothelium induces rapid endoproteolytic cleavage of L-selectin from the cell surface, generating soluble L-selectin (sL-selectin). Comparable with humans, sL-selectin is present in adult mouse sera at approximately 1.7 μg/ml. Adhesion molecule-deficient mice prone to spontaneous chronic inflammation and mice suffering from leukemia/lymphoma had increased serum sL-selectin levels. By contrast, serum sL-selectin levels were reduced in Rag-deficient mice lacking mature lymphocytes. The majority of serum sL-selectin had a molecular mass of 65–75 kDa, consistent with its lymphocyte origin. sL-selectin influences lymphocyte migration in vivo and that the increased sL-selectin levels present in certain pathologic conditions may adversely affect leukocyte migration (Tu et al. 2002).

26.4 L-Selectin: Carbohydrate Interactions

The binding specificity of L-selectin towards structurally defined sulphated oligosaccharides of the blood group Le^a and Le^x series, and of the glycosaminoglycan series heparin, chondroitin sulphate and keratan sulphate has been evaluated in several studies. L-selectin interacts with oversulfated chondroitin/dermatan sulfates containing GlcAβ1/IdoAα1-3GalNAc (4, 6-O-disulfate) (Kawashima et al. 2002). Leid et al. (2002) provided a comprehensive comparison of the L-selectin/cytoskeletal interaction with other functionally important surface antigens.

26.4.1 Glycan-Dependent Leukocyte Adhesion

Each selectin recognizes related but distinct counter-receptors displayed by leukocytes and/or the endothelium. These counter-receptors correspond to specific glycoproteins whose 'activity' is enabled by carefully controlled post-translational modifications. The characterization of the glycans associated with E- and P-selectin counter-receptors, and of mice with targeted deletions of glycosyltransferase and sulfotransferase genes, disclose that neutrophil E- and/or P-selectin counter-receptor activities derive, minimally, from essential synthetic collaborations amongst polypeptide N-acetylgalactosaminyl- transferase(s), a β-N-acetylglucosaminyltransferase that assembles core-2-type O-glycans, β-1,4-galactosyltransferase(s), protein tyrosine sulfotransferase(s), α-2,3-sialyltransferases, and a pair of α-1,3 fucosyltransferases (Lowe 2003).

26.4.1.1 Specificity of L-Selectin Towards Sulphated Oligosaccharides

L-selectin binds to 3′-sialyl-Le^x and –Le^a and to 3′-sulfo-Le^x and –Le^a sequences. Sulphated blood group Le^a/Le^x type sequences, with sulphate at the 3-position of galactose, have emerged as potent ligands for the E- and L-selectins. The recombinant soluble form of rat L-selectin (L-selectin-IgG Fc chimera) was shown to bind to lipid-linked oligosaccharides 3-O, 4-O and 6-O sulphated at galactose, such as sulphatides and a mixture of 3-sulphated Le^a/Le^x type tetrasaccharides isolated from ovarian cystadenoma, as well as to the HNK-1 glycolipid with 3-O sulphated glucuronic acid. The L-selectin was found to bind to the individual 3-sulphated Le^a and Le^x sequences (penta-, tetra- and trisaccharides), and with somewhat lower intensities to their non-fucosylated analogues. Green et al. (1995) proposed that the binding of the lymphocyte membrane L-selectin to endothelial glycosaminoglycans may provide a link between the selectin-mediated and integrin-mediated adhesion systems in leukocyte extravasation cascades. The possibility is also raised that lymphocyte L-selectin interactions with glycosaminoglycans may contribute to pathologies of glycosaminoglycan-rich tissues, e.g. cartilage loss in rheumatoid arthritis and inflammatory lesions of the cornea.

Conformational studies of selectins with NMR of the sulphated (Su) Le^a in comparison with the non-sulphated analogue, which is less strongly bound by E-selectin and not at all by L-selectin, revealed NMR parameters, which are in agreement for binding of both molecules. Molecular dynamics calculations for $SuLe^a$ lead to the conclusion that the conformation of $SuLe^a$ approximates to a single-rigid structure, as for Le^a molecule. Comparison of experimentally and theoretically obtained parameters for $SuLe^a$ with those for the non-sulphated Le^a molecule indicated no detectable changes in the three-dimensional structure of the trisaccharide upon sulphation. Thus, the enhanced selectin binding to the sulphated Le^a is most likely due to favourable electrostatic interactions between the charged sulphate group and corresponding charged groups on the selectin protein (Kogelberg and Rutherford 1994).

Sialyl-Lewis^x Sequence 6-O-Sulfated at N-Acetylglucosamine as Ligand for L-Selectin: Oligosaccharide sequences based on sialyl-Le^x with 6-O-sulfation at galactose (6′-sulfo) or at N-acetylglucosamine (6-sulfo) and expressed on high endothelial venules are considered likely endogenous ligands for L-selectin. In the course of high performance TLC of three hexaglycosylceramides 6′-sulfo sialyl Le^x, 6-sulfo sialyl Le^x, and 6′,6-bis-sulfo sialyl Le^x, synthesized chemically for selectin recognition studies, two minor byproducts were detected and isolated from each parent compound. These were identified as isomers containing a de-N-acetylated sialic acid or having a modified carboxyl group. Binding experiments with the parent compounds and the non-sulfated sialyl Le^x glycolipid show that 6-sulfation potentiates, whereas 6′-sulfation virtually abolishes L-selectin binding. Whereas modification of the sialic acid carboxyl group markedly impaired L-selectin binding, de-N-acetylation resulted in enhanced binding. The natural occurrence on high endothelial venules of this 'super-active' de-N-acetylated form of 6-sulfo sialyl Le^x, and related structures, now deserves investigation (Galustian et al. 1997). The binding to 3′-sialyl-Le^x is strongly affected by the presence of 6-O-sulfate as found on oligosaccharides of the counter receptor, GlyCAM-1; 6-O-sulfate on the N-acetylglucosamine (6-sulfation) enhances, whereas 6-O-sulfate on the galactose (6′-sulfation) virtually abolishes binding. Interactions with 3′-sulfo-Le^x based on the Le^x pentasaccharide sequence also showed that the 6-sulfation enhances where as 6′-sulfation suppresses L-selectin

binding. Thus, for synthetic strategies to design therapeutic oligosaccharide analogs as antagonists of L-selectin binding, those based on the simpler 3′-sulfo-Le^x (and also the 3′-sulfo-Le^a) would be most appropriate (Galustian et al. 1999, 2002).

Endothelial sLe^a and sLe^x During Cardiac Transplant Rejection: Acute organ transplant rejection is characterized by a heavy lymphocyte infiltration. Alterations in the graft endothelium result into increased lymphocyte traffic into the graft. Lymphocytes adhere to the endothelium of rejecting cardiac transplants, but not to the endothelium of syngeneic grafts or normal hearts. Concomitant with the enhanced lymphocyte adhesion, the cardiac endothelium begins to de novo express sialyl Le^a and sialyl Le^x epitopes, which overlap to the sequences of L-selectin counter-receptors. The endothelium of allografts, but not that of syngeneic grafts or normal controls, also reacted with the L-selectin-immunoglobulin G fusion protein, giving proof of inducible L-selectin counter-receptors (Turunen et al. 1995).

Heparin Sulfate Proteoglycans as L-Selectin Ligand: Heparin has been used clinically as an anticoagulant and antithrombotic agent for over 60 years. Calcium-dependent, heparin-like L-selectin ligands had been noticed in cultured bovine endothelial cells (Norgard-Sumnicht et al. 1993). Subsequently, these ligands were identified as heparin sulfate proteoglycans (HSPGs) associated either with the cultured cells or secreted into the medium and extracellular matrix. Studies showed that HSPGs from cultured endothelial cells, which can bind to L-selectin are enriched with unsubstituted amino groups on their GAG chains (Norgard-Sumnicht and Varki 1995). Presentltly, known L-selectin ligands include sulfated Lewis-type carbohydrates, glycolipids, and proteoglycans. L-selectin binding chondroitin/dermatan sulfate proteoglycans are present in cartilage, whereas L-selectin binding heparan sulfate proteoglycans are present in spleen and kidney. L-selectin binds only a subset of renal heparan sulfates, attached to a collagen type XVIII protein backbone and predominantly present in medullary tubular and vascular basement membranes. L-selectin does not bind other renal heparan sulfate proteoglycans such as perlecan, agrin, and syndecan-4, and not all collagen type XVIII expressed in the kidney bind L-selectin. This indicates that there is a specific L-selectin binding domain on heparan sulfate glycosaminoglycan chains. Based on the model of heparan sulfate domain organization, Celie et al. (2005) proposed a model for the interaction of L-selectin with heparan sulfate glycosaminoglycan chains. This opens the possibility of active regulation of L-selectin binding to heparan sulfate proteoglycans, e.g. under inflammatory conditions (Celie et al. 2005).

Heparan Sulfate Deficiency Impairs L-Selectin-Mediated Neutrophil Trafficking: The potent anti-inflammatory property of heparin results primarily from blockade of P-selectin and L-selectin. Mice deficient in P- or L-selectins showed impaired inflammation, which could be further reduced by heparin. However, heparin had no additional effect in mice deficient in both P- and L-selectins. The sulfate groups at C6 on the glucosamine residues play a critical role in selectin inhibition. Such analogs may prove useful as therapeutically effective inhibitors of inflammation (Wang et al. 2002). Endothelial heparan sulfate deficiency impairs L-selectin- and chemokine-mediated neutrophil trafficking during inflammatory responses. L-selectin binding heparan sulfates attached to collagen type XVIII have been identified and a model for the interaction of L-selectin with heparan sulfate glycosaminoglycan chains has been proposed. Endothelial heparan sulfate is involved in the inflammation by inactivating N-acetyl glucosamine N-deacetylase-N-sulfotransferase-1 in endothelial cells and leukocytes, which is required for the addition of sulfate to the heparin sulfate chains. Mutant mice developed normally but showed impaired neutrophil infiltration in various inflammation models. Endothelial heparan sulfate has three functions in inflammation: by acting as a ligand for L-selectin during neutrophil rolling; in chemokine transcytosis; and by binding and presenting chemokines at the lumenal surface of the endothelium (Wang et al. 2005).

Some L-Selectin Ligand Not Recognized by MECA-79 in PLNs: In contrast to PLN addressin, which is recognized by mAb MECA-79, medullary venules expressed L-selectin ligands are not recognized by MECA-79. Both L-selectin ligands seem to be fucosylated by α1,3-fucosyltransferase (FucT)-IV or FucT-VII as rolling is absent in FucT-IV + $VII^{-/-}$ mice. Although MECA-79-reactive species predominate in HEVs, medullary venules express another ligand that is spatially, antigenically, and biosynthetically different from PLN addressin. The two distinct L-selectin ligands are segmentally confined to contiguous microvascular domains in PLNs (M'Rini et al. 2003).

26.4.1.2 Salivary MG2 Saccharides Function as Ligands for Neutrophil L-Selectin

The low-molecular-weight human salivary mucin (MG2) coats oral surfaces, where it is in a prime location for governing cell adhesion. Since oligosaccharides form many of the interactive facets on mucin molecules, Prakobphol et al. (1999) examined MG2 glycosylation in relation to the molecule's adhesive functions. Termini of MG2 oligosaccharide structures predominantly carry T, sialyl-T, Le^x, sialyl Le^x (sLe^x), lactosamine, and sialyl lactosamine. In addition, sLe^x determinants confer L-selectin ligand activity to this molecule. Adhesive interactions between

MG2 and cells that traffic in the oral cavity such as neutrophils and bacteria, revealed that under flow conditions, neutrophils tethered to MG2-coated surfaces at forces between 1.25 and 2 dyn/cm2. Together, results suggested that distinct subsets of MG2 saccharides function as ligands for neutrophil L-selectin and receptors for bacterial adhesion, a finding with interesting implications for both oral health and mucin function.

26.4.1.3 *H. pylori* Isolates Interact with L-, E- and P-Selectins

Carbohydrate components on *H. pylori* contribute to the persistent inflammation through interactions with leukocyte-endothelial adhesion molecules of the host. The LPS of most *H. pylori* strains contain sequences related to the Le^x or Le^a antigens, which are the ligands for the leukocyte-endothelium adhesion molecules of the host, namely, E, P- selectins. *H. pylori* isolates from patients with chronic gastritis, duodenal ulcer and gastric cancer for their interactions with the selectins provide evidence of interactions of isolates from each of the diagnostic groups with E- and L-selectins (Galustian et al. 2003). L-selectin interacts with *Helicobacter pylori* isolates from patients with chronic gastritis, duodenal ulcer and gastric cancer. Anaplasma phagocytophilum infected neutrophils showed reduced expression of P-selectin glycoprotein ligand 1 (PSGL-1, CD162) and L-selectin (CD62L) (Choi et al. 2003).

26.5 Cell Surface Ligands for L-Selectin

26.5.1 Subsets of Sialylated, Sulfated Mucins of Diverse Origins are Recognized by L-Selectin

Direct and indirect evidences indicate that L-selectin ligands required sulfate and sialic acid moieties for proper function. The mucin-type polypeptides GlyCAM-1, CD34, and MAdCAM-1 can function as ligands for L-selectin only when they are synthesized by the specialized HEV of lymph nodes. Since sialylation, sulfation, and possibly fucosylation are required for generating recognition, it was argued that other mucins known to have such components might also bind L-selectin. In support, it was shown that mucins secreted by human colon carcinoma cells, as well as those derived from human bronchial mucus can bind to human L-selectin in a calcium-dependent manner. As with Gly-CAM-1 synthesized by lymph node HEV, α2-3 linked sialic acids and sulfation seemed to play a critical role in generating this L-selectin binding. Taken together, studies indicated that a single unique oligosaccharide structure may not be responsible for high-affinity binding. Rather, diverse mucins with sialylated, sulfated, fucosylated lactosamine-type O-linked oligosaccharides can generate high-affinity L-selectin ligands, but only when they present these chains in unique spacing and/or clustered combinations, dictated by polypeptide backbone (Crottet et al. 1996; Tamatani et al. 1993) (Fig. 26.3).

26.5.2 GlyCAM-1

26.5.2.1 Mouse GlyCAM-1

A sulfated 50 kDa glycoprotein (Sgp50) called GlyCAM-1 has been identified as an HEV ligand for L-selectin. This endothelial ligand is an adhesion molecule that accomplishes cell binding by presenting carbohydrate(s) to the lectin domain of L-selectin, and the name GlyCAM 1 (**Gly**-cosylation-dependent **C**ell **A**dhesion **M**olecule 1) was proposed (Fig. 26.3). The GlyCAM-1 is present on HEV of LN and also in lactating mammary glands. The specifically glycosylated form of GlyCAM-1 plays an important role in leukocyte rolling along the inflamed endothelium. It is a secretory protein that is present in mouse serum. The mRNA encoding this glycoprotein is preferentially expressed in LN. The predicted sequence of a cDNA revealed a mucin-like molecule containing two serine/threonine-rich domains. The mucin-like endothelial glycoprotein appears to function as a scaffold that presents carbohydrates to the L-selectin lectin domain (Lasky et al. 1992). The GlyCAM-1 ligand contains a large percentage of serine and threonine residues, which are apparently O - glycosylated. The gene encoding GlyCAM-1 was found to map to murine chromosome 15 Dowbenko et al. (1993a). Adhesive interactions with the L selectin- lectin domain require that the GlyCAM 1 polypeptide chain be appropriately modified with carbohydrates. These carbohydrate modifications include the addition of sialic acid as well as sulfate residues to O-linked carbohydrate side chains that are clustered in two serine/threonine-rich domains of the mucin. An additional interesting structure that may have relevance to the association of GlyCAM 1 with the lumenal surface of the endothelium was a potential amphipathic helix at the C terminus of the glycoprotein. GlyCAM-1 has been shown to enhance β2-integrin function.

26.5.2.2 Rat GlyCAM

Dowbenko et al. 1993b cloned the rat homologue of GlyCAM 1. The sequence of this clone revealed a serine/threonine-rich protein that is highly homologous with the mouse GlyCAM 1. The mouse and the rat GlyCAM 1 homologues show a clustering of these potential O-linked carbohydrate acceptors in two domains of the protein.

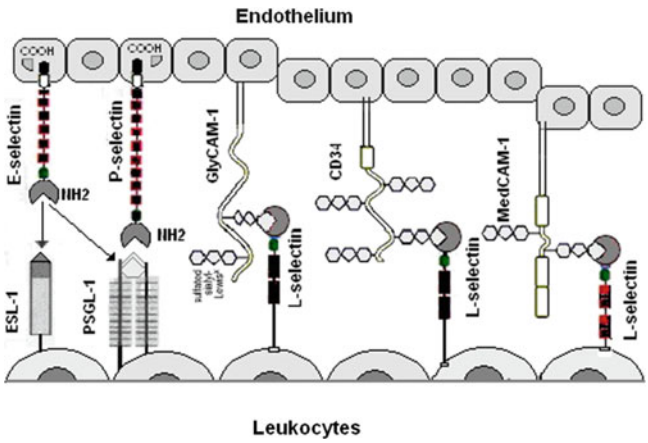

Fig. 26.3 Structures of selectins and their ligands. L-Selectin and the mucinlike vascular addressins direct naive lymphocyte homing to lymphoid tissues**.** E-selectin binds E-selectin ligand 1 (ESL-1) in mouse neutrophils, which is a chicken fibroblast receptor and not related to other adhesion receptor families. E-selectin also binds P-selectin glycoprotein 1 (PSGL-1) but with lower affinity than P-selectin. GlyCAM-1 lacks a transmembrane domain and may be secreted. L-Selectin is expressed on naive T cells, which bind to sulfated sialyl-Lewis^x moieties on the vascular addressins CD34 and GlyCAM-1 on high endothelial venules in order to enter lymph nodes. The relative importance of CD34 and GlyCAM-1 in this interaction is unclear. GlyCAM-1 is expressed exclusively on high endothelial venules but has no transmembrane region and it is unclear how it is attached to the membrane; CD34 has a transmembrane anchor and is expressed in appropriately glycosylated form only on high endothelial venule cells, although it is found in other forms on other endothelial cells. The addressin MAdCAM-1 is expressed on mucosal endothelium and guides entry into mucosal lymphoid tissue. The icon shown represents mouse MadCAM-1, which contains an IgA-like domain closest to the cell membrane; human MadCAM-1 has an elongated mucinlike domain and lacks the IgA-like domain. L-Selectin recognizes the carbohydrate moieties on the vascular addressins. EGF = epidermal growth factor; SCR = short consensus repeats. For selectins refer Fig. 26.1. ||||||||| in PSGL-1 referes to mucin domain

Interestingly, many of the serines and threonines are found to be spaced identically in the two homologues, consistent with the possibility that both density and position of the O-linked side chains may be important for appropriate L selectin-mediated adhesion. In support of its postulated functional importance, the C-terminal potential amphipathic helix is conserved in the rat homologue. Antibody against a relatively conserved portion of mouse GlyCAM 1 demonstrated an approximately 45-kDa sulfated ligand in rat lymph nodes that is analogous to that described for mouse lymph nodes (Dowbenko et al. 1993b; Samulowitz et al. 2002). The mC26 gene encoding GlyCAM-1 in the lactating mouse mammary gland comprises a 5,394 bp fragment of a genomic DNA, which codes for a protein highly expressed in the lactating mouse mammary gland (Nishimura et al. 1993). GlyCAM-1 is also expressed in the cochlea. GlyCAM-1 expressed in the cochlear region is heterogenous in terms of its glycosylation (Kanoh et al. 1999).

26.5.2.3 Complement Factor H as a Ligand for L-selectin in Human

There is no obvious GlyCAM-1 homologue in man. Malhotra et al. (1999) isolated three major glycoproteins of Mr 170, 70 and 50 kDa. The 170 kDa protein was identified as human complement protein Factor H. Human Factor H binds specifically to L-selectin in the presence of CaCl2, and binding was inhibited by anti-L-selectin antibodies, fucoidan and LPS. The interaction of Factor H with leukocyte L-selectin was shown to induce the secretion of TNF-α. It seems that a post-translationally modified form of human plasma Factor H is a potential physiological ligand for L-selectin (Malhotra et al. 1999).

26.5.3 CD34

CD34, a 90 kDa membrane-associated sialomucin, is expressed on the surface of hematopoietic stem/progenitor cells, stromal cells, and on the surface of HEV (Fig. 26.3). The CD34 binds L-selectin, which is important for leukocyte rolling on venules and lymphocyte homing to PLN. A predominant 105 kDa CD34 mucin-like protein has also been identified in human tonsil as peripheral addressin.

120 kDa Addressin Is L-Selectin-Binding Glycoform of CD34: A 120 kDa sialomucin has been identified as the predominant peripheral addressin in porcine lymph nodes. The 120 kDa porcine molecule has its ability to bind MECA-79 and an L-selectin-Fc chimera (LS-Fc). Whereas desialylation of 120 kDa ligand drastically reduced its binding to LS-Fc, this treatment appeared to enhance the binding of 120 kDa ligand to MECA-79. In contrast, the binding of both MECA-79 and LS-Fc to 120 kDa ligand was drastically reduced when de novo sulfation of this ligand was reduced by chlorate, a metabolic inhibitor of sulfation. N-Terminal amino acid sequences of the porcine 120 kDa protein revealed homology with human CD34. Taken together, these findings suggested that the porcine 120 kDa peripheral addressin is an L-selectin-binding glycoform of CD34 (Shailubhai et al. 1997).

Platelets Can Bind Reversibly to CD34$^+$ Cells from Human Blood and Bone: This interaction interferes with the accurate detection of endogenously expressed platelet glycoproteins (GPs). The interaction between these cells was dependent on divalent cations, and mediated by P-selectin. Enzymatic characterization showed the involvement of sialic acid residues. The presence of mRNA for PSGL-1 in the CD34$^+$ cells suggests that this molecule is present in these cells. Under conditions that prevent platelet adhesion, a small but distinct subpopulation of CD34$^+$ cells diffusely

expressed the platelet GPIIb/IIIa complex (Dercksen et al. 1995).

Functions in CD34-Deficient Mice: CD34-deficient mutant- and Wild-type animals do not show differences in lymphocyte binding to PLN HEV, in leukocyte rolling on venules or homing to PLN, in neutrophil extravasation into peritoneum in response to inflammatory stimulus, nor in delayed type hypersensitivity. However, eosinophil accumulation in the lung after inhalation of a model allergen, ovalbumin, was several-fold lower in mutant mice. Although CD34 was not expressed in these mice, a portion of its 90-kD band crossreactive with mAb MECA79 persisted on Western blot. Thus, CD34 seems an additional molecule(s) that might be involved in eosinophil trafficking into the lung (Suzuki et al. 1996). However, CD34 is clearly not the sole contributor of L-selectin ligand activity in HEVs, since CD34-null mice maintain virtually normal L-selectin-dependent lymphocyte homing activity.

Another HEV-expressed L-selectin ligand is the transmembrane sialomucin podocalyxin-like protein or PCLP. Like CD34, PCLP is expressed on some vascular endothelia, but it is also expressed on the foot processes of glomerular podocytes. HEV-derived PCLP interacts with recombinant L-selectin-Ig chimera and supports L-selectin-dependent lymphocyte adhesion under physiological conditions.

26.5.4 Mucosal Addressin Cell Adhesion Molecule-1 (MAdCAM-1)

The mucosal vascular addressin, mucosal addressin cell adhesion molecule-1 (MAdCAM-1), is an Ig family adhesion receptor preferentially expressed by venular endothelial cells at sites of lymphocyte extravasation in murine mucosal lymphoid tissues and lamina propria (Fig. 26.3). The MAdCAM-1 specifically binds to both human and mouse lymphocytes that express the homing receptor for Peyer's patches, the integrin α4β7. MAdCAM-1 interacts preferentially with the leukocyte β7 integrin LPAM-1 (α4β7), but also with L-selectin, and with VLA-4 (α4β7) on myeloid cells, and serves to direct leukocytes into mucosal and inflamed tissues. Expression of human MAdCAM-1 RNA is restricted to mucosal tissues, gut-associated lymphoid tissues and spleen. L-selectin counter-receptors in HEVs are recognized by mAb MECA-79, a surrogate marker for molecularly heterogeneous glycans termed PLN addressin (PNAd).

26.5.4.1 MAdCAM-1 Gene

Human MAdCAM-1 gene contains five exons where signal peptide, two Ig domains, and mucin domain are each encoded by separate exons. The transmembrane domain, cytoplasmic domain, and 3′ untranslated region are encoded together on exon 5. The mucin domain contains eight repeats in total that are subject to alternative splicing. Despite the absence of a human counterpart of the third IgA-homologous domain and lack of sequence conservation of the mucin domain, the genomic organizations of human and mouse MAdCAM-1 genes are similar. An alternatively spliced MAdCAM-1 variant that lacks exon 4 encoding the mucin domain, may mediate leukocyte adhesion to LPAM-1 without adhesion to the alternate receptor, L-selectin. The MAdCAM-1 gene was located at p13.3 on chromosome 19, in close proximity to the ICAM-1 and ICAM-3 genes (p13.2–p13.3) (Leung et al. 1997).

The mouse MAdCAM-1 gene is located on chromosome 10 and contains five exons. The signal peptide and each one of the three Ig domains are encoded by a distinct exon, whereas the transmembrane, cytoplasmic tail, and 3′-untranslated region of MAdCAM-1 are combined on a single exon. The mucin-like region and the third Ig domain are encoded together on exon 4. A short variant of MAdCAM-1 may be specialized to support α4β7-dependent adhesion strengthening, independent of carbohydrate-presenting function (Sampaio et al. 1995). The deduced amino acid sequence from full-length DNA encoding human brain MAdCAM-1 revealed an 18 amino acid signal peptide, two N-terminal Ig-like domains conserved (59–65%) in sequence with those of mouse homologue, an 86 amino acid mucin-like region rich in serine-threonine residues, a 20 amino acid transmembrane domain and a 43 amino acid charged cytoplasmic domain. No counterpart to the third IgA-like domain of mouse MAdCAM-1 was present; however, the serine-threonine-rich mucin domain was extended as two distinguishable major and minor mucin regions unrelated to the mouse domain. The major domain is formed from six tandem repeats of an eight amino acid sequence having the MUC-2-related consensus DTTSPEP/SP. Human MAdCAM-1 mRNA transcripts were restricted to small intestine, colon, spleen, pancreas and brain. Alternatively spliced MAdCAM-1 variants were identified that lack parts of the second Ig domain and all or part of the major mucin domain, indicating that the function of this vascular addressin is regulated by extensive modifications to its multi-domain structure (Leung et al. 1996).

Two Ig-like domains of human and macaque MAdCAM-1 are similar to the two amino-terminal integrin binding domains of murine MAdCAM-1. Human MAdCAM-1 exhibits considerable variation from murine MAdCAM-1 with respect to the length of the mucin-like sequence and the lack of a membrane proximal Ig/IgA-like domain. The MAdCAM-1 from different species demonstrated greater seleoffctive pressure for maintenance of amino acids involved in α4β7 binding than those sequences presumably involved in the presentation of carbohydrates for selectin binding (Shyjan et al. 1996).

26.5.4.2 Structural Requirement for MAdCAM-1 Binding to Lymphocyte Receptor α4β7

The murine MAdCAM-1 has two amino-terminal integrin binding Ig domains. A point mutation within the first Ig domain of MAdCAM-1 abolishes activation-independent α4β7 binding. This point mutation resides within an eight-amino acid motif with homology to sequences important for the integrin binding ability of the related vascular Ig family members, ICAM-1 and VCAM-1. The first domain of MAdCAM-1 is sufficient for interaction with α4β7, but sequences within the second domain support this interaction, either by providing additional contact points for integrin binding or by contributing to the conformation or presentation of the N-terminal domain. The second domain of MAdCAM-1 can also support activation-dependent LFA-1 binding to domain 1 of ICAM-1. These findings are similar to VCAM-1 binding to α4β7 and suggest that structural differences exist between vascular Ig-like ligands for α4 versus β2 integrins (Briskin et al. 1996). A crystal structure for two extracellular amino-terminal domains of human MAdCAM-1 confirmed their expected Ig superfamily topology. In second structure of this fragment, although the overall structure is similar to that previously reported, one edge strand in the amino-terminal domain is instead located on the opposite sheet. This alters the arrangement and conformation of amino acids in this region that had been shown to be crucial for ligand binding. MAdCAM-1 is also seen to form dimers within the crystal lattice raising the possibility that oligomerization may influence the biological role of this adhesion molecule (Dando et al. 2002).

26.5.5 PSGL-1 Binds L-Selectin

L-selectin binds with high affinity to the N-terminal region of P-selectin glycoprotein ligand-1 (PSGL-1) through cooperative interactions with three sulfated tyrosine residues and an appropriately positioned C2-O-sLe^x O-glycan (Leppanen et al. 2003). PSGL-1 binding to P-selectin controls early leukocyte rolling during inflammation. The L-selectin-dependent rolling after P-selectin blockade is completely absent in PSGL-1 deficient (PSGL-1$^{-/-}$) mice or wild-type mice treated with a PSGL-1 blocking mAb. It appeared that leukocyte-expressed PSGL-1 serves as the main L-selectin ligand in inflamed postcapillary venules (Sperandio et al. 2003). L-selectin binding to PSGL-1 initiates tethering events that enable L-selectin-independent leukocyte-endothelial interactions. Interestingly, antibodies and pharmacological inhibitors (e.g., rPSGL-Ig) that target the N-terminus of PSGL-1 reduce but do not abolish P-selectin-dependent leukocyte rolling in vivo whereas PSGL-1-deficient mice have almost no P-selectin-dependent rolling. However, Ridger et al. (2005) suggested that leukocytes can continue to roll in the absence of optimal P-selectin/PSGL-1 interaction using an alternative mechanism that involves P-selectin-, L-selectin-, and sLe^x-bearing ligands. L- and P-selectins collaborate to support leukocyte rolling in vivo when high-affinity PSGL-1 interaction is inhibited (Ridger et al. 2005) (see Chap 27 and Chap 28).

26.6 L-Selectin IN Pathological States

26.6.1 Gene Polymorphism in L-Selectin

LECAM-1 Genes in Ig A Nephropathy: Elucidating the genetic background of immunoglobulin A nephropathy (IgAN) and genetic factors associated with the pathogenesis of the disease, Takei et al. (2002) studied single-nucleotide polymorphisms (SNPs) in selectin gene cluster on chromosome 1q24–25 and found that two SNPs in the E-selectin gene (*SELE8* and *SELE13*) and six SNPs in the L-selectin gene (*SELL1*, *SELL4*, *SELL5*, *SELL6*, *SELL10*, and *SELL11*) were significantly associated with IgAN in Japanese patients. All eight SNPs were in almost complete linkage disequilibrium. *SELE8* and *SELL10* caused amino acid substitutions from His to Tyr and from Pro to Ser, and *SELL1* could affect promoter activity of the L-selectin gene. The TGT haplotype at these three loci was associated with IgAN (Fig. 26.3)

Polymorphism in Type 2 Diabetes Mellitus: Glomerular infiltration with monocytes/macrophages has been implicated in the pathogenesis of diabetic nephropathy. The LECAM-1 213PP genotype is a genetic risk factor for the development of nephropathy in type 2 diabetes mellitus (Kamiuchi et al. 2002). Strong relationship has been demonstrated between soluble L-selectin and diabetic retinopathy with strong correlation between sL-selectin and HbA1c. Soluble L-selectin is increased with poor glycemic control (Karadayi et al. 2003). In Finnish school children CAM is positive marker for precinical type 1diabetes in children (Toivonen et al. 2004).

Brucellosis: The 206Leu allele frequency occurred in 42% of the patients with coronary artery disease compared to % of the controls (Hajilooi et al. 2006). Higher frequency of L-selectin genotypes in patients with brucellosis than in controls and the association between the 206Leu allele and the occurrence of brucellosis relapse, suggest that the F206L polymorphism may make individuals more vulnerable to brucellosis (Rafiei et al. 2006).

26.6.2 Antitumor Effects of L-Selectin

26.6.2.1 Regulation of Host-Mediated Anti-Tumor Mechanisms by L-Selectin

Human tumor cells injected s.c. into mice lacking β3- or β3/β5-integrins or various selectins show enhanced tumor growth compared with growth in control mice. There was increased angiogenesis in mice lacking β3-integrins. Tumor growth also was affected by bone marrow-derived cells in mice lacking any one or all three selectins, implicating both leukocyte and endothelial selectins in tumor suppression. Cells of the innate immune system, macrophages or perhaps natural killer cells, seemed to be implicated in tumor suppression (Taverna et al. 2004). Malignant melanoma is often accompanied by a host response of inflammatory cell infiltration that is highly regulated by multiple adhesion molecules. L-selectin and ICAM-1 contribute co-operatively to the anti-tumor reaction by regulating lymphocyte infiltration to the tumor (Yamada et al. 2006). The plasma level of sL-selectin is possibly useful for early diagnosis of relapse and extramedullary infiltration in acute myeloid leukemia (Aref et al. 2002; Chang et al. 2003).

Suppression of Metastasis in Lymph Nodes by L-Selectin-Mediated NK Cells: The NK cells are known to reject certain tumors in vivo and prevent metastasis of tumors into secondary lymphoid organs. In tumor-bearing hosts, NK cells are recruited to regional lymph nodes in wild-type mice, but not in mice deficient for L-selectin or L-selectin ligands. L-selectin on NK cells and L-selectin ligands on endothelial cells seem to be essential for NK cell recruitment to lymph nodes. Although L-selectin-deficient NK cells efficiently lysed tumor cells in vitro, NK cell-dependent suppression of tumor metastasis was diminished in mice deficient for L-selectin or L-selectin ligands because of insufficient NK cell recruitment to lymph nodes. Evidences indicate that L-selectin-mediated NK cell recruitment plays a crucial role in the control of tumor metastasis into secondary lymphoid organs (Chen et al. 2005).

26.6.2.2 Can L-Selectin Facilitate Metastasis?

Transgenic mice that express rat insulin promoter regulate simian virus 40 Tag (RIP-Tag) develop large, local cancers that metastasize to liver but not LN. Mice, that developed insulinomas, specifically had LN metastases; metastasis was blocked by an anti L-selectin mAb. The highly vascularized islet carcinomas shed tumor cells into the bloodstream, which is a necessary but insufficient condition for metastasis to occur; L-selectin can facilitate homing of such tumor cells to LN, resulting in metastasis (Qian et al. 2001). Surprisingly, L-selectin expressed on endogenous leukocytes also facilitates metastasis in both the syngeneic and xenogeneic (T and B lymphocyte deficient) systems Synergistic effects of L- and P-selectin in facilitating tumor metastasis can involve non-mucin ligands and implicate leukocytes as enhancers of metastasis (Borsig et al. 2002). It seems that L-selectin-mediated NK cell recruitment plays a crucial role in the control of tumor metastasis into secondary lymphoid organs (Chen et al. 2005). L-selectin deficiency also attenuates experimental metastasis. Although L-selectin deficiency did not affect platelet aggregation or initial tumor cell embolization, the association of leukocytes with tumor cells was reduced and tumor cell survival was diminished 24 h later. Inhibition of L-selectin by a function-blocking antibody also reduced metastasis. Therefore, L-selectin facilitation of metastasis progression involves leukocyte-endothelial interactions at sites of intravascular arrest supported by local induction of L-selectin ligands via fucosyltransferase-7. It provides an explanation for how L-selectin facilitates tumor metastasis (Laubli et al. 2006).

26.6.2.3 Adhesion Molecules in Kaposi's Sarcoma

Kaposi's sarcoma (KS) is a neoplasm with multifocal vascular lesions that is often seen in homosexual HIV-infected individuals. The products of leukocytes enhance the proliferation of KS cells in vitro and most likely are crucial for the development of KS lesions in vivo. Studies indicate that multiple proinflammatory agents can induce NF-kB binding activity and can enhance ICAM-1, VCAM-1, and E-selectin expression in KS cells. Thus, the induction of CAM expression could be an early event in the development of KS by recruiting leukocytes into KS lesions, thereby providing factors that could potentiate the development of KS (Sciacca et al. 1994; Yang et al. 1994).

Osteosarcomas and Rhabdomyosarcomas: Osteosarcomas and rhabdomyosarcomas are highly invading tumors. Before they can extravasate to the parenchymal organs and form metastases, they have to adhere to the endothelial cells lining the blood vessels and then penetrate through the endothelium. Human sarcoma cell lines and rhabdomyosarcoma RD express VLA-4 molecule on their surface and bind to the VCAM-I-expressing activated endothelial cell line Ea.hy 926. Sarcoma cells also adhere to recombinant sVCAM-I protein. On the other hand, these sarcoma cell lines do not express marked amounts of other ligands (such as CDII/18 or sialyl-Lex) for other endothelial adhesion molecules (ICAM-I, ICAM-2, E- and P-selectin) indicating that the VLA-4-VCAM-I dependent pathway might be of major importance in sarcoma extravasation (Mattila et al. 1992).

Selectins in the Triggering, Growth, and Dissemination of T-lymphoma Cells: The ICAM-1 expression by the host is essential for lymphoma dissemination. In selectin-deficient mice, though the absence of E-, P-, or L-selectins did not affect the triggering of radiation-induced thymic lymphoma, the absence of L-selectin on lymphoma cells reduced their capacity to grow in the thymus. This defect was overcome by altering the integrity of the L-selectin-mediated interactions in the thymus, as shown in L-selectin-deficient mice and by adoptive transfer experiments. Evidence shows that selectins play a significant role at different steps of T-cell lymphoma development (Belanger and St-Pierre 2005).

26.6.2.4 Role of CD62L$^+$ Cells and TGF-β in Patients with Gastric Cancer

CD62L$^+$ cells are decreased in the peripheral blood, but inversely increased in the spleen of gastric cancer patients. The increased CD62L$^+$ cells residing in the CD4$^+$ suppressor-inducer phenotype, and the removal of CD62L$^+$ cells from spleen cells results in a decrease of Con A-induced suppressor activity in vitro in one-way allogeneic MLR. The CD62L$^+$ cells included CD4$^+$CD25$^+$ regulatory T cells. The culture supernatant of CD62L$^+$ cells showed TGF-β activity, which was more significantly detectable in splenic vein than in the peripheral blood, and TGF-β mRNA was detectable in the spleen from advanced gastric cancer patients. These results suggest that CD62L$^+$ cells migrate into the spleen with disease progression of gastric cancer and serve as suppressor-inducer cells with TGF-β production to induce regulatory T cells, contributing to disease-associated immunosuppression in advanced gastric cancer patients (Noma et al. 2005).

26.6.2.5 Reduced Expression of CD62L Can Identify Tumor-Specific T Cells

Reduced expression of CD62L can identify tumor-specific T cells in lymph nodes draining murine tumors. This strategy could isolate tumor-specific T cells from vaccinated patients. Tumor vaccine-draining lymph node (TVDLN) T cells of patients were separated into populations with reduced (CD62L^{Low}) or high levels of CD62L (CD62L^{High}). Effector T cells generated from CD62L^{Low} cells maintained or enriched the autologous tumor-specific type 1 cytokine response compared to unseparated TVDLN T cells in four of four patients showing tumor-specific cytokine secretion. Effector T cells generated from CD62L^{Low} or CD62L^{High} TVDLN were polarized towards a dominant type 1 or type 2 cytokine profile respectively. For CD62L^{Low} T cells the type 1 cytokine profile appeared determined prior to culture. Since a tumor-specific type 1 cytokine profile appears critical for mediating anti-tumor activity in vivo, this approach can be used to isolate T cells for adoptive immunotherapy (Meijer et al. 2004).

It was shown that tumor vaccine-sensitized draining lymph node (vDLN) cells activated ex vivo with bryostatin and ionomycin (B/I) are capable of inducing antigen-specific regression of a murine mammary tumor, 4T07. The vDLN cells not activated with B/I, were ineffective. It was suggested that B/I selectively activates tumor-sensitized (CD62L^{low}) lymphocytes, to account for the highly potent and tumor-specific activity. It was also hypothesized that CD8$^+$ CD62L^{low} cells may be preferentially activated by B/I treatment, infiltrate the tumors and mediate tumor regression in mice. It was suggested that CD62L^{low} cells are preferentially activated by B/I, leading to a highly effective anti-tumor T cell population (Chin et al. 2004).

26.6.2.6 CD44 Glycoform as E- and L-Selectin Ligand on Colon Carcinoma Cells

Engagement of E-selectin and L-selectin with relevant counter-receptors expressed on tumor cells contributes to the hematogenous spread of colon carcinoma. The LS174T colon carcinoma cell line expresses CD44 glycoform known as hematopoietic cell E-/L-selectin ligand (HCELL), which functions as a high affinity E- and L-selectin ligand on these cells. Expression of HCELL confers robust and predominant tumor cell binding to E- and L-selectin, highlighting a central role for HCELL in promoting shear-resistant adhesive interactions essential for hematogenous cancer dissemination (Burdick et al. 2006).

26.6.3 Autoimmune Diseases

26.6.3.1 L-Selectin in Autoimmune Diabetes

Administration of anti-L-selectin (CD62L) mAb to neonatal non-obese diabetic (NOD) mice mediates long term protection against the development of insulitis and overt diabetes, suggesting that CD62L has a key role in the general function of beta cell-specific T cells.

CD4$^+$CD62L$^+$ Regulatory T Cells in Controlling Onset of Diabetes in Mice: Autoimmune diabetes is characterized by an early mononuclear infiltration of pancreatic islets and later selective autoimmune destruction of insulin-producing β cells. Lymphocyte homing receptors are the candidate targets to prevent autoimmune diabetes. L-selectin (CD62L), expressed in naive T and B cells can be blocked in vivo with specific antibodies such as Mel-14, which partially impairs insulitis and diabetes in autoimmune diabetes-prone NOD mice. Genetic blockade of leukocyte

homing into peripheral lymph nodes can prevent the development of diabetes. Though L-selectin plays a small role in the homing of autoreactive lymphocytes to regional (pancreatic) lymph nodes in NOD mice (Mora et al. 2004), experimental evidences indicate that $CD4^+$ regulatory T cells control progression of autoimmune insulitis in NOD mice. You et al. (2004) showed that diabetes onset is prevented in such mice by infusion of polyclonal $CD4^+$ T cells expressing L-selectin (CD62L) but not prevented or only marginally prevented by $CD4^+CD25^+$ T cells. Report argues for the role of $CD4^+CD62L^+$ T cells present within the polyclonal diabetogenic population in mediating this apparently paradoxical effect. The central role of $CD4^+CD62L^+$ regulatory T cells in controlling disease onset was confirmed in a transgenic model of autoimmune diabetes and possibly through intervention of homeostatic mechanisms as part of their mode of action (You et al. 2004). Despite these observations, the patterns of T cell activation, migration, and beta cell-specific reactivity were similar in NOD mice in different genotypes, suggesting that CD62L expression is not essential for the development of type 1diabetes in NOD mice (Friedline et al. 2002). Nevertheless, CD62L expression is necessary for the diabetes-delaying effect of transfer of $CD4^+CD25^+$ splenocytes in vivo, but not for their suppressor function in vitro (Szanya et al. 2002).

26.6.3.2 L-Selectin Deficiency Reduces Immediate-Type Hypersensitivity

Antigen-sensitized $CD4^+CD62L^{low}$ memory/effector T helper 2 cells can induce airway hyperresponsiveness in an antigen free setting (Nakagome et al. 2005). Dermal and pulmonary inflammatory disease in E-selectin and P-selectin double-null mice is reduced in triple-selectin-null mice (Collins et al. 2001). P- and E-selectin mediate CD4+ Th1 cell migration into the inflamed skin in a murine contact hypersensitivity model. In this model, not only CD4+ T cells but also CD8+ T cells infiltrate the inflamed skin, and the role of CD8+ type 1 cytotoxic T (Tc1) cells as effector cells has been demonstrated. In mice deficient in both P- and E-selectin, the infiltration of CD8+ T cells in the inflamed skin is reduced, which suggests that these selectins participate in CD8+ T cell migration. Tc1 cells are able to migrate into the inflamed skin of wild-type mice. This migration is partially mediated by P- and E-selectin, as shown by the reduced Tc1 cell migration into the inflamed skin of mice deficient in both, P- and E-selectin or wild-type mice treated with the combination of anti-P-selectin and anti-E-selectin Abs. During P- and E-selectin-mediated migration of Tc1 cells, P-selectin glycoprotein ligand-1 appears to be the sole ligand for P-selectin and one of the ligands for E-selectin. P- and E-selectin-independent migration of Tc1 cells into the inflamed skin was predominantly mediated by L-selectin. These observations indicate that all three selectins can mediate Tc1 cell migration into the inflamed skin (Hirata et al. 2002).

The deposition of immune complexes (IC) induces an acute inflammatory response with tissue injury. IC-induced inflammation is mediated by inflammatory cell infiltration, a process highly regulated by expression of multiple adhesion molecules. The cutaneous reverse passive Arthus reaction examined in mice lacking L-selectin (L-selectin$^{-/-}$), ICAM-1 (ICAM-1$^{-/-}$), or both (L-selectin/ICAM-1$^{-/-}$), indicates that ICAM-1 and L-selectin cooperatively contribute to the cutaneous Arthus reaction by regulating neutrophil and mast cell recruitment (Kaburagi et al. 2002). Repeated Ag exposure in wild-type littermates resulted in increased levels of serum L-selectin, also observed in atopic dermatitis patients (Shimada et al. 2003). These studies demonstrates that L-selectin and ICAM-1 cooperatively regulate the induction of the immediate-type response by mediating mast cell accumulation into inflammatory sites and suggests that L-selectin and ICAM-1 are potential therapeutic targets for regulating human allergic reactions

26.6.3.3 L-Selectin Is Required for Early Neutrophil Extravasation

L -selectin (CD62L) and CD44 are major adhesion receptors that support the rolling of leukocytes on endothelium, the first step of leukocyte entry into inflamed tissue. The requirement for these receptors for inflammatory cell recruitment during Ag-induced arthritis was studied in CD44-deficient, L-selectin-deficient, and CD44/L-selectin double knockout mice. Study suggested a greater requirement for L-selectin than for CD44 for neutrophil extravasation during the early phase of Ag-induced arthritis (Szanto et al. 2004). Verdrengh et al. (2000) described a dual role for selectins in *S. aureus*-induced arthritis: on the one hand, blockade of these selectins leads to less severe arthritic lesions in the initial stage of the disease; on the other, delayed recruitment of phagocytes decreases the clearance of bacteria (Verdrengh et al. 2000).

26.6.3.4 L-Selectin in Mouse CNS During EAE

Adhesion molecules facilitate infiltration of leukocytes into CNS of mice with experimental allergic encephalomyelitis (EAE). Cellular infiltration and expression of the adhesion molecules ICAM-1 (CD54), VCAM-1 (CD106), L-selectin (CD62L), and leukosialin (CD43) in EAE-susceptible SWXJ mice preceded the EAE clinical symptoms by a minimum of 3 days, suggesting a causal role of adhesion molecules in the initiation of CNS inflammation. However, prophylactic injections of mAbs against either of ICAM-1, L-selectin, or CD43, did not ameliorate the clinical severity of EAE in these mice (Dopp et al. 1994). In order to study the role of CD62L in the immunopathology of EAE, Grewal et al. (2001) crossed

CD62L-deficient mice with myelin basic protein-specific TCR (MBP-TCR) transgenic mice. CD62L-deficient MBP-TCR transgenic mice failed to develop antigen-induced EAE, and, despite the presence of leukocyte infiltration, damage to myelin in the CNS was not seen. EAE could, however, be induced in CD62L-deficient mice upon adoptive transfer of wild-type macrophages. Study indicated that CD62L is not required for activation of autoimmune CD4 T cells but is important for the final destructive function of effector cells in the CNS and supports a novel mechanism whereby CD62L expressed on effector cells is important in mediating myelin damage (Grewal et al. 2001).

26.6.3.5 Central and Effector Memory T Cells to Recall Responses

The absolute number of memory $CD8^+$ T cells in the spleen following antigen encounter remains stable for many years. However, the relative capacity of these cells to mediate recall responses was studied by Roberts et al. (2005). A dual adoptive transfer approach demonstrated a progressive increase in the quality of memory T cell pools in terms of their ability to proliferate and accumulate at effector sites in response to secondary pathogen challenge. This temporal increase in efficacy occurred in $CD62L^{low}$ (effector memory) and $CD62L^{high}$ (central memory) subpopulations, but was most prominent in the CD62L hi subpopulation. Data indicated that the contribution of effector memory and central memory T cells to the recall response changes substantially over time (Roberts et al. 2005).

During infection with lymphocytic choriomeningitis virus, $CD8^+$ T cells differentiate rapidly into effectors ($CD62L^{low}CD44^{high}$) that differentiate further into the central memory phenotype ($CD62L^{high}CD44^{high}$) gradually. Van Faassen et al. (2005) indicated that the potency of the pathogen can influence the differentiation and fate of $CD8^+$Tcells enormously, and the extent of attrition of primed $CD8^+$ T cells correlates inversely to the early differentiation of $CD8^+$ T cells primarily into the central $CD8^+$ T cell subset (van Faassen et al. 2005).

26.6.4 CD62L in Other Conditions

Adhesion Molecules in Inflammatory Bowel Disease: Mucosal endothelium has become one of the major areas of investigation in gut inflammation. It is now well recognised that it plays an active role in the pathogenesis of both forms of inflammatory bowel disease, Crohn's disease and ulcerative colitis, since endothelial cells regulate mucosal immune homeostasis, acting as "gatekeepers", controlling leukocyte accumulation in the interstitial compartment. This process is mediated by leukocyte-endothelial adhesion molecules. The major molecules that mediate leukocyte-endothelial interactions, have been reviewed and the results of the most recent clinical trials targeting adhesion molecules in inflammatory bowel disease summarized (Danese et al. 2005). Compared to controls, the total amount of platelet P-selectin (tP-selectin) does not change in patients with inflammatory bowel disease (IBD) and 5-aminosalicylic acid medication. However, on gender basis, the male patients showed higher levels of total P-selectin compared to male controls. Increased total P-selectin levels may alter the inflammatory response and susceptibility to thromboembolic disease. As found with sP-selectin, total P-selectin showed gender dependent differences, which are important to consider for future studies (Fagerstam and Whiss 2006).

Appendix plays an important role in the pathogenesis of colitis (Farkas et al. 2005). Since appendectomy can protect against development of ulcerative colitis and Crohn's disease and since. T cells affect the appendix in the development of colitis, Farkas et al. (2005) demonstrated the preferential migration of $CD62L^+CD4^+$ cells into the appendix as compared to the colon. This migration pattern correlated with up-regulation of integrin $\alpha4\beta7$ and CD154 (CD40 ligand) on T cells. Thus In a chronic ileitis model, pathogenic $CD4^+$ T cells alternatively engage L-selectin in order to recirculate to the chronically inflamed small intestine (Rivera-Nieves et al. 2005). L-selectin is important in experimental abdominal aortic aneurysm (AAA) formation in rodents. L-selectin-mediated neutrophil recruitment may be a critical early step in AAA formation (Hannawa et al. 2005). The resident flora plays a critical role in initiation and perpetuation of intestinal inflammation, as demonstrated in experimental models of colitis where animals fail to develop disease under germ free conditions. Strauch et al. (2005) indicated that bacterial antigens are crucial for the generation and/or expansion of T_{reg} cells in a healthy individual. Therefore, bacterial colonisation is of great importance in maintaining the immunological balance.

Other Conditions: During acute familial Mediterranean fever (FMF) there was no change in L-selectin expression, but there was an increased neutrophil surface CD11b compared with normal controls. Neutrophils of FMF patients regulate CD11b and L-selectin expression induced by chemoattractant (FMLP) stimulation, similar to that in controls (Molad et al. 2004). Considering that the inflammation is the basic stage in the early period of ^{131}I therapy (RAI) of hyperthyroidism, E- and L-selectins are not useful indicators in thyroid, while ICAM-1 and IL-6 may be important in the thyroid during radioiodine therapy, especially Graves' disease (Jurgilewicz et al. 2002). Inflammatory

cells play a crucial role in wound healing. Although ICAM-1 contributes to wound repair to a greater extent than L-selectin, a role for L-selectin was revealed in the absence of ICAM-1. The impaired wound repair was associated with reduced infiltration of neutrophils and macrophages in ICAM-$1^{-/-}$ and L-selectin/ICAM-$1^{-/-}$ mice. Results suggested a distinct role of ICAM-1 and L-selectin in wound healing and the delayed wound healing in the absence of these molecules is likely because of decreased leukocyte accumulation at the wound site (Nagaoka et al. 2000). Soluble L-selectin increases in serum samples from subjects with *cryptococcosis* than in those from uninfected subjects (Jackson et al. 2005).

26.7 Oligonucleotide Antagonists IN Therapeutic Applications

Selectin-directed therapeutic agents are now proven to be effective in blocking many of the pathological effects resulting from leukocyte entry into sites of inflammation. Studies are being focused on how the selectins interact with the increasing array of other adhesion molecules and inflammatory mediators. L-selectin expression on CD3+, CD4+ and CD8+ T cells was significantly lower in HIV infected children than in the control group. The percentage of neutrophils expressing CD62L was significantly reduced in patients with severe immunologic suppression. Altered leukocyte functions such as migration and homing resulting from reduced expression of CD62L may be an important contributor of the progressive dysfunction of the immune system in HIV infected children (Gaddi et al. 2005).

26.7.1 Monomeric and Multimeric Blockers of Selectins

Selectins bind to carbohydrate ligands in a calcium-dependent manner and play critical roles in host defense and possibly in tumor metastasis. It is possible to isolate peptides mimicking carbohydrate ligands by screening the peptides for binding to anticarbohydrate antibodies and then use them to inhibit carbohydrate-dependent experimental tumor metastasis (Fukuda et al. 2000). The monomeric and polymeric compounds, 4-nitrophenylthiomannoside, phenylmannoside, conjugated with polyacrylic acid, and α-mannose, conjugated with polyacrylamide, inhibited the binding of the model ligand to P- and L-selectins (but not to E-selectin). These compounds (i.v.) caused a dose-dependent reduction of neutrophil accumulation in rat peritoneum. The polysaccharide mannan was inactive in both types of experiments. The conjugate of phenylmannoside with polyacrylic acid was the most effective blocker in vitro as well as in vivo. The inhibitory effect of (s.c) 4-nitrophenylthiomannoside was indicated on mouse peritonitis (Ushakova et al. 2001). Ikegami-Kuzuhara et al. (2001) investigated the ability of a synthetic sugar derivative, OJ-R9188, [N-(2-tetradecylhexadecanoyl)-O-(L-alpha-fucofuranosyl)-D-seryl]-L-glutamic acid 1-methylamide 5-L-arginine salt, to block binding of selectins to their ligands in vitro and inhibit the infiltration of leukocytes in vivo. OJ-R9188 prevented the binding of human E-, P- and L-selectin-IgG fusion proteins to immobilized sialyl Le^x-pentasaccharide glycolipid. In a mouse model of thioglycollate-induced peritonitis, OJ-R9188 inhibited neutrophil accumulation in the peritoneal cavity. Thus blocking selectin-sLe^x binding site is a promising strategy for the treatment of allergic skin diseases.

The potency of oligosaccharides $SiaLe^x$, Sia Le^a, HSO_3 Le^x, and HSO_3 Le^a, their conjugates with polyacrylamide (PAA), and other monomeric and polymeric selectin inhibitors has been compared with that of the polysaccharide fucoidan. PAA-conjugates, containing tyrosine-O-sulfate (sTyr) in addition to one of the sialylated oligosaccharides, are the potent synthetic blockers in vitro. Compared with fucoidan, the bi-ligand glycoconjugate HSO_3 Le^a-PAA-sTyr displayed similar inhibitory activity in vitro towards L-selectin and about ten times lower activity towards P-selectin. All of the synthetic polymers displayed a similar ability to inhibit neutrophil extravasation in the peritonitis model (in vivo). Evidence indicates that monomeric $SiaLe^x$ is considerably more effective as a selectin blocker in vivo than in vitro, whereas the opposite is true for fucoidan and the bi-ligand neoglycoconjugate HSO_3 Le^a-PAA-sTyr (Ushakova et al. 2005).

26.7.2 Synthetic and Semisynthetic Oligosaccharides

The SELEX (systematic evolution of ligands by exponential enrichment) yields high affinity oligonucleotides with unexpected binding specificities. Nuclease-stabilized randomized oligonucleotides subjected to SELEX against recombinant L-selectin yielded calcium-dependent antagonists which shared a common consensus sequence. Unlike sialyl Le^x, these antagonists were specific to L-selectin since they showed little binding to E- or P-selectin. However, they showed binding to native L-selectin on peripheral blood lymphocytes and blocked L-selectin-dependent interactions with the natural ligands on HEV (O'Connell et al. 1996).

While high affinity recognition of natural ligands is associated with α1-3(4)fucosylated, α2-3sialylated (and/or sulfated) lactosamine sequences, small oligosaccharides that potentialy inhibit the selectins were found by Koenig et al. (1997). Using synthetic and semisynthetic oligosaccharides

related to those on natural ligands Koenig et al. (1997) confirmed that α2-3-linked sialic acids, and α1-3(4) fucosylation are important for recognition. Immobilized targets for the three selectins indicated that the binding sites for sialic acid and sulfate are very close, or identical. While O-sulfate esters mostly improved L- and P-selectin recognition, effects depended upon their position and number. Of particular note, the "major capping group" of GlyCAM-1 was not an unusually potent or highly selective inhibitor of L-selectin, even when studying the interaction of L-selectin with native GlyCAM-1 itself (Koenig et al. 1997).

Nishida et al. (2000) described a synthetic approach for artificial L- and P-selectin blockers. This synthesis involves radical bi- and terpolymerizations of p-(N-acrylamido)phenyl 3- or/and 6-sulfo-β-D-galactoside with allyl α-L-fucoside in the presence of acrylamide. Each of the two glycosyl monomers constructs a key carbohydrate module responsible for selectins/sulfated sialyl Lewis^x bindings. Whereas an acrylamide copolymer carrying 3-sulfo-galactoside showed no activity for any selectins, the fucosylated terpolymer showed a potent activity to block both of P- and L-selectins/sLe^x binding at a concentration of a few μg/ml. The enhanced activity is apparently ascribed to the cooperative binding effects of the fucoside and the 3-sulfo-galactoside residues.

27.1 Platelet Adhesion and Activation

When a blood vessel is injured, control of bleeding starts with the rapid adhesion of circulating platelets to the site of damage. Within seconds, the adhered platelets are activated, secrete the contents of storage organelles, spread out over the damaged area and recruit more platelets to the developing thrombus. However, if this process occurs in a diseased, sclerotic or occluded vessel, the resulting platelet thrombus may break away and block the coronary artery, causing a heart attack, or restrict blood supply to the brain, causing a stroke. The glycoprotein (GP) Ib-IX-V complex, a member of the leucine-rich protein family, is a constitutive platelet membrane receptor for von Willebrand Factor (vWF), a multimeric adhesive glycoprotein found in the matrix underlying the endothelial cell lining of the blood vessel wall and in the plasma. Binding of vWF to the Ib-IX-V complex regulates adhesion of platelets to the sub-endothelium at high shear flow, and initiates signal transduction leading to platelet activation. The GP Ib-IX-V complex also constitutes a binding site for α-thrombin, an interaction that facilitates thrombin-dependent platelet activation. Analysis of GP Ib-IX-V complex and vWF has identified discrete amino acid sequences that mediate their interaction. An anionic/sulfated tyrosine sequence of the GP Ib α-chain that is critical for binding of Ib-IX-V complex to both vWF and α-thrombin is analogous to sulfated anionic amino acid sequences mediating interactions of other adhesive proteins, including P-selectin binding to PSGL-1 and Factor VIII binding to vWF (Andrews et al. 1997).

27.2 P-Selectin (GMP-140, PADGEM, CD62): A Member of Selectin Adhesion Family

27.2.1 Platelets and Vascular Endothelium Express P-Selectin

Selectins are adhesion receptors that mediate leukocyte adhesion to platelets or endothelial cells through Ca^{2+}-dependent interactions with cell surface oligosaccharides. The selectin family consists of three closely related cell-surface molecules with differential expression by leukocytes (L-selectin), platelets (P-selectin), and vascular endothelium (E- and P-selectin). The forms, functions and some clinical applications of L-selectins have been discussed in previous chapter (Chap. 26). P-selectin and E-selectin are adhesion receptors for monocytes and neutrophils and expressed by stimulated endothelial cells. P-selectin is stored in Weibel-Palade bodies, and rapidly delivered to plasma membrane upon exocytosis of these secretory granules. E-selectin is not stored, and its synthesis is induced by cytokines. The fate of the two proteins has been studied after their surface expression by following the intracellular routing of internalized antibodies to the selectins. After a brief surface exposure, internalized E-selectin is degraded in the lysosomes, whereas P-selectin returns to the storage granules from where it can be reused. E-selectin and P-selectin are two closely related vascular cell adhesion proteins. P-selectin is a 140-kDa glycoprotein expressed on endothelial cells and platelets and expressed on the surface of these cells in response to inflammatory stimuli. P-selectin mediates the tethering and rolling of leukocytes along the endothelium during early step of leukocyte extravasation. Each selectin has an amino-terminal C-type lectin domain that possesses carbohydrate binding site, which recognizes certain vascular mucin-type glycoproteins bearing the carbohydrate structure sialyl-Lewis^x (sLe^x or CD15s) (Neu5Acα2-3Galβ1-4(Fucα1-3) GlcNAc). In addition to sLex carbohydrate, P-selectin binds sulfated proteoglycan, 3-sulfated galactosyl ceramide (sulfatide), and heparin. The clinical prognosis and metastatic progression of many epithelial carcinomas has been correlated independently with production of tumor mucins and with enhanced expression of sialyl-Lewis^x.

P-selectin is also expressed on macrophages in the arterial wall after carotid denudation injury and spontaneous atherosclerosis in atherosclerosis-prone apoE-deficient (apoE$^{-/-}$) mice. Furthermore, P-selectin mRNA expression

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_27, © Springer-Verlag Wien 2012

was readily detectable in macrophage-rich plaques of atherosclerotic innominate arteries and blood monocyte-derived macrophages from apoE$^{-/-}$ mice. Thus, macrophages in carotid injury-induced neointimal lesions and spontaneous atherosclerotic plaques of the innominate artery acquire the ability to express P-selectin, as does regenerating endothelium. These findings provide a potential new paradigm in macrophage-mediated vascular inflammation, atherosclerosis, and neointimal hyperplasia after arterial injury (Li et al. 2005) (Fig. 27.1).

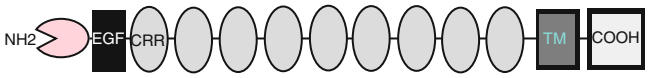

Fig. 27.1 Domain organization of selectin-P (CD62) also called granule membrane protein 140 (GMP-140). The extracellular portion of P-selectin contains an amino terminal domain homologous to C-type lectins and an adjacent epidermal growth factor (*EGF*)-like domain. The single EGF element that is found in P-selectin is followed by nine repetitive elements, each ~60 amino acids long, which resemble protein motives found in complement regulatory repeats (*CRR*) and a transmembrane (*TM*) sequence. A short cytoplasmic sequence is at the carboxyl terminus (*COOH*) of P-selectin. The number of amino acids present in the mature P-selectin as deduced from the cDNA sequences is 789

27.2.2 Human Granule Membrane Protein 140 (GMP-140)/P-Selectin

A structurally and functionally related group of genes, lymph node homing receptor (LHR), granule membrane protein 140 (GMP-140), and endothelial leukocyte adhesion molecule 1 (ELAM-1) constitute a gene cluster on mouse and human chromosome 1. GMP-140 is an inducible granule membrane protein of the selectin family of cell surface receptors that mediate interactions of leukocytes with the blood vessel wall. After cellular activation, it is rapidly redistributed to the plasma membrane. The cDNA-derived primary structure of GMP-140 predicted a cysteine-rich protein with multiple domains, including a "lectin" region, an "EGF:" domain, nine tandem consensus repeats related to those in complement-binding proteins, a transmembrane domain, and a short cytoplasmic tail. Some cDNAs also predicted a soluble protein with a deleted transmembrane segment. The domain organization of GMP-140 is similar to that of ELAM-1, which binds neutrophils. This similarity suggests that GMP-140 belongs to a new family of inducible receptors with related structure and function on vascular cells. In situ hybridization mapped GMP-140 to human chromosome 1 bands 21–24 consistent with chromosomal localization of LHR. Gene linkage analysis in the mouse indicated that these genes and serum coagulation factor V (FV) all map to a region of distal mouse chromosome 1 that is syntenic with human chromosome 1, with no crossovers identified between these four genes in 428 meiotic events. Moreover, long range restriction site mapping demonstrated that these genes map to within 300 kb in both the human and mouse genomes. Studies suggest that LHR, ELAM-1, and GMP-140 comprise the selectins that arose by multiple gene duplication events before divergence of mouse and human. The location of these genes on mouse and human chromosome 1 is consistent with a close evolutionary relationship to the complement receptor-related genes, which also are positioned on the same chromosomes in both species and with which these genes share a region of sequence homology (Johnston et al. 1989; Watson et al. 1990).

Two variant cDNAs for GMP-140 have been identified, one predicting a soluble form of the molecule lacking the transmembrane domain and the other predicting a molecule containing eight instead of nine consensus repeats. The human gene encoding GMP-140, which spans over 50 kbp, contains 17 exons. Almost all exons encode distinct structural domains, including the lectin-like domain, the EGF-like domain, each of the nine consensus repeats, and the transmembrane region. Each of the two deletions found in the variant cDNAs is precisely encoded by an exon, suggesting that these forms of GMP-140 are derived from alternative splicing of mRNA. Transcripts encoding the putative soluble form of GMP-140 can be amplified from both platelet and endothelial cell RNA by PCR (Johnston et al. 1990).

27.2.3 Murine P-Selectin

P-selectin contains a NH2-terminal carbohydrate-recognition domain, an epidermal growth factor motif, nine consensus repeats, a transmembrane domain, and a cytoplasmic tail. E-selectin (ELAM-1) and P-selectin (PADGEM) have both been described as human endothelial cell adhesion molecules for neutrophils and monocytes. The molecular cloning and sequencing of murine cDNA for P-selectin revealed the presence of lectin, EGF-like, transmembrane, and cytoplasmic domains, which are highly conserved between mouse and human, with an overall amino acid identity of 79% (Sanders et al. 1992; Weller et al. 1992). cDNA clones covering the full-length coding sequence of the homologous mouse proteins for both endothelial selectins were isolated by Weller et al. (1992). Rat P-selectin cDNA shows a significant nucleotide and amino-acid identity with human and mouse P-selectin. Similar to mouse P-selectin, the rat sequence lacks the equivalent of human complement regulatory protein-like repeat 2 (CR2). Seven potential N-linked glycosylation sites are conserved between the three species, suggesting that carbohydrate modification

may play an important role in P-selectin function. P-selectin mRNA is undetectable in tissues of vehicle-treated animals.

Mouse P-selectin, like E-selectin, is transiently induced by TNF-α in several endothelioma cell lines derived from mouse tissues. The TNF induced, newly synthesized P-selectin protein is detected on the cell surface. Thus, P-selectin can be regulated on two different levels. The transport of stored P-selectin to the cell surface is controlled by regulated secretion of storage granules. Cell surface appearance of E an d P selectins on human umbilical vein endothelial cells (HUVEC) can be regulated by different mechanisms: E-selectin is transcriptionally induced, within hours, by TNF-α while P-selectin is transported from storage granules to the plasma membrane within minutes upon induction by various stimulating agents. After injection of endotoxin, the cellular response in vivo includes a rapid increase in the level of mRNA, presumably for new synthesis of P-selectin. After administration of endotoxin, the highest levels of mRNA expression were detected in liver, lung, kidney, thymus, spleen, and small intestine and heart (Sanders et al. 1992; Auchampach et al. 1994).

27.2.3.1 Rabbit P-Selectin

In rabbit platelets, P-selectin is an alpha-granule membrane protein that mediates leukocyte adhesion and thrombus propagation. The sequences of tryptic peptides of rabbit P-selectin showed an overall sequence identity of 74% with human P-selectin, and 69–77% identity with cow, dog, mouse, rat and sheep P-selectins. The apparent molecular mass of reduced rabbit P-selectin is 117 + 7 kDa which is approximately 8 kDa larger than the unreduced protein (109 + 5 kDa). Rabbit P-selectin appears smaller than human P-selectin, but is comparable to other species P-selectins, that have fewer 'complement regulatory protein' repeat domains. Rabbit P-selectin is nearly absent from the surface of platelets (290 + 30 molecules/cell). However, cellular activation with thrombin causes nearly a 30-fold increase in expression to 14,200 + 1,100 molecules/cell. P-selectin is expressed on the surface of rabbit platelets activated by other agonists like ADP, A23817 and epinephrine. P-selectin in rabbit platelets is similar in structure, cell localization and expression to human and other species P-selectins (Reed et al. 1998).

27.2.4 P-Selectin Promoter

27.2.4.1 Multiple Initiation Sites in 5′-Flanking Region of P-Selectin Gene

The 5′-flanking region of the human P-selectin gene shows multiple transcriptional initiation sites from -95 to -25 nucleotides relative to the start of protein-coding sequence. P-selectin gene is regulated by a combination of cis elements and their cognate transcription factors. Transfection experiments indicated that the sequence from -249 to -13 was sufficient to promote high level gene expression. Deletions to -197, -147, and -128 gradually reduced expression to basal levels, and further deletion to -100 abolished expression. The putative regulatory elements in short 5′-flanking sequence included a CACCC sequence, two inverted repeats similar to binding sites for the Ets and NF-kB/rel families, a GATA motif, and a sequence related to the GT-IIC element of the SV40 enhancer. The GATA element was functional, as it bound recombinant GATA-2 (Pan and McEver 1993).

27.2.4.2 Species-Specific Mechanisms for Transcriptional Regulation in Endothelial Cells

The 5′-flanking region of murine P-selectin gene was compared with the human gene. The murine and human genes shared conserved Stat-like, Hox, Ets, GATA, and GT-IIC elements. In the murine gene, a conserved GATA element bound to GATA-2 and functioned as a positive regulatory element, whereas a conserved Ets element bound to GA-binding protein and functioned as a negative regulatory element. However, the murine P-selectin gene had several features not found in the human gene. These included an insertion from -987 to -649 that contained tandem GATA and tandem AP1-like sequences, which resembled enhancers in β-globin locus control regions. Both tandem elements bound specifically to nuclear proteins. The murine gene lacked the unique κB site specific for p50 or p52 homodimers found in the human gene. Instead, it contained two tandem κB elements and a variant activating transcription factor/cAMP response element site, which closely resembled sites in the E-selectin gene that are required for TNF-α or LPS-inducible expression. Deletional analysis of the murine 5′-flanking region revealed several sequences that were required for either constitutive or inducible expression (Pan et al. 1998a).

27.2.4.3 kB Site in P-Selectin Promoter

Pan and McEver (1995) identified and characterized a kB site (-218GGGGGTGACCCC-207) in the promoter of the human P-selectin gene. The κB site is unique in that it binds constitutive nuclear protein complexes containing p50 or p52, but not inducible nuclear protein complexes containing p65. Furthermore, the element bound recombinant p50 or p52 homodimers, but not p65 homodimers. The p50 or p52 homodimers contacted the guanines at positions -218 to -214 on the coding strand and at -210 to -207 on the noncoding strand. Changes in the three central residues at -213 to -211 altered binding specificity for members of the NF-kB/Rel family. Data suggest that Bcl-3 differentially regulates the effects of p50 and p52 homodimers bound to kB site of the

P-selectin promoter. This site may be a prototype for kB elements in other genes that bind specifically to p50 and/or p52 homodimers.

kB Sites and an ATF/CREB for TNF-α- or LPS-Induced Expression of Murine P-Selectin Gene: The ATF-a_o cDNA, a variant of the ATF/CREB transcription factor family contains a large in-frame deletion of 525 bp that removes the P/S/T-rich putative transactivation domain and binds E-selectin promoter, NF-ELAM1/δ A. The putative mRNAs for ATF-a_o and ATF-a are present at varying ratios in different tissues. ATF-a_o is an important member of the ATF family with a negative regulatory role in transactivation (Pescini et al. 1994). The TNF-α and LPS augment the expression of a reporter gene driven by murine, but not the human P-selectin promoter in transfected endothelial cells. The regions from -593 to -474 and from -229 to -13 in the murine P-selectin promoter are required for TNF-α or LPS to stimulate reporter gene expression. Within these regions, there are two tandem kB elements, a reverse-oriented kB site and a variant ATF/cAMP response element (ATF/CRE), that participate in TNF-α or LPS-induced expression. The tandem kB elements bound to NF-kB heterodimers and p65 homodimers, the reverse-oriented kB site bound to p65 homodimers, and the variant ATF/CRE bound to nuclear proteins that included ATF-2. Co-overexpression of p50 and p65 enhanced murine P-selectin promoter activity in a kB site-dependent manner. Results indicated that kB sites and the variant ATF/CRE are required for TNF-α and LPS to optimally induce the expression of murine P-selectin gene. The presence of these elements in the murine, but not the human, P-selectin gene may explain in part why TNF-α or LPS stimulates transcription of P-selectin in a species-specific manner. Thus, both species-specific and conserved mechanisms regulate transcription of the human and murine P-selectin genes (Pan et al. 1998b).

Interference of Sp1 and NF-kB: Gene activation by NF-kB/Rel transcription factors is modulated by synergistic or antagonistic interactions with other promoter-bound transcription factors. For example, Sp1 sites are often found in NF-kB-regulated genes, and Sp1 can activate certain promoters in synergism with NF-kB through nonoverlapping binding sites. It was found that Sp1 acts directly through a subset of NF-kB binding GC box sites. In contrast, NF-kB does not bind to a GC box Sp1 site. Sp1 can activate transcription through immunoglobulin k-chain enhancer or P-selectin promoter NF-kB sites. The p50 homodimers replace Sp1 from the P-selectin promoter by binding site competition and thereby either inhibit basal Sp1-driven expression or, in concert with Bcl-3, stimulate expression. The interaction of Sp1 with NF-kB sites thus provides a means to keep an elevated basal expression of NF-kB-dependent genes in the absence of activated nuclear NF-kB/Rel (Hirano et al. 1998).

27.2.4.4 Stat6 Activation Is Essential for IL-4 Induction of P-Selectin Transcription

Agonists of P-selectin expression fall into two categories: those that induce a very rapid, transient increase, lasting only hours, and those that induce prolonged upregulation lasting days. The latter group includes IL-4 that is a mediator of chronic P-selectin upregulation. The increase in P-selectin expression induced by IL-4 results from increased transcriptional activation of the P-selectin gene. Khew-Goodall et al. (1999) demonstrated the existence of two functional signal transducers and activator of transcription 6 (Stat6) binding sites on the P-selectin; binding of at least one site at activated Stat6 is essential for IL-4-induction in P-selectin transcription. Site 1 (nt -142) bound Stat6 with a higher affinity than did site 2 (nt -229). IL-4 also induced prolonged activation of Stat6, which was contingent on the continuous presence of IL-4. The sustained activation of Stat6 induced by IL-4 is likely to be a key factor leading to the prolonged activation of the P-selectin promoter, thereby resulting in prolonged P-selectin upregulation.

27.2.4.5 c-GMP Dependent Down-Regulation of P-Selectin Expression

The NO receptor, soluble guanylate cyclase (sGC), is expressed in endothelial cells. Fluorescence-activated cell sorting analysis in vitro and a specific P-selectin antibody in vivo revealed that selective down-regulation of P-selectin expression accounted the anti-adhesive effects of sGC activation. Thus, sGC plays a key anti-inflammatory role by inhibiting P-selectin expression and leukocyte recruitment (Ahluwalia et al. 2004).

27.2.5 Structure-Function Studies

27.2.5.1 Amino Acid Residue in E- and P-Selectin EGF Domains and Carbohydrate Specificity

Both E- and P-selectin have an EGF domain that is immediately adjacent to C-terminal lectin domain. The mutagenic substitution of single amino acid residues in either the P- or E-selectin EGF domain can dramatically alter selectin binding to sLe^x, heparin, or sulfatide. Substitution of E- and P-selectin EGF domain residue Ser128 with an arginine results in E- and P-selectin proteins that have lost the requirement for α1-3-linked fucose and are thus able to bind to sialyllactosamine (Graves et al. 1994). Additionally, conservative substitution of EGF domain residues 124 and 128 can alter E-selectin binding such that it is able to adhere to heparin or sulfatide and reduce P-selectin adherence to

these ligands. The distance between the substituted EGF domain amino acid residues and the primary carbohydrate binding site within the lectin domain and their relative positioning as determined by crystal structure analysis of the E-selectin lectin and EGF domains suggest that there is little direct contact between the two domains. Selectin oligosaccharide binding may be modulated by both domains and that wild-type E- and P-selectin/sLe^x binding interactions may be significantly different from those previously hypothesized (Revelle et al. 1996a).

27.2.5.2 Monomeric Soluble- and Membrane P-Selectins

Ushiyama et al. (1993) expressed two soluble forms of P-selectin, one truncated after the ninth repeat (tPS) and the other lacking the transmembrane domain due to alternative RNA splicing (asPS). When visualized by electron microscopy, each was a monomeric rod-like structure with a globular domain at one end, whereas membrane P-selectin (mPS) from platelets formed rosettes with the globular domains facing outward. While tPS and asPS are asymmetric monomers, mPS is oligomeric. HL-60 cells adhered to immobilized tPS and asPS, although less efficiently than to mPS. 125I-Labeled tPS and asPS bound to approximately 25,000 sites/neutrophil and approximately 36,000 sites/HL-60 cell with an apparent K_D of 70 nM. Treatment of HL-60 cells with O-sialoglycoprotease eliminated the binding sites for asPS. Thus; (1) P-selectin is a rigid, asymmetric protein; (2) monomeric soluble P-selectin binds to high affinity ligands with sialylated O-linked oligosaccharides on leukocytes; and (3) oligomerization of mPS enhances its avidity for leukocytes (Ushiyama et al. 1993).

27.2.5.3 Cytoplasmic Domain of P-Selectin

The cytoplasmic domains of many membrane proteins have short sequences, usually including a tyrosine or a di-leucine, that function as sorting signals. The cytoplasmic domain of P-selectin was sufficient to confer rapid turnover on LDL-R. The 35-residue cytoplasmic domain of P-selectin contains signals for sorting into regulated secretory granules, for endocytosis, and for movement from endosomes to lysosomes. The domain has a membrane-distal sequence, YGVFTNAAF that resembles some tyrosine-based signals. Deletion of 10 amino acids from the cytoplasmic domain of P-selectin implicates this sequence as a necessary element of a lysosomal targeting signal. Sorting of P-selectin away from efficiently recycled proteins occurs in endosomes. This sorting event represents a constitutive equivalent of receptor down regulation, and may function to regulate the expression of P-selectin at the surface of activated endothelial cells (Green et al. 1994). However, mutations and deletions in the putative tyrosine-based motif in the cytoplasmic tail of human P-selectin did not clearly implicate these residues as critical components of a short internalization signal in transfected CHO cells, and it was not possible to identify a short internalization signal in the cytoplasmic tail of P-selectin. Residues throughout the cytoplasmic domain, and perhaps the transmembrane sequence to which the domain is attached, affect the efficiency of internalization (Setiadi et al. 1995).

Norcott et al. (1996) reported that P-selectin contains signals that target a chimera composed of horseradish peroxidase (HRP) and P-selectin, to the synaptic-like microves. Mutagenesis of the chimera followed by transient expression showed that at least two different sequences within the carboxy-terminal cytoplasmic tail of P-selectin are necessary, but that neither is sufficient for trafficking to the synaptic-like microvesicles (SLMV). One of these sequences is centred on the 10 amino acids of the membrane-proximal C1 exon that is also implicated in lysosomal targeting. The other sequence needed for trafficking to the SLMV includes the last four amino acids of the protein. Blagoveshchenskaya et al. (1998b) discovered a lysosomal targeting signal, KCPL, located within the C1 domain of the cytoplasmic tail. Alanine substitution of this tetrapeptide reduced lysosomal targeting to the level of a tailless HRP-P-selectin chimera, which was previously found to be deficient in both internalization and delivery to lysosomes. A proline residue within this lysosomal targeting signal makes a major contribution to the efficiency of lysosomal targeting. The sequence KCPL within the cytoplasmic tail of P-selectin is a structural element that mediates sorting from endosomes to lysosomes. A balance of positive and negative signals is required for proper lysosomal sorting of P-selectin. Within the sequence KCPL, Cys-766 plays a major role along with Pro-767, whereas Lys-765 and Leu-768 make no contribution to promoting lysosomal targeting. In addition, HRP-P-selectin chimeras were capable of acylation in vivo with ^{3H}palmitic acid at Cys-766, since no labeling of a chimera in which Cys-766 was replaced with Ala was detected (Blagoveshchenskaya et al. 1998a). The cytoplasmic domain is acylated at Cys766 through a thioester bond. Fatty acid acylation may regulate intracellular trafficking or other functions of P-selectin (Fujimoto et al. 1993).

P-selectin mutants expressed in AtT-20, a murine cell line with secretory granules containing the hormone corticotropin ('ACTH') revealed that wild-type P-selectin and mutants with alanine substitutions at 14 different positions in the cytoplasmic tail were concentrated in the tips of the cellular processes, which contained the majority of corticotropin granules. However, targeting to the cell tips was greatly decreased for Tyr^{777}—>Ala, Tyr^{777}—>Phe, Gly^{778}—>Ala, Phe^{780}—>Ala and Leu^{768}/Asn^{769}—>Ala/Ala mutants. Results indicated that Tyr^{777}, Gly^{778} and Phe^{780} form part of an atypical tyrosine-based motif, which also requires the

presence of Leu768 and/or Asn769 to mediate sorting of P-selectin to secretory granules (Modderman et al. 1998).

Within the cytoplasmic domain of P-selectin, Tyr^{777} is needed for the appearance of P-selectin in immature and mature dense core granules (DCG), as well as for targeting to synaptic-like microvesicles (SLMV). The latter destination also requires additional sequences (Leu^{768} and $^{786}DPSP^{789}$) which are responsible for movement through endosomes en route to the SLMV. Leu^{768} also mediates transfer from early transferrin (Trn)-positive endosomes to the lysosomes; i.e., operates as a lysosomal targeting signal. Together, results are consistent with a model of SLMV biogenesis which involves an endosomal intermediate in neuroendocrine PC12 cells. In addition, the impairment of SLMV or DCG targeting results in a concomitant increase in lysosomal delivery, illustrating the entwined relationships between routes leading to regulated secretory organelles (RSO) and to lysosomes (Blagoveshchenskaya et al. 1999). The addition of the cytoplasmic domain of P-selectin to FIX modifies the cellular fate of the FIX molecule by directing the recombinant protein toward regulated-secretory granules without altering its coagulant activity (Plantier et al. 2003).

27.2.6 P-Selectin-Sialyl Lewis^x Binding Interactions

P-selectin adhesion to leukocytes is mediated by the amino-terminal lectin domain that binds sLe^x carbohydrate (Neu5Acα2-3Galβ1-4(Fucα1-3)GlcNAc). Using known binding interactions that occur between the rat MBP and its ligand (oligomannose) as a template (Weis et al. 1992), and substituting Ala-77 with lysine, it was observed that P-selectin-carbohydrate binding specificity changed from sLe^x to oligomannose. Results indicated that P-selectin binds sLe^x in a shallow cleft that is similar to the MBP saccharide-binding cleft. Additionally, Lys-113 has been implicated earlier in P-selectin binding to both sLe^x and 3-sulfated galactosylceramide (sulfatide). But Revelle et al. (1996b) demonstrated that Lys-113 is probably not involved in P-selectin binding to either sulfatide or sLe^x. Functionally, it appeared that P-selectin has retained a conserved carbohydrate and calcium coordination site that enables it to bind carbohydrate in a manner that is quite similar to that which has been determined for the rat mannose-binding protein (Revelle et al. 1996b). Several peptides corresponding to amino acid sequences within the lectin domains of selectins inhibit neutrophil (PMN) adhesion to P-selectin. One of the active regions, 109–118 aa contains residues, which are critical for E-selectin binding to sLe^x counter receptor. Peptide sequences which inhibited PMN binding to the fusion proteins were not necessarily those that inhibited fusion protein binding to sLe^x. In addition, various amino acid substitutions could be tolerated at the 111 and 113 positions without altering inhibitory activity. Modeling suggests that structural conformations of peptide analogues could explain the differences in biological activity of peptide analogues compared to mutants of the native protein (Tam et al. 1996).

Compared to weak binding of selectins to sLe^x-like glycans, selectins bind with high-affinity to specific glycoprotein counterreceptors, including PSGL-1. Somers et al. (2000) reported crystal structures of human P- and E-selectin constructs containing the lectin and EGF (LE) domains co-complexed with s-Le^x the crystal structure of P-selectin LE co-complexed with the N-terminal domain of human PSGL-1 modified by both tyrosine sulfation and s-Le^x. These structures reveal differences in how E- and P-selectin bind SLe^x and the molecular basis of the high-affinity interaction between P-selectin and PSGL-1.

27.2.7 Functions of P-Selectin

27.2.7.1 Mediation of Leukocyte and Platelet Rolling on the Vessel Wall

Selectins not only mediate leukocyte rolling, but also platelet rolling on the vessel wall. The functional significance of platelet rolling has not been established. The process could be important for hemostasis leading to firm platelet adhesion at sites of denuded endothelium and/or in inflammation. After activation, platelets may help in leukocyte recruitment as shown by studies of lymphocyte homing to peripheral lymph nodes. Surprisingly, work with the P-selectin mutant mice has also revealed an anti-inflammatory aspect of platelet P-selectin. P-selectin binding to leukocytes promoted the transcellular production of an anti-inflammatory mediator limiting the extent of acute glomeluronephritis. In addition, soluble P-selectin was shown to be shed from both activated platelets and endothelium and there are strong indications that it too could have an attenuating effect on inflammatory disease progression. The selectin-deficient mice demonstrated crucial role of P- and E-selectins in the homing of hematopoietic progenitor cells to the bone marrow. The selectin mutant mice have taught us a great deal about the role of selectins in normal physiology and in pathology. Further studies are needed to explore the regulation of shedding of the selectins and the function of soluble selectins in vivo. Exploring new territories of selectin-mediated interactions may provide a basis for developing

new interventions and treatments for diseases in which the role of selectins has not yet been suspected (Hartwell and Wagner 1999).

27.2.7.2 Migration of T Lymphocyte Progenitors to Thymus

It has been shown that P-selectin is expressed by thymic endothelium and that lymphoid progenitors in bone marrow and thymus bind P-selectin. Parabiosis, competitive thymus reconstitution and short-term homing assays indicated that P-selectin and its ligand PSGL-1 are functionally important components of the thymic homing process. Accordingly, thymi of mice lacking PSGL-1 contained fewer early thymic progenitors and had increased empty niches for prothymocytes compared with wild-type mice. Furthermore, the number of resident thymic progenitors controling thymic expression of P-selectin suggested that regulation of P-selectin expression by a thymic 'niche occupancy sensor' may be used to direct progenitor access (Rossi et al. 2005).

27.2.7.3 Acute Emigration of Neutrophils

Whereas P-selectin is known to be involved in early stages of an inflammatory response, Johnson et al. (1995) indicated that it is additionally responsible for leukocyte rolling and macrophage recruitment in more prolonged tissue injury. P-Selectin also mediates rolling or slowing of neutrophils, while ICAM-1 contributes to the firm adhesion and emigration of neutrophils. Removing the function of either molecule partially prevents neutrophil emigration. P-selectin-deficient mice exhibit peripheral neutrophilia (Mayadas et al. 1993). This is not caused by changes in bone marrow precursors nor by a lack of neutrophil margination. Bullard et al. (1995) generated a line of mice with mutations in both of these molecules. While mice with either mutation alone show a 60–70% reduction in acute neutrophil emigration into the peritoneum during *S. pneumoniae*-induced peritonitis, double mutant mice show a complete loss of neutrophil emigration. In contrast, neutrophil emigration into the alveolar spaces during acute *S. pneumoniae*-induced pneumonia is normal in double mutant mice. These data demonstrate organ-specific differences, since emigration into the peritoneum requires both adhesion molecules while emigration into the lung requires neither. In the peritoneum, P-selectin-independent and ICAM-1-independent adhesive mechanisms permit reduced emigration when one of these molecules is deficient, but P-selectin-independent mechanisms cannot lead to ICAM-1-independent firm adhesion and emigration (Bullard et al. 1995).

27.2.7.4 P-Selectin Mediates Adhesion of Leukocytes, Platelets, and Cancer Cells

The P-selectin has long been known to support leukocyte rolling and emigration at sites of inflammation. Rolling under the hydrodynamic drag forces of blood flow is mediated by the interaction between selectins and their ligands across the leukocyte and endothelial cell surfaces. The high strength of binding combined with force-dependent rate constants and high molecular elasticity are tailored to support physiological leukocyte rolling (Fritz et al. 1998). Multiple-targeted deficiencies in selectins revealed a predominant role for P-selectin in leukocyte recruitment (Robinson et al. 1999). P-selectin is also a key molecule in hemostasis and thrombosis, mediating platelet rolling, generating procoagulant microparticles containing active tissue factor and enhancing fibrin deposition. Elevated levels of plasma P-selectin are indicative of thrombotic disorders and predictive of future cardiovascular events. Because the interaction between P-selectin and its receptor P-selectin glycoprotein ligand-1 (PSGL-1/CD162) represents an important mechanism by which P-selectin induces the formation of procoagulant microparticles and recruits the microparticles to thrombi, anti-thrombotic strategies are currently aimed at inhibiting this interaction. Recent developments also suggest that the procoagulant potential of P-selectin could be used to treat coagulation disorders such as hemophilia A (Cambien and Wagner 2004).

Stimulated endothelial cells and activated platelets express P-selectin, which interacts with PSGL-1 for leukocyte rolling on stimulated endothelial cells and heterotypic aggregation of activated platelets onto leukocytes. Cross-linking of PSGL-1 by P-selectin also primes leukocytes intracellularly for cytokine and chemoattractant-induced β2-integrin activation for firm adhesion of leukocytes. Furthermore, P-selectin mediates heterotypic aggregation of activated platelets to cancer cells and adhesion of cancer cells to stimulated endothelial cells. P-selectin blockade significantly inhibits inflammation and neointimal formation after arterial injury. In atherosclerosis, both platelet and endothelial cell P-selectins are important. Platelet P-selectin expression, but not endothelial P-selectin, plays a crucial role in the development of neointimal formation after arterial injury, and therapeutic strategies targeting leukocyte-platelet interactions could be effective in inhibiting restenosis (Wang et al. 2005). Chen and Geng (2006) provided a comprehensive summary of the functional roles and the biological importance of P-selectin-mediated cell adhesive interactions in the pathogeneses of inflammation, thrombosis, and the growth and metastasis of cancers (Chen and Geng 2006). Crystal structures of lectin and EGF–like domains of P-selectin show 'bent' and 'extended' conformations. An extended conformation would be 'favored' by forces exerted on a selectin bound at one end to a ligand and at the other end to a cell experiencing hydrodynamic drag force. The introduction of an *N*-glycosylation site to 'wedge open' the interface between the lectin and EGF-like domains of P-selectin increased the affinity of

P-selectin for its ligand PSGL-1, and thereby the strength of P-selectin-mediated rolling adhesion. Similarly, an asparagine-to-glycine substitution in the lectin-EGF-like domain interface of L-selectin enhanced rolling adhesion under shear flow. These results demonstrate that force, by 'favoring' an extended selectin conformation, can strengthen selectin-ligand bonds (Phan et al. 2006).

The selectins must resist applied forces to mediate leukocyte tethering and rolling along the endothelium and have 2 conformational states. Selectin–ligand bond dissociation increases only modestly with applied force, and exhibits catch bond behavior in a low-force regime where bond lifetimes counterintuitively increase with increasing force. Both allosteric and sliding–rebinding models have emerged to explain catch bonds. Waldron TT and Springer (2009) suggest a large residue into a cleft that opens within the lectin domain to stabilize the more extended, high-affinity selectin conformation. This mutation stabilizes the high-affinity state, but surprisingly makes rolling less stable. The position of the mutation in the lectin domain provides evidence for an allosteric pathway through the lectin domain, connecting changes at the lectin–EGF interface to the distal binding interface (Fig. 27.2).

Superoxide Anion Release by Monocytes and Neutrophils Through P-Selectin: The leukocytes are functionally modified by their adhesion to activated platelets. The levels of superoxide anion production were found to be markedly elevated when thrombin-activated platelets were used. The extent of this enhancement was much smaller when leukocytes were cultured with resting platelets than activated platelets. The membranes prepared from activated platelets also induced superoxide anion production, but the culture supernatant of activated platelets did not. This indicated that the adhesion of activated platelets to the leukocytes through P-selectin is a crucial step for the activation of leukocyte function, and support the idea that activated platelets are actively involved in inflammation processes (Nagata et al. 1993).

Two Sites on P-Selectin Are Involved in Adhesion of Monocytes to Thrombin-Activated EC: Peptides derived from both the lectin (residues 19–34 and 51–61) and EGF-like (residues 127–139) domains inhibit the adhesion of peripheral blood mononuclear cells (PBMC), elutriated monocytes and a monocytic cell line (U937) to thrombin-activated EC. All three peptides, when conjugated to BSA and coated on plastic plates, mediated U937 cell adhesion. This study shows that two sites on P-selectin, the lectin and EGF-like domains, are involved in the adhesion of monocytes to thrombin-activated EC (Murphy and McGregor 1994).

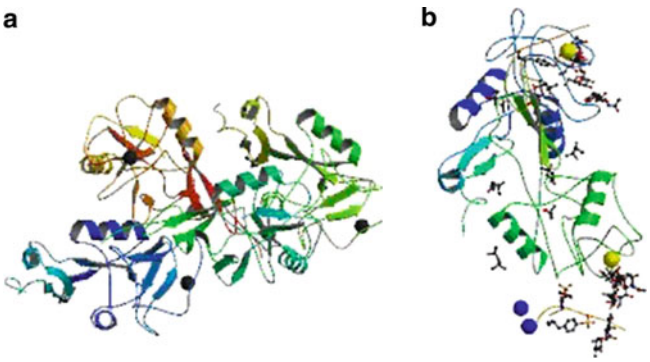

Fig. 27.2 (**a**) Crystal structure of human P-selectin lectin/EGF domains (PDB ID: 1G1Q); (**b**) crystal structure of P-selectin lectin/EGF domains complexed with PSGL-1 peptide (PDB ID:1G1S) (Somers et al. 2000)

27.2.7.5 P-Selectin Regulates MCP-1 and TNF-α Secretion

Adhesion of human monocytes to P-selectin, the most rapidly expressed endothelial tethering factor, increased the secretion of monocyte chemotactic protein-1 (MCP-1) and TNF-α by the leukocytes when they were stimulated with platelet-activating factor (PAF). Tethering by P-selectin specifically enhanced nuclear translocation of NF-kB required for expression of MCP-1, TNF-α, and other immediate-early genes. Results demonstrate that P-selectin, through its ligands on monocytes, may locally regulate cytokine secretion in inflamed tissues (Weyrich et al. 1995). P-selectin plays an important role in PAF-induced injury in mice, and the selectins and the integrin-ICAM-1 system work in concert to mediate the inflammatory response to PAF in vivo (Sun et al. 1997).

27.2.7.6 B Lymphocyte Binding to E- and P-Selectins

Activated but not resting B cells are able to interact with E and P selectins. This binding capacity of activated B cells paralleles the induction of different carbohydrate epitopes (Lewis^x, sialyl-Lewis^x, CD57 and CDw65) as well as other molecules bearing these or related epitopes in myeloid cells (L-selectin, αLβ2 and αXβ2 integrins, and CD35) involved in the interaction of different cell types with selectins. B cells infiltrating inflamed tissues like in Hashimoto's thyroiditis, also express these selectin-binding carbohydrates in parallel with the expression of E-selectin by surrounding follicular dendritic cells. Thus, in addition to the involvement of integrins, E- and P-selectins could play an important role in the interaction of B lymphocytes with the endothelium during B cell extravasation into lymphoid tissues and inflammatory foci as well as in their organization into lymphoid organs (Postigo et al. 1994).

27.2.7.7 Nonrolling Interaction Mediated by P-Selectin

The renal glomerulus is one of the few sites within the microvasculature in which leukocyte recruitment occurs in capillaries. Following infusion of anti-glomerular basement membrane (GBM) Ab, leukocytes became adherent in glomerular capillaries via a process of immediate arrest, without undergoing prior detectable rolling. However, despite the absence of rolling, this recruitment involved nonredundant roles for the P-selectin/P-selectin glycoprotein ligand-1 and β2 integrin/ICAM-1 pathways, suggesting that a novel form of the multistep leukocyte adhesion cascade occurs in these vessels. Perhaps, anti-GBM Ab-induced leukocyte adhesion in glomeruli occurs via a pathway that involvs a nonrolling interaction mediated by platelet-derived P-selectin (Kuligowski et al. 2006).

27.2.7.8 P-Selectin-Dependent, PSGL-1-Independent Rolling

Interestingly, antibodies and pharma-cological inhibitors (e.g., rPSGL-Ig) that target the N-terminus of PSGL-1 reduce but do not abolish P-selectin-dependent leukocyte rolling in vivo whereas PSGL-1-deficient mice have almost no P-selectin-dependent rolling. Therefore, Ridger et al. (2005) investigated mechanisms of P-selectin-dependent, PSGL-1-independent rolling. Data suggest that leukocytes can continue to roll in the absence of optimal P-selectin/PSGL-1 interaction using an alternative mechanism that involves P-selectin-, L-selectin-, and sialyl Le^x-bearing ligands.

27.3 P-Selectin Glycoprotein Ligand-1 (PSGL-1)

27.3.1 PSGL-1: The Major Ligand for P-Selectin

Based on site-directed mutagenesis, blocking monoclonal antibodies, and biochemical analyses, the extreme amino terminal extracellular domain of PSGL-1 is critical for interactions with selectins The current hypothesis is that for high affinity interactions with P-selectin, PSGL-1 must contain O-glycans with a core-2 branched motif containing the s-Lewis X antigen (NeuAc α2—>3Gal β1—>4[Fuc α1—>3]GlcNAc β1—>R). In addition, high affinity interactions require the co-expression of tyrosine sulfate on tyrosine residues near the critical O-glycan structure. This review addresses the biochemical evidence for this hypothesis and the evidence that PSGL-1 is an important in vivo ligand for cell adhesion (Cummings 1999; Moore 1998; Kum et al. 2009).

27.3.1.1 Human (PSGL-1, CD162)

Human P-selectin glycoprotein ligand-1 (PSGL-1, CD162) is expressed on the surface of myeloid cells and serves as the high affinity counter receptor for P-selectin. PSGL-1 is a disulfide-bonded, homodimeric mucin (approximately 250 kDa) on leukocytes that binds to P-selectin on platelets and endothelial cells during the initial steps in inflammation. PSGL-1 is a transmembrane glycoprotein, which is constitutively expressed on leukocytes, binds selectins. It mediates the initial tethering of leukocytes to activated platelets and endothelium. PSGL-1 is an essential adhesive molecule mediating the rolling of leukocytes on the endothelial cells and the recruitment of leukocytes to the inflamed tissue. In addition to its direct role in capture of leukocytes from the blood stream, PSGL-1 also functions as a signal-transducing receptor and initiates a series of intracellular signal events during the activation of leukocytes. PSGL-1 shares common features with platelet glycoprotein Ibα. A recently described polymorphism in this receptor that results in a variable number of tandem repeats (VNTR) sequence present either 16, 15 or 14 times (alleles A, B or C) could, similar to GP Ibα, be functionally relevant. PSGL-1 is a disulfide-bonded, homodimeric mucin (approximately 250 kDa) on leukocytes that binds to P-selectin on platelets and endothelial cells during the initial steps in inflammation. Genes involved in inflammatory processes are candidates for predisposition to prothrombotic syndromes. Moreover, adhesion to E-selectin inhibits the proliferation of human $CD34^+$ cells isolated either from blood, or steady-state bone marrow (Winkler et al. 2004). A dimeric sialoglycoprotein from myeloid cells with subunits of Mr of 120 kDa is selectively recognized by P-selectin. This P-selectin ligand carries α2-3-linked sialic acids and the sialyl-$Lewis^x$ (sialyl Le^x) tetrasaccharide motif and contains < 1% of the total membrane-bound sialic acids and a very small fraction of the total sialyl Le^x on neutrophil membranes. The predominant form of sialic acid on the ligand is N-acetylneuraminic acid. The P-selectin ligand carries large numbers of closely spaced sialylated O-linked oligosaccharides. The 120-kDa ligand is the major determinant of P-selectin: myeloid cell interaction in vivo (Norgard et al. 1993). Platelet PSGL-1 expression is 25–100-fold lower than that of leukocytes. Presence of a functional PSGL-1 on platelets suggests one of the mechanism by which selectins and their ligands participate in inflammatory and/or hemostatic responses (Frenette et al. 2000).

The predicted amino acid sequence of a functional ligand for P-selectin from an HL-60 reveals a novel mucin-like transmembrane protein. Binding of transfected COS cells to P-selectin requires coexpression of both the protein ligand and a fucosyltransferase. This binding is calcium dependent and can be inhibited by mAb to P-selectin. Cotransfected COS cells express the ligand as a homodimer of 220 kDa. A soluble ligand construct, when coexpressed with fucosyltransferase in COS cells, also mediates P-selectin binding and is immunocrossreactive with the

major HL-60glycoprotein that specifically binds P-selectin (Sako et al. 1993). In vitro studies have suggested that PSGL-1 may also be a ligand for E- and L-selectins. However, P-selectin-PSGL-1 interaction alone is sufficient to mediate rolling in vivo and that E-selectin-PSGL-1 interaction supports slow rolling (Norman et al. 2000).

27.3.1.2 The Mouse Homolog of PSGL-1

The *mouse* homolog of PSGL-1, flanking the entire ORF of 397 amino acids is composed of a single exon. Mouse and human PSGL-1 show an overall similarity of 67% and an identity of 50% and contain a similar domain organization. However, there are 10 threonine/serine-rich decameric repeats in mouse PSGL-1 as compared to 15 threonine-rich repeats in human PSGL-1. The mouse PSGL-1 gene, *Selpl,* was mapped to a position on mouse chromosome 5 (Chr 5). Moderate expression of a PSGL-1 mRNA occurs in species in most tissues and high levels of expression in blood, bone marrow, brain, adipose tissue, spleen, and thymus. Whereas certain mouse myeloid cell lines including PU5-1.8, WEHI-3B, and 32 DC13 express high levels of PSGL-1 mRNA, only WEHI-3B and 32 DC13 bind to P-selectin. WEHI-3B cells bind significantly better to P-selectin than to E-selectin. Thus, mouse PSGL-1 has structural and functional homology to human PSGL-1 but is characterized by differences in the composition and number of the decameric repeats. PSGL-1 on mouse myeloid cells is critical for high-affinity binding to P-selectin but not E-selectin (Yang et al. 1996).

27.3.1.3 PSGL-1 in Equine

A high baseline level of P-selectin expression in circulating equine platelets suggests a primed state toward inflammation and thrombosis via P-selectin/PSGL-1 adhesion. Equine PSGL-1 (ePSGL-1) subunit is predicted to be 43 kDa and composed of 420 amino acids with a predicted 18-amino-acid signal sequence showing 78% homology to hPSGL-1. Though earlier work has shown that binding of P-selectin requires sulfation of at least one of three tyrosines and O-glycosylation of one threonine in the N-terminus of human PSGL-1, the corresponding domain in ePSGL-1, spanning residues 19–43, contains only one tyrosine in the vicinity of two threonines at positions 25 and 41. The ePSGL-1 contains 14 threonine/serine-rich decameric repeats as compared to hPSGL-1 which contains 14–16 threonine-rich decameric repeats. The transmembrane and cytoplasmic domains display 91% and 74% homology to corresponding human PSGL-1 domains, respectively. Overall, there is 71% homology between ORF of ePSGL-1 and hPSGL-1. The greatest homologies between species exist in the transmembrane domain and cytoplasmic tail while substantial differences exist in the extra-cellular domain (Xu et al. 2005).

27.3.1.4 Bovine PSGL-1

The ORF of bovine PSGL-1 (bPSGL-1) cDNA is 1,284 bp in length, predicting a protein of 427 amino acids including an 18-amino-acid signal peptide, an extra-cellular region with a mucin-like domain, and transmembrane and cytoplasmic domains. The amino acid sequence of bPSGL-1 demonstrated 52%, 49% and 40% overall homology to equine, human and mouse, respectively. A single extracellular cysteine, at the transmembrane and extracellular domain junction, suggests a disulfide-bonding pattern. Alignment of bovine with equine, human and mouse PSGL-1 demonstrates high conservation of transmembrane and cytoplasmic domains, but diversity of the extracellular domain, especially in the anionic NH_2-terminal of PSGL-1, the putative P-selectin binding domain. In the NH_2-terminal of bPSGL-1, there are three potential tyrosine sulfation sites and three potential threonine O-glycosylation sites, all of which are required for P-selectin binding in human PSGL-1. The bPSGL-1 shares only 57% homology in amino acid sequence with the corresponding epitope region in human PSGL-1 without cross-reactivity with bovine leukocytes (Xu et al. 2006).

27.3.1.5 Eosinophil Versus Neutrophil PSGL-1

Studies have indicated an important role for P-selectin in eosinophil adhesion. Eosinophils bound to twofold more blood vessels within the nasal polyp tissue than neutrophils. The eosinophil P-selectin ligand is a sialylated, homodimeric glycoprotein consistent with the known structure of PSGL-1. However, expression of PSGL-1 by eosinophils was greater than on neutrophils. The eosinophil ligand had a molecular mass of approximately 10 kDa greater than the neutrophil ligand, which was not due to differences in N-glycosylation. Eosinophils expressed the 15-decapeptide repeat form of PSGL-1 compared with neutrophils that have the 16-decapeptide repeat form. The increased binding of eosinophils, compared with neutrophils, to P-selectin in both an ex-vivo and in vitro assay suggests that P-selectin may have a role directing the specific migration of eosinophils in diseases such as asthma (Symon et al. 1996). While the roles of P- and E-selectin in neutrophil recruitment are well established, the mechanisms of L-selectin-mediated neutrophil recruitment remain elusive. One proposal is that tethering is mediated by L-selectin on flowing neutrophils interacting with PSGL-1 on adherent neutrophils. To clarify this point, Shigeta et al. (2008) examined the impact of L-selectin deficiency in PSGL-1-deficient mice. In L-selectin and PSGL-1 double-knockout mice, Shigeta et al. (2008) provided evidence for the existence of another L-selectin ligand distinct from PSGL-1 in inflammation and indicated that such a ligand is expressed on endothelial cells, that promotes neutrophil rolling in vivo.

27.3.2 Genomic Organization

27.3.2.1 The PSGL-1Gene

The PSGL-1 gene from human placenta contains a single intron of approximately 9 kb in the 5′-untranslated region; the complete coding region resides in exon 2. The genomic clone differs from the cDNA clone isolated from HL-60 cells in that it encodes an extra copy of the decameric repeat located in the extracellular domain of PSGL-1. Further analysis indicated that the PSGL-1 genes of HL-60 and U-937 cells contain 15 repeats, whereas the PSGL-1 genes of polymorphonuclear leukocytes, monocytes, and several other cell lines contain 16 repeats. There was no functional difference among these two variants of PSGL-1. The organization of the PSGL-1 gene closely resembles those of CD43 and human platelet glycoprotein GPIb α, both of which have an intron in the 5′-noncoding region, a long second exon containing the complete coding region, and TATA-lesspromoters. The gene for human PSGL-1, designated SELPLG, was mapped to chromosome 12q24 (Veldman et al. 1995).

27.3.3 Specificity of PSGL-1 as Ligand for P-Selectin

P-, L, and E- Selectins Have Overlapping Leukocyte Ligand Specificities: Although, L-selectin binds multiple ligands expressed on endothelial cells and P-selectin is proposed to interact exclusively with PSGL-1 on leukocytes, one study showed that L-selectin binds leukocytes through PSGL-1, although at lower levels than P-selectin. L-selectin binding to PSGL-1 appeared to be specific since it was blocked by Abs to L-selectin or PSGL-1, and required appropriate glycosylation of PSGL-1. The lectin and EGF domains of L- and P-selectin contributed significantly to binding through similar, if not identical, regions of PSGL-1. The different chimeric selectins revealed that the lectin domain was the dominant determinant for ligand binding, while cooperative interactions between the lectin, EGF, and short consensus repeat domains of the selectins also modified ligand binding specificity. It seems that L-selectin binding to PSGL-1 expressed by leukocytes may mediate neutrophil rolling on stationary leukocytes bound to cytokine-induced endothelial cells, which is a L-selectin-dependent process (Tu et al. 1996). The proposed ligands for P- and E-selectin receptors contain the Le^x core and sialic acid. Since both E-selectin and P-selectin bind to sialylated Lex, Larsen et al. (1992) evaluated whether E-selectin and P-selectin recognize the same counter-receptor on leukocytes. Although sialic acid and Le^x are components of the P-selectin ligand and the E-selectin ligand, results indicated that the ligands are related, having overlapping specificities, but are structurally distinct. A protein component containing sialyl Le^x in proximity to sialyl-2,6 βGal structures on the P-selectin ligand may contribute to its specificity for P-selectin.

27.3.4 Structural Polymorphism in PSGL-1 and CAD Risk

27.3.4.1 PSGL-1 Is Highly Polymorphic and Shows Structural Polymorphism

P-selectin and P-selectin glycoprotein ligand constitutes a receptor/ligand complex that is likely to be involved in the development of atherosclerosis and its complications. PSGL-1 is highly polymorphic and contains a structural polymorphism that potentially indicates functional variation in the human population (Afshar-Kharghan et al. 2001; Tregouet et al. 2003). The functional relevance of a variable number of tandem repeats polymorphism affecting the PSGL-1 has been demonstrated. Platelet glycoprotein (GP) Ibα and leukocyte PSGL-1 are membrane mucins with a number of structural and functional similarities. Like GP Ibα, PSGL-1 is affected by a variable number of tandem repeat polymorphism in its mucin-like region. By PCR amplification of the genomic region encoding the PSGL-1 repeats, three allelic variants were identified in the human population. The three alleles-A, B, and C-from largest to smallest, contained 16, 15, and 14 decameric repeats, respectively, with the B variant lacking repeat 2 and the C variant retaining repeat 2 but lacking repeats 9 and 10. Allele frequencies were highest for the A variant and lowest for the C variant in the two populations studied (frequencies of 0.81, 0.17, and 0.02 in white persons and 0.65, 0.35, and 0.00 in Japanese). The coding and regulatory sequences of the PSGL-1 showed nine polymorphisms. The identified polymorphisms were genotyped in the AtheroGene study. Haplotype analysis revealed that two polymorphisms of PSGL-1, the M62I and the VNTR, independently influence plasma PSGL-1 levels. Conversely, haplotypes of PSGL-1 are not associated with CAD risk (Tregouet et al. 2003).

Hancer et al. (2005) determined the allele and genotype frequencies of polymorphisms GP Ibα Kozak and PSGL-1 in the Turkish population. Allele frequencies of T and C were calculated to be 0.873 and 0.127 for the GPIbα Kozak polymorphism and no significant difference was found between Turkish and French populations. In contrast, the difference between Turkish and Japanese population was highly significant. In the PSGL-1 group, allele frequencies of A, B and C were calculated as 0.818, 0.160, 0.022 respectively. Thus, for the PSGL-1, although the difference between Turkish and French populations was not significant, the difference between the Turkish and Japanese was extremely significant. A Turkish population database has

been established for these gene polymorphisms (Hancer et al. 2005).

Short Alleles Protect Against Premature Myocardial Infarction: Neutrophils, carrying short alleles, exhibit a significantly lower capacity to bind activated platelets. These alleles consistently protect against transient ischemic attack, probably because of their lesser adhesive capacity. The role of this polymorphism in premature myocardial infarction was evaluated for the fact that genetic risk factors are more relevant in the development of disease in young patients. Hence, Roldan et al. (2004) genotyped 219 Caucasian patients who had suffered a premature myocardial infarction (MI) and 594 control subjects from Mediterranean area. The frequency of the short alleles (B and C) was significantly lower in patients than in controls. Multiple regression analysis revealed that B and C alleles had an independent protective effect on the development of premature MI.

In Cerebro-Vascular Disease, CHD, and Venous Thrombosis: The variable number of tandem repeat (VNTR) polymorphism in the PSGL-1 gene has been associated with ischemic cerebro-vascular disease (CVD) and with CHD. A recently described polymorphism in this receptor that results in VNTR sequence present 16, 15 or 14 times (alleles A, B or C) could, similar to GPIbα be functionally relevant. The allelic frequency of this polymorphism in 469 individuals from the south of Spain, was similar to that described in other Caucasian populations: 85% A, 14% B and 1% C alleles. Lozano et al. (2001) identified two new polymorphisms genetically linked to the C isoform, resulting in the Ser273Phe and Met274Val changes. Neutrophils carrying the shortest C allele and the amino acid variations in residues 273 and 274 exhibited a significantly lower capacity to bind activated platelets than A/B and A/A samples. The distribution of VNTR was analyzed in three case-control studies including 104 patients of CVD, 101 patients of CHD and 150 deep venous thrombosis (DVT) patients. Smaller (B and C) alleles seemed to be associated with a lower risk of developing CVD but not to be related to CHD or DVT (Lozano et al. 2001).

In another study involving low number of CHD patients (281) and 397 healthy blood donors, the prevalence of homozygous carriers of the PSGL-1 VNTR allele with 15 repeat units was significantly higher in the CHD patients (5.3% vs. 1.5%) than in controls, suggesting an effect of this marker in CHD. But genotyping, performed in a larger sample size including 2,578 CHD patients, 731 patients without CHD, and 1,084 healthy blood donors, failed to confirm the putative role of PSGL-1 VNTR polymorphism in CHD. Frequencies of the PSGL-1 VNTR 15 repeats for homozygous carriers were 2.2% in healthy blood donors, 2.3% in patients without CHD and 2.7%, in CHD cases, respectively. Based on these results, the PSGL-1 VNTR polymorphism is not a genetic risk factor for CHD (Bugert et al. 2003). Thus, polymorphisms of the PSGL-1 may influence the neutrophil-platelet binding, and may represent a risk factor for CVD

Multiple Sclerosis and PSGL-1: PSGL-1 represents a crucial step in the pathogenesis of multiple sclerosis (MS). Three hundred twenty-one MS patients and 342 controls were genotyped for the presence of a polymorphism in the PSGL-1 gene, consisting of a VNTR originating three alleles: A, B and C, in order to test whether they influence the susceptibility and the course of the disease. No significant differences among allelic frequencies of A, B and C alleles in MS as compared with controls were observed. However, the C allele of the VNTR polymorphism in PSGL-1 is likely to be associated with PP-MS. As this allele has been demonstrated to have a very low efficiency in mediating lymphocyte binding to brain endothelium during attacks, its high frequency in PP-MS could be related to the absence of exacerbations in such patients (Scalabrini et al. 2005).

27.3.5 Carbohydrate Structures on PSGL-1

27.3.5.1 Primitive Human Hematopoietic Progenitors Adhere to P-Selectin

P-selectin binds human hematopoietic progenitors (colony-forming unit-granulocyte-macrophage [CFU-GM] and burst-forming unit-erythroid [BFU-E]) as identified by their expression of CD34 antigen. In addition, P-selectin binds all precursors (pre-CFU) of committed myeloid progenitors. This suggested that PSGL-1 comprises a P-selectin ligand expressed by primitive hematopoietic cells, but did not preclude the existence of additional P-selectin ligands on these cells. It has been proposed that only covalently dimerized PSGL-1 can bind P-selectin. Epperson et al. (2000) examined whether covalent dimers of PSGL-1 are required for binding to P-selectin. Recombinant forms of PSGL-1, in which the single extracellular Cys (Cys-320) was replaced with either Ser (C320S-PSGL-1) or Ala (C320A-PSGL-1), suggested that Cys(320)-dependent dimerization of PSGL-1 is not required for binding to P-selectin and that a monomeric fragment of PSGL-1 is sufficient for P-selectin recognition (Epperson et al. 2000).

27.3.5.2 Structure Containing GalNAc-Lewis^x and Neu5Acα2-3Galβ1-3GalNAc Sequences on PSGL-1

The PSGL-1-P-selectin interaction is calcium dependent and requires presentation of sialyl-Le^x -type structures on the

O-linked glycans of PSGL-1. The selectins interact under normal and pathological situations with certain sialylated, fucosylated glycoconjugate ligands containing sialyl-Le^x (Neu5Acα2-3Galβ1-4(Fucα1-3)GlcN Ac). Much effort has gone into the synthesis of sialylated and sulfated Le^x analogs as competitive ligands for the selectins. Other studies have shown that sulfate esters can replace sialic acid in some selectin ligands (Yuen et al. 1992; Imai et al. 1993). Since the natural selectin ligands GlyCAM-1 and PSGL-1 carry sialyl-Le^x as part of a branched Core 2 O-linked structure, Koenig et al. (1997) synthesized Galβ1-4(Fucα1-3) GlcNAcβ1-6(SE-3Galβ1^{+++}-3)GalNAc1αOMe and found it to be a moderately superior ligand for L and P-selectin. Jain et al. (1998) synthesized Galβ1-4(Fucα1-3)GlcNAcβ1-6 (Neu5Acα2^{+++} 3Galβ1-3)-GalNAc α1-OB, which was found to be 2- to 3-fold better than sialyl Le^x for P and L selectin, respectively. The unusual structure GalNAcβ1-4(Fucα1-3)GlcNAcβ1-OMe (GalNAc-Le^x-O-methyl glycoside) also proved to be a better inhibitor of L- and P-selectin than sialyl-Le^x-OMe. In view of Core 2 branched structures, Jain et al. (1998) synthesized a molecule that is 5- to 6-fold better at inhibiting L- and P-selectin than sialyl-Le^x-OMe. By contrast to un-branched structures, substitution of a sulfate ester group for a sialic acid residue in such a molecule resulted in a considerable loss of inhibition ability. Thus, the combination of a sialic acid residue on the primary (β1-3) arm, and a modified Le^x unit on the branched (β1-6) arm on an O-linked Core 2 structure generated a monovalent synthetic oliogosaccharide inhibitor superior to Sialyl-Le^x for both L- and P-selectin (Jain et al. 1998). The density of α-Gal epitopes on PSGL-1 is dependent on the expression of O-linked glycans with core 2 structures and lactosamine extensions. Hence, the structural complexity of the terminal Gal-Gal expressing O-glycans with both neutral as well as sialic acid-containing structures is likely to contribute to the high adsorption efficacy (Liu et al. 2005). Moore et al. (1994) suggested that PSGL-1 from human neutrophils displays complex, sialylated, and fucosylated O-linked poly-N-acetyllactosamine that promote high affinity binding to P-selectin, but not to E-selectin.

27.3.5.3 Carbohydrate and Non-Carbohydrate Moieties of PSGL-1 in Binding P-Selectin

In order to define the modifications required for PSGL-1 to bind P- and E-selectin, CHO cells were transfected with cDNAs for PSGL-1 and specific glycosyltransferases. CHO cells synthesized only core 1 O-linked glycans (Galβ1-3GalNAc α1-Se r/Thr), which lacked core 2 O-linked glycans (Galβ1-3(Galβ1-4GlcNAcβ1-6)GalNAc α1 -Ser/Thr). PSGL-1 expressed on transfected CHO cells bound P- and E-selectin only when it was co-expressed with both C2GnT and a α1,3 fucosyltransferase (Fuc-TIII, Fuc-TIV, or Fuc-TVII). Results indicated that PSGL-1 requires core 2 O-linked glycans that are sialylated and fucosylated to bind P- and E-selectin. PSGL-1 also requires tyrosine sulfate to bind P-selectin but not E-selectin (Li et al. 1996). Sako et al. (1995) reported the identification of a non-carbohydrate component of the binding determinant that is critical for high affinity binding to P-selectin. Located within the first 19 amino acids, this anionic polypeptide segment contains at least one sulfated tyrosine residue. This sulfotyrosine-containing segment of PSGL-1, in conjunction with sLex presented on O-linked glycans, constitutes the high affinity P-selectin-binding site (Sako et al. 1995).

27.3.6 Role of PSGL-1

Selectin-dependent rolling is the earliest observable event in the recruitment of leukocytes to inflamed tissues. Several glycoproteins decorated with sialic acid, fucose, and/or sulfate, have been shown to bind the selectins. The best-characterized selectin ligand is PSGL-1 that supports P-selectin- dependent rolling in vitro and in vivo.

27.3.6.1 PSGL-1 Mediates Rolling of Neutrophils on P-Selectin

Neutrophils roll on P-selectin expressed by activated platelets or endothelial cells under the shear stresses in the microcirculation. PSGL-1 accounts for the high affinity binding sites for P-selectin on leukocytes, and it must interact with P-selectin for neutrophils to roll on P-selectin at physiological shear stresses (Moore et al. 1995). Activated T cells regulate inflammatory diseases in the intestinal tract. P-selectin and PSGL-1 are dominating molecules in supporting adhesive interactions of CD8 T cells in inflamed colonic venules and may be useful targets to protect against pathological inflammation in the large bowel (Asaduzzaman et al. 2009). Human PSGL-1 interacts with CCL27, a skin-associated chemokine that attracts skin-homing T lymphocytes. Hirata et al. (2004) suggest a role for PSGL-1 in regulating chemokine-mediated responses, in addition to its role as a selectin ligand. The aspartyl protease BACE1 cleaves the amyloid precursor protein and the sialyltransferase ST6Gal I and is important in the pathogenesis of Alzheimer's disease. It was shown that BACE1 acts on PSGL-1, which mediates leukocyte adhesion in inflammatory reactions and that PSGL-1 is an additional substrate for BACE1 (Lichtenthaler et al. 2003).

Memory T cells expressing Cutaneous lymphocyte-associated antigen (CLA) occur in humans and accumulate in normal and inflamed skin. These cells uniformly bind to E-selectin, yet only a subset binds to P-selectin. Findings indicate that unlike memory CLA^+ $CD4^+$ T cells, when activated these cells can broadly bind to P-selectin,

suggesting a more diverse tissue trafficking capacity (Ni and Walcheck 2009).

27.3.6.2 Interaction of ERM Proteins with Syk Mediates Signaling by PSGL-1

In addition to its direct role in capture of leukocytes from the bloodstream, PSGL-1 also functions as a signal-transducing receptor and initiates a series of intracellular signal events during activation of leukocytes. Antibody engagement of PSGL-1 up-regulates the transcriptional activity of CSF-1 promotor and increases the endogenous expression of CSF-1 mRNA in Jurkat cell. The PSGL-1 associates with Syk. This association is mediated by the actin-linking proteins moesin and ezrin, which directly interact with Syk in an ITAM-dependent manner. PSGL-1 engagement induces tyrosine phosphorylation of Syk and SRE-dependent transcriptional activity. Study revealed a new role for ERMs (ezrin/radixin/moesin) as adaptor molecules in the interactions of adhesion receptors and intracellular tyrosine kinases and showed that PSGL-1 is a signaling molecule in leukocytes (Urzainqui et al. 2002). Studies suggest that signal transduced by PSGL-1 up-regulates the transcriptional activity of CSF-1, and non-receptor tyrosine kinase Syk participates in this pathway (Ba et al. 2005). The PSGL-1 peptide corresponding to the 18-residue juxtamembrane region from the mouse PSGL-1 cytoplasmic tail (residues 2–19 in Fig. 27.3) binds to the radixin FERM domain with a dissociation constant K_D of 201 nm.

Structural Basis of PSGL-1 Binding to ERM Proteins: Proteins involved in mediating cell migration and attachment have been identified using molecular genetic and biochemical approaches and many of these proteins contain highly conserved protein interaction domains. One such family of proteins is: which contains a FERM (Four.1 protein, ezrin, radixin, moesin) domain that functions as a protein docking surface with the cytosolic tail of transmembrane proteins such as CD44. On activation, ERM proteins mediate the redistribution of PSGL-1 on polarized cell surfaces to facilitate binding to target molecules. ERM proteins recognize a short binding motif, Motif-1, conserved in cytoplasmic tails of adhesion molecules, whereas PSGL-1 lacks Motif-1 residues important for binding to ERM proteins. The crystal structure of the complex between the radixin FERM domain and a PSGL-1 juxtamembrane peptide reveals that the peptide binds the groove of FERM subdomain C by forming a β-strand associated with strand β5C, followed by a loop flipped out towards the solvent (Takai et al. 2007) (Fig. 27.4).

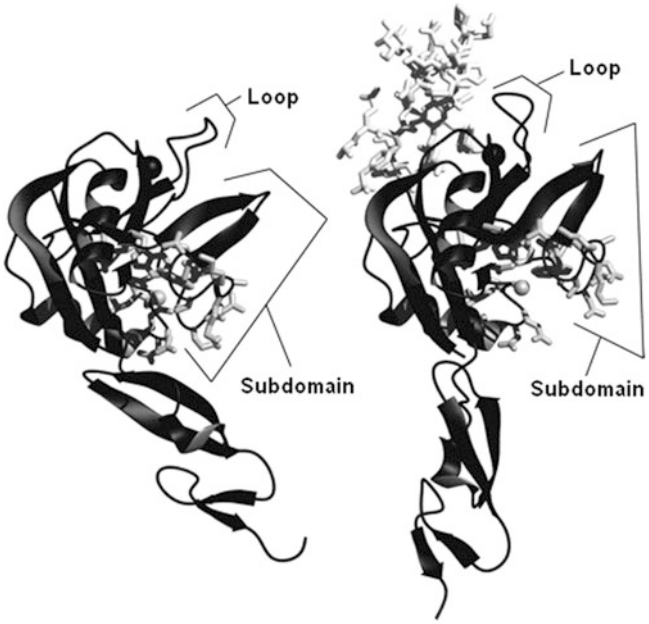

Fig. 27.3 Opening of a cleft in the lectin domain in the extended selectin conformation. (*Left*) P-selectin in the unliganded conformation (PDB ID code 1G1Q). (*Right*) P-selectin in the liganded, extended conformation (1G1S). In each structure, the Cβ atom of Ala-28 in the cleft is shown as a *gray sphere*, and other side chains that line the cleft are shown as *white sticks*. The divalent cation in the ligand binding site is shown as a larger *black sphere*. Molecules are shown as *ribbons* in identical orientations after superposition on the lectin domain (Adapted with permission from Waldron and Springer 2009 © National Academy of Sciences, USA)

27.4 Other Ligands of P-Selectin

CD24 as a Ligand for P-Selectin in Carcinoma Cells: P-selectin can also bind to breast and a small cell lung carcinoma cell line, which are negative for PSGL-1. But CD24, a mucin-type glycosyl phosphatidyl-inositol-linked cell surface molecule on human neutrophils, pre B lymphocytes, and many tumors can promote binding to P-selectin. Results establish a role of CD24 as a ligand for P-selectin on tumor cells. The CD24/P-selectin binding pathway could be important in the dissimination of tumor cells by facilitating the interaction with platelets or endothelial cells (Aigner et al. 1997).

CD44v as Ligands on Colon Carcinoma Cells: Variant isoforms of CD44 (CD44v) on LS174T colon carcinoma cells possess P-/L-/E-selectin binding activity, in contrast to the standard isoform of CD44 (CD44s) on hematopoietic-progenitor cells (HPCs), which is primarily

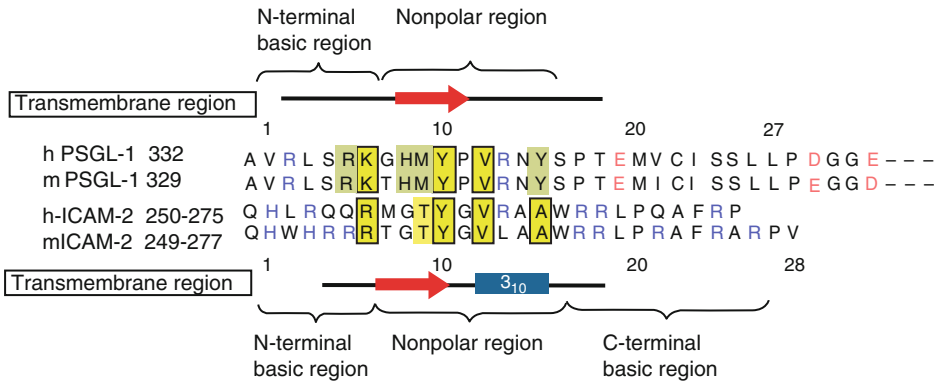

Fig. 27.4 Comparison of FERM-binding sequences in PSGL-1 and ICAM-2. The juxtamembrane region of the cytoplasmic tail of PSGL-1 is compared with that of ICAM-2, a member of the Ig superfamily of adhesion molecules that bind the FERM domain of ERM proteins. Basic and acidic residues are in *blue* and *red*, respectively. Compared with the ICAM-2 tail that displays three characteristic regions which include the N-terminal basic region, the middle nonpolar region and the C-terminal basic region, the PSGL-1 juxtamembrane region lacks the corresponding C-terminal basic region and instead contains acidic residues. PSGL-1-specific residues that are important in stabilizing conformation and binding are highlighted in *green*. The residue numbering for PSGL-1 follows that of ICAM-2. Part of the nonpolar region forms a short β-strand (residues 8–11; a *red arrow*) in FERM–PSGL-1 complex. Of the 18 PSGL-1 peptide residues, 17 (residues 2–18; indicated with *bold lines*) were defined in the current electron density map. The secondary structure of the mouse ICAM-2 cytoplasmic tail is shown at the *bottom* of the alignment. Conserved Motif-1 residues (RXXTYXVXXA) present in ICAM-2 are highlighted in *yellow* and the most important residues for binding to the FERM domain are *boxed*. PSGL-1 lacks Thr and Ala of Motif-1 (Reprinted with permission from Takai et al. 2007 © John Wiley and Sons)

an L-/E-selectin ligand. Moreover, the selectin-binding determinants on CD44v from LS174T cells are sialofucosylated structures displayed on O-linked glycans, akin to those on PSGL-1, but distinct from the HECA-452-reactive N-glycans on CD44s expressed on HPCs. Hanley et al. (2006) suggested that CD44v selectin ligands offer a unifying perspective on the apparent enhanced metastatic potential associated with tumor cell CD44v over-expression and the critical role of selectins in metastasis.

E-Selectin Promotes Growth Inhibition and Apoptosis of Hematopoietic Progenitor Cells Independent of PSGL-1: In human bone marrow, PSGL-1 is expressed by primitive bone marrow $CD34^+$ cells, mediates their adhesion to P-selectin, and inhibits their proliferation. Moreover, adhesion to E-selectin inhibits the proliferation of human $CD34^+$ cells isolated either from blood, or steady-state bone marrow. Furthermore, a subpopulation, which does not contain the most primitive hematopoietic progenitor cells, undergoes apoptosis following E-selectin-mediated adhesion. Studies suggest that an E-selectin ligand(s) other than PSGL-1 transduces growth inhibitory and pro-apoptotic signals and requires post-translational fucosylation to be functional (Winkler et al. 2004).

Lysosomal Membrane Glycoprotein-1 Can Present Ligands for E-Selectin: Lysosomal membrane glycoprotein (lamp)-1 and -2 are the most abundant glycoproteins in lysosomal membrane. A small amount of lamp-1 and lamp-2 molecules, however, can be present on the cell surface. The extent of adhesion to E-selectin and cell surface sialyl-Le^x determinants is proportional to the amount of cell surface lamp-1. Moreover, it was demonstrated that such adhesion can be inhibited by soluble lamp-1 generated from CHO cells expressing sialyl-Le^x structures. Results indicate that lamp-1 can efficiently present ligands for E-selectin and at the same time can be a useful reagent for inhibition of E-selectin (and possibly P-selectin)-mediated interaction (Sawada et al. 1993).

Sulfatides: Leukocytes may be important in the development of intimal hyperplasia. Sulfatides (3-sulfated galactosyl ceramides) are native ligands of L- and P-selectin. Findings suggest that neutrophil accumulation on the subendothelial matrix or adherence of platelets mediated by adhesive interactions between L- or P-selectin and sulfatides may contribute to the development of intimal hyperplasia. The neutrophil accumulation may be mediated by an increase in Mac-1 caused by the agonistic effects of sulfatides on the neutrophil membrane surface, or by an increase in L- and P-selectin ligands resulting from the binding of sulfatides onto the exposed subendothelial matrix (Shimazawa et al. 2005).

E-Selectin (CD62E) and Associated Adhesion Molecules

28

G.S. Gupta

28.1 E-Selectin (Endothelial Leukocyte Adhesion Molecule 1: ELAM-1)

28.1.1 Endothelial Cells Express E-Selectin (ELAM-1/CD62E)

E-selectin, also known as CD62 antigen-like family member E (CD62E), endothelial-leukocyte adhesion molecule 1 (ELAM-1), or leukocyte-endothelial cell adhesion molecule 2 (LECAM2), is a cell adhesion receptor expressed on endothelial cells activated by cytokines. Like other selectins, it plays an important part in inflammation. In humans, E-selectin is encoded by the *E-sel* gene. E-selectin or ELAM-1 is a member of the lectin/epidermal-growth-factor/complement-regulatory-protein-like cell-adhesion molecule family, which includes structurally related molecules referred to as selectins. Whereas P-selectin is stored in Weibel-Palade bodies, and it reaches the plasma membrane after exocytosis of these granules, E-selectin is not stored, and its synthesis is induced by cytokines. The fate of E-selectin has been studied after its surface expression following the intracellular routing of internalized antibodies to the selectin. After a brief surface exposure, internalized E-selectin is degraded in the lysosomes, whereas P-selectin returns to the storage granules from where it can be reused (Subramaniam et al. 1993). The presence of selectins on the cell surface is tightly regulated and abnormal appearance is associated with a number of inflammatory disease conditions. Multiple studies indicate that the selectins mediate neutrophil, monocyte, and lymphocyte rolling along the venular wall (Tedder et al. 1995).

28.1.1.1 E-Selectin Expression Is Not Confined to Endothelium

Proper differentiation and maturation of trophoblast contributes to the fetal-maternal vascular interface of the mature placenta and is required for all subsequent stages of embryogenesis. E-selectin is expressed in a unique pattern in secondary trophoblast giant cells, trophoblast lining the central artery, and a subpopulation of labyrinthine trophoblast all located at the fetal-maternal interface of the murine placenta. Placentae lacking E-selectin show increased trophoblast glycogen cells and fewer labyrinthine neutrophils compared with normal placentae, suggesting that recognition of E-selectin on trophoblast by counter-receptors on other cells contributes to placental development (Milstone et al. 2000). The E-selectin-specific monoclonal antibody H4/18 to keratinocytes in inflamed human oral mucosa, particularly gingival epithelium shows that E-selectin expression is not confined to endothelium (Pietrzak et al. 1996). The E-selectin and ICAM-1 are also localized to subfoveal choroidal neovascular membranes (CNVMs) in patients with age-related macular degeneration (AMD). Mesothelial cells can express a set of adhesion molecules overlapping with, but distinct from those expressed in vascular endothelium (ICAM-1, ICAM-2, VCAM-1, E-selectin), which are functionally relevant for interacting with mononuclear phagocytes (Jonjic et al. 1992).

28.2 E-Selectin Genomic DNA

28.2.1 Human E-Selectin

A full-length cDNA for E-selectin was isolated by transient expression in COS cells. The ELAM-1 clone express a surface structure recognized by E-selectin specific monoclonal antibodies and supported the adhesion of human neutrophils and the promyelocytic cell line HL-60. The primary sequence of E-selectin predicts an amino-terminal lectin-like domain, an EGF domain, and six tandem repetitive motifs (about 60 amino acids each) related to those found in complement regulatory proteins. A similar domain structure is also found in L-selectin homing receptor, and in P-selectin, a membrane glycoprotein of platelet and endothelial secretory granules (Bevilacqua et al. 1989) (Fig. 28.1).

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_28, © Springer-Verlag Wien 2012

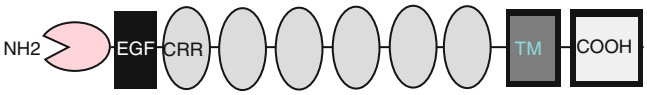

Fig. 28.1 Domain composition of human E-selectin. The extracellular portion of E-selectin contains an amino terminal domain homologous to C-type lectins and an adjacent epidermal growth factor (*EGF*)-like domain. The single EGF element, found in E-selectin is followed by six repetitive elements, each ~60 amino acids long, which resemble protein motives found in complement regulatory proteins (*CRR*), and a transmembrane (*TM*) sequence. A short cytoplasmic sequence is at the carboxyl terminus of E-selectin. The number of amino acids present in the mature E-selectin as deduced from the cDNA sequences is 589

The *E-sel* gene is present in a single copy in the human genome and contains 14 exons spanning about 13 kb of DNA. The positions of exon-intron boundaries correlate with the putative functional subdivisions of the protein. Introns are found at similar positions in all of the six complement regulatory repeats suggesting that these elements arose by internal gene duplication. A consensus TATAA element is located upstream of the transcriptional start site. The E-selectin promoter contains an inverted CCAAT box and consensus NF-kB- and AP-1-binding sites. The *E-sel* gene was assigned to the q12 greater than qter region of human chromosome. Two other members of the selectin gene family, the LAM-1/L-selectin and CD62P/P-selectin have been localized to the long arm of chromosome 1, as have the structurally related complement binding proteins, suggesting that these genes may share a common evolutionary history (Collins et al. 1995). Furthermore, the location of these genes on mouse and human chromosome 1 is consistent with a close evolutionary relationship to the complement receptor-related genes, which also are positioned on the same chromosomes in both species and with which these genes share a region of sequence homology (Watson et al. 1990).

28.2.2 E-Selectin Gene in Other Species

Murine E-selectin is encoded by a single-copy gene, spanning about 13 kb, which is structurally organized into 14 exons and 13 introns; very similar to its human counterpart. The exon/intron architecture exactly parallels the domain structure of the encoded protein. The nucleotide sequence of murine *E-sel* from heart tissue of an IL-1-treated mouse shows an overall similarity of 70% to human *E-sel* cDNA. Highest expression of murine *E-sel* gene occurs in heart and only low expression in lung tissue. Within the promoter, most of the identified regulatory elements are conserved. An exception is the NF-kB box sequence, which, in the murine *E-sel* promoter, does not correspond to the consensus NF-kB sequence (Becker-Andre et al. 1992). Transient expression in COS cells demonstrated that the lectin and EGF domains were sufficient to mediate the binding of mouse and human neutrophils as well as HL60 cells (Norton et al. 1993). The porcine gene comprises 12 exons and 11 introns. Two pseudoexons are contained within intron 4 and intron 6. These sequences are similar to the corresponding exons in the human E-selectin sequence; however, they are not present in the porcine E-selectin-encoding cDNA. Transcription starts at position −498 relative to the translation initiation site. The first ATG is located within exon 2. Translation stops in exon 11 leaving exon 12 untranslated in its entirety (Winkler et al. 1996).

28.3 E-Selectin Gene Regulation

28.3.1 Transcriptional Regulation of CAMs

The innate immune system plays an important role as a first defense against pathogens and involves the recognition of bacteria and viruses, and byproducts thereof, by Toll receptors on immunecompetent cells. Activated cells synthesize and secrete cytokines, which in turn activate systemic responses directed at clearing the pathogen. The "inflammatory triad" of IL-1, TNF-α and LPS are potent stimulators of the endothelial cell (EC) activation/adhesion molecules: ICAM-1, E-selectin (ELAM-1), and VCAM-1 (Bender et al. 1994; Fries et al. 1992). These inflammatory triad molecules, as well as the Toll receptors, initiate intracellular signaling cascades that activate nuclear factor κB (NF-κB), activator protein-1 (AP-1), cAMP responsive element binding proteins (CREBs), and various other transcription factors, which are essential for the regulation of numerous genes, many of which play important roles in immunological processes. The positive regulatory elements required for maximal levels of cytokine induction have been defined in the promoters of all three genes of cell adhesion molecules (CAMs). DNA binding studies reveal a requirement for NF-κB and other transcriptional activators. The organization of the cytokine-inducible element in the E-selectin promoter is remarkably similar to that of the virus-inducible promoter of the human IFN-β gene in that both promoters require NF-κB, ATF-2, and high mobility group protein I(Y) for induction. Based on this structural similarity, a model was proposed for the cytokine-induced E-selectin enhancer that is similar to the stereospecific complex proposed for the IFN-β gene promoter. In these models, multiple DNA bending proteins facilitate the assembly of higher order complexes of transcriptional activators that interact as a unit with the basal transcriptional machinery. The assembly of unique enhancer complexes from similar sets of transcriptional factors may provide the specificity required to regulate complex patterns of gene expression and correlate with the distinct patterns of expression of the leukocyte adhesion

molecules. Not only IL-1 but also weakly oxidized LDL, glycated LDL, and hypoxia may be possible factors that cause the expression of ELAM-1 (Collins et al. 1995).

28.3.2 Induction of E-Selectin and Associated CAMs by TNF-α

28.3.2.1 Cell Surface Expression of CAMs Can be Regulated by Different Mechanisms

Expression of some of the endothelial-leukocyte adhesion molecules is dynamically regulated at sites of leukocyte recruitment. For example, endothelial expression of E-selectin and VCAM-1 is dramatically induced, and expression of ICAM-1 is substantially increased at sites of inflammation. These dynamic changes in surface proteins provide the endothelial cell with a mechanism of regulating cell-cell interactions. The three endothehial cell-surface proteins have different patterns of expression, and are structurally and functionally distinct. Transcription of all three of these genes is substantially increased when endothelial cells are exposed to cytokines. Cell surface appearance of E-selectin and P-selectin on human umbilical vein endothelial (HUVE) cells can be regulated by different mechanisms. E-selectin is transcriptionally induced, within hours, by TNF-α while P-selectin is transported from storage granules to the plasma membrane within minutes upon induction by various stimulating agents (Weller et al. 1992).

PKC Pathway in Expression of CAMs: A protein kinase C agonist, 12-deoxyphorbol 13 phenylacetate 20-acetate (dPPA), selective for the β I isozyme, induces NF-kB-like binding activity and surface expression of E-selectin and VCAM-1 in human umbilical vein endothelial cells (HUVECs), similar to TNF-α. Induction of E-selectin and VCAM-1 expression by dPPA was completely inhibited by the PKC inhibitors staurosporine and Ro31-7549. The PKC inhibitors also reduced TNF-α-induced VCAM-1 expression. However, neither dPPA nor TNF translocated PKC from cytosolic to plasma/or nuclear membrane particulate fractions in HUVEC. These results indicated that activation of the βI PKC isozyme is sufficient for expression of E-selectin and VCAM-1, and suggested that PKC might mediate the effects of TNF-α and dPPA without requiring the translocation normally associated with activation of PKC (Deisher et al. 1993b). Inhibitors of topoisomerase II prevent cytokine-induced expression of VCAM-1, while augmenting the expression of ELAM-1 on human HUVECs. It appeared that topoisomerase II activity may differentially regulate the expression of adhesion molecules on HUVEC (Deisher et al. 1993a). The lower classic PKC activity on pretreatment with phorbol ester (phorbol 12-myristate 13-acetate (PMA) markedly decreased IL-1β-induced E-selectin mRNA expression in HUVEC in the presence of fetal calf serum and bFGF, although the induction of ICAM-1 mRNA expression was only influenced a little by the PKC down-regulation. On the other hand, TNFα-induced gene expression of these adhesion molecules was unaffected by such PKC modulation. Promoter analysis of E-selectin indicated that the NF-ELAM1/ATF element is critical for the synergistic effect of the cotreatment with IL-1β and PMA (Tamaru and Narumi 1999).

Tyrosine Phosphorylation in Endothelial Adhesion Molecule Induction: Induction of endothelial adhesion molecules by TNFα can occur independently of PKC. Activation of a protein tyrosine kinase (PTK) has been implicated in the upregulation of VCAM-1 by IL-4 on endothelial cells. The PTK inhibitors herbimycin A or genistein suppress induction of endothelial VCAM-1 and E-selectin, as well as subsequent monocytic cell adhesion to endothelial cells stimulated by TNF. Inhibition studies indicated that specific tyrosine phosphorylation following PTK activation is involved in the mobilization of NF-kB, and VCAM-1 mRNA expression. This may have implications for pathophysiological conditions that involve the upregulation of these molecules (e.g. inflammation and atherosclerosis) (Weber 1996)

E-Selectin Expression by Double-Stranded RNA and TNF-α: Since the double stranded RNA (dsRNA)-activated kinase (PKR) mediates dsRNA induction of NF-kB, murine aortic endothelial (MuAE) cells from wild-type and PKR-null mice were investigated for the role of PKR in the induction of E-selectin expression by dsRNA (pIC) and TNF-α. Study indicated that PKR is required for full activation of E-selectin expression by pIC and TNF-α in primary MuAE cells identifying activating transcription factor 2 as a new target for PKR-dependent regulation and suggested a role for PKR in leukocyte adhesion (Bandyopadhyay et al. 2000).

TNF-α Activates Two Signaling Pathways, NF-kB and JNK/p38, Both Required for Expression of E-Selectin: Transcriptional regulation of the E-selectin promoter by TNFα requires multiple NF-kB binding sites and a cAMP-responsive element/activating transcription factor-like binding site designated positive domain II (PDII). Read et al. (1997) while studying the role of MAP kinases in induced expression of E-selectin, suggested that TNFα activates two signaling pathways, NF-kB and JNK/p38, which are both required for maximal expression of E-selectin (Xu et al. 1998). Moreover, transient overexpression of catalytically inactive JNK or truncated TRAF2 (TNF receptor-associated

factor 2) partially inhibits endogenous E-selectin protein expression in human endothelial cells. Min and Pober (1997) suggest that TNF activates parallel TRAF-NF-kB and TRAF-RAC/CDC42-JNK-c-Jun/ATF2 pathways to initiate E-selectin transcription. Furthermore, endogenous inhibitors of the MAPK cascade, such as the dual-specificity phosphatases may be important for the postinduction repression of MAPK activity and E-selectin transcription in endothelial cells. These inhibitors may play an important role in limiting the inflammatory effects of TNF-α and IL-1β (Wadgaonkar et al. 2004).

IL-4 Suppression of TNFα-Stimulated E-Selectin Gene: IL-4, secreted by activated T-helper 2 lymphocytes, eosinophils, and mast cells, stimulates the expression of pyrogen-induced upregulation of ICAM-1, E-selectin and VCAM-1 in cultured HUVEC (Kapiotis et al. 1994). IL-4 stimulates a number of immune system genes via activation of STAT6. However, IL-4 can concomitantly suppress the expression of other immune-related gene products, including k light chain, FcγRI, IL-8, and E-selectin (Bennett et al. 1997).

Regulation by Cyclosporin A and Transcription Factor NFAT: Nuclear factor of activated T cells (NFAT) supports the activation of cytokine gene expression and mediates the immunoregulatory effects of cyclosporin A (CsA). Activated endothelial cells also express NFAT. CsA completely suppressed the induction of NFAT in endothelial cells and inhibited the activity of GM-CSF gene regulatory elements. CsA also suppressed E-selectin, but not VCAM-1 expression in endothelial cells, even though E-selectin promoter is activated by NF-kB rather than NFAT. Hence, induction of cell surface expression of E-selectin by TNF-α is reduced in presence of CsA, and this was reflected by a decrease in neutrophil adhesion. This suggests a mechanism by which CsA could function as an antiinflammatory agent (Cockerill et al. 1995).

28.3.2.2 TNF-α-Induced Cell Adhesion to Human Endothelial Cells Through TNF-Receptors

Mackay et al. (1993) reported that TNF-α triggers cell responses through two distinct membrane receptors. The HUVEC express both TNF receptor types, TNF-R55 and TNF-R75. But the TNF-α-induced cell adhesion to HUVEC is controlled almost exclusively by TNF-R55, but not through TNF-R75. This finding correlated with the exclusive activity of TNF-R55 in the TNF-α-dependent regulation of the expression of the ICAM-1, E-selectin, and VCAM-1. However, both TNF-R55 and TNF-R75 upregulate α2 integrin expression in HUVEC. The predominant role of TNF-R55 in TNF-α-induced adhesion in HUVEC may correlate with its specific control of NF-kB activation, since kB elements are known to be present in ICAM-1, E-selectin, and VCAM-1 gene regulatory sequences (Mackay et al. 1993).

Fish TNF-α Displays Different Sorts of Bioactivity to Their Mammalian Counterparts: In two complementary fish models, gilthead seabream and zebrafish, the proinflammatory effects of fish TNF-α are mediated through the activation of endothelial cells leading to the expression of E-selectin and different chemokines in endothelial cells, thus explaining the recruitment and activation of phagocytes observed in vivo in both species. Results indicate that fish TNF-α displays different sorts of bioactivity to their mammalian counterparts and point to the complexity of the evolution that has taken place in the regulation of innate immunity by cytokines (Roca et al. 2008).

28.3.3 IL-1-Mediated Expression of CAMs

Stimulation of E-selectin, VCAM-1, and ICAM-1 after treatment with IL-1β, TNF-α, and LPS, in a dose-dependent fashion was observed in cultured human intestinal microvascular endothelial cells (HIMEC). Each molecule displayed a time-related response comparable to those obtained with HUVEC (Haraldsen et al. 1996). Sphingomyelin hydrolysis to ceramide did not trigger, but rather enhanced cytokine-induced E-selectin expression. Sphingomyelin hydrolysis to ceramide did not mediate all the effects of IL-1β, although it might play important roles in IL-1β signal transduction in HUVECs (Masamune et al. 1996).

The infiltration of leukocytes into the CNS is associated with many pathologic conditions of the brain. The elevated levels of IL-1 in brain appear to accompany the pathogenesis. The evidences suggest that IL-1 can induce the expression of adhesion molecules for leukocytes on glial cells and a role for NF-kB in the induction process. Thus, the expression of adhesion molecules for leukocytes on glial cells in response to IL-1 may represent an important mechanism for retention of immune cells in the CNS that may be a prologue to inflammatory conditions in the brain (Moynagh et al. 1994; Couffinhal et al. 1994).

28.4 Factors in the Regulation of CAMs

28.4.1 NF-kB: A Dominant Regulator

A growing body of evidence demonstrates that nuclear transcription factor NF-kB acts as a dominant regulator of transcription of endothelial CAMs, E-selectin, VCAM-1 and

ICAM-1 genes. This molecular pathway may be involved in the pathogenesis of acute inflammatory diseases. Pharmacologic antagonism of transcription from these genes therefore represents a novel approach to the development of anti-inflammatory therapeutics and NF-kB may represent a prime target for therapeutic intervention in pathologic conditions associated with EC activation such as allo- and xenograft rejection, atherosclerosis, ischemic reperfusion injury and vasculitis.

NF-kB Is Required for TNF-α-Induced Expression of CAMs in Endothelial Cells: In response to inflammation stimuli, TNF-α induces expression of CAMs in ECs. Studies suggested that NF-kB and p38 MAP kinase (p38) signaling pathways play central roles in this process. However, subsequent analysis revealed that p38 activity is not essential for TNF-α-induced CAMs. Rajan et al. (2008) demonstrated that NF-kB, but not p38, is critical for TNF-α-induced CAM expression. In addition to TNF-α, Tie-1, an endothelial specific cell surface protein upregulates VCAM-1, E-selectin, and ICAM-1, partly through a p38-dependent mechanism (Chan et al. 2008). Similarly, LPS can activate p38 MAPK in equine ECs and that both neutrophil adhesion to LPS-activated EDVEC and prostacyclin (PGI_2) release are dependent upon p38 MAPK phosphorylation. Results reveal that inhibition of this kinase may reduce inflammatory events in the endotoxemic horse (Brooks et al. 2009).

NF-kB and IkBα: An Inducible Regulatory System in Endothelial Activation: Endothelial cells encode transcripts encoding the p50/p105 and p65 components of NF-kB and the rel-related proto-oncogene c-rel. These transcripts are transiently increased by TNF-α. Stimulation of endothelial cells with TNF-α resulted in nuclear accumulation of the p50 and p65 components of NF-kB and their binding to the E-selectin kB site. Endothelial cells also express I kB-α (MAD-3), an inhibitor of NF-kB activation. Level of I kB-α inhibitor falls rapidly after TNF-α stimulation. In parallel, p50 and p65 accumulate in the nucleus, where as RNA transcripts for IkB-α are dramatically upregulated. Studies suggest that NF-kB and IkB-α system may be an inducible regulatory mechanism in endothelial activation (Read et al. 1994, 1996). TNF causes persistent activation of NF-κB in human EC and that this may result from sustained reductions in I kB-β levels (Johnson et al. 1996).

Nuclear NF-kB DNA-binding activity was rapidly increased within lung and heart tissues of rats administered endotoxin, consistent with the translocation of NF-kB complexes from the cytoplasm to the nucleus. NF-kB activation preceded the transcriptional activation of E-selectin, VCAM-1, and ICAM-1 genes. These molecular events were temporally associated with the sequestration of leukocytes and the development of pulmonary inflammation. Report supported that NF-κB activation is the underlying molecular mechanism for constitutive expression of E-selectin, VCAM-1, and ICAM-1 on human B lymphocytes, plasma cells and in hepatic vascular lining cells though the hepatic parenchymal cells, despite NF-kB activation do not express E- selectin mRNA. This indicated that NF-kB activation alone is not sufficient for E-selectin gene transcription in vivo (Essani et al. 1996; Manning et al. 1995; Wang et al. 1995).

Platelet factor 4 (PF4), a platelet-specific chemokine, has been localized to atherosclerotic lesions, including macrophages and endothelium. The PF4, which is able to increase expression of E-selectin by endothelial cells, represents one of the potential mechanisms by which platelets may participate in atherosclerotic lesion progression (Yu et al. 2005). E-selectin and its RNA are upregulated in HUVE cells exposed to PF4. It appeared that activation of NF-kB is critical for PF4-induced E-selectin expression. The LDL receptor-related protein as the cell surface receptor may mediate this effect (Yu et al. 2005). The POZ domain of FBI-1 (factor that binds to the inducer of short transcripts of HIV-1) interacts with the Rel homology domain of the p65 subunit of NF-kB in in vivo and in vitro protein-protein interactions. FBI-1 enhanced NF-kB-mediated transcription of E-selectin genes in HeLa cells upon stimulation and overcame gene repression (Lee et al. 2005).

Glucocorticoid-Mediated E-Selectin Repression: Induction of E-selectin expression by stimuli such as TNF-α or LPS is reduced markedly in the presence of dexamethasone, a potent anti-inflammatory agent. E-selectin promoter analysis revealed that induction by proinflammatory stimuli as well as repression by dexamethasone are mediated by the same promoter region containing three closely spaced binding sites for NF-kB and an element, NF-ELAM-1, constitutively occupied by ATF and c-Jun. NF-ELAM-1 contributes to maximal promoter activity, but does not confer glucocorticoid inhibition, as demonstrated by site-directed mutagenesis. In contrast, transcription directed by the E-selectin NF-kB elements is reduced strongly in the presence of dexamethasone, thus identifying NF-kB as the primary target for glucocorticoid-mediated E-selectin repression. The interference by glucocorticoids receptor (GR) with the transcriptional activation potential of DNA-bound NF-kB complexes might contribute to mechanisms underlying the anti-inflammatory effects of glucocorticoids (Brostjan et al. 1997; Ray et al. 1997).

28.4.2 Cyclic AMP Inhibits NF-kB-Mediated Transcription

Cytokines induce the expression of E-selectin, VCAM-1, and ICAM-1 on HUVECs. Expression of these surface

proteins is differently affected by cAMP. Increased cAMP levels decrease E-selectin and VCAM-1 but increase ICAM-1 expression. The cAMP repression of E-selectin occurs at the transcription level. This effect is abolished by protein kinase A (PKA) inhibition, suggesting that repression is mediated by PKA-driven phosphorylation. A minimal E-selectin promoter sequence necessary to confer cytokine inducibility is also sufficient to mimic the cAMP effect in transfected HUVECs. There are two regions (NF-kB and NF-ELAM1) of the minimal promoter that bind transcription factors necessary for E-selectin induction. Increased cAMP did not alter the binding of the complexes formed on either the NF-kB or NF-ELAM1 site. In contrast, in IL-1-treated HUVECs transactivity due to an NF-kB site was reduced by elevated cAMP. Increased cAMP in HUVECs appears to induce a protein kinase activity that reduces the cytokine signal for E-selectin and VCAM-1 expression (Ghersa et al. 1994). Ollivier et al. (1996) examined the molecular mechanism by which agents that elevate intracellular cAMP inhibit the expression of TNFα, tissue factor, ELAM-1, and VCAM-1 genes. Both forskolin and dibutyryl cAMP, which elevate intracellular cAMP by independent mechanisms, inhibited TNFα and tissue factor expression at the level of transcription. Induction of NF-kB-dependent gene expression in transiently transfected human monocytic THP-1 cells and HUVEC was inhibited by elevated cAMP and by over-expression of the catalytic subunit of PKA. This indicated that activation of PKA reduced the induction of a distinct set of genes in monocytes and endothelial cells by inhibiting NF-kB-mediated transcription.

Cilostazol Inhibits Cytokine-Induced NF-kB Activation Via AMP-Activated Protein Kinase Activation: Cilostazol is a selective inhibitor of phosphodiesterase-3 that increases intracellular cAMP levels and activates PKA, thereby inhibiting platelet aggregation and inducing peripheral vasodilation. Cilostazol also inhibited TNFα-induced NF-kB activation and TNFα-induced I κB kinase activity. Furthermore, cilostazol attenuated the TNFα-induced gene expression of various pro-inflammatory and cell adhesion molecules, such as VCAM-1, E-selectin, ICAM-1, MCP-1, and PECAM-1 in HUVEC. Hattori et al. (2009) suggested that cilostazol might attenuate the cytokine-induced expression of adhesion molecule genes by inhibiting NF-κB following AMP-activated protein kinase.

28.4.3 Peroxisome Proliferator-Activated Receptors

Peroxisome proliferator-activated receptors (PPARs) are nuclear receptors which down-regulate inflammatory signaling pathways. Three peroxisome proliferator-activated receptors (PPARs) have been identified: PPARα, PPARβ/δ, and PPARγ, all of which have multiple biological effects, especially the inhibition of inflammation. The expressions of 3 PPAR isoforms and PPAR-responsive genes are markedly upregulated in spontaneously hypertensive rats (SHR) compared with those of Wistar-Kyoto rats (WKY). An enhanced inflammatory response in the organs of SHR might play a key role in pathogenesis of hypertension and secondary organ complications. Changes (increases) in PPARs expression may reflect a compensatory mechanism to the inflammatory status of hypertensive rats (Sun et al. 2008). PPAR-γ has an essential role in adipogenesis and glucose homeostasis. The PPAR-γ is expressed in vascular tissues including endothelial cells. Its activity is regulated by many pharmacological agonists. PPAR-γ might be involved in the control of inflammation and in modulating the expression of various cytokines. PPAR-γ activation suppresses the expression of vascular adhesion molecules in ECs and the ensuing leukocyte recruitment. Evidence shows that constitutive activation of PPAR-γ is sufficient to prevent ECs from converting into a pro-inflammatory phenotype (Wang et al. 2002).

The PPAR activators have been shown to inhibit the expression of E-selectin of HVECs in response to TNF-α. Troglitazone, pioglitazone, α-clofibrate, and 15-deoxy-δ 12,14-prostaglandin J2 inhibited the TNF-α-stimulated E-selectin gene transcription. The activators caused a significant induction of liver regenerating factor 1 (LRF1)/ATF3, which bound to NF-ELAM1 site and repressed the TNF-α-induced E-selectin gene expression. It appears that the effect of PPAR activators is mediated, in part, through the induction of LRF1/ATF3 (Nawa et al. 2000). In another study, pioglitazone inhibited the expression of VCAM-1 protein and mRNA on HUVEC after IL-1β stimulation, though it showed little effect on the expression of ICAM-1 and E-selectin. The study revealed that pioglitazone can influence monocyte-EC binding by inhibiting VCAM-1 expression on activated EC and neutrophil-EC binding by inhibiting upregulation of CD11b/CD18 on activated neutrophils. This might provide a molecular basis of anti-inflammatory effect of PPAR activators (Nawa et al. 2000; Imamoto et al. 2004).

The role of PPAR-δ in endothelial activation remains poorly understood. In human umbilical vein endothelial cells (HUVECs), the synthetic PPAR-δ ligands GW0742 and GW501516 significantly inhibited TNF-α-induced expression of VCAM-1 and E-selectin, as well as ensuing endothelial-leukocyte adhesion. Activation of PPAR-δ upregulated the expression of antioxidant genes: SOD-1, catalase, and thioredoxin and decreased ROS production in ECs. This shows that ligand activation of PPAR-δ in ECs has a potent antiinflammatory effect, probably via a binary mechanism involving the induction of antioxidative genes and the release of nuclear corepressors (Fan et al. 2008).

PPAR-δ agonists may have a potential for treating inflammatory diseases such as atherosclerosis and diabetes. Alterations of PPAR functions can contribute to HIV-1-induced dysfunction of brain endothelial cells. Treatment with HIV-1 transactivator of transcription (Tat) protein decreased PPAR transactivation in brain endothelial cells. Tat-induced up-regulation of inflammatory mediators, such as IL-1β, TNF-α, CCL2, and E-selectin were markedly attenuated in hCMEC/D3 over-expressing PPARα or PPARγ. Data suggest that targeting PPAR signaling may provide a novel therapeutic approach to attenuate HIV-1-induced local inflammatory responses in brain endothelial cells (Huang et al. 2008).

28.4.4 Endogenous Factors Regulating CAM Genes

In order to understand the role of complement components as regulators of expression of endothelial adhesive molecules in response to immune complexes (ICs), Lozada et al. (1995) showed that ICs stimulate both the endothelial adhesiveness for leukocytes and expression of E-selectin, ICAM-1, and VCAM-1. ICs (BSA-anti-BSA) stimulated EC adhesiveness for added leukocytes in the presence of complement-sufficient human serum. Studies showed that ICs stimulate ECs to express adhesive proteins for leukocytes in presence of a heat-labile serum factor, C1q (Lozada et al. 1995).

Native LDL (n-LDL) increases HUVEC adherence of mononuclear cells. Such phenotypic changes suggest that n-LDL alters the usual expression of cell adhesion molecules to enhance the adhesive properties of the endothelium. n-LDL increased ICAM-1 protein expression corresponded with increased ICAM-1 mRNA levels. n-LDL also appeared to increase E-selectin and VCAM-1 message levels, but these changes were not statistically significant. n-LDL increase of ICAM-1 expression seems to enhance the adhesive properties of the endothelium. Such perturbations in HUVEC function likely represent a proinflammatory response to protracted n-LDL exposure and one of the early steps in atherogenesis (Smalley et al. 1996).

Adrenomedullin (AM) and corticotrophin (ACTH) are both vasoactive peptides produced by a variety of cell types, including ECs. Their role in inflammation and the immune response was studied by Hagi-Pavli et al. (2004). AM and ACTH induce cell surface expression of E-selectin, VCAM-1, and ICAM-1 on HUVEC. This effect appears to be mediated in part via elevation of cAMP, and that both peptides elevate cAMP. The effect of AM and ACTH is inhibited by the adenylyl cyclase inhibitor SQ-22528. This demonstrates a role for AM and ACTH in the regulation of the immune and inflammatory response through adhesion molecules (Hagi-Pavli et al. 2004).

Methylation May Play a Role in Blocking E-Selectin Expression in Non-Endothelial Cells: The E-selectin promoter in cultured endothelial cells is under-methylated in comparison with non-expressing HeLa cells. Plasmid constructs carrying a reporter driven by E-selectin promoter and methylated in vitro are not transcribed in either an in vitro transcription system or in transiently transfected cells. The NF-kB site in the promoter of E-selectin is the likely target for this methylation-mediated repression in a minimal promoter carrying only this and an associated element. Thus, methylation is likely to play a role in blocking E-selectin expression in non-endothelial cells (Smith et al. 1993).

28.4.5 Tat Protein Activates Human Endothelial Cells

Tat protein, an HIV gene product, functions as a transactivator for HIV replication and is known to be secreted extra-cellularly by infected cells. Tat stimulates endothelial cells. This is evidenced by the expression of E-selectin, critical for the initial binding of leukocytes to the blood vessel wall, and its effect on increased synthesis of IL-6, a cytokine known to enhance endothelial cell permeability. Furthermore, tat acts synergistically with low concentrations of TNF-α to enhance IL-6 secretion. Tat activates human CNS-derived endothelial cells (CNS-EC) by the increase in the expression of E-selectin, the synthesis of IL-6, and the secretion of plasminogen activator inhibitor-1. It was suggested that secreted tat protein may increase leukocyte binding, and alter the blood-brain barrier permeability to enhance dissemination of HIV-infected cells into the CNS (Hofman et al. 1994). Treatment of HUVEC with Tat induces the cell surface expression of ICAM-1, VCAM-1, and E-selectin-1 and the effect on expression of adhesion molecules was potentiated by TNF. Like TNF, Tat also enhanced the adhesion of human promyelomonocytic HL-60 cells to EC (Dhawan et al. 1997). Both Tat and TNF activated p65 translocation and binding to an oligonucleotide containing the E-selectin kB site 3 sequence. A super-repressor adenovirus (AdIkBαSR) that constitutively sequesters IkB in the cytoplasm as well as cycloheximide or actinomycin D inhibited Tat- or TNF-mediated kB translocation and E-selectin up-regulation (Cota-Gomez et al. 2002).

28.4.6 Reactive Oxygen Species (ROS)

ROS is critical signal in the activation of NF-kB and in E-selectin expression: Decreased NO activity, the formation of ROS and increased endothelial expression of the redox-

sensitive VCAM-1 gene in the vessel wall are early and characteristic features of atherosclerosis. Through this mechanism, NO may function as an immunomodulator of the vessel wall and thus mediate inflammatory events involved in the pathogenesis of atherosclerosis (Khan et al. 1996). Reactive oxygen intermediates may act as second messengers in the activation of NF-kB.

Antioxidants and NO Inhibit Adhesion Molecule Expression: Using the antioxidant pyrrolidine dithiocarbamate (PDTC) for the study of the effect of NF-kB inhibition in TNF-α-induced EC activation in vitro, Ferran et al. (1995) showed that PDTC strongly reduces the TNF-α-mediated induction of E-selectin, VCAM-1, and ICAM-1. The N-acetyl-L-cysteine (NAC) is a thiol-containing antioxidant that inhibits agonist-induced monocytic cell adhesion to endothelial cells. Unlike PDTC, which specifically inhibits VCAM-1, NAC inhibits IL-1β -induced mRNA and cell surface expression of both E-selectin and VCAM-1. Although NAC reduced NF-kB activation in EC, the antioxidant had no appreciable effect when an oligomer corresponding to the consensus NF-kB binding site of the E-selectin gene was used. (Faruqi et al. 1997). Trans fatty acid intake could also affect biomarkers of inflammation and endothelial dysfunction including C-reactive protein (CRP), IL-6, sTNFR-2, E-selectin, sICAM-1 and sVCAM-1. Higher intake of trans fatty acids could adversely affect endothelial function, which might partially explain why the positive relation between trans fat and cardiovascular risk is greater than one would predict based solely on its adverse effects on lipids (Lopez-Garcia et al. 2005). Findings support that TNF-α induces NF-kB activation of the resultant E-selectin gene by a pathway that involves formation of ROS and that the E-selectin expression can be inhibited by the antioxidant action of NAC or PDTC. The results support the hypothesis that generation of ROS in endothelial cells induced by proinflammatory cytokines such as TNF-α is a critical signal mediating E-selectin expression (Rahman et al. 1998; Spiecker et al. 2000). The inhibitory effects of NO on adhesion molecule expression differ from that of antioxidants in terms of the mechanism by which NF-kB is inactivated (Spiecker et al. 2000). NO inhibited IL-1α-stimulated VCAM-1 expression in a concentration-dependent manner. NO also decreased the endothelial expression of E-selectin and to a lesser extent ICAM-1 and secretable cytokines (IL-6 and IL-8) (De Caterina et al. 1995).

28.4.7 Role of Hypoxia

Anoxia/reoxygenation (A/R) leads to a biphasic increase in neutrophil adhesion to HUVECs, with peak responses occurring at 30 min (phase 1) and 240 min (phase 2) after reoxygenation. It was indicated that A/R elicits a two-phase neutrophil-endothelial cell adhesion response that involves transcription-independent and transcription-dependent surface expression of different endothelial CAMs. Tissue injury that accompanies hypoxemia/reoxygenation shares features with the host response in inflammation, suggesting that cytokines, such as IL-1, may act as mediators in this setting. Human endothelial cells subjected to hypoxia elaborated IL-1 activity into conditioned media in a time-dependent manner. Production of IL-1 activity by hypoxic ECs was associated with an increase in the level of mRNA for IL-1 alpha, and was followed by induction of ELAM-1 and enhanced ICAM-1 during reoxygenation. This suggests that hypoxia is a stimulus, which induces EC synthesis and release of IL-1 alpha, resulting in an autocrine enhancement in the expression of adhesion molecules (Shreeniwas et al. 1992). Findings make the use of inducible enhancers a promising strategy for increasing tissue specific gene expression.

28.5 Binding Elements in E-Selectin Promoter

28.5.1 Transcription Factors Stimulating *E-sel* Gene

As seen, expression of E-selectin is cell and stimulus specific, as it is mainly expressed on endothelial cells in response to induction by IL-1 and TNF-α as well as LPS and phorbol myristate acetate. IL-1 and TNF-α initiate intracellular signaling cascades that activate NF-kB, activator protein-1 (AP-1), and cAMP responsive element binding proteins (CREBs), which are transcription factors essential for the regulation of numerous genes, many of which play important roles in immunological processes. In addition, E-selectin gene activity is transient. Expression is maximal 2–4 h following cytokine induction and returns to the basal level by 24 h. This tight regulation of gene activity is likely to require complex control mechanisms (Jensen and Whitehead 2003) .

Factors in addition to NF-kB appear to play a central role in determining the specific expression of ELEM-1 gene in response to cytokines. In support of this, Whelan et al. (1991) have shown that NF-kB alone, although essential, is not sufficient to mediate IL-1-induced activation of E-selectin gene. Hooft van Hujsduinen et al. (1992) identified two additional factors, which were referred to as NF-ELAM1 and NF-ELAM2 (binding at positions −153 to −144 and −104 to −100, respectively), that play critical roles in controlling cytokine-induced expression of the E-selectin gene. While neither of these elements alone is sufficient to confer enhancer activity on a heterologous promoter, NF-ELAM1 was shown to cooperate with NF-kB to augment cytokine-induced expression to levels

significantly above that observed with NF-kB alone. Hooft van Hujsduinen et al. (1992) demonstrated that NF-ELAM1 functionally cooperates with NF-kB in IL-1 induction of the E-selectin gene.

Multiple NF-kB Binding Sites in Human *E-sel* Gene: Promoter binding factors responsible for induced ELAM-1 gene expression include NF-kB, which binds at three sites within the E-selectin promoter; two of these NF-kB binding sites are partially overlapping, that have been reported to be required for full induction by cytokines. In band shift assays, Hooft van Huijsduijnen et al. (1993) detected two distinct NF-kB complexes in nuclear extracts from several cytokine-induced cells. A putative AP-1 site at position −499 to −493 within the promoter has been shown not to affect cytokine induction (Schindler and Baichwal 1994). The presence of a TNF-α-inducible element close to the transcriptional start site. 170 bp of upstream sequences was sufficient to confer TNF-α induction. Site-directed mutagenesis of this region revealed two regulatory elements (−129 to −110 and −99 to −80) that are essential for maximal promoter activity following cytokine treatment. Binding studies with crude nuclear extracts and recombinant proteins showed that the two elements correspond to three NF-kB binding sites (site 1, −126; site 2, 116; and site 3, −94). Thus induction of E-selectin gene requires the interaction of NF-kB proteins at multiple regulatory elements (Schindler and Baichwal 1994). Consequently, this promoter is often used to drive expression of luciferase in reporter assays and is frequently considered to be an "NF-kB-specific" promoter. Whitley et al. identified four positive regulatory domains (PDI to PDIV) in the E-selectin promoter that are required for maximal induction by TNF-α in endothelial cells. Two of these domains contain adjacent binding sites for NF-kB (PDIII and PDIV), where as the third corresponds to CRE/ATF site (PDII), and a fourth is a consensus NF-kB site (PDI) (Fig. 28.2). Mutations that decrease the binding of NF-kB to any one of the NF-kB binding sites in vitro abolish cytokine-induced E-selectin gene expression in vivo. A similar correlation was demonstrated between ATF binding to PDII and E-selectin gene expression (Whitley et al. 1994).

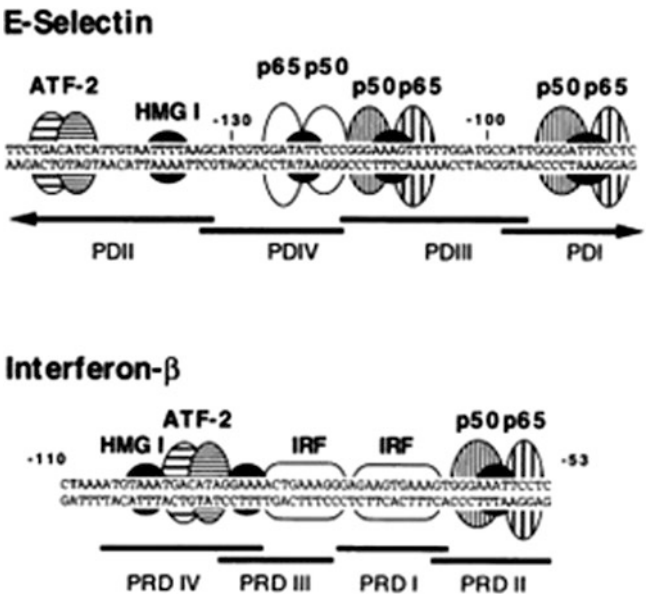

Fig. 28.2 Comparison of the human promoters for the IFN-β and E-selectin genes. The double-stranded DNA sequences of the IFN-β promoter from −110 to −53 and of the human E-selectin from −156 to −83, upstream of the transcriptional start site, are shown. Both regions contain four regulatory domains, designated PRDI through PRDIV, in the human IFN-P gene and PDI through PDIV in the E-selectin gene. Transcription factors that bind to each of the elements are shown for both genes. Those for the IFN-l gene are as follows (reviewed in reference 19): NF-KB binds to PRDII, IFN regulatory factor 1 (*IRF*) binds to PRDI and PDIII, and ATF-2 binds to PRDIV. Binding sites for HMG I(Y) are found in PRDII and PRDIV and are indicated. Transcription factors that bind to the E-selectin cytokine response region are as follows: NF-kB binds to PDI, PDIII, and PDIV, and ATF-a or ATF-2 homodimer or the corresponding c-Jun heterodimer binds to PDII. HMG I(Y) binds to a region within PDII as well as to the AT-rich regions in the kB sites contained in PDI, PDIII, and PDIV (Adapted with permission from Whitley et al. 1994 © American Society for Microbiology)

28.5.2 CRE/ATF Element or NF-ELAM1

Activating Transcription Factor (ATF) is a basic leucine zipper protein, whose DNA target sequence is widely distributed in cAMP response element (CRE). The CRE/ATF element of E-selectin promoter is necessary for full cytokine responsiveness. It differs from a consensus CRE by 1 nucleotide (G—>A conversion) and does not mediate transcriptional activation in response to cAMP. The cAMP actually decreases E-selectin synthesis induced by TNF-α in aortic endothelial cells; the cAMP-mediated inhibition maps to the CRE/ATF element. Study suggests that a change in the composition of the proteins binding to the CRE/ATF promoter element contributes to the competing effects of TNF-α and cAMP on E-selectin gene expression (De Luca et al. 1994). The abnormalities in activating transcription factor-2 (ATF-2) mutant mice demonstrate its absolute requirement for skeletal and CNS development, and for maximal induction of select genes with CRE sites, such as E-selectin (Reimold et al. 1996).

The cAMP-independent members of the ATF family bind specifically to the NF-ELAM1 promoter element (Fig. 28.2). This sequence operates in a cAMP-independent manner to induce transcription and thus it was defined as a

non-cAMP-responsive element (NCRE). It was found that ATFα is a component of the NF-ELAM1 complex and its over-expression activates the E-selectin promoter. Furthermore, the ability of over-expressed NF-kB to transactivate the E-selectin promoter in vivo was dependent on the NF-ELAM1 complex (Kaszubska et al. 1993). Hooft van Huijsduijnen et al. (1992) identified two proximal E-selectin promoter elements and their DNA-binding factors that are, in addition to NF-kB, essential for E-selectin transcription. This site, ACATCAT, is recognized by NF-ELAM-1. The site corresponds to NF-ELAM-1s preferential binding sequence (A/T)CA(G/T)CA(G/T). This element is identical to the T-cell δ A enhancer found in the T-cell receptor-α, -β, and CD3δ genes. Studies suggest that δ A/NF-ELAM-element can function as a modulator of NF-kB in endothelial cells both as well as a T-cell enhancer (Hooft van Huijsduijnen et al. 1992). It was shown that a novel protein-protein interaction occurs between the p50 and p65 subunits of NF-kB and certain ATFs. Furthermore, results demonstrate that NF-kB is dependent on NFELAM1 for strong induction of E-selectin expression. These studies demonstrate a novel mechanism operating to specifically control E-selectin gene transcription in response to cytokines.

28.5.3 HMG-I(Y) Mediates Binding of NF-kB Complex

The high-mobility-group protein I (Y) [HMG-I(Y)] also binds specifically to the E-selectin promoter and thereby enhances the binding of both ATF-2 and NF-kB to the E-selectin promoter in vitro. In addition to interaction of NF-kB and ATF with promotor elements, analysis of the E-selectin promoter revealed an additional region (−140 to −105 nt referred as −140/−105) which is essential in controlling promoter activation by cytokines. The HMG-I(Y) interacts specifically at two sites within this region. One of the HMG-I(Y)-binding sites overlaps a sequence element (−127/−118) diverging at only one position from the NF-kB consensus binding sequence. Lewis et al. (1994) searched whether −127/−118 element represents a second functional NF-kB-binding site within the E-selectin promoter. It was shown that p50, p65, and RelB are components of the complex interacting at this site. Mutations that interfere with HMG-I(Y) binding decrease the level of cytokine-induced E-selectin expression. Mutations at −127/−118 NF-kB site indicated that both NF-kB and HMG-I(Y) binding at this site are essential for IL-1 induction of the promoter. The binding affinity of the p50 subunit of NF-kB to both NF-kB sites within the E-selectin promoter was significantly enhanced by HMG-I(Y). Thus, HMG-I(Y) mediates binding of a distinct NF-kB complex at two sites within the E-selectin promoter (Fig. 28.2). Furthermore, a unique cooperativity between these NF-kB complexes is essential for induced E-selectin expression. These results suggest mechanisms by which NF-kB complexes are involved in specific gene activation (Lewis et al. 1994). Studies suggest that the organization of the TNF-α-inducible element of the E-selectin promoter is remarkably similar to that of the virus-inducible promoter of human β interferon gene in that both promoters require NF-kB, ATF-2, and HMG-I(Y). Thus, HMG-I(Y) functions as a key architectural component in the assembly of inducible transcription activation complexes on both promoters (Whitley et al. 1994). HMG-I(Y) binds to the A/T-rich core found at the centre of these binding sites. Distamycin, an antibiotic that also binds A/T-rich DNA, inhibits HMG-I(Y) DNA binding. The distamycin effect on transcription was mediated through one of the three NF-kB-HMG-I(Y) binding sites (NF-kBII) within the promoter. This suggests that the NF-kB-HMG-I(Y) complex interacting at the NF-kBII site plays a role not only in cytokine induction of E-selectin expression, but also in its down-modulation (Ghersa et al. 1997).

28.5.4 Phased-Bending of E-Selectin Promoter

As suggested, DNA elements required for IL-1 inducibility are located in the proximal promoter: an NF-ELAM site, two NF-kB sites (I and II), the NF-E-selectin 2 element and a TATA box. IL-1 induced promoter activity is exquisitely sensitive to the spatial arrangements of these elements. Phasing of the ATF and NF-kB II elements indicates that their relative helix orientation is more important than distance per se. This sensitivity is partly due to a requirement for correctly oriented, transcription factor-induced DNA-bending. (1) Band shift analyses with permuted ATF- and NF-kB elements showed that their associated factors all bend DNA. (2) One can functionally replace the NF-E-selectin/ATF element by a subset of a panel of DNA fragments that contain defined bends in various planes. It appears that the main role of the factors binding at the NF-E-selectin/ATF element is to alter the conformation of the E-selectin promoter, presumably looping distant enhancer elements into each other's proximity (Meacock et al. 1994).

28.6 E-Selectin Ligands

28.6.1 Carbohydrate Ligands (Lewis Antigens)

Various Lewis Antigens, Lewis A (Le^a), Lewis B (Le^b), and Sialyl Lewis A (sLe^a) have been studied in different biological contexts, for example in microbial adhesion and cancer. Adhesion molecules recognize carbohydrate

moieties sLe^x, s-diLe^x, or sLe^a, though with different affinity. The potency of oligosaccharides sLe^x, sLe^a, HSO_3Le^x, and HSO_3Le^a, their conjugates with polyacrylamide (40 kDa), and other monomeric and polymeric selectin inhibitors was compared with that of the polysaccharide fucoidan. The monomeric sLe^x is more effective as a selectin blocker in vivo than in vitro, whereas the opposite is true for fucoidan and the bi-ligand neoglycoconjugate HSO_3LeA-PAA-sTyr (Ushakova et al. 2005). Melanoma cell lines show differential binding to different Lewis antigens. For example melanoma cell line NKI-4 binds to E-selectin, but not to P-selectin. Cell line NKI-4 does not express sLe^x, but was positive for sdiLe^x and sLe^a. In contrast, melanoma cell lines, MeWo and SK-MEL-28, expressing either sdiLe^x or sLe^a on the cell surface, bound neither E-selectin nor P-selectin (Kunzendorf et al. 1994). High metastatic colonic carcinoma cells express relatively more Lamp molecules and sLe^x structures on the cell surface than their corresponding low metastatic counterparts (Saitoh et al. 1992). High and low metastatic colonic carcinoma cells differ in their adhesion efficiency to E-selectin-expressing cells. The high metastatic cells, as compared to their low metastatic counterparts, bind more efficiently to activated human endothelial cells that express E-selectin. In addition, the high metastatic cells also adhere more efficiently to mouse endothelioma cells after activation with IL-1β. It was also shown that the adhesion can be inhibited by soluble Lamp-1 or soluble leukosialin that contain sLe^x termini (Sawada et al. 1994). Among O-glycans released from an ovarian cystadenoma glycoprotein using ethylamine, three variants of the sulfated $Le^{a/x}$ sequences were identified as ligands for E-selectin, one of which is based on the unusual backbone Gal-3/4GlcNAc-3Gal-3Gal (Chai et al. 1997).

28.6.1.1 Sialyl-Lewis^x

The sLe^x determinant (Neu5Ac α2 → 3Gal β1 → 4[Fuc α-1 → 3]GlcNAc) has been identified as a major ligand in the selectin-mediated adhesion of neutrophils and monocytes to activated endothelium or platelets. This carbohydrate epitope is formed by the sequential action of α3-sialyltransferase and α3-fucosyltransferase on N-acetyllactosamine (Gal β1 → 4 GlcNAc) disaccharide termini of glycoconjugates. In addition, the α3 fucosyltransferase of the cells can use sialylated acceptors. Characterization of the product obtained with a sialylated oligosaccharide indicated that the enzyme can catalyze the formation of the sLe^x structure. The enzyme studied appeared to be a myeloid-type and was involved in the synthesis of sLe^x in leukocytes provided that its expression is at a sufficiently high level (Easton et al. 1993). A single amino acid can determine the ligand specificity of E-selectin. Kogan et al. (1995) developed a model of E-selectin binding to the sLe^x tetrasaccharide, (Neu5Ac α2 → 3Gal β1 → 4(Fuc α 1 → 3)GlcNAc), using the E-selectin-bound solution conformation of sLe^x (Cooke et al.1994) and the crystallographic structures of E-selectin (Graves et al. 1994) (ligand unbound) and the MBP (Weis et al. 1992) (ligand bound). Analysis of this model indicated that the alteration of one E-selectin amino acid, alanine 77, to a lysine residue might shift binding specificity from sLe^x to mannose. The E-selectin mutant protein possessing this change displays preferential binding to mannose containing oligosaccharides and that further mutagenesis of this mannose-binding selectin confers galactose recognition in a predictable manner. These mutagenesis data support the presented model of the detailed interactions between E-selectin and the sLe^x oligosaccharide.

Evidences suggest for density-dependent binding of the membrane-associated E-selectin not only to 3′-sialyl-lacto-N-fucopentaose II (3′-S-LNFP-II) and 3′-sialyl-lacto-N-fucopentaose III (3′-S-LNFP-III), which express the sialyl Le^a and sLe^x antigens, respectively, but also to the nonsialylated analogue LNFP-II; there is a threshold density of E-selectin required for binding to these sialylated sequences, and binding to the nonsialylated analogue is a property only of cells with the highest density of E-selectin expression. The presence of fucose linked to subterminal rather than to an internal N-acetylglucosamine is a requirement for E-selectin binding. Moreover, the presence of sialic acid 3-linked to the terminal galactose of the LNFP-II or LNFP-III sequences substantially enhances E-selectin binding where as the presence of 6-linked sialic acid abolishes E-selectin binding (Larkin et al. 1992).

28.6.1.2 Sulfated Polysaccharide Ligands

A new class of oligosaccharide ligand—sulfate-containing—for the human E-selectin molecule from among oligosaccharides was identified on ovarian cystadenoma glycoprotein. Several components with strong E-selectin binding activity were revealed among acidic oligosaccharides. The smallest among these preparations showed equimolar mixture of the Le^a- and Le^x/SSEA-1-type fucotetrasaccharides sulfated at position 3 of outer galactose. The binding activity was substantially greater than those of lipid-linked Le^a and Le^x/SSEA-1 sequences and is at least equal to that of the 3′- sLe^x/SSEA-1 glycolipid analogue (Yuen et al. 1992). The sulfo derivative of sLe^x, GM 1998-016, which blocks the P- and E-selectins interaction with a ligand, showed a significant decrease in bacterial translocation, both local (MLN) and systemic, in association with the decrease in the neutrophil infiltration, the oxygen free radicals production and the cytokines. Thus, sulfo derivative of sLe^x shows a protective effect in experimental model of bacterial translocation, downregulating the inflammatory response and the leukocyte-endothelium interactions (Garcia-Criado et al. 2005).

Interactions with Fuco-Oligosaccharides: Sweeney et al. (2000) found that sulfated fucans, whether branched and linear, are capable of increasing mature white cells in the periphery and mobilizing stem/progenitor cells of all classes. Though the presence of sulfate groups was necessary, yet it was not sufficient. Significant mobilization of stem/progenitor cells and leukocytosis, elicited in selectin-deficient mice ($L^{-/-}$, $PE^{-/-}$ or $LPE^{-/-}$) similar to that of controls, suggested that the mode of action of sulfated fucans is not through blockade of known selectins. The influence of the location of fucose residue(s) was investigated using 14 structurally defined and variously fucosylated oligosaccharides. Results showed that the recognition motifs for E-selectin include 4-fucosyl-lacto (Le^a) and 3-fucosyl-neo-lacto (Le^x) sequences strictly at capping positions and not Le^x at an internal position as a part of VIM-2 antigen sequence. Additional fucose residues α1-2-linked to neighboring galactoses or α1-3-linked to inner N-acetyglucosamines or to reducing-terminal glucose residues of the tetrasaccharide backbone had little or no effect on the selectin binding (Martin et al. 2002).

Selectin/MBP Chimeras Bind Selectin Ligand sLe^x Through Ca^{2+}Dependent Subsite: Selectin/MBP chimeras created by transfer of key sequences from E-selectin into MBP bind the selectin ligand sLe^x through a Ca^{2+} dependent subsite, present in many C-type lectins, and an accessory site containing positively charged amino acid residues. These chimeras demonstrate selectin-like interaction with sLe^x and can be faithfully reproduced even though structural evidence indicates that the mechanisms of binding to E-selectin and the chimeras are different. Selectin-like binding to the nonfucosylated sulfatide and sulfoglucuronyl glycolipids can also be reproduced with selectin/MBP chimeras that contain the two subsites involved in sLe^x binding. Results indicate that binding of structurally distinct anionic glycans to C-type carbohydrate-recognition domains can be mediated by the Ca^2-dependent subsite in combination with a positively charged region that forms an ionic strength-sensitive subsite (Blanck et al. 1996; Bouyain et al. 2001).

E-Selectin Receptors on Human l Neutrophils: The human neutrophil receptor for E-selectin has not been established. Sialylated glycosphingolipids with 5N-acetyllactosamine (LacNAc, Galβ1-4GlcNAcβ1-3) repeats and 2–3 fucose residues are major functional E-selectin receptors on human neutrophils. E-selectin-expressing cells tethered and rolled on selected glycolipids, whereas P-selectin-expressing cells failed to interact. Results support that the glycosphingolipid NeuAcα2-3Galβ1-4GlcNAcβ1-3[Galβ1-4(Fucα1-3)GlcNAcβ1-3](2)[Galβ1-4GlcNAcβ1-3](2)Galβ1-4GlcβCer (and closely related structures) are functional E-selectin receptors on human neutrophils (Nimrichter et al. 2008; Gege et al. 2008).

Enzymes Involved in the Synthesis of Lewis Antigens: The enzymes involved in the synthesis of Lewis antigens have been identified. FucT-VI is an enzyme involved in the biosynthesis of sLe^x, in myeloid cells (Koszdin and Bowen 1992). Their biosynthesis is complex and involves β1 → 3-galactosyltransferases (β3Gal-Ts) and a combined action of α2- and/or α4-fucosyltransferases (Fuc-Ts). O-glycans with different core structures have been identified, and the ability of β3Gal-Ts and Fuc-Ts to use them as substrates has been tested (Holgersson and Lofling 2006). This knowledge enables us to engineer recombinant glycoproteins with glycan- and core chain-specific Lewis antigen substitution. Such tools may be important for investigations on the fine carbohydrate specificity of Le B-binding lectins, such as Helicobacter pylori adhesins and DC-SIGN, and may also prove useful as therapeutics (Holgersson and Lofling 2006).

28.6.1.3 Transcriptional Control of Expression of Carbohydrate Ligands

Cell adhesion mediated by selectins and their carbohydrate ligands is involved in the adhesion of cancer cells to endothelial cells during the course of hematogenous metastasis of cancer. Extravasation and tissue infiltration of malignant cells in patients with adult T-cell leukemia is mediated by the interaction of selectins and their carbohydrate ligand sialyl-Le^x, which is strongly and constitutively expressed on the leukemic cells. Constitutive expression of Lewis X in these cells is due to the transcriptional activation of Fuc-T VII, the rate-limiting enzyme in the sLe^x synthesis, induced by the Tax protein encoded by the human T-cell leukemia virus-1, the etiological virus for this leukemia. This transactivation is in clear contrast to the regulation of typical CRE-element found in various cellular genes in that it is independent of phosphorylation-dependent regulation. This must be the reason for the strong and constitutive expression of sialyl-Le^x, which exacerbates the tissue infiltration of leukemic cells. This is a good example corroborating the proposition that the abnormal expression of carbohydrate determinant at the surface of malignant cells is intimately associated with the genetic mechanism of malignant transformation of cells (Kannagi 2001).

28.6.2 E-Selectin Ligand-1

E-Selectin-Ligand-1 Is a Variant of FGF-R: A 150 kDa glycoprotein is the major ligand for E-selectin on plasma membranes of myeloid cells. Mouse c-DNA for this E-selectin ligand (ESL-1) predicted amino-acid sequence, which is 94% identical (over 1,078 amino acids) to the

chicken cysteine-rich FGF-R, except for a unique 70-amino-acid aminoterminal domain of mature ESL-1. Fucosylation of ESL-1 is imperative for affinity isolation with E-selectin-IgG. ESL-1, with a structure essentially identical to that of a receptor functions as a cell adhesion ligand of E-selectin (Steegmaier et al. 1995). E-selectin binds to ESL-1 with a fast dissociation rate constant of 4.6 s^{-1} and a calculated association rate constant of 7.4×10^4 m^{-1} s^{-1}. A K_D of 62 μM resembles the affinity of L-selectin binding to glycosylation-dependent cell adhesion molecule-1. The affinity of the E-selectin-ESL-1 interaction did not change significantly from 5°C to 37°C, indicating that the enthalpic contribution to the binding is small at physiological temperatures, and that, in contrast to typical protein-carbohydrate interactions, binding is driven primarily by favorable entropic changes (Wild et al. 2001). MG160 is a conserved membrane sialoglycoprotein of the Golgi apparatus displaying over 90% amino acid sequence identities with two apparently unrelated molecules, namely, a chicken fibroblast growth factor receptor (CFR), and ESL-1 (Steegmaier et al. 1995). MG160 from rat brain membranes binds to b-FGF. The gene for MG160 has been assigned to human chromosome 16q22-23 (Mourelatos et al. 1996).

28.6.3 PSGL-1 and Relating Ligands

The selectin family of adhesion molecules mediates tethering and rolling of leukocytes to the vessel wall in the microcirculation. Selectins promote these interactions by binding to glycoconjugate ligands expressed on apposing cells. Selectin-mediated rolling is a prerequisite for firm adhesion and subsequent transendothelial migration of leukocytes into tissues. PSGL-1 interacts with selectins to support leukocyte rolling along vascular wall. PSGL-1 (CD162 P) is a dimeric mucin-like 120-kDa glycoprotein on leukocyte surfaces that binds to P-, L- and E- selectin and promotes cell adhesion in the inflammatory response (see Chap. 26 and 27). Present understanding on selectin functions reveals that selectins and their ligands have a complex role during inflammatory diseases. Among selectin ligands, mucin PSGL-1 has a well-documented role in organ targeting during inflammation in animal models. Although inhibition of selectins and their ligands in animal models of inflammatory diseases has proven the validity of this approach in vivo, only a limited number of anti-selectin drugs have been tested in humans. Results in clinical trials for asthma and psoriasis show that, although very challenging, the development of selectin antagonists holds concrete promise for the therapy of inflammatory diseases (Rossi and Constantin 2008).

PSGL-1 requires sialylated, fucosylated O-linked glycans and tyrosine sulfate to bind P-selectin. Less is known about the determinants that PSGL-1 requires to bind E-selectin. Tyrosine residues on PSGL-1 expressed in CHO cells were shown to be sulfated. Phenylalanine replacement of three tyrosines within a consensus sequence for tyrosine sulfation abolished binding to P-selectin but not to E-selectin. Results suggest that PSGL-1 requires core 2 O-linked glycans that are sialylated and fucosylated to bind P- and E-selectin. PSGL-1 also requires tyrosine sulfate to bind P-selectin but not E-selectin (Li et al. 1996). Studies using CHO-E and -P monolayers demonstrated that the first 19 amino acids of PSGL-1 are sufficient for attachment and rolling on both E- and P-selectin and that a sialyl Le^x-containing glycan at Threonine-16 was critical for this sequence of amino acids to mediate attachment to E- and P-selectin. However, a sulfated-anionic polypeptide segment within the amino terminus of PSGL-1 is necessary for PSGL-1-mediated attachment to P- but not to E-selectin. In addition, PSGL-1 had more than one binding site for E-selectin: one site located within the first 19 amino acids of PSGL-1 and one or more sites located between amino acids 19 through 148 (Goetz et al. 1997).

28.6.3.1 PSGL-1-Dependent and -Independent E-Selectin Rolling

PSGL-1 supports P-selectin-dependent rolling in vivo and in vitro. However, controversy exists regarding the importance of PSGL-1-dependent and -independent E-selectin rolling. Using antibodies against PSGL-1 and PSGL-$1^{-/-}$ mice, Zanardo et al. (2004) demonstrated abolition of P-selectin-dependent rolling but only partial inhibition of E-selectin-mediated rolling in the cremaster microcirculation following local administration of TNF-α. Data support an E-selectin ligand present on PSGL-$1^{-/-}$ neutrophils that is down-regulatable upon systemic but not local activation. In P- and E-selectin-dependent cutaneous contact hypersensitivity model, binding studies showed no E-selectin ligand down-regulation. In conclusion, it was suggested that E-selectin mediates PSGL-1-dependent and independent rolling and the latter can be down-regulated by systemic activation and can replace PSGL-1 to support the development of inflammation (Zanardo et al. 2004; Shigeta et al. 2008).

28.6.3.2 PSGL-1 Participates in E-Selectin-Mediated Progenitor Homing

The nature and exact function of selectin ligands involved in hematopoietic progenitor cell (HPC) homing to the bone marrow (BM) are not clear. Using murine progenitor homing assays, it was found that PSGL-1plays a partial role in HPC homing to BM. Homing studies with PSGL-1-deficient HPCs pretreated with anti-α4 integrin antibody revealed that PSGL-1 contributes to approximately 60% of E-selectin ligand-mediated homing activity. Results thus underscore a major difference between mature myeloid cells and immature stem/progenitor cells in that E-selectin ligands

cooperate with α4 integrin rather than P-selectin ligands (Katayama et al. 2003). PSGL-1, expressed by primitive human bone marrow $CD34^+$ cells, mediates their adhesion to P-selectin and inhibits their proliferation. Adhesion to E-selectin also inhibits the proliferation of human and mouse $CD34^+$ cells. Furthermore, a subpopulation, which does not contain the most primitive hematopoietic progenitor cells, undergoes apoptosis following E-selectin-mediated adhesion. This shows that PSGL-1 is not the ligand involved in E-selectin-mediated growth inhibition and apoptosis, but an E-selectin ligand(s) other than PSGL-1 transduces growth inhibitory and proapoptotic signals and suggests the requirement of posttranslational fucosylation (Winkler et al. 2004).

28.6.3.3 PSGL-1 Decameric Repeats Regulate Selectin-Dependent Rolling Under Flow Conditions

PSGL-1 regulates leukocyte rolling by binding P-selectin, and also by binding E- and L-selectins with lower affinity. L- and P-selectin bind to N-terminal tyrosine sulfate residues and to core-2 O-glycans attached to Thr-57, whereas tyrosine sulfation is not required for E-selectin binding. PSGL-1 extracellular domain contains decameric repeats, which extend L- and P-selectin binding sites far above the plasma membrane. It was suggested that decamers may play a role in regulating PSGL-1 interactions with selectins. Deletion of decamers abrogated sL-selectin binding and cell rolling on L-selectin, whereas their substitution partially reversed these diminutions. P-selectin-dependent interactions with PSGL-1 were less affected by decamer deletion. Analysis showed that decamers are required to stabilize L-selectin-dependent rolling. However, adhesion assays performed on recombinant decamers demonstrated that they directly bind to E-selectin and promote slow rolling. Therefore, the role of decamers is to extend PSGL-1N terminus far above the cell surface to support and stabilize leukocyte rolling on L- or P-selectin. In addition, they function as a cell adhesion receptor, which supports approximately 80% of E-selectin-dependent rolling (Tauxe et al. 2008). Tomita et al. (2009) investigated cutaneous wound healing in $PSGL\text{-}1^{-/-}$ mice in comparison with $E\text{-selectin}^{-/-}$, $P\text{-selectin}^{-/-}$, and $P\text{-selectin}^{-/-}$ mice treated with an anti-E-selectin antibody. PSGL-1 contributes to wound healing predominantly as a P-selectin ligand and partly as an E-selectin ligand by mediating infiltration of inflammatory cells.

E-selectin binding to PSGL-1 can activate β2 integrin lymphocyte function-associated antigen-1 by signaling through spleen tyrosine kinase (Syk). This signaling is independent of G αi-protein-coupled receptors, results in slow rolling, and promotes neutrophil recruitment to sites of inflammation. An ITAM-dependent pathway involving Src-family kinase Fgr and the ITAM-containing adaptor proteins DAP12 and FcRγ is involved in the initial signaling events downstream of PSGL-1 that are required to initiate neutrophil slow rolling (Zarbock et al. 2008).

28.6.3.4 Hematopoietic Cell E-/L-selectin Ligand (HCELL) (CD44) in Stem Cell Homing

Though a glycoform of PSGL-1 functions as the principal E-selectin ligand on human T lymphocytes, the E-selectin ligand(s) of human hematopoietic progenitor cells (HPCs) is not well defined. While the PSGL-1 expressed on human HPCs is an E-selectin ligand, HSCs express a novel glycoform of CD44 known as hematopoietic cell E-/L-selectin ligand (HCELL) that acts as ligand. Current understanding of the molecular basis of HSC homing describes the fundamental "roll" of HCELL in opening the avenues for efficient HSC trafficking to the bone marrow, the skin and other extramedullary sites (Sackstein 2004). The E-selectin ligand activity of CD44 is expressed on primitive $CD34^+$ human HPCs, but not on more mature hematopoietic cells. Under physiologic flow conditions, this molecule mediates E-selectin-dependent rolling interactions over a wider shear range than that of PSGL-1, and promotes human HPC rolling interactions on E-selectin expressed on human BM endothelial cells (Dimitroff et al. 2001). The LS174T colon carcinoma cell line expresses the CD44 glycoform known as hematopoietic cell E-/L-selectin ligand (HCELL), which functions as a high affinity E- and L-selectin ligand on these cells. Burdick et al. (2006) measured the binding of LS174T cells transduced with CD44 short interfering RNA (siRNA). It indicated that expression of HCELL confers robust and predominant tumor cell binding to E- and L-selectin, highlighting a central role for HCELL in promoting shear-resistant adhesive interactions essential for hematogenous cancer dissemination.

28.6.3.5 CD43 as a Ligand for E-Selectin on CLA^+ Human T Cells

Human memory T cells that infiltrate skin express the carbohydrate epitope cutaneous lymphocyte-associated antigen (CLA). Expression of the CLA epitope on T cells has been described on PSGL-1 and associated with the acquisition of both E-selectin and P-selectin ligand functions. The CD43, a sialomucin expressed constitutively on T cells, can also be decorated with the CLA epitope and serves as an E-selectin ligand. CLA expressed on CD43 is found exclusively on the 125 kDa glycoform bearing core-2-branched O-linked glycans. CLA^+ CD43 from human T cells supported tethering and rolling in shear flow via E-selectin but did not support binding of P-selectin. The identification and characterization of CD43 as a T-cell E-selectin ligand distinct from PSGL-1 expands the role of CD43 in the regulation of T-cell trafficking and provides new targets for the modulation of immune functions in skin (Fuhlbrigge et al. 2006). It has been reported that CD43 on activated T cells functions as an

E-selectin ligand and thereby mediates T cell migration to inflamed sites, in collaboration with PSGL-1, a major P- and E-selectin ligand. CD43 on neutrophils also functions as an E-selectin ligand. Observations suggest that CD43 generally serves as an antiadhesive molecule to attenuate neutrophil-endothelial interactions, but when E-selectin is expressed on endothelial cells, it also plays a proadhesive role as an E-selectin ligand (Matsumoto et al. 2008).

28.6.4 Endoglycan, a Ligand for Vascular Selectins

While several ligands have been characterized on human T cells, monocytes and neutrophils, there is limited information concerning ligands on B cells. Endoglycan (EG) together with CD34 and podocalyxin comprise the CD34 family of sialomucins. EG was previously implicated as an L-selectin ligand on endothelial cells. EG is present on human B cells, T cells and peripheral blood monocytes. Upon activation of B cells, EG increased with a concurrent decrease in PSGL-1. Expression of EG on T cells remained constant under the same conditions. Native EG from several sources (a B cell line, a monocyte line and human tonsils) was reactive with HECA-452, a mAb that recognizes sialyl Lewis X and related structures. Finally, an EG construct supported slow rolling of E- and P-selectin bearing cells in a sialic acid and fucose dependent manner, and the introduction of intact EG into a B cell line facilitated rolling interactions on a P-selectin substratum. These findings indicate that endoglycan can function as a ligand for vascular selectins (Kerr et al. 2008). Basigin (Bsg)/CD147 is a ligand for E-selectin that promotes renal inflammation in ischemia/reperfusion (I/R). Bsg is a physiologic ligand for E-selectin that plays a critical role in renal damage induced by I/R (Kato et al. 2009).

28.6.5 L-Selectin as E-Selectin Ligand

L-Selectin from Human, but Not from Mouse Neutrophils Binds E-Selectin: L-selectin has been suggested as a carbohydrate presenting ligand for E- and P-selectin. However, affinity experiments with an E-selectin-Ig failed to detect L-selectin in the isolated E-selectin ligands from mouse neutrophils. In contrast to mouse neutrophils, L-selectin from human neutrophils could be affinity-isolated as a major ligand from cell extracts using E-selectin-Ig as affinity probe. It was suggested that L-selectin on human neutrophils is a major glycoprotein ligand among very few glycoproteins that could be isolated by an E-selectin affinity matrix. The difference between human and mouse L-selectin suggests that E-selectin-binding carbohydrate moieties are attached to different protein scaffolds in different species (Zollner et al. 1997). L-selectin acquires E-selectin-binding activity following phorbol ester (PMA) treatment of the Jurkat T cell line and anti-CD3/IL-2-driven proliferation of human T lymphocytes in vitro. It appears that L-selectin on human T lymphoblasts is one of the several glycoproteins that interacts directly with E-selectin and contributes to rolling under flow (Jutila et al. 2002).

In addition to endogenous ligands for E-selectin, several proteins are found in cancer cell lines or solid tumors that act as ligands for E, L, and P selectins. E-selectin ligands present on cancer cells are: (1) Glycodelin A (GdA) is primarily produced in endometrial and decidual tissue and secreted to amniotic fluid Glycodelins is expressed in in ovarian cancer can act as an inhibitor of lymphocyte activation and/or adhesion (Jeschke et al. 2009); (2) The cysteine-rich fibroblast growth factor receptor (FGF-R) represents the main E-selectin ligand (ESL-1) on granulocytes. Hepatic stellate cells (HSC) are pericytes of liver sinusoidal endothelial cells, which are involved in the repair of liver tissue injury and angiogenesis of liver metastases. HSC express FGF-R together with FucT7 and exhibit a functional E-selectin binding activity on their cell surface (Antoine et al. 2009). (3) Although B-cell precursor acute lymphoblastic leukemia (BCP-ALL) cell lines do not express the ligand PSGL-1, a major proportion of carbohydrate selectin ligand was carried by another sialomucin, CD43, in NALL-1 cells. CD43 plays an important role in extravascular infiltration of NALL-1 cells and the degree of tissue engraftment of BCP-ALL cells may be controlled by manipulating CD43 expression (Nonomura et al. 2008). (4) Thomas et al. (2009a) identified podocalyxin-like protein (PCLP) as an alternative selectin ligand. PCLP on LS174T colon carcinoma cells possesses E-/L-, but not P-, selectin binding activity. PCLP functions as an alternative acceptor for selectin-binding glycans. The finding that PCLP is an E-/L-selectin ligand on carcinoma cells offers a unifying perspective on the apparent enhanced metastatic potential associated with tumor cell PCLP overexpression and the role of selectins in metastasis (Thomas et al. 2009b). (5) E-selectin has been shown to play a pivotal role in mediating cell-cell interactions between breast cancer cells and endothelial monolayers during tumor cell metastasis. The counterreceptor for E-selectin was found as CD44v4. However, CD44 variant (CD44v) isoforms was functional P-, but not E-/L- selectin ligands on colon carcinoma cells. Furthermore, a ~180-kDa sialofucosylated glycoprotein(s) mediated selectin binding in CD44-knockdown cells. This glycoprotein was identified as carcinoembryonic antigen (CEA). CEA serves as an auxiliary L-selectin ligand, which stabilizes L-selectin-dependent cell rolling against fluid shear (Thomas et al. 2009b). Zen et al. (2008) identified a ~170 kDa human

CD44 variant 4 (CD44v4) as E-selectin ligand. Purified CD44v4 has a high affinity for E-selectin via sLe^x moieties.

28.7 Structural Properties of E-Selectin

28.7.1 Soluble E-Selectin: An Asymmetric Monomer

The gene coding for a soluble form of human E-selectin (sE-selectin) has been expressed in CHO cells. The sE-selectin showed a broad band of M_r 75 kDa on nonreducing SDS-PAGE and eluted with M_r 310 kDa from size exclusion chromatography. Matrix-assisted laser-desorption MS gave a molecular weight of 80 kDa, while the minimum monomer molecular weight from the gene sequence should be 58.571 kDa, demonstrating that the monomeric molecule thus expressed had 27% carbohydrate. Equilibrium ultracentrifugation gave an average solution molecular weight of 81.6 kDa. Velocity ultracentrifugation gave a sedimentation coefficient of 4.3S and, from this, an apparent axial ratio of 10.5:1, assuming a prolate ellipsoid of revolution. An analysis of the NMR NOESY spectra of sE-selectin, sialyl-$Lewis^x$, and sE-selectin with sialyl-$Lewis^x$ demonstrated that the recombinant protein binds sialyl-$Lewis^x$ productively. Hence, in solution, sE-selectin is a functional elongated monomer (Hensley et al. 1994). E-selectin-expressed in COS cells bind the promyelocytic cell line HL-60 by a Ca^{2+} dependent mechanism. Although E-selectin is homologous to mammalian lectins, its interaction with HL-60 cells is not inhibited by simple carbohydrate structures. E-selectin-expressing COS cells also bind human neutrophils and the human colon carcinoma cell line HT-29, but not the B-cell line Ramos (Hession et al. 1990).

The three-dimensional structure of the ligand-binding region of human E-selectin reveals limited contact between the two domains and a coordination of Ca^{2+} not predicted from other C-type lectins. Structure/function analysis indicates a defined region and specific amino-acid side chains that might be involved in ligand binding. The features of E-selectin/ligand interaction have important implications for understanding the recruitment of leukocytes to sites of inflammation. The selectins bind weakly to sialyl Lewis-X (sLe^X)-like glycans, but with high-affinity to specific glycoprotein counterreceptors, including PSGL-1. The crystal structure of human E-selectin constructs containing the lectin and EGF (LE) domains co-complexed with sLe^X has been elucidated (Fig. 28.3) (Somers et al. 2000). Somers et al. (2000) also solved crystal structure of P-selectin-lectin and EGF domains co-complexed with the N-terminal domain of human PSGL-1 modified by both tyrosine sulfation and sLe^X. These structures reveal differences in binding of E- and P-selectin to sLe^X and the molecular basis of interaction between P-selectin and PSGL-1.

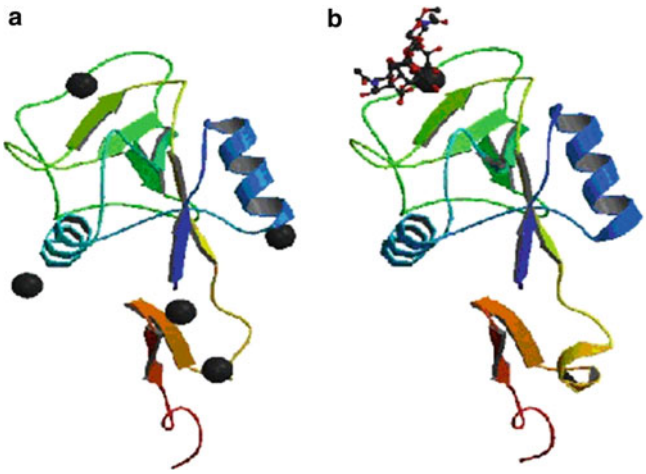

Fig. 28.3 (**a**) Crystal structure of E-selectin lectin-EGF domains (PDB ID: 1ESL) (Graves et al. 1994); (**b**) crystal structure of E-selectin lectin-EGF domains complexed with s-Le^x (PDB ID: 1G1T; Somers et al. 2000). Serum sE-selectin ranges from 0.13 to 2.8 ng/ml, suggesting that even in the absence of overt inflammatory processes E-selectin is being synthesized and released into the bloodstream. In addition, bacteremic patients with hypotension, but not those without, showed markedly elevated sE-selectin values. The blood-derived form of E-selectin is biologically active

28.7.2 Complement Regulatory Domains

Studies have shown that different animal species express E-selectin mRNAs that encode different numbers of complement regulatory (CR) domains. The isolation of these two rat E-selectin cDNA fragments, which differ only for the presence of CR5, represents the first direct evidence for the existence of E-selectin CR-variant mRNAs in the same species. Moreover, the sequence of the $CR5^-$ cDNA is consistent with its origin from an mRNA splice variant of a $CR5^+$ mRNA. Billups et al. (1995) demonstrated the presence of the two predicted mRNA species in rat heart tissue and investigated their expression in response to LPS. Although both mRNA variants were greatly induced by LPS, the $CR5^-$ form was more abundant in both treated and control tissues. This difference in mRNA abundance indicates different levels of CR5 variant proteins that perform functionally distinct tasks in E-selectin dependent inflammatory processes (Billups et al. 1995).

Consensus Repeat Domains: To study the structural characteristics of E-selectin necessary for mediating cell

adhesion, Li et al. (1994) examined the role of consensus repeat domains in E-selectin function. E-selectin containing all six consensus repeat domains (Lec-EGF-CR6) at its COOH terminus was the most potent in blocking neutrophil or HL-60 cell adhesion to either immobilized E-selectin or cytokine-stimulated HUVE cells. Therefore, although the lectin and EGF domains are necessary and sufficient for mediating cell adhesion, the additional six consensus repeat domains, present in native E-selectin, contribute to the enhanced binding of E-selectin to its ligand (Li et al. 1994).

Modulation by Metal Ions: Since E-selectin recognizes carbohydrate ligands in a Ca^{2+}-dependent manner, Anostario and Huang (1995) examined the E-selectin structure by limited proteolysis. Apo-Lec-EGF-CR6, a Ca^{2+}-free form of soluble E-selectin containing the entire extracellular domain, was sensitive to limited proteolysis by Glu-C endoproteinase. Amino-terminal sequencing analysis of the proteolytic fragments revealed that the major cleavage site is at Glu98, which is in the loop (residues 94–103) adjacent to the Ca^{2+} binding region of the lectin domain. Upon Ca^{2+} binding, Lec-EGF-CR6 was protected from proteolysis. This Ca^{2+}-dependent protection was augmented upon sialyl Lewis x (sLex) binding. This implied that Ca^{2+} binding to E-selectin induces a conformational change and perhaps facilitates ligand binding. Ba^{2+} was a potent antagonist in blocking Lec-EGF-CR6-mediated HL-60 cell adhesion. Sr2 + also bound to apo-Lec-EGF-CR6 tighter than Ca^{2+} Thus, E-selectin function can be modulated by different metal ions (Anostario and Huang 1995).

28.7.3 Three-Dimensional Structure

The three-dimensional structure of the ligand-binding region of human E-selectin has been determined at 2.0 A resolution. The structure reveals limited contact between the two domains and a coordination of Ca^{2+} not predicted from other C-type lectins. Structure/function analysis indicates a defined region and specific amino-acid side chains that may be involved in ligand binding. These features of the E-selectin/ligand interaction have important implications for understanding the recruitment of leukocytes to sites of inflammation (Graves et al. 1994). Surface presentation of adhesion receptors influences cell adhesion, although the mechanisms underlying these effects are not well understood. The orientation and length of an adhesion receptor influences its rate of encountering and binding a surface ligand but does not subsequently affect the stability of binding (Huang et al. 2004).

28.8 Functions of E-Selectin

28.8.1 Functions in Cell Trafficking

In antigen-challenged mice a significant increase in leukocyte rolling and adhesion, and a very dramatic increase in emigration have been observed for 24 h. Although rolling and adhesion was dramatically blunted in P-selectin- or P selectin/ICAM-1-deficient mice, emigrated cell number was similar to that observed in wild-type mice. Leukocyte rolling, adhesion and emigration were almost totally abrogated over in E/P-selectin-deficient mice, demonstrating that antigen-induced leukocyte recruitment can be entirely disrupted in the absence of both endothelial selectins (McCafferty et al. 2000). The absence of P-selectin, and not E-selectin, resulted in an altered adhesion environment with subsequent expansion of megakaryocyte progenitors and immature megakaryoblasts, enhanced secretion of TGF-β1, and apparent increased responsiveness to inflammatory cytokines (Banu et al. 2002; Khew-Goodall et al. 1993).

In vitro assays suggest that both E-selectin and chemokines can trigger arrest of rolling neutrophils, but E-selectin$^{-/-}$ mice have normal levels of adherent neutrophils in inflamed venules (Asaduzzaman et al. 2009). Smith et al. (2004) showed that E-selectin- and chemokine-mediated arrest mechanisms are overlapping and identified CXCR2 as an important neutrophil arrest chemokine in vivo.

28.8.1.1 Trafficking of Th1 Cells to Lung Depends on Selectins

Expression of CD62E and CD62P is induced in the lungs of mice primed and then challenged with intratracheal (i.t.) SRBC. In addition, endogenous lymphocytes accumulate in the lungs of E- and P-selectin-deficient ($E^{-/-}P^{-/-}$) mice after i.t. SRBC challenge. $E^{-/-}P^{-/-}$ mice showed a 85–95% decrease in $CD8^+$ T cells and B cells in the lungs at both early and late time points (Curtis et al. 2002). Both P- and E-selectin play an important role in Th1 lymphocyte migration to lung (Clark et al. 2004). Moreover, Yiming et al. (2005) suggested that interactions of circulating inflammatory cells with P-selectin critically determine proinflammatory endothelial activation during high tidal volume ventilation.

Changes in P-Selectin/ICAM-1 in Mutant Mice Are Organ-Specific: Mice homozygous for an E-selectin null mutation were viable and exhibited no obvious developmental alterations. Neutrophil emigration during an inflammatory response is mediated through interactions between adhesion molecules on endothelial cells and neutrophils.

P-Selectin mediates rolling or slowing of neutrophils, while ICAM-1 contributes to the firm adhesion and emigration of neutrophils. Removing the function of either molecule partially prevents neutrophil emigration. While mice with either mutation alone showed a 60–70% reduction in acute neutrophil emigration into the peritoneum during *Streptococcus pneumoniae*-induced peritonitis, double mutant mice showed a complete loss of neutrophil emigration. In contrast, neutrophil emigration into the alveolar spaces during acute *S. pneumoniae*-induced pneumonia was normal in double mutant mice. These results demonstrated organ-specific differences, since emigration into the peritoneum requires both adhesion molecules while emigration into the lung requires neither (Bullard et al. 1996).

28.8.1.2 Cooperation Between E-Selectin and CD18 Integrin

CD18-deficient mice ($CD18^{-/-}$ mice) suffer from a severe leukocyte recruitment defect in some organs, with no detectable defect in other models. Mice lacking E-selectin ($CD62E^{-/-}$ mice) have either no defect or a mild defect of neutrophil infiltration, depending on the model. The $CD18^{-/-}CD62E^{-/-}$, but not $CD18^{-/-}CD62P^{-/-}$, mice generated by cross-breeding failed to thrive, reaching a maximum body weight of 10–15 g. To explore the mechanisms underlying reduced viability, Forlow et al. (2000) suggested that the greatly reduced viability of $CD18^{-/-}CD62E^{-/-}$ mice appeared to result from an inability to mount an adequate inflammatory response. This study showed that cooperation between E-selectin and CD18 integrins is necessary for neutrophil recruitment and that alternative adhesion pathways cannot compensate for the loss of these molecules (Forlow et al. 2000).

28.8.1.3 Selectin-Independent Leukocyte Rolling and Adhesion

To study selectin-independent leukocyte recruitment and the role of ICAM-1, Forlow and Ley (2001) generated mice lacking all three selectins and ICAM-1 ($E/P/L/I^{-/-}$) by bone marrow transplantation. A striking similarity of leukocyte adhesion efficiency in $E/P/L^{-/-}$ and $E/P/I^{-/-}$ mice suggests a pathway in which leukocyte rolling through L-selectin required ICAM-1 for adhesion and recruitment. Comparison of data with mice lacking individual or other combinations of adhesion molecules revealed that elimination of more adhesion molecules further reduces leukocyte recruitment but the effect is less than additive.

28.8.2 E-Selectin in Neutrophil Activation

Neutrophil adherence to activated endothelium mediated by E-selectin is reversibly inhibited by hypothermia. The protective effect of hypothermia (e.g., in cardiopulmonary bypass) may, in part, be mediated by transiently inhibiting the expression of an endothelial cell activation phenotype (Haddix et al. 1996). In transgenic mice, the number of blood neutrophils was reduced, without any other obvious phenotype or tissue damage. These neutrophils, however, displayed two significant changes: first, an alteration in the levels of expression of two membrane receptors involved in neutrophil adhesion to endothelial cells, namely a marked increased in the Mac-1 antigen (CD11b/CD18) and a decrease in L-selectin; second, an increased oxidative activity when compared to blood neutrophils of non-transgenic mice. These observations indicated that the binding of E-selection with neutrophils bearing its ligands promotes neutrophil activation in vivo (Araki et al. 1996). Mac-1 (CD11b/CD18) is the major neutrophil glycoprotein decorated with sLe^x and ligation of these carbohydrate moieties significantly impairs neutrophil functions. Protein-binding assays indicate that sLe^x moieties on Mac-1 are critical for binding interaction of Mac-1 to E-selectin. Ligation of Mac-1 sLe^x by anti-sLe^x antibody induces a significant degranulation of neutrophil secondary granules at the absence of chemoattractant stimulation. This "dysregulated" degranulation induced by anti-sLe^x antibody strongly inhibits neutrophil transmigration in response to formyl-Met-Leu-Phe (fMLP). Thus, Mac-1 sLe^x moieties play a critical role in regulating β2 integrin functions during neutrophil transmigration and degranulation (Zen et al. 2007).

However, E-selectin-deficient mice displayed no significant change in the trafficking of neutrophils in several models of inflammation, although blocking both endothelial selectins by treatment of the E-selectin-deficient animals with an anti-murine P-selectin antibody significantly inhibited neutrophil emigration in two distinct models of inflammation. Labow et al. (1994) demonstrated that the majority of neutrophil migration in both models requires an endothelial selectin but that E-selectin and P-selectin are functionally redundant. Studies on the functional effects of mAbs against murine E-selectin on neutrophil recruitment in vivo, leukocyte rolling and circulating leukocyte concentrations in vivo, and adhesion of myeloid cells to E-selectin transfectants and recombinant E-selectin-IgG fusion protein in vitro indicated that E-selectin serves a function, other than rolling, that appears to be critically important for neutrophil recruitment to inflammatory sites in Balb/c mice (Ramos et al. 1997).

28.8.3 P- and E-Selectin in Differentiation of Hematopoietic Cells

The P- and E-selectins are critically important for adhesion and homing of hematopoietic progenitor cells (HPC) into the

bone marrow. The most primitive HPC capable of long-term in vivo repopulation express PSGL-1, a receptor common to both P- and E-selectin. In addition, P-selectin delays the differentiation of HPC whereas E-selectin enhances their differentiation along the monocyte/granulocyte pathway, describing different roles for these selectins in the regulation of hematopoiesis. Thus, the two endothelial selectins, E-selectin and P-selectin, have very different effects on HPC. E-selectin accelerates the differentiation of maturing HPC towards granulocyte and monocyte lineages while maintaining the production of more immature CFU-S(12) in ex vivo liquid suspension culture. In marked contrast, P-selectin delays the differentiation of Lin^- $Sca\text{-}1^+$ $c\text{-}kit^+$ cells, allowing enhanced ex vivo expansion of CFC and CFU-S(12) but not HSCs (Eto et al. 2005; Schweitzer et al. 1996).

Role in Loose Adhesion of Allogeneic Lymphocytes and in Structural and Functional Lung Alterations: The interaction between host lymphocytes and graft endothelial cells plays an important role in graft rejection. Isogeneic perfusion induced nonspecific endothelial cell activation, which was characterized by up-regulation of E-selectin, ICAM-1, and of TNF-α. It was revealed that E-selectin expression (1) is not a consequence of TNF-α triggering, (2) E-selectin expression up-regulates its own expression and expression of I-A, VCAM-1, TNF-α, and lymphotoxin-α mRNAs, and down-regulates expression of LFA-3 and ICAM-1 mRNAs. Study indicated that the E-selectin plays major role in the loose adhesion of allogeneic lymphocytes and in structural and functional lung alterations (Joucher et al. 2004).

Memory B Lymphocytes from Secondary Lymphoid Organs Interact with E-Selectin: A subset of human tonsillar B cells that interact with E-selectin but not with P-selectin have a phenotype of non-germinal center ($CD10^-$, $CD38^-$, $CD44^+$), memory (IgD^-) cells. Furthermore, FucT-VII is expressed selectively in $CD44^+$ E-selectin-adherent B lymphocytes. These results assigned resident memory B lymphocytes a adhesion function, the rolling on E-selectin that provides insights on the adhesion pathways involved in homing of memory B cells to tertiary sites (Montoya et al. 1999).

28.8.4 Transmembrane Signaling in Endothelial Cells

In addition to supporting rolling and stable arrest of leukocytes, there is increasing evidence that E-selectin functions in transmembrane signaling into endothelial cells during these adhesive interactions. Adhesion of HL-60 cells (which express ligands for E-selectin), or antibody-mediated cross-linking of E-selectin, results in the formation of a Ras/Raf-1/phospho-MEK macrocomplex, extracellular signal-regulated protein kinase (ERK1/2) activation, and c-fos up-regulation. These downstream events require an intact cytoplasmic domain of E-selectin. Tyrosine-603 plays an important role in mediating the association of E-selectin with SHP2, and the catalytic domain of SHP2, in turn, is critical for E-selectin-dependent ERK1/2 activation. Events suggest that cross-linking of E-selectin by engagement of ligands on adherent leukocytes can initiate a multifunctional signaling pathway in the activated endothelial cell at the sites of inflammation (Hu et al. 2001).

Src-Family Kinases Mediate an Outside-In Signal: E-selectin-ligand engagement differs between lymphocytes and PMN, and that these differences may be accentuated by the CR1 and CR2 domains in the E-selectin (Hammel et al. 2001). In cell suspensions subjected to high-shear rotatory motion, human PMN adhered to E-selectin-expressing CHO (CHO-E), and formed homotypic aggregates when challenged by E-selectin-IgG fusion protein, by a mechanism that involved β2 integrins. It appeared that Src-family kinases, and perhaps Pyk2, mediate a signal necessary for β2 integrin function in PMN tethered by E-selectin (Totani et al. 2006).

E-Selectin Is Unique in Clustering Sialylated Ligands and Transducing Signals: Two adhesive events critical to efficient recruitment of neutrophils at vascular sites of inflammation are up-regulation of endothelial selectins that bind sLe^x ligands and activation of β2-integrins that support neutrophil arrest by binding ICAM-1. Neutrophils rolling on E-selectin is sufficient for signaling cell arrest through β2-integrins binding of ICAM-1 in a process dependent upon ligation of L-selectin and PSGL-1. Spatial and temporal events showed that binding of E-selectin to sLe^x on L-selectin and PSGL-1 drives their co-localization into membrane caps at the trailing edge of neutrophils rolling on HUVECs and on an L-cell monolayer co-expressing E-selectin and ICAM-1. Inhibition of p38 and p42/44 mitogen-activated protein kinase blocked the cocapping of L-selectin and PSGL-1 and the subsequent clustering of high-affinity β2-integrins. Results suggest that E-selectin is unique among selectins in its capacity for clustering sialylated ligands and transducing signals leading to neutrophil arrest in shear flow (Green et al. 2004).

C-Type Lectins: Lectin Receptors on NK Cells

KLRB Receptor Family and Human Early Activation Antigen (CD69)

29

Rajesh K. Gupta and G.S. Gupta

29.1 Lectin Receptors on NK Cell

29.1.1 NK Cell Receptors

Natural killer cells are important component of the innate immune system, providing protection against intracellular infection particularly viruses and also neoplasia through direct cytotoxic mechanisms and the secretion of cytokines. They mediate their effects through direct cytolysis, release of cytokines and regulation of subsequent adaptive immune responses. They are called 'natural' killers because, unlike cytotoxic T cells, they do not require a previous challenge and preactivation to become active. NK cells can be activated by a range of soluble factors, including type I interferons, IL-2, IL-12, IL-15 and IL-18, but also by direct cell to cell contact between NK cell receptors and target cell ligands. NK cells possess an elaborate array of receptors, which regulate NK cytotoxic and secretory functions upon interaction with target cell MHC class I proteins. Determination of structures of NK cell receptors and their ligand complexes has led to a fast growth in our understanding of the activation and ligand recognition by these receptors as well as their function in innate immunity. B and T cells significantly and differentially influence the homeostasis and the phenotype of NK cells. The function of NK cell is tightly regulated by a fine balance of inhibitory and activating signals that are delivered by a diverse array of cell surface receptors. A prerequisite for a NK cell attack is the presence on target cells of ligands for activating receptors and low level or absence of ligands for inhibitory receptors. It was believed that NK self-tolerance was achieved by expression on each NK cell of at least one self-MHC specific inhibitory receptor. However, this dogma has been challenged after identification of a NK cell population in normal mice that lack inhibitory receptors specific for self-MHC class I molecules (Kumar and McNerney 2005; Fernandez et al. 2005). Therefore, it was made clear that some additional surface receptors contribute to NK self-tolerance and to the modulation of NK cell responses. The characterization and the identification of their physiological ligands allow us a comprehensive understanding of NK cell function.

NK cell receptors (NKR) include: (1) non-HLA class I–specific receptors, such as CD56, CD57, or CD161 (Lee et al. 2003), (2) as well as receptors that recognize HLA class I molecules or their structural relatives. Later group comprises killer receptors belonging to the immunoglobulin family (KIR), such as KIR2DL1/S1 and KIR2DL2/3/S2 (Moretta and Moretta 2004) or immunoglobulin-like transcripts (ILTs), which are expressed mainly on B, T, and myeloid cells, although some members are also expressed on NK cells. The immunoglobulin-like transcripts (ILTs) include CD94/NKG2 heterodimers (also called KLRD/KLRC), rodent Ly49 (KLRA), NKG2D (KLRK), NKR-P1 (KLRB), and KLRG1 belonging to the C-type lectin receptor family, called killer cell lectin-like receptors (KLR approved symbol) (Borrego et al. 2001; Vetter et al. 2000). The superfamily of KLRs was originally discovered in NK cells in rats. Functionally, NK cell surface receptors are divided into two groups, the inhibitory and the activating receptors. Classically, inhibitory signals are mediated by receptors that recognize MHC class I molecules or their structural relatives such as MICA, ULBP, RAE-1, and H-60. The inhibitory form of NK receptors provides the protective immunity through recognizing class I MHC molecules with self-peptides on healthy host cells (Raulet et al. 2001; Yokoyama and Plougastel 2003).

Recent studies also suggest that MHC class I-independent inhibitory signals can also result in inhibition of cytotoxic cells and some NK cell specificities may be conveyed by orphan receptors expressed on NK cells (Lebbink and Meyaard 2007; Kumar and McNerney 2005). The recent identification of non-MHC class I ligands for inhibitory immune receptors, such as KLRG1, KLRB1 and LAIR-1, indicates that MHC class I-independent inhibitory immune receptors play crucial roles in inducing peripheral tolerance.

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_29, © Springer-Verlag Wien 2012

The presence of these receptors on many other immune cell types besides effector cells suggests that tight regulation of cell activation is necessary in all facets of the immune response in both normal and diseased tissue. Lebbink and Meyaard (2007) gave an overview of the known ligand-receptor pairs by grouping the ligands according to their properties and discussed implications of these interactions for the maintenance of immune balance and for the defense against tumors and pathogens (Lebbink and Meyaard 2007). Different mechanisms, through which NK cells can be activated, are shown in Fig. 29.1 (also see Fig. 31.1 in Chap. 31).

29.1.2 NKC Gene Locus

The human NK cell gene locus (NKC) is located on the short arm of chromosome 12 and contains a number of genes encoding C-type lectin receptors important for NK cell function. A part of human chromosome 12p12.3-p13.2 containing NKC has been sequenced. Genes among them are: CD94 and the five NKG2 genes. A detailed analysis shows that all six genes are found within a region of 100–200 kb proximal of the marker D12S77. The gene order established is D12S77—CD94—NKG2D—NKG2F—NKG2E—NKG2C—NKG2A. The NKG2 genes are of identical transcriptional orientation, whereas the CD94 gene is placed in opposite orientation. The tight genomic linkage of these genes and the identical orientation of the NKG2 genes suggest coordinate regulation of expression during differentiation of NK cells (Renedo et al. 2000; Sobanov et al. 1999). Renedo et al. (2000) localized 17 genes, 5 expressed sequence tags, and 49 STSs within this contig and established the order of the genes as tel-M6PR-MAFAL (HGMW-approved symbol KLRG1)-A2M-PZP-A2MP-NKRP1A (HGMW-approved symbol KLRB1)-CD69-AICL (HGMW-approved symbol CLECSF2)-KLRF1-OLR1-CD94 (HGMW-approved symbol KLRD1)-NKG2D (HGMW-approved symbol D12S2489E)-PGFL-NKG2F (HGMW-approved symbol KLRC4)-NKG2E (HGMW-approved symbol KLRC3)-NKG2A (HGMW-approved symbol KLRC1)-LY49L (HGMW-approved symbol KLRA1)-cen (Renedo et al. 2000).

In marmoset monkey, NKC is 1.5 times smaller than its human counterpart, but the genes are colinear and orthologous. One exception is the activating NKG2CE gene, which is probably an ancestral form of the NKG2C- and NKG2E-activating receptor genes of humans and great apes. Analyses of NKC genes in nine additional marmoset individuals revealed a moderate degree of polymorphism of the CD94, NKG2A, NKG2CE, and NKG2D genes. Furthermore, expression analyses identified several alternatively spliced transcripts, particularly of the CD94 gene. Several products of alternative splicing of NKC genes are highly conserved among primates (Averdam et al. 2007).

29.2 The Ever-Expanding Ly49 Receptor Gene Family

29.2.1 Activating and Inhibitory Receptors

The molecular mechanism that explains why NK cells do not kill indiscriminately has been elucidated. It is due to several specialized receptors that recognize MHC class I molecules expressed on normal cells. The lack of expression of one or more HLA class I alleles leads to NK-mediated target cell lysis. Different types of receptors specific for groups of HLA-C, HLA-B, and, later HLA-A alleles had been identified. While in most instances, they function as inhibitory receptors, an activatory form of the HLA-C-specific receptors has been identified in some donors. The mouse lectin-related Ly49 family and the human KIR family represent structurally distinct, yet functionally analogous, class I MHC receptors that are expressed on NK cells and some T cells. The functional similarity of these two families has been borne out by the demonstration of identical signal transduction pathways associated with each receptor family. The Ly49 family therefore provides a useful model system to study the role of this class of receptors in the regulation of the immune system. Reports relating to the Ly49 repertoire in several mouse strains have revealed an additional evolutionary parallel between KIR and Ly49 receptor families. There is now an appreciation of the variation in the number and type of Ly49s expressed in different mouse strains, similar to the previously demonstrated differences in the number of KIR genes found in humans. Different reviews have appeared describing properties of members of the Ly49 gene family, their MHC class I recognition and associated signal transduction pathways. The Ly49 receptor repertoire may be initially generated by a stochastic process that distributes receptors randomly to different cells and treats the two alleles of a given Ly49 gene independently. However, class I-MHC-dependent “education” processes shape the functional repertoire. The education processes silence potentially auto-aggressive NK cells, probably by ensuring that each NK cell expresses at least one self-specific Ly49 receptor. In addition, NK cell clones that express multiple self-specific Ly49 receptors are disfavored by the education processes, perhaps to confer greater discrimination on to individual NK cells (Raulet et al. 2001; Anderson et al. 2001).

29.2.1.1 Two Structurally Dissimilar NK Cell Receptor Families, Ly49 and KIR

In mice, C-type lectin receptors are represented by the Ly49 family of receptors, whereas in humans, NK cells express the distantly related CD94, which forms MHC class I-specific heterodimers with NKG2 family members. The Ly49 family of receptors is encoded by a highly polymorphic multigene

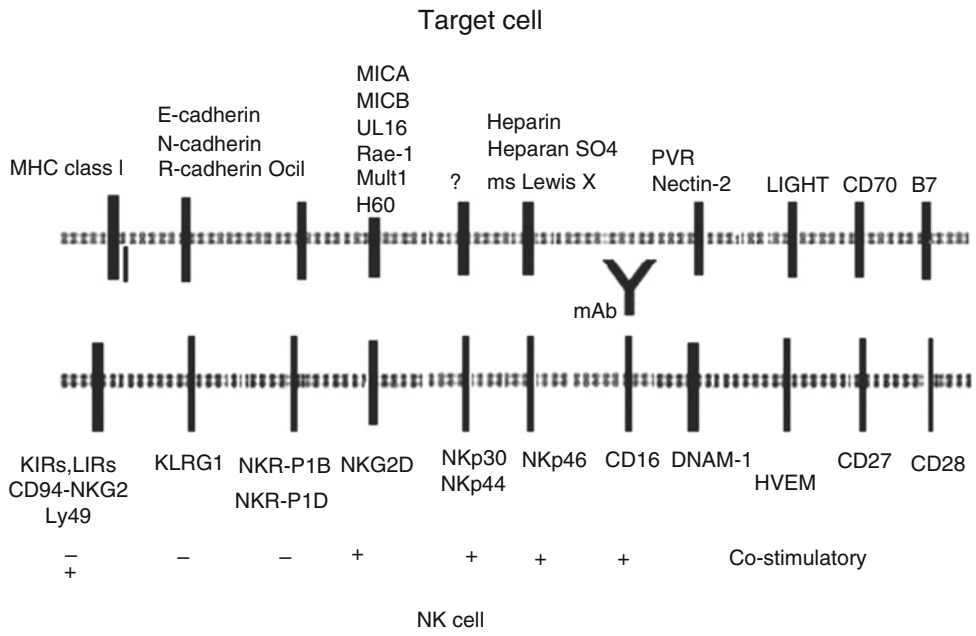

Fig. 29.1 The activating or the non-inhibitory NK receptors mediate the killing of tumor or virally infected cells through their specific ligand recognition. During target cell recognition, these cells receive both activating and inhibitory signals. Integration of opposing signals from two types of receptors determines the appropriate response: activation or inhibition of NK cells

family in mouse and is also present in multiple copies in rat. However, this gene exists as a single copy in primates and is mutated to non-function in humans. Humans also express MHC class I-specific p50/p58/p70 family of Ig-like receptors, and have been identified in mice. One Ly49-like gene, Ly49L, exists in humans but is incorrectly spliced and assumed to be nonfunctional. Mouse KIR-like genes have not been found, and the evidence suggests that the primate KIRs amplified after rodents and primates diverged. Thus, two structurally dissimilar families, Ly49 and KIR, had evolved to play similar roles in mouse and human NK cells respectively. It is not known, however, when the Ly49L gene became nonfunctional and if this event affected the functional evolution of the KIRs. The distribution of these gene families in different mammals has not been well studied, nor it is known if any species uses both types of receptors. However, the Ly49L gene shows evidence of conservation in other mammals and that the human gene likely became nonfunctional 6–10 million years ago. Furthermore, baboon lymphocytes express both full-length Ly49L transcripts and multiple KIR genes (Mager et al. 2001).

Interestingly, many activating and inhibitory receptors come in pairs, with a strong homology of the extracellular domains and partially overlapping ligand specificity but opposite signaling capacities. Examples for these paired receptors are KIRs, which comprise inhibitory and activating receptors, both recognizing the same major MHC class I ligand. Also in the family of KLRs can be found antithetic pairs that are specific for the same ligand but transmit opposing signals. For example, the NKG2A-CD94 heterodimer transmits an inhibitory signal and NKG2C-CD94 signals in an activating fashion while both receptors recognize the same ligand, HLA-E. The structures of activating and inhibitory NK cell surface receptors and their complexes with ligands and complexes with class I MHC homologs have been reviewed (Dimasi et al. 2004; Natarajan et al. 2002; Radaev and Sun 2003). Although CD94/NKG2 is expressed in both humans and rodents, KIRs are only expressed in humans and Ly49s only in rodents. Examples of other C-type lectin-like NK cell receptors that occur as individual genes are CD69, and activation-induced C-type lectin (AICL).

29.2.1.2 Ly49 Gene Expression in Different Inbred Mouse Strains

Mouse NK cells family of Ly49 contains at least 23 expressed members (A-w) and is further subdivided into activating and inhibitory subfamilies based on intracellular and transmembrane characteristics. The level of sequence identity between different members varies dramatically. However, comparison of the extracellular domain has revealed that several of the Ly49 molecules also form "pairs," where one member is activating and the other is inhibitory. Until recently, most Ly49 molecules described have come from the C57B1/6 strain of inbred mice. Using molecular cloning and immunochemical analysis it has been revealed that different mouse strains express novel Ly49

molecules. Comparison of the allelic forms of some Ly49 molecules has shown that the dividing line between different genes and different alleles is blurred (Deng and Mariuzza 2006; Deng et al. 2008).

29.2.1.3 Mouse Ly49 NK Receptors: Balancing Activation and Inhibition

In addition to lysis, a major consequence of triggering the murine activating NK receptor Ly49D is the expression of cytokines and chemokines. The activating Ly49D murine NK cell receptor can potently synergize during co-stimulation with IL-12 and IL-18 for selective production of IFN-γ. Activation both in vitro and in vivo and synergistic production of IFN-γ by Ly49D expressing NK cells results from cytokine stimulation combined with co-receptor ligation. Costimulation of the activating Ly49D murine NK cell receptor with IL-12 or IL-18 is capable of over-riding the inhibitory Ly49G2 receptor blockade for cytokine production both in vitro and in vivo. This synergy is mediated by and dependent upon Ly49D-expressing NK cells and results in significant systemic expression of IFN-γ. This would place NK cells and their activating Ly-49 receptors as important initiators of microbial, antiviral, and antitumor immunity and provide a mechanism for the release of activating Ly49 receptors from inhibitory receptor blockade (Ortaldo and Young 2003, 2005) (Fig. 29.2).

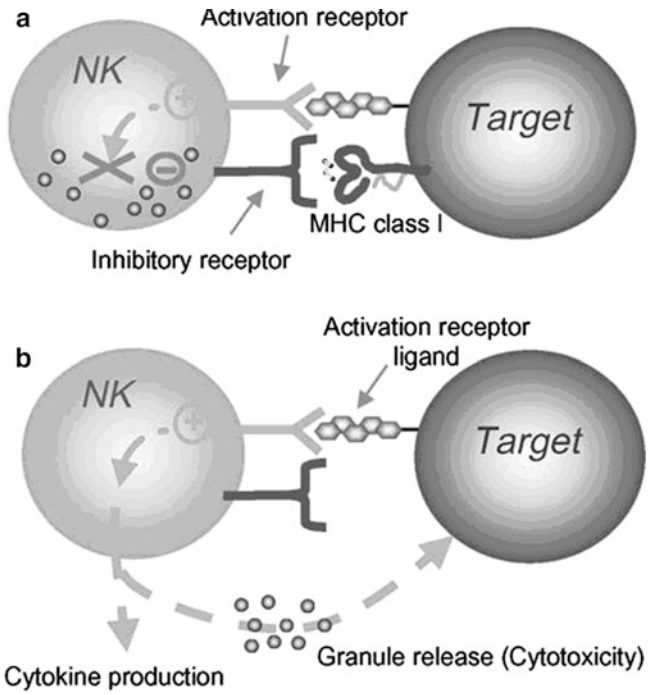

Fig. 29.2 NK cell activation is controlled by the integration of signals from activation and inhibitory receptors. (**a**) Inhibitory NK cell receptors recognize self MHC class I and restrain NK cell activation. (**b**) When unimpeded by the inhibitory receptors, binding of NK cell activation receptors to their ligands on target cells results in NK cell stimulation. In the absence or downregulation of self MHC class I on the target cells, these stimulatory signals are no longer suppressed, resulting in NK cell responses including cytokine production and granule release leading to cytotoxicity. Note that this model indicates that NK cells do not kill by default; that is, when MHC class I inhibition is absent, the NK cell must still be stimulated through activation receptors. Moreover, whether or not an individual NK cell is activated by a target is determined by this complex balance of receptors with opposing function and expression of the corresponding ligands. In general, however, inhibition dominates over activation. Finally, NK cells can be directly stimulated by cytokines such as interleukin-12 that trigger the production of other cytokines by NK cells (not shown). These direct cytokine-mediated responses are not affected by MHC class I expression (Reproduced from French and Yokoyama 2004)

29.2.2 Crystal Analysis of CTLD of Ly49I and comparison with Ly29A, NKG2D and MBP-A

Dimasi and Biassoni (2005) reviewed the functions and X-ray crystal structure of the Ly49 NK cell receptors (Ly49A and Ly49I) (Fig. 29.3a, b), and the structural features of the Ly49/MHC class I interaction as revealed by the X-ray crystal structures of Ly49A/H-2D^d and the Ly49C/H-2K^b. The Ly49 monomer consists of two α-helices (α1 and α2), and two anti-parallel β-sheets formed by β-strands β0, β1, β5; β2, β2′, β3 and β4 (Fig. 29.3). To form the Ly49 homodimer, the monomers associate through strand β0, creating an extended anti-parallel β-sheet. In Ly49A, the C-terminal ends of the α2 helices pack against one another, creating a 'closed' dimer (Dimasi and Biassoni 2005). In Ly49C and Ly49I, however, the α2 helices are not juxtaposed in the interface, opening these dimers by ~20° compared with Ly49A. An important consequence of this variability in Ly49 dimerization geometry is to modulate the way these NK receptors bind MHC, as revealed by the Ly49A/H-2D^d and Ly49C/H-2K^b structures (Tormo et al. 1999; Dam et al. 2003, 2006). The complex structures provide a framework for understanding MHC-I recognition by NK receptors from both families and reveal striking differences in the nature of this recognition, despite the receptors' functional similarity (Sawicki et al. 2001). The crystal structure of inhibitory NK receptor Ly49I monomer, at 3.0 Å adopts a fold similar to that of other C-type lectin-like NK receptors, including Ly49A, NKG2D (Fig. 29.3) and CD69.

However, the Ly49I monomers associate in a manner distinct from that of these other NK receptors, forming a more open dimer. As a result, the putative MHC-binding surfaces of the Ly49I dimer are spatially more distant than the corresponding surfaces of Ly49A or NKG2D. These structural differences probably reflect the fundamentally different ways in which Ly49 and NKG2D receptors recognize their respective ligands. For example the single MICA binding site of NKG2D is formed by the precise

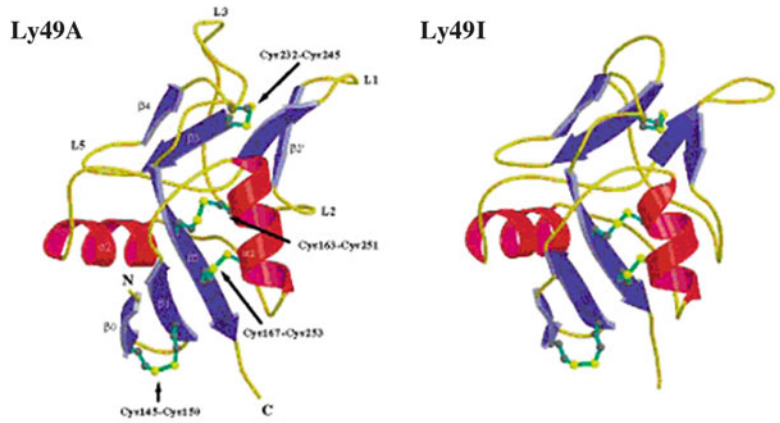

Fig. 29.3 Ribbon diagrams of C-type lectin-like domains of NK receptor Ly49A (PDB entry code 1QO3) (Tormo et al. 1999) and Ly49I (1JA3) (Dimasi et al. 2002). The secondary structural elements are colored as follows: β- strands *blue*, ®-helices *red*, and loop regions *gold*. The disulphide bonds are shown in green as ball-and-stick representation

juxtaposition of two monomers, each Ly49 monomer contains an independent binding site for MHC-I. Hence, the structural constraints on dimerization geometry may be relatively relaxed within the Ly49 family. Such variability may enable certain Ly49 receptors, like Ly49I, to bind MHC-I molecules bivalently, thereby stabilizing receptor-ligand interactions and enhancing signal transmission to the NK cell (Dimasi et al. 2002).

29.3 NK Cell Receptor Protein 1 (NKR-P1) or KLRB1

29.3.1 *Ly49* and *Nkrp1 (Klrb1)* Recognition Systems

Three classes of multigene family-encoded receptors enable NK cells to discriminate between polymorphic MHC class I molecules: Ly-49 homodimers, CD94/NKG2 heterodimers and the killer cell inhibitory receptors (KIR). Of these, CD94/NKG2 has been characterized in both rodents and humans (Chap. 31) and does not show lectin activity. In contrast, Ly-49 family members have hitherto been found only in rodents, and KIR molecules only in the human. Like *Ly49* (*Klra*), *Nkrp1(Klrb1)* locus encodes structurally and functionally related cell surface protein that regulates NK cell-mediated cytotoxicity and cytokine production. The Ly49 receptors are encoded in NKC that contains clusters of genes for other lectin-like receptors on NK cells and other hematopoietic cells. Though the NKR-P1 molecules were the first family of NK cell receptors identified, yet they remained enigmatic in their contribution to self-nonself discrimination until recently. The *Ly49* and *Nkrp1* genetically linked loci for receptor-ligand pairs suggest a genetic strategy to preserve this interaction and show several other contrasts with Ly49-MHC interactions. Despite their close relatedness and genetic linkage within NKC, these two multi-gene families have adopted dissimilar evolutionary strategies. While families, like *Ly49* are polygenic in rodents (Dissen et al. 1996), there is only a single family member (Ly49L) in humans (Westgaard et al. 1998). Ly49 genes are extremely polymorphic, with distinct gene numbers, remarkable allelic diversity, and varying MHC-I-ligand specificities and affinities among different murine haplotypes. In contrast, the *Nkrp1* genes have opted for overall conservation of genomic organization, sequences, and ligand specificities, with only limited allelic polymorphism (Carlyle et al. 2008).

29.3.2 NKRP1

The NKR-P1family of receptors has been of considerable interest due to its conservation in rats, mice, and humans (Lanier 2005; Brissette-Storkus et al. 1994). Rodents have several *Klrb1* genes encoding either activating or inhibitory NK receptors of C-type lectin superfamily, including Nkr-p1c, the NK1.1 Ag defining mouse NK cells (Plougastel et al. 2001a). In rats, the KLRs are encoded by the NK gene complex located on chromosome 4, and syntenic chromosomal regions have been identified in many other species. Several KLR gene families are clustered together in specific sub-regions of NKC, and there is considerable species-to-species variation in the number, expression patterns, and putative functions of the genes encoded by these different KLR families.

Initially thought as markers for NK cells, expression of NKR-P1 has now been documented in other cell types, including subsets of T cells as well as on granulocytes and spleen DCs. In mice, six NKR-P1 genes have been identified (Plougastel et al. 2001a), whereas in humans there appears to be only one gene, CD161 (NKR-P1A), expressed on most NK cells and subsets of thymocytes and fetal liver T cells

(Lanier 2005). Subsets of mature $CD3^+$ T cells, including $CD4^+$ and $CD8^+$ cells also express this receptor, particularly CD1d reactive NKT cells (Exley et al. 1998). This latter population is thought to be involved in the regulation of immune responses associated with a broad range of diseases, including autoimmunity, infectious diseases, and cancer (Godfrey et al. 2004). Rat NKR-P1A was shown to confer reactivity of an NK cell line to certain mouse tumor cell lines (Ryan et al. 1995), and some reports suggest a role for NKR-P1 receptors in the lysis of MHC allogeneic or semiallogeneic target cells (Dissen et al. 1996). Khalturin et al. (2003) identified a gene in the tunicate *Botryllus schlosseri* that encodes a lectin-like protein that is more similar in its extracellular domain to NKR-P1 than to other lectin-like genes (Mesci et al. 2006; Plougastel and Yokoyama 2006).

29.3.2.1 Rat NKR-P1

NKR-P1 is a 60-kDa homodimer expressed on rat NK cells. NKR-P1 may play a role in NK cell activation because antibody to NKR-P1 stimulates the release of granules from NK cells, and anti-NKR-P1 antibody causes redirected lysis by activated NK cells against targets that express FcR. NKR-P1 molecules in rodents may activate cytotoxicity by transducing biochemical signals. Structures of these molecules have not been elucidated. The murine NKR-P1 and Ly-49 molecules are encoded by members of polymorphic gene families that reside in the NK gene complex on the distal region of mouse chromosome 6. The rat NKR-P1 Ag shares several features with the mouse Ly-49 Ag, including selective cell surface expression on NK cells, homology to the C-type lectins, expression as a type II integral membrane protein, and disulfide-linked homodimeric structure. The mouse and rat NKR-P1-deduced polypeptide sequences are highly conserved, suggesting a similar tertiary structure. Although the deduced amino acid sequences of mNKR-P1 and Ly-49 reveal that these proteins are structurally similar, they are only 24% identical at the amino acid level and the cDNA sequences do not demonstrate significant nucleotide homology (Yokoyama and Plougastel 2003). NKR-P1 expresses at low levels on a small subset of rat T cells with an $NKR\text{-}P1_{dim}/TCR\text{-}\alpha\beta^+$ phenotype and on a small subset of cells with an $NKR\text{-}P1_{dim}/TCR\text{-}\alpha\beta^-$ phenotype ($\gamma\delta^+$ T cells?). The expression of functional NKR-P1 (i.e., ability to signal rADCC) correlates with and potentially contributes to MHC-unrestricted cytotoxicity (Brissette-Storkus et al. 1994; Chambers et al. 1992).

Peripheral blood neutrophils in normal animals express very low or undetectable levels of NKR-P1. Detectable level of NKR-P1 was induced as early as day 1 following small bowel transplantation in all allografted animals, whereas expression was only rarely detected in isografted animals (Webster et al. 1994). A major subset of non-alloreactive NK cells in PVG strain rats is generally low in Ly49 receptors, but expresses rat NKR-P1B(PVG) receptor (previously termed NKR-P1C). The $NKR\text{-}P1B^+$ NK subset is inhibited by a non-polymorphic target cell ligand, which is a C-type lectin-related molecule (Clr). Rat Clr molecules appear to be constitutively expressed by hematopoietic cells; expression in tumor cell lines is more variable (Kveberg et al. 2009).

Rat NK Activating and Inhibitory Receptors: While NKR-P1A is an activating receptor on rat NK cells (Giorda et al. 1992), the NKR-P1B receptor (Dissen et al. 1996), in contrast, has inhibitory structural features though it was not possible to prove NKR-P1B-specific inhibitory functions on primary cells since available anti-NKR-P1 mAb failed to distinguish NKR-P1A from NKR-P1B (Kveberg et al. 2006; Li et al. 2003). NKR-P1B functions as an inhibitory receptor because of the presence of an ITIM. Xu et al. (2005) showed that the frequency of $CD161^+$ (human NKR-P1A) NK cells in the epithelia of DA rats was greater than that of WKAH and F344 rats. DA rats have far stronger resistance in the colon to preneoplastic lesion than do other strains. Perhaps $CD161^+$ NK cells play an important role in immune-surveillance at the bottom of the crypt. These observations suggest some allelic variations among NKR-P1 molecules.

A Ly49-negative NK subset is known to selectively express an inhibitory rat NKR-P1 molecule termed NKR-P1C with unique functional characteristics. $NKR\text{-}P1C^+$ NK cells efficiently lyse certain tumor target cells, secrete cytokines upon stimulation. However, they specifically fail to kill MHC-mismatched lymphoblast target cells. The $NKR\text{-}P1C^+$ NK cell subset al.so appears earlier during development and shows a tissue distribution distinct from its complementary $Ly49s3^+$ subset, which expresses a wide range of Ly49 receptors (Kveberg et al. 2006). The NKR-P1C can act as an autonomous activation structure for NK cell cytotoxicity and cytokine secretion (Ryan et al. 1995). Thus, functionally distinct populations of rat NK cells possess different killer cell lectin-like receptor repertoires (Kveberg et al. 2006).

29.3.2.2 Mouse NKR-P1: Six Distinct Murine *Nkr-p1* Genes

An initial report described three distinct murine *Nkr-p1* genes: *Nkr-p1a, Nkr-p1b*, and *Nkr-p1c*. A fourth *Nkr-p1* gene, *Nkr-p1d*, was identified subsequently (Carlyle et al. 1999; Giorda et al. 1992). Later, genomic sequencing identified a fifth functional gene, *Nkr-p1f* (Plougastel et al. 2001a). Analysis of NK cells from different mouse strains revealed that the NK1.1 alloantigen epitope is shared by products of two distinct genes, *Nkr-p1b* and *Nkr-p1c* (Carlyle et al. 1999; Kung et al. 1999). This discovery led to the first demonstration of the inhibitory function of mouse NKR-P1B (Carlyle et al. 1999; Kung et al. 1999) and to the cDNA cloning of a related inhibitory receptor, the B6-derived NKR-P1D (Carlyle et al. 1999; Kung et al. 1999).

Since then, there have been a total of five NKR-P1 proteins identified to date: three stimulatory receptors, NKR-P1A, NKR-P1C, and NKR-P1F, which possess a charged transmembrane arginine (R) residue thought to be important for association with the FcRγ adaptor protein (Arase et al. 1997; Carlyle et al. 1999; Plougastel et al. 2001a; Ryan and Seaman 1997); and two inhibitory receptors, NKR-P1B and NKR-P1D (Carlyle et al. 2004; Iizuka et al. 2003; Plougastel et al. 2001b), which possess a consensus cytoplasmic ITIM (L/VxYxxL/I/V). The *Nkr-p1* gene cluster is located on NKC on chromosome 6 in mice, syntenic to a similar region on chromosome 4 in rats and chromosome 12 in humans (Yokoyama and Plougastel 2003; Ryan and Seaman 1997).

29.3.2.3 NK1.1 (NKR-P1C)

NK1.1 (mouse NKR-P1C) is a member of a family of NKR NKR-P1 family of disulfide-linked homodimeric type II transmembrane C-type lectin-like receptors initially defined in rats (Ryan and Seaman 1997). First described in 1977 (Glimcher et al. 1977), the original NK1.1 alloantigen has been widely used as a marker to identify NK cells and NKT cells in C57BL/6 (B6) mice. In mice, NK1.1 is expressed on almost all NK cells and on a subset of T cells, NK T cells. Almost all NK1.1$^+$ T cells recognize their TCR ligands in association with the Ag-presenting molecule CD1d, and the majority of NK1.1$^+$ T cells in the thymus, liver, and secondary lymphoid tissues express the invariant Vα14Jα18 TCR (Brigl and Brenner 2004; Godfrey et al. 2004; Kronenberg and Gapin 2002; Taniguchi et al. 2003). Subsets of NK1.1$^+$ T cells are CD4$^+$, CD8$^+$, or CD4$^-$CD8$^-$. In the thymus, blood, and secondary lymphoid tissues, NK1.1$^+$ T cells represent 1–2% of all T cells; in the liver and bone marrow, they represent 20–40% of all T cells (Hammond et al. 2001). Mouse NKR-P1C (NK1.1) is expressed on CD117$^+$ progenitor thymocytes capable of giving rise to cells of the T and NK lineages. NKR-P1C engagement with a mAb leads to IFN-γ production and the directed release of cytotoxic granules from NK cells. The NK2.1 antigen is likely to be anchored in the plasma membrane by a peptide moiety. In addition to be present on a splenic NK cell subset, the NK2.1 antigen was shown to be expressed by a small number of CD^4-CD^8-thymocytes and by a subset of CD^4-CD^8-IgG$^-$ lymph node cells. Finally, unlike NKR-P1, the rat homologue of the murine NK1.1 antigen, neither the NK2.1 nor the NK1.1 antigen is expressed by polymorphonuclear leukocytes.

In contrast to the NKR-P1C$^+$ T cells in mouse liver, the majority of NKR-P1A$^+$ T cells in the human liver are CD8$^+$. Almost all of the NKR-P1A$^+$ T cells in the human liver expressed CD69, suggesting that they were activated. Furthermore, the NKR-P1A$^+$ T cells in the human liver exhibited strong cytotoxicity against a variety of tumor cell lines including K562, Molt4 and some colonic adenocarcinoma cell lines (Ishihara et al. 1999).

Strain-Dependent NK1.1 Alloreactivity of Mouse NK Cells: Historically, NK cells from selected mouse strains have been phenotypically defined using NK-1 alloantigen-specific antisera (Glimcher et al. 1977) or the anti-NK1.1 mAb, PK136 (Koo and Peppard 1984). The NK1.1 alloantigen is now known to identify NK cells from CE, B6, NZB, C58, Ma/My, ST, SJL, FVB, and Swiss outbred mice, but not BALB/c, AKR, CBA, C3H, DBA, or 129 mice (Carlyle et al. 2006). All of *Nkr-p1* genes were reportedly identified in B6 mice, but it is now clear that *Nkr-p1b* is not expressed by B6 mice but is expressed in other strains (Iizuka et al. 2003). In B6 mice, the PK136 mAb binds only NKR-P1C, which can be considered the NK1.1 antigen (Glimcher et al. 1977), but the Ab also binds NKR-P1B in mouse strains that express it (Iizuka et al. 2003).

The underlying molecular basis for the lack of NK1.1 reactivity of NK cells from BALB/c and other mouse strains remains an enigma. The lack of NK1.1 reactivity could be due to deletion of *Nkrp1* genes, defective gene expression, or allelic polymorphism in BALB/c mice. Extreme variation in gene content between the BALB/c and B6 haplotypes has been observed previously for the related *Ly49* gene family (Anderson et al. 2005). This suggests that other NK gene complex regions, including the *Nkrp1-Ocil/Clr* region, also may be subject to rapid evolutionary divergence and/or polymorphism. Since cognate ligands for NKR-P1 have been identified (Carlyle et al. 2004; Iizuka et al. 2003; Kumar and McNerney 2005), a BALB/c defect in NKR-P1 expression could be functionally significant for NK cell function and innate immunity. Determination of the gene content of the BALB/c *Nkrp1-Ocil/Clr* region and the basis of the BALB/c defect in NK1.1 expression could have implications for the importance of the NKR-P1–Ocil/Clr system in self-nonself discrimination in mice and other species (Kumar and McNerney 2005).

To investigate the NK1.1$^-$ phenotype of BALB/c NK cells, Carlyle et al. (2006) studied NK1.1 epitope mapping and genomic analysis of the BALB/c *Nkrp1* region. Analysis reveals that, unlike the *Ly49* region, the *Nkrp1-Ocil/Clr* region displays limited genetic divergence between B6 and BALB/c mice. In fact, significant divergence is confined to the *Nkrp1b* and *Nkrp1c* genes. Strikingly, the B6 *Nkrp1d* gene appears to represent a divergent allele of the *Nkrp1b* gene in BALB/c mice and other strains. Allelic divergence of the *Nkrp1b/c* gene products and limited divergence of the BALB/c *Nkrp1-Ocil/Clr* region explain the strain-specific NK1.1 alloantigen reactivity of mouse NK cells (Carlyle et al. 2006).

Mouse NKR-P1B, a NK1.1 Antigen with Inhibitory Function: The mouse NK1.1 Ag originally defined as NKR-P1C (CD161) mediates NK cell activation. Another member of the mouse CD161 family, NKR-P1B, represents a novel NK1.1 Ag. In contrast to NKR-P1C, which functions

as an activating receptor, NKR-P1B inhibits NK cell activation. Association of NKR-P1B with Src homology 2-containing protein tyrosine phosphatase-1 provides a molecular mechanism for this inhibition. The existence of these two NK1.1 Ags with opposite functions suggests a potential role for NKR-P1 molecules, such as those of the Ly-49 gene family, in regulating NK cell function (Carlyle et al. 1999).

29.4 Human NKR-P1A (CD161)

29.4.1 Cellular Localization

CD161 (human NKR-P1A) is a major phenotypic marker of NK and NKT cell types and is thought to be involved in the regulation of functions of these cells. As against six NKR-P1 genes in mice, there appears to be only one gene in humans. Human NKR-P1A is found on a subset of peripheral T cells, including $CD4^+$ and $CD8^+$ T cells, invariant NKT cells, and $\gamma\delta$-TCR^+ T cells, fetal liver T cells and on a subset of $CD3^+$ thymocytes. It is predominantly expressed on T cells with the memory phenotype ($CD45RO^+$) (Lanier 2005; Werwitzke et al. 2003). Comparison of the predicted amino acid of human NKR-P1A with rat and mouse NKR-P1 indicates 46% homology. NKR-P1A is located on human chromosome 12, the syntenic of mouse chromosome 6, where murine NKR-P1 genes are located.

CD161 is type II transmembrane C-type lectin-like receptor and expressed on the cell membrane as disulphide-linked homodimer. In contrast to rodents, no clear functional role has been ascribed to CD161 in humans. Engagement of CD161 on cultured NK cells can result in inhibition of cytotoxicity (Poggi et al. 1999). The functional consequences of treating human NK cells with anti-CD161 mAb are more complex, resulting in no effect, activation, or inhibition, depending on the NK cell population studied (Lanier 2005; Poggi et al. 1997a), although mAb to CD161 has also been reported to trigger proliferation of immature thymocytes (Poggi et al. 1999). These diverse responses elicited by anti-NKR-P1 mAb suggest that additional, functionally distinct, isoforms or alleles of NKR-P1 may exist in humans. Consistent with the latter observation, human NKR-P1A, though not involved in direct activation of NKT cells or their recognition of the CD1d molecule, is an important costimulatory molecule for this population of T cells (Exley et al. 1998). The molecular basis of such widely different functional activities of human CD161 is not clear. Although both human NK cells and a subset of human T cells express the CD56 marker, only a small minority of $CD161^+$ T cells also express CD56 (Loza et al. 2002). Gene encoding the NKR-P1 from cattle showed identity to human nucleotide sequences at 90% and 75%, respectively, and all structural residues of C-type lectin carbohydrate recognition domains were conserved. The identification of two of its members allows to hypothesise the existence of a bovine NK gene complex, prospectively located on chromosome 5 (Govaerts and Goddeeris 2001).

While CD161 is expressed on the minority of human blood T cells, $CD161^+$ T cells expressing either CD4 or CD8 represent the majority of T cells from the epithelial and lamina propria layers of the human duodenum and colon (Ishihara et al. 1999; O'Keeffe et al. 2004). The latter cells contain few, if any, $V\alpha24V\beta11$ invariant NK T cells and secrete IFN-γ and TNF-α without IL-4 after in vitro stimulation. An abundance of $CD161^+$ T cells was also found in the liver and intestinal epithelial cells of the jejunum; the majority of the latter cells were $CD161^+CD8^+$ T cells (Iiai et al. 2002). CD161 is also expressed on human monocytes and dendritic cells. Bone marrow-derived DC of rat uniformly expressed low levels of CD161 and expressed OX62 in a bimodal distribution (Brissette-Storkus et al. 2002). Engagement of CD161 on the cell surface using an appropriate mAb induced the production of IL-1β and IL-12 by monocytes and dendritic cells, respectively (Azzoni et al. 1998; Poggi et al. 1997b). CD161on $CD4^+$ T cells and $\gamma\delta$-TCR^+ T cells has been implicated in transendothelial migration (Poggi et al. 1999). Unexpectedly, the $CD8^+CD161^+$ cells contained an anergic $CD8\alpha^+CD8^{\beta low/-}CD161^{high}$ T cell subset that failed to proliferate, secrete cytokines, or mediate NK lytic activity (Takahashi et al. 2006).

29.4.2 Transcriptional Regulation

Although the 5′-flanking region of NKR-P1C from C57Bl/6 mouse is TATA-less, there is an initiator region and a downstream promoter element, which together form the principal minimal functional promoter. Analyses of the 10-kb 5′-flanking region revealed potential binding sites for regulatory factors, and a single hypersensitive site (HS) of about a 9-kb upstream of the transcriptional initiation site. This site, HS1, could act as a transcriptional enhancer element in a NK cell line. The minimal upstream cis-acting elements point to a complex regulatory mechanism involved in the lineage-specific control of NKR-P1C expression in NK lymphocytes (Ljutic et al. 2003). IL-12, in contrast to IL-2, strongly up-regulates the expression of NKRP1A on human NK cells. The NKRP1A in turn, can regulate the NK cell activation induced via different triggering pathways. This would imply that NKRP1A-mediated functions may be regulatd by the cytokine microenvironment that NK cells may encounter at inflammatory sites (Poggi et al. 1999).

The stochastic expression of individual members of NK cell receptor gene families on subsets of NK cells has attracted considerable interest in the transcriptional

regulation of these genes. Each receptor gene can contain up to three separate promoters with distinct properties. The recent discovery that an upstream promoter can function as a probabilistic switch element in the Ly49 gene family has revealed a novel mechanism of variegated gene expression. An important question to be answered is whether or not the other NK cell receptor gene families contain probabilistic switches. The promoter elements currently identified in the Ly49, NKR-P1, CD94, NKG2A, and KIR gene families are described (Anderson 2006).

29.4.3 Ligands of CD161/ NKR-P1

29.4.3.1 Binding of Carbohydrates to NKR-P1

A diversity of high-affinity oligosaccharide ligands has been identified for NKR-P1 that contains an extracellular Ca^{2+}-dependent lectin domain. Dimerization of soluble recombinant rat NKR-P1 is predominantly dependent on the presence of an intact juxta-membrane stalk region and independent of N-glycosylation. Aminosugars have a good affinity for the NKR-P1A protein. NKR-P1 is a lectin with a preference order of GalNAc > GlcNAc >> Fuc >> Gal > Man. At neutral pH, Ca^{2+} is tightly associated with the protein. However, NKR-P1 can be decalcified at pH 10 with a total loss of carbohydrate binding. NKR-P1 differs from other calcium-dependent animal lectins in its pattern of monosaccharide recognition and in the tightness of Ca^{2+} binding. NK-resistant tumor cells are rendered susceptible by preincubation with liposomes expressing NKR-P1 ligands, suggesting that purging of tumor or virally infected cells in vivo may be a therapeutic possibility (Bezouska et al. 1994).

While N-acetylD-mannosamine was the best neutral monosaccharide ligand, its participation in the context of an extended oligosaccharide sequence was equally important. The IC_{50} value for the GalNAcβ1 —>ManNAc disaccharide was nearly 10^{-10} M with a further possible increase depending on the type of the glycosidic linkage and the aglycon nature (Krist et al. 2001). GlcNAc and chitooligomers were identified as strong activation ligands for NKR-P1 protein in vitro and in vivo. Their clustering brings about increase of their affinity to the NKR-P1 by 3–6 orders. In analogy with previous observations with GlcNAc clustered on protein or PAMAM backbones the synthetic chitooligomer clusters should provide considerably better ligands in the in vivo antitumor treatment (Semenuk et al. 2001). NKR-P1A also binds to the chitobiose core of uncompletely glycosylated N-linked glycans, and to linear chitooligomers (Bezouska et al. 1997).

Ligands for NKR-P1A include a fully sulphated disaccharide, sucrose octasulphate as observed by NMR spectroscopy and described for the screening of compound libraries for bioaffinities. These findings raise the possibility that NKR-P1A recognises sulphated natural ligands in common with certain other members of the C-type lectin family (Kogelberg et al. 2002). Uncharacterized receptors on human NK cells interact with ligands containing the terminal Galα(1,3)Gal xenoepitope. Among carbohydrate binding proteins from NK cells that bind αGal or N-acetyllactosamine (LacNAc), created by deletion of α1,3galactosyltransferase (GT) in animals is NKRPIA. Moreover, exposing LacNAc by removal of αGal resulted in an increase in binding. This may be relevant in later phases of xenotransplant rejection if $GT^{-/-}$ pigs, like $GT^{-/-}$ mice, display increased LacNAc expression (Christiansen et al. 2006). Structural studies suggested the preference of these receptors for either linear (NKR-P1) or branched (CD69) carbohydrate sequences (Pavlícek et al. 2004). Recombinant soluble form of rat NKR-P1 also recognized carbohydrate GalNac and GlcNac moieties. Ganglioside GM2 and heparin related-IS oligosaccharides representing the high affinity ligands for this receptor, increased the sensitivity of targets for killing by the rat effectors isolated from blood and spleen in vitro. Synthetic three mono- and bivalent LacdiNAc glycomimetics proved to be powerful ligands of NKR-P1 and CD69. A synthetic bivalent tethered di-LacdiNAc is the best currently known precipitation agent for both of these receptors and has promising potential for the development of immunoactive glycodrugs (Bojarová et al. 2009).

29.4.3.2 Ocil/Clr-b as Ligand in Rodents

While ligands for the stimulatory NKR-P1A/C receptors remain elusive, ligands for inhibitory NKR-P1B and NKR-P1D receptors (Carlyle et al. 2004) and activating NKR-P1F receptors are products of the *Ocil/Clr* family of genes (Carlyle et al. 2004; Iizuka et al. 2003; Zhou et al. 2001; Plougastel et al. 2001a), which are intermingled with the *Nkrp1* genes themselves in the NK gene complex. Ocil/Clr-b molecules have been shown to be the ligands for several members of the NKR-P1 family of receptors (Giorda et al. 1992; Ryan and Seaman 1997). The activating NKR-P1F receptor recognizes Clr-g (encoded by *Clec2i*) (Iizuka et al. 2003). The *Clr* genes are interspersed between the *Nkr-p1* genes. The cloning, expression, and function of Ocil/Clr-b as a ligand for the inhibitory NKR-P1B and NKR-P1D receptors have been reported. This suggests that specific receptor-ligand pairs are not inherited separately, but rather en bloc (Iizuka et al. 2003; Carlyle et al. 2004).

The NKR-P1 receptors have been shown to recognize other lectin-like molecules in contrast to other lectin-like NKRs, which recognize class I MHC molecules or relatives of class I MHC molecules. The inhibitory NKR-P1B/D orphan NK cell receptors functionally interact with Ocil/Clr-b ligand and can mediate missing self recognition of

tumor cells by mouse NK cells. The findings of Clr ligands have created a renewed interest in the NKR-P1 family, because these ligands and their receptors represent a form of self-nonself discrimination that is independent of MHC class I, a principle that can now be extended to other NK cell receptors (Kumar and McNerney 2005). It is speculated that the NKR-P1 proteins and their Clr ligands may be descended from a common C-type lectin-like ancestral protein that engaged in homophilic interactions. The Ocil/Clr-b is expressed broadly on normal hematopoietic cells but is frequently down-regulated on tumor cells, indicating that NKR-P1B/D receptors play a role in "missing self-recognition" of Ocil/Clr-b. Clr-b is also named as osteoclast inhibitory lectin, because it was also identified as an osteoblast-derived glycoprotein, which inhibits in vitro osteoclastogenesis (Hu et al. 2004; Zhou et al. 2001).

29.4.3.3 LLT1 as Ligand in Humans

Although mice have multiple *Clr* family genes, only one ortholog, *CLEC2D* (also named lectin-like transcript-1 or LLT1), exists in humans. Like mouse Clr-b, human LLT1 blocks osteoclast differentiation (Hu et al. 2004; Zhou et al. 2001). The LLT1 (alternative name, CLEC2D) is a physiologic ligand for NKR-P1A in humans. The human LLT1 is similar to the mouse Clr molecules and is expressed on cells of lymphocytic origin (Boles et al. 1999; Carlyle et al. 2004; Aldemir et al. 2005; Rosen et al. 2005). Human LLT1 is expressed on NK, T, and B cells and localized to the NK gene complex within 100 kb of CD69. In addition to NK and T cells, LLT1 is expressed on TLR-activated plasmacytoid dendritic, TLR-activated monocyte-derived DCs, and on B cells stimulated through TLR9, surface Ig, or CD40. Interactions between NKR-P1A on NK cells and LLT1 on target cells inhibit NK cell-mediated cytotoxicity and cytokine production and can inhibit TNF-α production by TCR-activated NKR-P1A$^+$ CD8$^+$ T cells. In contrast, NKR-P1A failed to inhibit or augment the TCR-dependent activation of NKR-P1A-bearing CD4$^+$ T cells. Expression of LLT1 on activated DCs and B cells suggests that it might regulate the cross-talk between NK cells and APCs (Rosen et al. 2008).

The cDNA encodes a predicted protein of 191 amino acid residues with a transmembrane domain near the N-terminus and an extracellular domain of 132 amino acid residues with similarity to CRD of C-type lectins. The predicted protein of LLT1 shows 59% and 56% similarity to AICL and CD69, respectively. The predicted protein does not contain any intracellular ITIM motifs, suggesting that LLT1 may be involved in mediating activation signals. The human LLT1 shows 43–48% of homology to Clr at the amino acid level and seems to be primarily expressed by monocytes and B cells in peripheral blood (Mathew et al. 2004).

Engagement of CD161 on NK cells with LLT1 expressed on target cells inhibited NK cell-mediated cytotoxicity and IFN-γ secretion. Conversely, LLT1/CD161 interaction in the presence of a TCR signal enhanced IFN-γ production by T cells (Aldemir et al. 2005). The lytic activity of NK cells is negatively regulated via CD161 expression mediated by IL-12 (Azzoni et al. 1998). However, LLT1 is induced rapidly in PMA-stimulated PBMCs (Eichler et al. 2001) and in IL-2-activated NK cells or T cells (Boles et al. 1999). Cross-linking of LLT1 with an Ab induced production of IFN-γ by NK cells (Mathew et al. 2004). LLT1-containing liposomes bind to NKR-P1A$^+$ cells, and binding is inhibited by anti-NKR-P1A mAb. Moreover, LLT1 on target cells can inhibit NK cytotoxicity via interactions with NKR-P1A (Rosen et al. 2005). This interaction inhibits NK cell-mediated cytotoxicity and IFN-γ production while enhancing CD3-triggered IFN-γ production by T cells. It appears that LLT1, expressed by gliomas, contributes to tumor-associated immunosuppression by affecting the lytic activity of NK cells (Roth et al. 2006, 2007).

Oosteoclast Inhibitory Lectin: Osteoclast inhibitory lectin (Ocil) is an inhibitor of osteoclast formation and shows promise as an antiresorptive protein. Murine, rat, human Ocils (mOcil, rOcil, and hOcil respectively) are type II membrane C-type lectins expressed by osteoblasts and other extraskeletal tissues, with the extracellular domain of each, are able to inhibit in vitro osteoclast formation. The hOcil is highly conserved with mOcil in its C-lectin domain, genomic structure, and activity to inhibit osteoclastogenesis (Hu et al. 2004). The hOcil gene predicts a 191 amino acid membrane protein, with the 112 amino acid C-type lectin region in the extracellular domain, having 53% identity with rOcil and mOcil. The hOcil gene is 25 kb in length, comprising five exons, and is a member of a superfamily of NK cell receptors encoded by the NK gene complex located on chromosome 12. Human Ocil mRNA expression is upregulated by IL-1α and prostaglandin E2 in human osteogenic sarcoma MG63 cells, but not by dexamethasone or 1,25 dihydroxyvitamin D3. In addition, Ocil can also inhibit bone resorption by mature, giant-cell tumor-derived osteoclasts (Hu et al. 2004). Ocil is notably localized in bone, skin, and other connective tissues, binds a range of physiologically important glycosaminoglycans, and this property may modulate Ocil actions upon other cells (Gange et al. 2004).

29.4.4 Signaling Pathways

The mechanisms of signaling pathways of CD161 are poorly understood. Different rodent NKR-P1 molecules use different signal transduction pathways to achieve their different functions. The cytoplasmic tail of rodent NKR-P1s has been reported to associate with *Src* family kinases such as p56^{lck}

and various heterotrimeric G proteins (Ljutic et al. 2005), whereas the activating NKR-P1C molecule associates with the γ-chain of the FcR (Arase et al. 1997) and the inhibitory isoform NKR-P1B (expressed by NK cells of SJL/J mice) recruits Src homology protein 1 on cross-linking (Carlyle et al. 1999; Kung et al. 1999).

Target cells expressing class I MHC bound to NKR-P1-expressing NK cells can generate a great variety of intracellular signals that are largely resistant to PTX treatment (Maghazachi et al. 1996). The functional homodimeric form of NKR-P1 selectively binds and activates G_z, G_s, $G_{q/11}$, and G_{i3}, as revealed in [^{35} S]GTP γS binding (Ho and Wong 2001) and to $G\alpha_o$ and $G\alpha_z$ which are also activated in the process of NK cell lysis of allogeneic and tumor target cells (Maghazachi et al. 1996). The activation of NKR-P1 induces IP_3 production, Ca^{2+} flux, interferon- γ secretion, degranulation and cytotoxicity of NK cells (Ho and Wong 2001).

Humans: The cytoplasmic tail of human CD161 (NKR-P1A) does not contain the CxCP/S/T lck-binding motif found in CD4, CD8, and rodent NKR-P1 (Exley et al. 1998; Ljutic et al. 2005). Although it has been reported that human NKR-P1A can be found in association with *Src* family kinases, including p56^{lck} (Cerný et al. 1997), others report a failure to reproduce these observations (Exley et al. 1998). To identify molecules that can interact with the cytoplasmic tail of human CD161 (NKR-P1A), Pozo et al. identified acid sphingomyelinase as a novel intracellular signaling pathway linked to CD161. The mAb-mediated cross-linking of CD161, in both transfectants and primary human NK cells, triggers the activation of acid, but not neutral sphingomyelinase. The sphingomyelinases represent the catabolic pathway for *N*-acyl-sphingosine (ceramide) generation, an emerging second messenger with key roles in the induction of apoptosis, proliferation, and differentiation and define a novel signal transduction pathway for the CD161 in NK and NKT cell biology (Pozo et al. 2006).

Rodents: Cross-linking of the stimulatory rat NKR-P1A or mouse NKR-P1C molecules stimulates phosphatidylinositol turnover and Ca^{2+} flux (Ryan and Seaman 1997), as well as NK cell-mediated cytotoxicity and cytokine production (Arase et al. 1997). Sequence analysis revealed that all murine NKR-P1 proteins possess the Cys-X-Cys-Pro (CxCP) motif also found in the cytoplasmic domains of CD4 and CD8 that mediates association with the Src-related nonreceptor protein tyrosine kinase, p56^{lck}. Campbell and Giorda (1997) demonstrated a physical association between the rat NKR-P1A cytoplasmic CxCP motif and p56^{lck}; however, no functional requirements for this association were shown. A feature of the inhibitory NKR-P1 receptors is the presence of an ITIM in the cytoplasmic domains of mouse NKR-P1B/D. Studies have shown that, like other ITIM-bearing receptors expressed by NK cells, mouse NKR-P1B binds Src homology 2 (SH2)-containing protein tyrosine phosphatase-1 (SHP-1) in a phosphorylation-dependent manner, suggesting a molecular mechanism for the inhibition of NK cell cytotoxicity through NKR-P1B (Carlyle et al. 1999; Kung et al. 1999). The requirement for SHP-1 recruitment to the cytoplasmic ITIM in mediating NKR-P1 inhibition was substantiated by Ljutic et al. (2005). During NKR-P1 signaling in mice, both NKR-P1B and NKR-P1C functionally associate with the tyrosine kinase, p56(lck) p56^{lck}. Mutation at putative Lck-recruitment CxCP motif abolished signal transduction through NKR-P1B/C. Lck appears to be involved in the initiation of NKR-P1 signaling, and SHP-1 in effector function of NKR-P1 receptor (Ljutic et al. 2005).

Ljutic et al. (2005) proposed a model for the initiation and effector signaling through the stimulatory and inhibitory mouse NKR-P1 receptors (Fig. 29.4). Model suggests that the initial phosphorylation of ITIM tyrosine in NKR-P1B is mediated by Lck, providing a docking site for the SH2 domain of the SHP-1 phosphatase, leading in turn to dephosphorylation and inhibition of proximal kinases. In contrast, association of Lck with the stimulatory NKR-P1C receptor leads, upon cross-linking, to transphosphorylation of the cytoplasmic ITAM tyrosines in the FcRγ adaptor protein, in turn leading to recruitment of Syk kinase and activation of downstream second messengers. Thus, findings support a stepwise model for the signaling requirements of the stimulatory and inhibitory NKR-P1 receptors (Fig. 29.4). The identification of cognate ligands for the NKR-P1 receptors (Carlyle et al. 2004; Iizuka et al. 2003) leads to new insight into the physiology of NKR-P1-mediated recognition of target cells by this functionally dichotomous receptor family (Ljutic et al. 2005).

29.4.5 Functions of NKR-P1

The biological function of human CD161 is still insufficiently understood; probably it is involved in regulation of the cytotoxic functions of the cells and in regulation of cytokine production. NKR-P1 molecules are involved in natural killing of certain tumor targets. The loss during differentiation of NKR-P1 and CD2, which are involved in target adhesion and triggering of NK cells, is consistent with the poor cytolytic capacity reported for these cells (Head et al. 1994). The NK1.1 (NKR-P1C) molecule is the most specific serological marker on murine NK cells in C57BL/6 mice. Studies of NKR-P1 have indicated that anti-NKR-P1 mAb induced NK cells to kill otherwise insensitive targets, NK cell phosphoinositol turnover and Ca^{2+} flux. Results demonstrate that immobilized anti-NK1.1 triggers only a subpopulation of NK cells

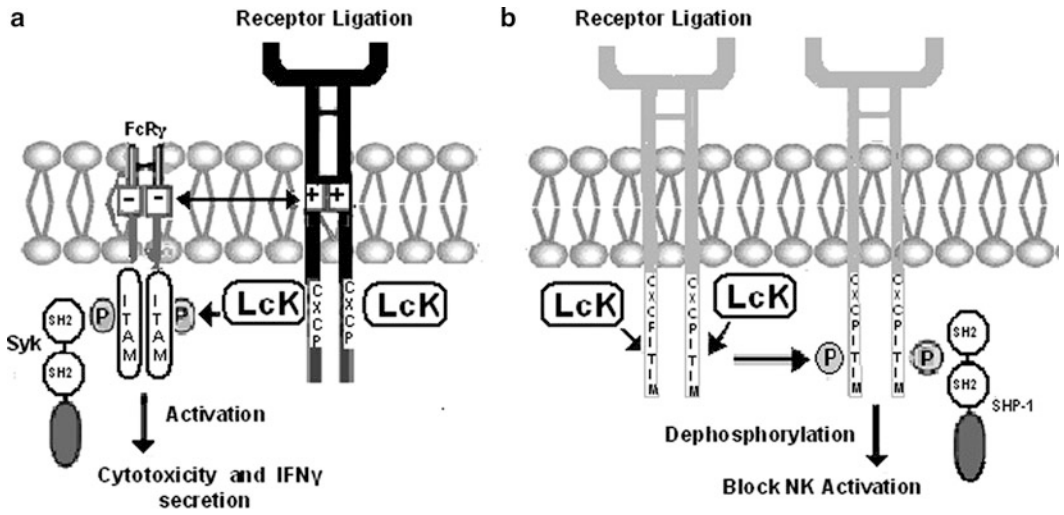

Fig. 29.4 Signaling mechanisms of stimulatory and inhibitory NKR-P1 receptors. (**a**) Upon receptor cross-linking, Lck associated with cytoplasmic tail of stimulatory NKR-P1C phosphorylates ITAM tyrosines in the FcRγ adaptor protein, in turn leading to recruitment of Syk and activation of downstream second messengers. (**b**) Phosphorylation of the cytoplasmic ITIM tyrosine in NKR-P1B is mediated by Lck, providing a docking site for the SH2 domain of SHP-1, leading to dephosphorylation and inhibition of proximal kinases

(Yokoyama and Plougastel 2003) and that NK cell responses can be greatly diminished after in vivo treatment with these mAbs (Levik et al. 2001).

The sequencing of the chicken MHC led to the identification of two ORFs, designated B-NK and B-lec that were predicted to encode C-type lectin domains. The genes for B-NK and B-lec are located next to each other in opposite orientations in the chicken MHC. The B-NK is an inhibitory receptor expressed on NK cells, whereas B-lec is an activation-induced receptor with a broader expression pattern. The B-NK and B-lec genes share greatest homology with CTLD receptors encoded by human NK gene complex, in particular NKR-P1 and lectin-like transcript 1 (LLT1), respectively. Like human NKR-P1, B-NK has a functional inhibitory signaling motif in the cytoplasmic tail and is expressed in NK cells. In contrast, B-lec contains an endocytosis motif in the cytoplasmic tail, and like LLT1, is an early activation Ag. B-NK and B-lec are potential candidate genes for the MHC-mediated resistance to MDV. Both glycosylated type II membrane proteins form disulphide-linked homodimers (Rogers and Kaufman 2008; Rogers et al. 2005).

29.5 NKR-P1A in Clinical Disorders

29.5.1 Autoimmune Reactions

Experimental Autoimmune Neuritis: NK cells are implicated in T cell-mediated autoimmune diseases. Experimental autoimmune neuritis (EAN) is a $CD4^+$ T cell-mediated animal model of the Guillain-Barré syndrome in human. Lymphoid cells co-cultured with IL-12 and IL-18 cytokines transferred aggressive clinical and histological EAN into all recipients. NKR-$P1^+$ cells (including NK and NKT cells) played an immunosuppressive function in passive transfer EAN and depletion of NKR-$P1^+$ cells by anti-NKR-P1 Ab and complement induced a more serious form of EAN. Nevertheless, lymphoid cells co-cultured with both IL-12 and IL-18 induced high levels of IFNγ and promoted Th1 differentiation partially through NKR-$P1^+$ cells and to some extent, NKR-$P1^+$ cell depletion inhibited the autoreactivity of lymphoid cells treated with IL-12 and IL-18 (Sun et al. 2007; Yu et al. 2002).

Autoimmune Uveoretinitis: Kitaichi et al. (2002) treated experimental autoimmune uveoretinitis (EAU)-susceptible mice with anti-CD161c antibodies to deplete natural NK cells. Results indicated that the severity of EAU is augmented by $NK1.1^+$ NK cells.

Rheumatic Diseases: The number of both $CD4^-CD8^-$ and $CD4^+$ NKT cells are selectively decreased in the peripheral blood of patients with rheumatic diseases. In addition, both the frequency and the absolute number of $CD161^+CD8^+$ T cells were decreased in the peripheral blood of patients suffering from SLE, MCTD, SSc and PM/DM. Thus there is also an abnormality of NKT cells in the $CD8^+$ population (Mitsuo et al. 2006).

Graves' Disease: To clarify changes in the intra-thyroidal NKT cell subset in patients with Graves' disease (GD),

Watanabe et al. (2008) examined intrathyroidal and peripheral lymphocytes patients and peripheral lymphocytes in healthy volunteers. The proportion of $CD161^+$ T cell receptor $V\alpha24^+$ $V\beta11^+$ cells was lower in the thyroid of patients than in the peripheral blood of the same patients and in the peripheral blood of healthy subjects. These results indicated that the proportion of intra-thyroidal NKT cells is decreased in patients with GD and that this decrease may contribute to incomplete regulation of autoreactive T cells in GD (Watanabe et al. 2008).

Type 1 Diabetes Mellitus: Invariant NKT cells are considered to be important in some autoimmune diseases including Type 1 diabetes mellitus (T1DM). The published reports are contradictory in regard to the role of iNKT cells in T1DM. Kis et al. (2007) studied iNKT cell frequency and the function of different iNKT cell subgroups in T1DM and suggested that the decrease in the $CD4^+$ population among the iNKT cells and their Th1 shift indicates dysfunction of these potentially important regulatory cells in T1DM.

Asthma: In humans, T cells expressing NKR-P1A constitute around 20% of the circulating $CD3^+$ cells and are potentially immunoregulatory in several diseases. González-Hernández et al. (2007) suggested that during an asthma attack, IFN-γ produced by $CD161^+$ T cells could help to reestablish the Th1/Th2 equilibrium and can be related to asthama.

Atopic Dermatitis: Atopic dermatitis is a chronic inflammatory skin disease associated with cutaneous hyperreactivity to environmental triggers and is often the first step in the atopic march that results in asthma and allergic rhinitis. Helper T cells and their cytokines, in addition to IgE and eosinophils, play a major role in the pathogenesis of atopic dermatitis. NKT cells may play a role in atopic dermatitis status. The reduction of $V\alpha24^+CD161^+$ NKT cells subtypes may be involved in the immunopathogenesis of atopic dermatitis (Ilhan et al. 2007).

29.5.2 Other Diseases

Evidence suggests that NK and NKT cells contribute to inflammation and mortality during septic shock caused by cecal ligation and puncture (CLP). Further studies indicated that NK but not CD1-restricted NKT cells contribute to acute CLP-induced inflammation. NK cells appear to mediate their proinflammatory functions during septic shock, in part, by migration into the peritoneal cavity and amplification of the proinflammatory activities of specific myeloid cell populations. This study provides a new insight into the mechanisms used by NK cells to facilitate acute inflammation during septic shock (Etogo et al. 2008). Selective reduction in the population of colonic mucosal NKR^+ T cells may contribute to the development of intestinal inflammation in ulcerative colitis (Shimamoto et al. 2007).

Hepatitis C virus (HCV) causes chronic infection accompanied by a high risk of liver failure. A subset of $CD161^+CD56^{+/-}$ NKT cells can recognize glycolipids presented by CD1d and positively or negatively regulate inflammatory responses, implicated in several models of hepatitis. CD1d is expressed at very low levels in the healthy liver, but there is a large fraction of $CD161^+CD56^+$ NKT cells. There are high levels of non-classical proinflammatory hepatic CD1d-reactive T cells in HCV infection. Durante-Mangoni et al. (2004) confirmed large numbers of hepatic $CD161^+$ T cells, lower levels of $CD56^+$ T cells, and small numbers of iNKT cells in HCV infection. However, hepatic CD1d-reactivity was not restricted to any of these populations (Durante-Mangoni et al. 2004). CD161 was significantly expressed on HCV-specific cells but not on $CD8^+$ T cells specific for human immunodeficiency virus (3.3%), cytomegalovirus (3.4%), or influenza (3.4%). Northfield et al. (2008) proposed that expression of CD161 indicates a unique pattern of T cell differentiation that might help elucidate the mechanisms of HCV immunity and pathogenesis. Functional capacities and coexpression patterns of lectin-like receptors on lymphocytes are differentially affected in HIV patients depending on the state of therapy or the cell type (NK or T cells), respectively (Jacobs et al. 2004). Reports identify a novel population of human T cells that could contribute to destructive as well as protective immune responses in the liver. It is likely that CD1d-reactive T cells may have distinct roles in different tissues (Exley et al. 2002).

Cytomegaloviruses are known to encode several gene products that function to subvert MHC-dependent immune recognition. Voigt et al. (2007) characterized a rat cytomegalovirus (RCMV) C-type lectin-like (RCTL) gene product with homology to the Clr ligands for the NKR-P1 receptors. RCMV infection rapidly extinguished host Clr-b expression, thereby sensitizing infected cells to killing by NK cells. However, the RCTL protein functioned as a decoy ligand to protect infected cells from NK killing via direct interaction with the NKR-P1B inhibitory receptor. Findings indicate a strategy adopted by cytomegaloviruses to evade MHC-independent self-nonself discrimination. The existence of lectin-like genes in several poxviruses suggests that this may be a common theme for viral evasion of innate immunity (Voigt et al. 2007). The $V\delta2^+$ $TCR\gamma\delta^+$ T lymphocyte subset, expressing the NKRP1a, is expanded in patients with relapsing-remitting multiple sclerosis and uses this molecule to migrate through endothelium. Poggi et al. (2002) suggested that subsets of γδT lymphocytes may migrate to the site of lesion in multiple sclerosis using two different signaling pathways to

extravasate. The mechanism involved in the spontaneous acceptance of liver allografts in some rat strain combinations remains unclear. Immunoregulatory NKR-P1TCRαβT (NKT) cells primarily produce IL-4 and IFN-γ, and enhance the polarization of immune responses to Th2 and Th1, respectively. The role of graft-derived NKT cells in inducing the spontaneous acceptance of rat orthotopic liver transplantation (OLTx) has suggested that graft-derived NKT cells might be responsible for spontaneous acceptance in the rat OLTx (Kiyomoto et al. 2005).

29.5.3 NKR-P1A Receptor (CD161) in Cancer Cells

NK cells were originally defined by their ability to spontaneously eliminate rare cells lacking expression of MHC-I self molecules, which is commonly referred to as "missing self" recognition. The molecular basis for missing self recognition emerges from the expression of MHC-I-specific inhibitory receptors on the NK cell surface that tolerize NK cells toward normal MHC-I-expressing cells. By lacking inhibitory receptor ligands, tumor cells or virus-infected cells that have down-modulated surface MHC-I expression become susceptible to attack by NK cells. Killer cell Ig-like receptors (KIR; CD158) and Ig-like transcripts (ILTs), CD94/NKG2 heterodimers, NKG2D, NKR-P1, and KLRG1 belonging to the C-type lectin receptor family, called killer cell lectin-like receptors (KLR approved symbol) (Borrego et al. 2001; Vetter et al. 2000). constitute a family of MHC-I binding receptors that play major roles in regulating the activation thresholds of NK cells and some T cells in humans. Although the function of NKR on T cells infiltrating tumors and their potential effect on antitumor immunity has been investigated, little is known about T cells expressing CD161 in cancer patients. $CD4^+CD161^+CD56^-$ cells represent a distinct memory T-cell population significantly increased in cancer patients. Depending on the type of signals provided by the tumor microenvironment, $CD4^+CD161^+$ cells may regulate the immune response (Iliopoulou et al. 2006).

Cutaneous malignant melanoma is one of the most immunogenic tumors. CD8 T-lymphocytes and NK cells are believed to be important effector cells involved in eliciting a protection against melanoma (Lozupone et al. 2004). The early stages of cutaneous primary melanoma are evidenced by changes in the number of $CD8^+DR^+$ or $CD8^+CD161^+$ T-cells with respect to healthy individuals. In addition, the number of CD56 NK cells was also increased at early disease stages. Campillo et al. (2006) provided evidence of immune activation in early stages of cutaneous melanoma, together with an increase of cells expressing CD158a in patients bearing the corresponding HLA-C ligand. Low expression of CD161 and activating NKG2D receptors is associated with a significant impairment in NK cell activity in metastatic melanoma (MM) patients (Konjević et al. 2007).

Glioblastoma is the most malignant intrinsic brain tumor. The activating NK and costimulatory T-cell ligands that are expressed by glioma cells are overridden by several inhibitory signals, including the immunosuppressive molecule TGF-ß (Friese et al. 2004). Glioma cells showing high surface expression of classic MHC class I molecules and a significant expression of the nonclassic MHC molecules HLA-E and HLA-G immune escape phenotype by interacting with different NK cell receptors (Lanier 2005). A tolerance factor is another molecule that may help immune escape of gliomas by inhibition of NK and T cells. Glioma cells express LLT1 mRNA and protein in vitro and in vivo, whereas expression levels in normal brain are low. It appears that LLT1, expressed by gliomas, contributes to tumor-associated immunosuppression by affecting the lytic activity of NK cells (Roth et al. 2006, 2007). LLT1 expression in human gliomas increases with the WHO grade of malignancy. TGF-β up-regulates the expression of LLT1 in glioma cells. Small iRNA-mediated down-regulation of LLT1 in LNT-229 and LN-428 cells promotes their lysis by NK cells. Thus, LLT1 acts as a mediator of immune escape and contributes to the immunosuppressive properties of glioma cells (Roth et al. 2007). Co-culture of NK cells and DCs results in their reciprocal co-activation, and an enhancement of lysis of tumor target cells (Yang et al. 2006).

In rat 9L gliosarcoma, a substantial number of cells express NKR-P1, a marker expressed only on rat lymphocytes capable of non-MHC-restricted cytotoxicity. Previous investigations have determined the existence of three populations of $NKR\text{-}P1^+$ lymphocytes in normal rats, including $NKR\text{-}P1_{bright}$/T-cell receptor $(TCR)^-/CD3\text{-}/CD5^-$ (~5–15%), $NKR\text{-}P1_{dim}$/$TCR\beta^+/CD3^+/CD5^+$ (1–5%), and $NKR\text{-}P1_{dim}$/TCR $\gamma\delta/CD3^+/CD5^+$ (~0.5–2%). It was suggested that there is selective localization of cells capable of mediating antitumor responses in 9L, but that tumor-associated factors may down-regulate their function and expression of NKR-P1 (Chambers et al. 1996).

Because the activity of cytotoxic cells is suppressed in most cancer patients, it was suggested that the *Klrb1* expression might be suppressed in cancerous cells. The transcription of the KLRB1 was suppressed in tumor tissues in 68% patients with nonsmall-lung-cancer and 57% patients with esophageal squamous-cell carcinoma. This parameter can be a marker of lung and esophageal cancers (Pleshkan et al. 2007).

29.6 Human Early Activation Antigen (CD69)

CD69 belongs to a subfamily of CTLDs, which are referred to as NK-cell domains (NKDs). Its gene maps in the NK gene complex, close to other genes coding for NK receptors.

CD69 is a dimeric glycoprotein of 33 and 27 kDa. The CD69 has a structural homology with other type II lectin cell surface receptors, such as T cell antigen Ly49, the low avidity IgE receptor (CD23), and the hepatic asialoglycoprotein receptors. The CD69, one of the first described members of the NKC family of receptors (López-Cabrera et al. 1993; Ziegler et al. 1994), is present at the cell surface as a disulfide linked homodimer, with subunits of 28 and 32 kDa resulting from the differential glycosylation at a single extracellular *N*-linked glycosylation site. Contrary to other NKC gene products, whose expression is restricted to NK cells, CD69 has been found on the surface of most hematopoietic lineages. It is one of the earliest markers induced upon activation in T and B lymphocytes, NK cells, macrophages, neutrophils, and eosinophils. In addition, it is constitutively expressed on monocytes, platelets, Langerhans cells, and a small percentage of resident lymphocytes in thymus and secondary lymphoid tissues (Sánchez-Mateos et al. 1989). The activation of T lymphocytes induces the expression of CD69. It functions as a signal transmitting receptor in lymphocytes, NK cells, and platelets. Although CD69 is absent from peripheral blood resting lymphocytes, it is expressed by in vivo activated lymphocytes infiltrating sites of chronic inflammation in several pathologies, as well as by lymphocytes after in vitro activation with different stimuli. The TNF-α gene expression and protein secretion could be induced in peripheral blood T cells through CD69 molecule. CD69-deficient mice revealed its modulatory role on B cell development and antibody synthesis (Lauzurica et al. 2000).

29.6.1 Organization of CD69 Gene

The CD69 gene mapped on chromosome 12 p13-p12. The cDNA coding for CD69 exhibited a single open reading frame of 597 bp coding and predicted a 199-amino acid protein of type II membrane topology, with extracellular (COOH-terminal), transmembrane, and intracellular domains. The CD69 clone hybridized to a 1.7-kb mRNA species, which was rapidly induced and degraded after lymphocyte stimulation, consistent with the presence of rapid degradation signals at the 3′ untranslated region. The CD69 protein shares functional characteristics with other members of this superfamily, which act as transmembrane signaling receptors in early phases of cellular activation (López-Cabrera et al. 1993)

The genomic structure of the human gene encoding CD69 sequence is divided into five exons separated by four introns. The first two exons corresponded to separate functional domains: cytoplasmic tail and the transmembrane region. The final three exons encoded the CRD. The major transcription initiation site has been located 30 nt downstream of a consensus TATA box (Santis et al. 1994). The conserved intron position between the exons encoding the CRD indicated that this protein is closely related to other type-II C-type lectins, such as the asialoglycoprotein receptor, the CD23, and NKR-P1 and Ly49. In contrast to the broad NKR-P1 and Ly-49 gene families, CD69 is a single-copy gene. The mouse CD69 gene has phorbol ester-inducible promoter element within the first 700 bp upstream of the start of transcription. Chromosomal mapping placed the mouse CD69 gene on the long arm of chromosome 6 near the NK gene complex that contains the related NKR-P1 and Ly-49 gene families. The human CD69 gene mapped to chromosome 12p13 near the related NKG2 gene cluster and in a region associated with rearrangements in approximately 10% of cases of childhood acute lymphocytic leukemia (Ziegler et al. 1994). Recombinant CD69 protein exists as a disulfide-linked homodimer on the cell surface and crystallizes as a symmetrical dimer, similar to those formed by the related NK cell receptors Ly49A and CD94.

The 5′-flanking region of the promoter of CD69 gene contains a potential TATA element 30 bp upstream of the major transcription initiation site and several putative binding sequences for inducible transcription factors (NF-kB, Egr-1, AP-1), which might mediate the inducible expression of this gene. The proximal promoter region spans positions −78 to +16 containing the cis-acting sequences necessary for basal and phorbol 12-myristate 13-acetate-inducible transcription of CD69 gene. Removal of the upstream sequences located between positions −78 and −38 resulted in decreased promoter strength and abolished the response to phorbol 12-myristate 13-acetate. The TNF-α is capable of inducing the surface expression of CD69 molecule as well as the promoter activity of fusion plasmids that contain 5′-flanking sequences of *CD69* gene, suggesting that TNF may regulate in vivo the expression of CD69 (López-Cabrera et al. 1995).

29.6.2 Src-Dependent Syk Activation of CD69-Mediated Signaling

CD69 engagement leads to the rapid and selective activation of the tyrosine kinase Syk, but not of the closely related member of the same family, ZAP70, in IL-2-activated human NK cells. The requirement for Src family kinases in the CD69-triggered activation of Syk suggests a role for Lck in this event. It was demonstrated that Syk and Src family tyrosine kinases control the CD69-triggered tyrosine phosphorylation and activation of phospholipase Cγ2 and the Rho family-specific exchange factor Vav1 and are responsible for CD69-triggered cytotoxicity of activated NK cells. Thus CD69 receptor functionally couples to the activation of Src family tyrosine kinases, which, by inducing Syk

activation, initiate downstream signaling pathways, induce rise in intracellular Ca^{2+}. Synthesis of different cytokines and/or proliferation regulates CD69-triggered functions on human NK cells (Pisegna et al. 2002; Llera et al. 2001). The receptor-proximal signaling pathways activated by CD69 cross-linking are involved in CD69-mediated cytotoxic activity. CD69 engagement leads to the activation of ERK enzymes belonging to the MAPK family, and that this event is required for CD69-mediated cell degranulation. The co-engagement of CD94/NKG2-A inhibitory receptor effectively suppressed both CD69-triggered cell degranulation in RBL transfectants, through the inhibition of ERK activation, and CD69-induced cytotoxicity in human NK cells. Thus, CD69-initiated signaling pathways and functional activity are negatively regulated by CD94/NKG2-A inhibitory complex (Llera et al. 2001). The wide distribution of CD69, along with its activating signal-transducing properties, suggest an important role of CD69 in the physiology of leukocyte activation (Llera et al. 2001)

29.6.3 Crystal Analysis of CD69

The structure of extracellular portion of NK cell receptors are divergent from true C-type lectins and are referred to as NK-cell domains (NKDs). CD69 NKD adopts the canonical CTLD fold but lacks the features involved in Ca^{2+} and carbohydrate binding by C-type lectins. The NKD of human CD69 at 2.27 A resolution reveals conservation of the C-type lectin-like fold, including preservation of the two α-helical regions found in Ly49A and MBP. Using comparative computer modeling, a 3-D model of the extracellular domain of CD69 based on the crystal structure of the MBL was generated. The sequence of CD69 appears to be highly compatible with the C-type lectin fold. Compared with MBL and selectins, CD69 displays significant deletions in loop regions. The conserved calcium binding sites found in the C-type lectin family are not conserved in CD69; only one of the nine residues coordinated to Ca^{2+} in MBP is conserved in CD69 and no bound Ca^{2+} is evident in the crystal structure. In this respect, CD69 departs from some of the conserved motifs seen in crystal structures of MBL and selectins. The CD69 model shows cavity-shaped hydrophobic regions surrounded by charged residues. One of these cavities is proximal to a potential low affinity calcium binding site and may be implicated in specific interactions with ligands. Surprisingly, electron density suggestive of a puckered six-membered ring was discovered at a site structurally analogous to the ligand-binding sites of MBP and Ly49A. This sugar-like density may represent, or mimic, part of the natural ligand recognized by CD69 (Bajorath and Aruffo 1994; Natarajan et al. 2000). CD69 NKD dimerizes noncovalently, both in solution and in crystalline state. The dimer interface consists of a hydrophobic, loosely packed core, surrounded by polar interactions, including an interdomain β-sheet. The intersubunit core shows certain structural plasticity that may facilitate conformational rearrangements for binding to ligands. The surface equivalent to the binding site of other members of the CTLD superfamily reveals a hydrophobic patch surrounded by conserved charged residues that probably constitutes the CD69 ligand-binding site (Llera et al. 2001).

NKG2 Subfamily C (KLRC)

30

Rajesh K. Gupta and G.S. Gupta

30.1 NKG2 Subfamily C (KLRC)

30.1.1 NKG2 Gene Family and Structural Organization

NKG2 receptors are type II C-type, lectin-like, integral membrane glycoproteins, which are expressed on the cell surface as heterodimers with CD94, which is an invariant type II C-type, lectin-like polypeptide. CD94 lacks a cytoplasmic tail and therefore, cannot transduce signals. It is however essential for the expression of NKG2 receptors. Four distinct genes, A/B, C, E/H, and F, encode the NKG2 receptors. Of these receptors, CD94/NKG2A is an inhibitory one, as it contains a long cytoplasmic tail with two ITIMs. Others have short cytoplasmic tails, and each associates noncovalently with a homodimer of DAP-12, as in the case of activating KIRs. The NKG2 family of genes (HGMW-approved symbol KLRC) contains at least six members (NKG2-A, -B, -C, -E, -F and -H) which are localized to human chromosome 12p12.3-p13.2, in the same region where CD69 genes have been mapped. In addition, the human CD94 and NKR-P1A genes map to the short arm of chromosome 12. The physical distance spanned by NK gene complex (NKC) in humans ranges between 0.7 and 2.4 megabases (Renedo et al. 1997). The NKG2 and CD94 genes are localized in a small region (< 350 kb) and mapped in the following order: (NKG2-C/NKG2-A)/NKG2-E/NKG2-F/NKG2-D/CD94. Sequence analysis of 62 kb spanning the NKG2-A, -E, -F, and -D loci allowed the identification of two LINE elements that could have been involved in the duplication of the NKG2 genes. Presence of one MIR and one L1ME2 element at homologous positions in the NKG2-A and NKG2-F genes is consistent with the existence of rodent NKG2 gene(s). The 5′-ends of the NKG2-A transcripts were mapped into two separate regions showing the existence of two separate transcriptional control regions upstream of the NKG2-A locus and defining putative promoter elements for these genes (Plougastel and Trowsdale 1998). Restriction mapping and sequencing revealed the NKG2-C, -D, -E, and -F genes to be closely linked to one another, and of the same transcriptional orientation. The NKG2-C, -E, and -F genes, despite being highly similar, are variable at their 3′ ends. It was found that NKG2-C consists of six exons, whereas NKG2-E has seven, and the splice acceptor site for the seventh exon occurs in an Alu repeat. NKG2-F consists of only four exons and part of exon IV is in some cases spliced to the 5′ end of the NKG2-D transcript. NKG2-D has only a low similarity to the other NKG2 genes Glienke et al. (1998). The murine NKG2-D-like sequence also maps to the murine NK complex near CD94 and Ly49 family members.

30.1.1.1 Association of NKG2 Family Proteins with CD94

NKG2 family proteins have been shown to be covalently associated with CD94. Structural heterogeneity in NKG2 gene family and the formation of heterodimers with CD94 provides the creation of a diverse class of NK cell repertoire (Houchins et al. 1997; Lazetic et al. 1996). The human CD94 glycoprotein forms disulfide-bonded heterodimers with the NKG2A/B, NKG2C, and NKG2E glycoproteins. Human NKG2-F gene is localized 25 kb from NKG2-A, and related to NKG2-D cDNA. Despite the similarities with other NKG2 genes, NKG2-F encodes a putative protein which does not contain any lectin domain. However, a conserved 24-amino acid sequence, present in all members of NKG2 family, suggests that NKG2-F is also able to form heterodimers with CD94 (Plougastel and Trowsdale 1997). NK cells inhibited upon HLA recognition express the CD94/p43 dimer, whose specificity for HLA molecules partially overlaps the Ig-SF receptor system (López-Botet et al. 1997). In addition to NK cells, CD94-NKG2-A/B heterodimers are also expressed by TCR-γ/δ cells, and a subset of TCR-α/β cells. The human NKG2A-CD94 (KLRC1) and NKG2C-CD94 (KLRC2) heterodimers recognize the nonclassic MHC class I molecule, HLA-E (Qa-1 in

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_30, © Springer-Verlag Wien 2012

mice) as ligand, which primarily displays peptides derived from the signal peptides of classic MHC class I molecules. NKG2D (KLRK1) molecules are also expressed by T cells, mediating co-stimulatory functions dependent on the availability of the adaptor protein DAP10 (Fig. 30.1).

30.1.2 Human NKG2-A, -B, and -C

The NKG2 cDNA clone is expressed in all NK cells. The original isolate, from a CD3- NK cell clone, was found to cross-hybridize with a family of transcripts that fell into four distinct groups designated NKG2-A, -B, -C, and -D. All four human transcripts encode type II membrane proteins of 215–233 amino acids. NKG2-A and -B peptides appear to be alternative splicing products of a single gene *Nkg2a*, which encodes two isoforms, NKG2A and NKG2B, with the latter lacking the stem region. NKG2-C is highly homologous with group A, having 94% homology in the external (C-terminal) domain and 56% homology throughout the internal and transmembrane regions. Cell surface expression of NKG2A is dependent on the association with CD94 since glycosylation patterns characteristic of mature proteins are found only in NKG2A that is associated with CD94. The induction of an inhibitory signal is consistent with the presence of two ITIM (V/LXYXXL) on the cytoplasmic domain of NKG2A. Similar motifs are found on Ly49 and KIR receptors, which also transmit negative signals to NK cells (Brooks et al. 1997). Brostjan et al. (2002) found differential expression of inhibitory (NKG2-A/B) versus triggering (NKG2-C and potentially -E, -F, -H) NK receptor chains. The generation of the splice variants NKG2-E and -H seemed to occur at a constant ratio. NKG2-D is distantly but significantly related (21% amino acid homology) to the first three groups. Large panel of NK clones indicated that NKG2-A$^-$ P25$^+$ NK clones express the NKG2-C transcript (Cantoni et al. 1998).

30.1.2.1 Promoter Sequences

Brostjan et al. (2000) established app. 3 kb of upstream promoter sequences of the human NKG2-C, -E and -F genes and compared with available NKG2-A sequences. Extended regions of homology contain numerous putative transcription factor binding sites conserved in the NKG2 genes. However, variation in Alu insertion among family members has led to promoter structures unique to the respective family members, which could contribute to differences in transcriptional initiation as well as gene-specific regulation.

NKG2C gene is deleted in Japanese population. The location of the break-point was determined to be 1.5–1.8 kb telomeric from the 3′ end of NKG2A. The frequency of NKG2C deletion haplotype was 30.2% in Japanese and 30.0% in Dutch populations. The frequency of homozygous deletion was 4.1% in Japanese and 3.8% in Dutch. *Nkg2c* deletion in Japanese and Dutch suggests that NKG2C is not essential for survival and reproduction, and is not associated with rheumatic diseases (Miyashita et al. 2004). Each of the NKG2 molecules is paired with CD94 for expression and recognizes HLA-E and Qa-1b as a ligand.

30.1.2.2 NKG2 Receptors on Fetal NK Cells and T Lymphocytes

Using mAb against NKG2A/C/E, Van Beneden et al. precipitated the NKG2A as a 38-kDa protein that decreased drastically from 2 week after birth. Phenotypic analysis showed that ~ 90% of fetal NK cells and ~ 50% of adult NK cells express high levels of CD94/NKG2. The remaining 50% of adult NK cells expressed low surface levels of CD94/NKG2. Expression of CD94/NKG2 was not restricted to NK cells, but was also observed on NK T and memory T cells. Functional analysis showed that CD94/NKG2$^+$ fetal NK cells could discriminate between MHC class I-positive and MHC class I-negative tumor cells. The expression levels of CD94/NKG2 were similar in wild-type compared with $\beta2m^{-/-}$ mice (Stevenaert et al. 2003). CD94/NKG2 receptors are also expressed on a subpopulation of peripheral CD8 memory TCR αβ lymphocytes and on mature TCR Vγ3$^+$ cells in the fetal thymus. Skin-located Vγ3 T cells, the progeny of fetal thymic Vγ3 cells, also expressed CD94/NKG2 and Ly49E but not the other members of the Ly49 family. This suggested that Vγ3 T cells expressing CD94/NKG2 receptors are mature and display a memory phenotype, and that CD94/NKG2 functions as an inhibitory receptor on these T lymphocytes (Van Beneden et al. 2002).

30.1.3 Murine NKG2A, -B, -C

The genes coding for *NKG2A,-B, -C* are clustered on the distal mouse chromosome 6 and on the rat chromosome 4 in a region designated the NK gene complex. The deduced amino acid sequence of mouse NKG2-A contains only one consensus cytoplasmic ITIM. NKG2-A from B6 and BALB/c mice differ by six amino acid residues in the extracellular domain. Murine NKG2B, like its human conterpart, appears to be a splice variant of NKG2-A, and lacks a large portion of the stalk region. Murine NKG2-C lacks an ITIM in its cytoplasmic domain, a feature shared by human and rat NKG2-C. However, unlike the human counterpart, the transmembrane domain of mouse NKG2-C does not contain a charged amino acid residue. Mouse NKG2-A mRNA was detected in IL-2-activated NK cells and spleen cells but not in other tissues (Lohwasser et al. 1999). The identification of a rat CD94 orthologue implied that NK cell receptors equivalent to NKG2/CD94 also exist in rat. The rat NKG2A

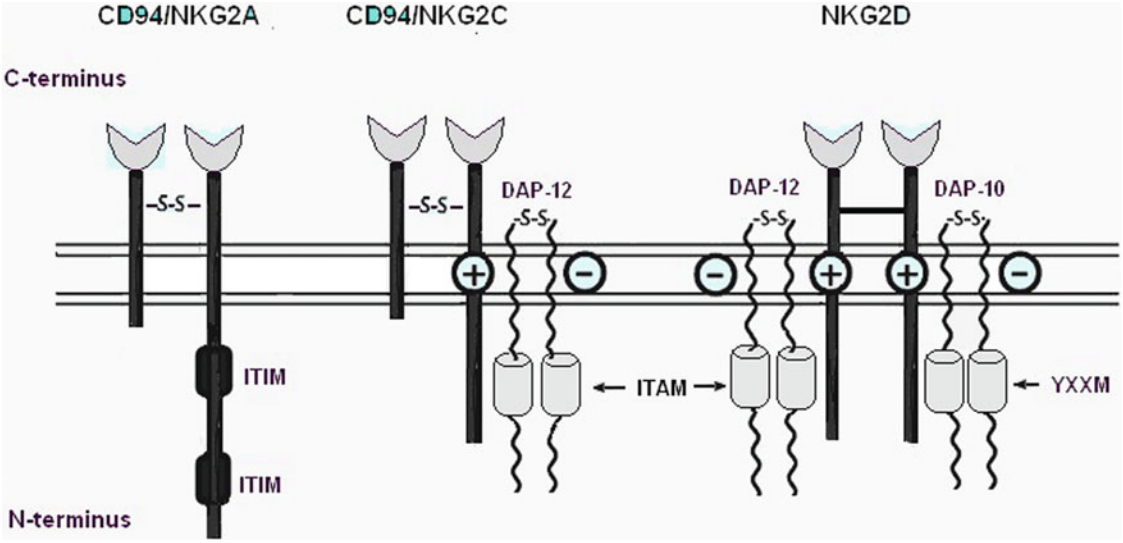

Fig. 30.1 How inhibitory and activating C-lectin receptors operate in NK cells. The C-type lectin receptors are disulfide-linked heterodimers of CD94 and NKG2 family members, either the inhibitory NKG2A or the activating NKG2C, and recognize the nonclassical MHC class I molecule HLA-E. Similar to KIRs with long cytoplasmic tails, ITIM-containing NKG2A signals through SHP-1/2 that mediate inhibitory signals. Likewise, NKG2C has a positively charged transmembrane domain that interacts with DAP-12 and transduces activating signals through Syk family members. NKG2D exists as a homodimer on the surface of NK cells. The dimmer is formed as an extension of an anti parallel β-sheet across the interface with a twofold crystallographic axis perpendicular to the extended sheet (Chap. 31) (Call et al. 2010). The NKG2D dimmer interface is primarily composed of a central hydrophobic core encased by a hydrogen bond and a salt bridge network. In contrast to NKG2C, NKG2D is only distantly related to the other NKG2 family members, does not associate with CD94, and binds to the MHC-like ligands MICA, MICB, and ULBP family. Through its positively charged transmembrane domain NKG2D associates with the adaptor molecule DAP-10 that contains an YXNK motif to bind PI-3 kinase (PI3K) and sends activating signals through this alternative pathway (see Chap. 31 for details). As the PI3K cascade is not inhibited by SHP-1/2, NKG2D may be able to mediate a dominant activation

expression is strain dependent, with high expression in DA and low in PVG NK cells, correlating with the expression of rat CD94. Presence of Ly-49 genes and the existence of rat NKG2 genes in addition to a CD94 orthologue suggest that NK cells utilize different C-type lectin receptors for MHC class I molecules in parallel.

30.1.4 NKG2 Receptors in Monkey

Labonte and Letvin (2004) demonstrated a significant variability in NKG2 mRNA expression in peripheral blood mononuclear cells (PBMCs) from rhesus monkeys. In the absence of DAP12, rhesus monkey NKG2A is preferentially expressed at the cell surface with CD94 due to a single amino acid difference in the transmembrane of NKG2A and NKG2C. In the presence of DAP12, the ability of NKG2C to compete for cell surface CD94 heterodimerization is enhanced and approaches that of NKG2A (LaBonte et al. 2004). Both *M. fascicularis* and *M. mulatta* NK cells express NKp80, NKG2D, and NKG2C molecules, which display a high degree of sequence homology with their human counterpart and reduced surface expression of selected NK cell-triggering receptors associated with a decreased NK cell function in some animals (Biassoni et al. 2005). The full-length cDNAs for CD94, NKG2A, and NKG2CE, in three unrelated squirrel monkeys showed three alternatively spliced forms of CD94 in which part of intron 4 was included in the mature transcript, suggesting evolutionary pressure for changes in the corresponding loop 3 region of the lectin domain (Andersen et al. 2004). Squirrel monkey NKG2A contains a three-nucleotide indel (insertions or deletions) that results in an additional amino acid in the predicted NKG2A protein compared to NKG2A in other species. Transmembrane-deleted forms of CD94 and NKG2CE were also expressed in the squirrel monkey (LaBonte et al. 2007). The NKC of marmoset is 1.5 times smaller than its human counterpart, but the genes are colinear and orthologous. Analyses of NKC genes in additional marmoset individuals revealed a moderate degree of polymorphism of the CD94, NKG2A, NKG2CE, and NKG2D genes. Expression analyses identified several alternatively spliced transcripts, particularly of the CD94 gene (LaBonte et al. 2007).

30.1.5 NKG2 Receptors in Other Species

In contrast to human, the cattle have multiple distinct NKG2A genes, some of which show minor allelic variation. All of the sequences designated NKG2A have two ITIM in the cytoplasmic domain and one putative gene has, in addition, a charged residue in the transmembrane domain. NKG2C appears to be essentially monomorphic in cattle. All of the NKG2A sequences are similar apart from NKG2A-01, which, in contrast, shares the majority of its carbohydrate recognition domain with NKG2-C. Most of the genes appear to generate multiple alternatively spliced forms. The CD94/NKG2A heterodimers in cattle, in contrast to other species, bind several ligands. Because NKG2C is not polymorphic, this raises questions as to the combined functional capacity of the CD94/NKG2 gene families in cattle (Birch and Ellis 2007).

The NKC is not known in chicken. Instead, NK receptor genes were found in the MHC region. In chicken, two C-type lectin-like receptor genes were identified in a region on chromosome 1 that is syntenic to mammalian NKC region. Based on 3D structure and sequence homology, one receptor is the orthologue of mammalian CD69, and the other is highly homologous to CD94 and NKG2. Like CD94/NKG2 gene found in teleostean fishes, chicken CD94/NKG2 has the features of both human CD94 and NKG2A. The arrangement of several other genes that are located outside the mammalian NKC is conserved among chicken, human, and mouse. The chicken NK C-type lectin-like receptors in the NKC syntenic region indicate that this chromosomal region existed before the divergence between mammals and apes (Chiang et al. 2007). A cDNA clone derived from the bony fish *Paralabidochromis chilotes* encodes a protein related to the CD94/NKG2 subfamily of the NK cell receptors. The gene encoding this receptor in a related species, Oreochromis niloticus, has a similar structure to the human CD94/NKG2 genes and is a member of a multigene cluster that resembles the mammalian NK cell gene complex (Sato et al. 2003).

The 1,176 bp cDNA of a C-type lectin gene, from a homozygous rainbow trout contains a 714 bp ORF predicting a 238-amino-acid (27 kDa) protein. The predicted sequence contains a 48 aa cytoplasmic domain, a 20 aa transmembrane domain (TM), a 46 aa stalk region and a 124 aa CRD. Sequence alignment and phylogenetic analysis of the CRD indicated that the protein had similarity with human dendritic cell immunoreceptor (DCIR), gp120 binding C-type lectin (gp120BCL) and mammalian hepatic lectins. The N-terminus (aa 4-183) has similarity with NKG2, important in human NK cell function (Zhang et al. 2000). This indicated that the CD94/NKG2 subfamily of NK cell receptors must have arisen before the divergence of fish and tetrapods and may have retained its function for >400 million years

30.1.6 Inhibitory and Activatory Signals

The induction of an inhibitory signal is consistent with the presence of two ITIM (V/LXYXXL) on the cytoplasmic domain of NKG2A. Similar motifs are found on Ly49 and KIR receptors, which also transmit negative signals to NK cells (Brooks et al. 1997).

Association of DAP12 with Activating CD94/NKG2C NK Cell Receptors: While inhibitory NK cell receptors for MHC class I express ITIM that recruit intracellular tyrosine phosphatases and prevent NK cell effector function, the activating NK cell receptors lack intrinsic sequences required for cellular stimulation. In contrast, the NKG2C and -E/H associate with DAP12 via a positively charged residue in their transmembrane domains and function as activation receptors. Therefore, the NKG2A/-2B contain an ITIM sequences in its cytoplasmic domain, which may be responsible for the inhibitory function of these receptors, whereas NKG2C and -E/H, lack ITIMs and associate with DAP12 via a positively charged residue in their transmembrane domains function as activation receptors and potentially transmit positive signals. Efficient expression of CD94/NKG2C on the cell surface requires the presence of DAP12. The charged residues in the transmembrane domains of DAP12 and NKG2C are necessary for this interaction (Lanier et al. 1998) (Fig. 30.1).

30.2 CD94 (KLRD1)

30.2.1 Human CD94 in Multiple Transcripts

CD94 is a receptor for human leukocyte antigen class I molecules. The CD94 is a type II membrane protein encoded by a unique gene of the C-type lectin superfamily. The primary sequences of NKG2 molecules A/B, C, and E share 27–32% identity with CD94 within the C-type lectin domain with minimal insertions or deletions, suggesting a strong structural similarity between CD94 and the NKG2 molecules. However, homodimeric CD94 has been found on the surface of certain transfected cell lines in which the expression of NKG2 is absent. Cell surface expression of NKG2A is dependent on the association with CD94 as glycosylation patterns are found only in NKG2A that is associated with CD94. Three new alternative transcripts of the *cd94* gene were identified by Lieto et al. (2006) in addition to the originally described canonical CD94Full. One of the transcripts, termed CD94-T4, lacks the portion that encodes the stem region. CD94-T4 associates with both NKG2A and NKG2B, but preferentially associates with the latter. This is probably due to the absence of a stem region in both CD94-T4 and NKG2B.

CD94 Binding with NKG2: Functionally, CD94 exists in a heterodimeric disulfide-linked complex with NKG2A/B, -C, or -E (Lazetic et al. 1996; Brooks et al. 1997; Cantoni et al. 1998) and has been shown to bind to a 26-kD NKG2A or a 43-kD protein on the surface of NK cells. The cloned CD94 molecule also covalently assembles with at least two different glycoproteins to form functional receptors. The human CD94 glycoprotein forms disulfide-bonded heterodimers with the NKG2A/B, NKG2C, and NKG2E glycoproteins. Structural heterogeneity in the NKG2 gene family and the formation of heterodimers with CD94 provides the creation of a diverse class of NK cell repertoire (Lazetic et al. 1996). Homology of CD94 with the NK cell-associated NKR-P1 and NKG2 C-type lectin genes is limited to the structural motifs conserved in the carbohydrate recognition domain. An unexpected feature of CD94 is the essential absence of a cytoplasmic domain, implying that association with other receptors may be necessary for the function of this molecule (LaBonte et al. 2001; Boyington et al. 2000).

CD94 Promoter Genes: CD94 gene expression is regulated by distal and proximal promoters that transcribe unique initial exons specific to each promoter. This results in two species of transcripts; the CD94 mRNA and a CD94C mRNA. All NK cells and $CD94^+$, $CD8^+\alpha\beta$ T cells transcribe CD94 mRNA. Stimulation of NK and $CD8^+\alpha\beta$ T cells with IL-2 or IL-15 induced the transcription of CD94C mRNA. The distal and proximal promoters both contain elements with IFN-γ-activated and Ets binding sites, known as GAS/EBS. Additionally, an unknown element, termed site A, was identified in the proximal promoter. EMSA analyses showed that constitutive factors could bind to oligonucleotide probes containing each element. After treatment of primary NK cells with IL-2 or IL-15, separate inducible complexes could be detected with oligonucleotide probes containing either the proximal or distal GAS/EBS elements. These elements are highly conserved between mice and humans, which suggests that both species regulate CD94 gene expression via mechanisms that predate their evolutionary divergence (Lieto et al. 2003).

30.2.2 Mouse CD94

Mouse CD94 is 54% identical and 66% similar to human CD94, and is a member of the C-type lectin superfamily. Mouse CD94 is expressed efficiently on the cell surface of cells transiently transfected with the corresponding cDNA, but surface CD94 was unable to mediate detectable binding to MHC class I-expressing Con-A blasts. Notably, mouse CD94, like human CD94, has a very short cytoplasmic tail, suggesting the existence of partner chains that may play a role in ligand binding and signaling. Like its human counterpart, the mouse CD94 protein associates with different NKG2 isoforms and recognizes the atypical MHC class I molecule Qa-1b.

Like many other C-type lectins expressed by NK cells, mouse *Cd94* maps to the NK complex on distal chromosome 6, synteneic to human CD94. The mouse *Cd94* is highly expressed specifically by mouse NK cells, raising the possibility that mice, like humans, express multiple families of MHC class I-specific receptors on their NK cells. The murine NKG2D-like sequence also maps to the murine NK complex near *Cd94* and Ly49 family members. The genomic organization of the mouse *Cd94* gene contains six exons separated by five introns. Exons I and II encode the 5′ untranslated region (UTR) and the transmembrane domain. Exon III encodes the stalk region and exons IV-VI encode the carbohydrate recognition domain (CRD). The *Cd94* promoter region and putative regulatory DNA elements have been identified (Lohwasser et al. 2000).

The murine *Cd94* gene has two promoters. Lymphoid cell types use these two promoters differentially. The promoter usage seen in adult cells is established during fetal development. The differential promoter usage by NK cells appears to be susceptible to perturbation, as both the murine NK cell line LNK, as well as cultured C57BL/6 NK cells showed altered promoter usage relative to fresh NK cells. Since, the promoter activity observed in transfection assays did not correlate with expression of the endogenous *Cd94* gene, it suggested the involvement of chromatin structure/methylation in transcriptional regulation (Wilhelm et al. 2003). The identification of two of NK cell receptors with residues of C-type lectin CRDs indicated the existence of a bovine NK gene complex, prospectively located on chromosome 5 (Govaerts and Goddeeris 2001). Bovine CD94, named KLRJ1, is most similar to Ly-49 (KLRA) and mapped to the bovine NK gene complex on chromosome 5. It suggests that KIR multigene families with divergent signaling motifs exist also in bovine species and that the primate and bovine KIR multigene families have evolved independently (Storset et al. 2003).

30.3 Cellular Sources of NKG2/CD94

NKG2 family proteins have been shown to be covalently associated with CD94. Structural heterogeneity in NKG2 gene family and the formation of heterodimers with CD94 provides the creation of a diverse class of NK cell repertoire (Houchins et al. 1997; Lazetic et al. 1996). The NKG2 cDNA clone is expressed on all NK cells. The proportion of $CD94^+NKG2C^-$ ($NKG2A^+$) NK cells and the level of expression of NKG2D, NKp30 and NKp46 decreases with age (Sundström et al. 2007). NK cells derived from human umbilical cord blood (CB) are the major effector cells involved in graft-versus-host disease (GVHD) and graft-versus-leukemia (GVL). The

expression of NKG2A/CD94 was significantly higher on CB NK cells. The high expression of NKG2A/CD94 and low expression of granzyme B may be related with the reduced activity of CB NK cells (Tanaka et al. 2007; Wang et al. 2007). CD94-NKG2-A/B heterodimers are also expressed by TCR-γ/δ cells, and a subset of TCR-α/β cells. NKG2A, commonly expressed on cytotoxic T cells, has been found on activated T helper (Th) cells. In identifying markers differentiating between Th1 and Th2 lymphocytes, Freishtat et al. (2005) identified co-induction of NKG2A and CD56 on activation of Th2 cells.

As in NK cells, CD94 is expressed on Th1 cells together with members of the NKG2 family of molecules, including NKG2A, C, and E. Meyers et al. (2002) proposed that CD94/NKG2 heterodimers may costimulate effector functions of differentiated Th1 cells. Tanaka et al. (2004) found increased expression of CD94/NKG2A on $CD3^+/CD8^+$ T cells from G-CSF mobilized peripheral blood mononuclear cells (G-PBMC) after stimulation with immobilized anti-CD3 mAb with or without cytokines. A large majority of multiple myeloma (MM) $CD8^+$ cells do not express a functional CD94 receptor. It seemed that their ability to 'fine-tune' an appropriate immune response against tumor cells is impaired (Besostri et al. 2000). Activating and inhibitory CD94/NKG2 receptors regulate CTL responses by altering TCR signaling, thus modifying antigen activation thresholds set during thymic selection. Reports suggest that TCR antigenic specificity dictates NKG2A commitment, which critically regulates subsequent activation of CTL (Jabri et al. 2002). NK cells are the most abundant lymphocyte population at the maternal-fetal interface. They are considered to be important during placentation by controlling trophoblast invasion.

Bellon et al. (1999) studied the expression of CD94 heterodimers in different αβ or γ/δ T cell clones. While most of the $CD94^+NKG2A^-$ T cells have a low to intermediate expression of CD94, the cross-linking of the CD94/NKG2 heterodimer in one of these CD8αβ $CD94^+NKG2A^-$ T cell clones (K14B06) resulted in to induce the up-regulation of CD25 and the secretion of IFN-γ and to trigger the redirected cytotoxicity in a TCR-independent manner. The CD94 heterodimer showed a 39-kDa band with a similar activating heterodimer found on other NK cells and led to identification of NKG2H in K14B06 T cells. The NKG2H is an alternative spliced form of *NKG2E* gene and displayed a charged residue in the transmembrane portion and a cytoplasmic tail, which lacks ITIM. The expression of NKG2H forms part of the activating CD94/Kp39 heterodimer present on K14B06 cells.

Melanocyte differentiation antigen MART-1 specific T cells express CD94/NKG2 receptors. Detailed analysis revealed the exclusive presence of inhibitory NKG2-A/B receptors in the vitiligo-like leukoderma, whereas both the inhibitory receptors and the activating NKG2-C/E isoforms were present within the tumor (Pedersen et al. 2002).

Expression of CD94/NKG2 Receptors by Viral- and Bacterial-Specific CD8 T Cells Subsets of CD8 T cells express receptors that are critical in regulating the activity of NK cells. NKG2A/CD94 receptor expression is up-regulated by antiviral $CD8^+$ T cells during acute polyoma infection; this is responsible for down-regulating their antigen-specific cytotoxicity during both viral clearance and virus-induced oncogenesis. Miller et al. (2003) suggested that CD94/NKG2 expression is not correlated with inhibition of T cell function. This was shown following acute infection, with lymphocytic choriomeningitis virus (LCMV), of C57BL/6 and BALB/cJ mice, which expressed Ag-specific CD94/NKG2 $CD8^+$ T cells, and hence CD94/NKG2 expression is not necessarily correlated with inhibition of T cell function (c/r Miller et al. 2003). Wojtasiak et al. (2004) established that while Ag-stimulated gB-specific CD8 T cells primarily express inhibitory isoforms of CD94/NKG2 receptors, these cells remained capable of producing IFNγ upon peptide stimulation.

30.4 The Crystal Analysis of CD94

30.4.1 An Intriguing Model for CD94/NKG2 Heterodimer

Functionally, CD94 exists in a heterodimeric disulfide-linked complex with NKG2A/B, -C, or -E. A twofold related crystallographic dimer was observed in CD94 crystals in which two monomers hydrogen bond through their respective first β strands, creating an extended six-stranded antiparallel β sheet. The interface of this elongated dimer is relatively flat and contains a central hydrophobic region (residues Val66, Tyr68, Ile75, Phe107, and Met108) (Fig. 30.2a), surrounded by hydrophilic residues. A significant part of the interface observed in this dimer involves loop 3, where the helix-to-loop transformation has occurred in CD94, suggesting that this loop conformation may be partly stabilized through hydrophobic interactions across the dimer interface (Boyington et al. 1999). The extracellular ligand-binding domain of human CD94, corresponding to residues 34–179, was expressed in a bacterial expression system and refolded in vitro. The crystal structure of this fragment at 2.6 Å resolution showed that final model comprises residues Cys59 to Ile179. The molecule, with overall dimensions of approximately $42 \times 37 \times 33$ Å, consists of a three stranded antiparallel β sheet (strands 1,

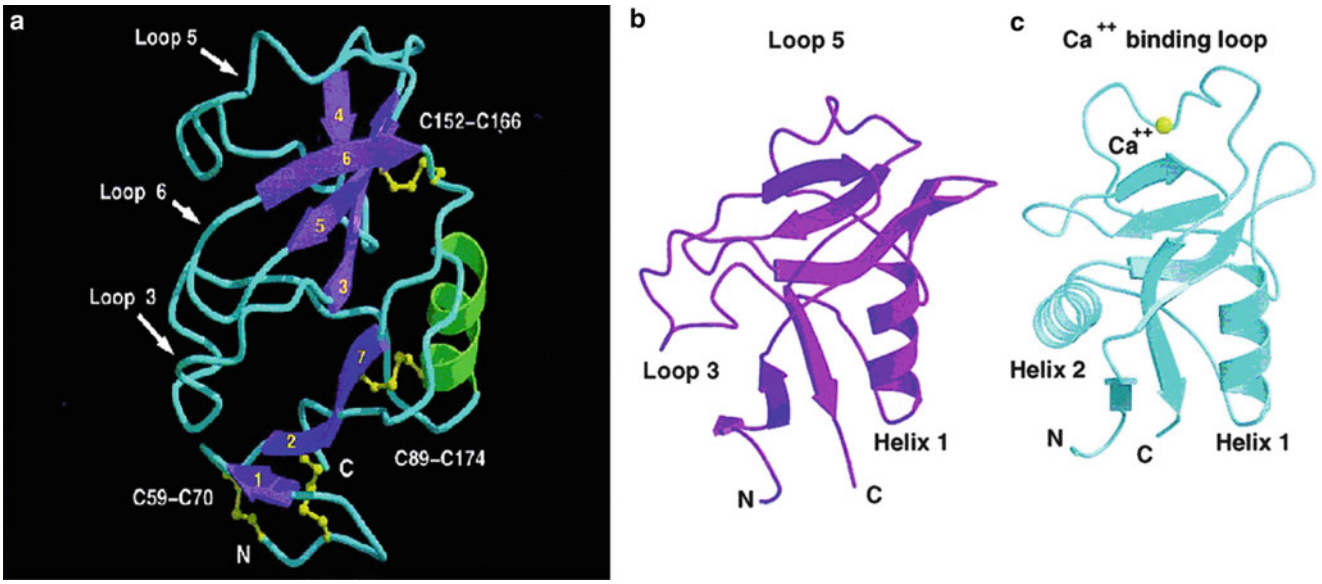

Fig. 30.2 (**a**). **Ribbon diagram of the structure of CD94**. β strands are shown in *purple* and are numbered according to their order in the sequence; the α helix is shown in *green*. The disulfide bonds are represented by *yellow ball-and-stick models* and labeled. Secondary structure assignments are as follows: β strands 1–7 corresponding to residues 66–68, 71–75, 115–122, 127–129, 151–155, 161–165, and 171–176; α helix 1 corresponding to residues 82–91. 2, and 7), a four stranded antiparallel β sheet (strands 4, 3, 5, and 6) and an α helix after strand 2 (Fig. 30.2). There are four intrachain disulfide bonds in CD94, three of which are the characteristic invariant disulfides (Cys61–Cys72, Cys89–Cys174, and Cys152–Cys166) found in long-form C-type lectins. The fourth disulfide, Cys59–Cys70, which forms a looped structure with N-terminal β strands, is unique to the structure of CD94. The only extracellular cysteine not involved in intrachain disulfide pairing, Cys58, is expected to pair with the equivalent cysteine of NKG2 (e.g., Cys116 in NKG2A) to form the interchain disulfide in the CD94/NKG2 heterodimer (Boyington et al. 1999).

Unlike the canonical C-type lectin fold, CD94 lacks one of two major a helices present in other C-type lectin structures known till this date. Specifically, the region from residues 102 to 112 (within loop 3), corresponding to the second helix of the consensus C-type lectin fold, adopts a loop conformation in CD94. The putative Ca^{2+}-dependent carbohydrate-binding loop (loop 5, residues 142–152) is 2–5 residues shorter in CD94 compared to other C-type lectins of known structure and displays a markedly different conformation as well as a different sequence. Apart from the missing helix and the conformation of the Ca^{2+}-binding loop, the rest of the CD94 structure is quite similar to the classical C-type lectin fold even though the average sequence identity is only 20% between CD94 and C-type lectins of known structure.

The primary sequences of NKG2-A/-B, -C, and -E suggest a strong structural similarity between CD94 and the NKG2 molecules. The dimerization of CD94 brings the two N-terminal α carbons to within 7.4 Å of each other, which is consistent with having a disulfide bond between the two chains of the receptor. Modeling of CD94 homodimer structure reveals that of the five hydrophobic core residues at the dimer interface of CD94, three are completely conserved in the NKG2 sequences, and two are replaced with other nonpolar residues. This distinctly hydrophobic patch forms the largest contiguous nonpolar surface on both the CD94 monomer and the model of NKG2. While the CD94 homodimer has no interchain salt bridges, there are two potential regions of charge complementarity across the modeled CD94/NKG2 interface: one between Asp106 of CD94 and Lys135 of NKG2A and the other between Arg69 of CD94 and Glu122 of NKG2A. Lys135 and Glu122 are each conserved throughout NKG2A/B, -C, and -E sequences, but are replaced by Ser and Lys, respectively, in CD94, creating an unfavorable Arg69–Lys64 interaction across the CD94/CD94 interface. This helps to explain the favorable interaction between CD94 and NKG2 compared to CD94 homodimerization (Boyington et al. 1999).

The areas of greatest sequence divergence between human CD94 and NKG2 occur outside the dimer interface in the C-terminal half of the molecule, forming a contiguous surface at one end of CD94 (Fig. 30.3). These variable regions border each other to form a flat, uninterrupted surface across one face of the molecule opposite from the N- and C-termini. Based on this structure and sequence alignments, it was postulated that the putative ligand-binding site resides within this variable region including

Fig. 30.3 Ribbon models showing two views of the CD94 dimer: each monomer is colored with a different *green shade*. Regions that have low sequence identity with the NKG2 sequences are colored *purple*. The *top view* is rotated 90° from the *bottom view* along the *horizontal axis*. In the *bottom view*, residues in the hydrophobic core of the dimer interface (V66, Y68, I75, F107, and M108) are represented by *ball-and-stick models*. These residues are colored *red* in one monomer and *yellow* in the other (Reprinted with permission from Boyington et al. 1999 © Elsevier)

residues 110–115, 120–124, 137–142, 144–150, 159–165, and 167–171 of human CD94 and the equivalent residues of human NKG2. The variable region of CD94 has an overall net negative charge, with seven acidic residues and only three basic residues. In contrast, the corresponding regions of the NKG2A sequence is considerably more positively charged than CD94, with six basic residues and four acidic residues (Boyington et al. 1999).

30.5 CD94/NKG2 Complex

30.5.1 CD94 and NKG2-A Form a Complex for NK Cells

The CD94/NKG2 family of receptors play an important role in regulating responses against infected and tumorigenic cells. While soluble NKG2A, -B and -C lectin domains interact with CD94 lectin domains to form complexes, NKG2D and human NKR-P1 lectin domains do not (Ding et al. (1999). The NKG2-B protein, which is an alternatively spliced product of the NKG2-A gene, can also assemble with CD94. Both NKG2-A and NKG2-B proteins contain ITIM. This provides the molecular basis of the inhibitory function mediated by the CD94/NKG2-A receptor complexes. Soluble NKG2C, -D and CD94 lectin domains bind solubilized purified HLA class I antigens independently, whereas NKG2A and -B require association of CD94 lectin domains for binding. Through differential CD94/NKG2 gene expression, human NK cells generate diverse repertoires, each cell having an inhibitory receptor for autologous HLA class I. The lytic capacity of a NK cell is regulated, in part, by the balance in cell surface expression between inhibitory CD94/NKG2A and activating CD94/NKG2C heterodimers (Lazetic et al. 1996; Borrego et al. 2006; Carretero et al. 1997).

The heterodimeric CD94/NKG2A receptor, expressed by mouse NK cells, transduces inhibitory signals upon ligation of its ligand, Qa-1b. The CD94/NKG2C and CD94/NKG2E also bind to Qa-1b. Within their extracellular CRDs, NKG2C and NKG2E share extensive homology with NKG2A (93–95% amino acid similarity). CD94/NKG2 molecules are the only Qa-1b binding receptors on NK cells. However, NKG2C/E receptors differ from NKG2A in their cytoplasmic domains (only 33% similarity) and contain features that suggest that CD94/NKG2C and CD94/NKG2E may be activating receptors (Vance et al. 1998, 1999).

30.6 Acquisition of NK Cell Receptors

Coordinated Acquisition of Inhibitory and Activating Receptors: The stages of human NK cell differentiation are not well established. Culturing $CD34^+$ progenitors, Grzywacz et al. (2006) identified 2 non-overlapping subsets of differentiating $CD56^+$ cells based on CD117 and CD94 [$CD117^{high}CD94^-$ and $CD117^{low/-}CD94^+$ cells]. Both populations expressed CD161 and NKp44, but differed with respect to NKp30, NKp46, NKG2A, NKG2C, NKG2D, CD8, CD16, and KIR. These two subsets represent distinct stages of NK cell differentiation, since purified $CD117^{high}$ $CD94^-$ cells gave rise to $CD117^{low/-}CD94^+$ cells. The identified stages of NK-cell differentiation suggested an evidence for coordinated acquisition of HLA-specific inhibitory receptors (i.e., CD94/NKG2A) and function in developing human NK cells. However, CD94/NKG2 receptor acquisition by NK cells does not require lymphotoxin-β receptor expression (Stevenaert et al. 2005).

Hierarchy of NK Cell Response Is Determined by Class and Quantity of Inhibitory Receptors for Self-HLA-B and HLA-C Ligands: Yu et al. (2007) evaluated the resting NK repertoire analyzing the responsiveness of NK subgroups expressing discrete combinations of non-KIR and KIR class I-specific receptors. CD94:NKG2A and

ILT2-expressing cells have a modest response to class I-negative target cells, but NK cells expressing inhibitory KIRs to self-MHC class I ligands, both HLA-B and HLA-C ligands, achieve significantly higher effector capacity. These findings defined how inhibitory receptor and autologous HLA interactions impact single-cell function and demonstrated how hierarchy of NK cell response is determined by class and quantity of inhibitory receptors for self-HLA-B and HLA-C ligands. These findings have important implications for the resting NK response to viral pathogens and malignancy and for donor selection in allogeneic hemopoietic cell transplantation (Yu et al. 2007; Salmon-Divon et al. 2005).

30.7 Regulation of CD94/NKG2

30.7.1 Transcriptional Regulation of NK Cell Receptors

The stochastic expression of individual members of NK cell receptor gene families on subsets of NK cells has attracted considerable interest in the transcriptional regulation of these genes. The discovery that an upstream promoter can function as a probabilistic switch element in the Ly49 gene family has revealed a mechanism of variegated gene expression. The other NK cell receptor gene families contain probabilistic switches. The promoter elements identified in the Ly49, NKR-P1, CD94, NKG2A, and KIR gene families have been reviewed. In the human population, there is a wide variation in the NK cell repertoire of KIRs and CD94:NKG2A expression. Variation is principally due to KIR gene variation and polymorphism, with a smaller effect due to MHC class I.

The human NKG2A gene of 3.9-kb genomic fragment contains a 1.65-kb region upstream of the exon 1, as well as exon 1 (untranslated), intron 1 and exon 2. A region immediately upstream from the most upstream transcriptional initiation site led to increased transcriptional activity. Within a DNase I hypersensitivity site to this region is 80-bp segment that shows two GATA (a zinc-finger transcription factor) binding sites. Mutation of GATA binding site II (−2,302 bp) but not GATA binding site I (−2,332 bp) led to decreased transcriptional activity. GATA-3 specifically binds to the NKG2A promoter in situ in NKL and primary NK cells, but not in Jurkat T cells. Thus GATA-3 is an important transcription factor for regulating NKG2A gene expression (Marusina et al. 2005; Muzzioli et al. (2007). The cAMP induced the upregulation of NKG2A at the mRNA level in human $CD8^+$ T lymphocytes. The PGE2/cAMP/PKA type I pathway appears to be involved in the expression of CD94/NKG2A on human $CD8^+$ T lymphocytes (Zeddou et al. 2005).

30.7.2 Regulation by Cytokines

Members of NKG2 family, NKG2A, -C, -D, and -E are sequentially expressed on $CD4^+$ cells. This expression was tightly regulated by cytokines, among which TGFβ1 and IL-10 are the main factors that positively contribute to the expression of CD94 and NKG2A (Romero et al. (2001). Ortega et al. (2004) found a constitutive expression of NKG2E in CD94-depleted resting human peripheral $CD4^+$ cells, whereas inductions of NKG2A (day 15) and NKG2C (day 20) after CD3-mediated stimulation required chronic cell activation and occurred after expression of CD94 (day 5). The mRNA induction of NKG2-A and NKG2-C genes was influenced by the presence of cytokines (IL-10 and TGF-β). This indicates that there are strict gene regulatory mechanisms for CD94 and NKG2 gene expression on $CD4^+$ cells, which are different from the mechanisms governing the expression of these same genes in $CD8^+$ cells (Gunturi et al. 2005). IL-12 modulates the expression of the CD94/NKG2-A inhibitory receptor by $CD8^+$ T cells in culture. Expression of the CD94/NKG2-A was also induced by IL-12 during T cell Ag stimulation. This implies the role of IL-12 in the modulation of immune responses through NKR induction (Derre et al. 2002; Gays et al. 2005).

Regulation by IL-15: The IL-15 provides an appropriate stimulus to the expression of CD94/NKG2A, but not of other class I-specific NK receptors in the process of maturation of NK cells from thymocytes (Mingari et al. 1997). Among different cytokines, only IL-2 or IL-15 induced cell proliferation when used alone. IL-15Rα-deficient (IL-15R$\alpha^{-/-}$) mice lack NK cells. However, when bone marrow (BM) progenitors from IL-15R$\alpha^{-/-}$ mice were cultured with IL-7, stem cell factor and flt3 ligand, followed by IL-15, they were able to differentiate into functional NK cells, indicating that IL-15Rα is not critical for NK cell development (Kawamura et al. 2003).

Autocrine IL-15 Mediates Intestinal Epithelial Cell Death: Intestinal intraepithelial lymphocytes (IELs), which reside between the basolateral faces of intestinal epithelial cells (IECs), provide a first-line defense against pathogens. IL-15 mediates the reciprocal interaction between IELs and IECs, an important interaction for the regulation of appropriate mucosal immunohomeostasis. These intraepithelial NK cells expressed Ly-49 antigens, NKG2 receptors, and perforin. It suggests the possibility that the apoptosis of IECs could be regulated by self-produced IL-15 through the

activation of intraepithelial NK cells. The IELs, T-cell receptor αβCD8$^+$ T cells located between epithelial cells, were thought to contribute to Fas ligand (FasL)-mediated epithelial cell death in coeliac disease, a condition characterized by excess IL-15.

IELs express CD94 in celiac disease (CD), which is characterized by IL-15 cytokine response of IELs to gluten-containing diet with concomitant increase in expression of IFN-β and down-regulatory IL-10 without increase of TNF-α or TGF-β1. CD is characterized by the presence of gliadin-specific CD4$^+$ T cells in the lamina propria and by the intraepithelial T-cell infiltration of unknown mechanism. In normal intestine, different proportions of IELs, which were mainly T cells, express NK receptors including CD94/NKG2. During active CD, the frequency of CD94$^+$ IELs, which were mostly αβT cells, conspicuously increased, while the expression of other NK markers was not modified. It appeared that the gut epithelium favors the development of T cells that express NK receptors. The specific and selective increase of IELs expressing CD94 may be related to T-cell receptor activation and/or IL-15 secretion (Jabri et al. 2000). In three major IEL-subsets γδIELs, CD4$^+$αβIELs and CD8$^+$αβELs, as well as CD94$^+$CD8$^+$αβIELs, all of which selectively expanded in active CD, CD8$^+$αβ IELs showed a significant increase in expression of both IFN-γ and IL-10. Production of IL-10 may be a common feature of IELs producing pro-inflammatory cytokines, thereby attempting to limit inflammation in an autocrine fashion (Ebert 2005; Forsberg et al. 2007; Kinoshita et al. 2002).

IL-21 Induces the Functional Maturation of Murine NK Cells: IL-21 stimulates mouse NK cell effector functions in vitro. The IL-21 is produced by CD4$^+$ T and NKT cells and mediates potent effects on a variety of immune cells including NK, -T, and -B cells. It achieves its stimulatory effect by inducing the development of mature NK cells into a large granular lymphocyte phenotype with heightened effector function. IL-21 treatment results in increased cell size and granularity and a corresponding decrease in cell viability and proliferative potential. These cells up-regulate the expression of the inhibitory CD94-NKG2A receptor complex and the activation markers CD154 and lectin-like-receptor G1. Surprisingly, IL-21 treatment also results in down-regulation of the pan-NK marker, NK1.1. These developmental changes suggested that IL-21 functions to induce the terminal differentiation of mouse NK cells, resulting in heightened NK cell-mediated cytotoxicity and immune surveillance (Brady et al. 2004).

IL-21 increases the proliferation of NKT cells in combination with IL-2 or IL-15, and particularly with the CD1d-restricted glycosphingolipid Ag α-galactosylceramide. Similar to its effects on NK cells, IL-21 enhances NKT cell granular morphology, granzyme B expression, and some inhibitory NK receptors, including Ly49C/I and CD94. This study suggests that NKT cells are potentially a major source of IL-21, and that IL-21 may be an important factor in NKT cell-mediated immune regulation (Coquet et al. 2007).

IFN-γ-Mediated Negative Feedback Regulation of NKT-Cell Function by CD94/NKG2: Activation of invariant NK T (iNKT) cells with CD1d-restricted T-cell receptor (TCR) ligands is a powerful means to modulate various immune responses. The CD94/NKG2A inhibitory receptor plays a critical role in down-regulating iNKT-cell responses. The iNKT-cell response is of limited duration and iNKT cells appear refractory to secondary stimulation. Both TCR and NK-cell receptors expressed by iNKT cells were rapidly down-modulated by priming with α-galactosylceramide (α-GalCer) or its analog OCH. TCR and CD28 were re-expressed more rapidly than the receptors CD94/NKG2A and Ly49, temporally rendering the primed iNKT cells hyperreactive to ligand restimulation. Blockade of the CD94/NKG2-Qa-1b interaction markedly augmented recall and primary responses of iNKT cells. This shows the critical role for NK-cell receptors in controlling iNKT-cell responses and provides a novel strategy to augment the therapeutic effect of iNKT cells by priming with OCH or blocking of the CD94/NKG2A inhibitory pathway in clinical applications (Kaiser et al. 2005; Ota et al. 2005).

30.8 Functions of CD94/NKG2

NK cell receptors create a delicate balance of activating and inhibitory signals. These receptors are present on different immune cells but play a major role for the innate immune system. For example, the NKG2A-CD94 heterodimer transmits an inhibitory signal and NKG2C-CD94 signals in an activating fashion while both receptors recognize the same ligand, HLA-E. CD94-NKG2-A/B heterodimers are expressed by NK cells, TCR-γ/δ cells, and a subset of TCR-α/β cells. Internalization of CD94/NKG2A is independent of ligand cross-linking or the presence of functional ITIM (Borrego et al. 2002). Thus, the mechanisms that control cell surface homeostasis of CD94/NKG2A are independent of functional signaling. Masilamani et al. (2008) indicated that CD94/NKG2A utilizes a novel endocytic mechanism coupled with an abbreviated trafficking pattern, perhaps to insure surface expression.

30.8.1 CD94/NKG2 in Innate and Adaptive Immunity

CD94/NKG2 receptor varies in function as an inhibitor or activator depending on which isoform of NKG2 is expressed. The lytic capacity of a NK cell is regulated, in part, by the balance in cell surface expression between inhibitory CD94/NKG2A and activating CD94/NKG2C heterodimers. The ligand for CD94/NKG2 is HLA-E in human and its homolog, Qa1 in mouse, which are both nonclassical class I molecules that bind leader peptides from other class I molecules. Although <5% of CD8 T cells express the receptor in a naive mouse, its expression is upregulated upon specific recognition of antigen. Similar to NK cells, most CD8 T cells that express high levels of CD94 co-express NKG2A, the inhibitory isoform. The engagement of this receptor can lead to a blocking of cytotoxicity. However, these receptors have also been implicated in the cell survival of both NK and CD8 T cells. It was found that the extent of apoptosis in $CD8^+$ T and NK cells was inversely related to the expression of CD94, with lower levels of apoptosis seen in $CD94^{high}$ cells after 1–3 days of culture. The expression of CD94/NKG2 is correlated with a lower level of apoptosis and may play an important role in the maintenance of $CD8^+$ T and NK cells. Thus, CD94/NKG2 receptors may regulate effector functions and cell survival of NK cells and CD8 T cells, thereby playing a crucial role in the innate and adaptive immune response to a pathogen (Gunturi et al. 2004, 2003; Lohwasser et al. 2001). However, NK cells whose inhibitory receptors lack any apparent self-ligand can also be found in healthy individuals. On examining these NK cells, Grau et al. (2004) detected NK cells whose sole inhibitory receptors were CD94/NKG2-A and that had no affinity for autologous HLA-C molecules. Findings demonstrated the presence of potentially autoreactive NK cells in otherwise healthy individuals.

CD94 Participates in Qa-1-Mediated Self Recognition by NK Cells: In comparison to human CD94/NKG2 heterodimer, mouse Ly-49, CD94/NKG2 homologues and CD94 have been observed on all NK and NK T cells as well as small fractions of T cells in all mouse strains tested. Two distinct populations of CD94 were identified among NK and NK T cells, $CD94^{bright}$ and $CD94^{dim}$ cells, independent of Ly-49 expression. Importantly, $CD94^{bright}$ but not $CD94^{dim}$ cells were found to be functional in the Qa-1/Qdm-mediated inhibition. Toyama-Sorimachi et al. (2001) suggested that mouse CD94 participates in the protection of self cells from NK cytotoxicity through the Qa-1 recognition, independent of inhibitory receptors for classical MHC class I such as Ly-49.

Qa-1b in Association with CD94/NKG2A on CD8 T Cells Regulates Cytotoxic T Cells: The CD94/NKG2A recognizes the non-classical MHC class I molecule Qa-1b and inhibits NK cytotoxicity. Qa-1b presents a peptide derived from the leader sequence of classical MHC class I molecules. During action of CD94/NKG2A in T cell-mediated cytotoxicity, tetrameric Qa-1b binds to almost all $CD8^+$, but not $CD4^+$ T cells. Most murine $CD8^+$ T cells constitutively express CD94 and NKG2A transcripts. Co-expression of Qa-1b and D(k) on target cells significantly inhibited cytotoxicity of D(k)-specific cytotoxic T lymphocytes generated by MLR, indicating that Qa-1b on antigen-presenting cells interacts with CD94/NKG2A on CD8 T cells and regulates classical MHC class I-restricted cytotoxic T cells (Lohwasser et al. 2001). The Qa-1-NKG2A interaction protected activated CD4+ T cells from lysis by a subset of $NKG2A^+$ NK cells and was essential for T cell expansion and development of immunologic memory. Findings suggest a new clinical strategy for elimination of antigen-activated T cells in the context of autoimmune disease and transplantation (Lu et al. 2007).

30.8.2 Modulation of Anti-Viral and Anti-Tumoral Responses of γ/δ T Cells

Viral, bacterial, protozoal, and cancer-associated Ags elicit strong responses in human γ/δ T lymphocytes. Vγ9Vδ2 T cells stimulated with nonpeptidic mycobacterial antigens produce IFN-γ and TNF-α. Signaling through the CD94/NKG2 receptor interferes with the synthesis of these cytokines. The CD94/HLA class I interaction is also involved in the cytotoxic activity of Vγ9Vδ2 T cells. The Vγ9Vδ2 T cell regulation through the CD94 receptor may be important for the potentially dual function in innate immunity, i.e., (1) NK-like and (2) TCR ligand-induced cytolytic activities (Poccia et al. 1997).

Different Mechanisms of CD94/NKG2-A Expression on γ/δ T Lymphocytes: Most adult peripheral blood γ/δ T cells express Vγ9Vδ2-encoded TCR that recognize a restricted set of nonpeptidic phosphorylated compounds, referred to as phosphoantigens. They also express MHC class I-specific inhibitory receptors, in particular CD94/NKG2-A heterodimers, which participate in the fine tuning of their TCR-mediated activation threshold. Most mature Vγ9Vδ2 T cells express surface CD94 receptors, unlike cord blood or thymus-derived Vγ9Vδ2 clones, thus suggesting a role for the microenvironment in inhibitory receptors expression. Most $CD94^-$ Vγ9Vδ2 peripheral blood lymphocytes (PBL), ex vivo, express an intracellular pool of CD94/

NKG2-A receptors that is translocated to the cell surface upon activation by phosphoantigens or IL-2. In sharp contrast, intracellular CD94/NKG2-A complexes are undetectable in $CD94^{-}$ thymus or PBL-derived mature Vδ2 T cell clones, and no surface induction is observed following phosphoantigen activation of T cell clones. These results provide the existence of distinct mechanisms controlling in vivo and in vitro induction of inhibitory receptors on Vγ9Vδ2 T cells (Boullier et al. 1998).

CD94/NKG2 Complex or KIRs Exert Inhibitory Effect on HLA-I-Mediated NK Cell Apoptosis: The $CD8^{dull}$, $CD8^{intermediate}$, and $CD8^{bright}$ NK cell clones can be identified. Triggering of CD8 with its natural ligand(s), such as soluble HLA class I (sHLA-I) leads to NK cell apoptosis. The magnitude of apoptosis directly correlated with the level of CD8 expression. The sHLA-I-induced apoptosis depends on the interaction with CD8, as it was inhibited by masking this molecule with specific mAbs. However, inhibitory receptor, such as CD94/NKG2 complex or KIRs exerted an inhibitory effect on sHLA-I-mediated apoptosis and secretion of FasL. Thus the interaction between sHLA-I and CD8 evoking an apoptotic signal is down-regulated by inhibitory receptor superfamily that functions as survival receptors in NK cells (Spaggiari et al. 2002).

30.9 NK Cells in Female Reproductive Tract and Pregnancy

NK cells are present in the various female reproductive tract (FRT) tissues; their regulation is largely dependent upon the FRT tissue where they reside. NK cells in the Fallopian tube, endometrium, cervix, and ectocervix expressed CD9 while blood NK cells did not. Unique subsets of NK cells are found in specific locations of the FRT. The NK cells in the lower reproductive tract did not express CD94, but they did express CD16. In contrast, NK cells in the upper FRT express high amounts of CD94 and CD69, but few NK cells expressed CD16. All FRT NK cells were able to produce IFN-γ upon stimulation with cytokines. These unique characteristics of the tissues may account of specific localization of different NK cell subsets (Mselle et al. 2007).

30.9.1 Decidual NK Cell Receptors

NK cells are the most abundant lymphocyte population at the maternal-fetal interface. They are considered to be important during placentation by controlling trophoblast invasion. In early human pregnancy, uterine decidual NK cells (dNK) are abundant (50–90% of lymphocytes) and considered as cytokine producers but poorly cytotoxic despite their cytolytic granule content, suggesting a negative control of this latter effector function. There is no clear evidence that dNK cells kill trophoblast cells. Instead they are able to secrete cytokines which are likely to be beneficial for the placental development, maternal uterine spiral arteries remodeling, and the antiviral immune response (Rabot et al. 2005). To investigate the basis of a negative control of effector function, El Costa et al. (2008) examined the relative contribution to the cytotoxic function of different activating receptors expressed by dNK. In fresh dNK, mAb-specific engagement of NKp46- and to a lesser extent NKG2C-, but not NKp30-activating receptors induced intracellular calcium mobilization, perforin polarization, granule exocytosis and efficient target cell lysis. It was found that in dNK, mAb-specific engagement of NKp30, but not NKp46, triggered the production of IFN-γ, TNF-α, MIP-1α MIP-1β, and GM-CSF pro-inflammatory molecules.

The balance of inhibitory and activating NK receptors on maternal dNK cells, most of which are $CD56^{bright}$, is thought to be crucial for the proper growth of trophoblasts in placenta and maintenance of pregnancy. The CD94/NKG2, a receptor for HLA-E, is expressed on trophoblasts. Women with alloimmune abortions have a limited inhibiting KIR repertoire and such miscarriages may occur because trophoblastic HLA class I molecules are recognized by dNK cells lacking the appropriate inhibitory KIRs (Varla-Leftherioti et al. 2003). dNK cells express normal surface levels of certain activating receptors, including NKp46, NKG2D, and 2B4, as well as KIRs and CD94/NKG2A inhibitory receptor. In addition, they are characterized by high levels of cytoplasmic granules despite their $CD56^{bright}$ $CD16^{-}$ surface phenotype. Moreover, in dNK cells, activating NK receptors display normal triggering capability whereas 2B4 functions as an inhibitory receptor. This might suggest that dNK cells, although potentially capable of killing, are inhibited in their function when interacting with cells expressing CD48 (Eidukaite et al. 2004; Vacca et al. 2006).

Kusumi et al. (2006) compared the expression patterns of NK receptor, CD94/NKG2A, and CD94/NKG2C, on dNK cells in early stage of normal pregnancy with those on peripheral NK cells, most of which are $CD56^{dim}$. The rate of NKG2A-positive cells was significantly higher for decidual $CD56^{bright}$ NK cells than for peripheral $CD56^{dim}$ NK cells, but the rates of NKG2C-positive cells were comparable between the two cell types. Interestingly, peripheral $CD56^{dim}$ NK cells reciprocally expressed inhibitory NKG2A and activating NKG2C, but decidual $CD56^{bright}$ NK cells that expressed activating NKG2C simultaneously expressed inhibitory NKG2A. The co-expression of inhibitory and activating NKG2 receptors may fine-tune the immunoregulatory functions of the dNK cells to control the

trophoblast invasion in constructing placenta (Kusumi et al. 2006).

Pre-eclamptic women had higher number of $CD56^+$ and $CD94^+$ cells in the decidua, indicating an altered receptor expression of dNK cells. The villous trophoblasts from women suffering from pre-eclampsia had significantly less IL-12 in placentae and significantly elevated IL-12 and IL-15 levels in serum. The altered receptor expression of dNK cells together with diminished placental IL-12 expression could implicate an altered NK cell-regulation in pre-eclampsia (Bachmayer et al. 2006).

Potentially cytotoxic $V\delta^+$ T lymphocytes recognize HLA-E on the trophoblast via their CD94/NKG2A receptors. While the percentage of viable $V\delta2^+$ T cells was higher, the percentage of $V\delta1^+$ T cells was lower in women at risk of premature pregnancy termination than in healthy pregnant women. Nonetheless, the percentage of $NKG2A^+$ $V\delta2^+$ T cells was significantly lower in pregnant women at risk of premature pregnancy termination. This indicates the involvement of γδ T lymphocytes in the pathogenesis of premature pregnancy termination (Szereday et al. 2003).

30.10 Signal Transduction by CD94/NKG2

30.10.1 Engagement of CD94/NKG2-A by HLA-E and Recruitment of Phosphatases

Many receptors share common signaling motifs to transmit their signal into the cell. Activating receptors usually signal via the immunoreceptor tyrosine-based activation motif (ITAM) containing tyrosine residues that can be phosphorylated upon receptor engagement and can recruit Syk family kinases. Inhibitory receptors often possess an Immunoreceptor Tyrosine-based Inhibition Motif (ITIM), which can recruit phosphatases upon phosphorylation. These phosphatases, like SHP-1 or SHP-2, are able to dephosphorylate and therefore inhibit intracellular factors that otherwise would promote cellular activation. NKG2C and NKG2D, the C-type lectin-like receptors, play important roles for the activation of NK cells. These receptors have no intracellular signaling domain but instead pair with the adaptor molecules DAP10 and/or DAP12 to mediate an activating signal. The src-family tyrosine kinases include SH2-domain-containing protein tyrosine phosphatase 1 (SHP-1), SHP-2, and SH2-domain-containing inositol polyphosphate 5′ phosphatase (SHIP1). SHP-1, in particular, has been demonstrated to associate with phosphorylated ITIMs and to mediate inhibition of NK cell cytotoxicity (Fig. 30.1). A selective engagement of the CD94/NKG2A receptor with a specific mAb was sufficient to induce tyrosine phosphorylation of NKG2A subunit and SHP-1 recruitment. Furthermore, mAb cross-linking of the CD94/NKG2A receptor, segregated from other NK-associated molecules by transfection into a leukemia cell line (RBL-2H3), promoted tyrosine phosphorylation of NKG2A and co-precipitation of SHP-1, together with an inhibition of secretory events triggered via FcεRI (Carretero et al. 1998).

Specific engagement of the receptor complex expressed on the surface of an NK clone induced the phosphorylation of MAPK. It was demonstrated that the MAPK pathway participates in the CD94-dependent TNF-α production and cytotoxicity. Cross-linking of the receptor induced calcium mobilization, serotonin release and phosphorylation of MAPK (Carretero et al. 2000). Palmieri et al. (1999) indicated that CD94/NKG2-A inhibits the CD16-triggered activation of two signaling pathways involved in the cytotoxic activity of NK cells. They thus provide molecular evidence to explain the inhibitory function of CD94/NKG2-A receptor on NK effector functions.

NK Cell inhibitory receptors can interfere with tyrosine phosphorylation of 2B4 (CD244), which is an NK cell activation receptor that can provide a co-stimulatory signal to other activation receptors. Cross-linking of 2B4 on NK cells and ligation of 2B4 in the context of an NK cell-target cell interaction leads to 2B4 tyrosine phosphorylation, target cell lysis, and IFN-γ release. Coligation of 2B4 with CD94/NKG2 completely blocks NK cell activation. The rapid tyrosine phosphorylation of 2B4 after contact of NK cells with sensitive target cells is abolished when CD94/NKG2 are engaged by their cognate MHC class I ligand on resistant target cells. These results demonstrate that NK inhibitory receptors can interfere with a step as proximal as phosphorylation of an activation receptor (Watzl et al. 2000; Zingoni et al. 2000.

30.11 Ligands for CD94/NKG2

30.11.1 HLA-E as Ligand for CD94/NKG2A

The protein HLA-E is a non-classical MHC molecule of limited sequence variability. Human HLA-E, transcribed in most tissues, is the primary ligand for CD94/NKG2A-inhibitory receptors. The apparent CD94-mediated specific recognition of different HLA class Ia allotypes, transfected into the HLA-defective cell line 730.221, depends on their selective ability to concomitantly stabilize the surface expression of endogenous HLA-E molecules, which confer protection against $CD94/NKG2A^+$ effector cells. Further studies on $CD94/NKG2^+$ NK cell-mediated recognition of .221 cells transfected with different HLA class I allotypes confirmed that the inhibitory interaction was mediated by CD94/NKG2A recognizing the surface HLA-E molecule, because only antibodies directed against either HLA-E, CD94, or CD94/NKG2A specifically restored lysis.

Consistent with the prediction that the ligand for CD94/NKG2A is expressed ubiquitously, the HLA-E distribution indicated that it is detectable on the surface of a wide variety of cell types (Lee et al. 1998; Brooks et al. 1999).

The inhibitory CD94/NKG2-A receptor has a higher binding affinity for HLA-E than the activating CD94/NKG2-C receptor and, that the recognition of HLA-E by both CD94/NKG2-A and CD94/NKG2-C is peptide dependent. There appeared to be a strong, direct correlation between the binding affinity of the peptide-HLA-E complexes for the CD94/NKG2 receptors and the triggering of a response by the NK cell (Braud et al. 1998; Vales-Gomez et al. 1999; Wada et al. 2004).

HLA-E-Bound Peptides Influence Recognition by CD94/NKG2 Receptors: Reports support the notion that the primary structure of HLA-E-bound peptides influences CD94/NKG2-mediated recognition, beyond their ability to stabilize surface HLA-E. Further, CD94/NKG2A$^+$ NK clones appeared more sensitive to the interaction with most HLA-E-peptide complexes than did effector cells expressing the activating CD94/NKG2C receptor. However, a significant exception to this pattern was HLA-E loaded with the HLA-G-derived nonamer. This complex triggered cytotoxicity very efficiently over a wide range of peptide concentrations, suggesting that the HLA-E/G-nonamer complex interacts with the CD94/NKG2 triggering receptor with a significantly higher affinity. Study raises the possibility that CD94/NKG2-mediated recognition of HLA-E expressed on extravillous cytotrophoblasts plays an important role in maternal-fetal cellular interactions (Llano et al. 1998). HLA-E interacts with CD94/NKG2A receptors on NK cells and this inhibits NK cell lysis of the cell displaying HLA-E (LaBonte et al. 2001; Boyington et al. 2000).

The uterine mucosa in early pregnancy (decidua) is infiltrated by large numbers of NK cells, which are closely associated with placental trophoblast cells. Trophoblast cells express HLA-E on their cell surface in addition to the expression of HLA-G and HLA-C. The vast majority of decidual NK cells bind to HLA-E tetrameric complexes and this binding is inhibited by mAb to CD94. This shows that recognition of fetal HLA-E by decidual NK cells may play a key role in regulation of placentation. The functional consequences of decidual NK cell interaction between CD94/NKG2 and HLA-E is the inhibition of cytotoxicity by decidual NK cells. It was suggested that HLA-E interaction with CD94/NKG2 receptors may regulate other functions besides cytolysis during implantation (King et al. 2000).

A Peptide from Leader Sequences of HSP 60 Binds Also to HLA-E: HLA-E also presents a peptide derived from the leader sequence of human heat shock protein 60 (HSP60). This peptide gains access to HLA-E intracellularly, resulting in up-regulated HLA-E/HSP60 signal peptide cell-surface levels on stressed cells. Notably, HLA-E molecules in complex with the HSP60 signal peptide are no longer recognized by CD94/NKG2A inhibitory receptors. Thus, during cellular stress an increased proportion of HLA-E molecules may bind the nonprotective HSP60 signal peptide, leading to a reduced capacity to inhibit a major NK cell population. Such stress induced peptide interference would gradually uncouple CD94/NKG2A inhibitory recognition and provide a mechanism for NK cells to detect stressed cells in a peptide-dependent manner (Crew et al. 2005; Michaelsson et al. 2002; Wooden et al. 2005).

30.11.2 CD94/NKG2-A Recognises HLA-G1

There is no evidence that p58 and p70 KIRs may interact with HLA-G1. By contrast, NK recognition of cells expressing HLA-G1 involves at least two non-overlapping receptor-ligand systems: (1) the direct engagement of the ILT2 (LIR1) receptor by HLA-G1; and (2) the interaction of CD94/NKG2A and CD94/NKG2C receptors with the non-classical class I molecule HLA-E, co-expressed on the surface upon binding to a nonamer (VMAPRTLFL) from the HLA-G leader sequence (López-Botet et al. 1999 ; Navarro et al. 1999). Perez-Villar et al. (1997) supported the idea that the CD94/NKG2 receptor is involved in the recognition of cells expressing HLA-G1.

CD94/NKG2 Is Predominant Receptor in Recognition of HLA-G at Maternal-Fetal Interface: NK cells isolated from adult peripheral blood kill the HLA-A-, HLA-B-, and HLA-C-deficient B lymphoblastoid cell line 730.221, but many are unable to kill 730.221 cells transfected with HLA-G, a molecule expressed preferentially on fetal cytotrophoblasts. The nonclassical human HLA-G is selectively expressed on fetal trophoblast tissue at the maternal-fetal interface in pregnancy. It seems that HLA-G may inhibit maternal NK cells through interaction with particular NK cell receptors. Recognition of HLA-G by NK cells was prevented in the presence of anti-CD94 mAb, implicating CD94/NKG2 as the predominant inhibitory NK cell receptor for HLA-G used by dNK cells (Soderstrom et al. 1997). Allan et al. (1999) suggested that the primary role of HLA-G may be the modulation of myelomonocytic cell behavior in pregnancy.

HLA-E and HLA-G Expression on Porcine Endothelial Cells Inhibit Xenoreactive Human NK Cells: Studies showed that peptides derived from the leader sequence of HLA-G binds and up-regulates the surface expression of HLA-E molecules, which was considered to consequently

provide negative signals to human NK cells. HLA-G protects porcine cells from human NK cells through a CD94/NKG2-independent pathway. These results demonstrated that both HLA-E and HLA-G could directly inhibit human NK cells in the absence of other endogenous HLA class I molecules (Sasaki et al. 1999). These results have implications in preventing xenograft rejection mediated by human NK cells.

30.11.3 Non-Classical MHC-I Molecule Qa-1b as Ligand

Vance et al. (1998) provided evidence that mouse NK cell CD94/NKG2A heterodimer recognizes Qa-1b. The NK recognition of Qa-1b results in the inhibition of target cell lysis. Inhibition appears to depend on the presence of Qdm (Qa-1 determinant modifier), a Qa-1b-binding peptide derived from the signal sequences of some classical class I molecules. Qa-1 predominantly assembles with a single Qdm. The Qa-1/Qdm complex is the primary ligand for CD94/NKG2A inhibitory receptors expressed on a major fraction of NK cells. Cells become susceptible to killing by NK cells under conditions where surface expression of the Qa-1/Qdm inhibitory ligand is reduced (Borrego et al. 1998).

Qdm (Qa-1 Determinant Modifier): Qdm peptide, derived from the signal/leader sequence of many MHC class Ia protein molecules, has the sequence (AMAPRTLLL). This peptide binds with- and accounts for almost all of the peptides associated with this molecule. The Qa-1b was found to bind related ligands representing peptides derived from the leaders of class I molecules from several mammalian species, indicating a conservation of this "Qdm-like" epitope throughout mammalian evolution (Kurepa et al. 1998). Human HLA-E, the homologue of Qa-1b, binds similar peptides derived from human class Ia molecules and interacts with CD94/NKG2 receptors on NK cells. All of the peptides, which bind HLA-E bound readily to Qa-1b. However, the exact circumstances under which Qa1 protects cells from NK lysis and, in particular the role of Qdm, were addressed by Gays et al. (2001). Results obtained with a series of substituted Qdm peptides suggest that residues at positions 3, 4, 5, and 8 of the Qdm sequence, AMAPRTLLL, are important for recognition of Qa1-Qdm complexes by inhibitory CD94/NKG2 receptors (Jensen et al. 2004). The CD94/NKG2A receptor, expressed by mouse NK cells, transduces inhibitory signals upon recognition of its ligand, Qa-1b. The CD94/NKG2C and CD94/NKG2E also bind to Qa-1b. Within their extracellular CRDs, NKG2C and NKG2E share extensive homology with NKG2A (93–95% amino acid similarity) and may bind Qa-1b.

The Qa-1b/Qdm Tetramer Binds to CD94/NKG2 Complex Expressed on CD94^{high} Murine NK Cells: Although very few CD8$^+$ T cells from naive mice express CD94/NKG2 receptors, approximately 50% of CD8$^+$ T cells taken from mice undergoing a secondary response against *Listeria monocytogenes* (LM) are CD94^{high} and bind the Qa-1b/Qdm tetramer. Also, CD94^{int} NK cells do not bind the tetramer, where as CD94^{int} CD8$^+$ T cells do, and this binding is dependent on the CD8 co-receptor (Gunturi et al. 2003).

A Peptide from HSP60 Binds to Qa-1 in Absence of Qdm: In the light of stress induced peptide interference by HSP-60 peptide to uncouple CD94/NKG2A inhibitory recognition and to provide a mechanism for NK cells to detect stressed cells in a peptide-dependent manner (Michaelsson et al. 2002), Davies et al. (2003) reported the isolation and sequencing of a HSP-60-derived peptide (GMKFDRGYI) from Qa-1. This peptide is the dominant peptide bound to Qa-1 in the absence of Qdm. A Qa-1-restricted CTL clone recognizes this HSP60 peptide, further verifying that it binds to Qa-1 and a peptide from the homologous *Salmonella typhimurium* protein GroEL (GMQFDRGYL). These observations have implications for how Qa-1 can influence NK cell and T cell effector function via the TCR and CD94/NKG2 family members, and how this effect can change under conditions that cause the peptides bound to Qa-1 to change (Davies et al. 2003).

30.12 Structure Analysis of CD94-NKG2 Complex

30.12.1 Crystal Analysis of NKG2A/CD94: HLA-E Complex

HLA-E binds peptides derived from the leader sequences of other HLA class I molecules. NK cell recognition of HLA-E molecules, via the CD94-NKG2 NK family, represents a central innate mechanism for monitoring MHC expression levels within a cell. Kaiser et al. (2008) determined the crystal structure of the NKG2A/CD94/HLA-E complex at 4.4-Å resolution, revealing two critical aspects of this interaction. First, the C-terminal region of the peptide, which displays the most variability among class I leader sequences, interacts entirely with CD94, the invariant component of these receptors. Second, residues 167–170 of NKG2A/C account for the approximately sixfold-higher affinity of the inhibitory NKG2A/CD94 receptor compared to its activating NKG2C/CD94 counterpart. These residues do not contact HLA-E or peptide directly but instead form part of the heterodimer interface with CD94. An evolutionary analysis across primates reveals that whereas CD94 is

evolving under purifying selection, both NKG2A and NKG2C are evolving under positive selection. It seemed that the evolution of the NKG2x/CD94 family of receptors has been shaped both by the need to bind the invariant HLA-E ligand and the need to avoid subversion by pathogen-derived decoys (Kaiser et al. 2008).

Changes in Peptide Conformation Affect Recognition of HLA-E by CD94-NKG2: The leader sequence-derived peptides bound to HLA-E exhibit very limited polymorphism, yet subtle differences affect the recognition of HLA-E by the CD94-NKG2 receptors. In order to prove this point, the structure of HLA-E was determined in complex with two leader peptides, namely, HLA-Cw*07 (VMAPRALLL), which is poorly recognised by CD94-NKG2 receptors, and HLA-G*01 (VMAPRTLFL), a high-affinity ligand of CD94-NKG2 receptors. A comparison of these structures revealed that allotypic variations in the bound leader sequences do not result in conformational changes in HLA-E heavy chain, although subtle changes in the conformation of the peptide within the binding groove of HLA-E were evident. Accordingly, results indicate that the CD94-NKG2 receptors interact with HLA-E in a manner that maximises the ability of the receptors to discriminate between subtle changes in both the sequence and conformation of peptides bound to HLA-E (Hoare et al. 2008).

30.12.2 CD94-NKG2A Binding to HLA-E

Petrie et al. (2008) described the crystal structure of CD94-NKG2A in complex with HLA-E bound to a peptide derived from the leader sequence of HLA-G. The CD94 subunit dominated the interaction with HLA-E, whereas the NKG2A subunit was more peripheral to the interface. Moreover, the invariant CD94 subunit dominated the peptide-mediated contacts, albeit with poor surface and chemical complementarity. There were few conformational changes in either CD94-NKG2A or HLA-E upon ligation, and such a "lock and key" interaction is typical of many receptor-ligand interactions. The structure provided insight into how this interaction can be modulated by subtle changes in the peptide ligand or by the pairing of CD94 with other members of NKG2 family (Petrie et al. 2008) (Figs. 30.4 and 30.5).

Results showed that the CD94-NKG2A docked toward the C-terminal end of the HLA-E antigen-binding cleft, binding at an angle of ~70° (Fig. 30.4a, b) in a manner that permitted CD94-NKG2A to sit across both the α1 and α2 helices of HLA-E (Fig. 30.4). A comparison of the CD94-NKG2A–HLA-$E^{VMAPRTLFL}$ complex with the nonligated CD94-NKG2A and HLA-$E^{VMAPRTLFL}$ structures revealed no significant conformational change in either HLA-E or CD94-NKG2A upon complex formation. The one disordered loop of the nonligated CD94-NKG2A heterodimer (residues 199–204 in NKG2A) became ordered in the complex, although this observation was attributable to crystal-packing effects, as this loop did not contact HLA-$E^{VMAPRTLFL}$. Only one residue, Gln 112 of CD94, was reorientated upon ligation to maximize the complementarity at the interface. Accordingly, this "lock and key" engagement between HLA-$E^{VMAPRTLFL}$ and CD94-NKG2A exemplified the "innate characteristic" of this interaction.

Analysis of the electrostatic surfaces of HLA-E and CD94-NKG2A highlighted a role for charge complementarity at the CD94-NKG2A–HLA-E interface. Namely, a basic region on the α1 helix of HLA-E interacted with an acidic region on CD94 and, conversely, an acidic region on the HLA-E α2 helix docked with a distinct patch of basic charge on NKG2A. The CD94 footprint on HLA-E was broad, with residues within loops 2, 3, and 5, and β strands 6 and 7 from CD94 interacting with a region spanning residues 65–89 from α1 helix of HLA-E (Petrie et al. 2008). When compared with that of CD94, the footprint of NKG2A on HLA-E was markedly smaller and more focused with loop 3 and β strands 2, 5, and 6 interacting with residues 151–162 of the α2 helix of HLA-E. Nevertheless, analogous to the CD94–HLA-E interactions, the NKG2A–HLA-E contacts were dominated by polar residues. Accordingly, the large and predominantly polar network of interactions between CD94-NKG2A and HLA-E underscored the specificity of this interaction and highlighted the dominant role of the CD94 subunit with respect to the NKG2A subunit (Petrie et al. 2008).

The location of the CD94-NKG2A footprint on HLA-$E^{VMAPRTLFL}$ was analogous to the positioning of the footprint of human NKG2D on its MHC-like ligands, MICA and, to a lesser extent, ULBP3 (Fig. 30.5). Nevertheless, there were notable differences between these footprints, which are attributable to the narrower cleft between the α helices of MICA and ULBP3 compared with HLA-E, and the structural differences between CD94-NKG2A and NKG2D. CD94-NKG2A possessed a flat interacting surface with HLA-E, whereas that of NKG2D was more "saddle-like," which enabled it to clamp around both α helices of the MHC-like ligands (Fig. 30.5) (Petrie et al. 2008). Accordingly, the innate NK receptors and the αβTCR focus on a similar region of the HLA-E or MHC-like ligand, regardless of whether the ligand presents peptide or not. However, the characteristics of the footprint deviate between these receptors, thereby providing a basis for the NKG2D promiscuity versus the CD94-NKG2A specificity.

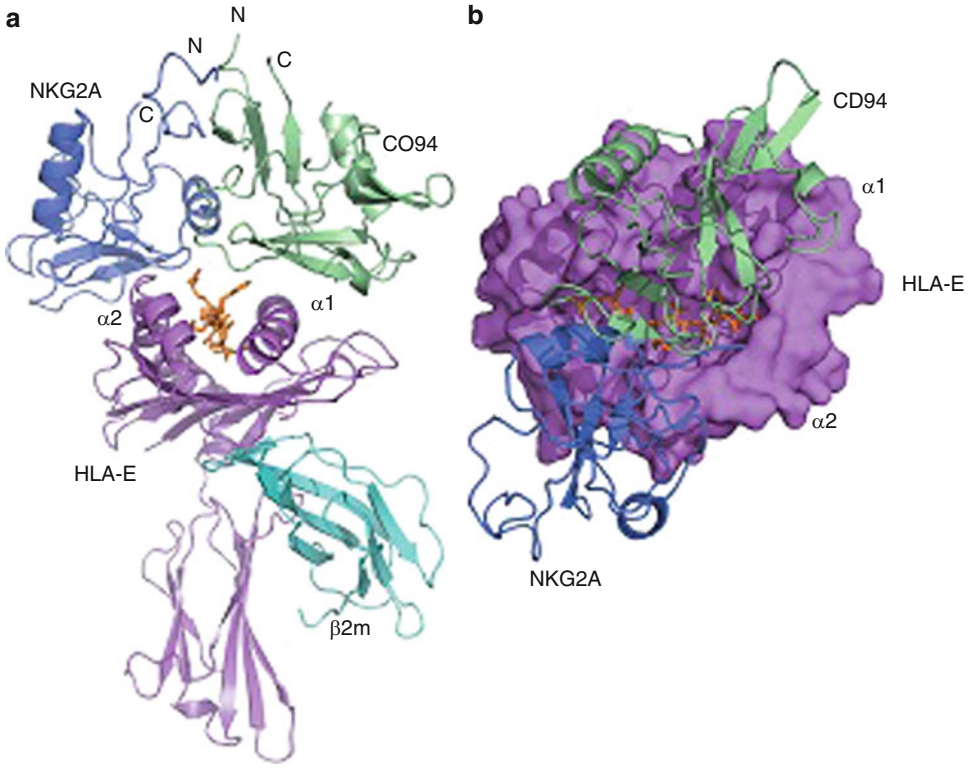

Fig. 30.4 The CD94-NKG2A – HLA-E VMAPRTLFL complex: NKG2A and CD94 are represented as *blue* and *pale green* ribbon structures, respectively. The heavy chain of HLA-E and β 2 m are shown as *violet* and *cyan ribbons*, respectively, with the VMAPRTLFL peptide in *orange sticks*. (**a**) Side view of CD94-NKG2A docking onto HLA-E VMAPRTLFL. (**b**) *Top view* of CD94-NKG2A docking onto the surface of HLA-E VMAPRTLFL (Adapted with permission from Petrie et al. 2008 © Rockefeller University Press)

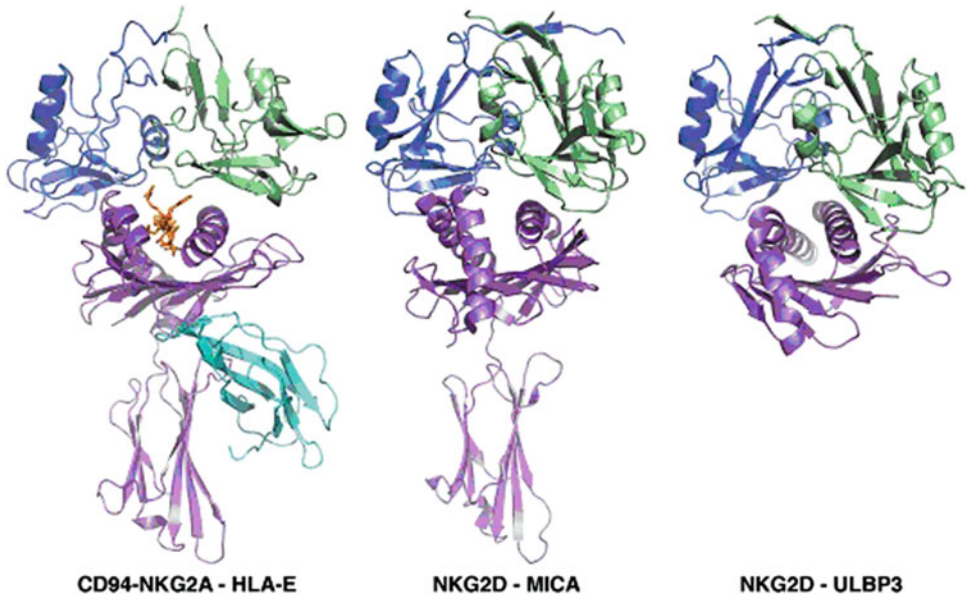

Fig. 30.5 Comparison of polar versus nonpolar interactions by CD94-NKG2A and NKG2D homodimer: Nonpolar interactions are represented in *purple*, and polar interactions are in *blue*. In situations where a residue makes both nonpolar interactions as well either a salt bridge or hydrogen bond, it was represented as making a polar interaction. Ribbon representation of CD94-NKG2A in complex with HLA-E ^{VMAPRTLFL} and NKG2D homodimers binding to MICA and ULBP3. The subunit of the NKG2D homodimer equivalent to CD94 is represented in *pale green*, and the subunit equivalent to NKG2A is in *blue*. The MHC-like molecules, MICA and ULBP3, not associated with β2m (represented in *cyan*), are represented in *violet* (Adapted with permission from Petrie et al. 2008 © The Rockefeller University Press)

30.13 Inhibitory Receptors in Viral Infection

Virus Associated Innate Immunity in Liver: The expression of inhibitory receptor CD94/NKG2A is up-regulated on NK cells in patients with chronic hepatitis C. HLA-E, a ligand for NKG2A, was expressed in all human hepatoma cell lines as well as in nontransformed hepatocytes, but not in K562 cells, a classic NK-sensitive target. Aberrant expression of CD94/NKG2A should have negative impact on innate resistance and subsequent adaptive immunity toward HCV-infected or transformed cells in chronic hepatitis C (Takehara and Hayashi 2005).

Kanto (2008) sought to clarify the role of innate immune system in the pathogenesis of HCV infection. DCs are known to sense virus infection via toll-like receptors (TLR) or retinoic acid inducible gene-I (RIG-I), resulting in the secretion of type-I IFN and inflammatory cytokines. Blood DCs consist of two subsets; myeloid DC (MDC) and plasmacytoid DC (PDC). In MDC from HCV-infected patients, the levels of TLR/RIG-I-mediated IFN-β or TNF-α induction are lower than those in uninfected donors suggesting that their signal transduction in MDC is impaired. In response to IFN-α, DC are able to express MHC class-I related chain A/B (MICA/B) and activate NK cells following ligation of NKG2D.

Interestingly, DC from HCV-infected patients are unresponsive to exogenous IFN-α to enhance MICA/B expression and fail to activate NK cells. Alternatively, NK cells from HCV-infected patients down-regulate DC functions in the presence of HLA-E-expressing hepatocytes by secreting IL-10 and TGF-β1. Such functional alteration of NK cells in HCV infection is ascribed to the enhanced expression of inhibitory receptor NKG2A/CD94 compared to the healthy counterparts. Invariant NKT cells activated by CD1d-positive DC secrete both Th1 and Th2 cytokines, serving as immune regulators. The frequency of NKT cells in chronic HCV infection does not differ from those in healthy donors. Activated NKT cells produce higher levels of IL-13 but comparable levels of IFN-γ with those from healthy subjects, showing that NKT cells are biased to Th2-type in chronic HCV infection. It is evident that the cross-talks among DC, NK cells and NKT cells are critical in shaping subsequent adaptive immune response against HCV (Kanto and Hayashi 2007; Kanto 2008).

Qa-1b-Dependent Modulation of DC and NK Cell Cross-Talk In Vivo: DC trigger activation and IFN-γ release by NK cells in lymphoid tissues, a process important for the polarization of Th1 responses. Colmenero et al. (2007) showed that the interaction between Qa-1b expressed on DC and its CD94/NKG2A receptor on NK cells is important in the regulation of DC-induced NK cell IFN-γ synthesis. NK cells from CD94/NKG2A-deficient mice displaying higher IFN- γ production upon DC stimulation along with other experiments demonstrated that Qa-1b is critically involved in regulating IFN- γ synthesis by NK cells in vivo through its interaction with CD94/NKG2A inhibitory receptors. This receptor-ligand interaction may be essential to prevent unabated cytokine production by NK cells during an inflammatory response (Colmenero et al. 2007).

CD94/NKG2 Receptors During HIV-1 Infection: NK HIV has evolved several strategies to evade recognition by the host immune system including down-regulation of MHC class I molecules. However, reduced expression of MHC class I molecules may stimulate NK cell lysis in cells of haematopoietic lineage. Dysfunction of cytotoxic activity of T and NK lymphocytes is main feature in patients with AIDS. The augmented expression of CD94 observed in HIV-infected individuals could be related to high levels of IL-10 in HIV-1-infected individuals (Galiani et al. 1999). The functional capacities and coexpression patterns of NK receptors (CD94 and CD161) are differentially affected depending on the state of therapy [HAART or HAART naïve] or the cell type (NK or T cells), respectively (Jacobs et al. 2004). However, Mela et al. (2005) suggested that changes in the NK cell repertoire during HIV-1 infection were not the result of HIV-1 viraemia alone but resembled those associated with concomitant infections (Mela et al. 2005).

Increased NK Cell Activity in Viremic HIV-1 Infection: Abnormal upregulation of CD94/NKG2A inhibitory NKR on CTLs could be responsible for a failure of immunosurveillance in cancer or HIV infection. Despite reduced NK cell numbers in subjects with ongoing viral replication, NK cells were significantly more active in secreting both IFN-γ and TNF-α than NK cells from aviremic subjects or HIV-1-negative controls and expressed significantly higher levels of CD107a, while the numbers of $CD3^-/CD56^+/CD94^+$ and $CD3^-/CD56^+/CD161^+$ NK cells were reduced. Therefore, viremic HIV-1 infection is associated with a reduction in NK cell numbers and a perturbation of NK cell subsets, but increased overall NK cell activity (Alter et al. 2004). However, Zeddou et al. (2007) showed that the chronic stimulation with HIV antigens in viraemic patients leads to a decreased rather than increased CD94/NKG2A expression on $CD8^+$ T lymphocytes and NK cells. Ballan et al. (2007) observed an increased frequency of NK cells expressing inhibitory KIRs in infected children. Moreover, increased expression of KIR2DL3, NKG2C, and NKp46 on NK cells correlated with decreased $CD4^+$ T-lymphocyte percentage, an indicator of disease severity in HIV-1- infected children (Ballan et al. 2007; Goodier et al. 2007)

NKG2C is a Triggering Receptor in Vδ1 T Cell-Mediated Cytotoxicity Against HIV-Infected CD4 T Cells: γδT cells share with NK cells many cell-surface proteins, including the NKG2 receptor. A subset of γδT cells that express the variable Vδ1 region plays a critical role in immune regulation, tumor surveillance and viral infection. Dramatic expansion of Vδ1 T cells has been observed in HIV infection. Results raise the possibility that induction of NKG2C expression on Vδ1 T cells plays a key role in the destruction of HIV-infected CD4 T cells during HIV disease (Fausther-Bovendo et al. 2008). Nattermann et al. (2005) demonstrated that HIV-mediated up-regulation of HLA-E is an additional evasion strategy targeting the antiviral activities of NK cells, which may help the virus in establishing chronic infection (Nattermann et al. 2005; Martini et al. 2005).

SIV-Infected Rhesus Monkeys

The NK cells from simian immunodeficiency virus (SIV)-infected rhesus monkeys are significantly impaired in their ability to secrete IFN-γ, TNF-α, and IL-2, while NK cell function in SIV-infected long-term non-progressor monkeys is similar to that of normal monkeys. The activating molecules NKG2C and NKG2C2 are significantly down-regulated in peripheral blood mononuclear cells of SIV-infected rhesus monkeys, suggesting that the dysregulation of these molecules may contribute to the abnormal NK cell function observed in the setting of infection (LaBonte et al. 2006).

Regulation of Cytolytic Activity of HSV-Specific Memory CD8$^+$ T Cells: Evidences suggest that sensory neurons regulate the effector functions and phenotype of CD8$^+$ T cells during active immunosurveillance of herpes simplex virus (HSV) latency. After ocular infection, HSV-specific CD8$^+$ T cells migrate to and retained in the ophthalmic branch of the trigeminal ganglia (TG). Virus-specific CD8 + T cells maintain an activation phenotype and secrete IFN-γ in the latent TG. The activated virus-specific memory CD8$^+$ T cells, although potentially cytolytic, also express the CD94-NK cell receptor subfamily G2a inhibitory molecule and are unable to exert cytotoxicity when engaged by Qa-1b expressing targets. Suvas et al. (2006) indicated that the Qa-1b and CD94-NKG2a interaction regulate cytolytic activity of HSV-specific memory CD8$^+$ T cells in the latently infected TG and serves to protect irreplaceable neurons from destruction by the immune system.

CD94/NKG2A Expression During Polyoma Virus Infection: Memory CD8$^+$ T cells form critical component of durable immunity because of their capacity to rapidly proliferate and exert effector activity upon Ag rechallenge. In mice infected with polyoma virus, the majority of persistence-phase antiviral CD8$^+$ T cells expressed the inhibitory NK cell receptor CD94/NKG2A. The CD94/NKG2A expression was associated with Ag-specific recall of polyoma virus-specific CD8$^+$T cells. Polyoma virus-specific CD8$^+$ T cells that expressed CD94/NKG2A were found to preferentially proliferate; this proliferation was dependent on cognate Ag both in vitro and in vivo. In addition, CD94/NKG2A$^+$ polyoma-specific CD8$^+$ T cells had an enhanced capacity to produce IL-2 upon ex vivo Ag stimulation compared with CD94/NKG2A$^-$ polyoma-specific CD8$^+$ cells (Byers et al. 2006).

NK Cell Receptors in Response to HCMV/MCMV Infection: Human cytomegalovirus (HCMV) infection is a pattern of complexity shown by host-pathogen interactions. To avoid recognition by CTLs, HCMV inhibits the expression of HLA class I molecules. As a consequence, engagement of inhibitory NKRs specific for HLA class I molecules is impaired, and infected cells become vulnerable to an NK cell response driven by activating receptors. In addition to the well-defined role of the NKG2D, the involvement of other triggering receptors (i.e., activating KIR, CD94/NKG2C, NKp46, NKp44, and NKp30) in response to HCMV is under investigation. (Gumá et al. 2006a).

During HCMV infection, the CD94/NKG2C$^+$ cells express lower levels of NKp30 and NKp46 and higher proportions of KIR$^+$ and CD85j$^+$ cells than CD94/NKG2A$^+$ cells. The CD8$^+$ T cell compartment of human CMV-seropositive individuals characteristically contains a high proportion of cells that express NKRs which may contribute to the surveillance of virus-infected cells. Like other NKR, CD94/NKG2C is predominantly expressed by a CD8$^+$ T cell subset, though TCRγδ$^+$ NKG2C$^+$ and rare CD4$^+$ NKG2C$^+$ cells are also detected in some individuals. Studies support the notion that CD94/NKG2C may constitute an alternative T cell activation pathway capable of driving the expansion and triggering the effector functions of a CTL subset in response to HCMV (Guma et al. 2004, 2005).

The increase of CD94/NKG2C$^+$ NK cells in healthy individuals infected with human CMV suggested that HCMV infection may shape the NK cell receptor repertoire (Gumá et al. 2006c). The CD94/NKG2C$^+$ cells outnumbered the CD94/NKG2A$^+$ subset. Results support that the interaction of CD94/NKG2C with HCMV-infected fibroblasts, concomitant to the inhibition of HLA class I expression, promotes an outgrowth of CD94/NKG2C$^+$ NK cells (Gumá et al. 2006b). In addition to NKG2C, to escape from NK cell-mediated surveillance, HCMV interferes with the expression of NKG2D ligands in infected cells. Saez-Borderias et al. (2006) suggested that NKG2D functions as a prototypic costimulatory receptor in a subset of HCMV-specific CD4$^+$ T lymphocytes and thus might have a role in the response against infected HLA class II$^+$ cells displaying NKG2D

ligands. In the acute phase of infection, a strong induction of CD94 on $CD3^+$ T cells was observed with surface expression of activating $CD94^{dim}$ NKG2C dimers appearing before inhibitory $CD94^{bright}$ NKG2A ones (van Stijn et al. 2008).

NK Cell Recognition of MCMV-Infected Cells: Studies on mouse model have shown that NK cells deploy multiple mechanisms to deal with mouse cytomegalovirus (MCMV) infection, which involve receptors of the C-lectin type superfamily. While reviewing these attack-counterattack measures, Vidal and Lanier (2006) pointed to the central role of NK cells in host resistance to infection. Following acute infection, MCMV replicates persistently in the salivary glands, despite the vigorous response of activated CD8 T cells that infiltrate this gland. Virus-specific CD8 T lymphocytes from this organ were found to express the CD94/NKG2A receptor that confers an inhibitory response to CTLs. In response to MCMV infection, expression of the CD94/NKG2A ligand, Qa-1b, increased dramatically in the sub-mandibular gland (SMG) prior to up-regulation of $H\text{-}2D^d$. However, there was no net negative impact on virus-specific T-cell function. Thus, the expression of inhibitory CD94/NKG2A receptors does not account for the failure of MCMV-specific CTLs to clear the SMG of infection (Cavanaugh et al. 2007).

Epstein-Barr Virus Differs with HCMV: Following activation of Epstein-Barr virus (EBV)-infected B cells from latent to productive (lytic) infection, there is a concomitant reduction in the level of MHC class I molecules and an impaired antigen-presenting function that may facilitate evasion from EBV-specific $CD8^+$ cytotoxic T cells. In some other herpesviruses studied, such as HCMV, evasion of virus-specific $CD8^+$ effector responses via down-regulation of surface MHC class I molecules is supplemented with specific mechanisms for evading NK cells. Pappworth et al. (2007) reported that EBV differs from HCMV in matters such as: resistance to lysis by NK cell lines, down-regulation of HLA-A, -B, and -C molecules that bind to the KIR family of inhibitory receptors and also the down-regulation of HLA-E molecules that bind CD94/NKG2A inhibitory receptors. Conversely the ligands for NK cell-activating receptors NKG2D and DNAM-1, respectively, were elevated. These results highlight a fundamental difference between EBV and HCMV with regards to evasion of innate immunity.

Induction of CD94 and NKG2 in $CD4^+$ T Cells by Influenza A Virus (IAV) Infection: Graham et al. (2007) investigated CD94 and NKG2 gene expression in memory CD4 T-cell clones established from the spleens of C57BL/10 ($H\text{-}2^b$) and BALB/c ($H\text{-}2^d$) mice infected with IAV. The in-vivo-generated CD4 Th1 cells, but not Th2 cells, expressed full-length CD94 and NKG2A following activation with viral peptide. A truncated isoform of NKG2A was detectable in a Th2 cell clone. NKG2D, but not NKG2C or E, was also differentially expressed in Th1 cells. Graham et al. (2007) suggested that CD94 and NKG2A may exist in multiple isoforms and help to distinguish helper T-cell subsets.

30.14 Pathophysiological Role of CD94/NKG2 Complex

30.14.1 Polymorphism in NKG2 Genes

CD94 is highly conserved, while the NKG2 genes exhibit some polymorphism. For all the genes, alternative mRNA splicing variants were frequent among the human clones. Similar alternative splicing occurs in human and chimpanzee to produce the CD94B variant from the CD94 gene and the NKG2B variant from the NKG2A gene. Whereas single chimpanzee orthologs for CD94, NKG2A, NKG2E, and NKG2F were identified, two chimpanzee paralogs of the human NKG2C gene were defined. The chimpanzee Pt-NKG2CI gene encodes a protein similar to human NKG2C, whereas in the chimpanzee Pt-NKG2CII gene the translation frame changes near the beginning of the carbohydrate recognition domain, causing premature termination. Genomic DNA from 80 individuals representing six primate species was typed for the presence of CD94 and NKG2. Each species gave distinctive typing patterns, with NKG2A and CD94 being most conserved. Seven different NK complex genotypes within the panel of 48 common chimpanzees were due to differences in Pt-NKG2C and Pt-NKG2D genes (Shum et al. 2002).

30.14.2 Phenotypes Associated with Leukemia

The polymorphic nature of NK cell receptor genes generates diverse repertoires in the human population, and displays specificity in the innate immune response. This was substantiated by Verheyden et al. (2004) who suggested that an important percentage of leukemic patients express a KIR phenotype in favor of escape from NK cell immunity. Studies have revealed the existence of a distinct type of NK cell leukaemia of the juvenile type, which shows with hypersensitivity to mosquito bites (HMB) as a clinical manifestation and is infected with clonal Epstein-Barr virus (EBV). This disorder is thus called HMB-EBV-NK disease and has been reported mostly from Japan. More than 98% of NK cells from the patients with HMB-EBV-NK disease exhibited CD94 at a higher level than did normal NK cells, whereas p70 or NKAT2, belonging to Ig-like receptor, was not expressed in those NK cells. Leukaemic NK cells transcribed mRNA for CD94-associated molecule NKG2C at an abnormally high level, and upon stimulation with IL-2 and/or IL-12 they

expressed NKG2A as well. The expression of these receptors provides insights into phenotypic markers for the diagnosis of this type of NK cell leukaemia (Seo et al. 2000).

B-Cell Chronic Lymphocytic Leukaemia: Reduced reactivity of cytotoxic T cells (CTL) towards tumor cells can result into tumor progression and loss of tumor control. In B-cell chronic lymphocytic leukaemia (B-CLL), the reactivity of tumor-reactive CTL seems to relate inversely to disease stage. Analysis of $CD8^+$ T from patients with advanced disease (Binet stage C) had a significantly greater percentage of CTL expressing CD158b, CD158e, and CD94 than patients with non-progressive disease (Binet stage A) and healthy controls. The increased expression of KIR and CD94 on CTL in advanced stage B-CLL may significantly contribute to the impaired anti-tumor immune response in these patients (Junevik et al. 2007).

Heat Shock Protein 70: A Link Between NK Cells and Tissue Response: Stress-inducible heat shock protein 70-kDa (Hsp70) provides a molecular link between inflammatory responses and tissue repair. In addition to molecular chaperoning, Hsp70 exerts modulatory effects on endothelial cells and leukocytes involved in inflammatory networks. The 14 amino acid sequence (aa-450-463) TKDNNLLGRFELSG (TKD) of Hsp70 has been identified as a tumor-selective recognition structure for NK cells. The receptor CD94 participates in the interaction of NK cells with Hsp70-protein and Hsp70-peptide TKD. Hsp70 reactivity could be associated with elevated cell surface densities of CD94 after TKD stimulation independent of MHC class I molecules (Gross et al. 2003). Incubation of peripheral blood lymphocytes with TKD plus low-dose IL-2 enhances the cytolytic activity of NK cells against Hsp70 membrane-positive tumors, in vitro and in vivo. From clinical Phase I trial, reinfusion of Hsp70-activated autologous NK cells is safe and warrant additional studies in patients with lower tumor burden (Krause et al. 2004). Further studies of Gross et al. (2008) revealed that Hsp70 peptide initiates NK cell killing of leukemic blasts after stem cell transplantation and that Hsp70 is the target structure for TKD-activated NK cells. Studies indicated that Hsp70 (as an activatory molecule) and HLA-E (as an inhibitory ligand) expression influence the susceptibility of leukemic cells to the cytolytic activities of cytokine/TKD-activated NK cells (Stangl et al. 2008).

30.14.3 CD94/NKG2A on NK Cells in T Cell Lymphomas

The NK and cytotoxic T-cell lymphomas and noncytotoxic nodal T-cell lymphoma controls are stained for variety of NKR molecules including CD94, NKG2A, and p70. The NK-cell lymphomas expressed at least the CD94/NKG2A complex. Detection of CD94/NKG2A may be a useful tool to the diagnosis of NK-cell lymphomas and to delineate the subgroup of cytotoxic T-cell lymphomas (Haedicke et al. 2000; Kamarashev et al. 2001). However, a restricted KIR repertoire without monoclonal T-cell receptor rearrangement (mTCR-R) supports a NK lineage in nasal-type extranodal NK/T-cell lymphoma (NTENL) but does not correlate with clinical findings. Developing NK cells express first CD94, then NKG2A, NKG2E, and finally NKG2C. This sequence suggests an immature $CD94^-$ and a mature $CD94^+$ subtype of NTENL (Lin et al. 2003).

30.14.4 CD94/NKG2 Subtypes on Lymphocytes in Melanoma Lesions

Vetter et al. (2000) characterized the expression of CD94/NKG2 on tumor-infiltrating lymphocytes in melanoma lesions. 5–10% of the tumor-infiltrating lymphocytes, both in primary and metastatic melanoma lesions, expressed CD94. More than 95% of these $CD94^+$ cells coexpressed CD8 and the percentage of CD94 expression within the $CD8^+$ cell population ranged from 5% to 20% with a higher expression in metastatic lesions. RT-PCR revealed the presence of NKG2-C/E in all primary and metastatic lesions. In contrast, the inhibitory NKG2-A/B was only present in 50% of primary tumors, whereas 80% of tumor-infiltrating lymphocytes in metastatic lesions expressed these transcripts. In healthy humans, the number of inhibitory NK cell receptors is higher than that of activating receptors, but the opposite was true for tumor-infiltrating lymphocytes in melanoma (Casado et al. 2005; Naumova et al. 2005).

Becker et al. (2000) demonstrated that the expression of CD94/NKG2 on T cells depends on the state of differentiation during the immune response to solid tumors. To this end Becker et al. identified clonally expanded T cells which were present both in the sentinel lymph node of primary melanoma, as well as in the tumor itself. Within the early stages of T cell activation, i.e. priming in the lymph node, T cells did not express CD94/NKG2 whereas the same T cell clones expressed high levels of CD94/NKG2 having reached the effector state at the tumor site. It is likely that NK cell receptors are involved in peripheral regulatory mechanisms avoiding overwhelming immune responses and immunopathology, particularly in situations of long-lasting immune activation. However, DBA/2J mice are naturally CD94-deficient and do not express cell-surface CD94/NKG2A receptors, even on neonatal NK cells. Thus, self-tolerance of neonatal NK cells cannot be attributed to CD94/NKG2A expression. The results of Vance et al. (2002) lead to the reconsideration of current models of NK cell development and self-tolerance.

30.14.5 Cancers of Female Reproductive Tract

Very often, up-regulation of inhibitory NKRs has been linked to the modulation of virus- and/or tumor-specific immune responses in animal models. However, in human cervical cancer, the percentage expression of Ig-like NKR^+CD8^+ T lymphocytes was similar in gated $CD8^+$-autologous tumor-infiltrating lymphocytes (TILs) and peripheral blood mononuclear cells (Sheu et al. 2005). On the contrary, cervical cancer-infiltrating $CD8^+$ T lymphocytes expressed up-regulated CD94/NKG2A compared with peripheral blood $CD8^+$ T cells and/or normal cervix-infiltrating $CD8^+$ T lymphocytes, where as CD94 and NKG2A mainly expressed on $CD56^-$ $CD161^-$ $CD8^+$ TILs within the cancer milieu. Cytotoxicity experiments showed that up-regulated expressions of CD94/NKG2A restrain $CD8^+$ T lymphocyte cytotoxicity. This study indicated that cervical cancer cells could promote the expression of inhibitory NKRs via IL-15- and possibly TGF-β-mediated mechanism and abrogate the antitumor cytotoxicity of TILs. $CD8^+$ T cells express higher ratios of CD94 and NKG2A in TILs than in peripheral blood mononuclear cells (PBMCs) in human endometrial carcinoma (EC). Increased expression of CD94/NKG2A restricted to tumor-infiltrating $CD8^+$ T cell subsets may shape the cytotoxic responses, which indicate a possible role of tumor escape from host immunity in human EC (Chang et al. 2005).

30.14.6 Disorders of Immune System

CD94 in Pathogenenesis of Behcet's Disease: Behcet's disease (BD) is a multisystemic disorder with a possible underlying pathology of immune-mediated vasculitis. An imbalance in cytotoxic activity and cytokine production and genetic susceptibility associated with HLA-B*51 and B*2702 has been implicated in its pathogenesis. The BD patients show increased $CD3^+$ T cells, with no change in NK cells. Increased expression of CD94 in BD was observed on $CD16^+CD56^+$ and on $CD3^+$ and $CD3^+CD56^+$ T cells. Considering the defined regulatory mechanisms of NK cells through HLA class I binding receptors, the interactions of NK and T cells through the NK receptors may be important in the pathogenesis of BD. Although the effects of SNPs remain unclear, results indicate that the SNPs of CD94/NKG2A and its haplotypes, as well as its ligand HLA-E, are associated with BD immune systems (Seo et al. 2007).

Behcet's Uveitis: Behçet's uveitis, characterized by chronic recurrent uveitis and obliterating retinal vasculitis, frequently causes bilateral blindness. Intraocular infiltration of $TCR\alpha\beta^+$ $CD8^{bright}$ $CD56^+$ cells is a distinct feature in Behçet's uveitis. Interestingly, $CD45RA^{dim}$ $CD45RO^-$ phenotypes were expanded, and CD94 expression was markedly up-regulated in contrast to the down-regulation of NKG2D. Furthermore, these subsets were polarized to produce IFN-γ and contained high amounts of preformed intracellular perforin while exclusively expressing surface FasL upon PI stimulation. Hence, $CD8^{bright}$ $CD56^+$ T cells in Behçet's uveitis are characterized by cytotoxic effector phenotypes with functional NK receptors and function as strong cytotoxic effectors through both FasL-dependent and perforin-dependent pathways. The combined low dose cyclosporine and prednisone treatments in active Behçet uveitis may down-regulate the NK-like effector functions of $CD8^{bright}$ $CD56^+$ T cells (Ahn et al. 2005).

$CD8^+$ Regulatory T Cells in Multiple Sclerosis: To investigate $CD8^+$ regulatory T cell influence on multiple sclerosis development, peripheral blood and cerebrospinal fluid (CSF) $CD8^+$ T cell clones (TCCs) recognizing MBP(83–102) and MOG(63–87)-specific $CD4^+$ T cells were analysed. During exacerbations, CD94/NKG2A expression was significantly higher in $CD8^+$ TCCs, limiting their cytotoxic activity. Moreover, IL-15 and IFN-γ significantly increased CD94 and NKG2A expression. Evidence suggests that CD94/NKG2A receptors play an important role in regulating T cell activity during the course of MS (Correale and Villa 2008).

Negative Regulation of CD8+ TNF-α by CD94/NKG2A: Lung injury due to influenza pneumonia is mediated after Ag recognition by $CD8^+$ T cell in the distal airways and alveoli. TNF-α produced by Ag-specific $CD8^+$ T cells appears primarily responsible for this immunopathology. Zhou et al. (2008) suggested negative regulation of $CD8^+$ TNF-α by CD94/NKG2A when engaged with its receptor, Qa-1b. TNF-α production by $CD8^+$ T cells was enhanced by NKG2A blockade in vitro, and mice deficient in Qa-1b manifested greater pulmonary pathology upon $CD8^+$ T cell-mediated clearance in influenza pneumonia. It appears that CD94/NKG2A transduces a biologically important signal in vivo to activated $CD8^+$ T cells that limits immunopathology in severe influenza infection.

Susceptibility for Rheumatoid Arthritis: To examine a possible association between variations in CD94 and NKG2 genes and genetic susceptibility to rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE), Hikami et al. (2003) carried out a systematic polymorphism screening of NKG2A, NKG2C and CD94 genes on a population basis. Although human NKG2-A, -C and CD94 are generally conserved with respect to amino acid sequences, NKG2A is

polymorphic in the noncoding region, and that the number of genes encoded in the human NKC is variable among individuals, as shown for leukocyte receptor complex (LRC), HLA and Fcγ receptor (FCGR) regions (Hikami et al. 2003). Park et al. (2008) revealed that the major NKG2A c.338-90*A/*A, NKG2C102*Ser/*Ser, and NKG2D72*Ala/*Ala genotypes in RA were significantly associated compared with controls. The minor NKG2A c.338-90*G/*G, NKG2C102*Phe/*Phe, and NKG2D72*Thr/*Thr genotypes showed a risk of RA compared with controls.

Synovial NK cells were similar to the well-characterized $CD56^{bright}$ peripheral blood (PB) NK-cell subset present in healthy individuals. However, compared to peripheral blood subset the synovial NK cells expressed a higher degree of activation receptors including CD69 and NKp44, the latter being up-regulated also on CD56(bright) NK cells in the peripheral blood of patients. Activated synovial NK cells produced IFN-γ and TNF, which were further up-regulated by antibody masking CD94/NKG2A, and down-regulated by target cells expressing HLA-E in complex with peptides known to engage CD94/NKG2A. It suggested that synovial NK cells have an activated phenotype and that CD94/NKG2A is the key regulator of synovial NK-cell cytokine synthesis. Human eosinophils express several inhibitory receptors IRp60, LIR3/ILT5, FcγRIIB, and p75/AIRM but not LIR1/ILT2, p58.1, p58.2, p70, or NKG2A/CD94 (Munitz et al. 2006; de Matos et al. 2007).

$CD94/NKG2A^+$ T Cells in Patients with Psoriasis: Psoriasis is a common inflammatory cutaneous disorder characterized by activated T-cell infiltration. T lymphocytes bearing NKRs have been suggested to play an important role in the pathogenesis of psoriasis. Liao et al. (2006) demonstrated increased proportions of particular subsets of inhibitory $CD158b^+$ and/or $CD94/NKG2A^+$ T cells in patients with psoriasis. The elevation of these inhibitory NKR-expressing T cells was correlated with disease severity, which may signify the unregulated cytokine production in the pathogenesis of psoriasis.

CD94/NKG2A in Sarcoidosis Patients: The majority of the lung NK cell subpopulation expressed CD56(bright). In contrast, there was a predominant CD56(dim) subset in the blood of both patients and healthy controls. Most lung NK cells expressed HLA-E-specific inhibitory receptor (i.e. CD94/NKG2A), but only a few lung NK cells expressed KIRs specific for HLA-A, -B or -C molecules. After in vitro stimulation, both lung NK and $CD56^+$ T-cells produced considerable amounts of IFN-γ and TNF-α. Thus, patients with pulmonary sarcoidosisproduce a distinct phenotype of NK cells with the capacity to produce cytokines (Katchar et al. 2005).

Frequency of CD94/NKG2A in Peritoneal NK Cells in Patients with Endometriosis: In women with endometriosis, the percentage of CD94/NKG2A-positive peritoneal NK cells was significantly higher than in the control group. It was associated with high levels mRNA transcripts of HLA-E, the ligand of CD94/NKG2A. The increased expression of CD94/NKG2A in peritoneal NK cells may mediate the resistance of endometriotic tissue to NK cell-mediated lysis leading to the progression of the disease (Galandrini et al. 2008).

Lymphoproliferative Disease of Granular Lymphocytes: Mitsui et al. (2004) analysed the chemokine receptors and NKRs in addition to NK-cell markers in patients with lymphoproliferative disease of granular lymphocytes (LDGL). There were no marked differences in the expression patterns of chemokine receptors between NK- and T-LDGL patients. Although restricted NKR subsets were expressed on both NK- and T-large granular lymphocytes (LGLs), CD94 was the most widely expressed marker.

CD94 and KIRs After Transplantation: The effect of NK cell alloreactivity on the outcome of haploidentical hematopoietic stem cell transplantation (HSCT), with or without in vitro T cell depletion, remains controversial. KIRs recognize HLA-C and -B epitopes on target cells, thereby regulating NK cell activity. The occurrence of a GVHD or the receipt of high doses of T cells in the allograft altered KIR reconstitution. The high levels of CD94 expression in donors or in recipients by day 60 might be a good predictor for poor prognosis (Zhao et al. 2007). While hepatic $CD56^+$ T cells are not expanded in malignancy, downregulation of KIR and CD94 expression may be a mechanism by which the hepatic immune system can be activated to facilitate tumor rejection (Norris et al. 2003).

NK cells mediate bone marrow allograft rejection. It was shown that murine NK cells recognize allogeneic target cells through Ly-49s and CD94/NKG2 heterodimers. NKG2I is the activating receptor mediating recognition and rejection of allogeneic target cells (Koike et al. 2004). NKG2I was composed of 226 amino acids, showed ~40% homology to the murine NKG2D and CD94 The expression of NKG2I was largely confined to NK and NKT cells. The cross-linking of NKG2I enhanced interleukin 2– and interleukin 12–dependent interferon- production (Koike et al. 2004).

NKG2D Activating Receptor

31

Rajesh K. Gupta and G.S. Gupta

31.1 NKG2D Activating Receptor (CD314, Synonyms KLRK1)

Information on receptor ligand systems used by NK cells to specifically detect transformed cells has been accumulating rapidly. Killer cell lectin-like receptor subfamily K, member 1, also known as KLRK1, is the product of human gene. The KLRK1 has been designated as CD314 and contains a C-type lectin-like domain (CTLD). KLRK1 is also known as: KLR; NKG2D; NKG2-D; FLJ17759; FLJ75772; D12S2489E. Human NKG2D was originally identified in 1991 as an orphan receptor on NK cells (Houchins et al. 1991). Although genetically mapping near the C-type lectin receptors CD94 and NKG2A-E, the NKG2D activating NK cell receptor has little sequence homology with these receptors and is expressed as a homodimer that signals through DAP10 rather than CD94 (Chap. 30). NKG2D binds to two distinct families of ligands, the MHC class I chain-related peptides (MICA and MICB) and the UL-16 binding proteins (ULBP). These ligands are upregulated in cells that have undergone neoplastic transformation, and NK cytotoxicity on tumor cells correlates with tumor expression of MICA and ULBP. The NKG2D differs from other members of the NKG2 family in significant ways. They do not form heterodimers with CD94 on the cell surface. Instead, they are expressed as homodimers, and each homodimer associates noncovalently with a homodimer of the adaptor protein DAP-10. The cytoplasmic tail of DAP-10 carries a YxxM motif, which can recruit the regulatory subunit p85 of phosphatidylinositol-3 kinase and Grb2 (see also Chap. 30).

The NKG2D (KLRK1) is also widely expressed on T cells and other immune system cells, providing stimulatory or co-stimulatory signals. NKG2D drives target cell killing following engagement of diverse, conditionally expressed MHC class I-like protein ligands whose expression can signal cellular distress due to infection or transformation. The NKG2D ligand-binding site recognition is highly degenerate that demonstrates its ability to simultaneously accommodate multiple non-conservative allelic or isoform substitutions in the ligands. The NKG2D degeneracy is achieved using distinct interaction mechanisms at each rigid interface: recognition degeneracy by "rigid adaptation." While forming similar complexes with their ligand (HLA-E), other NKG2x NKR family members do not require such recognition degeneracy. However, NK cells are known to efficiently kill target cells that do not express HLA class I molecules, thus implying the existence of triggering receptors for non-HLA ligands (Zhang et al. 2005).

31.2 Characteristics of NKG2D

31.2.1 The Protein

NKG2D is encoded by the *KLRK1* (killer cell lectin-like receptor subfamily member 1) gene. NKG2D is a type II homodimeric transmembrane protein with an extracellular C-type (i.e. Ca^{2+}-binding) lectin-like domain. The NKG2D gene exists within the "NK complex" on human chromosome 12 and mouse chromosome 6 (Ho et al. 1998). The physical location of the *Cd94* (centromeric) and *Nkg2d* (telomeric) genes were mapped between *Cd69* and the *Ly49* cluster in the NK complex. Genes within this complex encode structurally similar type II lectin-like receptors, and many of these genes are expressed primarily in NK cells. In mice, alternative DNA splicing generates two isoforms of NKG2D that differ in the length of their cytoplasmic domains (NKG2D-S (short) and NKG2D-L (long)). Their ability to induce cellular activation is mediated via association with two membrane-bound, signaling adaptor molecules, DAP10 and DAP12. Two NKG2D isoforms, NKG2D-S and NKG2D-L, are known to associate differentially with DAP10 and DAP12 adaptor proteins. The mouse (Ho et al. 1998), rat (Berg et al. 1998), and porcine (Yim et al. 2001) homologues of NKG2D

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_31,

have been identified. Interspecies amino acid sequence identities range from 52% to 78% for the entire protein (mouse and rat are the most closely related sequences) and from 72% to 90% within the lectin domain. Function of NKG2D was first described in 1999 by two separate groups investigating MICA/MICB ligands (Bauer et al. 1999) or signal transduction through the DAP10 adapter protein (Wu et al. 1999). Ho et al. (1998) cloned C57BL/6-derived cDNAs homologs to human NKG2-D and CD94. Among normal tissues, murine NKG2-D transcripts are highly expressed only in activated NK cells, including both $Ly49A^+$ and $Ly49A^-$ subpopulations. Additionally, mNKG2-D is expressed in murine NK cell clones KY-1 and KY-2. NKG2D is present on the surface of natural killer (NK) cells, some NKT cells, $CD8^+$ cytotoxic T cells, subsets of γδ T cells, and under certain conditions $CD4^+$ T cells. Present in both humans and mice, NKG2D binds to a surprisingly diverse family of ligands that are distant relatives of MHC-class-I molecules. There is increasing evidence that ligand expression can result in both immune activation (tumor clearance, viral immunity, autoimmunity, and transplantation) and immune silencing (tumor evasion).

Tolerance of NK cells toward normal cells is mediated through their expression of inhibitory receptors that detect the normal expression of self in the form of MHC-I molecules on target cells. These MHC-I-binding inhibitory receptors recruit tyrosine phosphatases, which are believed to counteract activating receptor-stimulated tyrosine kinases. The perpetual balance between signals derived from inhibitory and activating receptors controls NK cell responsiveness and provides an interesting paradigm of signaling cross talk. MacFarlane and Campbell (2006) and Champsaur and Lanier (2010) reviewed the knowledge of the intracellular mechanisms by which cell surface receptors influence biological responses by NK cells with a special emphasis on the dynamic signaling events at the NK immune synapse and the unique signaling characteristics of specific receptors, such as NKG2D.

31.2.2 Orthologues to Human NKG2D

The CLEC12B is a lectin-like NK cell receptor on myeloid cells. The extracellular domain of CLEC12B shows a considerable homology to activating NKG2D, but unlike NKG2D, CLEC12B contains an ITIM in its intracellular domain. Despite the homology, CLEC12B does not appear to bind NKG2D ligands and therefore does not represent the inhibitory counterpart of NKG2D. However, CLEC12B has the ability to counteract NKG2D-mediated signaling, and this function is dependent on the ITIM and the recruitment of the phosphatases SHP-1 and SHP-2. This receptor seems to play a role in myeloid cell function (Hoffmann et al. 2007).

The rat orthologue to human NKG2D (hNKG2D) represents a separate, single gene NKLLR family, named NKR-P2. Rat NKR-P2 is expressed in NK cells and strongly expressed in resting CD81 and CD41 T cells. Sequence analysis showed that the two molecules form a distinct NKLLR family, not related to NKG2A/B, -C or -E than to other NKLLR families. *Nkrp2* is a single-copy gene containing seven introns, mapping to the rat NK gene complex. Rat NKR-P2 differs from the human orthologue in that its cytoplasmic tail contains 13 additional amino acids, encoded by a separate exon (Berg et al. 1998). NKR-P2 is a potent activation receptor on rat DCs (Srivastava et al. 2008)

31.3 NKG2D Ligands

31.3.1 The Diversity of NKG2D Ligands

The NKG2D drives target cell killing following engagement of diverse, conditionally expressed MHC class I-like protein ligands whose expression can signal cellular distress due to infection or transformation. NKG2D recognizes some self ligands such as MICA/B in human and RAE-1 in mice. The interaction of NKG2D with its ligands plays an important role in immunosurveillance of tumors and infectious pathogens, but dysregulation of this system may lead to autoimmunity. Several human NKG2D ligands (NKG2DLs), UL16-binding proteins (ULBP) 1, 2, 3 and 4, retinoic acid early transcript 1G (RAET1G) and MHC class I-related chains A and B have been reported. However, the list of ligands for NKG2D, often up-regulated during cellular distress, is growing. Moreover, NKG2D ligands have an intrinsic ability to regulate tissue-associated immune compartments. Certain cytokines and specifically the IFNs regulate expression of specific NKG2D ligands on murine tumors. Why there is such diversity of NKG2D ligands is not known but one hypothesis is that they are differentially expressed in different tissues in response to different stresses. The expression of diverse NKG2D-binding molecules in different tissues and different properties is consistent with multiple modes of infection- or stress-induced activation.

Rodent homologs of MICA and MICB have not been identified, but other molecules with weak homology to MHC class I, notably RAE-I and H-60, serve as ligands for mouse NKG2D. Like MICA and MICB, RAE-1 and H-60 are frequently expressed on tumor but not normal cells, suggesting that NKG2D functions as a receptor for tumor surveillance by NK cells. In addition, HCMV glycoprotein UL16 binding proteins (ULBP) and mouse UL16-binding protein–like transcript 1 (MULT1) have been identified as ligand for human and mouse NKG2D respectively. UL16 is believed to act as a decoy receptor for NKG2D ligands, facilitating viral evasion of the immune system. Although the homodimeric NKG2D

ligands are distant structural homologs of MHC class I, including MICA, MICB, ULBP3, and RAE-1β, unlike true MHC class I molecules, NKG2D ligands neither bind peptides (or other small molecules) nor β_2m, and ULBP3 and RAE-1β even lack the heavy chain α3 domain, existing on the cell surface as glycophosphatidylinositol-linked α1/α2 platform domains. In humans, MICA and MICB are minimally expressed in normal tissues, but are upregulated in stressed cells and epithelial tumors. The interaction of mouse NKG2D with RAE-1, H-60 and MULT1 is disrupted by the HCMV-encoded MHC class I homologs m152, m155, m157 and m144. By preventing NK cell activation, this disruption promotes viral survival (Cerwenka 2009; Deng and Mariuzza 2006; Eagle et al. 2006 Eagle and Trowsdale 2007; Mans et al. 2007).

31.3.2 MHC Class I Chain Related (MIC) Proteins

31.3.2.1 A Second Lineage of Mammalian MHC Class I Genes

MHC class I genes typically encode polymorphic peptide-binding chains which are ubiquitously expressed and mediate the recognition of intracellular antigens by cytotoxic T cells. They constitute diverse gene families in different species and include the numerous so-called non-classical genes in the mouse H-2 complex, of which some have been adapted to variously modified functions. Bahram et al. (1994, 2005) identified a distinct family of five related sequences in human MHC which are distantly homologous to class I chains. These MIC genes (*M*HC class *I c*hain-related genes) evolved in parallel with the human class I genes and with those of most if not all mammalian orders. The MIC-A gene is located near HLA-B and is by far the most divergent mammalian MHC class I gene known. It is further distinguished by its unusual exon-intron organization and preferential expression in fibroblasts and epithelial cells. However, the presence of diagnostic residues in the MIC-A amino acid sequence translated from cDNA suggests that the putative MIC-A chain folds similarly to typical class I chains and may have the capacity to bind peptide or other short ligands. These results define a second lineage of evolutionarily conserved MHC class I genes. Major structural deviations of MIC-A from HLA-A2 (Bjorkman et al. 1987) include a deletion of amino acid positions 45–49 and an insertion of 6 amino acids at position 147. This implies that MIC-A and possibly other members in this family have been selected for specialized functions that are either ancient or derived from those of typical MHC class I genes, in analogy to some of the nonclassical mouse H-2 genes (Bahram et al. 1994).

The MIC-A and MIC-B are inducible by stress on cell surface and recognized by immunocytes bearing the receptor NKG2D, including intestinal epithelial Vδ1 γδ T cells, which may play a role in immunological reaction in intestinal mucosa. NKG2D ligands are expressed by infected and transformed cells. They transmit danger signals to NKG2D-expressing immune cells, leading to lysis of NKG2D ligand-expressing cells. Expression of MIC-A and MIC-B has been proposed to play an important role in the immunosurveillance of tumors Groh et al. (1998). Proteolytic shedding of NKG2D ligands from cancer cells therefore constitutes an immune escape mechanism impairing anti-tumor reactivity by NKG2D-bearing cytotoxic lymphocytes. Serum levels of sMICA have been shown to be of diagnostic significance in malignant diseases of various origins (Sutherland et al. 2006). NKG2D homodimers form stable complexes with monomeric MICA in solution and also with cell surface MICB, which has structural and functional properties similar to those of MICA. Comparison of allelic variants of MICA revealed large differences in NKG2D binding that were associated with a single amino acid substitution at position 129 in α2 domain. Varying affinities of MICA alleles for NKG2D may affect thresholds of NK-cell triggering and T-cell modulation (Steinle et al. 2001). MICA has no function in antigen presentation.

31.3.3 Retinoic Acid Early (RAE) Transcripts

31.3.3.1 A Cluster of MHC Class I Related Genes on Human Chromosome 6

In addition to human MIC-A and MIC-B, human ligands also include retinoic acid early transcript-1 proteins (RAET-1, originally called unique long 16) [UL-16-binding proteins (ULBP)]. Radosavljevic et al. (2002) identified a cluster of ten human MHC class I related genes, among which 6 encode potentially functional glycoproteins. The 180-kb cluster containing these genes is not located within the MHC on 6p44.3, but near the tip of its long arm at q24.2-q31.3, close to the human equivalent of the mouse H2-linked t-complex, a sub-chromosomal region syntenic to a segment of mouse chromosome 10. Mouse chromosome 10 harbors the orthologous MHC class I related transcript loci, *Raet1a-d*. The human identified loci were called *RAET1E-N*. Human RAET1 products are all devoid of membrane-proximal Ig-like α3 domain. Most, but not all RAET1 products, are predicted to remain membrane-anchored via GPI-linkage and are known to display an atypical pattern of polymorphism. *RAET1* transcripts are absent from hematopoietic tissues, but largely expressed in tumors.

Mouse NKG2D ligands include the family of retinoic acid inducible genes-1 (RAE-1α), the minor histocompatibility antigen H60, two H60 variants (H60b and H60c), and mouse UL16-binding protein–like transcript 1 (MULT1) (Diefenbach et al. 2003; Carayannopoulos et al. 2002). Ligands for mouse NKG2D were identified by their capacity to bind dimeric NKG2D-Fc fusion proteins or tetrameric NKG2D-streptavidin

complexes (Cerwenka et al. 2000; Diefenbach et al. 2000). Members of RAET1 family (RAE-1α) are MHC class I-related genes located within a 180-kb cluster on chromosome 6q24.2-q31.3. RAET1 proteins contain MHC class I-like α-1 and α-2 domains. RAET1E and RAET1G differ from the other RAET1 proteins (e.g., RAET1I, or ULBP1) in that they have type I membrane-spanning sequences at their C termini rather than GPI anchor sequences (Radosavljevic et al. 2002).

The mouse NKG2D ligands are expressed at appreciable levels on thymocytes but at low levels or not at all on most normal tissues (Cerwenka et al. 2000; Diefenbach et al. 2000). Expression is up-regulated, however, on many tumor cells. RAE-1 mRNA was detected throughout early embryos and in the brain/head region of day 10–14 embryos, but transcripts were not observed in day 18 embryos (Cerwenka et al. 2000; Nomura et al. 1996). Very low levels of *Rae-1* transcripts were detected in adult spleen and liver, and transcripts were absent from adult brain and kidney. *Rae-1* transcripts were present in several transformed cell lines. Expression of NKG2D ligands RAE-1, MULT1, and H60 within the CNS following JHM strain of mouse hepatitis virus (JHMV) infection demonstrated a functional role for NKG2D in host defense during acute viral encephalitis by selectively enhancing CTL activity by infiltrating virus-specific $CD8^+$T cells (Walsh et al. 2008).

The cDNAs encoding NKG2D ligands, RAE-1ß and RAE-1 (Cerwenka et al. 2000; Diefenbach et al. 2000) had been described earlier as products of retinoic acid early inducible (Rae-1) transcripts (Zou et al. 1996; Nomura et al. 1996). This family is known to contain at least four distinct loci encoding polypeptides that share 92–95% amino acid identity. All RAE-1 family members were shown to bind NKG2D (Zou et al. 1996; Savithri and Khar 2006). Savithri and Khar (2006) described the cloning of a ligand for NKR-P2, the rat ortholog of human and mouse NKG2D, termed as rat RAE-1-like transcript (RRLT). The RRLT ligand is homologous to mouse RAE-1 family of proteins, but differs from them in being transmembrane anchored. Strid et al. (2008) reported that epidermis-specific upregulation of RAE-1 induces changes in the organization of tissue-resident Vγ5Vδ1 TCR$γδ^+$ intraepithelial T cells and Langerhans cells, followed by epithelial infiltration by unconventional αβT cells. Whereas local $Vγ5Vδ1^+$ T cells attempted to limit carcinogenesis, Langerhans cells unexpectedly promoted it.

31.3.3.2 The UL16-Binding Proteins

The UL16-binding proteins (ULBPs, also termed as retinoic acid early transcripts, encoded by RAET1 genes) are a family of human, MHC class I-related, cell surface proteins. ULBP1 was identified based on its ability to bind to human CMV (HCMV) glycoprotein, UL16. ULBP2 and ULBP3 were subsequently discovered as expressed sequence tags with high homology to ULBP1. Unlike traditional MHC class I proteins, ULBPs are GPI-linked, lack an $α_3$ domain, and do not associate with $β_2$-microglobulin (Cosman et al. 2001). ULPB transcripts were found in various tissues in healthy individuals, including heart, lung, liver, and testis (Cosman et al. 2001). UL16 also binds to a member of another family of nonclassical MHC class I proteins, MIC-B (Groh et al. 1996). Presently, the human RAET1/ULBP gene family comprises of ten members (RAET1E to N) with six loci encoding for potentially functional proteins. These are ULBP1 or RAET1I, ULBP2 or RAET1H, ULBP3 or RAET1N, and RAET1L, which are glycosylinositol phospholipid (GPI)-linked glycoproteins and ULBP4 or RAET1E and ULBP5 or RAET1G, which are transmembrane glycoproteins. The RAET1 products contain α1 and α2 domains but lack α3 domain and do not associate with β2-microglobulin. RAET1/ULBPs have tissue-specific expressions, and some of them are also polymorphic. The MIC-B and the closely related MIC-A protein share some similar properties with ULBPs (Sutherland et al. 2002).

ULBPs are important activators of NK cells. Soluble recombinant forms of ULBPs bind to human NK cells and stimulate NK cytotoxicity against tumor targets (Kubin et al. 2001). Soluble ULBPs also induce production of the cytokines IFN-γ, GM-CSF, TNF-α, and TNF-β, and the chemokines macrophage-inflammatory protein (MIP)-1α, MIP-1β, and I-309. In all cases, costimulation with IL-12 has a superadditive effect on the production of these factors (Cosman et al. 2001; Kubin et al. 2001).

UL16-binding proteins are frequently expressed by malignant transformed cells, a variety of leukemias, carcinomas, melanomas, and tumor cell lines and mediate cytotoxicity of NKG2D-positive NK cells, $CD8^+$ αβ T cells and γδ T cells in vitro and in vivo to tumor cells. ULBPs 1, 2, 3 and 4 are functional ligands of the NKG2D/DAP10 receptor complex on human NK cells. ULBP1, −2, −3, −4 and RAET1L are linked to membrane through GPI. Two more members of the RAET1/ULBP gene cluster, RAET1E and RAET1G have been characterized by Bacon et al. (2004). The encoded proteins RAET1E and RAET1G were similar to the ULBP in their class I-like α1 and α2 domains, but differed in one aspect: instead of being GPI-anchored, their sequences were like type 1 membrane-spanning molecule and contain transmembrane and cytoplasmic domains. Both proteins were capable of being expressed at the cell surface. Both proteins bound the activating receptor NKG2D, and RAET1G bound the human CMV protein UL16. Tissue expression of ULBP4 differs from other members of the family, in that it is expressed predominantly in the skin (Chalupny et al. 2003). ULBP-1 can be detected on mature DCs both in situ in the T cell areas of lymph nodes as well as in vitro after artificial maturation (Schrama et al. 2006). Human gastric cancer cell lines, which expressed ULBP are susceptible to NK cells in a NKG2D-dependent manner. However, cancer cells which had no ULBP on their surface were resistant to NK cells. ULBP 1, 2, and 3 being GPI-anchored proteins are sensitive to

phosphatidylinositol-specific phospholipase C (PI-PLC). Down-regulation of NKG2D by soluble ULBP provides a potential mechanism by which gastric cancer cells escape NKG2D-mediated attack by the immune cells (Song et al. 2006). The ULBP4 binds to TCRγ9/δ2 and induces cytotoxicity to tumor cells through both TCRγδ and NKG2D (Kong et al. 2009).

In the NKG2D/ULBP3 complex, the structure of ULBP3 resembles α1 and α2 domains of classical MHC molecules without a bound peptide. The lack of α3 and β2m domains is compensated by replacing two hydrophobic patches at the underside of the class I MHC-like β sheet floor with a group of hydrophilic and charged residues in ULBP3. NKG2D binds diagonally across the ULBP3 α helices, creating a complementary interface, an asymmetrical subunit orientation, and local conformational adjustments in the receptor. The interface is stabilized primarily by hydrogen bonds and hydrophobic interactions. Unlike the KIR receptors that recognize a conserved HLA region by a lock-and-key mechanism, NKG2D recognizes diverse ligands by an induced-fit mechanism (Radaev et al. 2001).

Monocyte-derived DCs (mDCs) and NK cells are reciprocally activated via cytokines and cell-cell contact. ULBPs have been detected on human mDCs. While ULBP1 was upregulated on mDCs in response to LPS or infection with human respiratory syncytial virus (RSV), the expression of ULBP2 was induced by LPS and poly I:C, indicating that the TLR-containing adapter molecule-1, IFN inducing pathway is associated with ULBP2 (Ebihara et al. 2007).

Proteolytic cleavage of ULBP2 produces truncated and soluble forms that may counteract NKG2D-mediated tumor immune surveillance. It is suggested that RAET1E can produce a soluble, 35-kDa protein (termed as RAET1E2) lacking the transmembrane region by selective splicing in tumor cells. The expressions of both RAET1E2 transcripts and protein can be found in different tumor cells and tissues. Incubation of NK-92 cells with RAET1E2 protein decreases the surface expression of NKG2D and in marked reduction in cytotoxiccity to tumor cells. These results suggest for an immune escape mechanism of tumors via alternative splicing of ULBP RNA to generate RAET1E2 that may impair NKG2D-mediated NK cell cytotoxicity to tumors (Cao et al. 2007).

31.3.4 Role of NKG2D Ligands

As NKG2D plays an important role in the immunosurveillance of tumors, studies suggest that release of MIC-A from cancer cells constitutes an immune escape mechanism that systemically impairs antitumor immunity. The interaction of human NK cells with MIC-A-positive human cancer cells in an in vivo setting showed that MIC-A overexpression can function as NK cell-mediated immunotherapy in experimental lung cancer. Moreover, low-dose application of the proteasome inhibitor bortezomib enhances expression of human NKG2D ligands MIC-A and MIC-B on hepatocellular carcinoma cells (Armeanu et al. 2008; Busche et al. 2006).

An understanding of effects of hyperthermia on NK cell cytotoxicity is important for maximizing the clinical benefits in cancer therapy. At temperatures above 40°C, (normally achieved during fever or exercise), both enhancing and inhibitory effects on cytotoxic activity of NK cells against tumor cells have been reported. Dayanc et al. (2008) have shown that thermal stress (using a temperature of 39.5°C) enhances human NK cell cytotoxicity against tumor target cells. This effect requires function of the NKG2D receptor of NK cells, and is maximal when both NK and tumor cell targets are heated. Heat sensitive cellular targets affected by hyperthermia on tumor cells include HSPs, MIC-A and MHC Class I. The expressions of NKG2D ligands were induced by both heat shock and ionizing radiation in various cell lines with peaks at 2 h and 9 h after treatment, respectively, although inducibility of each NKG2D ligand was dependent on cell lines (Kim et al. 2006). The available studies indicate a strong potential for heat-induced enhancement of NK cell activity in mediating, at least in part, the improved clinical responses seen when hyperthermia is used in combination with other therapies (Dayanc et al. 2008).

31.3.5 Regulation of Ligands

The three main mechanisms by which NKG2D ligand transcription can be induced are: DNA damage, TLR stimulation, and cytokine exposure. The DNA damage response pathway is involved in maintaining the integrity of the genome. The PI3K-related protein kinases ATM (ataxia telangiectasia, mutated) and ATR (ATM and Rad3 related) sense DNA lesions, specifically double-strand breaks and stalled DNA replication, respectively. This sensing results in cell-cycle arrest and DNA repair, or cell apoptosis if the DNA damage is too extensive to be repaired. This pathway has been shown to be constitutively active in human cancer cells (Bartkova et al. 2005; Gorgoulis et al. 2005; Stephan and David 2006). The DNA damage response, previously known to arrest the cell cycle and enhance DNA repair functions, or to trigger apoptosis, may also participate in alerting the immune system to the presence of potentially dangerous cells (Gasser et al. 2005). Gasser et al. provided evidence that this pathway actively regulates NKG2D ligand transcription (Gasser et al. 2005). Both mouse and human cells upregulated NKG2D ligands following treatment with DNA-damaging agents. This effect was dependent on ATR function, as inhibitors of ATR and ATM kinases prevented ligand upregulation in a dose-dependent fashion. These findings provide a link between the constitutive activity of

the DNA damage response in tumors (Bartkova et al. 2005; Gorgoulis et al. 2005) and the frequent upregulation of NKG2D ligands by these transformed cells. The exact mechanism linking the ATR/ATM-dependent recognition of DNA damage and the transcription of NKG2D ligands remain elusive (Champsaur and Lanier 2010). Toll-like receptor (TLR) signaling and Cytokines can also influence NKG2D ligand expression. In particular, interferons have pleiotropic effects on NKG2D ligand expression. Transforming growth factor (TGF-β) also decreases the transcription of MICA, ULBP2, and ULPB4 on human malignant gliomas. Therefore, cytokines and interferons can differentially affect NKG2D ligand expression in different cell types and environments. Other stimuli have also been reported to induce NKG2D ligand transcription.

Various mechanisms are responsible for the post-transcriptional regulation of NKG2D ligands. A group of endogenous cellular microRNAs (miRNAs) that bound to the 3′-UTR (untranslated region) of MICA and MICB, repressed their translation. Nice et al. showed that MULT1 protein undergoes ubiquitination dependent on the lysines in its cytoplasmic tail, resulting in its rapid degradation. Thomas et al. have recently described the capacity of the KSHV (Kaposi's sarcoma-associated herpesvirus)-encoded E3 ubiquitin ligase K5 to down-regulate cell surface expression of MICA and MICB. In this case, ubiquitination resulted in the redistribution of MICA to the plasma membrane, rather than its targeting to degradation as observed with MULT1 (Champsaur and Lanier 2010).

31.4 Crystal Structure of NKG2D

The basic folding pattern of murine NKG2D is similar to other C-type lectin domains such as CD94, Ly49A, rat MBP-A, and CD69 despite relatively low sequence homology (Boyington et al. 1999; Natarajan et al. 2000; Tormo et al. 1999; Weis et al. 1991). However, the precise mode of dimeric assembly varies among these natural killer receptors, as well as their surface topography and electrostatic properties.

31.4.1 Structures of NKG2D-Ligand Complexes

The NKG2D structure provides the first structural insights into the role and ligand specificity of this stimulatory receptor in the innate and adaptive immune system (Wolan et al. 2001) (Fig. 31.1). Crystal structures have been determined for mouse and human NKG2Ds in complex with MICA (Li et al. 2001). The structure of MICA - NKG2D complex reveals an NKG2D homodimer bound to a MICA monomer in an interaction that is analogous to that seen in αß-T cell receptor-MHC-I protein complexes. Similar surfaces on each NKG2D monomer interact with different surfaces on either the α1 or α2 domains of MICA. The binding interactions are large in area and highly complementary. The central section of the α2-domain helix, disordered in the structure of MICA alone, is ordered in the complex and forms part of the NKG2D interface. The extensive flexibility of the interdomain linker of MICA is shown by its altered conformation when crystallized alone or in complex with NKG2D (Li et al. 2001). Although there is little obvious sequence similarity between the human and mouse NKG2D ligands, there appears to be considerable structural similarity as evidenced by the ability of mouse NKG2D to react with human ligands, MICB, ULBP1, and ULBP2 (Kubin et al. 2001).

In NKG2D/ULBP3 complex, the structure of ULBP3 resembles the α1 and α2 domains of classical MHC molecules without a bound peptide. The lack of α3 and β2m domains is compensated by replacing two hydrophobic patches at the underside of the class I MHC-like β-sheet floor with a group of hydrophilic and charged residues in ULBP3. NKG2D binds diagonally across the ULBP3 α-helices, creating a complementary interface, an asymmetrical subunit orientation, and local conformational adjustments in the receptor. The interface is stabilized primarily by hydrogen bonds and hydrophobic interactions. Unlike the KIR receptors that recognize a conserved HLA region by a lock-and-key mechanism, NKG2D recognizes diverse ligands by an induced-fit mechanism (Radaev et al. 2001).

Rodent RAE-1 proteins (α, β, γ and δ) are distant MHC class I homologs, comprising isolated α1α2 platform domains. The crystal structure of RAE-1β was distorted from other MHC homologs and displayed noncanonical disulfide bonds. The loss of any remnant of a peptide binding groove was facilitated by the close approach of the groove-defining helices through a hydrophobic, leucine-rich interface. The RAE-1β-murine NKG2D complex structure resembled the human NKG2D-MICA receptor-ligand complex and further demonstrated the promiscuity of the NKG2D ligand binding site (Li et al. 2002).

The interaction of NKG2D receptor with several MHC I-like ligands has been analyzed thermodynamically. NKG2D ligand-binding site recognition is highly degenerate, as demonstrated by NKG2D's ability to simultaneously accommodate multiple non-conservative allelic or isoform substitutions in the ligands. In TCRs, "induced-fit" recognition explains cross-reactivity, but analyses of multiple NKG2D-ligand pairs showed that rather than classical "induced-fit" binding, NKG2D degeneracy is achieved using distinct interaction mechanisms at each rigid interface: recognition

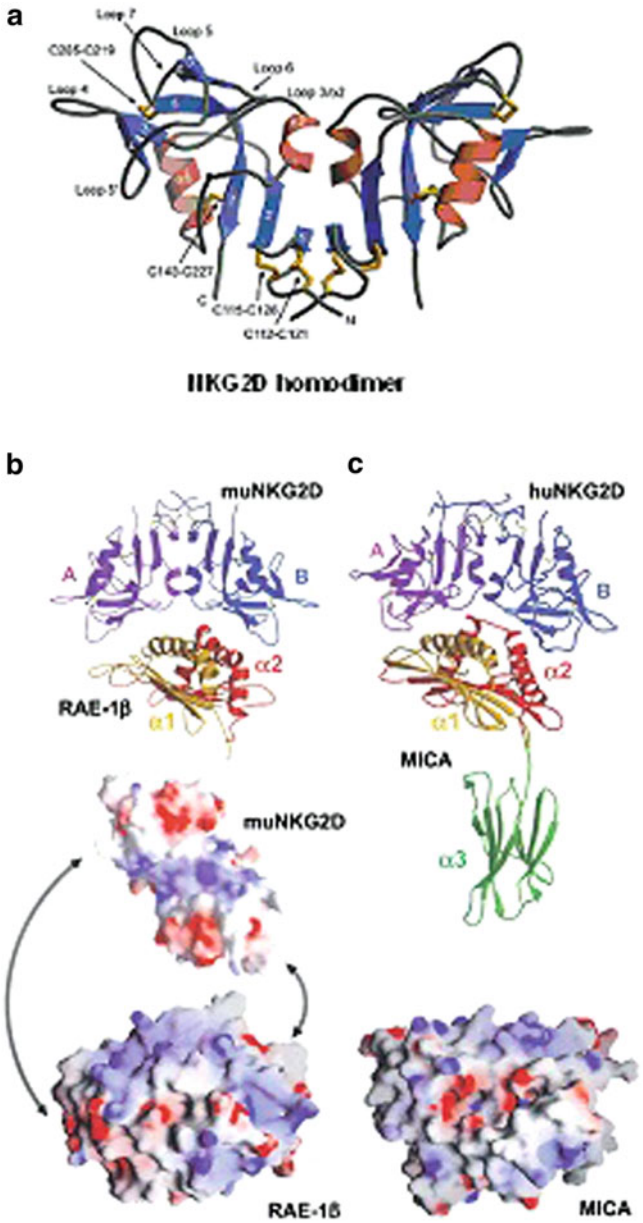

Fig. 31.1 (**a**) **Anatomy of killer cell lectin-like receptor subfamily K, member 1 (KLRK1) or NKG2D**. Structure of murine NKG2D homodimer shows side view showing the NH_2 terminus at the *bottom* of the structure that would connect to the membrane at the cell surface by a stalk comprised of 16 residues. The dimer is formed primarily of an extension of the first β-sheet (β1) across the interface. The NKG2D structure has a C-type lectin fold like the one reported in CD94 (Boyington et al. 1999), Ly49A (Tormo et al. 1999) and rat MBP-A (Weis et al. 1991). However, loop 5 in NKG2D is not a Ca^{2+}-dependent carbohydrate-binding loop like rat MBP-A. Only CD94 does not contain an α2-helix in loop 3 (Figure not shown) (Adapted with permission from Boyington et al. 1999 © Elsevier). (**b**) and (**c**) **Structures of murine NKD NK cell receptor-ligand complexes:** ribbon representations (*top*) and GRASP molecular surfaces (*bottom*) are shown for the structures of (**a**) the muNKG2D–RAE-1β, and (**b**) huNKG2D–MICA. Ribbons of the ligands are colored by domain: α1, *yellow*; α2, *red*; α3 (when present), *green*; and β_2-m (when present), *cyan*; ribbons of the receptors are colored by chain: *blue* or *purple*. Molecular surfaces of the platform domains are oriented such that the view is looking down onto the NKG2D binding surface of RAE-1 and MICA. In (**a**), the molecular surface of muNKG2D was included in an orientation looking down onto the RAE-1 binding surface, as if the receptor had been peeled away from the complex. Molecular surfaces are colored by electrostatic potential, with positively charged areas in blue and negatively charged areas in red. The RAE-1β-murine NKG2D complex structure resembles the human NKG2D-MICA receptor-ligand complex and demonstrates the promiscuity of the NKG2D ligand binding site (Adapted with permission from Li et al. 2002 © Elsevier)

Table 31.1 Activating homodimeric receptors and co-receptors with two basic TM residues

	Receptor	Signaling polypeptide	Ligand	Protein family
Human	NKG2D	DAP10	MIC-A/MIC-B; ULBPs(RAET1)	C-type lectin
	NKG2F (NKp80)	DAP12	AICL	C-type lectin
	NKp46	ξ/γ	Heparin, lewis-x	Ig-SF
	NKp30	ξ/γ	HLA-B-associated transcript 3;B7h6	Ig-SF
	NKp44	DAP12	Heparan sulfate epitope(s)	Ig-SF
Mouse	NKG2D	DAP10	MIC-A/MIC-B; ULBPs (RAET1)	C-type lectin
	Ly49D	DAP12	H2-D	C-type lectin
	Ly49H	DAP12	m157	C-type lectin
	NKRP1C	ξ/γ	unknown	C-type lectin
	NKRP1F	?	Clr-g	C-type lectin

TM transmembrane residues

degeneracy by "rigid adaptation." While likely forming similar complexes with their ligand (HLA-E), other NKG2x NKR family members do not require such recognition degeneracy (Strong and McFarland 2004).

31.5 DAP10/12 Adapter Proteins

31.5.1 DAP10

A number of receptors that are primarily expressed by human and/or murine NK cells represent homodimers with a basic residue in each transmembrane (TM) domain and may thus form a hexameric structure (Table 31.1). The human NKp46 receptor can assemble with Fcγ or ξ-ξ signaling dimers (Pessino et al. 1998), and experiments demonstrated that it forms a homodimer (Garrity et al. 2005). The human NKp80 and NKp40 and mouse Ly49H and Ly49D receptors assemble with DAP12 (Smith et al. 1998), whereas the mouse NKR-P1C receptor assembles with Fcγ (Lanier 2005). The stoichiometry described for NKG2D–DAP10 complex may be relevant for several receptors from the C-type lectin and immunoglobulin families.

In the recognition of self from non-self, activating and inhibitory receptors signal immune cells via adapter molecules, which determine the outcome of immune response. NKG2D lacks signal elements in its cytoplasmic domain. However, DAP10, the transmembrane adapter protein expressed broadly in hematopoietic cells, associates with NKG2D activating receptor forming a multisubunit complex, which recognizes self-proteins upregulated during tumorigenesis, infection, and autoimmune response. NKG2D can deliver stimulatory signals only in association with DAP10 or DAP12. Human NKG2D transduces activation signals exclusively via an associated DAP10 adaptor containing a YxNM motif, whereas murine NKG2D can signal through either DAP10 or the DAP12 adaptor, which contains an ITAM sequence. DAP10 signaling is thought to be mediated, at least in part, by PI3K and is independent of Syk/Zap-70 kinases. NKG2D couples to the non-ITAM-containing DAP10 and initiates at least two signaling branches that are both required for cytotoxicity. The NKG2D-mediated response can be modulated by factors such as cytokine milieu and possibly the particular ligand expressed. This nontraditional NKG2D-DAP10 initiated signal pathway enables lymphocytes to differentially respond to ligands based on cellular environment (Upshaw and Leibson 2006).

31.5.2 KARAP (DAP12 or TYROBP)

The signaling adaptor protein KARAP/DAP12/TYROBP (killer cell activating receptor-associated protein/DNAX activating protein of 12 kDa/tyrosine kinase binding protein) belongs to the family of transmembrane polypeptides bearing an intracytoplasmic immunoreceptor tyrosine-based activation motif (ITAM). This adaptor, initially characterized in NK cells, is associated with multiple cell-surface activating receptors expressed in both lymphoid and myeloid lineages. The main features of KARAP/DAP12 describe its involvement in a broad array of biological functions. KARAP/DAP12 is a wiring component for NK cell anti-viral function (e.g. mouse cytomegalovirus via its association with mouse Ly49H) and NK cell anti-tumoral function (e.g. via its association with mouse NKG2D or human NKp44). KARAP/DAP12 is also involved in inflammatory reactions via its coupling to myeloid receptors, such as triggering receptors expressed by myeloid cells (TREM) displayed by neutrophils, monocytes/macrophages and dendritic cells. Moreover, bone remodeling and brain function are also dependent upon the integrity of KARAP/DAP12 signals, as shown by the analysis of KARAP/DAP12-deficient mice and KARAP/DAP12-deficient Nasu-Hakola patients (Tomasello and Vivier 2005).

31.5.3 Characterization of DAP10 and DAP12

Human, mouse, pig, and the bovine DAP10 cDNA clones codes for a phosphatidyl-inositol-3 (PI-3) kinase-binding site (YxxM) in its cytoplasmic region. Similar to human, mouse, pig, the bovine DAP12 demonstrates one ITAM in its cytoplasmic domain (Fig. 31.2). The short mouse NKG2D-S and the bovine NKG2D could associate with either DAP10 or DAP12 adaptor protein for its cell surface expression. The advances in our understanding of the structural properties and signaling pathways of the inhibitory

and activating NK cell receptors, with a particular focus on the ITAM-dependent activating receptors, the NKG2D-DAP10 receptor complexes system have been reviewed (Lanier 2008, 2009).

NKG2D is required for cytolysis of tumor cells and both activated and expanded $CD8^+$ T cells and NK cells use DAP10. In addition, direct killing was partially dependent on the DAP12 signaling pathway. Silencing human NKG2D, DAP10, and DAP12 reduces cytotoxicity of activated $CD8^+$ T cells and NK cells in human effector cell function (Karimi et al. 2005), although NKG2D function was normal in patients lacking functional DAP12, indicating that DAP10 is sufficient for human NKG2D signal transduction (Rosen et al. 2004).

31.5.3.1 NKG2D Receptor Assembles in the Membrane with Two Signaling Dimers into a Hexameric Structure

The human receptor NKG2D assembles with the DAP10 signaling dimer and it was thought that one NKG2D homodimer pairs with a single DAP10 dimer by formation of two salt bridges between charged transmembrane (TM) residues. However, stoichiometry analysis demonstrated that one NKG2D homodimer assembles with four DAP10 chains giving hexameric structure (Fig. 31.2). Selective mutation of one of the basic TM residues of NKG2D resulted in loss of two DAP10 chains, indicating that each TM arginine serves as an interaction site for a DAP10 dimer. Assembly of the hexameric structure was cooperative because this mutation also significantly reduced NKG2D dimerization. A monomeric NKG2D TM peptide was sufficient for assembly with a DAP10 dimer, indicating that the interaction between these proteins occurs in the membrane environment. Formation of a three-helix interface among the TM domains involved ionizable residues from all three chains: the TM arginine of NKG2D and both TM aspartic acids of the DAP10 dimer. The organization of the TM domains thus shows similarities to the T cell antigen receptor-CD3 complex, in particular to the six-chain assembly intermediate between T cell antigen receptor and the CD3δε and CD3γε dimers. Binding of a single ligand can thus result in phosphorylation of four DAP10 chains, which may be relevant for the sensitivity of NKG2D receptor signaling, in particular in situations of low ligand density (Garrity et al. 2005) (Fig. 31.2). DAP10 signaling is involved in adjusting the activation threshold and generation of NKT cells and T_{reg} to avoid autoreactivity, but also modulates antitumor mechanisms (Hyka-Nouspikel and Phillips 2006).

31.5.3.2 Association of Adapter Proteins with NKG2D Splice Variants

It has been reported that the long form of murine NKG2D (NKG2D-L) associates exclusively with DAP10, whereas the short form of NKG2D (NKG2D-S) can pair with either DAP10 or DAP12. The short isoform was almost undetectable in naive NK cells. However, using two distinct cell types, it was observed that like the short isoform, the long variant of NKG2D also associates not only with DAP10 but also with DAP12. Cross-linking either isoform of NKG2D induces a calcium flux when associated exclusively with DAP10 or DAP12 (Rabinovich et al. 2006). The differential adapter pairing has functional consequences, as the different adapters trigger distinct signaling cascades. The cytoplasmic YINM motif of DAP10 recruits the p85 subunit of phosphoinositide kinase-3 (PI3K) and growth factor receptor-bound protein 2 (Grb2). DAP12 carries an immunoreceptor tyrosine-based activation motif (ITAM) whose phosphorylation leads to the recruitment of the zeta-chain associated protein kinase 70 (Zap70) and spleen tyrosine kinase (Syk). Thus, NKG2D engagement can result in both the PI3K and Grb2 and Syk and Zap70 signaling cascades (Fig. 31.2). It appears that signaling via mouse NKG2D isoforms is more complex than originally presented (Champsaur and Lanier 2010).

31.5.4 NKG2D Receptor Complex and Signaling

Each NKG2D homodimer associates with two homodimers of DAP10, forming a hexameric structure. Whether a single NKG2D homodimer can pair with both DAP10 and DAP12 homodimers has not yet been determined, but one could imagine this scenario to be beneficial to induce both signaling cascades upon triggering a single receptor. Crystal structures of both mouse and human NKG2D receptors in the soluble form and bound to ligands suggest that NKG2D binds to its ligands through "rigid adaptation" recognition, allowing binding to a wide variety of ligands (Champsaur and Lanier 2010).

The NK cell signaling pathway illustrates the signals produced by the activating cell surface receptors that initiate PTK (protein tyrosine kinase)-dependent pathways through their noncovalent association with transmembrane signaling adaptors that harbor ITAMs. Vivier et al. (2004) described the mechanism by which these positive pathways are antagonized by intracytoplasmic PTPs (protein tyrosine phosphatases) that are activated upon engagement of cell surface receptors with intracytoplasmic ITIMs. The tyrosine phosphorylation status of several signaling components that are substrates for both PTKs and PTPs is thus key to the propagation of the NK cell effector pathways. Additional cell surface receptors that are not directly coupled to ITAMs also participate in NK cell activation, such as NKG2D (which is noncovalently associated with the DAP10 transmembrane signaling adaptor), adhesion molecules, and cytokine receptors (Vivier et al. 2004).

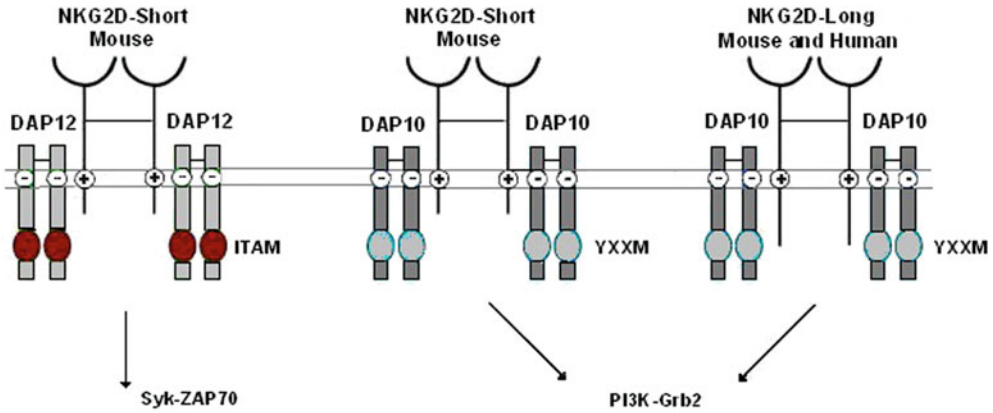

Fig. 31.2 Schematic representation of the NKG2D receptor complexes and ITAM-mediated signaling in NK cells: Hexameric NKG2D–DAP10 or NKG2D–DAP12 receptor complexes: Murine NKG2D exists as a homodimer on the surface of NK cells (Fig. 31.1a). The side view shows that the dimmer is formed as an extension of an anti parallel β-sheet across the interface with a two-fold crystallographic axis perpendicular to the extended sheet. The NKG2D dimmer interface is primarily composed of a central hydrophobic core encased by a hydrogen bond and a salt bridge network (Call et al. 2010). Each TM domain of human NKG2D assembles with one DAP10 dimer. This interaction involves both TM aspartic acids of DAP10 and the TM arginine (Garrity et al. 2005). NKG2D signals via association with adapter molecules through charged residues in the transmembrane domain. Mouse NKG2D associates with both DAP10 and DAP12 signaling molecules, whereas human NKG2D associates with DAP10 only. The pairing of NKG2D with DAP12 results in the phosphorylation of immunoreceptor tyrosine-based activation motif (ITAM) and triggering of the Syk and/or Zap70 cascade. Association with DAP10 leads to tyrosine phosphorylation on the YINM motif and triggering of the PI3K and Grb2 signaling cascade. ITAM-bearing signaling subunits are phosphorylated, probably by Src family kinases, after receptor engagement. Syk and/or ZAP-70 (both of which are expressed by human and mouse NK cells) are recruited to the phosphorylated ITAMs, initiating a cascade of downstream signaling as depicted. The signaling pathways depicted are hypothetical and were deduced by synthesizing results from many studies investigating ITAM-coupled receptor signaling in human and mouse NK cells (Reproduced with permission from Champsaur and Lanier 2010 © John Wiley and Sons)

Findings suggest how NKG2D-DAP10 mediates cytotoxicity and provides a framework for evaluating activation by other receptor complexes that lack ITIM (Upshaw et al. 2006).

Isoforms of PLC-γ in NK Cell Cytotoxicity and Innate Immunity: The two isoforms of PLC-γ couple immune recognition receptors to important calcium- and PKC-dependent cellular functions. It has been assumed that PLC-γ 1 and PLC-γ2 have redundant functions and that the receptors can use whichever PLC-γ isoform is preferentially expressed in a cell of a given hemopoietic lineage. The ITAM-containing immune recognition receptors can use either PLC- γ1 or PLC-γ2, whereas the NK cell-activating receptor NKG2D preferentially couples to PLC-γ2. Experimental models evaluating signals from either endogenous receptors (FcR verus NKG2D-DAP10) or ectopically expressed chimeric receptors (with ITAM-containing cytoplasmic tails vs DAP10-containing cytoplasmic tails) showed that PLC-γ1 and PLC-γ 2 both regulate the functions of ITAM-containing receptors, whereas only PLC-γ2 regulates the function of DAP10-coupled receptors. These data suggest that specific immune recognition receptors can differentially couple to the two isoforms of PLC-γ (Upshaw et al. 2005). Cytotoxicity was completely abrogated in PLC-γ2-deficient cells, regardless of whether targets expressed NKG2D ligands or others. It was suggested that exocytosis of cytotoxic granules, but not cellular polarization toward targets, depends on intracellular Ca^{2+} rise during NK cell cytotoxicity. In vivo, PLC-γ2 regulates selective facets of innate immunity because it is essential for NK cell responses to malignant and virally infected cells but not to bacterial infections (Caraux et al. 2006). Hence PLCγ1 and PLCγ2 play non-redundant and obligatory roles in NK cell ontogeny and in its effector functions (Regunathan et al. 2006).

Phosphatidylinositol 3-kinase Activation in the Formation of NKG2D Immunological Synapse: In human cells, NKG2D signaling is mediated through the associated DAP10 adapter. However, Giurisato et al. (2007) showed that engagement of NKG2D by itself is sufficient to stimulate the formation of the NK immunological synapse (NKIS), with recruitment of NKG2D to the center synapse. Mutagenesis studies of DAP10 revealed that the phosphatidylinositol 3-kinase binding site, but not the Grb2 binding site, was required and sufficient for recruitment of DAP10 to the NKIS. Surprisingly, in the absence of the Grb2 binding site, Grb2 was still recruited to the NKIS. Since the recruitment of Grb2 was dependent on phosphatidylinositol-trisphosphate (PIP3), the possibility that recruitment to the NKIS is mediated by a pleckstrin homology (PH) domain-containing binding partner for Grb2 was explored. It was found that the PH domain of SOS1, but not that of

Vav1, was able to be recruited by PIP3. These results demonstrate how multiple mechanisms can be used to recruit the same signaling proteins to the plasma membrane (Giurisato et al. 2007).

Many NK Cell Receptors Activate ERK2 and JNK1 to Trigger Microtubule Organizing Center: The NK activating receptors on NK cell signal the polarization of the microtubule organizing center (MTOC) together with cytolytic granules to the synapse with target cells. After ligation of any one of these receptors, Src family kinases initiate activation of two signal pathways, the phosphoinositide-3 kinase —>ERK2 and the phospholipase Cγ —>JNK1 pathways. Both are required for polarization of the MTOC and cytolytic granules, a prerequisite for killing the targets. Crosslinking of CD28, NKG2D, NKp30, NKp46, NKG2C/CD94, or 2B4 leads to the phosphorylation of both ERK2 and JNK1, although they use different proximal signaling modules. Thus, many, if not all, activating receptors stimulate these two distal pathways, independent of the proximal signaling module used. By contrast, CD2, DNAM-1, and β1-integrin cross-linking do not activate either pathway; they may be costimulatory molecules or have another function in the synapse (Chen et al. 2007).

In search of signaling pathway involved after NKG2D ligation, Li et al. either incubated NKG2D-bearing human NKL tumor cell line with K562 target cells or cross-linked with NKG2D mAb induced strong activation of the MAP kinases. Selective inhibition of JNK MAP kinase greatly reduced NKG2D-mediated cytotoxicity toward target cells and blocked the movement of the MTOC, granzyme B, and paxillin (a scaffold protein) to the immune synapse. NKG2D-induced activation of JNK kinase was also blocked by inhibitors of Src protein tyrosine kinases and phospholipase PLCγ, upstream of JNK. A second MAP kinase pathway through ERK was also shown to be required for NK cell cytotoxicity. Thus, activation of two MAP kinase pathways is required for cytotoxic granule and MTOC polarization and for cytotoxicity of human NK cells when NKG2D is ligated (Li et al. 2008).

Regulation of NK Cell-Mediated Cytotoxicity by the Tyrosine Kinase Itk: In activated human NK cells, the tyrosine kinase IL-2-inducible T cell kinase (Itk) differentially regulates distinct NK-activating receptors. Itk plays a complex role in regulating the functions initiated by distinct NK cell-activating receptors. Enhanced expression of Itk leads to increases in calcium mobilization, granule release, and cytotoxicity upon stimulation of the ITAM-containing FcR, suggesting that Itk positively regulates FcR-initiated cytotoxicity (Khurana et al. 2007). Gross et al. (2008) identified a molecular basis for the segregation of NK cell receptor-induced signals for cytokine release and target cell killing and suggested the roles for CARD-protein/Bcl10/Malt1 complexes in ITAM receptor signaling in innate and adaptive immune cells (Gross et al. 2008).

31.6 Functions of NKG2D

31.6.1 Engagement of NKG2D on γδ T Cells and Cytolytic Activity

Engagement of NKG2D on NK cells and γδ T cells can trigger cytolytic activity. The number of γδ T cells has been found to increase in some tumor tissues. This was demonstrated in transfectants that express the MIC proteins (Bauer et al. 1999; Cosman et al. 2001), the ULBPs (Cosman et al. 2001), the Rae-1 proteins (Cerwenka et al. 2000; Diefenbach et al. 2000) and H-60 (Cerwenka et al. 2000; Diefenbach et al. 2000). The parent cell lines were resistant to NK lysis while the transfectants were readily susceptible to NK lytic activity. The results also indicated that the NKG2D activating signal can overcome the inhibitory signals resulting from MHC class I recognition (Bauer et al. 1999; Cosman et al. 2001). Populations of γδ T cells that occur in tumors and in the intestinal epithelium also killed target cells, which expressed MIC proteins (Girardi et al. 2001). Most tumor cells express comparable levels of MICA and MICB as well as ULBP (Groh et al. 1999). Most epithelial tumors were susceptible to allogeneic γδT-cell lysis and in the case of an established ovarian carcinoma to autologous γδT cell killing. The NKG2D pathway appears to be involved in the lysis of different melanomas, pancreatic adenocarcinomas, squamous cell carcinomas of the head and neck, and lung carcinoma (Wrobel et al. 2007). The $CD56^+$ γδ T cells are potent anti-tumor effectors capable of killing squamous cell carcinoma and may play an important therapeutic role in patients with head and neck cancer and other malignancies (Alexander et al. 2008). Despite the increase in γδ T cells in some cancers, the levels of NKG2D receptors, responsible for the cytolytic effect of γδ T cells, were lower in cancer patients than in healthy adults (Bilgi et al. 2008) (see Section 31.7.2 on Immune Evasion Mechanisms). Based on the surface expression of CD56 and CD16 or inhibitory and activatory receptors, NK cells from cord blood (CB) could be divided into four subsets. Interestingly, CB NK cells, similar to the naïve T cells, express CD45RA but not CD45RO molecules. Moreover, CD27, a memory T cell marker, highly expressed on $CD56^{hi}CD16^-$ NK cells. The killing-associated molecules, NKG2A, NKG2D, CD95 and the intracellular granzyme B and perforin are heterogeneously expressed among the 4 subsets. Addition of IL-12 into cultures resulted in the induction of IFN-γ expression by

$CD56^{hi}$ $CD16^{-}$ and $CD56^{lo}$ $CD16^{-}$ subsets and the enhancement of NK cytolytic activity (Fan et al. 2008).

Activation of Vγ 9Vδ 2T Cells by NKG2D: Human γδT cells expressing a Vγ 9Vδ2 T-cell receptor (TCR) kill various tumor cells including autologous tumors. In addition to TCR-dependent recognition, activation of NKG2D-positive γδT cells by tumor cell-expressed NKG2D ligands can also trigger cytotoxic effector function. Human Vγ9 Vδ2 T cells recognize phosphoantigens, certain tumor cells, and cells treated with aminobisphosphonates. Evidences suggest that Vγ9 Vδ2T cells may also be directly activated by NKG2D. Culture of PBMC with immobilized NKG2D-mAb or NKG2D ligand MICA induces the up-regulation of CD69 and CD25 in NK and Vγ9 Vδ2 but not in CD8 T cells. Furthermore, NKG2D triggers the production of TNF-α but not of IFNγ, as well as the release of cytolytic granules by Vγ9 Vδ2 T cells. Due to remarkable similarities in NKG2D function in NK and Vγ9 Vδ2 T cells, it suggests a new perspective for Vγ9 Vδ2 T cell-based immunotherapy based on NKG2D ligand-expressing tumors (Rincon-Orozco et al. 2005). Trichet et al. (2006) reported that activating NKRs have less affinity for their MHC ligands than homologous inhibitory NKRs. Despite this, activating NKRs recognizing MHC class I molecules play an important role in the increased killing by Vγ9Vδ2 T cells of tumor cells with down-regulated MHC class I molecule expression, and suggest that these T cells will best lyse tumor cells combining MHC class I molecule expression down-regulation with up-regulated NKG2D ligand expression (Trichet et al. 2006).

31.6.2 NKG2D: A Co-stimulatory Receptor for Naive $CD8^+$ T Cells

$CD8^+$ T cells require a signal through a co-stimulatory receptor in addition to TCR to become activated. The role of CD28 in co-stimulating T cell activation is well established. The CD28 has a cytoplasmic YXXM motif that activates PI3-kinase via the DAP10 adapter protein (Wu et al. 1999) suggesting a similar co-stimulatory capacity of NKG2D. It is likely that NKG2D acts as a co-stimulatory molecule only under restricted conditions or requires additional cofactors. Whereas NKG2D can only function as a co-stimulatory receptor on $CD8^+$ αβ T cells under the domination of αβ TCR in spite of deficiency of co-stimulatory molecule CD28, NKG2D can directly activate NK cells even in the presence of inhibitory signals from MHC-I and corresponding receptor complexes. Results indicate that NKG2D can regulate the priming of human naive $CD8^+$ T cells, which may provide an alternative mechanism for potentiating and channeling the immune response (Maasho et al. 2005). In mice, however, two alternative splicing products NKG2D polypeptides associate differentially with the DAP10 and DAP12 signaling subunits and that differential expression of these isoforms and of signaling proteins determines whether NKG2D only functions as a co-stimulatory receptor in the adaptive immune system ($CD8^+$ T cells) or as both a primary recognition unit and a co-stimulatory receptor in the innate immune system (NK cells and macrophages) (Cao and He 2004; Diefenbach et al. 2002; Ogasawara and Lanier 2005). The 4-1BB co-stimulatory molecule expressed by resting $CD8^+$ T cells is an essential regulator of NKG2D in $CD8^+$ T cells. Kim et al. (2008) proposed that 4-1BB plays a critical role in protecting NKG2D from TGF-β1-mediated down-modulation.

Experiments with blocking antibodies revealed that NKG2D engagement contributed to cytolytic activity only during later stages of the infection when MHC class I expression was down-regulated and the MIC proteins were up-regulated. Lytic activity absolutely required the T cell receptor, and NKG2D provided a co-stimulatory signal. Same T cell clones secreted increased levels of cytokines in response to their target antigens when simultaneous NKG2D engagement occurred. Co-stimulation was also observed in mouse macrophages (Diefenbach et al. 2000; Groh et al. 2001). Transfectants expressing H-60 or Rae-1ß were used to stimulate activated macrophages. TNF-α transcription and nitric oxide production were enhanced in response to the signal, but only in the presence of LPS, which also provided an activating signal to macrophages (Ehrlich et al. 2005). NKG2D functions as a prototypic costimulatory receptor in a subset of human cytomegalovirus (HCMV)-specific $CD4^+$ T lymphocytes and thus may have a role in the response against infected HLA class II^+ cells displaying NKG2D ligands (Saez-Borderias et al. 2006).

31.6.3 NKG2D in Cytokine Production

The activating signal of NKG2D can also elicit cytokine production. NK cell production of MIP-1ß, TNF-α and IFN-γ was enhanced upon treatment with soluble ULBP (Kubin et al. 2001). A much more striking effect of ULBP was observed when IL-12 was included in the culture. Similarly, HCMV-specific γδ T cells produced IFN-γ, TNF-α, IL-2, and IL-4 when exposed to target antigen presented by C1R cells. Cytokine secretion was strongly enhanced if the C1R cells were transfected with MICA (Groh et al. 2001).

It was shown that dendritic epidermal T cells (DETCs), also known to express NKG2D, constitutively express NKG2D-S, NKG2D-L, DAP10, and DAP12 transcripts as

well as cell surface NKG2D protein. Blocking of NKG2D inhibited DETC-mediated cytotoxicity against target cells that do not express T cell receptor ligands. Cross-linking of NKG2D on DETCs induced IFNγ production. Thus, DETCs constitutively express NKG2D that acts as a primary activating receptor, and plays important role in cutaneous immune surveillance (Nitahara et al. 2006). Chan et al. (2006) described a third DC lineage, termed interferon-producing killer DCs (IKDCs), distinct from conventional DCs and plasmacytoid DCs. They produce substantial amounts of type I IFN and IL-12 or IFNγ, depending on activation stimuli. Upon stimulation with CpG oligodeoxy-nucleotides, ligands for Toll-like receptor (TLR)-9, IKDCs kill typical NK target cells using NK-activating receptors. Their cytolytic capacity subsequently diminishes, associated with the loss of NKG2D receptor and its adaptors, DAP10 and DAP12. By virtue of their capacity to kill target cells, followed by antigen presentation, IKDCs provide a link between innate and adaptive immunity (Chan et al. 2006).

31.6.4 Heterogeneity of NK Cells in Umbilical Cord Blood

NK cells from umbilical cord blood (CB) play an important role in allogeneic stem cell transplantation and defending infections of newborn. The proportion of NK cells is high in CB, but the IFN-γ production low compared to later part in life. In contrast, the proportion of T cells is low in CB, an observation that indicates a deviation of the regulatory function of NK cells in CB compared to later in life. Additionally, the level of expression of NKG2D, NKp30 and NKp46 decreased with age. These age related changes in NK cell populations defined by the expression of activating and inhibitory receptors may be the result of pathogen exposure and/or a continuation of the maturation process that begins in the bone marrow (Sundström et al. 2007). Human NK cells from cord blood are the key effector cells involved in graft-versus-host disease (GVHD) and graft-versus-leukemia (GVL). The activity of CB NK cells was shown to be lower than that of adult peripheral blood (PB) NK cells. Though, the expression of activating NK receptors, CD16, NKG2D and NKp46 did not show significant difference between CB and PB NK cells, the expression of inhibitory receptor NKG2A/CD94 was significantly higher on CB NK cells. The high expression of NKG2A/CD94 and low expression of granzyme B may be related with the reduced activity of CB NK cells (Wang et al. 2007).

31.7 Cytotoxic Effector Function and Tumor Immune Surveillance

31.7.1 Anti-Tumor Activity

Recent advances clearly implicate that NKG2D recognition plays an important role in tumor immune surveillance and that NKG2D primarily acts to trigger perforin-mediated apoptosis. NKG2D-mediated tumor rejection was demonstrated in a murine system using the tumor-forming RMA cell line (Cerwenka et al. 2001). RMA transfectants expressing Rae-1 proteins were rejected. In vivo depletion experiments demonstrated that tumor rejection was mediated by NK cells, and studies in CD1 deficient mice demonstrated that CD1-restricted NKT cells were not involved in the rejection. A second report using similar methods confirmed that ectopic expression of the NKG2D ligands, Rae-1ß or H60, in several tumor cell lines resulted in potent rejection of the tumor cells by syngeneic mice (Diefenbach et al. 2001). Cell depletion experiments demonstrate that both NK cells and $CD8^+$ T cells are involved in this rejection. These authors also report a potent immune memory in contrast to observation of Cerwenka et al. (2001). NKG2D ligands might be useful in the design of tumor vaccines. Though the ligands for the NKG2D stimulatory receptor are frequently upregulated on tumors, rendering them sensitive to NK cells killing, Guerra et al. (2008) provided the evidence in NKG2D-deficient mice that NKG2D was not necessary for NK cell development but was critical for immunosurveillance of epithelial and lymphoid malignancies in transgenic models. These findings provided important genetic evidence for surveillance of primary tumors by an NK cell receptor.

The importance of the NKG2D pathway was further illustrated in mice deficient for either IFNγ or TNF-related apoptosis-inducing ligand, whereas mice depleted of NK cells, T cells, or deficient for perforin did not display any detectable NKG2D phenotype. Furthermore, IL-12 therapy preventing MCA-induced sarcoma formation was also largely dependent on the NKG2D pathway. The data begin to place the NKG2D pathway into the context of other recognition-effector systems used by NK cells (Hayakawa and Smyth 2006a, b). Ewing sarcoma (EWS) cells are potentially susceptible to NK cell cytotoxicity due to the expression of activating NK cell receptor ligands. The use of cytokine-activated NK cells rather than resting NK cells in immunotherapy may be instrumental to optimize NK cell reactivity to EWS (Verhoeven et al. 2008; von Strandmann et al. 2006).

Tumor-Derived Exosomes Down-Modulate NKG2D Expression: Soluble NKG2D ligands and growth factors, such as TGFβ1 emanating from tumors, are mechanisms for down-regulating NKG2D expression. Cancers thereby impair the capacity of lymphocytes to recognize and destroy them (Groh et al. 2002). Exosomes derived from cancer cells express ligands for NKG2D and express TGF β1. Exosomes produced by various cancer cell lines, or by mesothelioma patients triggered down-regulation of surface NKG2D expression by NK cells and $CD8^+$ T cells. Other markers remained unchanged, indicating the selectivity and non-activatory nature of the response. Exosomal NKG2D ligands were partially responsible for this effect. Exosomally expressed TGF β1 was the principal mechanism. NKG2D is a likely physiological target for exosome-mediated immune evasion in cancer (Clayton et al. 2008).

NKR-P2, the rat orthologue of human NKG2D, is a potent activation receptor on rat DCs. A potential agonistic anti-NKR-P2 mAb (1A6) mimics the NKR-P2 ligand and induces activation and maturation of DCs. Interaction of DCs with 1A6 enhances nitric oxide-mediated apoptosis in tumor cells. Cross-linking of NKR-P2 with 1A6 up-regulates MHC II and decreases endocytic activity of DC, thus suggeting a pivotal role in adaptive immune responses. Blocking of 1A6-mediated activation and maturation with inhibitors of PI3K, p38K and ERK1/2K suggests the involvement of MAP kinase in signal transduction. 1A6 cross-linking activates NF-kB, which acts as key executioner of DC activation (Srivastava et al. 2007).

NK Cell-Mediated Cytotoxicity in Human Lung Adenocarcinoma: Although adenocarcinoma (ADC) cells express heterogeneous levels of NKG2DLs, they are often resistant to NK cell-mediated killing. Resistance of ADC-Coco to allogeneic polyclonal NK cells and autologous NK cell clones are correlated with shedding of NKG2DLs resulting from a matrix metalloproteinase (MMP) production. Treatment of ADC-Coco cells with a MMP inhibitor (MMPI) combined with IL-15 stimulation of autologous NK cell clones lead to a potentiation of NK cell-mediated cytotoxicity. This lysis is mainly NKG2D mediated, since it is abrogated by anti-NKG2D-neutralizing mAb. These results suggest that MMPIs, in combination with IL-15, may be useful for overcoming tumor cell escape from the innate immune response (Le Maux Chansac et al. 2008).

31.7.2 Immune Evasion Mechanisms

Acute Myeloid Leukemia (AML): Little is known regarding the regulation of NKp46 and NKG2D expression in AML. Mononuclear and polymorphonuclear phagocytes down-regulate the cell surface density of NKp46 and NKG2D on NK cells with $CD56^{dim}$ phenotype in vitro by a mechanism that is dependent on the availability of phagocyte-derived reactive oxygen species (ROS). Histamine maintained NKp46 and NKG2D expression despite the presence of inhibitory phagocytes by targeting an H2 receptor on phagocytes. By contrast, NKp46 and NKG2D expression by the $CD56^{bright}$ subset of NK cells was resistant to inhibition by phagocytes. These findings are suggestive of a mechanism of relevance to the regulation of NKp46/NKG2D receptor expression (Romero et al. 2006).

Malignant blood cells in AML display low levels of ligands for NKG2D and can thus evade NK immunosurveillance. Rohner et al. (2007) attempted to up-regulate NKG2D-L ULBP using anti-neoplastic compounds with myeloid differentiation potential. Combinations of 5-aza-2′-deoxycytidine, trichostatin A, vitamin D3, bryostatin-1, and all-trans-retinoic acid, used together with myeloid growth factors and IFNγ, increased cell surface ULBP expression in the AML cell line HL60 and in primary AML blasts. Up-regulation of ULBP ligands was associated with induction of myelomonocytic differentiation of AML cells. Higher ULBP expression increased NKG2D-dependent sensitivity of HL60 cells to NK-mediated killing (Rohner et al. 2007).

Myelodysplastic Syndromes: (MDS) are characterized by ineffective hematopoiesis with potential for progression to acute myeloid leukemia (AML). Findings suggest that impairment of NK cytolytic function derives in part from reduced activating NK receptors such as NKG2D in association with disease progression. Evasion of NK immunosurveillance may have importance for MDS disease progression (Epling-Burnette et al. 2007).

Human Melanomas: Several human melanomas (cell lines and freshly isolated metastases) do not express MICA on the cell surface but have intracellular deposits of this NKG2DL. Fuertes et al. (2008) identified a strategy developed by melanoma cells to evade NK cell-mediated immune surveillance based on the intracellular sequestration of immature forms of MICA in the endoplasmic reticulum. The low expression of CD161 and activating NKG2D receptors, without increased expression of KIR receptors CD158a and CD158b, as well as a decrease in the cytotoxic, $CD16^{bright}$ NK cell subset, is associated with a significant impairment in NK cell activity in metastatic melanoma patients. Furthermore, the predictive pretherapy finding that IL-2, IFN, IFN and RA, unlike RA alone, can enhance NK cell activity of metastatic melanoma patients against FemX melanoma tumor cell line can be of help in the design and development of therapeutic regimens (Konjević et al. 2007).

Risk of Colorectal Cancer with the High NK Cell Activity NKG2D Genotype: Cancer patients with advanced disease display signs of immune suppression, which constitute a major obstacle for effective immunotherapy. Both T cells and NK cells are affected by a multitude of mechanisms of which the generation of reactive oxygen species is of major importance. Two weeks of high-dose treatment with the anti-oxidant vitamin E may enhance NK cell function in cancer patients by protecting from oxidative stress. Vitamin E treatment was associated with a minor, but consistent, induction of NKG2D expression in patients with colorectal cancer (Hanson et al. 2007; Melum et al. 2008).

It is reported that there are two haplotypes of NKG2D, HNK1 (high NK activity) and LNK1 (low NK activity). The HNK1 is reported to reduce the overall cancer risk. To elucidate its impact on colorectal cancer (CRC), Furue et al. (2008) found a reduced risk of CRC with the NKG2D HNK1. It was suggested that the HNK1 genotype, associated with high NK cell activity, might be an independent protective factor for CRC among the Japanese population.

Differing Phenotypes Between Intraepithelial and Stromal Lymphocytesin Tongue Cancer: The significance of tumor-infiltrating lymphocytes (TIL) has attracted much attention in relation to the prognosis of patients. The tumor nest-infiltrating (intraepithelial) $CD8^+$ T cells frequently expressed PD-1, an inhibitory receptor, in sharp contrast to those in the stroma or in the lichen planus. Conversely, the intraepithelial $CD8^+$ T cells only infrequently expressed NKG2D, an activating receptor, in contrast to those in the stroma or in the lichen planus. Furthermore, the intraepithelial NK cells expressed NKG2A, an inhibitory receptor, more frequently than those in the stroma or the lichen planus. Collectively, the intraepithelial $CD8^+$ T cells and NK cells are phenotypically inactivated, whereas stromal counterparts are phenotypically just as active as those in the lichen planus. These results suggest the first-step occurrence of an immune evasion mechanism in the tumor nest of oral squamous cell carcinoma (Katou et al. 2007). The expression of NKG2D on $CD8^+$ T lymphocytes from esophageal cancer patients was significantly lower than in those of normal controls. The decreased NKG2D expression on $CD8^+$ T cells was correlated with disease severity (Osaki et al. 2009).

Cholangiocarcinoma in Primary Sclerosing Cholangitis: Melum et al. (2008) investigated the influence of genetic variations in the NKG2D-MICA receptor-ligand pair on the risk of cholangiocarcinoma (CCA) in patients with primary sclerosing cholangitis (PSC). Seven SNPs covering the NKG2D gene were genotyped in Scandinavian PSC patients and controls. This suggested that genetic variants of the NKG2D receptor are associated with development of CCA in PSC patients and the interaction between NKG2D and MICA is involved in protection against CCA in PSC. Patients who are homozygous for the nonrisk alleles are unlikely to develop CCA; this finding could be helpful in identifying PSC patients with a low CCA risk.

Gastric Cancer: Some studies suggest that the NKG2D expression on $CD8^+$ T cells is down-regulated and this reduction may be involved in immune evasion in cancer patients. In gastric cancer patients, NKG2D expression on circulating $CD8^+$ T cells was down-regulated and significantly correlated with IFN-γ production in gastric cancer patients. There was no difference in soluble MICA between gastric cancer patients and normal controls. Decreased NKG2D expression may be one of the key factors responsible for immune evasion by tumors in gastric cancer (Osaki et al. 2007).

MIF in the Immune Escape of Ovarian Cancer: The proinflammatory cytokine macrophage migration inhibitory factor (MIF) stimulates tumor cell proliferation, migration, and metastasis; promotes tumor angiogenesis; suppresses p53-mediated apoptosis; and inhibits antitumor immunity by unknown mechanisms. Functionally, MIF may contribute to the immune escape of ovarian carcinoma by transcriptionally down-regulating NKG2D in vitro and in vivo which impairs NK cell cytotoxicity toward tumor cells. Perhaps inhibitors of MIF can be used for the treatment of MIF-secreting cancers (Krockenberger et al. 2008).

31.8 NKG2D in Immune Protection and Inflammatory Disorders

31.8.1 NKG2D Response to HCMV

Human cytomegalovirus (HCMV) infection is a paradigm of the complexity of host-pathogen interactions. To avoid recognition by cytotoxic T lymphocytes (CTL) HCMV inhibits the expression of HLA-I molecules. As a consequence, engagement of KIR, CD94/NKG2A, and CD85j (ILT2 or LIR-1) NKR specific for HLA-I molecules is impaired, and infected cells become vulnerable to an NK cell response driven by activating receptors. In addition to the well-defined role of the NKG2D, the involvement of other triggering receptors (i.e., activating KIR, CD94/NKG2C, NKp46, NKp44, and NKp30) in the response to HCMV is being explored (Gumá et al. 2006). To escape from NK cell-mediated surveillance, HCMV interferes with the expression of NKG2D ligands in infected cells. In addition, the virus may keep NK inhibitory receptors engaged preserving HLA-I molecules with a limited role in antigen presentation (i.e., HLA-E) or, alternatively, displaying class I surrogates. Despite considerable progress in the field, a number of issues

regarding the involvement of NKR in the innate immune response to HCMV remain uncertain.

31.8.2 HTLV-1-Associated Myelopathy

Human T cell lymphotropic virus type I (HTLV-1)-associated myelopathy/tropical spastic paraparesis (HAM/TSP) is a chronic inflammatory disease of the CNS that resembles multiple sclerosis. Disease progression involves production of IL-15 and its receptor through transactivation. Substantial proportions of HAM/TSP patient CD4 T and CD8 cells are positive for NKG2D and both subsets express MIC. Engagement of MIC by NKG2D promotes spontaneous HAM/TSP T cell proliferation and, apparently, CTL activities against HTLV-1-infected T cells. Perhaps it is the viral strategy that exploits immune stimulatory mechanisms to maintain a balance between promotion and limitation of infected host T cell expansions (Azimi et al. 2006).

NKG2D in Clearance of Picornavirus from Infected Murine Brain: The role of NKG2D-mediated augmentation in the clearance of viral infections from CNS was explored using Theiler's murine encephalomyelitis virus model. Studies suggest that NKG2D-positive $CD8^+$ cytotoxic T cells enter the brain, and that NKG2D ligands are expressed in the brain during acute infection. The interruption of NKG2D ligand recognition via treatment with a blocking antibody attenuates the efficacy of viral clearance from the CNS (Deb and Howe 2008).

31.8.3 Protection Against Bacteria

The NKG2D-activating receptor interacts with ligands expressed on the surface of cells stressed by pathogenic and nonpathogenic stimuli. Lysis of bronchial epithelial cells is not MHC I restricted but depends on NKG2D signaling. It appears that respiratory epithelium has antigen presenting function and directly alloactivates cytotoxic $CD8^+$ T cells, which show nonclassical effector function (Kraetzel et al. 2008). In response to acute pulmonary *Pseudomonas aeruginosa* infection, the expression of mouse NKG2D ligands (Rae1) increased in airway epithelial cells and alveolar macrophages in vivo and also increased the cell surface expression of human ULBP2 on airway epithelial cells in vitro. NKG2D receptor blockade inhibited the pulmonary clearance of *P. aeruginosa* and also resulted in decreased production of Th1 cytokines and nitric oxide in the lungs of *P. aeruginosa*-infected mice. These results suggest the importance of NKG2D-mediated immune activation in the clearance of acute bacterial infection and that epithelial cell-lymphocyte interactions mediate pulmonary cytokine production and bacterial clearance (Borchers et al. 2006).

Expression of the activating receptors NKp30, NKp46, and NKG2D is enhanced on NK cells after exposure to *M. tuberculosis*-infected monocytes, whereas expression of DNAX accessory molecule-1 and 2B4 was not. Anti-NKG2D and anti-NKp46 inhibited NK cell lysis of M. tuberculosis-infected monocytes, but Abs to NKp30, DNAX accessory molecule-1, and 2B4 had no effect. Following infection of monocytes, the expression of the ULBP1, but not of ULBP2, ULBP3, or MICA/B was up-regulated. Therefore, NKp46 and NKG2D are the principal receptors involved in lysis of *M. tuberculosis*-infected mononuclear phagocytes, and that ULBP1 on infected cells is the major ligand for NKG2D. It appears that TLR2 contributes to up-regulation of ULBP1 expression (Vankayalapati et al. 2005).

31.8.4 Autoimmune Disorders

Studies have shown that NK-DC interaction plays an important role in the induction of immune response against tumors and certain viruses. The effect of this interaction is bidirectional. Coculture with NK cells causes several fold increase in IL-12 production by *Toxoplasma gondii* lysate Ag-pulsed DC. In vitro blockade of NKG2D neutralizes the NK cell-induced up-regulation of DC response. Results emphasize the critical role played by NKG2D in the NK-DC interaction (Guan et al. 2007). A role for NKG2D has been indicated in several autoimmune diseases in humans and in animal models of type 1 diabetes (T1DM) and multiple sclerosis, and treatment with monoclonal antibodies to NKG2D attenuated disease severity in these models.

NKG2D in Progression of Autoimmune Diabetes: RAE-1 is present in prediabetic pancreas islets of NOD mice and the autoreactive $CD8^+$ T cells infiltrating the pancreas express NKG2D. Treatment with a nondepleting anti-NKG2D monoclonal antibody (mAb) during the prediabetic stage completely prevented disease by impairing the expansion and function of autoreactive $CD8^+$ T cells. These results suggest that NKG2D is associated with disease progression and suggest a new therapeutic target for autoimmune type I diabetes (Ogasawara et al. 2004).

Rheumatoid Arthritis: Stimulation of T cell autoreactivity by anomalous expression of NKG2D and its MIC ligands in rheumatoid arthritis has been suggested by Groh et al. (2003). With the reported expansion of peripheral $CD4^+CD28^-NKG2D^+$ T cells in rheumatoid arthritis (RA), this interaction is important in triggering autoimmunity. But in studies of Schrambach et al. (2007), despite occasional and indiscriminate expansion of incriminated T cell subpopulation, no correlation could be observed between the $CD4^+CD28^-NKG2D^+$ T cells and auto-immunity.

Moreover, in situ, the presence of NKG2D matched that of $CD8^+$, but not that of $CD4^+$ T cells (Schrambach et al. 2007).

NKG2D Does Not Differ in Systemic Lupus Erythematosus: Schepis et al. (2009) studied NK cells in SLE, a B-cell-driven systemic autoimmune disease and found that $CD56^{bright}$ NK cells increase in SLE patients, regardless of disease activity, in association with some increased expression of NKp46/CD335 on NK cells. Other receptors on lymphocytes or NKRs, including CD94, NKG2C/CD159c, NKG2D/CD314, NKp30/CD337, NKp44/CD336, CD69 did not differ between patient groups.

Sjögren's Syndrome: Izumi et al. (2006) found that NK cell number, NK cell killing activity, and NKG2D were significantly decreased, and the expression of NKp46, as well as the percentage of apoptotic NK cells, were significantly increased in primary Sjögren's syndrome (SS) patients compared with healthy controls. Data suggested that reduced NK cell numbers, probably a result of apoptotic death, might contribute to impaired NK cell activity in patients with primary SS.

NKG2D and Its Ligands in Allograft Transplant Rejection: The early "danger" signals associated with transplantation lead to rapid up-regulation of NKG2D ligands. A second wave of NKG2D ligand up-regulation is mediated by the adaptive immune response to allografts. Treatment with an Ab to NKG2D was highly effective in preventing CD28-independent rejection of cardiac allografts. Notably, NKG2D blockade did not deplete $CD8^+$ T cells or $NK1.1^+$ cells nor affect their migration to the allografts. Results suggest a functional role of NKG2D and its ligands in the rejection of solid organ transplants (Kim et al. 2007; Zhang and Stastny 2006).

Role of CD45 for Cytokine and Chemokine Production from Killing in Primary NK Cells: Engagement of receptors on the surface of NK cells initiates a biochemical cascade ultimately triggering cytokine production and cytotoxicity. Huntington et al. (2005) investigated the role of cell surface phosphatase CD45 in NK cell development and intracellular signaling from activating receptors. Stimulation via MHC class I-binding receptor, Ly49D on $CD45^{-/-}$ primary NK cells resulted in the activation of phosphoinositide-3-kinase and normal cytotoxicity but failed to elicit a range of cytokines and chemokines. This blockage was associated with impaired phosphorylation of Syk, Vav1, JNK, and p38, and mimics results obtained using inhibitors of the src-family kinases (SFK). These data, supported by analogous findings after CD16 and NKG2D stimulation of $CD45^{-/-}$ primary NK cells, place CD45 upstream of SFK in NK cells after stimulation via immunoreceptor tyrosine-based activation motif-containing receptors. Thus CD45 is a pivotal enzyme in eliciting a subset of NK cell responses.

Interaction Between Human NK Cells and Stromal Cells: It appears that HLA-I molecules do not protect bone marrow stromal cells (BMSC) from NK cell-mediated injury. But NK cells, activated upon binding with BMSC, may regulate BMSC survival (Poggi et al. 2005). While the NK receptors NKp30 and NKp46 are responsible for the delivery of lethal hit to APC, the NKG2D-activating receptor, the MICA, and the ULBP are involved in stromal cell killing. These events are dependent on the activation of phosphoinositol 3-kinase and consequent release of perforins and granzymes. Altogether, studies support the notion that NK cells can recognize self-cells possibly affecting both APC function and interaction between lymphocytes and microenvironment leading to autoreactivity (Poggi et al. 2007). Activated T cells become susceptible to autologous NK lysis via NKG2D/NKG2DLs interaction and granule exocytosis, suggesting that NK lysis of T lymphocytes via NKG2D may be an additional mechanism to limit T-cell responses (Cerboni et al. 2007; Coudert and Held 2006; Poggi et al. 2005).

31.9 Decidual/Placental NK Cell Receptors in Pregnancy

Inhibitory and Activating Receptors on Decidual/Placenta NK Cells: The interaction of decidual KIRs with on HLA-C trophoblast cells appears to block NK cytotoxicity against trophoblast cells. NK cell receptors protect the trophoblasts and the outcome of pregnancy depends on women's NKRs. Peripheral blood NK cells express CD56 surface antigen in low ($CD56^{dim}$) or high ($CD56^{bright}$) density. In contrast to $CD56^{bright}$ NK cells, $CD56^{dim}$ cells express KIR such as CD158a, CD158b, and NKB1. Evidences indicate that $CD56^{bright}$ cells are specialized NK cells that regulate immunological response mechanisms rather by cytokine supply than by their cytotoxic potential. The poor cytolytic capacity of $CD56^{bright}$ NK cells can be explained by weak ability in forming conjugates with target cells and low contents of perforin and granzyme A in their granules (Jacobs et al. 2001). The balance of inhibitory and activating NKRs on maternal decidual NK cells, most of which are $CD56^{bright}$, is thought to be crucial for the proper growth of trophoblasts in placenta.

In Recurrent Spontaneous Abortions (RSA): Women with alloimmune abortions have a limited inhibiting KIR repertoire and such miscarriages could occur because

trophoblastic HLA class I molecules are recognized by decidual NK cells lacking the appropriate inhibitory KIRs (Varla-Leftherioti et al. 2003). Ntrivalas et al. (2005) suggested that CD158a and CD158b inhibitory receptor expression by $CD56^{dim}/CD16^{+}$ and $CD56^{bright}/CD16^{-}$ NK cells were significantly decreased, and CD161-activating receptor expression by $CD56^{+}/CD3^{+}$ NKT cells was significantly increased in women with implantation failures when compared with normal controls, suggesting an imbalance between inhibitory and activating receptor expression on NK cells of women with implantation failures. The expression of CD94/NKG2, the receptor for HLA-E, on trophoblasts, motivated Kusumi et al. (2006) to investigate the expression patterns of inhibitory receptor CD94/NKG2A, and activating receptor, CD94/NKG2C, on decidual NK cells in early stage of normal pregnancy and to compare them with those on peripheral NK cells, most of which are $CD56^{dim}$. The rate of NKG2A-positive cells was significantly higher for decidual $CD56^{bright}$ NK cells than for peripheral $CD56^{dim}$ NK cells, but the rates of NKG2C-positive cells were comparable between the two cell types. Interestingly, peripheral $CD56^{dim}$ NK cells reciprocally expressed inhibitory NKG2A and activating NKG2C, but decidual $CD56^{bright}$ NK cells that expressed activating NKG2C simultaneously expressed inhibitory NKG2A. The co-expression of inhibitory and activating NKG2 receptors may fine-tune the immunoregulatory functions of the decidual NK cells to control the trophoblast invasion in constructing placenta (Kusumi et al. 2006).

Down-Regulation of NKG2D on PBMC by MICA and MICB: A novel mechanism for fetal evasion of maternal immune attack, based on the down-regulation of the activating NKR NKG2D on peripheral blood mononuclear cells (PBMC) by soluble MHC class I chain-related proteins A and B has been proposed. A similar immune escape pathway has been described in tumors. The MIC mRNA is constitutively expressed by human placenta and restricted to the syncytiotrophoblast on the apical and basal cell membrane and in cytoplasmic vacuoles as MIC-loaded microvesicles/exosomes. Simultaneously, the cell surface NKG2D expression on maternal PBMC was down-regulated compared with nonpregnant controls. The soluble MIC molecules in pregnancy serum were shown to interact with NKG2D and down-regulate the receptor on PBMC from healthy donors, with the consequent inhibition of the NKG2D-dependent cytotoxic response. These results suggested a new physiological mechanism of silencing the maternal immune system that promotes fetal allograft immune escape and supports the view of the placenta as an immunoregulatory organ (Mincheva-Nilsson et al. 2006).

Decidual NK Cells Are Not Cytotoxic: In early pregnancy, invading fetal trophoblasts encounter abundant maternal decidual (d) dNK cells. dNK express perforin, granzymes A and B and the activating receptors NKp30, NKp44, NKp46, NKG2D, and 2B4 as well as LFA-1. Even though they express essential molecules required for lysis, fresh dNK displayed very low lytic activity on classical MHC I negative targets K562 and 721.221. dNK formed conjugates and activating immune synapses with 721.221 and K562 cells in which CD2, LFA-1 and actin were polarized toward the contact site. However, in contrast to peripheral NK cells, they failed to polarize their microtubule organizing centers and perforin-containing granules to the synapse, accounting for their lack of cytotoxicity (Kopcow et al. 2005).

31.10 Regulation of NKG2D Functions

31.10.1 NKG2D Induction by Chronic Exposure to NKG2D Ligand

It seems that signaling capacity of NKG2D receptor complexed with ligands is altered. The prolonged encounter with tumor cell-bound, but not soluble, ligand can completely uncouple the receptor from mobilization of $(Ca^{2+})_i$ and the exertion of cell-mediated cytolysis. However, cytolytic effector function is intact since NKG2D ligand-exposed NK cells can be activated via Ly49D receptor. While NKG2D-dependent cytotoxicity is impaired, prolonged ligand exposure results in constitutive IFNγ production, suggesting sustained signaling. The functional changes are associated with a reduced presence of the relevant signal transducing adaptors DAP-10 and KARAP/DAP-12 (Coudert et al. 2005). Coudert et al. (2008) found that sustained NKG2D engagement induces cross-tolerization of several unrelated NK cell activation receptors. It was observed that receptors that activate NK cells via the DAP12/KARAP and DAP10 signaling adaptors cross-tolerize preferentially NK cell activation pathways that function independent of DAP10/12, such as antibody-dependent CMC and missing-self recognition. These results identify NK cell activation receptors that can tolerize mature NK cells (Coudert et al. 2008).

Inhibitory Role of Ly49 Receptors on NKG2D: The inhibitory role of Ly49 receptors on NKG2D-mediated activation has only started emerging. Evidence suggests that NKG2D-mediated cytotoxicity and cytokine production result from the fine balance between activating and inhibitory receptors, thereby defining the NK cell-mediated immune responses (Regunathan et al. 2005). It is hypothesised that NKG2D-mediated activation is a function of 'altering the balance' in the signaling strength between the activating NKG2D and inhibiting Ly49 receptors. Balance in the signaling strength depends on the expression levels of activating ligands on the

target cells. Qualitative and quantitative variations of MHC class I molecules expressed on the target cells also plays a major role in determining this 'altered-balance'. Consequently, the nature of Ly49 receptors expressed on specific NK subsets determines the level of NKG2D-mediated NK cell activation. These observations provide a firm basis of 'altered-balance' in NK signaling and describe an active interplay between inhibitory Ly49 and activating NKG2D receptors (Malarkannan 2006; Regunathan et al. 2005)

31.10.2 Effects of Cytokines and Other Factors

Elevated TGF-β1 Down-Regulates NKG2D Surface Expression: Lee et al. (2004) showed that TGF-β1 secreted by tumors is responsible for down-regulating of NKG2D and poor NK lytic activity. The elevated plasma level of TGF-β1in human lung and colorectal cancer patients compared with in normal controls was inversely related with surface expression of NKG2D on NK cells in these patients. In a murine model of head and neck squamous cell carcinoma (SCC VII/SF), SCC VII/SF tumors expressed high levels of TGF-β1, which were down-modulated by vaccination with rvv-IL-2 (Dasgupta et al. 2005). TGF-β is known to play a major role for the reduced expression of NKG2D in cancer patients. The protected expression of NKG2D by IL-2/IL-18 provides insight into the mechanism of NKG2D regulation (Song et al. 2006). An inverse correlation does exist between NK cell activation and $CD4^+CD25^+$ regulatory T (T_{reg}) cells expansion in tumor-bearing patients. Results indicated that T_{reg} cells expressed membrane-bound TGF-β, which directly inhibited NK cell effector functions and down-regulated NKG2D receptors on the NK cell surface. Thus T_{reg} cells generated during tumor growth can blunt the NK cell functions of the innate immune system (Ghiringhelli et al. 2005).

Interleukin-15 stimulates NKG2D: IL-15 is the major physiologic growth factor responsible for NK cell differentiation, survival and cytolytic activity of mature NK cells. The IL-15 treatment increases NKG2D transcripts and surface expression in NK cells. The up-regulatory effect of IL-15 on NK cytolysis is partly dependent on the interaction of NKG2D and MICA (Zhang et al. 2008b). IL-15 activates peripheral blood mononuclear cells to lyse *Cryptosporidium*-infected epithelial cells. Flow cytometry revealed that IL-15 increased expression of NKG2D on NK cells. Thus, IL-15 has an important role in activating an NK cell-mediated pathway that leads to the elimination of intracellular protozoans from the intestines (Dann et al. 2005). Results also indicate that the pro-inflammatory cytokines (IL-2, IL-15 and IL-21) can modify the peripheral repertoire of NK cells (de Rham et al. 2007).

Interleukin-12, 18 and 21: IL-12 improves cytotoxicity of NK cells and expression of NKG2D. IL-12, produced primarily by APCs, plays an important role in the interaction between the innate and adaptive arms of immunity acting upon T and NK cells to generate CTLs. Ortaldo et al. (2006) demonstrated that cross-linking of NKG2D and NK1.1 results in a synergistic NK IFN- IFNγ response when combined with IL-12 or IL-18. Multiple convergent signals maximize the innate immune response by triggering complementary biochemical signaling pathways (Ortaldo et al. 2006; Zhang et al. 2008a).

IL-21 mediates its biological effects via the IL-21R in conjunction with the common receptor γ-chain that is also shared by members of the IL-2 family. Human primary NK and $CD8^+$ T cells with IL-21 in combination with IL-2- results in significant reduction of surface expression of NKG2D, compared with that in cells treated with IL-2 alone. This was attributed to a dramatic reduction in DAP10 promoter activity. In contrast to NKG2D expression, IL-21 was able to induce the expression of the NK activation receptors NKp30 and 2B4 as well as the co-stimulatory receptor CD28 on $CD8^+$ T cells (Burgess et al. 2006). IL-21 has a synergistic effect by increasing the numbers of NK cells on a large scale. IL-2 and IL-15 may induce the expression of KIRs, the NKG2D and NKp31. Findings indicated that the pro-inflammatory cytokines IL-21 and others (IL-2 and IL-15) can modify the peripheral repertoire of NK cells (de Rham et al. 2007). IL-21 can promote the anti-tumor responses of the innate and adaptive immune system. Mice treated with IL-21 reject tumor cells more efficiently, and a higher percentage of mice remain tumor-free compared with untreated controls. In certain tumor models, IL-21-enhanced tumor rejection is NKG2D dependent. IL-21 therapy may work optimally against tumors that can elicit a NKG2D-mediated immune response (Takaki et al. 2005).

Other Factors: NKG2D, expressed on γδ T cells participates in demyelination since blockade of NKG2D interactions in vivo resulted in 60% reduction in demyelination (Dandekar et al. 2005). All-trans retinoic acid (ATRA), a metabolite of vitamin A plays an important role in regulating immune responses. ATRA suppressed cytotoxic activities of NK92 cells without affecting their proliferation. It suppressed NF-kB activity and prevented IkBα degradation in a dose-dependent way, inhibited IFN-γ production and gene expression of granzyme B and NKp46 (Li et al. 2007). Activation of NK cells is triggered by multiple receptors. SLP-76 is required for CD16- and NKG2D-mediated NK cell cytotoxicity, while MIST negatively regulates these responses in an SLP-76-dependent manner (Hidano et al. 2008). Tryptophan (Trp) catabolism mediated by indoleamine 2,3-dioxygenase (IDO) plays a central role in the regulation of T-cell-mediated

immune responses and NK-cell functions. The effect of l-kynurenine appears to be restricted to NKp46 and NKG2D, while it does not affect other surface receptors such as NKp30 or CD16 (Della Chiesa et al. 2006).

31.11 Role in Immunotherapy

Requirement of DNAM-1, NKG2D, and NKp46 in NK Cell-Mediated Killing of Myeloma Cells: Ovarian carcinoma cells display ubiquitous expression of DNAX accessory molecule-1 (DNAM-1) ligand PVR and sparse/heterogeneous expression of MICA/MICB and ULBP1, ULBP2, and ULBP3. In line with the NK receptor ligand expression profiles, antibody-mediated blockade of activating receptor pathways revealed a dominant role for DNAM-1 and a complementary contribution of NKG2D signaling in tumor cell recognition. Thus, resting NK cells are capable of directly recognizing ovarian carcinoma as a potential target for adoptive NK cell-based immunotherapy (Carlsten et al. 2007). DNAM-1 is also important in the NK cell-mediated killing of myeloma cells expressing the cognate ligands (El-Sherbiny et al. 2007). Heat shock proteins (HSPs) are known activate both adaptive and innate immune responses. Vaccination with autologous tumor-derived HSP96 of colorectal cancer patients, radically resected for liver metastases, induced a significant boost of NK activity detected as cytokine secretion and cytotoxicity in the presence of NK-sensitive targets. Increased NK activity was associated with an enhanced expression of NKG2D and/or NKp46 receptors (Pilla et al. 2005).

Immunotherapy with Chimeric NKG2D Receptors: Adoptive transfer of tumor-reactive T cells is a promising antitumor therapy for many cancers. Adoptive transfer of selected populations of alloreactive HLA class I-mismatched NK cells in combination with pharmacologic induction of NKG2D-ligands merits clinical evaluation as a new approach to immunotherapy of human acute myeloid leukemia (AML) (Diermayr et al. 2008). Barber et al. designed a chimeric receptor linking NKG2D to the CD3ζ chain of the T-cell receptor to target ovarian tumor cells. More than 80% of primary human ovarian cancer samples express ligands for NKG2D on the cell surface. Engagement of chimeric NKG2D receptors (chNKG2D) with ligands for NKG2D leads to T-cell secretion of proinflammatory cytokines and tumor cytotoxicity. ChNKG2D-expressing T cells lysed ovarian cancer cell lines. T cells from ovarian cancer patients that express chNKG2D secrete proinflammatory cytokines when cultured with autologous tumor cells. chNKG2D T cells can be used therapeutically in a murine model of ovarian cancer and offer potential application as immunotherapy for ovarian cancer (Barber et al. 2007). Most myeloma tumor cells express NKG2D ligands and respond to human chNKG2D T cells. The chNKG2D T cells can be generated with serum-free media, and maintained effector functions on cryopreservation (Barber et al. 2008a). The chNKG2D T-cell-mediated therapeutic effects were mediated by both cytokine-dependent and cytotoxic mechanisms in vivo (Zhang et al. 2007). Specifically, chNKG2D T cell expression of perforin, GM-CSF, and IFN-γ were essential for complete antitumor efficacy (Barber et al. 2008b).

Regulatory T Cells Suppress NK Cell-Mediated Immunotherapy: $CD4^+CD25^+$ regulatory T cells (Treg) that suppress T cell-mediated immune responses may also regulate other arms of an effective immune response. In particular, T_{reg} directly inhibit NKG2D-mediated NK cell cytotoxicity in vitro and in vivo, effectively suppressing NK cell-mediated tumor rejection. In vitro, T_{reg} were shown to inhibit NKG2D-mediated cytolysis largely by a TGF-β-dependent mechanism and independently of IL-10. Adoptively transferred T_{reg} suppressed NK cell antimetastatic function in RAG-1-deficient mice. Depletion of T_{reg} before NK cell activation via NKG2D and the activating IL-12 cytokine dramatically enhanced NK cell-mediated suppression of tumor growth and metastases. The study shows at least one mechanism by which T_{reg} can suppress NK cell antitumor activity and requirement of subsequent NK cell activation to promote strong innate anti-tumor immunity (Smyth et al. 2006; Roy et al. 2008).

Rajesh K. Gupta and G.S. Gupta

In earlier Chapters we discussed mouse and human NK cell lectin receptors which can deliver inhibitory or activatory NK cell cytotoxicity in presence or absence of MHC-I molecules. Among non-lectin inhibitory receptors, killer immunoglobulin (Ig)-like receptors (KIRs) recognize different allelic groups of HLA-A, -B or -C molecules. Immunoglobulin-like transcript 2 (ILT2 or LIR1 or CD85j) receptors are more 'promiscuous', as they recognize a large number of HLA class I alleles, while CRD containing CD94-NKG2A recognizes HLA-E, an HLA class I molecule with a limited polymorphism. It is well known that various HLA class I alleles provide signal sequence peptides that bind HLA-E and enable it to be expressed on the cell surface. Importantly, each type of KIR is expressed only by a subset of NK cells (Braud et al. 1998). A common characteristic of the various HLA class I-specific inhibitory receptors is the presence, in their cytoplasmic tail, of ITIM that enable them to recruit and activate SHP-1 and SHP-2-phosphatases (Moretta et al. 2001; Lanier 1998). In turn, these phosphatases switch off the activating signaling cascade initiated by the various activating receptors (Moretta and Moretta 2004). In this chapter we continue discussing cytotoxic receptors which do not depend on HLA antigens for their action and do not contain ITIM motif in their cytoplasmic tail as well as activating NK cell receptors which are of recent origin but do not contain lectin-like domain till date.

32.1 Killer Cell Lectin-Like Receptor F-1 (NKG2F/KLRC4/*CLEC5C*/NKp80)

32.1.1 NKp80 or Killer Cell Lectin-Like Receptor Subfamily F-Member 1 (KLRF1)

Killer cell lectin-like receptor subfamily F-member 1 (KLRF1), also known as KLRC4 or NKp80, is a human gene which is localized 25 kb from NKG2-A (Roda-Navarro et al. 2000) and related to NKG2-D cDNA on the high-resolution physical map of chromosome 12p. It encodes a putative type II transmembrane glycoprotein. The 3′ end of NKp80/KLRC4/KLRF1 transcript includes the first non-coding exon found at the 5′ end of the adjacent D12S2489E gene transcript (Renedo et al. 2000). The genomic structure of the NKp80/KLRF1 gene and the existence of one spliced variant have been described. It is expressed at the mRNA level in peripheral blood leukocytes, activated NK cells, monocytes and NK and myeloid cell lines. NKp80, a C-type lectin-like receptor, stimulates the cytotoxicity of NK cells and releases cytokine. Roda-Navarro et al. described the existence of one alternative spliced form, lacking the stalk region of the extracellular domain and two novel KLRF1 alternative spliced variants coding for truncated proteins lacking the C-type lectin-like domain (Plougastel and Trowsdale 1998a, b; Roda-Navarro et al. 2001). A conserved 24-amino acid sequence, present in all members of the NKG2 family, suggests that NKG2-F is also able to form heterodimers with CD94 (Plougastel and Trowsdale 1998a, b).

NKp80 is a type II transmembrane protein of 231 amino acids identical to the putative protein encoded by a cDNA termed KLRF1 (Vitale et al. 2001) (Fig. 32.1). NKp80 is protein with a C-type lectin domain in its extracellular region. NKp80 is expressed at the cell surface as a dimer of ~80 kDa on virtually all NK cells and by a minor subset of T cells characterized by the CD56 surface antigen and shown to function as a co-receptor rather than as true receptor with natural cytotoxicity receptors (NCR) to induce activation of NK cell-mediated cytotoxicity. NKp80 surface expression was also detected in all $CD3^-$ and in 6/10 $CD3^+$ large granular lymphocyte expansions derived from patients with lympho-proliferative disease of granular lymphocytes. mAb-mediated cross-linking of NKp80 resulted in induction of cytolytic activity and Ca^{2+} mobilization. The NKp80 recognizes a ligand on normal T cells that may be down-regulated during tumor transformation. Indeed, it induces natural cytotoxicity only when co-engaged with a triggering receptor (Vitale et al. 2001). NK cells in monkeys were generally identified by negative selection of peripheral

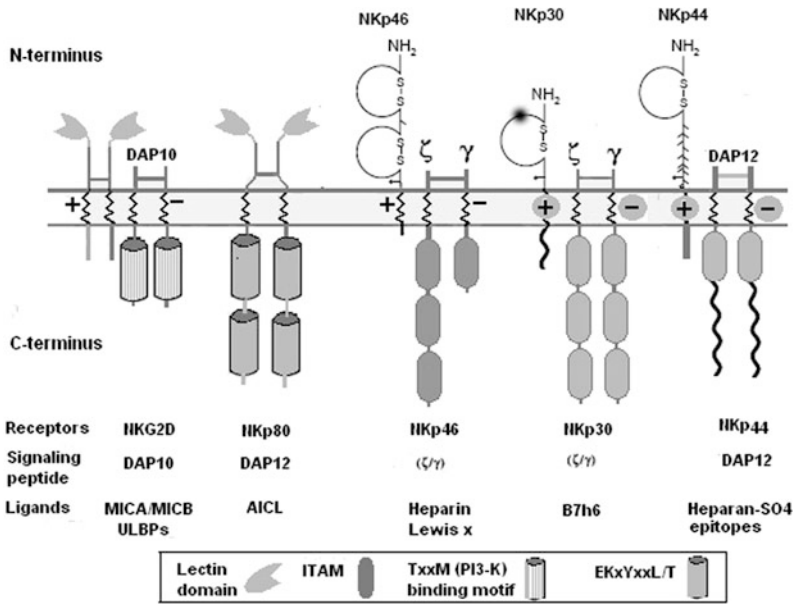

Fig. 32.1 Activating NK cell receptors and co-receptors and their cellular ligands. The Figure illustrates the molecular structure of the NK receptors NKG2D, NKp80, NKp46, NKp30, NKp44. Their interaction with signaling polypeptides or with relevant cytoplasmic molecules is also shown

blood mononuclear cells (PBMCs) for the absence of T-cell, B-cell, and monocyte markers.

32.1.1.1 Triggering Receptors in Sub-Human Primate NK Cells

Mavilio et al. (2005) indicated that mAb-mediated ligation of NKp80 induced NK cell cytotoxicity, while NKG2A inhibited the lysis of target cells by NK cells from macaques, as well as from humans. This phenotypic and functional characterization of NKG2A and NKp80 in rhesus and pig-tailed macaque NK cells is useful in the analysis of their innate immune system. Both M. fascicularis and M. mulatta NK cells express NKp80, which displayed a high degree of sequence homology with their human counterpart. Analysis of NK cells in simian HIV-infected M. fascicularis revealed reduced surface expression of selected NK cell-triggering receptors associated with a decreased NK cell function only in some animals (Biassoni et al. 2005). Functional characterization for NKp46, NKp30, NKp80, and NKG2D on Pan troglodytes NK cells revealed that, in this AIDS-resistant species, relevant differences to human NK cells involve NKp80 and particularly NKp30, which is primarily involved in NK-DC interactions (Rutjens et al. 2007).

32.1.2 NKp80/KLRF1 Associates with DAP12

The presence of two ITIM within the cytoplasmic tail of NKp80/KLRF1 suggests an inhibitory role in NK cell and monocyte activity. NKG2F/KLRF1 is an orphan gene within the NKG2 family whose translated product would contain both a positively charged residue in its transmembrane region, an intracellular ITIM-like sequence (YxxL) and an extracellular domain (62 residues) that is truncated relative to other NKG2 molecules. Expression of NKp80/KLRF1 appears to be confined to intracellular compartments probably due to its inability to associate with CD94. It can, however, associate with DAP12 thereby providing activation signaling potential. Since it was not possible to demonstrate phosphorylation of Tyr residue in the ITIM-like motif, it was suggested that it is a mock ITIM. NKG2F, a receptor component with an unidentified partner(s), can regulate cell activation through competition for DAP12 with other receptors, such as NKG2C and -E/H, or it could simply be a vestigial gene product (Kim et al. 2004). Using the NK cell line NK92MI, Dennehy et al. (2011) demonstrated that NKp80, but not NKp80 mutated at tyrosine 7 (NKp80/Y7F), is tyrosine phosphorylated. Accordingly, NKp80/Y7F, but not NKp80/Y30F or NKp80/Y37F, failed to induce cytotoxicity. Altogether, report suggests that NKp80 uses an atypical hemi-ITAM and Syk kinase to trigger cellular cytotoxicity (Fig. 32.1).

32.2 Activation-Induced C-Type Lectin (CLECSF2): Ligand for NKp80

Thomas et al. (2008) demonstrated that the ligand for NKp80 is the myeloid-specific CTLR activation-induced C-type lectin (AICL), which is encoded in the natural killer gene complex (NKC) adjacent to NKp80. Hamann et al. (1997) cloned a cDNA of a molecule, designated activation-induced C-type lectin (AICL), whose gene maps to the human NKC proximal to the CD69 gene. AICL is a myeloid-specific activating orphan receptor that is upregulated by Toll-like receptor stimulation. AICL is a 149-amino acid polypeptide with a

short cytoplasmic tail of seven amino acids and a C-type lectin domain separated from the transmembrane region by only nine amino acids. The AICL shows highest sequence similarity to the domains of CD69 and the 17.5 chicken-like lectin. NKp80 binds to the genetically linked receptor AICL, which, like NKp80, is absent from rodents. AICL-NKp80 interactions promote NK cell-mediated cytolysis of malignant myeloid cells. In addition, during crosstalk between NK cells and monocytes, NKp80 stimulated the release of proinflammatory cytokines from both cell types. Thus, NKp80-AICL interactions may contribute to the initiation and maintenance of immune responses at sites of inflammation (Welte et al. 2006). The Kaposi's sarcoma-associated herpesvirus (KSHV) immune evasion gene, K5, reduces cell surface expression of AICL. Down-regulation of AICL requires the ubiquitin E3 ligase activity of K5 to target substrate cytoplasmic tail lysine residues. The down-regulation of ligands for both the NKG2D and NKp80 activation pathways provides KSHV with a powerful mechanism for evasion of NK cell antiviral functions (Thomas et al. 2008).

The AICL is also expressed on a minor fraction of human $CD8^+$ T cells that exhibit a high responsiveness and an effector memory phenotype. The $NKp80^+$ T-cell subset is characterized by the co-expression of other NK receptors and NKp80 ligation augmentes CD3-stimulated degranulation and IFNγ secretion by effector memory T cells. Hence, NKp80 may enable effector memory CD8 T cells to interact functionally with cells of myeloid origin at sites of inflammation (Kuttruff et al. 2009).

32.3 KLRG1 (Rat MAFA/CLEC15A or Mouse 2F1-Ag)

32.3.1 Mast Cell Function-Associated Antigen (MAFA)

The mAb G63 identified a membrane component of mast cells, called as mast cell function-associated antigen (MAFA). Mast cell antigen is a glycoprotein with an M_r of 28–40 kDa, and is present on the surface of rat mucosal and serosal mast cells. Its density on cells of the mucosal mast cell line RBL-2H3 is $1–2 \times 10^4$ copies per cell. Cross-linking of this protein by mAb G63 results in the inhibition of Fc ε RI-mediated secretion of RBL-2H3 cells and inhibits biochemical processes initiated by FcεRI aggregation, such as the hydrolysis of phosphatidylinositides, the influx of Ca^{2+} ions, and the synthesis and release of inflammatory mediators and in redistribution of the membrane component recognized by G63 (Ortega et al. 1991). Based on MAFA density the rat mucosal mast cell line, RBL-2H3, can be classified into two subpopulations: cells carrying either high or low density of a MAFA (Cohen-Dayag et al. 1992). The MAFA is expressed at a ratio of approximately 1:30 with respect to the Type I FcεRI on rat mast cell line. Despite this stoichiometry, clustering MAFA by its specific mAb G63 substantially inhibits secretion of both granular and de novo synthesized mediators induced upon FcεRI aggregation. Since the FcεRIs apparently signal from within raft micro-environments, Barisas et al. (2007) investigated co-localization of MAFA within these membrane compartments containing aggregated FcεRI and suggested for constitutive interactions between FcεRI and MAFA.

32.3.2 MAFA Is a Lectin

The recombinant MAFA (rMAFA) was expressed as a monomeric and disulfide-linked homodimeric glycoprotein in the membrane of insect cells. The rMAFA binds specifically the terminal mannose residues in a Ca^{2+}-dependent manner. Results support the notion that the extracellular domain of the MAFA is able to bind ligands, which may be modulatory for the mast cell response (Binsack and Pecht 1997). The MAFA interferes with the coupling cascade of the type 1 FcεR upstream to PLCγ1 activation by protein-tyrosine kinases. The MAFA cDNA shows that MAFA contains a single ORF, encoding a 188-amino acid-long type II integral membrane protein. The 114C-terminal amino acids display sequence homology with the CRD of calcium-dependent animal lectins. The cytoplasmic tail of MAFA contains a YXXL (YSTL) motif, which is conserved among related C-type lectins and is an ITIM. Changes in the MAFA tyrosyl- and seryl-phosphorylation levels are observed in response to binding of mAb G63, antigenic stimulation, and a combination of both treatments (Guthmann et al. 1995b). The high conservation of cysteinyl residues suggests an important role for intrachain disulfide bonds in attaining its structure and biological activity. The MAFA clustering by G63 inhibits the de novo synthesis and secretion of IL-6 induced by the FcεRI stimulus. Experiments suggested that MAFA might have a role in cell adhesion in addition to its immunomodulatory capacity (Guthmann et al. 1995a).

32.3.3 Interactions of MAFA with FcεR

The nature of MAFA-FcεRI interactions giving rise to this inhibition remains unclear. By time-resolved phosphorescence anisotropy, Song et al. (2002) studied the rotational behavior of both MAFA and FcεRI as ligated by various reagents involved in FcεRI -induced degranulation and MAFA-mediated inhibition there of. Clustering the FcεRI-IgE complex by antigen or by anti-IgE increases the

phosphorescence anisotropy of G63 Fab and slows its rotational relaxation. Studies indicated that unperturbed MAFA associates with clustered FcεRI (Song et al. 2002).

Clustering of MAFA Induces Tyrosyl Phosphorylation of the FcεRI-β Subunit: Clustering of MAFA on the surface of rat mucosal mast cells RBL-2H3 leads to suppression of the secretory response induced by FcεRI. The MAFA is located in the vicinity of the FcεRI on resting cells, and clustering of Fcε RI leads to no significant change in the proximity of the two molecular species. Reports suggest that the secretory response inhibition by MAFA interferes with the signal transduction cascade initiated via the FcεRI (Jürgens et al. 1996). The inhibition was found to take place upstream to the production of inositol phosphates and the transient increase in free cytosolic Ca^{2+} ion concentration. Hence it probably interferes with the cascade at the level of the protein tyrosyl kinases (PTK) activity (Schweitzer-Stenner et al. 1999).

Studies indicate that MAFA's inhibitory action involves at least two different enzymes: Following the tyrosyl-phosphorylation of MAFA ITIM by the PTK Lyn, two phosphatases SHIP and SHP2 are recruited at the plasma membrane where they propagate the inhibitory signals. The inhibition has been shown to take place upstream to the production step of inositol phosphates in the FcεRI coupling cascade. Syk tyrosine phosphorylation and activation, as well as LAT (linker for activation of T cells) tyrosine phosphorylation, both induced by FcεRI clustering, were found to be reduced upon MAFA clustering. In contrast, the activity of the SH2-containing protein tyrosine phosphatase (SHP-2) increased. Reports suggest that one possible mechanism by which MAFA affects the FcεRI stimulation cascade is suppression of Syk activity, i.e. MAFA clustering leads SHP-2 to act on Syk, thereby reducing its tyrosine phosphorylation and its activity (Abramson et al. 2002; Xu et al. 2001). MAFA has also a capacity of modulating the cell cycle of RBL-2H3 line and cell proliferation rate by inhibiting RasGTP formation in the Ras signaling pathway (Abramson et al. 2002; Licht et al. 2006).

Inhibition of FcεRI-Induced de Novo Synthesis of Mediators by MAFA: Aggregation of the type 1 Fc-ε-RI on mast cells initiates a network of biochemical processes culminating in secretion of both granule-stored and de novo-synthesized inflammatory mediators. A strict control of this response is obviously a necessity. MAFA selectively regulates the FcεRI stimulus–response coupling network and the subsequent de novo production and secretion of inflammatory mediators. Specifically, MAFA suppresses the PLC-γ2-[Ca^{2+}]i, Raf-1-Erk1/2, and PKC-p38 coupling pathways, while the Fyn-Gab2-mediated activation of PKB and Jnk is essentially unaffected. Hence, the activities of several transcription/nuclear factors for inflammatory mediators (NF-kB, NFAT) are markedly reduced, while those of others (Jun, Fos, Fra, p90rsk) are unaltered. This results in a selective inhibition of gene transcription of cytokines including IL-1beta, IL-4, IL-8, and IL-10, while that of TNF-alpha, MCP-1, IL-3, IL-5, or IL-13 remains unaffected. These results illustrate the capacity of an ITIF-containing receptor to cause tight and specific control of the production and secretion of inflammatory mediators by mast cells (Abramson et al. 2006).

32.3.4 MAFA Gene

MAFA is encoded by a single-copy gene that spans 13 kb in the rat genome and is composed of five exons. Three separate exons encode the CRD of the MAFA, defining its close homology to the genes of CD23, CD69, CD72, NKR-P1, and Ly49. Analysis of the 5′ flanking region of the gene reveals that a cell type-specific promoter is located within the first 664 bp upstream of the transcription origin. The promoter lacks any obvious TATA box and drives gene transcription originating from multiple start sites. Examination for possible polymorphism of the MAFA transcripts revealed two transcripts, generated by alternative splicing. The transcription of the MAFA gene was detected in normal rat lungs, where both transmembranal and soluble MAFA appear to be expressed. Lung immunohistochemical analysis further suggests that MAFA expression is restricted to mast cells.

32.4 KLRG1 (OR 2F1-AG): A Mouse Homologue of MAFA

32.4.1 KLRG1: A Mouse Homologue of MAFA

The KLRG1or formarly known as 2F1-AG or MAFA is expressed by NK cells and memory T cells in man and mice. A mAb (2F1), specific for mouse NK cells, recognized the mouse homolog of MAFA that is expressed on rat mast cells. The 2F1 antigen (2F1-Ag) and rat MAFA are highly conserved and contain a cytoplasmic ITIM used in inhibitory signaling. The human homologue is closely related to the rodent MAFA/2F1-Ag proteins. Like rat MAFA, 2F1-Ag is probably encoded by a single gene, which exhibits relatively little polymorphism. While rat MAFA is considered a mast cell antigen, it was not possible to detect cell surface expression of 2F1-Ag by mouse mast cell lines, bone marrow-derived mast cells, or peritoneal mast cells. However, mouse bone marrow-derived mast cells were devoid of 2F1-Ag mRNA. Instead, 40% of mouse NK cells express 2F1-Ag (Hanke et al. 1998).

The mouse MAFA (mMAFA) gene expression is strongly induced in effector $CD8^+$ T cells and lymphokine-activated NK cells but not in effector $CD4^+$ T cells and in mouse mast cells. Moreover, mMAFA gene expression was only found in effector $CD8^+$ T cells that had been primed in vivo with live virus because in vitro activated $CD8^+$ T cells did not express mMAFA. Sequence comparison revealed a high degree of conservation (89% similarity) between rat MAFA and mMAFA (Blaser et al. 1998). Using a mAb (2F1), Corral et al. (2000) characterized a mouse NK cell KLRG. KLRG1 is expressed on 30–60% of murine NK cells, and a small fraction of T cells, and is composed of a homodimer of glycosylated 30–38-kDa subunits. Cell surface expression of KLRG1 by NK cells is down-regulated in mice deficient for expression of class I molecules, in contrast to the Ly49 lectin-like NK receptors, which are up-regulated in class I-deficient mice. KLRG1 does not bind class I molecules in a cell-cell adhesion assay. Transgenic expression of KLRG1 was unaffected by class I deficiency, indicating that class I molecules do not affect the KLRG1 protein directly, and suggesting that regulation is at the level of expression of the endogenous KLRG1 gene. Evidence showed that class I molecules regulate KLRG1 via interactions with inhibitory Ly49 molecules and SHP-1 signaling (Corral et al. 2000). The KLRG1 is an inhibitory C-type lectin expressed on NK cells and activated CD8 T cells. The mouse gene spans about 13 kb and consists of five exons. Short interspersed repeats of the B1 and B2 family, a LINE-1-like element, and a (CTT)170 triplet repeat were found in intron sequences. In contrast to human KLRG1 and to the murine KLR family members, mouse KLRG1 locates outside the NK complex on Chromosome 6 between the genes encoding CD9 and CD4 (Voehringer et al. 2001).

32.4.1.1 KLRG1 on Effector and Memory CD8 T Cells

KLRG1 was present on 1–3% of adult splenic CD8 cells that expressed CD8αβ heterodimers as well as a polyclonal TCR Vβ repertoire indicative of conventional CD8 cells and $CD8^+$ effector/memory cells that can secrete cytokines but have poor proliferative capacity. Spontaneous IFN-γ production by approximately 20% of $KLRG1^+$ CD8 cells identified them as pro-inflammatory effector cells. In contrast to NK cells, Ly49 and KLRG1 expression on CD8 cells was found to be mutually exclusive. KLRG1 triggering interferes with TCR αβ -mediated Ca^{2+} mobilization and cytotoxicity, raising the possibility that KLRG1 functionally participates in down-regulation of CD8 T cell responses (Beyersdorf et al. 2001). Furthermore, $CD8^+$ cells expressing CD57, a marker of replicative senescence, also expressed KLRG1 and a population of $CD57^-KLRG1^+$ cells has also been identified. The combination of KLRG1 and CD57 expression might thus aid in refining functional characterization of $CD8^+$ T cell subsets (Ibegbu et al. 2005). KLRG1 expression is dramatically induced on $CD8^+$ T cells during both a viral and a parasitic infection. The engagement of KLRG1 on a transfected NK cell line inhibits both cytokine production and NK cell-mediated cytotoxicity (Robbins et al. 2002, 2003).

The acquisition of the NK cell inhibitory markers NK1.1 and KLRG on T cells exposed to high numbers of DCs suggests a role for these molecules in the protection of antigen-responsive T cells from exhaustion by overstimulation. Using a mAb for human KLRG1, Voehringer et al. (2002) identified human T cells that are capable of secreting cytokines but fail to proliferate after stimulation. Furthermore, the lack of proliferative capacity of CD8 T cells correlates better with KLRG1 expression than with absence of the CD28 marker.

32.4.1.2 Characterization of Mouse CD4 T Cell Subsets Defined by Expression of KLRG1

In normal mice, while a polyclonal TCR repertoire suggests thymic origin of $KLRG1^+$ $CD4^+$ cells, KLRG1 expression was found to be restricted to peripheral $CD4^+$ T cells. Based on phenotypic analyses, a minority of $KLRG1^+$ $CD4^+$ cells are effector/memory cells with a proliferative history. The majority of $KLRG1^+$ $CD4^+$ cells are, however, bonafide Treg cells that depend on IL-2 and/or CD28 and express both FoxP3 and high levels of intracellular CD152. KLRG1 expression represents a distinctive subset of senescent effector/memory and potent regulatory $CD4^+$ T cells (Beyersdorf et al. 2007).

$CCR7^+$ central memory (T_{CM}) $CD4^+$ T cells play a central role in long-term immunological memory. Reports indicate that a proportion of $CD4^+$ T_{CM} is able to produce effector cytokines. Stubbe et al. (2008) characterized cytokine-producing human $CD4^+$ T_{CM} specific for cleared protein and persistent viral Ag. The type of Ag stimulation is the major determinant of $CD4^+$ T_{CM} differentiation. CMV-specific T_{CM} were significantly more differentiated than protein Ag-specific T_{CM} and included higher proportions of IFN-γ-producing cells. The expression of KLRG1 by protein Ag- and CMV-specific T_{CM} was associated with increased production of effector cytokines. $KLRG1^+$ T_{CM} expressing high levels of CD127 suggests that they can survive long term under the influence of IL-7 (Stubbe et al. 2008). Studies with hepatitis C virus (HCV)-specific $CD8^+$ T also demonstrated central memory ($CCR7^+$) and early-differentiated phenotypes of HCV-specific $CD8^+$ T cells (Bengsch et al. 2007).

32.4.1.3 KLRG1 in Cord Blood

Umbilical cord blood T cells in humans represent a homogenous pool of naive T cells. However, analysis of KLRG1 expression in cord blood revealed an unexpected heterogeneity of human T cells in newborns. A substantial subsets of

CD4 (30%) and CD8 (20%) αβ T cells in cord blood expressed KLRG1. In contrast to T cells in adult, $KLRG1^+$ T cells in cord blood exhibited predominantly a naive $CCR7^+CD45RA^+$ and $CD11a^{low}$ phenotype. After birth, KLRG1 expression in T cells from peripheral blood decreased rapidly to reappear in effector/memory T cells in adults. $KLRG1^+$ T cells in cord blood expressed a diverse T cell receptor β repertoire and the cells proliferated normally, in contrast to $KLRG1^+$ T cells from adults (Marcolino et al. 2004). In naive C57BL/6 mice KLRG1 is expressed on a subset of $CD44^{high}CD62L^{low}$ T cells. KLRG1 expression can be detected on a small number of Vα14*i* NK T cells but not on $CD8\alpha\alpha^+$ intraepithelial T cells that are either $TCR\gamma\delta^+$ or $TCR\alpha\beta^+$ (Eberl et al. 2005).

32.4.1.4 ER Stress Regulator XBP-1 Contributes to Effector CD8+ T Cell Differentiation During Acute Infection

The transcription factor X-box-binding protein-1 (XBP-1) plays an essential role in activating the unfolded protein response in the ER. The IRE-1/XBP-1 pathway is activated in effector $CD8^+$ T cells during acute infection. An XBP-1 splicing reporter was enriched in terminal effector cells expressing high levels of KLRG1. Over-expression of the spliced form of XBP-1 in $CD8^+$ T cells enhanced KLRG1 expression during infection, whereas XBP-$1^{-/-}$ $CD8^+$ T cells or cells expressing a dominant-negative form of XBP-1 showed a decreased proportion of $KLRG1^{high}$ effector cells. These results suggest that, in the response to pathogen, activation of ER stress sensors and XBP-1 splicing contribute to the differentiation of end-stage effector $CD8^+$ T cells (Kamimura and Bevan 2008).

32.4.1.5 Viral and Bacterial Infections Induce Expression of Multiple NK Cell Receptors in Responding $CD8^+$ T Cells

Viral infections are often accompanied by extensive proliferation of reactive CD8 T cells. NK cell receptors are also expressed by certain memory phenotype $CD8^+$ T cells, and in some cases are up-regulated in T cells responding to viral infection. The majority of pathogen-specific $CD8^+$ T cells initiated expression of the inhibitory CD94/NKG2A heterodimer, the KLRG1 receptor, and a murine NK cell marker (10D7); very few Ag-specific T cells expressed Ly49 family members. The up-regulation of these receptors was independent of IL-15 and persisted long after clearance of the pathogen. Thus, CD94/NKG2A expression is a common consequence of $CD8^+$ T cell activation (McMahon et al. 2002).

After a defined number of divisions, normal somatic cells enter a nonreplicative stage termed senescence. The KLRG1 is a unique marker for replicative senescence of murine CD8 T cells. KLRG1 expression is induced in a substantial portion (30–60%) of CD8 T cells in C57BL/6 mice infected with lymphocytic choriomeningitis virus (LCMV), vesicular stomatitis virus, or vaccinia virus. Similarly, KLRG1 was found on a large fraction of LCMV gp33 peptide-specific TCR-transgenic (tg) effector and memory cells activated in vivo using an adoptive transfer model. Thus study demonstrates that senescent CD8 T cells are induced in abundant numbers during viral infections in vivo (Voehringer et al. 2001).

The frequency of $CD8^+$ T cells expressing KLRG1, unable to undergo further clonal expansion, was markedly elevated in $CD8^+$ T cells from old donors. Moreover, the elevated frequency of CMV-specific $CD8^+$ T cells in the elderly was due to an accumulation of cells bearing this dominant negative receptor. The fraction of CMV-specific T cells able to secrete IFN-γ after specific antigenic stimulation was significantly lower in the elderly than in the young, although the total number of functional cells was comparable. Therefore, the majority of the clonally expanded virus-specific $CD8^+$ cells in the elderly was dysfunctional. Thus, T cell responses are altered in the aged by an accumulation of replicatively senescent dysfunctional T cells carrying receptors for persistent herpes viruses (Ouyang et al. 2003).

The repetitive and persistent antigen stimulation leads to an increase in KLRG1 expression of virus-specific $CD8^+$ T cells in mice and that virus-specific $CD8^+$ T cells are mostly $KLRG1^+$ in chronic human viral infections (HIV, cytomegalovirus, and Epstein-Barr virus) while $CD8^+$ T cells targeting resolved viral antigens (influenza virus) typically display high CD127 and low KLRG1 expressions. Thus, by using KLRG1 as a T-cell marker, results suggest that the differentiation status and function of virus-specific $CD8^+$ T cells are directly influenced by persistent antigen stimulation (Thimme et al. 2005).

As a result of clonal expansion T lymphocytes, some T lymphocytes acquire a senescent phenotype, fail to replicate in response to further antigenic stimulation, and express KLRG1 and/or CD57. The T lymphocytes with a senescent phenotype are mobilized and subsequently removed from the bloodstream in response to acute high-intensity exercise (Simpson et al. 2007). There is a greater proportion of senescent $CD3^+/CD8^+$ T-lymphocytes in the blood of older adults compared to young at rest and immediately after exhaustive exercise, indicating that the greater frequency of $KLRG1^+$/CD8+ T-lymphocytes in older humans is ubiquitous and not localised to the peripheral blood (Simpson et al. 2008).

32.4.2 NK Cell Maturation and Homeostasis Is Linked to KLRG1 Up-Regulation

KLRG1 expression is acquired during periods of NK cell division such as development and homeostatic proliferation. $KLRG1^+$ NK cells are mature in phenotype, and these cells have a slower in vivo turnover rate, reduced proliferative

response to IL-15, and poorer homeostatic expansion potential compared with mature NK cells lacking KLRG1. Results indicate that NK cells acquire KLRG1 on their surface during development, and this expression correlates with functional distinctions from other peripheral NK cells in vivo (Huntington et al. 2007). While both IL-7 and IL-15 induced proliferation of KLRG1^{low} CD8^{+} T cells, KLRG1^{high} cells exhibited an extraordinarily high level of resistance to cytokine-driven proliferation in vivo despite their dramatic accumulation upon IL-15 administration. Thus, IL-15 and IL-2 greatly improve the survival of KLRG1^{high} CD8^{+} T cells, which are usually destined to perish during contraction, in the absence of proliferation (Rubinstein et al. 2008).

32.4.3 Cadherins as Ligands of KLRG1

Cadherins have been identified as ligands for mouse and human KLRG1, which binds three of the classical cadherins (E-, N-, and R-). Cadherins are ubiquitously expressed in vertebrates and mediate cell–cell adhesion by homotypic or heterotypic interactions. By expression cloning using the mouse KLRG1 tetramer as a probe, human E-cadherin was found to be a xenogeneic ligand with a syngeneic interaction between mouse KLRG1 and mouse E-cadherin. KLRG1 also binds N- and R-cadherins. E-cadherin binding of KLRG1 prevents the lysis of E-cadherin–expressing targets by KLRG1^{+} NK cells (Ito et al. 2006; Tessmer et al. 2007). E-cadherin is expressed by normal epithelial cells, Langerhans cells, and keratinocytes and is usually down-regulated on metastatic cancer cells. KLRG1 ligation by E-cadherin in healthy tissue may thus exert an inhibitory effect on primed T cells (Gründemann et al. 2006). E-cadherin function is often inactivated during development of human carcinomas and splice-site mutations resulting in in-frame loss of exon 8 or 9 occur frequently in diffuse type gastric carcinomas. KLRG1 ligation by E-, N-, or R-cadherins may regulate the cytotoxicity of killer cells to prevent damage to tissues expressing the cadherins (Ito et al. 2006; Schwartzkopff et al. 2007; Tessmer et al. 2007).

Li et al. (2009) determined the structure of KLRG1 in complex with E-cadherin. KLRG1 mediates missing self recognition by binding to a highly conserved site on classical cadherins, enabling it to monitor expression of several cadherins (E-, N- and R-) on target cells (Fig. 32.2). This site overlaps the site responsible for cell–cell adhesion, but is distinct from the integrin $\alpha_E\beta_7$ binding site. Li et al. (2009) proposed that E-cadherin might co-engage KLRG1 and $\alpha_E\beta_7$, and that KLRG1 overcomes its exceptionally weak affinity for cadherins through multipoint attachment to target cells, resulting in inhibitory signaling.

32.5 MAFA-Like Receptor in Human NK Cell (MAFA-L)

32.5.1 Characteristics and Biological Properties

Butcher et al. (1998) identified a receptor gene in NK cell gene complex on human chromosome 12p12-13 encoding a putative type II transmembrane glycoprotein. The product was 54% identical to the rat MAFA, which inhibits mast cell activation by IgE. The human MAFA-like receptor (MAFA-L) and the rat MAFA protein are expressed by basophils and both have an ITIM in the cytoplasmic tail, consistent with an inhibitory role in basophil activation. Like other genes in the NK cell gene complex, MAFA-L is also expressed by NK cells as well as the monocyte-like cell-line U937. Expression in NK cells is restricted to peripheral blood NK cells, where as decidual NK cells did not express MAFA-L. While MAFA-L and rat MAFA might have a similar role in basophils, the expression of MAFA-L in other cell types implies additional functions for this molecule.

Human MAFA cDNA product is similar to the rat MAFA having an intracellular domain containing a putative ITIM and an extracellular C type lectin-like domain. However, in contrast to rat MAFA, the amino acid sequence suggests the presence of two additional extracellular N-linked glycosylation sites. In addition, alternative mRNA transcripts are observed that differ substantially from those found in the rat (Lamers et al. 1998).

32.6 Killer Cell Lectin Like Receptor Subfamily E, Member 1 (KLRE1)

A novel NK receptor, killer cell lectin like receptor subfamily E, member 1 (KLRE1) (also known as NKG2I), belonging to KLRs family has been characterized (Koike et al. 2004; Westgaard et al. 2003; Wilhelm and Mager 2003). A series of experiments using anti–KLRE-1 mAbs indicate that this receptor plays a role in the cytotoxicity mediated by NK cells in vitro (Koike et al. 2004; Westgaard et al. 2003). KLRE1 receptor is a type II transmembrane protein with a C-terminal lectin-like domain and belongs to the NKG2 family. Rat *Klre1* gene was mapped to the NK gene complex. KLRE1 was shown to be expressed by NK cells and a subpopulation of CD3^{+} cells, with pronounced inter-strain variation. KLRE1 can be expressed on the NK cell surface as a disulphide-linked dimer. The predicted proteins do not contain ITIMs or a positively charged amino acid in the transmembrane domain. Despite absence of a signaling motif, KLRE1 has nevertheless been shown to regulate NK cell-mediated cytotoxicity. Thus, KLRE1 may form a functional heterodimer with ITIM-

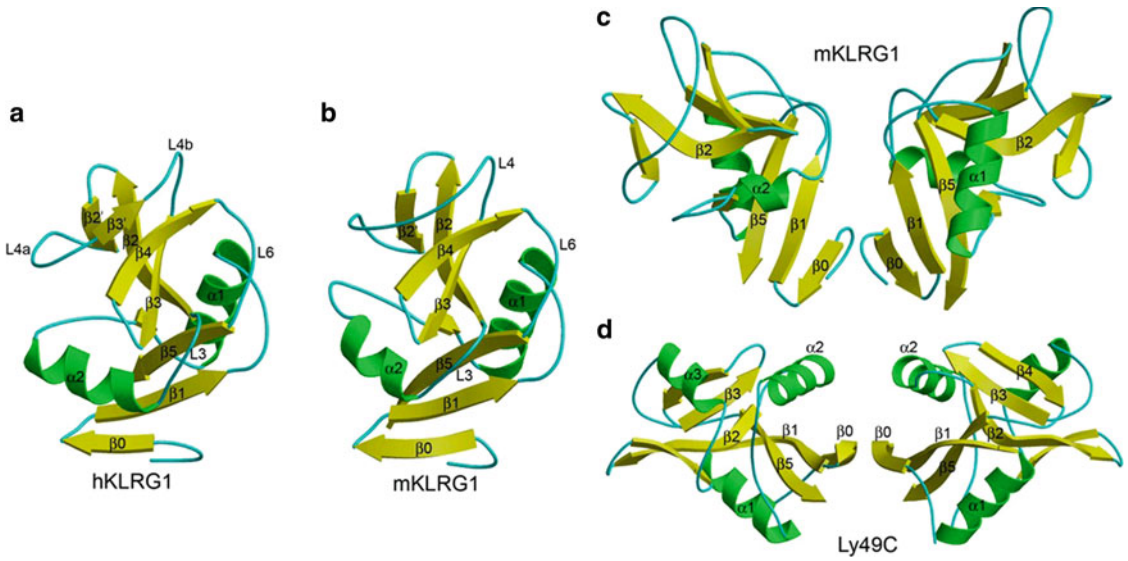

Fig. 32.2 Structure of KLRG1 (**a**) Ribbon diagram of human KLRG1, as observed in the hKLRG1–hEC1 complex. Secondary structure elements are labeled. α-helices are colored in *green*, β-stands in *yellow*, and loops in *cyan*. (**b**) Structure of mouse KLRG1 in unbound form. (**c**) Mouse KLRG1 homodimer, as observed in the mKLRG1–hEC1 complex. This dimer was not observed in structures of mKLRG1 alone or in the hKLRG1–hEC1 complex. (**d**) Structure of the Ly49C homodimer (PDB ID: 3C8J). Secondary structure elements are colored as in (**a**) (Adapted by permission from Li et al. 2009 © Elsevier)

bearing partner that recruits SHP-1 to generate an inhibitory receptor complex (Westgaard et al. 2003). Murine NK receptor, NKG2I, which was composed of 226 amino acids, showed ~40% homology to the murine NKG2D and CD94 in the C-type lectin domain. The expression of NKG2I was largely confined to NK and NKT cells, but was not seen in T cells. Furthermore, anti-NKG2I mAb inhibited NK cell–mediated cytotoxicity, whereas cross-linking of NKG2I enhanced IL-2 and IL-12–dependent IFN-γ production. NKG2I is an activating receptor mediating recognition and rejection of allogeneic target cells (Koike et al. 2004).

KLRE/I1 and KLRE/I2: A Pair of Heterodimeric Receptors: Saether et al. (2008) demonstrated that KLRE1 forms functional heterodimers with either KLRI1 or KLRI2. Cotransfection with KLRE1 was necessary for surface expression of the NKR chains KLRI1 and KLRI2 in 293T cells and can be co-precipitated with KLRI1 or KLRI2 from transfected NK cell lines. Unlike other KLRs, KLRE1/KLRI1 and KLRE1/KLRI2 heterodimers predominantly migrate as single chains in SDS-PAGE, indicating noncovalent association. KLRI1 showed activity of SH-2 domain-containing phosphatase 1. Ab to KLRE1 induced inhibition in KLRI1-transfected cells but increased cytotoxicity in KLRI2 transfectants, demonstrating that KLRE/I1 is a functional inhibitory heterodimer in NK cells, whereas KLRE/I2 is an activating heterodimeric receptor (Saether et al. 2008).

KLRE-1 in BM Allograft Rejection: KLRE-1-deficient mice were born at an expected frequency and showed no aberrant phenotype on growth and lymphoid development. However, KLRE-1-deficient cells showed a severely compromised allogeneic cytotoxic activity compared with the wild-type cells. Allogeneic bone marrow (BM) transfer culminated in colony formation in the spleen of KLRE-1-deficient mice, whereas no colony formation was observed in wild-type recipient mice. Therefore, KLRE-1 is a receptor mediating recognition and rejection of allogeneic target cells in the host immune system (Shimizu et al. 2004). These results indicate that NKG2I on NK cells recognizes putative ligands present on allogeneic BM cells and induces signals leading to the rejection of allografts. It should be mentioned that administration of anti-NK1.1, anti–asialo GM1, or anti–Ly-49D mAb also abrogated the rejection of allogeneic BM grafts, but these effects were primarily due to the depletion of NK cells expressing these molecules

32.7 KLRL1 from Human and Mouse DCs

KLRL1 belongs to the KLR family and is a novel inhibitory NK cell receptor. The KLRL1 from human and mouse DCs is a type II transmembrane protein with an ITIM and a C-type lectin-like domain. The KLRL1 gene is located in the central region of the NK gene complex in both humans and mice, on human chromosome 12p13 and mouse chromosome 6F3, adjacent to the other KLR genes. KLRL1 is preferentially expressed in lymphoid tissues and immune cells, including NK cells, T cells, DCs, and monocytes or macrophages. KLRL1 forms a heterodimer with an as yet

unidentified partner. Human and mouse KLRL1 both contain a putative ITIMs, and associates with the tyrosine phosphatases SHP-1 and SHP-2 (Han et al. 2004).

32.8 Natural Cytotoxicity Receptors

The function of NK cells are finely regulated by a series of inhibitory or activating receptors. The inhibitory receptors, specific for MHC class I molecules, allow NK cells to discriminate between normal cells and cells that have lost the expression of MHC class I (e.g., tumor cells). The general molecular strategies that allow NK cells to spare normal cells and kill tumor or virally infected cells have been clarified. The major receptors responsible for NK cell triggering are NKp46, NKp30, NKp44 and NKG2D. The NK-mediated lysis of tumor cells involves several such receptors, while killing of DCs involves only NKp30. The target-cell ligands recognized by some receptors have been identified, but those to which major receptors bind are not yet known. Nevertheless, functional data suggest that they are primarily expressed on cells upon activation, proliferation or tumor transformation. Thus, the ability of NK cells to lyse target cells requires both the lack of surface MHC class I molecules and the expression of appropriate ligands that trigger NK receptors.

32.8.1 NK Cell Triggering: The Activating Receptors

Provided that turning NK cells 'off' represents the major fail-safe device to prevent the NK-mediated attack of normal HLA class I^+ autologous cells, an 'on' signal must be generated upon interaction of NK cells with potential target cells. This signal is extinguished whenever appropriate interactions occur between inhibitory receptors and MHC class I molecules. On the other hand, the 'on' signal can be readily detected when NK cells interact with target cells that lack MHC class I molecules. The receptors responsible for NK cell activation in the process of natural cytotoxicity were identified recently and characterized. Collectively termed natural cytotoxicity receptors (NCRs), NKp46 (Sivori et al. 1997; Pessino et al. 1998), NKp44 (Vitale et al. 1998; Cantoni et al. 1999) and NKp30 (Pende et al. 1999) possess limited homology with known human molecules and no homology to each other (Moretta et al. 2000, 2001) (Fig. 32.1). As their expression is restricted to NK cells, they represent the most accurate surface markers for human NK cell identification. NCRs play a major role in the NK-mediated killing of most tumor cell lines (Moretta et al. 2001). Moreover, their surface density on NK cells correlates with the magnitude of the cytolytic activity against NK-susceptible target cells (Sivori et al. 2000). The ligands of NCRs are still not defined. However, as revealed by cytolytic assays, they are expressed by cells belonging to different histotypes (Moretta et al. 2001; Sivori et al. 2000; Costello et al. 2002; Pende et al. 2002). While NKp46 and NKp30 enable a precise identification of all NK cells, regardless of whether these cells are resting or activated (which is not true for other widely used NK cell markers including CD56 and CD16), NKp44 is selectively expressed by activated NK cells (Vitale et al. 1998; Cantoni et al. 1999; Moretta et al. 2001). This might explain, at least in part, the higher levels of cytolytic activity of activated NK cells cultured in IL-2.

NKG2D, a surface receptor of the NKG2 family, also plays a role in NK-mediated cytolysis. NKG2D is not restricted to NK cells, but is also expressed by cytolytic T lymphocytes. NKG2D is specific for the stress-inducible MICA and MICB or ULBP proteins. These ligands are expressed predominantly, but not exclusively, by cells of epithelial origin (Chap. 31).

32.8.2 Activating Receptors and Their Ligands

Natural cytotoxicity receptors (NCRs) (Moretta et al. 1999) are involved in NK cell triggering upon recognition of non-HLA ligands. These receptors appear to complement each other in the induction of target cell lysis by NK cells. Other triggering surface molecules expressed by NK cells (but shared by other leukocyte types) appear to function primarily as co-receptors (Fig. 32.1). That is, their ability to signal depends on the simultaneous co-engagement of one or another triggering receptor (Moretta et al. 2001). They may function to amplify signaling by true receptors. Other molecules that function as a triggering co-receptor in NK cells were found to be 2B4, NTB-A, the Poliovirus receptor (PVR, CD155) and Nectin-2 (CD112); the last two are members of the nectin family.

32.8.2.1 NKp46, NKp44, and NKp30

Sivori et al. (1997) identified a surface molecule (p46), which induces strong NK cell triggering and, unlike other NK cell antigens, is expressed exclusively by NK cells. NKp46 is expressed by all resting or activated NK cells. Unlike other NK cell antigens, the expression of p46 was strictly confined to NK cells. The p46-mediated induction of Ca^{2+} increases or triggering of cytolytic activity was down-regulated by the simultaneous engagement of inhibitory receptors including p58, p70, and CD94/NKG2A. Both the unique cellular distribution and functional capability of p46 molecules suggest a possible role in the mechanisms of non-MHC-restricted cytolysis mediated by human NK cells.

Vitale et al. (1998) identified a 44-kD surface molecule (NKp44) that is absent in freshly isolated peripheral blood

lymphocytes but is progressively expressed by all NK cells in vitro after culture in IL-2. Different from other markers of cell activation, NKp44 is absent in activated T lymphocytes or T cell clones. NKp44 was not detected in any of the other cell lineages analyzed. The mAb-mediated cross-linking of NKp44 in cloned NK cells resulted in strong activation of target cell lysis in a redirected killing assay. NKp44 functions as a triggering receptor selectively expressed by activated NK cells and that together with p46, may be involved in the process of non-MHC-restricted lysis. Both p46 and NKp44 are coupled to the intracytoplasmic transduction machinery via the association with CD3 or KARAP/DAP12, respectively; and these associated molecules are tyrosine phosphorylated upon NK cell stimulation (Fig. 32.1).

Pende et al. (1999) identified NKp30, a 30-kD triggering receptor selectively expressed by all resting and activated human NK cells. Although mAb-mediated cross-linking of NKp30 induces strong NK cell activation, mAb-mediated masking inhibits the NK cytotoxicity against normal or tumor target cells. NKp30 cooperates with NKp46 and/or NKp44 in the induction of NK-mediated cytotoxicity against the majority of target cells, whereas it represents the major triggering receptor in the killing of certain tumors. This receptor is associated with CD3 ζ chains that become tyrosine phosphorylated upon sodium pervanadate treatment of NK cells. Molecular cloning of NKp30 cDNA revealed a member of the immunoglobulin superfamily, characterized by a single V-type domain and a charged residue in the transmembrane portion. Moreover, NKp30 is encoded by the 1C7 gene. Although the identification of different NCRs constitutes a major step forward in our understanding of the NK cell physiology, both the nature and the distribution of the NCR ligands on target cells remain to be determined. The occupational exposure to mixture of toxics is one of the important factors in the diminution of the NK cell receptor expression (De Celis et al. 2008). Following exposure of women to toxic compounds, NKp30 and NKG2D receptor expression was diminished.

Similar to NKp46, NKp30 is selectively expressed by all NK cells, both freshly isolated and cultured in IL-2, thus representing an optimal marker for NK cell identification. Although both belong to the Ig-SF, NKp30 does not display any substantial homology with previously identified NK receptors. In many respects, NKp30 appeared similar to NKp42. Indeed, their parallel expression on all NK cells (including the rare $CD16^-$ cells), the existence for both of a high or low density pattern of surface expression, together with their similar functional characteristics, led to the thought that the surface molecule recognized by the new mAbs could be identical or strictly related to NKp42. However, NKp30 and NKp46 displayed different molecular masses and, functionally, appeared to play a complementary role in the induction of natural cytotoxicity. Moreover, molecular cloning revealed that NKp30 is a protein with very limited homology with NKp46, as the two molecules display only 13% identity and 15% similarity, and are encoded by genes located on different chromosomes.

Both NKp46 and NKp44 receptors are involved in recognition and lysis of a variety of tumor targets, but neither displays significant identity. NKp46 and NKp44 were shown to cooperate in the process of tumor cell lysis by human NK cells. However, studies indicated the existence of additional receptor(s) cooperating with NKp46 and NKp44. Indeed, NKp30 represents a receptor that may cooperate with NKp46 and NKp44 in the induction of cytotoxicity against a variety of target cells. Perhaps, NKp30 represents the major receptor in inducing NK-mediated killing of certain tumor target cells, the lysis of which is largely NKp46/NKp44 independent. Molecular cloning revealed that NKp30 is the product of 1C7, a gene mapped on human chromosome 6 in the HLA class III region. Persistent high risk Human papillomavirus (HPV) infection can lead to cervical cancer. NK cells play a crucial role against tumors and virus-infected cells through a fine balance between activating and inhibitory receptors. Expression of triggering receptors NKp30, NKp44, NKp46 and NKG2D on NK cells correlates with cytolytic activity against tumor cells and their down-regulation represents an evasion mechanism associated to low NK cell activity, HPV-16 infection and cervical cancer progression (Garcia-Iglesias et al. 2009).

mAbs to NCR block to differing extents the NK-mediated lysis of various tumors. Moreover, lysis of certain tumors can be virtually abrogated by the simultaneous masking of the three NCRs. There is a coordinated surface expression of the three NCRs, their surface density varying in different individuals and also in the NK cells isolated from a given individual. A direct correlation exists between the surface density of NCR and the ability of NK cells to kill various tumors. NKp46 is the only NCR involved in human NK-mediated killing of murine target cells. Accordingly, a homologue of NKp46 has been detected in mouse. Molecular cloning of NCR revealed novel members of the Ig superfamily displaying a low degree of similarity to each other and to known human molecules. NCRs are coupled to different signal transducing adaptor proteins, including CD3 ζ, Fc εRI γ, and KARAP/DAP12. Besides different NCRs, several other surface molecules that can mediate NK cell triggering have been identified in humans and rodents. These include CD2, CD69, CD28, 2B4, and NKR-P1 (Pende et al. 1999).

32.8.2.2 Ligands of Activating Receptors

Although many core questions regarding NK cell receptors have been answered in recent years, there are still relevant issues that remain to be tackled in NK cell physiology. One

major problem is with regard to the identification of the cellular ligands for the major triggering receptors (NKp46, NKp30 and NKp44) as well as for other receptors or co-receptors (Fig. 32.1). Available information is compatible with the concept that, similar to MICA/B, PVR or Nectin-2, they may also be represented by molecules primarily expressed by cells that have been 'stressed' by cytokine activation, proliferation, high temperature, viral infection or tumor transformation. NKp46 ligands are expressed in reticular dermis, and their expression is enhanced in the active proliferation zone (dermoepidermal junction) of nevi and melanomas. The physiological role of NKp46 ligands in the progression of malignancy is unknown (Cagnano et al. 2008). Myeloid DCs express ligands for NKp46 and NKp30 natural cytotoxicity receptors, which are partially reduced on HCMV infection; yet. The studies stress the importance of the dynamics of viral immune evasion mechanisms (Magri et al. 2011). NKp46 binds to heparin and heparan sulfate (HS); and also to multimeric sialyl Lewis X expressing transferrin secreted by human hepatoma HepG2 cells (HepTF). NKp46 binds to sulfate- and 2,3-NeuAc-containing glycans mainly via ionic interactions. The HS GAG are not ligands for NKp30 (Ito et al. 2011).

C-Type Lectins: Endocytic Receptors

Asialoglycoprotein Receptor and the Macrophage Galactose-Type Lectin

33

Anita Gupta

33.1 Asialoglycoprotein Receptor: The First Animal Lectin Discovered

Mammalian liver expresses endocytic cell surface receptors that specifically bind natural or synthetic molecules containing terminal galactosyl or N-acetylgalactosaminyl sugars. One of these hepatocyte receptors is the asialoglycoprotein receptor (ASGP-R), which mediates the endocytosis and subsequent lysosomal degradation of these glyco-molecules. The ASGP-R was the first mammalian lectin discovered by Morell et al. (1968) and is a member of the C-type lectin family, which require Ca^{2+} for ligand binding and to contain disulfide bridges in the CRD (Zelensky and Gready 2005). ASGP-R is an integral membrane protein, predominately expressed on the sinusoidal surface of mammalian hepatocytes. Morphometric analysis estimated that approximately 90% of the receptor molecules were at the sinusoidal face, approximately 10% at the lateral face, and approximately 1% at the bile canalicular face. Nonhepatic cells such as endothelial and Kupffer cells had no receptor specific for asialoglycoproteins (Matsuura et al. 1982). At cellular level, the basic molecular function of the receptor is to mediate the uptake and ultimate degradation of galactosyl/N-acetylgalactosaminyl-containing molecules (ligands). At the organism level, however, the physiological function is uncertain. Weigel (1994) proposed physiological role of ASGP-R in regulating the dynamic flux of galactosyl/N-acetylgalac tosaminyl glycoconjugates in mammals. The ASGP-R is one of the best characterized systems for receptor-mediated endocytosis via the clathrin-coated pit pathway (Breitfeld et al. 1985; Weigel and Yik 2002; Stockert 1995).

33.2 Rat Asialoglycoprotein Receptor

33.2.1 Characteristics

Hepatic plasma membrane receptors mediate the specific binding and uptake of partially deglycosylated glycoproteins. These receptors, referred to as hepatic lectins, have been isolated from several mammalian liver, peritoneal macrophages (Ashwell and Harford 1982) and avian species (Baenziger and Maynard 1980). While the mammalian (rabbit, rat, and human) receptors recognize galactose residues exposed upon removal of terminal sialic acid, the avian (chicken) receptor recognizes terminal N-acetylglucosamine exposed upon further removal of the galactose. In spite of this difference in binding specificity, the mammalian and avian receptors share a number of properties, such as a strict Ca^{2+} requirement for ligand binding and similar pH profiles for binding and release of ligand (Brown et al. 1983). The complete amino acid sequence of the chicken hepatic lectin (Drickamer and Mamon 1982) suggests a unique organization for this membrane protein with its NH2 terminus in the cytoplasm and COOH terminus outside the cell.

Rat ASGP-R contains three subunits, designated rat hepatic lectins (RHL) 1, 2, and 3 where as human ASGP-R contains two subunits, HHL1 and HHL2. Peptide mapping experiments suggest that the three polypeptides of rat RHL may be structurally related to each other (Schwartz et al. 1981; Warren and Doyle 1981). The predominant polypeptide RHL-l has an M_r of 41.5 kDa, while two less abundant species appeared to be of higher molecular weight (RHL-2 of 49.0 kDa and RHL-3 of 54 kDa); the RHL-1 represents 70–80% of the total mass of the receptor. Each of the RHL-1 and RHL-2/3 polypeptides is associated into homo-oligomers but are physically unlinked to each other. The complete sequence of the major RHL species (RHL-1) has been established (Drickamer et al. 1984; Schwartz 1984). The complete sequence of RHL-1 is 283 residues long, although 20% of the protein as isolated is missing the first two residues at NH2 terminus. The overall arrangement of the polypeptide, similar to chicken ASGP-R, consists of an NH2-terminal stretch of hydrophilic amino acids, a segment of about 30 uncharged residues, and a COOH-terminal portion which contains three oligosaccharide attachment sites. The COOH terminus of the rat and chicken receptors

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_33,

showed 28% identity. Evidence shows that there must be at least two distinct genes for RHL receptor polypeptides. ASGP-Rs are covalently modified by fatty acylation (Zeng et al. 1995; Zeng and Weigel 1996). The single Cys residue in the cytoplasmic domain of each RHL or HHL subunit is fatty acylated. Deacylation ofASGP-Rs with hydroxylamine results in the spontaneous formation of dimers through reversible disulfide bonds, indicating that deacylation concomitantly generates free thiol groups. Cys^{57} within the transmembrane domain of HHL1 is not normally palmitoylated. In conclusion, Cys^{35} in RHL1, Cys^{54} in RHL2 and RHL3, and Cys^{36} in HHL1 are fatty acylated. Cys^{57} in HHL1 and probably Cys^{56} in RHL1 are not palmitoylated.

The second subunit, RHL-2/3, consists of two species that are differentially glycosylated forms of a second, homologous polypeptide. The structure of RHL-2/3 polypeptide reveals that this protein is homologous to RHL-1 throughout its length but contains one major insertion of 18 amino acids near its NH2 terminus. RHL-1 and RHL-2/3 bind carbohydrate ligands through COOH-terminal, Ca^{2+}-dependent CRDs. Results indicate that RHL-1 and RHL-2/3 polypeptides are self-associated into two distinct molecules, each of which has galactose-binding activity (Halberg et al. 1987).

Structural analysis of wild-type and mutant forms of homologous C-type CRD from serum MBP suggests that carbohydrate ligands bind to the CRDs of RHL-1 at a conserved Ca^{2+}designated site two. The primary interaction with sugar is through hydroxyl groups that form coordination bonds with the $Ca^{2+}$and hydrogen bonds with protein side chains that also ligate the Ca^{2+} (Weis et al. 1992). The molecular basis for galactose binding to C-type CRDs has been studied in a mutant CRD from serum MBP which has been engineered to bind galactose. Three single amino acid replacements ($E^{185}Q$, $N^{187}D$, and $H^{189}W$) and insertion of a glycine-rich loop result in a modified CRD designated QPDWG, which has affinity and selectivity similar to RHL-1 (Iobst and Drickamer 1994). The crystal structures of this modified CRD and of a further mutant that binds *N*-acetylgalactosamine with high affinity have been solved (Kolatkar and Weis 1996; Kolatkar et al. 1998). These structures provide a basis for modeling the CRD of RHL-1. Murine ASGP-R cDNA exhibits homology with rat and human receptors. The membrane-bound M (mouse) HL polypeptide does not contain a cleavable N-terminal signal sequence and is probably anchored to the membrane via an internal insertion sequence (Sanford and Doyle 1990).

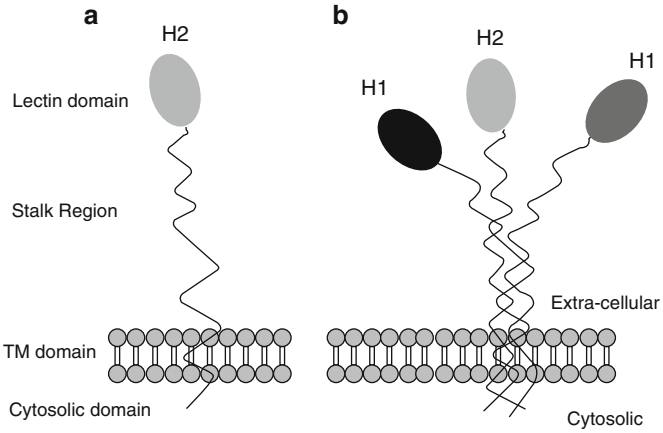

Fig. 33.1 Schematic presentation of asialoglycoprotein receptor (ASGP-R). (**a**) Each subunit, H1 and H2, consists of four domains; a *N*-terminal cytoplasmic domain, a single-pass transmembrane domain, an extracellular stalk segment and a C-type lectin carbohydrate recognition domain. (**b**) A hetero-oligomeric complex of two H1 and one H2 subunits has been proposed as the minimum size of an active ASGP-R

33.3 Human Asialoglycoprotein Receptor

33.3.1 Structural Characteristics

The human liver ASGP-R is a multichain heterooligomer composed of two homologous subunits, the major H1 and the minor H2, sharing 58% sequence identity. The ASGP-R from human liver and from the human hepatoma cell line HepG2 migrates as a single species of 45 kDa. The receptor encoding a cDNA clones has been isolated in H1 and H2 forms, with a protein sequence homology of 58%. Each subunit consists of four domains, a *N*-terminal cytoplasmic domain, a single-pass transmembrane domain, an extracellular stalk segment and a CRD, the latter being responsible for the ligand binding (Fig. 33.1a) (Weigel and Yik 2002; Chiacchia and Drickamer 1984; Shia and Lodish 1989). The H1 is a single-spanning membrane protein with amino terminus facing the cytoplasm and the carboxy terminus exposed on the exoplasmic side of plasma membrane. The transmembrane segment, residues 38–65, functions as an internal signal directing protein synthesis to the endoplasmic reticulum and initiating membrane insertion (Spiess 1987; Spiess and Handschin 1987). A notable difference between H1 and H2 is an 18-amino acid insert present in the cytoplasmic domain of only H2. Comparison of sequences of rat RHL-l and RHL-2 indicates that H1 is more homologous to R1 than to H2, and H2 is more similar to R2 than to H1 (Weigel and Yik 2002; Spiess and Lodish 1985).

Furthermore, while H1 only occurs as one protein isoform, H2 transcripts exist in multiple variants both in HepG2

cells and in the normal human liver. Some of these appear to be the result of alternative splicing events. Three splice variants of H2, designated H2a, H2b and H2c, have been isolated from human liver and HepG2 cells. However, H2a does not occur in native ASGP-R complexes. In contrast, both H2b and H2c associate with H1 in functional ASGP-Rs, but never together in the same receptor complex (Yik et al. 2002).

Though, H1 and H2 are highly homologous, the major H1 subunit is stably expressed by itself, whereas in the absence of H1 most of the H2 subunits are degraded in ER. Since the internal pool of H2 was also able to traffick to the cell surface, it was suggested that H2 recycles between the surface and intracellular compartments, similar to the constitutive recycling of hetero-oligomeric ASGP-R complexes. However, unlike H1, which can bind the ligand asialo-orosomucoid (ASOR), H2 failed to bind or endocytose ASOR. It seems that the H2 subunit of the human ASGP-R contains functional, although weak, signal(s) for endocytosis and recycling and has the ability to oligomerize. H2 homo-oligomers, however, do not create binding sites for desialylated glycoproteins, such as ASOR, that contain tri- and tetra-antennary N-linked oligosaccharides (Saxena et al. 2002).

The X-ray crystal structure of the carbohydrate recognition domain of the major subunit H1 was studied at 2.3 A resolution (Meier et al. 2000). While the overall fold of this and other known C-type lectin structures are well conserved, the positions of the bound calcium ions are not, indicating that the fold is stabilised by alternative mechanisms in different branches of the C-type lectin family. It was the first CRD structure where three calcium ions form an intergral part of the structure. In addition, the structure provided direct confirmation for the conversion of the ligand-binding site of the mannose-binding protein to an asialoglycoprotein receptor-like specificity suggested by Drickamer and colleagues. In agreement with the prediction that the coiled-coil domain of the ASGP-R is separated from the CRD and its N-terminal disulphide bridge by several residues, these residues are indeed not alpha-helical, while in tetranectin they form an alpha-helical coiled-coil (Drickamer 1988; Meier et al. 2000).

33.3.1.1 Position of Cysteine Is Critical for Palmitoylation of H1

The two subunits, H1 and H2 ASGP-R are palmitoylated at the cytoplasmic Cys residues near their transmembrane domains (TMD). The cytoplasmic Cys^{36} in H1 is located at a position that is five amino acids from the transmembrane junction. Neither the native amino acid sequence surrounding Cys^{36} nor the majority of the cytoplasmic domain sequence is critical for palmitoylation. Palmitoylation was also not dependent on the native TMD of H1. In contrast, the attachment of palmitate was abolished if the Cys residue was transposed to a position that was 30 amino acids away from the transmembrane border. Thus, the spacing of a Cys residue relative to the TMD in the primary protein sequence of H1 is the major determinant for successful palmitoylation (Yik and Weigel 2002).

33.3.1.2 Macrophage ASGP-Binding Protein

The primary structure of macrophage asialoglycoprotein-binding protein, M-ASGP-BP consists of 306 amino acid residues with a molecular mass of 34,242 Da. The sequence was highly homologous with that of the rat liver asialoglycoprotein receptor (RHL), particularly that of RHL-1 (the major form of RHL), throughout its whole length, and especially so in its putative membrane-spanning region and CRD. There were two N-glycosylation sites in M-ASGP-BP, the location of which were identical to those in RHL-1 (Ii et al. 1990). However, M-ASGP-BP was characteristic in having a shorter cytoplasmic tail, and an inserted segment of 24 amino acids containing an Arg-Gly-Asp sequence between the membrane-spanning region and carbohydrate recognition domain (Ii et al. 1990).

Ligand specificity and binding affinity depend on the arrangement of the subunits in the complex. Presence of both subunits is a prerequisite for the ASGP-R to reach full functionality. Although the subunit composition of the native receptor remains unspecified (Weigel and Yik 2002), a stoichiometry of 2:1 of H1 and H2 has been proposed as the minimum size of an active ASGP-R complex, exhibiting high affinity ligand binding (Fig. 33.1b) (Hardy et al. 1985; Schwartz 1984). Results suggest that the stalk segments of the receptor subunits oligomerize to constitute an α-helical coiled coil stalk on top of which the carbohydrate binding domains are exposed for ligand binding. This subunit ratio was partially supported by another study in which the functional receptor was suggested to be a 2:2 heterotetramer. Extracellular stalk segments of H1 and H2, responsible for the subunit oligomerization, were expressed and shown to associate in homo- and heterooligomers in vitro (Bider et al. 1996). A study of e binding of three different ^{125}I-labeled, galactose-terminated ligands to the hepatic galactose/N-acetylgalactosamine-specific lectin revealed that the different ligands manifest different physical parameters of binding. For example, there were many more total binding sites for di-tris-lac on the surface of rabbit hepatocytes than there were for asialoorosomucoid, although the dissociation constants were similar for these ligands (Hardy et al. 1985).

33.4 Ligand Binding Properties of ASGP-R

The ASGP-Rs specifically recognize galactose- or N-acetylgalactosamine-terminated oligosaccharides, present on desialylated glycoproteins. The ASGP-R recognizes with

high affinity (K_D in nM range) tri- and tetra-antennary N-linked sugar side chains with terminal galactose residues. Glycoproteins with such glycosylation patterns are rapidly endocytosed by the ASGP-R via clathrin-coated pits and vesicles. The specificity and affinity of ligand binding of ASGP-R depends on the number and spatial arrangement of several galactose-binding sites within the receptor complex. A single Gal residue exhibits only modest binding affinity with a K_D in the range of 1 mM. Additional sugars, from a mono- to a triantennary structure, result in a significant increase in affinity with K_D ~10 nM for the native receptor. Hence, high affinity binding is achieved through multiple interactions between the CRDs in a receptor complex and multiple sugar residues (Westerlind et al. 2004). Furthermore, the sugar spacing has been shown to be important for optimal receptor recognition. A spacer length of >20 Å, separating the sugar moieties from the branching point of the ligand, results in high affinity binding to the ASGP-R of Gal containing ligand constructs (Westerlind et al. 2004; Rensen et al. 2001). In addition, the ASGP-R clearly favors binding of Gal*N*Ac over Gal, showing an approximate 50-fold higher affinity for the former (Rensen et al. 2001; Baenziger and Maynard 1980). Studies indicate that both subunits are required for high-affinity ligand binding, i.e. for the simultaneous interaction with three galactose residues within an N-linked glycan. However, asialoorosomucoid (ASOR) and asialofetuin (ASF) bind to transfected COS-7 cells expressing subunit H1 in absence of the second subunit H2. It was found that, at a sufficiently high density of H1 on the cell surface, high-affinity binding of ASOR and ASF is the result of two or more glycans interacting with H1 oligomers with low affinity in a bivalent manner. ASOR displays a K_D of ⟨10 nM for the native receptor. It has also been observed to bind H1, overexpressed in transfected COS-7 cells, in the absence of H2 with a K_D of ⟨40 nM (Bider et al. 1996). In order to develop the non-viral Bioplex vector system for targeted delivery of genes to hepatocytes, Westerlind et al. (2004) evaluated the structure-function relationship for a number of synthetic ligands designed for specific interaction with the hepatic lectin ASGP-R. Uptake efficiency increased with number of displayed GalNAc units per ligand, in a receptor dependent manner. Thus, a derivative displaying six GalNAc units showed the highest uptake efficacy both in terms of number of internalizing cells and increased amount of material taken up by each cell. However, this higher efficiency was shown to be due not so much to higher number of sugar units, but to higher accessibility of the sugar units for interaction with the receptor (longer spacer) (Westerlind et al. 2004).

Analogous binding specificity can be engineered into the homologous rat MBP-A by changing three amino acids and inserting a glycine-rich loop (Iobst and Drickamer 1994). Crystal structures of this mutant complexed with β-methyl galactoside and N-acetylgalactosamine (GalNAc) revealed that as with wild-type MBPs, the 3- and 4-OH groups of the sugar directly coordinate Ca^{2+} and form hydrogen bonds with amino acids that also serve as Ca^{2+} ligands. The different stereochemistry of the 3- and 4-OH groups in mannose and galactose, combined with a fixed Ca^{2+} coordination geometry, leads to different pyranose ring locations in the two cases. The glycine-rich loop provides selectivity against mannose by holding a critical tryptophan in a position optimal for packing with the apolar face of galactose but incompatible with mannose binding. The 2-acetamido substituent of GalNAc is in the vicinity of amino acid positions identified by site-directed mutagenesis (Iobst and Drickamer 1996) as being important for the formation of a GalNAc-selective binding site (Kolatkar and Weis 1996). ASGP-R was also postulated to account for the low density lipoprotein (LDL) receptor-independent clearance of lipoproteins including chylomicron remnants (Ishibashi et al. 1996). Later, immunoglobulin A (Rifai et al. 2000) and fibronectin (Rotundo et al. 1998) emerged as likely candidates of natural ligands for ASGP-R. The clearance of apoptotic cells or a subpopulation of lymphocytes in the liver has been also attributed to ASGP-R (Stockert 1995).

33.4.1 Interaction with Viruses

It is particularly noteworthy that ASGP-R has also been proposed to be utilized as entry sites into hepatocytes by several hepatotropic viruses including hepatitis B virus (Treichel et al. 1994), Marburg virus (Becker et al. 1995), and hepatitis A virus (Dotzauer et al. 2000). The liver is one of the main target organs of Marburg virus (MBG), a filovirus causing severe haemorrhagic fever with a high fatality rate in humans and non-human primates. MBG grown in certain cells does not contain neuraminic acid, but has terminal galactose on its surface glycoprotein. The lack of neuraminic acid together with the marked hepatotropism of the MBG infection led to suggest that the ASGP-R of hepatocytes may serve as a receptor for MBG in the liver. MBG lacking sialic acid specifically binds to the ASGP-R. This observation may at least in part explain why the liver is a central target for MBG and may thus contribute to an understanding of the pathogenesis of this infection (Becker et al. 1995). Structural proteins of hepatitis C virus (HCV) genotype 1a bind to cultured human hepatic cells. This binding was decreased by calcium depletion and was partially prevented by ligands of ASGP-R, thyroglobulin, asialothyroglobulin, and antibody against a peptide in CRD of ASGP-R but not preimmune antibody (Saunier et al. 2003).

33.5 The Crystal Structure of H1-CRD

The structure of ASGP-R H1-CRD was solved in 2000 by X-ray crystallography (Meier et al. 2000). It is a globular protein, containing two α-helices and eight β-strands. The β-strands are arranged in a bent plane and form the core of the protein, while the α-helices are positioned on either side of the plane. Three calcium ions can be seen in the structure, forming an integral part of the protein as they pin together several loops. The two calcium ions at site 1 and 2 are seen in close proximity, both coordinated by Glu^{252}. Site 2 is of particular interest as it is essential for sugar binding and is present in all C-type lectins. Calcium binding site 3 is found close to the *N*- and *C*-terminus of the protein (Fig. 33.2).

C-type CRDs can be classified into short-form CRDs, with two disulfide bridges, or long-form CRDs, containing a conserved extension with an additional disulfide bond at the *N*-terminus. H1-CRD falls into the latter category, containing seven cysteines out of which six are engaged in three disulfide bridges. One bridge constitutes part of the sugar binding site, seen in the crystal structure between Cys^{254} and Cys^{268}. A second bond is formed between Cys^{181} and Cys^{276}, bringing the *C*- and *N*-terminus close together and contributes to the tertiary structure of the subunit. Finally, a third typical long-form CRD disulfide bridge is found at the *N*-terminus between Cys^{153} and Cys^{164}. The *N*-terminal residues 147–152, including the seventh odd cysteine (Cys^{152}), and the *C*-terminal residues 281–290 could not be positioned into the electron density and hence, cannot be seen in the crystal structure (Meier et al. 2000; Johansson 2007).

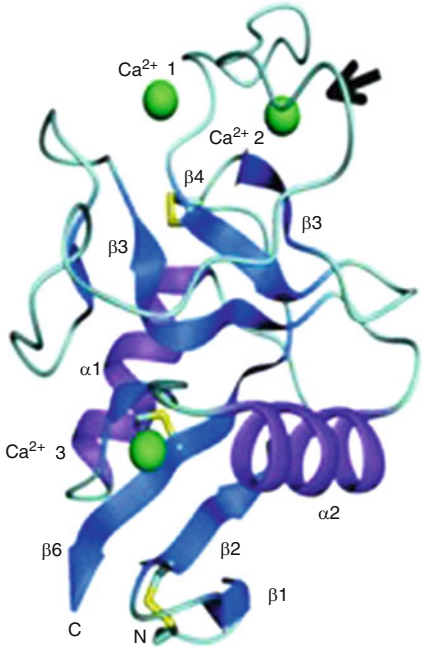

Fig. 33.2 Ribbon diagram of the carbohydrate recognition domain of the H1 subunit. The three calcium ions can be seen in *green*. The second calcium binding site, which is part of the sugar binding site, is denoted by a *black arrow*. The disulfide bridges are marked in *yellow* (PDB ID: 1DV8) (Adapted with permission from Meier et al. 2000 © Elsevier)

33.5.1 The Sugar Binding Site of H1-CRD

The specificity and affinity of ligand binding of ASGP-R depends on the number and spatial arrangement of several galactose-binding sites within the receptor complex. Studies indicate that both subunits are required for high-affinity ligand binding, i.e. for the simultaneous interaction with three galactose residues within an N-linked glycan. However, asialoorosomucoid (ASOR) and asialofetuin (ASF) bind to transfected COS-7 cells expressing subunit H1 in the absence of the second subunit H2. It was found that, at a sufficiently high density of H1 on the cell surface, high-affinity binding of ASOR and ASF is the result of two or more glycans interacting with H1 oligomers with low affinity in a bivalent manner. The region around the sugar binding site in H1-CRD is formed by one continuous stretch of the polypeptide chain from Arg^{236} to Cys^{268} (Johansson 2007).

Mutagenesis studies have been carried out with closely related protein RHL-1, aiming to deduce the residues giving rise to it's ligand binding specificity. RHL-1 has been used as a reference in attempts to mimic its Gal- and Gal*N*Ac-binding properties in other lectins, e.g. the MBP (Iobst and Drickamer 1994) and the macrophage galactose receptor (MGR) (Iobst and Drickamer 1996). Such studies form the basis for explanation of H1-CRDs sugar preference as well as its distinction between high- and low-affinity ligands. Introduction of two point mutations in MBP, $E^{185}Q$ and $N^{187}D$, corresponding to Q^{239} and D^{241} in RHL-1, was sufficient to achieve galactose binding in the protein, which is normally binding mannose (Iobst and Drickamer 1994). However, as the Gal affinity of the MBP mutant, designated QPD, was rather low it was concluded that other residues in H1-CRD also must contribute to the ligand binding. An additional mutation, $H^{189}W$, showed to increase the affinity significantly, making the galactose binding of mutant QPDW comparable to that of RHL-1. Selectivity for galactose over mannose was achieved by incorporating a glycine-rich stretch following the QPDW sequence, referred to as the QPDWG mutant. Stepwise mutations within the glycine rich loop, corresponding to residues Y^{244}, G^{245} and H^{246} in RHL-1, showed that they all contribute to the selectivity for Gal (Iobst and Drickamer 1994). However, the influence of the amino acids on the

selectivity could equally be attributed to stabilization and support of the protein structure as to an actual effect on the ligand binding.

RHL-1, as well as H1-CRD, shows preferential binding to Gal*N*Ac over Gal. The selectivity for Gal*N*Ac has been probed by mutations studies of MGR, which binds Gal and Gal*N*Ac with roughly equal affinity. The CRDs of RHL-1 and MGR are highly homologues (77%) and the difference in selectivity is likely to stem from divergences in the sequences. It was concluded that substitution of four amino acids in MGR, $V^{230}N$, $A^{258}R$, $K^{260}G$ and $S^{281}T$, is sufficient to induce Gal*N*Ac binding comparable with that of RHL-1. N^{230} increased the selectivity 20-fold, while the contributions by R^{258} and G^{260} were less prominent. The latter two residues only showed marginal or no effect at all when substituted individually, but a twofold increase when present together. It is possible that glycine contributes to the affinity by positioning arginine, which has the potential for forming hydrogen bonds with the ligand. T^{281} significantly increased the selectivity for Gal*N*Ac when inserted into MGR simultaneously with R^{258} and G^{260}, but is more likely to play an indirect role for ligand binding as it is predicted to be positioned at a considerable distance (10 Å). The residue appearing most important for achieving Gal*N*Ac binding is a histidine (His, H), found in both RHL-1 and MGR at position 256 and 278 respectively. Initial studies exchanging H^{278} in MGR for an alanine (Ala, A) resulted in an almost complete loss of Gal*N*Ac selectivity, but without any apparent effect on the galactose binding. The importance of the histidine was further investigated by repeating the substitution in RHL-1, causing a 25-fold loss in affinity for Gal*N*Ac, but without affecting that for Gal (Iobst and Drickamer 1996). Corresponding residue in MBP, T^{202}, was also substituted by histidine and resulted in a 14-fold increase in the relative affinity for Gal*N*Ac of the protein (referred to as the QPDWGH mutant) (Kolatkar et al. 1998).

33.5.2 Sugar Binding to H1-CRD

A model for sugar binding to H1-CRD has been proposed based on the mutagenesis experiments with MBP (Kolatkar and Weis 1996; Kolatkar et al. 1998). Crystallographic data of the QPDWG mutant could show that Gal and Gal*N*Ac bind directly to the Ca^{2+} in the second calcium binding site. The 3-OH and 4-OH groups of the sugar replaces two water molecules, normally coordinated by the calcium. In addition, the same OH groups also forms hydrogen bonds with amino acid chains that are Ca^{2+} site 2 ligands (Q^{239}, D^{241}, E^{252}, N^{264} in H1-CRD). Further interactions between the ligand and the protein are formed by stacking of the apolar face of the sugar against the side-chain of a tryptophan (W^{243} in H1-CRD) (Kolatkar and Weis 1996). The Gal*N*Ac-specific MBP mutant QPDWGH was also analyzed by crystallography.

Regions of the CRD of the receptor believed to be important in preferential binding to N acetylgalactosamine were inserted into the homologous CRD of a MBP mutant that was previously altered to bind galactose. Introduction of a single histidine residue corresponding to residue 256 of the hepatic ASGP-R was found to cause a 14-fold increase in the relative affinity for N-acetylgalactosamine compared with galactose. The relative ability of various acyl derivatives of galactosamine to compete for binding to this modified CRD suggest that it is a good model for the natural N-acetylgalactosamine binding site of the ASGP-R. Crystallographic analysis of this mutant CRD in complex with N-acetylgalactosamine reveals a direct interaction between the inserted histidine residue and the methyl group of the N-acetyl substituent of the sugar. The structure of this mutant reveals that the beta-branched valine side chain interacts directly with the histidine side chain, resulting in an altered imidazole ring orientation (Kolatkar et al. 1998).

33.5.2.1 Histidine 256: Responsible for pH Dependent Ligand Binding

Efficient release of ligands from CRD of the hepatic ASGP-R at endosomal pH requires a small set of conserved amino acids that includes a critical histidine residue. Mutagenesis studies of RHL-1 have shown that histidine 256 plays an important role in pH dependent ligand binding exhibited by the subunit (Wragg and Drickamer 1999; Feinberg et al. 2000). When these residues are incorporated at corresponding positions in an homologous galactose-binding derivative of serum MBP, the pH dependence of ligand binding becomes more like that of the receptor. The modified CRD displays 40-fold preferential binding to N-acetylgalactosamine compared with galactose, making it a good functional mimic of ASGP-R. In the crystal structure of the modified CRD bound to N-acetylgalactosamine, the His^{202} contacts the 2-acetamido methyl group and also participates in a network of interactions involving Asp^{212}, Arg^{216}, and Tyr^{218} that positions a water molecule in a hydrogen bond with the sugar amide group. These interactions appear to produce the preference for N-acetylgalactosamine over galactose and are also likely to influence the pK_a of His^{202}. Protonation of His^{202} would disrupt its interaction with an asparagine that serves as a ligand for Ca^{2+} and sugar. The structure of the modified CRD without sugar displays several different conformations that may represent structures of intermediates in the release of Ca^{2+} and sugar ligands caused by protonation of His^{202} (Feinberg et al. 2000).

In another work (Johansson 2007), His^{256} of H1-CRD was substituted by glutamate, the corresponding residue in H2-CRD. Binding of Gal*N*Ac to mutant $H^{256}E$ and WT H1-CRD was investigated at different pH ranging from 7.4 to 5. Results showed that binding of the Gal*N*Ac-polymer decreased at pH 6 or lower. $Hist^{256}$ clearly renders H1-CRD more sensitive to low pH compared to a glutamate in the

same position. His^{256} has been proposed to interact with Asn^{264}, which in turn is involved in both calcium- and ligand binding. The histidine stabilizes Asn^{264} by a hydrogen bond formed between the imidazole and the amide. Protonation of imidazole, caused by a drop in pH during endocytosis, will disrupt the hydrogen bond. As a consequence, the asparagine is destabilized and both ligand and calcium binding is disturbed.

33.6 Physiological Functions

A number of diverse physiological roles have been proposed for ASGP-R over the years. Among them, hepatic clearance of the desialylated and senascent serum proteins was most originally proposed. Later physiological and pathophysiological functions to this lectin include: the removal of apoptotic cells, clearance of lipoproteins, and the sites of entry for hepatotropic viruses. The primary function of the ASGP-R has been considered to be the removal and degradation of desialylated glycoproteins from the circulation. Normally, many oligosaccharide chains on glycoproteins carry terminal sialic acid residues. Upon removal of the sialic acid, caused by the action of neuraminidases, penultimate galactose residues are exposed and recognized by ASGP-R (Tozawa et al. 2001). The assembly of two homologous subunits, H1 and H2, is required to form functional, high affinity receptors on the cell surface. However, the importance of the individual subunits for receptor transport to the cell surface is controversial. To explore the significance of the minor H2 subunit for receptor expression and function in vivo, homozygous H2-deficient mice (*MHL-2*$^{-/-}$) are superficially normal. However, H1 expression in the liver is greatly reduced, indicating that H2 may H1 is strictly required for the stable expression of H2. Although these mice are completely unable to clear asialoorosomucoid, a high affinity ligand for asialoglycoprotein receptor, they do not accumulate desialylated glycoproteins or lipoproteins in their circulation (Ishibashi et al. 1994; Tozawa et al. 2001). Results suggest that ASGP-R is not ultimately responsible for the clearance of plasma glycoproteins, but is likely to possess other functions.

ASGP-R has been proposed to be involved in the metabolism of plasma lipoproteins and cellular fibronectin (Rotundo et al. 1998). However, studies with ASGP-R knock-out mice could not confirm this result, as the plasma levels of fibronectin and lipoprotein appeared unaffected in the absence of the receptor (Tozawa et al. 2001). ASGP-R has also been implicated in the clearance of apoptotic cells by the liver. Studies showed that the uptake of apoptotic bodies was blocked in the presence of an ASGP-R specific antibody or following the addition of receptor specific ligands such as ASF or Gal*N*Ac (Dini et al. 1992). Immunoglobulin A has also been proposed as a ligand for the receptor (Rifai et al. 2000). Finally, ASGP-R is thought to act as an entry point for a few specified pathogenic viruses to the hepatocytes. Experimental data indicate that the Marburg virus (Becker et al. 1995), the hepatitis B virus (Owada et al. 2006; Treichel et al. 1994) and the hepatitis C virus (Saunier et al. 2003) are capable of binding to the receptor, followed by infection of the host cell. Results on the infectivity of HBV in vitro showed that ASGP-R may be a specific HBV receptor once viral particles are desialylated (Owada et al. 2006).

Geuze et al. (1984) compared the endocytotic pathways of the receptors for ASGP-R, mannose-6-phosphate ligands (M6PR), and polymeric IgA (IgA-R). All three were found within the Golgi complex, along the entire plasma membrane, in coated pits and vesicles, and within a compartment of uncoupling of receptors and ligand (CURL). The receptors occurred randomly at the cell surface, in coated pits and vesicles. Within CURL tubules ASGP-R and M6PR were co-localized, but IgA-R and ASGP-R displayed microheterogeneity. Thus, in addition to its role in uncoupling and sorting recycling receptor from ligand, CURL serves as a compartment to segregate recycling receptor (e.g. ASGP-R) from receptor involved in transcytosis (e.g. IgA-R).

33.6.1 Impact of ASGP-R Deficiency on the Development of Liver Injury

Function of ASGP receptor is impaired in pathological states such as liver disease among alcoholics. The knockout ASGP-receptor$^{-/-}$mice, after various toxic challenges (alcohol, anti-Fas, CCl_4 and LPS/galactosamine), consistently showed more liver injury than the wild-type animals. This suggested that ASGP receptor functions as a protective agent. Thus, receptor-mediated endocytosis may be a novel mechanism that may be involved in the induction of toxin-induced liver injury. However, it is likely that impaired clearance of apoptotic bodies, perturbations in extracellular matrix deposition, oxidative stress, and cytokine dysregulation may play roles in the progression of disease (Lee et al. 2009). Overall, results suggest a possible link between hepatic receptors and liver injury. In particular, adequate function and content of the ASGP receptor may provide protection against various toxin-mediated liver diseases.

33.7 ASGP-R: A Marker for Autoimmune Hepatitis and Liver Damage

33.7.1 Autoimmune Hepatitis

Antibodies to ASGP-R have prognostic value. Circulating anti-ASGP-R autoantibodies in autoimmune hepatitis is independent of geographic or ethnic criteria. Results in different ethnic groups suggest highest frequency (76%) of

anti-human ASGP-R in autoimmune hepatitis patients (11/24 U.S.; 21/25 European; 28/30 Japanese), particularly in those with active disease before treatment (53/62, 85%), and decreased in titer with response to immunosuppressive therapy.

The research has been focused on the hepatocytes by examining endocytosis using the ASGP-R pathway as a model and identified multiple ethanol-induced impairments in receptor function. The altered uptake of apoptotic cells via ASGP-R may result in the release of proinflammatory mediators, the introduction of autoimmune responses, and inflammatory injury to the tissue. It was found that uptake of apoptotic bodies is impaired in hepatocytes isolated from ethanol-fed animals compared to controls, and that this impairment is linked to altered ASGP-R function. There is an attempt to examine a link between ethanol-impaired ASGP-R function, apoptotic body accumulation, and inflammation in the liver (Casey et al. 2008; McVicker et al. 2002). Hemolysis in patients with advanced alcoholic liver disease is a common clinical problem and indicates an unfavorable prognosis. All patients with liver disease have a soluble variant of the human s-ASGP-R in their serum, as well as high titers of autoantibodies against this receptor. Examination of patients with alcoholic liver disease reveal a high incidence for s-ASGP-R (36%) and anti-ASGP-R (27%) in patients with alcoholic liver cirrhosis compared to patients with cirrhosis due to viral hepatitis. This suggests a non-immunological mechanism for hemolysis in patients with alcoholic liver disease, mediated through agglutination by a soluble variant of the human ASGP-R and mechanical shear stress (Hilgard et al. 2004).

33.7.2 Hepatocellular Carcinoma

ASGP-Rs expression is decreased in various chronic liver diseases and hepatoma. Although the active shedding of the receptors clearly occurs in vitro, the significance of these shed receptors in blood will require further studies. The expression of ASGP-R on human hepatocellular carcinoma (HCC) cells might be exploited to reduce the extrahepatic toxicity of DNA synthesis inhibitors by their conjugation with galactosyl-terminating peptides. The results clearly demonstrated that DNA synthesizing cancer cells expressed the ASGP-R on their surface. The presence of ASGP-R on cell plasma membrane in the majority of differentiated HCCs and its maintenance on proliferating cells encourages studies in order to restrict the action of the inhibitors of DNA synthesis of HCC cells by their conjugation with galactosyl-terminating carriers internalized through this receptor (Trerè et al. 1999). Both acute and chronic phenobarbital administration decreased the number of ASGP-Rs per cell. Partial hepatectomy had a similar effect on the number of receptors per cell (Evarts et al. 1985).

33.7.3 Extra-Hepatic ASGP-R

In humans, ASGP-R is predominantly expressed by hepatocytes, at an estimated density of 100,000–500,000 binding sites per cell (Wall and Hubbard 1981; Matsuura et al. 1982) but does occur extrahepatically in thyroid, in small and large intestines, and in the testis. There is evidence of expression of the receptor in the T-cell line Jurkat. Moreover, Tera-1 cells derived from human testis gave rise to a weak signal, indicating presence of ASGP-R (Park et al. 1998). In the kidney, there has been evidence both for and against its existence in mesangial cells. Studies support ASGP-R expression in cells originating from human bone intestine and kidney (Park et al. 2006; Seow et al. 2002). Primary renal proximal tubular epithelial cells have a functional ASGP-R, consisting of the H1 and H2 subunit which are capable of specific ligand binding and uptake (Seow et al. 2002).

33.8 ASGP-R: A Model Protein for Endocytosis

Transport of macromolecules into the cell by receptor-mediated endocytosis follows a complex series of intracellular transfers, passing through distinct environments. The ASGP-R constitutively enters cells via coated pits and delivers ligand to these intracellular compartments. In addition to being a model of receptor-mediated endocytosis, the presence of the receptor on hepatocytes provides a membrane-bound active site for cell-to-cell interactions, has made possible the selective targeting of chemotherapeutic agents and foreign genes, and has also been implicated as a site mediating hepatitis B virus uptake. Regulated expression of receptor subunits and their intracellular trafficking during biosynthesis and endocytosis has provided insights into the relationship of receptor structure to its overall function. As a marker of hepatocellular differentiation, its study has uncovered a unique response to intracellular guanosine 3′, 5′-cyclic monophosphate and translational regulation of the receptor.

Receptor-mediated endocytosis serves as a mechanism by which cells can internalize macromolecules like peptides and proteins. The ASGP-R has been the focus of several studies aiming to understand endocytosis via the clathrin-coated pit pathway. Following binding of ligand to the ASGP-R at the cell surface, the receptor-ligand complex is endocytosed via clathrin-coated pits and directed to endosomes, where the

complex dissociates. The carbohydrate ligand is targeted for degradation in lysosomes while the receptor recycles to the cell surface with a vacant binding site (Spiess 1990). Upon ligand binding, the ASGP-Rs cluster into clathrin-coated domains of the membrane, which in turn invaginates. Clathrin-coated pits are then formed and subsequently turned into coated vesicles, which are internalized by the cell. With few exceptions, receptor-mediated endocytosis of specific ligands is mediated through clustering of receptor-ligand complexes in coated pits on the cell surface, followed by internalization of the complex into endocytic vesicles. During this process, ligand-receptor dissociation occurs, most probably in a low pH prelysosomal compartment. In most cases the ligand is ultimately directed to the lysosomes, wherein it is degraded, while the receptor recycles to the cell surface. In a human hepatoma cell line, Ciechanover et al. (1983) gained some insight into the complex mechanisms which govern receptor recycling as well as ligand sorting and targeting and explained why transferrin is exocytosed intact from the cells, while asialoglycoproteins are degraded in lysosomes. The receptor appears to be a transmembrane protein and is localized both to the cell surface as well as to several membranous intracellular compartments (Schwartz 1984). The ASGP-Rs meet a less grim fate as they are recycled and transported back to the plasma membrane (Geffen and Spiess 1992; Spiess 1990).

Recycling of the ASGP-R is a continuous process and occurs several hundred times during the life span of an individual receptor, the time of which is estimated to approximately 30 h (Schwartz 1984). Internalization of the ASGP-R takes place independently of ligand binding, but was shown to increase 2-fold upon binding of ASOR. Speculations attribute this enhanced internalization rate to a possible conformational change induced by ligand binding (Bider and Spiess 1998). Furthermore, a tyrosine residue in H1 has been shown to be of critical importance for efficient endocytosis of the ASGP-R. The corresponding residue in H2, a phenylalanine, does not appear to contribute to the internalization of hetero-oligomeric receptor complexes (Fuhrer et al. 1991, 1994).

Endosomal pH is an important determinant of recycling of the asialoglycoprotein receptor as well as other endocytic receptors (Mellman et al. 1986). The dissociation process that occurs in endosomes can be mimicked in vitro by ligand release at pH 5.4. In the case of the chicken hepatic lectin, an homologous endocytic receptor, pH modulates structural transitions between several distinct states of the CRD (Loeb and Drickamer 1988). At endosomal pH, the structural change causes an approximately 10-fold reduction in affinity for $Ca^{2+}$with concomitant loss of ligand binding activity. Site-directed mutagenesis of the CRD to residues His^{256}, Asp^{266}, and Arg^{270} singly and in combination indicate that these residues reduce the affinity of the CRD for Ca^{2+}, so that ligands are released at physiological Ca^{2+} concentrations. The proximity of these three residues to the ligand-binding site at Ca^{2+} site 2 of the domain suggests that they form a pH-sensitive switch for Ca^{2+} and ligand binding. Introduction of histidine and aspartic acid residues into the mannose-binding protein CRD at positions equivalent to His^{256} and Asp^{266} raises the pH for half-maximal binding of ligand to 6.1. The results, as well as sequence comparisons with other C-type CRDs, confirm the importance of these residues in conferring appropriate pH dependence in this family of domains (Wragg and Drickamer 1999).

Glycans as Endocytosis Signals Animal cells internalize specific extracellular macromolecules (ligands) by using specialized cell surface receptors that operate through a complex and highly regulated process known as receptor-mediated endocytosis, which involves the binding, internalization, and transfer of ligands through a series of distinct intracellular compartments. For the uptake of a variety of carbohydrate-containing macromolecules, such as glycoproteins, animal cells use specialized membrane-bound lectins as endocytic receptors that recognize different sugar residues or carbohydrate structures present on various ligands. Studies of how the asialoglycoprotein receptor functions have led to the discovery of two functionally distinct, parallel pathways of clathrin-mediated endocytosis (called the State 1 and State 2 pathways), which may also be utilized by all the other endocytic recycling receptor systems. Weigel and Yik (2002) discussed the characteristics and physiological importance of ASGP-R as an example of how lectins can function as endocytic receptors.

33.9 ASGP-R for Targeting Hepatocytes

The ASGP-R on mammalian hepatocytes provides a unique means for the development of liver-specific carriers, such as liposomes, recombinant lipoproteins, and polymers for drug or gene delivery to the liver, especially to hepatocytes (Wu et al. 1998). The abundant receptors on the cells specifically recognize ligands with terminal galactose or N-acetylgalactosamine residues, and endocytose the ligands for an intracellular degradation process. The use of its natural ligand, i.e. asialofetuin, or synthetic ligands with galactosylated or lactosylated residues, such as galactosylated cholesterol, glycolipids, or galactosylated polymers has achieved significant targeting efficacy to the liver. There are several examples of successful targeted therapy for acute liver injury with asialofetuin-labeled and vitamin E-associated liposomes or with a caspase inhibitor loaded in sugar-carrying polymer particles, as well as for the delivery of an antiviral agent, 9-(2-phosphonylmethoxyethyl) adenine. Liposome-mediated

gene delivery to the liver is more difficult than to other organs, such as to lungs. Galactosylated polymers are promising for gene delivery, but require further studies to verify their potential applications (Wu et al. 2002) (see Chap. 46).

Labeling conventional liposomes with asialofetuin was seen to result in a significant increase of liver uptake, compared to unlabeled liposomes, after intravenous injection into mice. The enhanced uptake was most likely mediated by the ASGP-R (Wu et al. 1998). Another study used glycolipids containing a cluster galactoside moiety for targeting to ASGP-R. The liver uptake of the glycolipid-liposomes was estimated to exceed 80% compared to less than 10% for conventional liposomes after injection. DNA-galactosylated cationic liposome complexes show higher DNA uptake and gene expression in the liver parenchymal cells in vitro than DNA complexes with bare cationic liposomes. In the in vitro gene transfer experiment, galactosylated liposome complexes are more efficient than DNA-galactosylated poly(amino acids) complexes but they have some difficulties in their biodistribution control. On the other hand, introduction of mannose residues to carriers resulted in specific delivery of genes to non-parenchymal liver cells. These results suggest advantages of these glycosylated carriers in cell-specific targeted delivery of genes (Hashida et al. 2001).

In order to reduce the extrahepatic side-effects of antiviral nucleoside analogues in the treatment of chronic viral hepatitis, these drugs were conjugated with galactosyl-terminating macromolecules. The conjugates selectively enter hepatocytes after interaction of the carrier galactose residues with the ASGP-R present in large amounts and high affinity only on these cells. The validity of this chemotherapeutic strategy has been endorsed by a clinical study (Fiume et al. 1997). Receptors like ASGP-R provide unique opportunity to target liver parenchymal cells. The results obtained so far reveal tremendous promise and offer enormous options to develop novel DNA based pharmaceuticals for liver disorders in near future. The ^{99m}Tc-labeled asialoglycoprotein analog, TcGSA (galactosyl-human serum albumin-diethylenetriamine -pentaacetic acid) has been applied to human hepatic receptor imaging. This method is unique and provides information that is totally independent of the ICG test or Child-Turcotte Score (Kokudo et al. 2003; Pathak et al. 2008).

33.10 Macrophage Galactose-Type Lectin (MGL) (CD301)

33.10.1 Human MGL (CD 301)

Serial analysis of gene expression in monocyte-derived DCs, monocytes, and macrophages revealed that 7 of the 19 C-type lectin mRNAs are present in immature DCs. Two of these, the macrophage mannose receptor (MMR) and the macrophage lectin specific for galactose/N-acetylgalactosamine (MGL), were found only in immature DCs (Steinman et al. 2003). Subcloning and sequencing the amplified mRNA, revealed nucleotide sequences encoding seven different human MGL (hMGL) subtypes, which were apparently derived from alternatively spliced mRNA. In addition, the hMGL gene locus on human chromosome 17p13 contains one gene. A single nucleotide polymorphism was identified at a position in exon 3 that corresponds to the cytoplasmic region proximal to the transmembrane domain. Of all the splicing variants, the hMGL variant 6 C was expressed at the highest levels on immature DCs from all donors tested.

Macrophage galactose-type lectins are a family of type II C-type lectins expressed in connective tissue macrophages and in bone marrow-derived DCs (Mizuochi et al. 1997; Denda-Nagai et al. 2002). The human macrophage C-type lectin was homologous to galactose- and N- acetylgalactosamine-specific C-type macrophage lectins of rodents. In the putative CRD, deduced amino acid sequence revealed 60 and 63% homology to galactose- and N- acetylgalactosamine-specific C-type macrophage lectins of mice and rats, respectively. The *Mgl* gene consists of ten exons and has been mapped to mouse chromosome 11 (Tsuiji et al. 1999). The *MGL* gene has been mapped to human chromosome 17p13.2 and contains one gene. The chromosome localization of MGL is distinct from that of many C-type lectins, MMR, DEC-205, DCIR, langerin, DC-SIGN, and Dectin-1, claimed to be specific for DCs. A single nucleotide polymorphism was identified at a position in exon 3 that corresponds to the cytoplasmic region proximal to the transmembrane domain. Of all the splicing variants, the hMGL variant 6 C was expressed at the highest levels on immature DCs. It was proposed that hMGL is a marker of immature DCs and that it functions as an endocytic receptor for glycosylated antigens (Higashi et al. 2002a). MGL is also called DC-asialoglycoprotein receptor (DC-ASGP-R) or human macrophage lectin (HML) (Higashi et al. 2002b; Valladeau et al. 2001; Suzuki et al. 1996). The liver-specific ASGP-R is closest homolog of MGL.

33.10.2 Murine MGL1/MGL2 (CD301)

Murine bone marrow–derived immature DCs also bind and internalize α-*N* acetylgalactosaminides conjugated to soluble polyacrylamide (α-GalNAc polymers), whereas mature DCs and bone marrow cells did not. It was suggested that mMGL is transiently expressed on bone marrow–derived DCs during their development and maturation and seemed to be involved in the uptake of glycosylated antigens for presentation (Denda-Nagai et al. 2002).

There are two MGL genes in mice: *Mgl1*, and *Mgl2* (Tsuiji et al. 2002; Onami et al. 2002; Dupasquier et al. 2006). The *Mgl* family is known to have two homologous

genes in mice, *Mgl1* and *Mgl2*, and these two lectins have distinct carbohydrate recognition specificities, although their distinct roles have not yet been defined (Tsuiji et al. 2002; Oo-Puthinan et al. 2008). MGL1 and/or MGL2 are mainly expressed on macrophages and immature DCs, and that these cells were observed mainly in the connective tissue of various organs, especially in skin, large intestines, and lymph nodes (Mizuochi et al. 1997). MGL'CD301 recognizes terminal galactose and (GalNAc) residues as monosaccharides in a calcium-dependent manner (Imai and Irimura 1994; Sato et al. 1992; Yamamoto et al. 1994; Denda-Nagai et al. 2010). These lectins were found to be involved in the uptake of mucin-like GalNAc-conjugated polymers by murine bone marrow-derived and human monocyte-derived DCs (Higashi et al. 2002b; Denda-Nagai et al. 2002), which was thought to be an important process of antigen processing. *Mgl1*-deficient mice did not show obvious defects in lymphoid and erythroid homeostasis (Onami et al. 2002). In an in vivo study with mouse embryos, MGL1 was shown to function as an endocytic receptor for X-irradiation-induced apoptotic cells, whereas *Mgl1*-deficient mice showed retarded clearance of apoptotic cells in neural tubes (Yuita et al. 2005). It is also suggested that MGL1 regulates trafficking of MGL1-expressing cells from skin to lymph nodes (Chun et al. 2000a, b; Kumamoto et al. 2004). Antigen-induced inflammatory tissue formation in skin was abrogated in *Mgl1*-deficient mice (Sato et al. 2005a), suggesting that MGL1 functioned under inflammatory conditions. MGL2 expresses in the skin and the cutaneous LNs. It was highly restricted to DDCs in the skin and the LNs. Evidence indicates that hapten-incorporated DDCs are sufficient to induce CHS in vivo. The availability of MGL2 as a marker for DDCs suggested the contribution of $MGL2^+$ DDCs for initiating contact hypersensitivity (Kumamoto et al. 2009).

The sequence of mMGL2 is highly homologous to the mMGL, which should now be called mMGL1. The ORF of mMGL2 contains a sequence corresponding to a type II transmembrane protein with 332 amino acids having a single extracellular C-type lectin domain. The 3′-untranslated region included long terminal repeats of mouse early transposon. The *Mgl*2 gene spans 7,136 base pairs and consists of ten exons, similar to the genomic organization of mMGL1. The mMGL2 mRNA was also detected in mMGL1-positive cells. The soluble recombinant proteins of mMGL2 exhibited carbohydrate specificity for α- and β-GalNAc-conjugated soluble polyacrylamides, whereas mMGL1 preferentially bound Lewis X-conjugated soluble polyacrylamides (Tsuiji et al. 2002).

The MGL, expressed by DC and macrophages, mediates binding to glycoproteins and lipids that contain terminal GalNAc moieties. MGL represents an exclusive marker for myeloid-type APC. Dexamethasone increased MGL expression on DC in a time- and dose-dependent manner. In contrast, DC generated in the presence of IL-10 did not display enhanced MGL levels. Furthermore, dexamethasone and IL-10 also differentially regulated expression of other C-type lectins, such as DC-SIGN and mannose receptor. Results indicate that depending on the local microenvironment, DC can adopt different C-type lectin profiles, which could have major influences on cell-cell interactions, antigen uptake and presentation (van Vliet et al. 2006b).

33.10.3 Ligands of MGL

Ligands of Human MGL: Van Die et al. (2003) identified an exclusive specificity for terminal α- and β-linked GalNAc residues that naturally occur as parts of glycoproteins or glycosphingolipids. Specific glycan structures containing terminal GalNAc moieties, expressed by the human helminth parasite *Schistosoma mansoni* as well as tumor antigens and a subset of gangliosides, were identified as ligands for MGL. The dendritic cell-specific DC-SIGN is a receptor for Schistosoma 8 MGL recognition of terminal GalNAc residues (Van Die et al. 2003).

Exclusive specificity of human MGL for rare terminal GalNAc structures was revealed on the tumor-associated mucin MUC1 and CD45 on effector T cells. Tumor glycoproteins, such as carcinoembryonic antigen and MUC-1/MUC1-Tn are known to interact with MGL on APCs. In vivo studies in mice demonstrated the potency of targeting antigens to C-type lectins on antigen-presenting cells for anti-tumor vaccination strategies (Aarnoudse et al. 2006). Glycosylation changes during malignant transformation create tumor-specific carbohydrate structures that interact with C-type lectins on DCs. The detection of MGL positive cells in situ at the tumor site together with the modified glycosylation status of MUC1 to target MGL on DC suggests that MGL positive antigen presenting cells may play a role in tumor progression (Saeland et al. 2007). Tumor-associated Tn-MUC1 glycoform is internalized through the MGL and delivered to the HLA class I and II compartments in dendritic cells (Napoletano et al. 2007). Soluble model antigens are efficiently internalized by MGL and subsequently presented to responder CD4+ T cells. The tyrosine-5 residue in the YENF motif, present in the MGL cytoplasmic domain, was essential for the MGL-mediated endocytosis in CHO cells. MGL contributes to the antigen processing and presentation capacities of DC and may provide a suitable target for the initiation of anti-tumor immune responses (van Vliet et al. 2007). Findings implicate MGL in the homeostatic control of adaptive immunity. van Vliet et al. (2008b) discussed the functional similarities and differences between MGL orthologs and compared MGL to its closest homolog, the liver-specific ASGP-R (van Vliet et al. 2008). Evidence

indicates that both N-linked glycoproteins and distinct lipooligosaccharide glycoforms of *C. jejuni* are ligands for the human MGL and that the *C. jejuni* N-glycosylation machinery can be exploited to target recombinant bacteria to MGL-expressing eukaryotic cells (van Sorge et al. 2009).

Studies indicate the involvement of a C-type lectin, the MMR and the macrophage surface molecule MGL that binds influenza virus, both of which are known to be endocytic. Binding of influenza virus to MMR and MGL occurred independently of sialic acid through Ca^{2+}-dependent recognition of viral glycans by the CRDs of the two lectins. Thus, lectin-mediated interactions of influenza virus with the MMR or the MGL are required for the endocytic uptake of the virus into macrophages, and these lectins can thus be considered secondary or coreceptors with sialic acid for infection of this cell type (Upham et al. 2010).

Ligands of Murine MGLs: Despite the high similarity between the primary sequences of MGL1 and MGL2, they have different carbohydrate specificities, respectively, for Lewis X and a/b-GalNAc structures (Tsuiji et al. 2002). Earlier studies on COS-1 transfectants of MGL suggested a specificity for galactose and *N*-acetylgalactosamine as monosaccharides (Suzuki et al. 1996). In contrast, recombinant MGL displayed restricted binding to GalNAc (Iida et al. 1999). MGL1 shows high affinity for the Lewis-X trisaccharide among 111 oligosaccharides tested, whereas MGL2 preferentially bound globoside Gb4. Molecular modeling illustrated potential direct molecular interactions of Leu^{61}, Arg^{89}, and His^{109} in MGL2 CRD with GalNAc (Oo-Puthinan et al. 2008). NMR analyses of the MGL1-Lewis-X complex presented a Lewis-X binding mode on MGL1 where the galactose moiety is bound to the primary sugar binding site, including Asp^{94}, Trp^{96}, and Asp^{118}, and the fucose moiety interacts with the secondary sugar binding site, including Ala^{89} and Thr^{111}. Ala^{89} and Thr^{111} in MGL1 are replaced with arginine and serine in MGL2, respectively. The hydrophobic environment formed by a small side chain of Ala^{89} and a methyl group of Thr^{111} is a requisite for the accommodation of the fucose moiety of the Lewis-X trisaccharide within the sugar binding site of MGL1 (Sakakura et al. 2008; Oo-Puthinan et al. 2008). Using a glycan array, murine MGL1 was highly specific for Lewis-X and Lewis-A structures, whereas mMGL2, more similar to the human MGL, recognized GalNAc and galactose, including the O-linked Tn-antigen, TF-antigen and core 2. Strikingly, MGL2 interacted strongly to adenocarcinoma cells, suggesting a potential role in tumor immunity (Singh et al. 2009).

Specific glycan structures containing terminal GalNAc moieties, expressed by the human helminth parasite *Schistosoma mansoni* as well as tumor antigens and a subset of gangliosides, were identified as ligands for MGL. Results indicated an endogenous function for DC-expressed MGL in the clearance and tolerance to self-gangliosides, and in the pattern recognition of tumor antigens and foreign glycoproteins derived from helminth parasites (van Vliet et al. 2005).

33.10.4 Functions of MGL

The MGL on immature DCs is involved in mediating down-regulation of effector T cell function and T cell death by interaction with CD45 avoiding potentially harmful T cell activation (van Vliet et al. 2006a). Several lines of evidence suggest that MGL may also be involved in the trafficking of APC that express this α/β-GalNAc-specific lectin (van Vliet et al. 2005; Dupasquier et al. 2006; Chun et al. 2000a, b). MGL1/2-positive cells represent a distinct sub-population of macrophages, having unique functions in the generation and maintenance of granulation tissue induced by antigenic stimuli (Sato et al. 2005a). It is highly likely that MGL1-positive cells are not involved in tissue remodeling when inflammation is driven by nonspecific stimuli (Sato et al. 2005b). Mice DCs have two MGL genes, *Mgl*1 and *Mgl*2. A report demonstrates the involvement of GalNAc residues in antigen uptake and presentation by DCs that lead to $CD4^+$ T cell activation.

Pregnant mice with $Mgl1^{+/-}$ genotype were mated with $Mgl1^{+/-}$ or $Mgl1^{-/-}$genotype males, and the embryos were used to assess a hypothesis that this molecule plays an important role in the clearance of apoptotic cells. After X-ray irradiation at 1 Gy of developing embryos at 10.5 days post coitus (d.p.c.), the number of $Mgl1^{-/-}$ pups was significantly reduced as compared with $Mgl1^{+/+}$ pups. Results strongly suggest that MGL1 is involved in the clearance of apoptotic cells (Yuita et al. 2005).

MGL induction in Activated Macrophages by Parasitic Infections: The expression of the two members of the mouse mMGL1 and mMGL2 is induced in diverse populations of alternatively activated macrophages (aaMF), including peritoneal macrophages elicited during infection with the protozoan *Trypanosoma brucei brucei* or the Helminth *Taenia crassiceps* and alveolar macrophages elicited in a mouse model of allergic asthma. In addition, interleukin-4 (IL-4) and IL-13 up-regulate mMGL1 and mMGL2 expression in vitro, and that in vivo, induction of mMGL1 and mMGL2 is dependent on IL-4 receptor signaling. Moreover, expression of MGL on human monocytes is also up-regulated by IL-4 (Raes et al. 2005).

Initiation of Contact Hypersensitivity In Vivo: The MGL, expressed in immature DCs, mediates binding to glycoproteins carrying GalNAc moieties. MGL ligands are

present on the sinusoidal and lymphatic endothelium of lymph node and thymus, respectively. MGL binding strongly correlated with the expression of the preferred MGL ligand, α-GalNAc-containing glycan structures. MGL^+ cells were localized in close proximity of the endothelial structures that express the MGL ligand. Strikingly, instead of inducing migration, MGL mediated retention of human immature DCs, as blockade of MGL interactions enhanced DC trafficking and migration. Thus, MGL^+ DCs are hampered in their migratory responses and only upon maturation, when MGL expression is abolished; these DCs will be released from their MGL-mediated restraints (van Vliet et al. 2008a).

Anti-Inflammatory Role in Murine Experimental Colitis: Inflammatory bowel disease is caused by abnormal inflammatory and immune responses to harmless substances, such as commensal bacteria, in the large bowel. MGL1 expressed on intestinal lamina propria macrophages functions through its inter-action with commensal bacteria by magnifying the IL-10 production by these cells. Results in $Mgl1^{-/-}$ mice and their wild-type littermates strongly suggest that MGL1/CD301a plays a protective role against colitis by effectively inducing IL-10 production by colonic lamina propria macrophages in response to invading commensal bacteria (Saba et al. 2009). Mgl1 is not required for the trafficking of type 2 Adipose tissue macrophages to adipose tissue. But MGL1 is a novel regulator of inflammatory monocyte trafficking to adipose tissue in response to diet-induced obesity (Westcott et al. 2009).

Dectin-1 Receptor Family

34

Rajesh K. Gupta and G.S. Gupta

34.1 Natural Killer Gene Complex (NKC)

Natural killer (NK) cell receptors belong to two unrelated, but functionally analogous gene families: the immunoglobulin superfamily, situated in the leukocyte receptor complex (LRC) and the C-type lectin receptors (CLRs) superfamily, located in the natural killer gene complex (NKC). Wong et al. (2009) described the largest NK receptor gene expansion seen to date and identified 213 putative C-type lectin NK receptor homologs in the genome of the platypus. Many have arisen as the result of a lineage-specific expansion. Orthologs of OLR1, CD69, KLRE, CLEC12B, and CLEC16p genes were also identified. The NKC is split into at least two regions of the genome: 34 genes map to chromosome 7, two map to a small autosome, and the remainder are unanchored in the current genome assembly. No NK receptor genes from the LRC were identified. The massive C-type lectin expansion and lack of Ig-domain-containing NK receptors represents the most extreme polarization of NK receptors found to date. This new data from platypus was utilized to trace the possible evolutionary history of the NK receptor clusters.

The myeloid cluster within NK gene complex comprises several CLRs genes of diverse and highly important functions in the immune system such as LOX-1 and DECTIN-1. The type II transmembrane CLRs are best known for their involvement in the detection of virally infected or transformed cells, through the recognition of endogenous (or self) proteinacious ligands. However, certain CLR families within the NKC, particularly those expressed by myeloid cells, recognize structurally diverse ligands and perform a variety of other immune and homoeostatic functions. One such family is the 'Dectin-1 cluster' of CLRs, which includes MICL (CLEC12A), CLEC-2 (CLEC1B), CLEC12B, CLEC9A, CLEC-1(CLEC-1A), in addition to Dectin-1 (CLEC7A), and LOX-1 (Fig. 34.1). Current understanding of these CLRs, high-lighting their ligands, functions and new insights into the underlying mechanisms of immunity and homeostasis has been reviewed by Huysamen and Brown (2009) and given in Table 34.1. The arrangement of genes within the primate cluster differs from the order and orientation of the corresponding genes in the rodent complex which can be explained by evolutionary duplication and inversion events. Analysis of individual genes revealed a high sequence conservation supporting the prime importance of the encoded proteins (Sattler et al. 2010; Sobanov et al. 2001).

34.2 β-Glucan Receptor (Dectin 1) (CLEC7A or CLECSF12)

β-1—>3-D-Glucans are biological response modifiers with potent effects on the immune system. A number of receptors are thought to play a role in mediating these responses, including murine Dectin-1, which was identified as a β-glucan receptor in humans. The receptor possessed a single C-type lectin-like CRD connected to the transmembrane region by a stalk and a cytoplasmic tail possessing an immunoreceptor tyrosine-based activation motif (ITAM). Dectin-1 is widely expressed in mouse tissues and acts as a pattern recognition receptor, recognizing a variety of carbohydrates containing β-1—>3- and/or β-1—>6-glucan linkages and intact *Saccharomyces cerevisiae* and *Candida albicans* (Brown and Gordon 2001). Dectin-2 and its isoforms, together with dectin-1, represent a unique subfamily of DC-associated C-type lectins (Ariizumi et al. 2000a).

34.2.1 Characterization of β-Glucan Receptor (Dectin 1)

Dectin-1 gene encodes a type II membrane-integrated polypeptide of 244 amino acids containing a single carbohydrate recognition domain motif at the COOH-terminal end. This molecule was expressed abundantly at both mRNA and

DOI 10.1007/978-3-7091-1065-2_34, © Springer-Verlag Wien 2012

protein levels by the XS52 DC line, but not by non-DC lines (Taylor et al. 2002). Dectin-1 mRNA was detected predominantly in spleen and thymus and in skin-resident DC, i.e. Langerhans cells. Dectin-1 was identified a 43-kDa glycoprotein in membrane fractions of XS52 DC line and from dectin-1 cDNA-transfected COS-1 cells. In vitro results suggest that dectin-1 on DC may bind to a ligand(s) on T cells, thereby delivering T cell co-stimulatory signals (Ariizumi et al. 2000b). Mouse Dectin 1 has a CRD consisting of six cysteine residues, which are highly conserved in C-type lectins. The human homologue of Dectin 1 is structurally and functionally similar to the mouse receptor. The human β-glucan receptor is a type II transmembrane receptor with a single extracellular CRD and an ITAM in its cytoplasmic tail.

Dectin-1 is regulated by different immune stimuli; GM-CSF and IL-4 up-regulate surface expression, whereas IL-10 and LPS down-regulate the expression (Willment et al. 2003). Murine dectin-1 has been suggested to have an alternative splice form that lacks the stalk region (Yokota et al. 2001). In humans, eight isoforms of the homologue of dectin-1 have been described (Willment et al. 2003). The most common isoforms, BGR-A and BGR-B (β-glucan receptor/dectin-1), represent full-length and stalkless isoforms, respectively, and both mediate the recognition of yeast particles in a β-glucan-dependent manner. The human homologue is expressed by cells similar to those in the mouse as well as by peripheral B cells and eosinophils (Willment et al. 2005). Human dectin-1 undergoes cell-specific isoform expression during monocyte maturation. Monocytes express both BGR-A and BGR-B, but during maturation to Mφ, the expression levels of BGR-A decrease with time. Immature DCs express high levels of both isoforms; however, DCs lose the expression of both isoforms when matured with LPS (Willment et al. 2005). RT-PCR analysis revealed that mice have at least two splice forms of dectin-1, generated by differential usage of exon 3, encoding the full-length dectin-1A and a stalkless MΦ dectin-1B. MΦ from BALB/c mice and genetically related mice expressed both isoforms in similar amounts, whereas MΦ from C57BL/6 and related mice mainly expressed the smaller isoform. Evidence suggests that dectin-1 isoforms are functionally distinct and indicate that differential isoform usage may represent a mechanism of regulating cellular responses to β-glucans (Heinsbroek et al. 2006). The Dectin-1 gene was

localized in NKC on human Chromosome 12p12.3-p13.2, between OLR1 and CD94 (position 21.8 cM on genetic map). The Dectin-1 gene is highly expressed at the mRNA level in DCs and is not further up-regulated during the maturation of DCs (Hermanz-Falcón et al. 2001). The amino acid sequence Try^{221}-Ile^{222}-His^{223} seemed critical for formation of a β-glucan binding site in CRD of dectin 1 (Adachi et al. 2004).

34.2.2 Crystal Structure of Dectin-1

Brown et al. (2007) reported dectin-1 crystal structures, including a short soaked natural β-glucan, trapped in the crystal lattice. In vitro characterization of dectin-1 in presence of its natural ligand indicates higher-order complex between dectin-1 and β-glucans. These combined structural and biophysical results considerably extend the current knowledge of dectin-1 structure and function, and suggest potential mechanisms of defense against fungal pathogens. Amino acid analysis indicates that dectin-1 is a 28-kDa type II membrane protein. An extracellular C-type lectin-like domain (CTLD) is connected by a stalk to a transmembrane region, followed by a cytoplasmic tail containing an ITAM-like motif (Ariizumi et al. 2000b). First recognized as a calcium-dependent carbohydrate-binding domain, the CTLD fold is also seen in non-calcium dependent protein recognition interactions. Few of the residues required for calcium coordination in classical CTLDs are conserved in dectin-1. In classical CTLDs, the long loop region (LLR) contains residues responsible for calcium binding, but these residues are absent in dectin-1 and no metal ions stabilize the LLR. As expected from sequence analysis, the dectin-1 fold is similar to that of other long-form CTLDs (Brown et al. 2007) (Fig. 34.2), comprising two antiparallel β-sheets and two α-helices.

The N and C termini are close together with domain integrity maintained by three disulphide bridges—Cys^{119}-Cys^{130}, Cys^{147}-Cys^{240}, and Cys^{219}-Cys^{232}—stabilizing the LLR. For their CTLDs alone, the residue identity between murine dectin-1 and its human homolog β-glucon receptor is 59.5%, implying that the structure of murine dectin-1 provides a reasonably good model for the structure of the human protein. Among several hydrophobic side chains exposed to solvent, Trp^{221} and His^{223} deserve attention and are in agreement with results of Adachi et al. (2004), who suggested that side groups of these amino acids participate in ligand binding and are conserved in all Dectin-1 homologues. Xray analysis of Dectin-1 structure revealed a shallow surface groove running between the Trp^{221} and His^{223} side chains (Fig. 34.2).

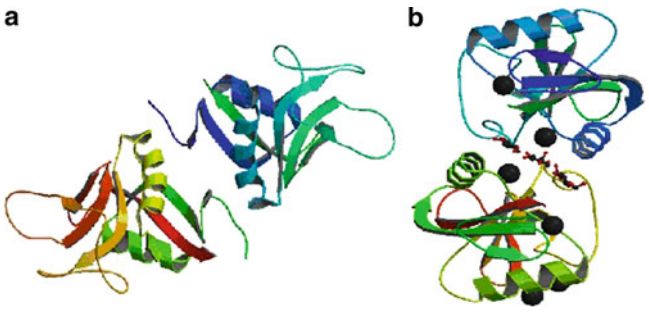

Fig. 34.2 Crystal structure of murine Dectin-1 (known as β–glucon receptor in humans). Two dectin-1 monomers (**a**) form a dimer into which a short β-glucan binds (**b**). (**a**) A cartoon diagram of the dectin-1 dimer (PDB: 2BPD), with each monomer from N terminus to C terminus. (**b**) Dectin-1 in complex with β-glucan (PDB: 2CL8). Disulphide linkages, the metal ion, and the bound β-glucan are shown

34.2.3 Interactions of Dectin-1 with Natural or Synthetic Glucans

Dectin-1 (CLEC7A) specifically recognizes β-D-(1—>3)-glucan, a polysaccharide and a component of fungal cell wall. As a result, dectin-1 is involved in recognition of fungi such as *C. albicans* and *Aspergillus fumigatus*. Due to the presence of (1—>3)-β-D-glucans on fungal cell walls, dectin 1 is considered important for recognizing fungal invasion. Although Dectin-1 is highly specific for β-D-(1—>3)-glucans, it does not recognize all glucans equally and interacts with β-D-(1—>3)-glucan over a very wide range of binding affinities (2.6 mM-2.2 pM). Among different polysachharides, Dectin-1 binding was detected exclusively to (1—>3)-linked glucose oligomers, the minimum length required for detectable binding being a 10- or 11-mer (Palma et al. 2006; Ujita et al. 2009). Dectin-1 can differentiate between glucan ligands based on structural determinants and can interact with both natural product and synthetic glucan ligands (Adams et al. 2008). Dectin-1 lacks residues involved in calcium ligation that mediates carbohydrate-binding by classical C-type lectins; nevertheless, it binds zymosan, a particulate β-glucan-rich extract of *Saccharomyces cerevisiae*, and binding is inhibited by polysaccharides rich in (1—>3)-β or both (1—>3)-β/(1—>6)-linked glucose (Palma et al. 2006). Dectin-1 is responsible for β-glucan-dependent, nonopsonic recognition of zymosan by primary macrophages and is an important target for examining the immunomodulatory properties of β-glucans for therapeutic drug design (Brown et al. 2002).

34.2.4 Regulation of Dectin-1

In mice, the expression of Dectin-1 can be influenced by various cytokines, steroids and microbial stimuli.

Interleukin-4 and IL-13, for example, which are associated with the alternative activation of macrophages, markedly increase the expression of Dectin-1 at the cell surface, whereas LPS and dexamethasone repress Dectin-1 expression (Willment et al. 2003). However, in *Pneumocystis*-infected mice, the mRNA levels of Dectin-1 gene decreased in AMΦs. This was associated with the decreased expression of Dectin-1 on the surface of these cells and reduced expression of mRNA of transcription factor PU.1 in AMΦs from *Pneumocystis*-infected mice. Down-regulation of PU.1 during *Pneumocystis* pneumonia appears to decrease the expression of Dectin-1 in AMΦs (Zhang et al. 2010). Leukocyte Dectin-1 levels are modulated in response to infections of fungal and nonfungal origin (Ozment-Skelton et al. 2009). Glucan phosphate (GP) resulted in a significant reduction in peripheral leukocyte membrane-associated Dectin-1 positivity. The systemic administration of GP has a specific and prolonged effect on loss of leukocyte membrane Dectin-1 positivity (Ozment-Skelton et al. 2006).

34.2.5 Signaling Pathways by Dectin-1

34.2.5.1 Raf-1 and CARD9 Dependent Pathways

Dectin-1-induced-signaling leads to the production of cytokines and non-opsonic phagocytosis of yeast by murine macrophages (LeibundGut-Landmann et al. 2007; Herre et al. 2004). Studies indicate that the alveolar macrophage inflammatory response, specifically the production of TNF-α, IL-1α, IL-1β, IL-6, CXCL2, CCL3-CSF, and GM-CSF, to live *A. fumigatus* is dependent on recognition via Dectin-1. The Dectin-1 is involved in calcium-independent recognition of β-(1—>3)-glucans exposed on particles such as zymosan, or many fungal species, including *Saccharomyces, Pneumocystis, Aspergillus* and *Candida* (Brown 2006; Brown et al. 2003; Heinsbroek et al. 2008). Signaling pathway activation of Dectin-1 depends on its ITAM the phosphorylation of which by Src kinase leads to the recruitment of spleen tyrosine kinase Syk in macrophages. Studies suggest that the increase in Dectin-1 expression by IL-4 involved the STAT signaling pathway (Murray 2007). Moreover, genetic models of macrophage specific peroxisome proliferator-activated receptor γ (PPARγ) or STAT-6 knockout mice showed that IL-4/IL-13/STAT-6/PPARγ axis is required for the maturation of alternatively activated macrophages (Odegaard et al. 2007; Ricote et al. 1998; Galès et al. 2010). In vitro and in vivo Dectin-1 is essential both to trigger the phagocytosis of non-opsonized *C. albicans* and the respiratory burst after yeast challenge and to control fungal gastrointestinal infection (Galès et al. 2010); the ManR alone is not sufficient to trigger antifungal functions during macrophage alternative activation. Interestingly, Dectin-1 and ManR were increased by IL-13 through the activation of the nuclear receptor PPARγ, suggesting that PPARγ could be a therapeutic target to eliminate fungal infection.

The intracellular signaling of Dectin-1 has been demonstrated to be mediated mainly by Raf-1 and Syk-adaptor molecule *C*aspase *A*ctivating *R*ecruitment *D*omain 9 (CARD9) dependent pathways to induce production of pro-inflammatory cytokines and reactive oxygen species (Underhill et al. 2005; Gringhuis et al. 2009; Rogers et al. 2005; Gross et al. 2006; Hara et al. 2007). Upon activation, dectin-1 recruites spleen Syk which in turn activates NF-κB, requiring the CARD9, a key adaptor for non-TLR signal transduction (Gross et al. 2006) and also has a critical function in NOD2-mediated activation of kinases p38 and Jnk, required for the production of pro-inflammatory cytokines in innate immune responses to intracellular pathogens (Hsu et al. 2007). LeibundGut-Landmann et al. (2007) showed that Dectin-1-Syk-CARD9 signaling induces DC maturation and secretion of pro-inflammatory cytokines like IL-6, TNF-α, IL-17 and IL-23 (Fig. 34.3). Several studies suggest that dectin-1 converges with Toll Like Receptor (TLR) signaling (Ferwerda et al. 2008; Dennehy et al. 2008) for the induction of cytokine responses and is able to promote Th17 and cytotoxic T-cell responses through activation of DCs (Gerosa et al. 2008; Leibundgut-Landmann et al. 2007; Gow et al. 2007). There is also evidence of Syk-dependent, but CARD9-independent, pathways, such as those leading to the induction of ERK, a MAP kinase regulating the Dectin-1-mediated production of cytokines, particularly IL-10 and IL-2 (Slack et al. 2007; Dillon et al. 2006).

Dectin-1 can also induce intracellular signaling through Syk-independent pathways. Phagocytosis in macrophages, for example, does not require Syk, although this response still involves the ITAM-like motif of the receptor (Brown 2006). These pathways are still largely uncharacterised, but Dectin-1 was found to induce a Syk-independent pathway involving the serine–threonine kinase Raf-1 (Gringhuis et al. 2009). This pathway was shown to integrate with the Syk pathway, at the level of NF-κB, and to be involved in controlling Dectin-1 mediated cytokine production. Thus, dectin-1 activates two independent signaling pathways, one through Syk and one through Raf-1, to induce immune responses.

Dectin-1 signaling can also directly modulate gene expression via activation of NFAT. Dectin-1-triggered NFAT activation plays a role in the induction of early growth response transcription factors, and cyclooxygenase-2. Furthermore, NFAT activation regulates IL-2, IL-10 and IL-12 p70 production by zymosan-stimulated DCs. This study establishes NFAT activation in myeloid cells as a novel mechanism of regulation of innate antimicrobial

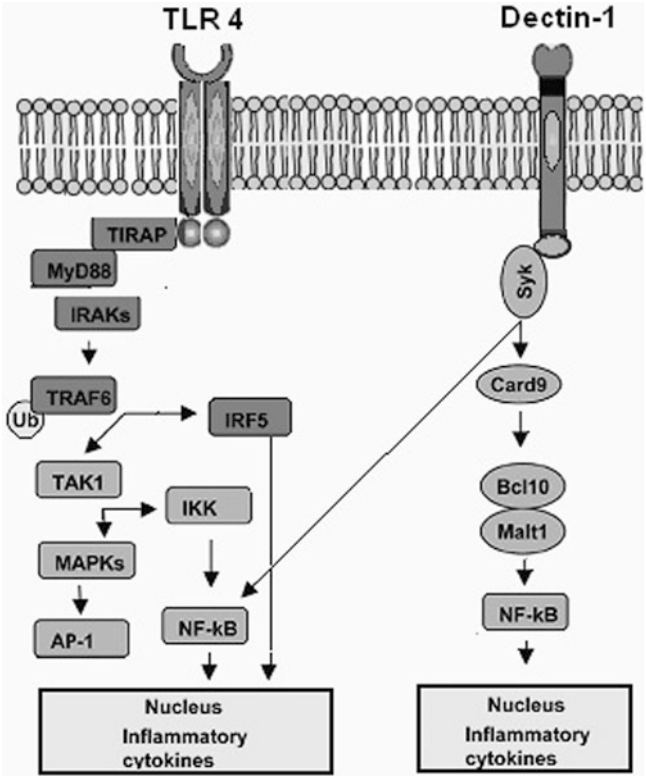

Fig. 34.3 Signaling pathway downstream of TLR4 and Dectin-1. Antigen presenting cells (APCs), including monocytes, macrophages and DCs, engage pathogens (fungi) and activate host responses via several PRRs including the Toll-like receptors (*TLR-4*) and Dectin-1. Dectin-1 is alternatively spliced into two functional isoforms, which differ by the presence or absence of a stalk region (shown in *dark black*). Dectin-1 recognises linear or branched 1—>3-linked β-glucan, which triggers intracellular signaling through at least two pathways, involving Syk kinase (shown in Figure) and Raf-1(not shown in Figure). Upon zymosan recognition, Dectin-1 can recruit Syk, and subsequently, Card9 relays the signal to the Bcl10-Malt1 complex to activate NF-κB, thus leading to the expression of inflammatory cytokines (IL-6, IL-10, IL-12, IL-17, IL-23, TNF). TLRs, on the contrary, which recognise various mannosylated and other fungal cell wall structures, signal through the MyD88-Mal mediated NF-κB pathway and induce the production of both pro and anti-inflammatory cytokines, including TNF, IL-10, IL-12 and TGFβ. Costimulation of both receptors can amplify the production of cytokines, including TNF, IL-23, IL-10 and IL-6 while downregulating the production IL-12, influencing the resultant generation of adaptive immunity (Lee and Kim 2007; Reid et al. 2009)

response (Goodridge et al. 2007). DCs stimulated through Dectin-1 can generate efficient Th, CTL and B cell responses and can therefore be used as effective mucosal and systemic adjuvants in humans (Agrawal et al. 2010). Engagement of Dectin-1 with β-glucan on the surface of murine primary microglia results also in an increase in tyrosine phosphorylation of Syk, a feature of Dectin-1 signaling pathway. Dectin-1 pathway may play an important role in antifungal immunity in the CNS (Shah et al. 2008).

34.2.5.2 PLCγ2 Is Critical for Dectin-1-Mediated Ca^{2+} Flux and Cytokine Production in DCs

Stimulation of DCs with zymosan triggers an intracellular Ca^{2+} flux that can be attenuated by a blocking anti-Dectin-1 antibody or by pre-treatment of cells with PLCγ-inhibitor U73122. This suggests that Dectin-1 could elicit Ca^{2+} signaling through PLCγ2 in Dectin-1 signal transduction pathway (Xu et al. 2009b). Lipid rafts are plasma membrane microdomains that are enriched in cholesterol, glycosphingolipids, and glycosylphosphatidylinositol-anchored proteins and play an important role in the signaling of ITAM-bearing lymphocyte antigen receptors. It was demonstrated that Dectin-1 translocates to lipid rafts upon stimulation of DCs with β-glucan. In addition, two key signaling molecules, Syk and PLCγ2 are also recruited to lipid rafts upon the activation of Dectin-1, suggesting that lipid raft microdomains facilitate Dectin-1 signaling. Xu et al. (2009a) indicated that Dectin-1 and perhaps also other CTLDs are recruited to lipid rafts upon activation and that the integrity of lipid rafts is important for the signaling and cellular functions initiated by this class of innate receptors.

34.2.5.3 Activation and Regulation of Phospholipase A2

Dectin-1 also mediates respiratory burst (Gantner et al. 2003) and its involvement has been suggested in the activation and regulation of phospholipase A2 (PLA2) and cyclooxygenase-2 (COX-2) (Suram et al. 2006). Secretory PLA_2 ($sPLA_2$) translocates from Golgi and recycling endosomes of mouse peritoneal macrophages to newly formed phagosomes and regulates the phagocytosis of zymosan, suggesting a role in innate immunity. The $sPLA_2$ regulates phagocytosis and contributes to the innate immune response against *C. albicans* through a mechanism that is likely dependent on phagolysosome fusion (Balestrieri et al. 2009). Co-stimulation of dectin-1 and DC-SIGN triggers the arachidonic acid cascade in human monocyte-derived DCs through both opsonic and nonopsonic receptors. The FcγR route depends on ITAM/Syk/cytosolic phospholipase A_2 axis, whereas the response to zymosan involves the interaction with dectin-1 and DC-SIGN (Valera et al. 2008).

34.2.6 Functions of Dectin-1

34.2.6.1 Recognition of Pathogens and Antifungal Defense

Dectin-1 has been shown to be involved in AMΦ recognition, nonopsonic phagocytosis, and killing of *Pneumocystis* organisms both in vitro and in vivo. Dectin-1 is a major β-glucan receptor on the surface of macrophages, DCs, neutrophils and it is also expressed on certain lymphocytes

(Taylor et al. 2002), subpopulations of MΦs in splenic red and white pulp, Kupffer cells, and MΦs and DCs in the lamina propria of gut villi (Reid et al. 2004). This is consistent with its role in pathogen surveillance. Tissue localization thus revealed potential roles of Dectin-1 in leukocyte interactions during innate immune responses and T cell development. Dectin-1 functionally interacts with leukocyte-specific tetraspanin CD37. Dectin-1 and CD37 colocalize on the surface of human APCs. Tetraspanin CD37 is important for dectin-1 stabilization in APC membranes and controls dectin-1-mediated IL-6 production (Meyer-Wentrup et al. 2007).

RAW 264.7 macrophages overexpressing Dectin-1 bind *Pneumocystis* organisms (Steele et al. 2003) and increases macrophage-dependent killing of *Pneumocystis* (Gross et al. 2006; Rapaka et al. 2007). Dectin-1-deficient mice have compromised clearance of *Pneumocystis* (Saijo et al. 2007) and *Candida albicans* (Taylor et al. 2007), as well as attenuated macrophage inflammatory responses to these organisms. Dectin-1 is centrally required for the generation of alveolar macrophage proinflammatory responses to *A. fumigatus* and provides in vivo evidence for the role of dectin-1 in fungal innate defense (Leal et al. 2010; Steele et al. 2005). Naive mice lacking Dectin-1 (Dectin-$1^{-/-}$) are more sensitive to intratracheal challenge with *A. fumigatus* than control mice, exhibiting >80% mortality within 5 days, ultimately attributed to a compromise in respiratory mechanics (Werner et al. 2009). A fusion protein consisting of Dectin-1 extracellular domain linked to the Fc portion of murine IgG1 augmented alveolar macrophage killing of *A. fumigatus* and shifted mortality associated with IPA via attenuation of *A. fumigatus* growth in the lung (Mattila et al. 2008). A role for Dectin-1 in promoting M. tuberculosis-induced IL-12p40 production by DC has been suggested by Rothfuchs et al. (2007) in which the receptor augments bacterial-host cell interaction and enhances the subsequent cytokine response through an unknown mechanism involving Syk signaling. Non-typeable *Haemophilus influenzae* (NTHi) can induce an innate inflammatory response in eosinophils that is mainly mediated via β-glucan receptors (Ahren et al. 2003; Weck et al. 2008). Dectin-1 is a potential targeting molecule for immunization and has implications for the specialization of DC subpopulations (Carter et al. 2006).

34.2.6.2 Collaborative Responses Mediated by Dectin-1 and TLR2

During fungal infection, a variety of receptors initiates immune responses, including TLR and the Dectin-1. TLR recognition of fungal ligands and subsequent signaling through myeloid differentiation factor 88 (MyD88) pathway (Fig. 34.3) was thought to be the most important interactions required for the control of fungal infection. However, recent studies have highlighted the role of Dectin-1 in induction of cytokine responses and the respiratory burst. Mitogen-activated protein kinase (MAPK) activation and TNF-α production in macrophage infected with *Mycobacterium avium* or *M smegmatis* is dependent on MyD88 and TLR2 but not TLR4, ManR, or CR3. Interestingly, the TLR2-mediated production of TNF-α by macrophages infected with *M smegmatis* requires dectin-1. A similar requirement for Dectin-1 in TNF-α production was observed for macrophages infected with *M bovis Bacillus Calmette-Guerin* (BCG), *M. phlei, M avium 2151*-rough, and *M tuberculosis H37Ra*. Studies established a significant role for Dectin-1, in cooperation with TLR2, to activate a macrophage's proinflammatory response to a mycobacterial infection (Yadav and Schorey 2006)

Saijo et al. (2007) argue that Dectin-1 plays a minor role in control of *Pneumocystis carinii* by direct killing and that TLR-mediated cytokine production controls *P. carinii* and *C. albicans*. By contrast, Taylor et al. (2007) argue that Dectin-1-mediated cytokine and chemokine production, leading to efficient recruitment of inflammatory cells, is required for control of fungal infection. Dennehy and Brown (2007) argued that collaborative responses induced during infection may partially explain these apparently contradictory results. It appears that Dectin-1 can mediate their own signaling, as well as synergize with TLR to initiate specific responses to infectious agents (Dennehy et al. 2009).

The DCs activated via Dectin can convert T_{reg} to IL17 producing cells (Osorio et al. 2008). Furthermore, they also prime cytotoxic T-lymphocyte (CTL) and mount potent CTL responses (LeibundGut-Landmann et al. 2008). Dectin-1 also induces antibody production in rodents (Kumar et al. 2009). Thus, DCs stimulated through Dectin-1 can generate efficient Th, CTL and B cell responses and can therefore be used as effective mucosal and systemic adjuvants in humans (Agrawal et al. 2010).

34.2.7 Genetic Polymorphism in Relation to Pathology

CARD9 is a susceptibility locus for inflammatory bowel disease (IBD) (Zhernakova et al. 2008). Dectin-1 polymorphism c.714T>G on chromosome 12p13 has been described with a transition from a tyrosine to an early stop codon on amino acid position 238 (p.Y238X) (Ferwerda et al. 2009). The functional consequence of this polymorphism is a complete loss of function, and immune cells expressing this truncated protein produce significantly less cytokines, including TNF-α, IL-1β and IL-17, upon in vitro stimulation with β-glucan or *C. albicans* (Plantinga et al. 2009). Th17 responses are considered to be involved in the pathogenesis

of auto-immune diseases. Interestingly, both NOD2 [Nucleotide-binding oligomerization domain-containing protein 2 (also known as caspase recruitment domain-containing protein 15 (CARD15)] and Dectin-1 are shown to be capable of inducing Th17 responses after activation (LeibundGut-Landmann et al. 2007; van Beelen et al. 2007). In this respect, the Dectin-1 c.714T>G polymorphism could influence the Th17 response towards fungi such as *C. albicans* in gastrointestinal tract. de Vries et al. (2009) demonstrated that Dectin-1 expression is elevated on macrophages, neutrophils, and other immune cells involved in the inflammatory reaction in IBD. The Dectin-1 c.714T>G polymorphism however, is not a major susceptibility factor for developing IBD.

It has been well established that fungal particles, either intact yeast or fungal cell wall components that can be recognized by dectin-1, such as zymosan, can act as adjuvants in several experimental models of RA (Leibundgut-Landmann et al.. 2007; Frasnelli et al. 2005; Hida et al. 2007). In addition, Yoshitomi et al. (2005) revealed that β-glucan induced autoimmune arthritis in genetically susceptible SKG mice could be prevented by blocking the dectin-1 receptor. These studies imply that dectin-1 plays a pivotal role in the innate immune system and is able to modulate adaptive immune responses, of which, especially Th17 responses are implicated in immunopathology. Furthermore, Dectin-1 is involved in the induction of arthritis in mouse models through induction of intracellular signaling on recognition of fungal components. As a consequence, dectin-1 mediated inflammatory responses could contribute to the aetiology or disease severity of RA. An early stop codon polymorphism Y238X (c.714T>G, rs16910526) in Dectin-1 (Veerdonk et al. 2009) has resulted in a complete loss of function of the protein. Cytokine production capacity of peripheral blood mononuclear cells (PBMCs) from individuals homozygous for the Dectin-1 Y238X polymorphism on β-glucan or *C. albicans* exposure are impaired, including TNF-α, interleukin (IL-)1β, IL-6, and IL-17 responses. In the same assays, individuals heterozygous for Dectin-1 Y238X polymorphism exhibited intermediate cytokine responses compared with wild-type individuals (Ferwerda et al. 2009). Considering both the involvement of Dectin-1 in pro-inflammatory responses and the significant consequences of the Y238X polymorphism for Dectin-1 function, Plantinga et al. (2010) suggest that Dectin-1 Y238X polymorphism does not play a role in the pathogenesis of RA. Although expression of dectin-1 was high in synovial tissue of RA patients, and reduced cytokine production was observed in macrophages of individuals bearing Dectin-1 Y238X polymorphism, loss of one functional allele of Dectin-1 was not associated with either susceptibility to or severity of RA (Plantinga et al. 2010).

34.3 The C-Type Lectin-Like Protein-1 (CLEC-1) or CLEC-1A

34.3.1 *CLEC-1* Gene

The region telomeric of CD94 contains, in addition to the LOX-1 and DECTIN-1, genes: the CLEC-1 and CLEC-2 genes within about 100 kb. Sequence similarities and chromosomal arrangement suggest that these genes form a separate subfamily of lectin-like genes within the NK gene complex. Human CLEC-1 displays a single CRD and a cytoplasmic tyrosine-based motif. It is homologous to the NK cell receptors NKG2s and CD94 and also to LOX-1and preferentially transcribes in DCs (Colonna et al. 2000; Sobanov et al. 2001). CLEC-1 is over-expressed in a model of rat allograft tolerance. CLEC-1 is expressed by myeloid cells and specifically by endothelial cells in tolerated allografts. CLEC-1 expression can be induced in endothelial cells by alloantigen-specific regulatory $CD4^{+}CD25^{+}$T cells. Expression of CLEC-1 is down-regulated by inflammatory stimuli but increased by the immunoregulators IL-10 or TGFβ. Interestingly, inhibition of CLEC-1 expression in rat DCs increases the subsequent differentiation of allogeneic Th17 T cells and decreases the regulatory $Foxp3^{+}$ T cell pool in vitro. In chronically rejected allograft, the decreased expression of CLEC-1 is associated with a higher production of IL-17. It is suggested that CLEC-1, expressed by myeloid cells and endothelial cells, is enhanced by regulatory mediators and moderates Th17 differentiation (Thebault et al. 2009).

34.4 CLEC-18 or the C-Type Lectin-Like Protein-2 (CLEC-2) or CLEC1B

34.4.1 Characterization

CLEC-1 and CLEC-18 (CLEC-2) possess a single CRD and a cytoplasmic tyrosine-based motif. Both are homologous to the NK cell receptors NKG2s and CD94 and also to LOX-1. CLEC-2 is expressed on the surface of transfected cells as a protein of approximately 33 kDa. The CLEC-2 is expressed on platelets and signaling through CLEC-2 is sufficient to mediate platelet aggregation (Suzuki-Inoue et al. 2006). The gene encoding CLEC-2 is located in the human NK complex on chromosome 12, along with the C-type lectin-like receptors NKG2D, LOX-1, and Dectin-1 (Sobanov et al. 2001). CLEC-2 is a type II transmembrane receptor, and its transcripts have been identified in immune cells of myeloid origin, including monocytes, DCs, and granulocytes, and in liver (Colonna et al. 2000). Human CLEC-2 has been reported to facilitate the capture of HIV-1. Xie et al.

(2008) identified two novel splicing variants of mCLEC-2 derived from omission of exon 2 and 2/4, respectively. These two variants had different expression profiles and subcellular localization from full-length mCLEC-2. Moreover, the full-length mCLEC-2 could be cleaved probably by proteases sensitive to aprotinin and PMSF into a soluble form that partially existed as a disulfide-linked homodimer. The interacting partner of the cytoplasmic region of CLEC-2 is RACK1, the receptor for activated C-kinase 1. Moreover, over-expression of RACK1 decreased the stability of CLEC-2 through promoting its ubiquitin-proteasome degradation, suggesting that RACK1 as a novel modulator of CLEC-2 expression (Ruan et al. 2009).

34.4.2 Ligands for CLEC-2

CLEC-2 has been shown to be a receptor on the surface of platelets for the snake venom toxin rhodocytin, which is produced by the Malayan pit viper *Calloselasma rhodostoma* (Shin and Morita 1998; Suzuki-Inoue et al. 2006) and the endogenous sialoglycoprotein podoplanin and functions as stimulator in platelet activation.

34.4.2.1 Rhodocytin/Aggretin

Aggretin, also known as rhodocytin, is a C-type lectin from *Calloselasma rhodostoma* snake venom. It is a potent activator of platelets, resulting in a collagen-like response by binding and clustering platelet receptor CLEC-2 (Suzuki-Inoue et al. 2006). The rhodocytin has been reported to bind to integrin α2β1 and glycoprotein (GP) Ibα on platelets, but it is also able to induce activation independent of two receptors and of GPVI. CLEC-2 in platelets confers signaling responses to rhodocytin when expressed in a cell line. CLEC-2 has a single tyrosine residue in a YXXL motif in its cytosolic tail, which undergoes tyrosine phosphorylation upon platelet activation by rhodocytin or an antibody to CLEC-2. The pathway in platelets included activation of CLEC-2 by rhodocytin, binding of Syk, initiation of downstream tyrosine phosphorylation, and the activation of PLCγ2. CLEC-2 is the first C-type lectin receptor on platelets which signals through this novel pathway (Suzuki-Inoue et al. 2006). Rhodocytin may induce cytokine TNF-α/IL-6 release after interaction with CLEC-2 and the subsequent MAPK and NF-kB activation in monocytes/macrophages (Chang et al. 2010).

The Rhodocytin/Aggretin at 1.7 A is an unique tetrameric quaternary structure. The two αβ heterodimers are arranged through twofold rotational symmetry, resulting in an antiparallel side-by-side arrangement. The Rhodocytin thus presents two ligand binding sites on one surface and can therefore cluster ligands in a manner reminiscent of convulxin and flavocetin. Molecular interaction of the rhodocytin with CLEC-2 was studied using molecular modeling after docking the aggretin αβ structure with the CLEC-2 N-terminal domain (CLEC-2N). This model positions the CLEC-2N structure face down in the "saddle"-shaped binding site which lies between the rhodocytin α and β lectin-like domains. A twofold rotation of this complex to generate the rhodocytin tetramer reveals dimer contacts for CLEC-2N which bring the N- and C-termini into the proximity of each other, and a series of contacts involving two interlocking β-strands close to N-terminus. A comparison with homologous lectin-like domains from the immunoreceptor family reveals a similar but not identical dimerization mode, suggesting this structure may represent the clustered form of CLEC-2 capable of signaling across the platelet membrane (Hooley et al. 2008). Rhodocytin displays a concave binding surface, which is highly complementary to the experimentally determined binding interface on CLEC-2. Using computational dynamic methods, surface electrostatic charge and hydrophobicity analyses, and protein-protein docking predictions, it was proposed that the $(\alpha\beta)_2$ rhodocytin tetramer induces clustering of CLEC-2 receptors on the platelet surface, which will trigger major signaling events resulting in platelet activation and aggregation (Watson et al. 2008).

34.4.2.2 Podoplanin as Ligand

Podoplanin (aggrus), a transmembrane mucin-like sialoglycoprotein, is involved in tumor cell-induced platelet aggregation, tumor metastasis, and lymphatic vessel formation. Podoplanin is an endogenous ligand for CLEC-2 and facilitates tumor metastasis by inducing platelet aggregation. Podoplanin induces platelet aggregation with a long lag phase, which is dependent upon Src and phospholipase Cγ2 activation. However, it does not bind to glycoprotein VI. This mode of platelet activation was reminiscent of the snake rhodocytin, the receptor of CLEC-2 (Suzuki-Inoue et al. 2006). Results suggest that CLEC-2 is a physiological target protein of podoplanin and imply that it is involved in podoplanin-induced platelet aggregation, tumor metastasis, and other cellular responses related to podoplanin (Kato et al. 2008; Suzuki-Inoue et al. 2007). In addition, indirect evidence indicates for an endogenous ligand for CLEC-2 in renal cells expressing HIV-1. Podoplanin is expressed on renal cells (podocytes) and acts as a ligand for CLEC-2 on renal cells (Christou et al. 2008). Incorporation of podoplanin into HIV released from HEK-293T cells is required for efficient binding to the attachment factor CLEC-2 (Chaipan et al. 2010). Mice, deficient in podoplanin, which is also expressed on the surface of lymphatic endothelial cells, show abnormal patterns of lymphatic vessel formation.

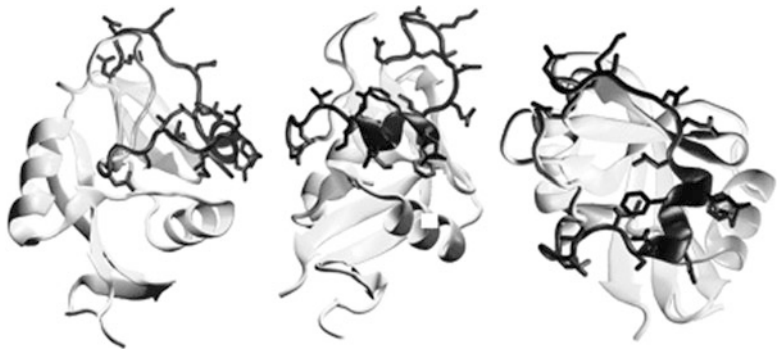

Fig. 34.4 Extracellular domain of the platelet-activating receptor CLEC-2: the semi-helical long loop region. Semi-helical long loop region dominates the upper surface of CLEC-2. The loop region is shown in *black* with the side chains illustrated. With respect to the *left panel*, the central panel is rotated 270° anticlockwise about the *y*-axis, and the *right panel* 90° anticlockwise about the *x*-axis. *B*, CLEC-2 is the only structurally characterized C-type lectin-like molecule with a formal helix in the long loop region (Adapted with permission from Watson et al. 2007 © American Society for Biochemistry and Molecular Biology)

Laminin VWF bridges exposed collagen, at damaged vessels, to GPIb. Subsequently, GPVI binds to collagen, leading to integrin α2β1 activation. Platelets also adhere to laminin, another major ECM component, through integrin α6β1, and are activated through GPVI. Laminin also interacts with VWF, leading to platelet adhesion via GPIb under sheer stress (Ozaki et al. 2009).

34.4.3 Crystal Structure of CLEC-2

The crystals of CLEC-2 belongs to the orthorhombic space group $P2_12_12_1$, with unit-cell parameters a = 35.407, b = 55.143, c = 56.078 A. The presence of one molecule per asymmetric unit is consistent with a crystal volume per unit weight (V_M) of 1.82 A^3 Da^{-1} and a solvent content of 32.6% (Watson and O'Callaghan 2005). Watson et al. (2007) solved the crystal structure of the extracellular domain of CLEC-2 and identified the key structural features involved in ligand binding. A semi-helical loop region and flanking residues (Fig. 34.4) dominate the surface that is available for ligand binding. The precise distribution of hydrophobic and electrostatic features in this loop will determine the nature of any endogenous ligand with which it can interact. Major ligand-induced conformational change in CLEC-2 is unlikely as its overall fold is compact and robust. However, ligand binding could induce a tilt of 3–10 helical portion of long loop region in CLEC-2. Mutational analysis and surface plasmon resonance binding studies support these observations (Watson et al. 2007).

34.4.4 Functions of CLEC-2

34.4.4.1 Platelet Activation

CLEC-2 has been described to play crucial roles in thrombosis/hemostasis, tumor metastasis, and lymphangiogenesis. Platelets play an essential role in wound healing by forming thrombi that plug holes in the walls of damaged blood vessels. To achieve this, platelets express a diverse array of cell surface receptors and signaling proteins that induce rapid platelet activation. Platelet glycoprotein receptors that signal via an ITAM or an ITAM-like domain, namely collagen receptor complex GPVI-FcR γ-chain and CLEC-2, respectively, support constitutive (i.e. agonist-independent) signaling. The CLEC-2 mediates powerful platelet activation through Src and Syk kinases, but regulates Syk through a novel dimerization mechanism via a single YXXL motif known as a hemITAM. Inhibition of constitutive signaling through Src and Syk tyrosine kinases by G6b-B may help to prevent unwanted platelet activation (Mori et al. 2008; O'Callaghan et al. 2009). CLEC-2 is a receptor for podoplanin, which is expressed at high levels in several tissues (Section 34.4.2.2) but is absent from vascular endothelial cells and platelets. Platelet activation at sites of vascular injury is critical for primary hemostasis, but can also trigger arterial thrombosis in vascular disease. The ability of rhodocytin or CLEC-2-specific antibodies to trigger platelet aggregation in the absence of other stimuli indicates the potency with which CLEC-2 can modulate platelet activity (Suzuki-Inoue et al. 2006). Therefore, CLEC-2 is a potential therapeutic target in thrombotic cardiovascular disease. In addition, a molecular understanding of the effects of rhodocytin could lead to more effective therapy of snake envenomation (Chaipan et al. 2006). Phenotypes in CLEC-2-deficient mice are lethal at the embryonic/neonatal stages associated with disorganized and blood-filled lymphatic vessels and severe edema. Transplantation of fetal liver cells from Clec-$2^{-/-}$ demonstrated that CLEC-2 is involved in thrombus stabilization in vitro and in vivo, possibly through homophilic interactions without apparent increase in bleeding tendency. These results reveal an essential function of CLEC-2 in hemostasis and thrombosis (May et al. 2009;

Kerrigan et al. 2009; Watson et al. 2009). CLEC-2 could be an ideal novel target protein for an anti-platelet drug, which inhibits pathological thrombus formation but not physiological hemostasis (Suzuki-Inoue et al. 2010; Spalton et al. 2009).

34.4.4.2 Lymphatic Vascular Development Through CLEC-2-SLP-76 Signaling

Although platelets appear by embryonic day 10.5 in the developing mouse, an embryonic role for these cells has not been identified. The SYK-SLP-76 signaling pathway is required in blood cells to regulate embryonic blood-lymphatic vascular separation, but the cell type and molecular mechanism underlying this regulatory pathway are not known. Bertozzi et al. (2010) demonstrated that platelets regulate lymphatic vascular development by directly interacting with lymphatic endothelial cells through CLEC-2 receptors. Podoplanin, expressed on surface of lymphatic endothelial cells, is required in nonhematopoietic cells for blood-lymphatic separation. These studies identify a nonhemostatic pathway in which platelet CLEC-2 receptors bind lymphatic endothelial podoplanin and activate SLP-76 signaling to regulate embryonic vascular development.

CLEC-2, originally thought to be restricted to platelets, is also expressed by peripheral blood neutrophils, and only weakly by bone marrow or elicited inflammatory neutrophils. On circulating neutrophils, CLEC-2 can mediate phagocytosis of Ab-coated beads and the production of proinflammatory cytokines, including TNF-α, in response to CLEC-2 ligand, rhodocytin. Like dectin-1, CLEC-2 can recruit the signaling kinase Syk in myeloid cells, however, stimulation of this pathway does not induce the respiratory burst. Thus, CLEC-2 also functions as an activation receptor on neutrophils (Kerrigan et al. 2009).

34.4.5 CLEC-2 Signaling

The CLEC-2 and Dectin-1 have been shown to signal through a Syk-dependent pathway, despite the presence of only a single YXXL in their cytosolic tails. Stimulation of CLEC-2 in platelets and in two mutant cell lines is dependent on YXXL motif and on proteins that participate in signaling by ITAM receptors, including Src, Syk, and Tec family kinases, and on phospholipase Cγ. Results demonstrate that CLEC-2 signals through a single YXXL motif that requires the tandem SH2 domains of Syk but is only partially dependent on the SLP-76/BLNK family of adapters (Fuller et al. 2007). Ligand binding by CLEC-2 promotes phosphorylation of a tyrosine in the cytoplasmic domain YXXL motif of CLEC-2 by Src kinases and further downstream signaling events trigger platelet activation and aggregation. The snake venom protein rhodocytin and the endogenous protein podoplanin have been identified as ligands. The structures of CLEC-2 and rhodocytin suggest that ligand binding could cluster CLEC-2 molecules at the platelet surface and initiate signaling.

The signaling pathway used by CLEC-2 shares many similarities with that used by receptors that have 1 or more copies of an ITAM, defined by the sequence YXX(L/I)X(6–12)YXX(L/I), in their cytosolic tails or associated receptor chains. Evidence suggests that Syk activation by CLEC-2 is mediated by the cross-linking through the tandem SH2 domains with a stoichiometry of 2:1. Cross-linking and electron microscopy demonstrated that CLEC-2 is present as a dimer in resting platelets and converted into larger complexes on activation. This is a unique mode of activation of Syk by a single YXXL-containing receptor (Hughes et al. 2010a, b). Pollitt et al. (2010) demonstrated that CLEC-2 translocates to lipid rafts upon ligand engagement and that translocation is essential for hemITAM phosphorylation and signal initiation. HemITAM phosphorylation, but not translocation, is also critically dependent on actin polymerization, Rac1 activation, and release of ADP and thromboxane A_2 (TxA_2). This reveals a unique series of proximal events in CLEC-2 phosphorylation involving actin polymerization, secondary mediators, and Rac activation (Pollitt et al. 2010).

34.5 CLEC9A (DNGR-1)

CLEC9A is a group V C-type lectin-like receptor located in the "Dectin-1 cluster" of related receptors, which are encoded within the NK-gene complex. Expression of human CLEC9A is highly restricted in peripheral blood, being detected only on $BDCA3^+$ dendritic cells and on a small subset of $CD14^+CD16^-$ monocytes. CLEC9A is expressed at the cell surface as a glycosylated dimer and can mediate endocytosis, but not phagocytosis. CLEC9A possesses a cytoplasmic ITAM that can recruit Syk kinase. This receptor can induce proinflammatory cytokine production and can function as an activating receptor (Huysamen et al. 2008). Mouse *Clec9A* encodes a type II membrane protein with a single extracellular C-type lectin domain. Surface staining of mAbs against mouse and humans revealed that *Clec9A* was selective for mouse DCs and was restricted to the $CD8^+$ conventional DC and plasmacytoid DC subtypes. A subset of human blood DCs also expressed CLEC9A (Caminschi et al. 2008).

Sancho et al. (2008) characterized a C-type lectin of the NK cell receptor group that was named DC, NK lectin group receptor-1 (DNGR-1). DNGR-1 is expressed in mice at high levels by $CD8^+$ DCs and at low levels by plasmacytoid DCs but not by other hematopoietic cells. Human DNGR-1 was also restricted in expression to a small subset of blood DCs that bear similarities to mouse $CD8\alpha^+$ DCs. The selective

expression pattern and observed endocytic activity of DNGR-1 suggested that it could be used for antigen targeting to DCs. DNGR-1 is a highly specific marker of mouse and human DC subsets that can be exploited for CTL cross-priming and tumor therapy.

In the mouse, the CD8α$^+$ subset of dendritic cells phagocytose dead cell remnants and cross-primes CD8$^+$ T cells against cell-associated antigens. Sancho et al. (2009) showed that CD8α$^+$ DCs use CLEC9A (DNGR-1), to recognize a preformed signal that is exposed on necrotic cells. Loss or blockade of CLEC9A does not impair the uptake of necrotic cell material by CD8$^+$ DCs, but specifically reduces cross-presentation of dead-cell-associated antigens in vitro and decreases the immunogenicity of necrotic cells in vivo. The function of CLEC9A requires a key tyrosine residue in its intracellular tail that allows the recruitment and activation of the tyrosine kinase SYK, which is also essential for cross-presentation of dead-cell-associated antigens. Thus, CLEC9A functions as a SYK-coupled C-type lectin receptor to mediate sensing of necrosis by the principal DC subset involved in regulating cross-priming to cell-associated antigens. In addition, DNGR-1 is a target for selective in vivo delivery of antigens to DC and the induction of CD8$^+$ T-cell and Ab responses (Joffre et al. 2010; Poulin et al. 2010).

34.6 Myeloid Inhibitory C-Type Lectin-Like Receptor (MICL/CLEC12A)

Marshall et al. (2004) reported the characterization of a human myeloid inhibitory C-type lectin-like receptor (MICL) which is primarily restricted to myeloid cells, including granulocytes, monocytes, macrophages, and dendritic cells. MICL contains a single C-type lectin-like domain and a cytoplasmic ITIM, and is variably spliced and highly N-glycosylated. It preferentially associates with the signaling phosphatases SHP-1 and SHP-2, but not with SHIP (Huysamen and Brown 2009). Chimeric construct combining MICL and the β-glucan receptor showed that MICL can inhibit cellular activation through its cytoplasmic ITIM. MICL is a negative regulator of granulocyte and monocyte function (Marshall et al. 2004). Although MICL was highly N-glycosylated in primary cells, the level of glycosylation varied between cell types. MICL surface expression was down-regulated during inflammatory/activation conditions in vitro, as well as during an in vivo model of acute inflammation. This suggests that human MICL may be involved in the control of myeloid cell activation during inflammation (Marshall et al. 2006). The murine homolog of MICL (mMICL) is structurally and functionally similar to the human orthologue (hMICL), although there are some notable differences. mMICL is expressed as a dimer and is not heavily glycosylated; however, like hMICL, the receptor can recruit inhibitory phosphatases upon activation, and is down-regulated on leukocytes following stimulation with selected TLR agonists. Like the human receptor, mMICL is predominantly expressed by myeloid cells. However, mMICL is also expressed by B cells and CD8$^+$ T cells in peripheral blood, and NK cells in the bone marrow. The mMICL recognises an endogenous ligand in a variety of murine tissues, suggesting that the receptor plays a role in homeostasis (Pyz et al. 2008).

34.7 CLEC12B or Macrophage Antigen H

Hoffmann et al. (2007) described a new member of CTLD family, CLEC12B. The extracellular domain of CLEC12B shows considerable homology to the activating natural killer cell receptor NKG2D, but unlike NKG2D, CLEC12B contains an ITIM (VxYxxL) within its cytoplasmic tail in its intracellular domain. Human CLEC12B is widely expressed at low levels in various human tissues, except the brain, and that the receptor is alternatively spliced, generating at least two isoforms, one of which lacks part of CRD and predicted to be nonfunctional (Hoffmann et al. 2007). Despite the homology of CLEC12B to NKG2D, CLEC12B does not appear to bind NKG2D ligands and therefore does not represent the inhibitory counterpart of NKG2D. However, CLEC12B has the ability to counteract NKG2D-mediated signaling, and that this function is dependent on the ITIM and the recruitment of the phosphatases SHP-1 and SHP-2. This receptor plays a role in myeloid cell function.

34.8 CLECSF7 (CD303)

C-type lectin domain superfamily member 7 was previously called CLECSF11 (C-type lectin domain superfamily member 11). The new designation is CLEC4C (C-type lectin domain family 4 member C). It is also named as blood dendritic cell antigen 2 (BDCA-2) or dendritic lectin, CD303 and contains one C-type lectin domain. It functions in antigen-capturing and targets ligand into antigen processing and peptide-loading compartments for presentation to T-cells. It may mediate potent inhibition of induction of IFN- α/β. Its expression in plasmacytoid dendritic cells may act as a signaling receptor that activates protein-tyrosine kinases and mobilizes intracellular Ca^{+2}. CLECSF7 does not seem to bind mannose (Fernandes et al. 2000). *HECL* (HGMW-approved symbol *CLECSF7*) gene maps close to the NK gene complex on human chromosome 12p47. Sequence analysis revealed a complete ORF of

549 bp comprising several putative glycosylation and phosphorylation sites as well as a C-terminal C-type CRD. *HECL* exhibits a significant degree of divergence from the NKCs that comprise the NK gene complex. The NKC receptors all belong to group V of the C-type lectin superfamily, where as HECL, is most closely related to the sole group II C-type lectins reported to map near this region of the genome, the murine *Nkcl* and *Mpcl* genes. Like Nkcl, HECL is expressed in a variety of hematopoietic cell types and has a complete Ca^{2+}-binding site 2. Despite the presence of critical amino acids for sugar binding in Ca^{2+} binding site 2, HECL does not seem to bind carbohydrate. Moreover, HECL is the first non-receptor-like C-type lectin to map near the NK gene complex (Fernandes et al. 2000).

34.9 Lectin-Like Oxidized LDL Receptor (LOX-1) (CLEC8A)

Endothelial activation, accumulation of oxidatively modified low density lipoprotein (Ox-LDL) and intense inflammation characterize atherosclerotic plaque in acute myocardial ischemia. Endothelial dysfunction, or activation, elicited by Ox-LDL and its lipid constituents has been shown to play a key role in the pathogenesis of atherosclerosis. Ox-LDL induces expression of lectin-like receptor (LOX-1) on endothelial cells and leads to the expression of matrix metalloproteinases (MMPs), which destabilize atherosclerotic plaque. LOX-1 and scavenger receptor for phosphatidylserine and oxidized lipoprotein (SR-PSOX) are type II and I membrane glycoprotoeins, respectively, both of which can act as cell-surface endocytosis receptors for Ox-LDL. In vivo, endothelial cells that cover early atherosclerotic lesions, and intimal macrophages and activated vascular smooth muscle cells (VSMC) in advanced atherosclerotic plaques dominantly express LOX-1 (Adachi and Tsujimoto 2006). In association with Ox-LDL, LOX-1 is a marker of atherosclerosis that induces vascular endothelial cell activation and dysfunction, resulting in pro-inflammatory responses, pro-oxidative conditions and apoptosis. In addition to binding Ox-LDL, it acts as a receptor for HSP70 protein involved in antigen cross-presentation to naive T-cells in DCs, thereby participating in cell-mediated antigen cross-presentation. Soluble LOX-1 concentration in human blood also has been shown to be elevated in coronary heart diseases especially in acute coronary syndrome (Kume and Kita 2004). In addition to endothelial cells, LOX-1 is expressed in macrophages and smooth muscle cells accumulated in the intima of advanced atherosclerotic plaques in vivo. LOX-1 is critical in foam cell formation of macrophages (Mφ) and smooth muscle cells (SMC). Inhibition of LOX-1 expression reduces foam cell formation and might influence lipid core formation in atherosclerotic lesions. In contrast to LOX-1 expressed by a variety of cell types, SR-PSOX expression appeared relatively confined to macrophages in atherogenesis.

34.9.1 General Features of LOX-1

LOX-1, the lectin-like oxidized LDL receptor is the receptor for Ox-LDL and is abundantly expressed in endothelial cells; it might mediate some of the actions of Ox-LDL in the endothelium. LOX-1 is initially synthesized as a 40-kDa precursor protein with N-linked high mannose-type carbohydrate, which is further glycosylated and processed into a mature form of 52-kD. The mature form of LOX-1 is a lectin-like receptor and is a homodimer linked through disulfide bond. It may form a hexamer composed of three homodimers. LOX-1 belongs to the same family as NKR and functionally undergoes dimerization. The LOX-1 is a type II membrane protein, and acts as a cell-surface endocytosis receptor for atherogenic Ox-LDL, though secretory form of LOX-1 also exists. Its mRNA was shown to be expressed in human atheromatous lesions. LOX-1 can support binding, internalization and proteolytic degradation of Ox-LDL, but not of significant amounts of acetylated LDL, which is a well-known high-affinity ligand for class A scavenger receptors and scavenger receptor expressed by endothelial cells (Sawamura et al. 1997). Cell-surface LOX-1 can be cleaved through some protease activities that are associated with the plasma membrane, and released into the culture media. The N-terminal amino-acid sequencing identified two cleavage sites (Arg86-Ser87 and Lys89-Ser90), both of which are located in the membrane proximal extracellular domain of LOX-1. LOX-1 is often co-localized with apoptotic cells and implicated in vascular inflammation and atherosclerotic plaque initiation, progression, and destabilization (Kume and Kita 2001).

Mouse LOX-1 is composed of 363 amino acids and has a C-type lectin domain type II membrane protein structure. Mouse LOX-1 has triple repeats of the sequence in extracellular "Neck domain," which is unlike human and bovine LOX-1. The LOX-1 binds Ox-LDL with two affinity constants in the presence of serum. The binding component with higher affinity showed the lowest value of K_D among the known receptors for Ox-LDL (Hoshikawa et al. 1998). Measurement of soluble LOX-1 in vivo may provide a novel diagnostic tool for the evaluation and prediction of atherosclerosis and vascular disease (Kume and Kita 2001). Soluble forms of LOX-1 are present in conditioned media of cultured bovine aortic endothelial cells (BAECs) and CHO-K1 cells transfected with LOX-1 cDNA. In TNF-α-activated BAECs, cell-surface expression of LOX-1 precedes soluble LOX-1 production. The soluble LOX-1 in cell-conditioned media is derived from LOX-1 expressed on the cell surface (Murase et al. 2000).

LOX-1 expression is not constitutive, but can be induced by proinflammatory stimuli, such as TNF-α, TGF-β and bacterial endotoxin, and fluid shear stress. It is up-regulated in atherosclerotic lesions, by Ox-LDL, reactive oxygen species, suggesting that it may participate in amplification of Ox-LDL-induced vascular dysfunction. This receptor is upregulated by angiotensin II, endothelin, cytokines and all participants in atherosclerosis and is up-regulated in the arteries of hypertensive, dyslipidemic, and diabetic animals. Defects in LOX-1 gene (HGMW-approved symbol *OLR1*) may be a cause of susceptibility to myocardial infarction. Defects in *OLR1* may also be associated with susceptibility to Alzheimer disease (AD). Upregulation of LOX-1 has been identified in atherosclerotic arteries of several animal species and humans, not only on the endothelial lining, but also in choroidal neovasculature of the atherosclerotic plaque (Mehta et al. 2006; Mukai et al. 2004; Vohra et al. 2006).

The extracellular domains of LOX-1 are post-translationally modified by N-linked glycosylation. LOX-1 is synthesized as a 40-kDa precursor protein with N-linked high mannose carbohydrate chains (pre-LOX-1), which is subsequently further glycosylated and processed into the 48-kDa mature form. Both TNF-α-activated bovine aortic endothelial cells and CHO-K1 cells stably expressing bovine LOX-1 (BLOX-1-CHO) exclusively produced a 32-kDa deglycosylated form of LOX-, follwing treatment with an N-glycosylation inhibitor, tunicamycin. The deglycosylated form of LOX-1 is not efficiently transported to the cell surface, but is retained in the ER or Golgi apparatus in TNF-α-activated bovine aortic endothelial cells, but not in BLOX-1-CHO cells. It shows that N-linked glycosylation plays key roles in the cell-surface expression and ligand binding of LOX-1 (Kataoka et al. 2000).

34.9.2 LOX-1 Gene in Human

The natural killer (NK) gene complex is a genomic region containing lectin-type receptor genes located on human chromosome 12 that contains several families of lectin-like genes including the CD94 and NKG2 NK receptor genes (Fig. 34.1). Bull et al. (2000) established a contig of PAC and BAC clones comprising about 1 Mb of the centromeric part of the NK gene complex. This region extending from LOX-1 gene and found within 100 kb telomeric of STS marker D12S77, contains CD94 and NKG2 NK receptor genes and reaches beyond D12S852 on the proximal side.

The human LOX-1 has the highest homology with C-type lectin receptors expressed on NK cells. The human LOX-1 gene is a single-copy gene and assigned to p12.3-p13.2 region of chromosome 12. In contrast, the cellular expression pattern of LOX-1 is different from that of NK cell receptors. A 1,753-bp fragment of 5′ flanking region of LOX-1 gene had a functional promoter activity and contains binding sites for several transcription factors, including STAT family and NF-IL6. The 5′-regulatory region contained several potential cis-regulatory elements, such as GATA-2 binding element, c-ets-1 binding element, 12-O-tetradecanoylphorbol 13-acetate-responsive element and shear-stress-responsive elements, which may mediate the endothelium-specific and inducible expression of LOX-1. The major transcription-initiation site was found to be located 29 nt downstream of the TATA box and 61 nt upstream from the translation-initiation codon. The minor initiation site was found to be 5 bp downstream from the major site. Most of the promoter activity of the LOX-1 gene was ascribed to the region (−150 to −90) containing the GC and CAAT boxes. The coding sequence was divided into six exons by five introns. The first three exons corresponded to the different functional domains of the protein (cytoplasmic, transmembrane and neck domains), and the residual three exons encoded the carbohydrate-recognition domain similar to other C-type lectin genes. Since the locus for a familial hypertension has been mapped to the overlapping region, LOX-1 might be the gene responsible for the hypertension. The expression of LOX-1 was upregulated by several cytokines (Aoyama et al. 1999; Yamanaka et al. (1998)).

34.9.2.1 Rat LOX-1 Gene

The genomic organization of rat LOX-1 shows several consensus sequences in 59-flanking region. Rat LOX-1 cDNA clone encodes a single-transmembrane protein with its N terminus in the cytoplasm (Nagase et al. 1997). The extracellular region consists of a spacer, 46-amino acid triple repeats, and C-type lectin-like domains. The rat LOX-1 gene, encoded by a single copy gene spanning over 19 kb, consists of eight exons (Fig. 34.5). The promoter region contained putative TATA and CAAT boxes and multiple cis-elements such as NF-kB, AP-1 and AP-2 sites, and a shear stress response element. Exon boundaries correlated well with the functional domain boundaries of the receptor protein (Nagase et al. 1998b). The rat endothelial receptor LOX-1 cDNA encodes a protein of 364 amino acids that showed approximately 60% similarity to its bovine and human counterparts. The protein consisted of intracellular N-terminal, transmembrane and extracellular lectin-like domains. Rat LOX-1 is unique in having three repeats of a 46-amino-acid motif between the transmembrane and lectin-like regions. Two isoforms of mRNA were found to be generated by alternative use of two polyadenylation signals in a tissue-specific manner. The 3′-untranslated region contained multiple A + U-rich elements for rapid degradation of mRNA. Northern-blot analysis revealed that LOX-1 mRNA was expressed predominantly in the lung. Nagase et al. (1998b) reported an unexpected blood-pressure-

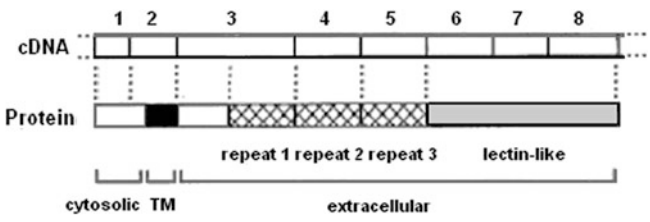

Fig. 34.5 Genomic organization of rat LOX-1. Schematic representation of the cDNA and protein. Exons in the cDNA and functional domains in the protein are indicated by *boxes*. The *solid box* represents the transmembrane (*TM*) domain. *Hatched boxes* represent the 46-amino acid repeat unit (*repeats 1–3*). The *dotted box* represents the C-type lectin-like domain (Adapted from Nagase et al. 1998; © American Society for Biochemistry and Molecular Biology)

associated regulation of LOX-1 expression, a new relation between lipid metabolism and blood-pressure control. The expression of LOX-1 was dramatically up-regulated in the aorta in hypertensive SHR-SP/Izm rats compared with very low levels in control WKY/Izm rats, suggesting a potential role for LOX-1 in the pathogenesis of hypertension as well as atherosclerosis.

34.9.3 Ligands for LOX-1

As a scavenger receptor, LOX-1 is capable of binding to a variety of structurally unrelated ligands. Ox-LDLs appear to play key roles in atherosclerotic progression and plaque rupture (Li et al. 2002b). LOX-1 is a major receptor for Ox-LDL in activated vascular smooth muscle cells (VSMC) as in endothelial cells. Human recombinant LOX-1 protein showed that the protein had specific Ox-LDL-binding activity (Huang et al. 2005). LOX-1 binds multiple classes of ligands that are implicated in the pathogenesis of atherosclerosis. Besides Ox-LDL, LOX-1 can recognize apoptotic/aged cells, activated platelets, and bacteria, implying versatile physiological functions (Chen et al. 2002; Shimaoka et al. 2001b). LOX- from bovine aortic endothelial cells (BAE) is the major binding protein for Ox-LDL on the surface of BAE and is expressed in atheromatous intima of human carotid artery as well as in intima of normal bovine aorta. In addition, human LOX-1 recognizes a key cellular phospholipid, PS (phosphatidylserine), in a Ca^{2+}-dependent manner, both in vitro and in cultured cells. A recombinant, folded and glycosylated LOX-1 molecule binds PS, but not other phospholipids. LOX-1 recognition of PS was maximal in presence of mM Ca^{2+} levels (Murphy et al. 2006). C-reactive protein (CRP), a risk factor for cardiovascular events and an amplifier of vascular inflammation through promoting endothelial dysfunction, can act as a novel ligand for LOX-1. This interaction could be disrupted with known LOX-1 ligands, such as Ox-LDL and carrageenan. In vivo assays revealed that in LOX-1 the basic spine arginine residues are important for binding, which is lost upon mutation of Trp^{150} with alanine. Simulations of the wild-type LOX-1 and of the Trp^{150}Ala mutant C-type lectin-like domains revealed that the mutation does not alter the dimer stability, but a different dynamical behaviour differentiates the two proteins. The symmetrical motion of monomers is completely damped by the structural rearrangement caused by the Trp^{150}Ala mutation. An improper dynamical coupling of the monomers and different fluctuations of the basic spine residues are observed, with a consequent altered binding affinity (Falconi et al. 2007). Mutagenesis studies demonstrated that the arginine residues forming the basic spine structure on LOX-1 ligand-binding interface were dispensable for CRP binding, suggesting a novel ligand-binding mechanism for LOX-1, distinct from that used for Ox-LDL binding. Study suggests that CRP- LOX-1 interaction may mediate CRP-induced endothelial dysfunction (Shih et al. 2009). Advanced glycation end product (AGE) is recognized by LOX-1. Cellular binding experiments revealed that AGE-bovine serum albumin (AGE-BSA) specifically binds CHO cells over-expressing bovine LOX-1 (bLOX-1). Cultured bovine aortic endothelial cells also showed specific binding for AGE-BSA (Jono et al. 2002). Interaction of AGE with AGE receptors induces several cellular phenomena potentially relating to diabetic complications. Study indicates that CD36-mediated interaction of AGE-modified proteins with adipocytes might play a pathological role in obesity or insulin-resistance (Kuniyasu et al. 2003).

Adhesion of bacteria to vascular endothelial cells as well as mucosal cells and epithelial cells appears to be one of the initial steps in the process of bacterial infection, including infective endocarditis. LOX-1 with C-type lectin-like structure, can support adhesion of bacteria and work as a cell surface receptor for Gram-positive and Gram-negative bacteria, such as *S. aureus* and *E. coli*, however, other unknown molecules may also be involved in the adhesion of *E. coli* to cultured bovine aortic endothelial cells, which is enhanced by poly(I) (Shimaoka et al. 2001a). Development of antagonists for LOX-1 might be a good therapeutic approach to vascular diseases (Chen et al. 2002)

34.9.4 Structural Analysis

34.9.4.1 Carbohydrate Recognition Domain

LOX-1 from human aortic ECs has a sequence identical to that from human lung. Human LOX-1 can recognize modified LDL, apoptotic cells and bacteria. The CRD is the ligand-binding domain of human LOX-1. LOX-1s carrying a mutation on each of six Cys in CRD resulted in a variety of N-glycosylation and failed to be transported to cell surface. This gave an evidence for the involvement of all six Cys in the intrachain disulfide bonds required for proper folding, processing and transport of LOX-1. The C-terminal sequence

(KANLRAQ) was also essential for protein folding and transport, while the final residues (LRAQ) were involved in maintaining receptor function. In addition, positively charged (R^{208}, R^{209}, H^{226}, R^{229} and R^{231}) and uncharged hydrophilic (Q^{193}, S^{198}, S^{199} and N^{210}) residues are involved in ligand binding, suggesting that ligand recognition of LOX-1 is not merely dependent on the interaction of positively charged residues with negatively charged ligands (Shi et al. 2001). Truncation of the lectin domain of LOX-1 abrogated oxLDL-binding activity (Chen et al. 2001). Deletion of the utmost C-terminal ten amino acid residues (261–270) was enough to disrupt the Ox-LDL-binding activity. Substitutions of Lys-262 and/or Lys-263 with Ala additively attenuated the activity. Serial-deletion analysis showed that residues up to 265 are required for the expression of minimal binding, although deletion of C-terminal three residues (268–270) still retained full binding activity. These results demonstrate distinct role of lectin domain as functional domain recognizing LOX-1 ligand.

To understand the interaction between hLOX-1 and its ligand Ox-LDL, Xie et al. (2003) reconstituted the functional C-type lectin-like domain (CTLD) of LOX-1 from inactive aggregates in *E. coli*. The CD spectra of the domain suggested that the domain has α-helical structure where as the blue shift of Trp residues indicated refolding of the domain. Like wild-type hLOX-1, the refolded CTLD was able to bind modified LDL. Thus, even though CTLD contains six Cys residues that form disulfide bonds, it recovered its specific binding ability on refolding. This suggests that the correct disulfide bonds in CTLD were formed by the artificial chaperone technique. Although the domain lacked N-glycosylation, it showed high affinity for its ligand in surface plasmon resonance experiments. Thus, unglycosylated CTLD is sufficient for binding modified LDL (Xie et al. 2003).

Though, the lectin-like domain of LOX-1 is essential for ligand binding, the neck domain is not. In particular, the large loop between the third and fourth cysteine of lectin-like domain plays a critical role for Ox-LDL binding as well as C-terminal end residues. Alanine-directed mutagenesis of the basic amino acid residues around this region revealed that all the basic residues are involved in Ox-LDL binding. Therefore, electrostatic interaction between basic residues in lectin-like domain of LOX-1 and negatively charged Ox-LDL is critical for the binding activity of LOX-1 (Chen et al. 2001). Chen et al. (2005) suggested that Ox-LDL/LOX-1 plays a role in signaling pathway in rat cardiac fibroblasts, which naturally express low levels of LOX-1. It was suggested that in cardiac fibroblasts, Ox-LDL binds to LOX-1 and activates p38 MAPK, followed by the expression of ICAM-1, VCAM-1, and MMP-1. Thus, fibroblasts transform into an endothelial phenotype on transfection with CMV-LOX-1wild-type (WT) and subsequent exposure to Ox-LDL.

Role of Cytoplasmic Sequences in Cell-Surface Sorting of LOX-1: The ability of LOX-1 binding to Ox-LDL can be distinguished from other NK receptors. Domain swapping of the lectin-like domain between LOX-1 and the NK cell receptors CD94, NKG2D, and LY-49A demonstrated the crucial role of this domain for recognition of Ox-LDL by LOX-1, but not for the correct cell-surface sorting of LOX-1. Using N-terminal deletions Chen and Sawamura (2005) found that the correct cell-surface localization is dependent on a positively charged motif present in the cytosolic juxtamembrane region of LOX-1. Furthermore, the extracellular localization of LOX-1 C-terminus is disrupted when cytoplasmic basic amino acids, Lys-22, Lys-23 and Lys-25 were mutated to Glu. These results indicated that the N-terminal cytoplasmic domain of LOX-1 determines the correct expression of lectin domain on the cell-surface.

Dominant-Negative LOX-1 Blocks Homodimerization of Wild-Type LOX-1-Induced Cell Proliferation: LOX-1 is thought to function as a monomer. Yet, Xie et al. (2004) suggest that human LOX-1 (hLOX-1) forms constitutive homo-interactions in vivo. Site-directed mutagenesis studies indicated that Cys^{140} has a key role in the formation of disulfide-linked hLOX-1 dimers. Eliminating this intermolecular disulfide bond markedly impairs the recognition of *E. coli* by hLOX-1. These dimers can act as a "structural unit" to form noncovalently associated oligomers. These results provided evidence for the existence of hLOX-1 dimers/oligomers (Xie et al. 2004).

Although Lys^{262} and Lys^{263} in C-terminus of bovine bLOX-1 play important roles in the uptake of Ox-LDL, mutation of these residues did not suggest as potential source of the dominant-negative property of bLOX-1. It is possible that dominant-negative human hLOX-1 forms a heterodimer with LOX-1-wild-type (WT) and blocks LOX-1-WT-induced cell signaling. Homodimerization of hLOX-1-WT was localized in cell membrane, and Ox-LDL activated ERK-1/2 without the translocation of hLOX-1-WT. Tanigawa et al. (2006a) gave an evidence that blocking cell-proliferative pathways at the receptor level could be useful for impairing LOX-1-induced cell proliferation.

34.9.4.2 Crystal Structure

The X-ray crystallography of 136–270 subunit revealed the presence of disulfide bonds. The 1.4 Å crystal structure of the extracellular C-type lectin-like domain of human Lox-1 reveals a heart-shaped homodimer with a ridge of six basic amino acids extending diagonally across the apolar top of Lox-1, a central hydrophobic tunnel that extends through the entire molecule, and an electrostatically neutral patch of 12 charged residues that resides next to the tunnel at each opening. Based on the arrangement of critical binding residues on the LOX-1 structure, a binding mode for the

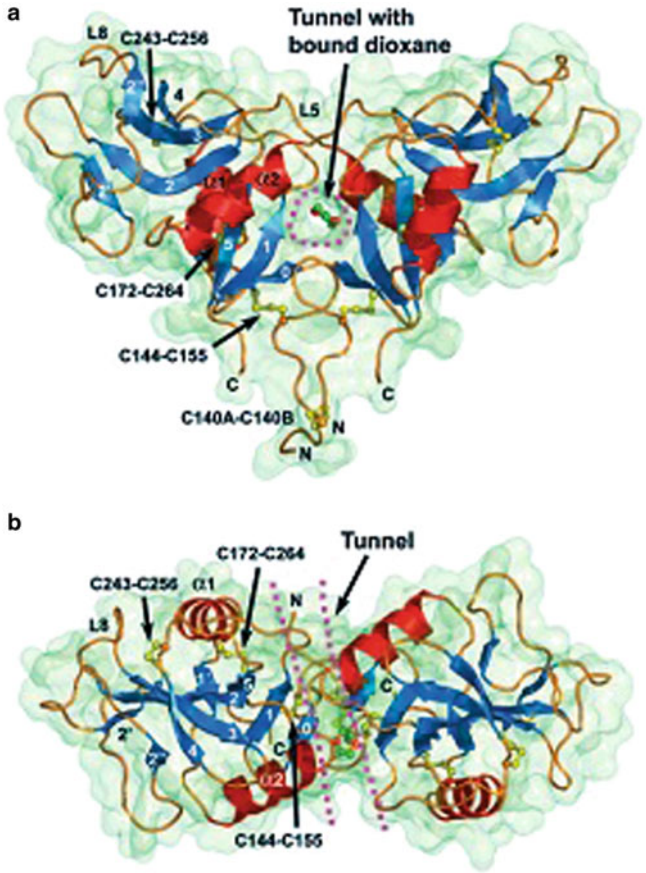

Fig. 34.6 Ribbon structure and transparent surface of human Lox-1 CTLD homodimer. *Side view* (**a**) and *top view* (**b**) (opposite the N and C termini) of Lox-1 from the high resolution monoclinic crystal. The central tunnel containing bound dioxane is outlined by a *dotted line*. α-Helices are in *red*; β-strands are *blue*. Secondary structures are *numbered* as proposed for CTLDs by Zelensky and Gready (2003). Loops are *numbered sequentially*. A semitransparent molecular surface representation is shown in *light green*. The disulfide bonds and dioxane are represented by *yellow* and *green ball-and-stick models*, respectively (Adapted with permission from Park et al. 2005a © American Society for Biochemistry and Molecular Biology)

recognition of modified LDL and other Lox-1 ligands has been proposed (Fig. 34.6) (Park et al. 2005a). The central hydrophobic tunnel that extends through the entire LOX-1 molecule is a key functional domain of the receptor and is critical for the recognition of modified LDL (Francone et al. 2009).

Ohki et al. (2005) determined the crystal structure of the ligand binding domain of 143–271 subunit (and mutagenesis of Trp^{150}; Arg^{208}; Arg^{209}; His^{226}; Arg^{229}; Arg^{231} and Arg^{248}) of LOX-1 at 2.4 Å and revealed a short stalk region connecting the domain to the membrane-spanning region, as a homodimer linked by an interchain disulfide bond. In vivo assays with LOX-1 mutants revealed that the "basic spine," consisting of linearly aligned arginine residues spanning over the dimer surface, is responsible for ligand binding. Single amino acid substitution in the dimer interface caused a severe reduction in LOX-1 binding activity, suggesting that the correct dimer arrangement is crucial for binding to Ox-LDL. Based on the LDL model structure, possible binding modes of LOX-1 to Ox-LDL are proposed (Ohki et al. 2005).

The crystal of the monomeric ligand-binding domain of LOX-1 belongs to space group $P2_12_12_1$, with unit-cell parameters a = 56.79, b = 67.57, c = 79.02 A. The crystal of the dimeric form belongs to space group C2, with unit-cell parameters a = 70.86, b = 49.56, c = 76.73 A, beta = 98.59°. Data for the dimeric form of the LOX-1 ligand-binding domain have been collected to 2.4 A. For the monomeric form of the ligand-binding domain, native, heavy-atom derivative and SeMet-derivative crystals have been obtained; their diffraction data have been measured to 3.0, 2.4 and 1.8 A resolution, respectively (Ishigaki et al. 2005).

The NECK domain of LOX-1 displays sequence similarity to the coiled-coil region of myosin, having been suggested it adopts a rod-like structure. The structural analysis of human LOX-1 reveals a unique structural feature of LOX-1 NECK. Despite significant sequence similarity with the myosin coiled-coil, LOX-1 NECK does not form a uniform rod-like structure. Although not random, one-third of the N-terminal NECK is less structured than the remainder of the protein and is highly sensitive to cleavage by a variety of proteases. The coiled-coil structure is localized at the C-terminal part of the NECK, but is in dynamic equilibrium among multiple conformational states on a mus-ms time scale. This chimeric structural property of the NECK region may enable clustered LOX-1 on the cell surface to recognize Ox-LDL (Ishigaki et al. 2007).

34.9.5 Functions of LOX-1

34.9.5.1 In Support of Cell Adhesion

LOX-1 can support adhesion of mononuclear leukocytes. Under a static condition, CHO-K1 cells stably expressing LOX-1 showed more prominent adhesion of human peripheral blood mononuclear leukocytes and human monocytic cell line than untransfected CHO-K1 cells. Mononuclear leukocytes also adhered to plastic plates precoated with recombinant soluble LOX-1 extracellular domain (Hayashida et al. 2002). Kakutani et al. (2000) showed the possibility that LOX-1 is involved in the platelet-endothelium interaction and hence directly in endothelial dysfunction. More importantly, the binding of platelets to LOX-1 enhanced the release of endothelin-1 from endothelial cells, supporting the induction of endothelial dysfunction, which would, in turn, promote the atherogenic process. LOX-1 may initiate and promote atherosclerosis, binding not only Ox-LDL but also platelets. LOX-1 can support

cell adhesion to fibronectin (FN) in a divalent cation-independent fashion. CHO-K1 cells expressing bovine LOX-1, but not untransfected CHO-K1 cells, can adhere to FN-coated plates, but not to collagen-coated plates, in presence of EDTA (Shimaoka et al. 2001a).

LOX-1 on Endothelial Cells Binds with Bacterial Ligands: Adhesion of bacteria to vascular endothelial cells as well as mucosal cells and epithelial cells appears to be one of the initial steps in the process of bacterial infection, including infective endocarditis. LOX-1 with C-type lectin-like structure, can support adhesion of bacteria and works as a cell surface receptor for Gram-positive and Gram-negative bacteria, such as *S. aureus* and *E. coli*, in a mechanism similar to that of class A scavenger receptors; however, other unknown molecules may also be involved in the adhesion of *E. coli* to cultured bovine aortic endothelial cells (BAEC), which is enhanced by poly-I (Palaniyar et al. 2002; Shimaoka et al. 2001b). Thus, LOX-1 is an adhesion molecule involved in leukocyte recruitment and represents an attractive target for modulation of endotoxin-induced inflammation (Honjo et al. 2003).

34.9.5.2 Role in Apoptosis

LOX-1 mediates Ox-LDL-induced apoptosis of endothelial cells, monocyte adhesion to endothelium, smooth muscle cells (SMCs), and phagocytosis of aged cells. LOX-1 activation by Ox-LDL causes endothelial changes that are characterized by activation of NF-kB through an increased ROSs, subsequent induction of adhesion molecules, and endothelial apoptosis. Ox-LDL also induced apoptosis of HCAECs and LOX-1 mediates in this function. Findings suggest that Ox-LDL through its receptor LOX-1 decreases the expression of anti-apoptotic proteins Bcl-2 and c-IAP-1. This is followed by activation of apoptotic signaling pathway, involving release of cytochrome c and Smac and activation of caspase-9 and then caspase-3 (Chen et al. 2004). Duerrschmidt et al. (2006) reported the presence of LOX-1 in granulosa cells from patients under in vitro fertilization therapy after Ox-LDL induced expression of LOX-1 mRNA. The Ox-LDL treatment caused autophagy form of programmed cell death in association with reorganization of the actin cytoskeleton. It suggested that follicular atresia is not under the exclusive control of apoptosis. The LOX-1-dependent autophagy represents an alternate form of programmed cell death. Obese women with high blood levels of Ox-LDL may display an increased rate of autophagic granulosa cell death.

34.9.5.3 In Organ Transplantation

The pathogenesis of posttransplant CAD, which is a major form of chronic rejection after cardiac transplantation, is not fully understood. Suga et al. (2004) investigated the expression of LOX-1 mRNA in murine allografted hearts that develop diffuse coronary obstruction. Results indicate that alloimmune responses induce up-regulation of LOX-1 mRNA in transplanted hearts and hence increased LOX-1 may be involved in the progression of obstructive vascular changes (Suga et al. 2004). In human atherosclerotic lesions, the expression of LOX-1 is significantly increased in atherosclerotic grafted vein and carotid artery specimens compared with that in normal arteries. LOX-1 expression was colocalized with apoptotic cells. The apoptotic cells were present mostly in the rupture-prone regions of the atherosclerotic plaque. These observations indicated that LOX-1 is extensively expressed in the proliferated intima of grafted veins and in advanced atherosclerotic carotid arteries (Li et al. 2002a, b; Jin et al. 2004).

Older-age renal allografts are associated with inferior survival, though the mechanisms are not clear. Since, ROS participate in aging and in chronic vascular disease, Brasen et al. (2005) reported that induction of LOX-1-related oxidation pathways and increased susceptibility to oxidative stress plays significant role in promoting vascular injury in old transplants independent of age of recipient (Brasen et al. 2005).

34.9.6 LOX-1 and Pathophysiology

LOX-1 in Atherogenesis: The expression of LOX-1 receptor activates a variety of intracellular processes that leads to expression of adhesion molecules and endothelial activation. The experimental evidence suggested that LOX-1 may contribute to the development of vascular injury. For example, LOX-1 is up-regulated in aorta from hypertensive, diabetic, and hyperlipidemic animal models. Also, LOX-1 over-expression is observed in atherosclerotic regions and damaged kidneys. In vivo, endothelial cells covering early atherosclerotic lesions and macrophages and smooth muscle cells accumulated in the intima of advanced atherosclerotic plaques express LOX-1. LOX-1 is cleaved at membrane proximal extracellular domain by some protease activities and released from the cell surface. Measurement of soluble LOX-1 in vivo may provide novel diagnostic strategy for the evaluation and prediction of atherosclerosis and vascular diseases (Kume and Kita 2001).

LOX-1 in Hypertensive Rats: LOX-1 is expressed in hypertensive state. LOX-1 expression was low in the aorta of salt-resistant (DR: 0.3% salt) and of Dahl salt-sensitive (DS: 8% salt) rats on a control diet, whereas it was elevated in salt-loaded DS rats. Results indicated that LOX-1 expression in aorta and vein was upregulated in hypertensive rats, which may be involved in impaired endothelium-dependent vasodilation in these rats (Nagase et al. 1997). In kidneys and glomeruli of hypertensive DS rats, LOX-1 gene

expression was markedly elevated compared with those of normotensive DR and DS rats. Prolonged salt loading further increased the renal LOX-1 expression in DS rats. Nagase et al. (2000) suggested a possible pathogenetic role for renal LOX-1 in the progression to hypertensive glomerulosclerosis.

LOX-1 and monocyte chemoattractant protein-1 (MCP-1) are involved in the initiation and progression of atherosclerosis. In order to examine differential role of LOX-1 and MCP-1 on the severity of early stage of atherosclerosis, Hamakawa et al. (2004) investigated atherosclerotic changes by exposure to hypertension and hyperlipidemia in common carotid arteries (CCAs) of stroke-prone spontaneously hypertensive rat (SHR-SP). Three groups were examined as: control [Wistar Kyoto rat (WKY) group], hypertension (SHR-SP group) and hypertension + hyperlipidemia [SHR-SP + high fat and cholesterol (HFC) group]. LOX-1 and MCP-1 expressions were coordinately up-regulated at mRNA and protein levels in an early stage of sclerosis depending on the severity of atherosclerotic stress. Thus, activations of LOX-1 and MCP-1 were collectively involved in the early stage of atherosclerosis (Hamakawa et al. 2004).

LOX-1 is critical in foam cell formation of macrophages (Mφ) and SMC. Inhibition of LOX-1 expression reduces foam cell formation and might influence lipid core formation in atherosclerotic lesions. Balloon-injury model of rabbit aorta revealed that LOX-1 mRNA is expressed 2 days after injury, and remained elevated until 24 weeks after injury. However, LOX-1 was not detected in media of non-injured aorta but expressed in both medial and neointimal SMC weeks after injury. Thus, LOX-1 mediates Ox-LDL-induced SMC proliferation and plays a role in neointimal formation after vascular injury (Eto et al. 2006) and confirmed in a rat model of balloon injury (Hinagata et al. 2006).

Platelet-Endothelium Interaction Mediated by LOX-1 Reduces NO in ECs: The role of LOX-1 in the thrombotic system was addressed by Cominacini et al. (2003b) following platelet interaction with LOX-1. The incubation of Bovine aortic endothelial cells (BAECs) and CHO-K1 cells stably expressing bovine LOX-1 (BLOX-1-CHO) cells with human platelets induced a sharp and dose-dependent increase in intracellular concentration of ROS and O_2^-. The increase in intracellular concentration of O_2^- was followed by a dose-dependent reduction in basal and bradykinin-induced intracellular NO concentration. The increase in O_2^- and the reduction of NO were inhibited by the presence of vitamin C and anti-LOX-1 mAb. The results show that one of the pathophysiologic consequences of platelet binding to LOX-1 may be the inactivation of NO through an increased cellular production of O_2^-.

Remnant lipoprotein particles (RLPs), products of lipolytic degradation of triglyceride-rich lipoprotein derived from VLDL, exert atherogenesis. RLPs stimulated superoxide formation and induction of cytokines in HUVECs via activation of LOX-1, consequently leading to reduction in cell viability with DNA fragmentation. The cilostazol exerts a cell-protective effect by suppressing these variables. Upon incubation of HUVECs with RLPs, adherent monocytes increased along with increased cell surface expression of adhesion molecules and increased expression of LOX-1 receptor protein. Cilostazol repressed these variables and hence it was suggested that cilostazol suppresses RLP-stimulated increased monocyte adhesion to HUVECs by suppression of LOX-1 receptor-coupled NF-kB-dependent nuclear transcription (Park et al. 2005b; Shin et al. 2004).

LOX-1 Contributes to Vein Graft Atherosclerosis: Ge et al. (2004) designed a study to examine the expression of LOX-1 in vein grafts atherosclerosis and the modulating effect of losartan (an AT-1 receptor antagonist) on it in male rabbits. After surgery, rabbits were fed with high cholesterol diet (HC), high cholesterol diet plus losartan (LHC) or regular chow (control) for 12 weeks. Study revealed that LOX-1 was expressed in endothelium and neointima of autologous vein grafts of rabbits. Increased LOX-1 expression was associated with vein grafts atherosclerosis development. Downregulation of LOX-1 by losartan might contribute to its attenuating effect on vein grafts atherosclerosis.

34.9.7 Macrophage Differentiation to Foam Cells

Foam cell formation from macrophages with subsequent fatty streak formation plays a key role in early atherogenesis. LOX-1 may play an important role in Ox-LDL uptake by macrophages and subsequent foam cell formation in this cell type (Yoshida et al. 1998). This role of LOX-1 was substantiated by studies on monocyte adhesion to human coronary artery endothelial cells (HCAECs) and endothelial injury in response to Ox-LDL in presence of antisense oligodeoxynucleotides to 5′-coding sequence of human LOX-1 gene. Studies indicated that LOX-1 is a key factor in Ox-LDL-mediated monocyte adhesion to HCAECs (Li and Mehta 2000). Depression of scavenger receptor function in monocytes by TGF-β1 at low concentrations reduced foam cell formation (Draude and Lorenz 2000). The expression of many genes is likely modulated during macrophage transformation into a foam cell. Functional consequences of modulation of three groups of genes: Scavenger Receptors including LOX-1, the PPAR family of nuclear receptors, and a number of genes involved in eicosanoid biosynthesis have been described (Shashkin et al. 2005). Scavenger receptors appear to play a key role in

uptake of Ox-LDL, while minimally-modified LDL appears to interact with CD14/TLR4. The regulation of scavenger receptors is, in part, mediated by the PPAR family of nuclear receptors (Shashkin et al. 2005).

Dendritic Cell Lectin Receptors (Dectin-2 Receptors Family)

35

Rajesh K. Gupta and G.S. Gupta

35.1 Dendritic Cells

Dendritic cells (DCs) are special subsets of antigen presenting cells characterized by their potent capacity to activate immunologically naive T cells to induce initial immune responses. DCs are far more potent than macrophages and B cells in their capacity to activate immunologically naive T cells. Infact, DCs are responsible for initiating T cell-mediated immune responses to a variety of antigens. Members of the DC family are distributed to virtually all the organs (except the brain), where they serve as tissue resident APCs, playing critical roles in presenting environmental, microbial, and tumor-associated antigens to the immune system. DCs operate at the interface of innate and acquired immunity by recognizing pathogens and presenting pathogen-derived peptides to T lymphocytes. As a component of the innate immune system, DCs organize and transfer information from the outside world to the cells of the adaptive immune system. DCs can induce such contrasting states as active immune responsiveness or immunological tolerance. Recent years have brought a wealth of information regarding DC biology and pathophysiology that shows the complexity of this cell system. Presentation of an antigen by immature (nonactivated) DC leads to tolerance, whereas mature, antigen-loaded DCs are geared towards the launching of antigen-specific immunity.

DCs Form a Major Resident Leukocyte Population in Human Skin Two main types of DCs are found in noninflamed skin: epidermal Langerhans cells (LCs) and dermal DCs. LCs express Langerin/CD207 that localizes to and forms Birbeck granules, as well as the CD1a class I–like molecule that presents glycolipids. Plasmacytoid dendritic cells (PDCs), which are also known as plasmacytoid T cells, plasmacytoid monocytes, natural IFN-α/ß–producing cells (natural IPCs), and type 2 predendritic cells (pDC2), constitute a subset of immature DCs, which is capable of differentiating in vitro into mature DCs with typical dendritic cell morphology and potent T cell stimulatory function when exposed to IL-3 alone, IL-3 and CD40L, viruses, and bacterial DNA containing unmethylated CpG motifs (CpG-DNA) (Dzionek et al. 2001; Ebner et al. 2004). Dzionek et al. (2000) identified two novel markers of PDCs, blood dendritic cell antigen-2 (BDCA-2) and BDCA-4, which enable direct identification of PDCs in human blood. BDCA-2 is presumably involved in ligand internalization, processing and presentation, as well as in inhibition of IFN-α/ß synthesis in PDCs.

Langerhans Cells Langerhans cells (LCs) are a unique population of dendritic cells found in the epidermis, where they capture and process antigens and subsequently migrate to the draining lymph nodes to activate naive T cells. About 70% of all dermal cells represent $CD45^+$ leukocytes. The vast majority of these cells (60% of total) express the mononuclear phagocyte markers murine macrophage galactose/*N*-acetylgalactosamine-specific C-type lectin (mMGL), F4/80 and CD11b. Studies suggest that mononuclear phagocyte populations form the majority of dermal cells underestimated earlier (Guironnet et al. 2002; Dupasquier et al. 2004). Evidences suggest that fresh human LCs are the only cells in the epidermis to express a fucose-mannose receptor on their surface (Condaminet et al. 1998). Freshly isolated LCs in epidermal cell suspensions phagocytose the yeast cell wall derivative zymosan, intact *S. cerevisiae*, *Corynebacterium parvum and S. aureus*, as well as 0.5–3.5 μ latex microspheres. Zymosan uptake by LCs is mediated by a mannose/β-glucan receptor(s) that is differentially expressed in mice and that is down-regulated during maturation of LCs in culture. In epidermis, they can be identified by expression of E-cadherin and cytoplasmic Birbeck granules (BGs) as their hallmark; the presence of Birbeck granules is the unique feature of LCs. BGs are disks

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_35,

of two limiting membranes, separated by leaflets with periodic "zipperlike" striations. Birbeck granules are unusual rod-shaped structures specific to epidermal LCs, whose origin and function remain undetermined. The normal dermis contains typical immunostimulatory myeloid DCs identified by CD11c and BDCA-1, as well as an additional population of poorly stimulatory macrophages marked by CD163 and FXIIIA (Zaba et al. 2007). Using Langerin as marker of LCs revealed the heterogeneity in the phenotype of gingival LC population (Seguier et al. 2003).

35.2 Dendritic Cell-Associated Lectins

35.2.1 Type-I and Type-II Surface Lectins on DC

The identification of DC-associated lectins is of particular interest, because one of the characteristic features of DC is the expression of many C-type lectins. DCs have a number of receptors for adsorptive uptake of antigens. Some are shared with other cells, such as Fcγ receptors, DEC-205, a type I membrane-integrated glycoprotein and the macrophage mannose receptor (MMR). Other receptors are more DC restricted, e.g., Langerin/CD207, DC-SIGN/CD209, asialoglycoprotein receptor or hepatic lectins (HL), and dendritic cell lectin (DLEC; also referred to as BDCA-2) (Abner et al. 2004; Dzionek et al. 2001) and C-type lectin receptor 1 (CLEC-1). Of the type II surface lectins, DCs express CD23, CD69, DCIR, dectin-1, and dectin-2 α, β, and γ isoforms) that form the list of DC-associated C-type lectin family. It was proposed that dectin-2 and its isoforms, together with dectin-1, represent a unique subfamily of DC-associated C-type lectins (Graham and Brown 2009). The cytoplasmic domains of the C-type lectins are diverse and contain several conserved motifs that are important for antigen uptake: a tyrosine-containing coated-pit intracellular targeting motif, a triad of acidic amino acids and a dileucine motif. Some type II C-type lectins contain potential signaling motifs (ITIM, ITAM, and proline-rich regions) (Table 35.1) (Fig. 35.1). Immature human dendritic cells express asialoglycoprotein receptor isoforms for efficient receptor-mediated endocytosis (Valladeau et al. 2001).

35.3 Macrophage Mannose Receptor (CD206) on DC

35.3.1 Expression and Characteristics

Humans express two types of mannose receptors, each encoded by its own gene: Macrophage mannose receptor 1 (CD206, MMR) and Macrophage mannose receptor 2 (C-type mannose receptor 2, Urokinase-type plasminogen activator receptor-associated protein, CD280). The macrophage mannose receptor (CD206) is a 175-kDa transmembrane glycoprotein that appears to be expressed on the surface of terminally differentiated macrophages and endothelial cell subsets whose natural ligands include both self glycoproteins and microbial glycans. The expression of the mannose receptor CD206 is regarded a differentiation hallmark of immature DCs, whereas monocytes, mature DCs, and epidermal LCs do not express CD206. In immature cultured DC, MMR mediates high efficiency uptake of glycosylated antigens. The expression of MMR by MHC class II positive APC in non-lymphoid organs of the mouse is also described. The MMR positive APC have been identified in peripheral organs: skin, liver, cardiac and skeletal muscle and tongue. The mannose receptor positive cells in salivary gland, thyroid and pancreas co-express MHC class II and the myeloid markers macrosialin and sialoadhesin, but not the DC markers CD11c or DEC-205 (Linehan 2005). Being an R-type lectin, structural details of mannose receptors have been discussed in Chap 14 and Chap 15 and hence readers are advised to consult these Chapters for more details.

The mannose receptor family consists of four members [the mannose receptor, the M-type phospholipase A_2 receptor, DEC-205 and Endo180 (or urokinase plasminogen activator receptor-associated protein)] all of which share a common extracellular arrangement of an amino-terminal cysteine-rich domain related to R-type domain, followed by a fibronectin type II domain and 8–10 C-type lectin-like CRD domains within a single polypeptide. In addition, all have a short cytoplasmic domain, which mediates their constitutive recycling between the plasma membrane and the endosomal apparatus, suggesting that these receptors function to internalize ligands for intracellular delivery. However, despite the common presence of multiple lectin-like domains, these four endocytic receptors have divergent ligand binding activities, and it is clear that the majority of these domains do not bind sugars. All of the MR family members except DEC-205 recycle back to the cell surface from early endosomes, but DEC-205 recycles from late endosomes. However, each receptor has evolved to have distinct functions and distributions.

Understanding the molecular basis of cell surface ligand recognition and endosomal release by the MR requires information about how individual domains interact with sugars as well as the structural arrangement of the multiple domains. The NH2-terminal cysteine-rich domain and the fibronectin type II repeat are not necessary for endocytosis of mannose-terminated glycoproteins. The CRDs 1–3 have at most very weak affinity for carbohydrate, where as, of the eight C-type CRDs, CRDs 4–8 are required for binding and endocytosis of mannose/GlcNAc/fucose-terminated ligands, but only CRD-4 has demonstrable sugar binding activity in isolation. CRD 4 shows the highest affinity binding and has multi-specificity for a variety of monosaccharides. As the main mannose-recognition domain of MR (CRD4) is the central ligand binding domain of the receptor, analysis of this domain suggests ways in which multiple CRDs in whole

Table 35.1 Characteristics of C-type lectins produced by dendritic cells (DCs) and Langerhans cells (LCs) (Adapted and modified from Figdor et al. 2002; Feinberg et al. 2011; Graham and Brown 2009; Shrimpton et al. 2009; Tateno et al. 2010)

receptor might interact with each other (Feinberg et al. 2000; Mullin et al. 1997). However, CRD 4 alone cannot account for the binding of the receptor to glycoproteins. At least 3 CRDs (4, 5, and 7) are required for high affinity binding and endocytosis of multivalent glycoconjugates. In this respect, the MR is like other carbohydrate-binding proteins, in which several CRDs, each with weak affinity for single sugars, are clustered to achieve high affinity binding to oligosaccharides (Taylor et al. 1992). The overall structure of CRD-4 (Fig. 15.1a) is similar to other C-type CRDs, containing two α helices and two small antiparallel β sheets. MBP (Fig. 15.1b). The core region of the CRD-4 domain, consisting of β strands 1–5 and the two α helices, superimposes on the equivalent residues of the rat MBP-A CRD. The principal difference resides in the position of helix α2, which is the most variable element of secondary structure among the C-type lectin-like folds.

The ectodomain of mannose receptor recognizes the patterns of sugars that adorn a wide array of bacteria, parasites, yeast, fungi, and mannosylated ligands. The capability to take up mannosylated protein antigens is important for the biologic function of DCs, as many glycoproteins derived from bacteria and fungi are mannosylated. The mannose receptor is also expressed by immature cultured DCs, where it mediates high efficiency uptake of glycosylated antigens, though its role in antigen handling in vivo is not clear. Endocytosis of mannose receptor -antigen complexes takes place via small coated vesicles, while non-mannosylated antigens were mainly present in larger vesicles. Shortly after internalization the mannose receptor and its ligand appear in the larger vesicles. Within 10 min, the mannosylated and non-mannosylated antigens co-localize with typical markers for MHC class II-enriched compartments and lysosomes (Tan et al. 1997). Peripheral blood DCs produce IFN-α in response to challenge by many enveloped viruses including herpes simplex virus (HSV) and HIV. The mannose receptor is an important receptor for the nonspecific recognition of enveloped viruses by DCs and stimulates the production of IFN-α by these viruses (Milone and Fitzgerald-Bocarsly 1998). The inflammatory dendritic-epidermal cells expressing MMR/CD206 in situ use CD206

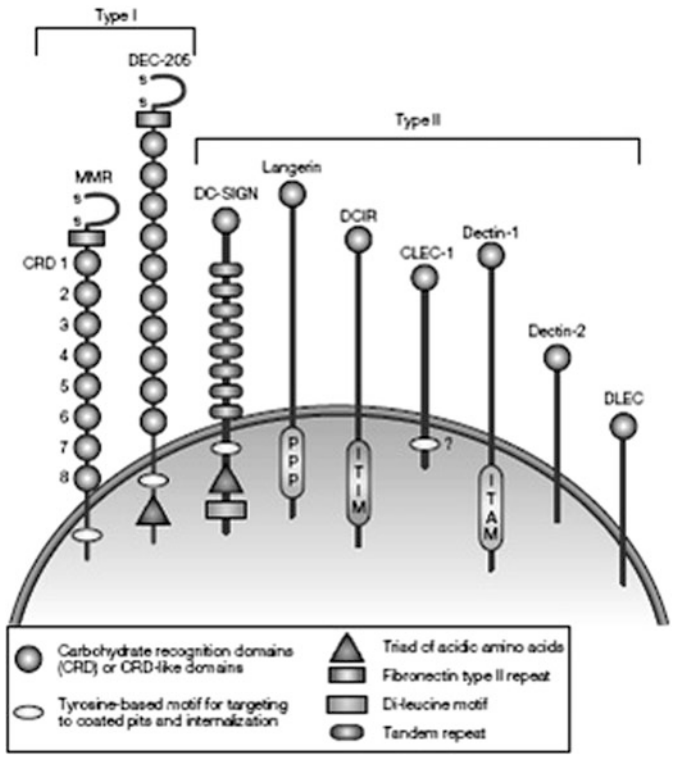

Fig. 35.1 Two types of C-type lectins or lectin-like molecules are produced by dendritic cells and Langerhans cells. Type I C-type lectins (MMR and DEC-205) contain an amino-terminal cysteine-rich repeat (S–S), a fibronectin type II repeat (FN) and 8–10 carbohydrate recognition domains (CRDs), which bind ligand in a Ca^{2+}-dependent manner. MMR binds ligand through CRD4 and CRD5. Type II C-type lectins contain only one CRD at their carboxy-terminal extracellular domain. The cytoplasmic domains of the C-type lectins are diverse and contain several conserved motifs that are important for antigen uptake: a tyrosine-containing coated-pit intracellular targeting motif, a triad of acidic amino acids and a dileucine motif. Other type II Ctype lectins contain other potential signaling motifs (ITIM, ITAM, proline-rich regions (P)). CLEC-1, C-type lectin receptor 1; DCIR, dendritic cell immunoreceptor; DC-SIGN, dendritic-cell specific ICAM-3 grabbing non-integrin; DLEC, dendritic cell lectin; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; MMR, macrophage Mannose receptor (Reprinted by permission from Macmillan Publishers Ltd: Nature Rev Immunol., Figdor et al. © 2002)

for receptor-mediated endocytosis (Wollenberg et al. 2002). The MMR and DEC-205 belonging to R type lectins, which are characterized by the presence of trefoil group. Hence these lectins have been discussed along with R type lectins (Chap. 14 and Chap. 15).

35.3.2 Functions of Mannose Receptor in DC

Endocytosis Through Mannose Receptors: One of the major functions proposed for mannose receptor found on DCs as well as on macrophages and hepatic endothelial cells is in enhancing the uptake and processing of glycoprotein antigens for presentation by MHC class II molecules. Targeting recycling endocytic receptors with specific Abs provides a means for introducing a variety of tumor-associated Ags into human DCs, culminating in their efficient presentation to T cells. The specific targeting of soluble exogenous tumor Ag to the DC MR (CD206) directly contributes to the generation of multiple HLA-restricted Ag-specific T cell responses (Ramakrishna et al. 2004). Cell surface-bound receptors are suitable sites for gene delivery into cells by receptor-mediated endocytosis. Presence of mannose receptor on DCs can be exploited for targeted gene transfer by employing mannosylated conjugates (Bonifaz et al. 2002). It was demonstrated that DCs transfected with ManPEI/DNA complexes containing adenovirus particles are effective in activating T cells of T cell receptor transgenic mice in an antigen-specific fashion (Diebold et al. 1999).

Langerin Mediates Efficient Antigen Presentation: The LCs show poor endocytic capacity and do not exploit MR-mediated endocytosis pathways. This may serve to avoid hyper-responsiveness to harmless protein antigens that are likely to be frequently encountered in the skin due to skin damage (Mommaas et al. 1999). This seems to be related to low level of expression of the MR (CD206) by epidermal LCs. However, some epidermal DCs may express CD206 under inflammatory skin conditions such as atopic dermatitis and psoriasis. The inflammatory dendritic epidermal cells expressing CD206 in situ can be used for receptor-mediated endocytosis (Wollenberg et al. 2002; Idoyaga et al. 2008).

Neonatal LCs preferentially utilize a wortmannin-sensitive, fluid-phase pathway, rather than receptor-mediated endocytosis, to internalize antigen (Bellette et al. 2003).

The mannose receptor mediates induction of IFN-α in peripheral blood DCs. Suppressed stimulation of IFN-α synthesis by herpes simplex virus (HSV) by monosaccharides as well as the yeast polysaccharide mannan, supported a role for lectin(s) in the IFN-α stimulation. Blood DC and IFN-α-producing cells responding to HSV stimulation also express mannose receptor. The mannose receptor is an important receptor for the nonspecific recognition of enveloped viruses by DCs and the subsequent stimulation of IFN-α production by these viruses (Milone et al. 1998).

35.4 DEC-205

DEC-205 is an endocytic receptor with 10 membrane-external, contiguous C-type lectin domains. DEC-205 is expressed at high levels on DCs in the T cell areas of lymphoid organs (Witmer-Pack et al. 1995). αDEC-205 antibodies selectively target these DCs in mice (Hawiger et al. 2001). Small amounts of injected antigen, targeted to DCs by the DEC-205 adsorptive pathway, are able to induce solid peripheral $CD8^+$ T cell tolerance. The antigen-presentation function of DCs is associated with the high-level expression of DEC-205, which mediates the efficient processing and presentation of antigens in vivo (Hawiger et al. 2001; Jiang et al. 1995; Mahnke et al. 2000; Maruyam et al. 2002). The DEC-205 is rapidly taken up by means of coated pits and vesicles, and is delivered to a multi-vesicular endosomal compartment that resembles the MHC class II-containing vesicles implicated in antigen presentation (refer Chap. 15). Results of Shrimpton et al. (2009) demonstrate that two areas of the CD205 molecule, within C-type lectin-like domains (CTLDs) 3 + 4 and 9 + 10, recognise ligands expressed during apoptosis and necrosis of multiple cell types. Thus, CD205 acts as a recognition receptor for dying cells, potentially providing an important pathway for the uptake of self-antigen in intrathymic and peripheral tolerance.

35.5 Langerin: A C-Type Lectin on Langerhans Cells

35.5.1 Human Langerin (CD207)

Use of mAbs restricted to human DCs has enabled the identification of Langerin (CD207), a Ca^{2+}-dependent type II the mannose-type lectin receptor. Langerin reactivity was strongly stimulated by LCs differentiation factor TGF-β and down-regulated by CD40 ligation. The monoclonal antibody, DCGM4, selectively stained Langerhans Cells; hence the antigen was termed Langerin. Langerin neither co-localized with MHC class II rich compartments nor with lysosomal LAMP-1 markers. The DCGM4 was rapidly internalized at 37°C. The Langerin was found as a 40-kDa protein with a pI of 5.2–5.5 (Valladeau et al. 1999) and only expressed by LCs. Langerin is responsible for Birbeck granule (BG) formation by membrane superimposition and zippering. Langerin is a mannose specific lectin expressed by LCs in epidermis and epithelia. Remarkably, transfection of Langerin cDNA into fibroblasts created a compact network of membrane structures with typical features of BG. Langerin is thus a potent inducer of membrane superimposition and zippering leading to BG formation. The induction of BG is a consequence of the antigen-capture function of Langerin, allowing routing into these organelles and providing access to a non-classical antigen-processing pathway (Valladeau et al. 2000, 2003).

The gene encoding Langerin is localized on chromosome 2p13, a region that does not contain any known genetic complex. The human Langerin gene spans over 5.6 kbp and is organized in six exons. Cloning of a cDNA for langerin shows that langerin gene has an open reading frame 987 bp predicting a polypeptide of 328 amino acids with a molecular weight of 37.5 kDa. The characteristics of different types of lectins and organization of various domains are schematically shown in Fig 35.1. Langerin is a type II transmembrane cell surface receptor with an intracytoplasmic portion of 43 amino acids with proline rich motif (WPREPPP) and an extracellular lectin domain. The extracellular domain of langerin consists of a neck region containing a series of heptad repeats and a C-terminal C-type carbohydrate-recognition domain (CRD). The CRD of Langerin contains a EPN (Glu-Pro-Asn) motif characteristic of lectins with mannose specificity. As in other lectins having a single CRD, Langerin features a particular domain located between the CRD and the transmembrane domain that is rich in leucine zipper sequences. The extracellular region of Langerin exists as a stable trimmer held together by a coiled-coil of α-helices formed by the neck region, a structure found in mannose binding proteins. Finally Langerin has two potential sites of N-glycosylation at positions 87–89 and 180-18 amino acids. Trimer formation is essential for binding to oligosaccharide ligands because, as is typical for C-type CRDs, the CRD of langerin has only low affinity for monosaccharides. Oligomerization of C-type lectins is also important for determining selectivity for particular oligosaccharide structures.

35.5.1.1 The CRD of Human Langerin

Langerin CRD crystals at 1.5 Å resolution belonged to the tetragonal space group $P4_2$, with unit-cell parameters a = b = 79.55, c = 90.14 Å (Thépaut et al. 2008). The CRD of human Langerin, expressed in the periplasm of *E. coli*, was crystallized and analysed for Xray crystallography for

apo-Langerin and for the complexes with mannose and maltose, respectively. The Langerin CRD (dubbed LangA) fold resembles that of DC-SIGN (Chap. 36). However, especially in the long loop region (LLR), which is responsible for carbohydrate-binding, two additional secondary structure elements were present: a 3_{10} helix and a small β-sheet arising from the extended β-strand 2, which enters into a hairpin and a new strand β2′. Unexpectedly, the crystal structures in the presence of maltose and mannose revealed two sugar-binding sites. One was calcium-dependent and structurally conserved in the C-type lectin family whereas the second one represented a calcium-independent type. Based on these data, a model for the binding of mannan was proposed and the differences in binding behavior between Langerin and DC-SIGN with respect to the Lewis X carbohydrate antigen and its derivatives were explained (Chatwell et al. 2008).

Crystal structures of the CRD of human langerin in complex with mannose or maltose show that it binds monosaccharides by ligation to a bound Ca^{2+} at a site that is conserved in all C-type CRDs (Chatwell et al. 2008). Interestingly, the co-crystals also show the presence of a second sugar-binding site that has not been seen in many C-type lectins. Both monosaccharide residues of maltose, or the monosaccharide mannose, are bound in this second site largely via polar interactions with backbone residues in a cleft formed between two of the large loop regions in the top half of the domain (Chatwell et al. 2008). This cleft is wider in langerin than in other C-type CRDs, most likely due to the absence of auxiliary Ca^{2+} sites present in many other CRDs, including those of mannose-binding protein and DC-SIGN (Feinberg et al. 2001). Like the full-length protein, truncated langerin exists as a stable trimer in solution. Glycan array screening with the trimeric fragment shows that high mannose oligosaccharides are the best ligands for langerin. Structural analysis of the trimeric fragment of langerin confirms that the neck region forms a coiled-coil of α-helices. Multiple interactions between the neck region and the CRDs make the trimer a rigid unit with the three CRDs in fixed positions and the primary sugar-binding sites separated by a distance of 42 Å. The fixed orientation of the sugar-binding sites in the trimer is likely to place constraints on the ligands that can be bound by langerin (Feinberg et al. 2010).

35.5.1.2 Polymorphisms in Human Langerin

Analysis of human genome has identified three SNPs that result in amino acid changes in the CRD of langerin. Expression of full-length versions of the four common langerin haplotypes in fibroblasts revealed that all of these forms can mediate endocytosis of neoglycoprotein ligands. However, fragments from the extracellular domain showed that two of the amino acid changes reduced the affinity of the CRD for mannose and decreased the stability of the extracellular domain. In addition, analysis of sugar binding by langerin containing the rare W264R mutation, previously identified in an individual lacking Birbeck granules, showed that this mutation could abolish sugar binding activity. It suggests that certain langerin haplotypes may differ in their binding to pathogens and thus might be associated with susceptibility to infection (Ward et al. 2006).

35.5.2 Mouse Langerin: Homology to Human Langerin

Mouse Langerin (m-Langerin) displays 65% and 74% homologies in total amino acid and lectin domains with those of human (h)-Langerin. The cognate mouse and rat genes were assigned to chromosome 6D1-D2 and chromosome 4q33 distal-q34.1 proximal respectively, syntenic to the h-Langerin gene on chromosome 2p35. m-Langerin transcripts were as expected detected in MHC class II^+, but not MHC class II^-, cells from epidermis. However, m-Langerin transcripts were also expressed in spleen, lymph nodes (LN), thymus, liver, lung and even heart, but not gut-associated lymphoid tissues. In single-cell lymphoid suspensions, m-Langerin transcripts were mainly detected in the $CD11c^+$ DC, especially the $CD11^{blow}/CD8^{high}$ fraction of spleen and LN. Unexpectedly, significant amounts of m-Langerin transcripts were detected in skin and LN of TGF-β1-deficient mice, although in much lower amounts than littermate controls. It indicates that Langerin expression is regulated at several levels: by TGF-β1, DC subsets, DC maturation and the tissue environment (Takahara et al. 2002). The organization of human and mouse Langerin genes are similar, consisting of six exons, three of which encode the CRD. The m-Langerin, detected as a 48-kDa species, is abundant in epidermal LC in situ and is down-regulated upon culture (Valladeau et al. 2002).

Riedl et al (2004) isolated m-Langerin cDNA from murine fetal skin-derived DCs (FSDDC). In vitro-generated FSDDC and epidermal LC expressed both full-length and δE3Langerin mRNA, but tissue expression was not restricted to skin. Mouse Langerin protein isoforms were readily detected in fibroblasts transfected with cDNAs encoding epitope-tagged Langerin and δE3Langerin. Full-length m-Langerin bound mannan, whereas δE3Langerin and soluble bacterial recombinant Langerin protein lacking the neck domain did not. Fibroblasts transfected with m-Langerin cDNA contained typical BG and cored tubules, whereas δE3Langerin cDNA did not induce BG or cored tubule formation in transfected fibroblasts. Developmentally regulated expression of Langerin isoforms provides a mechanism by which Langerin involvement in antigen uptake and processing could be regulated (Riedl et al. 2004).

35.5.3 Ligands of Langarin

Mannoside-binding capacity was detected in normal epithelial cells. The Langerin CRD shows specificity for mannose, GlcNAc, and fucose, but only the trimeric extracellular domain fragment binds to glycoprotein ligands. Langerin extracellular domain binds mammalian high mannose oligosaccharides, as well mannose-containing structures on yeast invertase but does not bind complex glycan structures. Full-length Langerin, stably expressed in rat fibroblast transfectants, mediates efficient uptake and degradation of a mannosylated neoglycoprotein ligand. The pH-dependent ligand release appears to involve interactions between the CRDs or between the CRDs and the neck region in the trimer (Stambach and Taylor 2003). A role for langerin in processing of glycoprotein antigens has been proposed. Langerin binds HIV through its CRD and plays a protective role against its propagation by the internalization of virions in Birbeck granules. Access to the CRD of Langerin appeared to be impaired in proliferatively active environments (malignancies, hair follicles), indicating presence of an endogenous ligand with high affinity to saturate the C-type lectin under these conditions (Plzák et al. 2002).

Using glycoconjugate microarray and other analyses, Langerin showed outstanding affinity to galactose-6-sulfated oligosaccharides, including keratan sulfate, while it preserved binding activity to mannose, as a common feature of the C-type lectins with an EPN motif. Mutagenesis study showed that Lys^{299} and Lys^{313} form extended binding sites for sulfated glycans. Consistent with the former observation, the sulfated Langerin ligands were found to be expressed in brain and spleen, where the transcript of keratan sulfate 6-*O*-sulfotransferase is expressed. Langerin also recognized pathogenic fungi, such as *Candida* and *Malassezia*, expressing heavily mannosylated glycans. Observations provide strong evidence that Langerin mediates diverse functions on Langerhans cells through dual recognition of sulfated as well as mannosylated glycans by its uniquely evolved C-type CRD (Tateno et al. 2010). For endogenous ligands, fibroblast membrane fractions seemed to contain 140 and 240-kDa proteins, which bind Langerin. Though mass spectrometry suggested types I and III procollagen and fibronectin as candidate ligands, results indicated that Langerin selectively interacts with at least one ligand in extracellular matrix (type I procollagen) and may have an unanticipated role in cell-matrix interactions to modulate LC development (Tada et al. 2006). Crystal structures of the carbohydrate-recognition domain from human langerin bound to a series of oligomannose compounds, the blood group B antigen, and a fragment of β-glucan reveal binding to mannose, fucose, and glucose residues by Ca^{2+} coordination of vicinal hydroxyl groups with similar stereochemistry. Likewise, a β-glucan fragment, Glcβ1-3Glcβ1-3Glc, binds to langerin through the interaction of a single glucose residue with the Ca^{2+} site. The fucose moiety of the blood group B trisaccharide Galα1-3(Fucα1-2)Gal also binds to the Ca^{2+} site (Feinberg et al. 2011). Langerin binds to an unusually diverse number of endogenous and pathogenic cell surface carbohydrates, including mannose-containing O-specific polysaccharides derived from bacterial lipopolysaccharides.

35.5.4 Functions of Langerin

From absence of classical macrophage mannose receptor (MMR) from LCs, it could be thought that Langerin might be involved in the endocytosis of microorganisms through mannosylated components. Experiments showed that Langerin is implicated in recognition and internalization of *Myobacteria, HIV, Leishmania* or *Candida* components (Valladeau et al. 2003).

Birbeck Granule (BG) Formation: Birbeck granules are unusual rod-shaped structures specific to epidermal LCs, whose origin and function remain undetermined (Fig. 35.2). The presence of Birbeck granules is the unique feature of LCs. The BGs are disks of two limiting membranes, separated by leaflets with periodic "zipperlike" striations. The identification of Langerin/CD207 has allowed researchers to decipher the mechanism of BG formation and approach an understanding of their function. Remarkably, transfection of Langerin cDNA into fibroblasts creates a dense network of membrane structures with features typical of BGs. Furthermore, mutated and deleted forms of Langerin have been engineered to map the functional domains essential for BG formation. Langerin is a potent LC-specific regulator of membrane superimposition and zippering, representing a key molecule to trace LCs and to probe BG function (McDermott et al. 2002; Valladeau et al. 2003).

In the steady state, Langerin is predominantly found in the endosomal recycling compartment and in BGs. Langerin internalizes by classical receptor-mediated endocytosis and the first BGs accessible to endocytosed Langerin are those connected to recycling endosomes in the pericentriolar area, where Langerin accumulates. Drug-induced inhibition of endocytosis results in the appearance of abundant open-ended Birbeck granule-like structures appended to the plasma membrane, whereas inhibition of recycling induces BGs to merge with a tubular endosomal network. In mature Langerhans cells, Langerin traffic is abolished and the loss of internal Langerin is associated with a concomitant depletion of BGs. An exchange of Langerin occurs between early endosomal compartments and the plasma membrane, with dynamic retention in the endosomal recycling compartment. Mc Dermott et al. (2002) suggested that BGs are not endocytotic structures, rather they

Fig. 35.2 Birbeck granules (BGs) are "tennis-racket" or rod shaped cytoplasmic organelles with a central linear density and a striated appearance. Birbeck granules were discovered by Michael Stanley Clive Birbeck (1925–2005), a British scientist and electron microscopist. Figure shows Birbeck granules, EM—Tennis racket shaped structures found in Langerhan's cells in histiocytosis X (Langerhan's cell histiocytosis) which includes eosinophilic granuloma, Letterer-Siwe disease and Hand-Schuller-Christian disease. The origin and function of BGs remain under question, but one theory is that they migrate to the periphery of the Langerhans cells and release its contents into the extracellular matrix. Another theory is that the Birbeck granule functions in receptor-mediated endocytosis, similar to clathrin-coated pits

are subdomains of the endosomal recycling compartment that form where Langerin accumulates. ADP-ribosylation factor proteins are implicated in Langerin trafficking and the exchange between BGs and other endosomal membranes (Mc Dermott et al. 2002).

Rab11A in Biogenesis of BG by Regulating Langerin Recycling and Stability: The extent to which Rab GTPases, Rab-interacting proteins, and cargo molecules cooperate in the dynamic organization of membrane architecture remains to be clarified. Langerin, accumulating in the Rab11-positive compartments of LCs, induces the formation of BGs, which are membrane subdomains of the endosomal recycling network. Results show that Rab11A and Langerin are required for BG biogenesis, and they illustrate the role played by a Rab GTPase in the formation of a specialized subcompartment within the endocytic-recycling system (Uzan-Gafsou et al. 2007).

Contact Hypersensitivity and LCs: The general role of LCs in skin immune responses is not clear because distinct models of LC depletion resulted in opposite conclusions about their role in contact hypersensitivity (CHS) responses. For example, LCs not only dispensable for CHS, but they regulate the response as well (Kaplan et al. 2005). While comparing various models, Bursch et al. (2007) suggested that dermal LCs could mediate CHS and provided an explanation for previous differences observed in the two-model systems (Bursch et al. 2007). Bennett and Clausen (2007) reviewed the impact of CD11c-DTR and Langerin-DTR mice on DC immunobiology, and highlighted the problems while interpreting data from these models. In another study Wang et al. (2008) found that acute depletion of mouse LC reduced CHS, but the timing of toxin administration was critical: toxin administration 3 days before priming did not impair CHS, whereas toxin administration 1 day before priming did. Moreover, LC elimination reduced the T cell response to epicutaneous immunization with OVA Ag. However, this reduction was only observed when OVA was applied on the flank skin, and not on the ear. Additionally, peptide immunization was not blocked by depletion, regardless of the site. Finally it was shown that conditions which eliminate epidermal LC but spare other Langerin$^+$ DC do not impair the epicutaneous immunization response to OVA. Overall, these results reconciled with previous conflicting data, and suggested that Langerin$^+$ cells do promote T cell responses to skin Ags, but only under defined conditions (Wang et al. 2008).

Langerin: A Natural Barrier to HIV-1 Transmission: The protective function of LCs is dependent on the function of Langerin and is thought to mediate HIV-1 transmission sexually. In the genital tissues, two different DC subsets are present: the LCs and the DC-SIGN$^+$-DCs. Although DC-SIGN$^+$-DCs mediate HIV-1 transmission, studies demonstrate that LCs prevent HIV-1 transmission by clearing invading HIV-1 particles. This protective function of LCs is dependent on the function of Langerin. Thus Langerin is a natural barrier to HIV-1 infection, and strategies to combat infection must enhance, preserve or, at the very least, not interfere with Langerin expression and function (de Witte et al. 2007, 2008).

35.6 DC-SIGN and DC-SIGNR on DCs

Additional C-type lectins with specificity for mannose, which have been characterized, are DC-SIGN (dendritic cell-specific ICAM-3 grabbing non-integrin where ICAM is intercellular adhesion molecule) and DC-SIGNR (DC-SIGN-related; L-SIGN, Liver-SIGN) (Geijtenbeek et al. 2004). DC-SIGN or CD209 is a mannose-specific C-type lectin expressed by DCs and plays an important role in the activation of T-lymphocytes. Evidences suggest that DC-SIGN can function both as an adhesion receptor and as a phagocytic

pathogen-recognition receptor, similar to the Toll-like receptors. Although major differences in the cytoplasmic domains of these receptors might predict their function, findings show that differences in glycosylation of ligands can dramatically alter C-type lectin-like receptor usage (Cambi and Figdor 2003).

DC-SIGN and DC-SIGNR may function in DC migration and DC/T-cell synapse formation through interaction with ICAM-2 and ICAM-3, respectively, as well as playing roles in pattern recognition by binding carbohydrates on the surface of viruses and other microbes in a manner similar to other C-type lectin receptors (Figdor et al. 2002). The DC-SIGN can also bind HIV gp120 in a calcium-dependent manner. DC-SIGN may deliver bound HIV to permissive cell types, mediating infection with high efficiency. Determination of the crystal structure of DC-SIGN/DC-SIGNR has revealed high-affinity binding to an internal feature of high-mannose oligosaccharides (Feinberg et al. 2001). This is in contrast to MBL and the MR, which have preferred specificity for terminal mannose residues. This, taken with evidence that DC-SIGN forms tetramers at the cell surface (Mitchell et al. 2001), provides a mechanism for lectins to exhibit different specificity, whilst all being loosely classified as 'mannose specific'. Recent experiments with model oligosaccharide ligands demonstrated distinct ligand preferences for both MR and DC-SIGN (Frison et al. 2003). The macrophage-expressed murine homolog of DC-SIGNR (SIGNR1) appears to function analogously to its human counterpart (Geijtenbeek et al. 2002; Kang et al. 2003) but has distinct activities compared to other murine DC-SIGN homologs.

35.7 Dectin-2 Cluster in Natural Killer Gene Complex (NKC)

35.7.1 Natural Killer Gene Complex

A number of genes encoding C-type lectin molecules have been mapped to the natural killer gene complex (NKC) at the distal region of mouse chromosome 6 and to a syntenic region on human chromosome 12p12-p13. In addition to those receptors which regulate NK cell function, related structures expressed on other cells types have also been localized to this chromosomal region. Although many receptors of the NKC are expressed primarily by NK and T cells, a growing number have been found to be expressed on myeloid cells (Pyz et al. 2006). In contrast to the NK and T cell specific receptors which function mostly in detection of tumorous or virally infected cells, largely by means of MHC class I recognition, the myeloid expressed receptors seem to have a more diverse repertoire of ligands and cellular functions, including pathogen recognition and maintenance of homeostasis (Yokoyama and Plougastel 2003). The Dectin-1 cluster of receptors is one such example, which includes Dectin-1, LOX-1, C-type lectin-like receptor-1 (CLEC-1), CLEC-2, CLEC12B, CLEC9A and myeloid inhibitory C-type lectin-like receptor (MICL) and form part of the Group V C-type lectin-like receptors (Huysamen and Brown 2009) and discussed in Chap. 34. Dectin-1 specifically recognizes fungal (1,3)-linked β-glucans, while CLEC9A recognizes a ligand in necrotic cells (Brown and Gordon 2001; Brown 2006). Another cluster of receptors of interest is the Dectin-2 family of C-type lectins. These receptors are clustered in the telomeric region of the NKC, in close proximity to the Dectin-1 family (Figs. 35.3 and 35.4) and also appear to have diverse functions in both immunity and homeostasis (Graham and Brown 2009). Dectin-1 is selectively expressed in DCs and to a lower extent in monocytes and macrophages. mRNA forms with and without a stalk exon are observed. This family of lectin-like genes encodes receptors with important immune and/or scavenger functions in monocytic, dendritic and endothelial cells (Sobanov et al. 2001).

The Dectin-2 cluster comprises Dectin-2, DCIR, DCAR, BDCA-2, MCL, Mincle and Clecsf8, which are members of the Group II C-type lectin family. These type II receptors are expressed on myeloid and non-myeloid cells and contain a single extracellular CRD and have diverse functions in both immunity and homeostasis. DCIR is the only member of the family which contains a cytoplasmic signaling motif (ITIM) and has been shown to act as an inhibitory receptor, while BDCA-2, Dectin-2, DCAR and Mincle all associate with FcRγ chain to induce cellular activation, including phagocytosis and cytokine production. Dectin-2 and Mincle have been shown to act as pattern recognition receptors for fungi, while DCIR acts as an attachment factor for HIV. In addition to pathogen recognition, DCIR has been shown to be pivotal in preventing autoimmune disease by controlling dendritic cell proliferation, whereas Mincle recognizes a nuclear protein released by necrotic cells (Graham and Brown 2009).

The amino acid sequences comprising the single C-type lectin domains of MCL, Mincle, DCIR and Dectin-2 are closely related to each other. These molecules show overall similarity to groups of animal C-type lectins, which demonstrate type II transmembrane topology. Sequence analysis suggests that MCL, Mincle, DCIR and Dectin-2 represent a subset of group II-related C-type lectins which may participate in analogous recognition events on macrophages and DCs. The genomic organization of the MCL gene and the sequence of the promoter region, with putative regulatory elements, have been described (Balch et al. 2002). Flornes et al (2004) reported the cDNA cloning and positional arrangement of C-type lectin superfamily (CLSF) receptor genes, which represent rat orthologues to human Mincle and

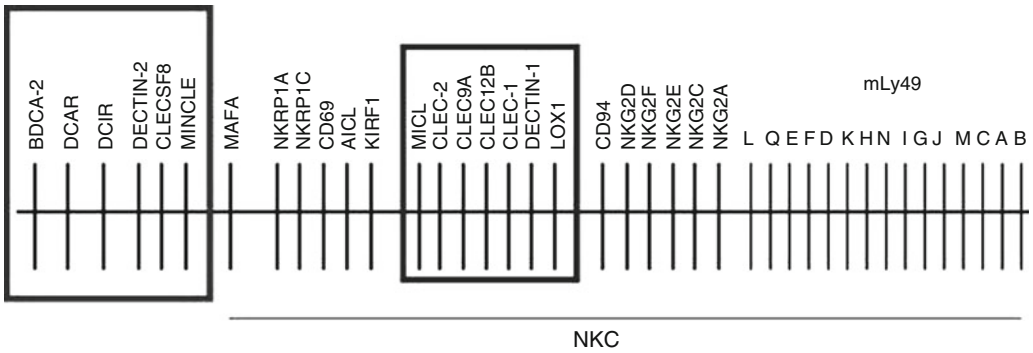

Fig. 35.3 The dectin-2 family genes form a cluster in the telomeric region of the NKC. The dectin-2 gene family includes BDCA-2, DCAR, DCIR, dectin-2, Clecsf8 and mincle, and form a cluster (*red square*) in the telomeric region of the NKC, close to the Dectin-1 cluster (*blue square*), on mouse chromosome 6 and human chromosome 12 (Adapted with permission from Graham and Brown 2009 © Elsevier)

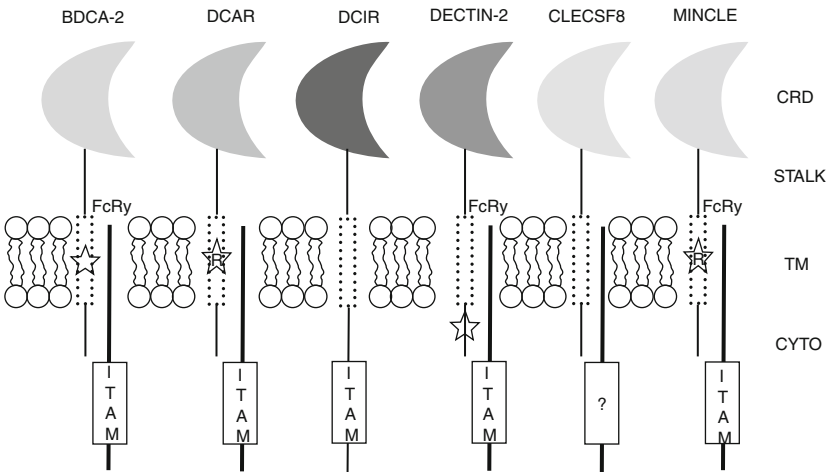

Fig. 35.4 Cartoon representation of the dectin-2 family of C-type lectins. Members of the dectin-2 family of C-type lectins are type II proteins with a single C-terminal extracellular carbohydrate recognition domain (CRD), a stalk region, a transmembrane region (TM), and a cytoplasmic domain (cyto). DCIR contains an immunoreceptor tyrosine-based signalling motif (ITIM) in its cytoplasmic domain, while BDCA-2, DCAR, dectin-2 and mincle associate with FcRγ chain which contains an ITAM. It is not yet known whether Clecsf8 associates with an adaptor molecule (?). The *star* represents the region responsible for association with the adaptor. R, arginine (Reprinted with permission from Graham and Brown 2009 © Elsevier)

DCIR and to mouse MCL and Dectin-2, as well as four other receptors DCIR2, DCIR3, DCIR4 and DCAR1, not reported in other species. Flornes et al (2004) also reported the cDNA cloning of human Dectin-2 and MCL, and of the mouse orthologues to the rat receptors. Similar to KLR some of these receptors exhibit structural features, which suggest that they regulate leukocyte reactivity; e.g., human DCIR and rodent DCIR1 and DCIR2 carry an ITIM, predicting inhibitory function. Conversely, Mincle has a positively charged amino acid in the transmembrane region, which suggests activating function in all three species. Sequence comparisons show that the receptors form a discrete family, more closely related to group II CLSF receptors than to the group V KLR. Most of the genes are preferentially expressed by professional APCs (DCs, macrophages and B cells) and neutrophils. In all three species, the genes map together, forming an evolutionary conserved gene complex, which is called as the antigen presenting lectin-like receptor complex (APLEC) (Flornes et al. 2004). Arce et al. (2001) identified a protein designated DLEC (dendritic cell lectin), which is a type II membrane glycoprotein of 213 amino acids and belongs to the human C-type lectin family. The cytoplasmic tail of DLEC lacks consensus signaling motifs and its extracellular region shows a single CRD, closest in homology to DCIR CRD. The DLEC gene has been localized linked to DCIR on the telomeric region of the NK gene complex.

DLEC mRNA is preferentially expressed in monocyte-derived DCs.

35.7.2 Antigen Presenting Lectin-Like Receptor Complex (APLEC)

In an experimental autoimmune rat model, a quantitative trait locus (QTL) conferring susceptibility to experimentally induced arthritis, a region on distal part of Chromosome 4 (Ribbhammar et al. 2003) was predicted to contain genes that encode proteins related to the human and mouse C-type lectin superfamily (CLSF) receptors: dendritic cell immunoreceptor (DCIR) (Bates et al. 1999), dendritic cell immunoactivating receptor (DCAR) (Kanazawa et al. 2003), dendritic cell lectin (DLEC; also referred to as BDCA-2) (Arce et al. 2001; Dzionek et al. 2001), dendritic cell associated C-type lectin 2 (Dectin-2) (Ariizumi et al. 2000; Fernandes et al. 1999), macrophage C-type lectin (MCL) (Balch et al. 1998) and macrophage inducible C-type lectin (Mincle) (Matsumoto et al. 1999). An important subgroup of CLSF receptors belongs to the opposing regulatory leukocyte receptors that come in two functional forms: activating and inhibitory, mediating their effects via protein tyrosine kinases and phosphatases, respectively. As a rule, the inhibitory variants have cytoplasmic tails containing immunoreceptor tyrosinebased inhibitory motifs (ITIMs) (Ravetch and Lanier 2000). The activating receptors lack such motifs, but contain instead a positively charged residue in the transmembrane (TM) region, mediating non-covalent association with chains containing immunoreceptor tyrosine- based activating motifs (ITAMs) (Lanier 2001). In the human and the mouse, regulatory roles for DCIR are suggested by the presence of an ITIM in the cytoplasmic tail, and for Mincle by a positively charged amino acid in the TM region. Functional studies of DCIR showed ITIM-dependent inhibition of B-cell receptor-mediated Ca^{2+} mobilization and protein tyrosine phosphorylation (Kanazawa et al. 2002), whereas antibody crosslinking of DLEC/BDCA-2 (Dzionek et al. 2001) and DCAR (Kanazawa et al. 2003) induced Ca^{2+} mobilization and protein tyrosine phosphorylation in dendritic cells. DCIR, DCAR and DLEC were reported to be preferentially expressed by professional antigen-presenting cells (APC), in particular by dendritic cells (Bates et al. 1999; Dzionek et al. 2001). Their suggested role as quantitative regulators of APC reactivity makes these receptors interesting candidates for being QTL associated with autoimmune diseases. Future positional cloning of QTL associated genes relies on exact definition of gene content and arrangement. Flornes et al. (2004) described cDNA cloning of the corresponding receptors in rat and for related receptors in rat, mouse and human. Flornes et al. (2004) described the cDNA cloning and positional arrangement of these receptor genes, which represent rat orthologues to human Mincle and DCIR and to mouse MCL and Dectin-2, as well as four novel receptors DCIR2, DCIR3, DCIR4 and DCAR1, not reported in other species. These genes are expressed mainly by professional APC (DCs, macrophages and B cells) and neutrophils and. map together, close to, but separate from NKC (Yokoyama and Plougastel 2003), with positions and orientations largely conserved between the human, the mouse and the rat.

35.7.2.1 Impact of APLEC on Arthritis and Autoimmunity

Congenic DA rats were resistant to oil-induced arthritis (OIA) when they carried PVG alleles for APLEC, which encodes immunoregulatory C-type lectin-like receptors. Five corresponding human APLEC genes were identified and targeted. The SNP rs1133104 in *Dcir* and a haplotype including that marker and 4 other SNPs in *Dcir* and its vicinity gave an indication of allelic association with susceptibility to RA in patients who were negative for antibodies to cyclic citrullinated peptide. Results supported that rat APLEC is associated with susceptibility to polyarthritis, and human APLEC and *Dcir* may be associated with susceptibility to anti-CCP-negative RA (Lorentzen et al. 2007). The APLEC locus is a major locus regulating the severity of experimentally induced arthritis in rats (Rintisch et al. 2010). Rat APLEC regulates autoimmunity and multiple phenotypes in several types of arthritis. However, delineating the genetic impact may require stratification for sex or mode of arthritis induction. This pathogenetic complexity should be considered when evaluating APLEC in inflammatory and autoimmune diseases, including RA (Guo et al. 2008a; Bäckdahl et al. 2009). In vivo and in vitro phenotypes in DA rats and APLEC-congenic rats suggested that both strains had a notably dichotomous expression of genes, with general down-regulation of all four *Dcir* genes and upregulation of *Mincle* and *Mcl*. It is suggested that human APLEC genes may similarly regulate infectious diseases, differential delayed type hypersensitivity (DTH) and status of general macrophage activation (Guo et al. 2009).

35.8 Dectin-2 (CLECF4N)

35.8.1 Characteristics

Dendritic cell-associated lectin-2 (Dectin-2) was discovered in an experimental murine model of acute myeloid leukemia as a receptor over-expressed in the spleen (Fernandes et al. 1999). It is the best characterized member of this receptor family and was identified as an over-expressed transcript in a myeloid leukaemia mouse model and in macrophages, neutrophils and pleuripotent myeloid

precursors (Fernandes et al. 1999). Tissue distribution of Dectin-2 is tightly restricted to myeloid cells of the macrophage and DC lineages. Dectin-2 surface expression on these cells was also found to be low but exhibited enhanced expression on inflammatory monocytes during the acute phase of an inflammatory reaction (Taylor et al. 2005). Dectin-2 is a C-type lectin-like receptor, which is associated to DC and involved in the initiation and maintenance of UV-induced tolerance. In naïve mice Dectin-2 is predominantly expressed by a wide variety of tissue macrophages and has a novel distribution pattern compared with other myeloid markers. Its expression is limited to DCs and notably absent from brain microglia and choroid plexus or meningeal macrophages. On peripheral blood monocytes, Dectin-2 expression is very low on the surface but is transiently and markedly up-regulated on induction of inflammation in vivo using a variety of stimuli. This change in Dectin-2 expression occurs on 'inflammatory' monocytes after arrival at the inflammatory lesion as demonstrated by adoptive cell-transfer studies, and is independent of whether the macrophages elicited by the stimuli ultimately expressed Dectin-2. Observations suggest Dectin-2 expression to be characteristic of monocyte activation/maturation at an inflammatory lesion and provide a new interpretation of Dectin-2 function in vivo (Taylor et al. 2005). Dectin-2 is encoded in the NK cell complex of C-type lectin-like genes and shares features with other classical C-type lectins in that it has conserved motifs for the recognition of mannose in a Ca^{2+}-dependent manner (Fernandes et al. 1999). Despite this, reports of a lectin activity of Dectin-2 have been contradictory (Fernandes et al. 1999; Ariizumi et al. 2000).

Clone 1B12 gene is expressed in a DC-specific manner as a type II membrane-integrated polypeptide of 209 amino acids containing a single CRD motif in the COOH terminus. The expression pattern of dectin-2 was almost indistinguishable from that of dectin-1; that is, both were expressed abundantly at mRNA and protein levels by the XS52 DC line, but not by non-DC lines, and both were detected in spleen and thymus, as well as in skin resident DC (i.e. Langerhans cells). One of the striking findings was the identification of two truncated isoforms of dectin-2, i.e. the β isoform with 34 aa deletions in the neck domain and the γ isoform with 41 aa deletions within the CRD domain. Genomic analyses indicated that a full-length dectin-2 (α isoform) is encoded by 6 exons, whereas truncated isoforms (β and γ) are produced by alternative splicing (Ariizumi et al. 2000a). RT-PCR and immunoblotting of multiple bands of dectin-2 transcripts and proteins confirmed molecular heterogeneity.

The human Dectin-2 (hDectin-2) (Kanazawa et al. 2004a; Gavino et al. 2005) transcripts have been localized in lung, spleen, lymph node, leukocytes, bone marrow and tonsils, but unlike mouse, Dectin-2 was not expressed in the human thymus. In peripheral blood cells, hDectin-2- transcripts were preferentially expressed in plasmacytoid, rather than myeloid DCs and constitutively expressed in $CD14^+$ monocytes and B cells. The hDectin-2 could be induced in $CD4^+$ T cells upon activation with Con A (Kanazawa et al. 2004a; Gavino et al. 2005). Similar to mouse Dectin-2, hDectin-2 appears to be upregulated in inflammatory settings, as gene expression in $CD14^+$ monocytes could be upregulated by treatment with GM-CSF, TGF-β1 and TNF-α and downregulated with the addition of IL-4 and IL-10 (Gavino et al. 2005). The hDectin-2 was also expressed on Langerhans cells.

A truncated isoform of hDectin-2 has been identified by Gavino et al. (2005). Truncated isoform of hDectin-2 lacks part of the intracellular domain and most of the transmembrane domain of the receptor. The lack of transmembrane region has been proposed to encode a secreted protein which may act as an antagonist to full-length Dectin-2 (Gavino et al. 2005). Human Dectin-1 isoform E also lacks a transmembrane region. This isoform is retained intracellularly where it interacts with Ran-binding protein, which is presumed to act as a scaffold protein to coordinate signals from cell surface receptors with intracellular signaling pathways (Xie et al. 2006). The Dectin-2 promoter was also defined as a Langerhans cell specific regulatory element and, while numerous splice forms of Dectin-2 mRNA were shown to be highly expressed in a Langerhans cell-like skin-derived cell line compared to other cell lines, these transcript were also found to be abundant in spleen and thymus (Ariizumi et al. 2000a; Bonkobara et al. 2001).

35.8.2 Ligands of Dectin-2

35.8.2.1 Dectin-2 Shows Specificity for High Mannose and Fucose

The CRD of Dectin-2 functions as a C-type lectin with specificity for glycoconjugates bearing high-mannose sugars, which was predicted to be due to the presence of an EPN motif in the CRD (Fernandes et al. 1999). The CRD of Dectin-2 exhibited cation-dependent mannose/fucose-like lectin activity, with an IC_{50} for mannose of approximately 20 mM compared to an IC_{50} of 1.5 mM for the MMR when assayed by similar methodology. The extracellular domain of Dectin-2 exhibited binding to live *Candida albicans* and the *Saccharomyces*-derived particle zymosan. Binding of *C. albicans* hyphae by RAW cells transduced with Dectin-2 resulted in tyrosine phosphorylation of intracellular proteins (Sato et al. 2006). Though, both mannose receptor and SIGNR1 were able to bind bacterial capsular

polysaccharides derived from *Streptococcus pneumoniae*, the Dectin-2 CRD exhibited only weak interactions to these capsular polysaccharides, indicative of different structural or affinity requirements for binding, when compared with the other two lectins. Glycan array analysis of the carbohydrate recognition by Dectin-2 indicated specific recognition of high-mannose structures ($Man_9GlcNAc_2$). The differences in the specificity of these three mannose-specific lectins indicated that mannose recognition is mediated by distinct receptors, with unique specificity, and are expressed by discrete subpopulations of cells. This highlights the complex nature of carbohydrate recognition by immune cells (McGreal et al. 2006; Sato et al. 2006).

Use of a soluble form of the CRD of Dectin-2 as a probe, revealed that the receptor could recognize zymosan and numerous pathogens including *S. cerevisiae, C. albicans, M. tuberculosis, Microsporum audounii, Trichophyton rubrum Paracoccoides brasiliensis, Histoplasma capsulatum* and capsule-deficient *Cryptococcus neoformans*. Although the binding to these pathogens differed greatly, binding could be inhibited by chelation of Ca^{2+} or in presence of mannose (McGreal et al. 2006; Sato et al. 2006). A glycan microarray showed that the receptor had specificity for high-mannose structures (McGreal et al. 2006). Dectin-2 has been shown to play a role in response to allergens. Dectin-2 on bone-marrow-derived DCs (BMDCs) was able to bind to extracts from house dust mite (*Dermatophagoides farinae* and *Dermatophagoides pteronyssinus*) and *Aspergillus fumigatus* in a mannose-dependent manner. Stimulation of mast cells co-expressing Dectin-2 and FcRγ chain with these extracts resulted in production of proinflammatory lipid mediators which are not produced by untransfected cells (Barrett et al. 2009).

Experiments with a soluble recombinant form of Dectin-2 have suggested the presence of a ligand on $CD4^+CD25^+$ T cells, and in vivo administration of this protein in mice impaired the development and maintenance of ultraviolet (UV)-induced tolerance (Aragane et al. 2003). It has been speculated that prevention of the interaction between endogenous Dectin-2 and T cells causes this defect, although the nature of this ligand was yet uncharacterized. UV-B irradiation was shown to increase Dectin-2 expression in Langerhans cells of the skin at both mRNA and protein levels (Bonkobara et al. 2005). It is possible that Dectin-2 recognises an endogenous ligand that is not a carbohydrate, perhaps via an alternative binding site to that which recognises fungi, as has been reported for other C-type lectins, such as Dectin-1 (Willment et al. 2001). However, while the expression of Dectin-2 was upregulated upon UV-B radiation in mice, it was downregulated in human cells. The discrepency may be due to use of $CD14^+$ monocytes as a surrogate model for epidermal Langerhans cells in the human experiment (Gavino et al. 2005).

35.8.2.2 Dectin-1 and -2, Share Several Important Features

DC-associated, dectin-2, shared several important features with dectin-1. First, both dectin-2 and dectin-1 exhibited a common domain structure, consisting of a relatively short cytoplasmic domain, a transmembrane domain, an extracellular neck domain, and a single CRD in the COOH termini. Second, dectin-1 mRNA and dectin-2 mRNA expression profiles were indistinguishable, i.e. both were expressed: (a) at relatively high levels in the XS52 DC line but not in other tested non-DC lines, (b) most abundantly in spleen and thymus, and (c) constitutively in the Ia^+ epidermal cell population (i.e. Langerhans cells). Third, expression of dectin-2 and dectin-1 proteins also occurred exclusively in the XS52 DC line among the tested cell lines. Despite these similarities, the degree of sequence homology between dectin-2 and dectin-1 was relatively low (19.6% identity in the overall sequence and 24.8% within the CRD motif). Thus, dectin-2 and dectin-1 represent two structurally independent, DC-associated C-type lectins.

35.8.2.3 Dectin-1 and Dectin-2 Receptors in Control of Fungal Infection

Both, dectin-1 and dectin-2 are type II- transmembrane proteins with extracellular domains containing a carbohydrate recognition domain highly conserved among C-type lectins (Ariizumi et al. 2000a, b). Dectin-1 is expressed widely by APC (Ariizumi et al. 2000a) and is a PRR for β-glucan in yeasts (Brown et al. 2003). Dectin-2 is constitutively expressed at very high levels by mature DC and can be induced on macrophages after activation (Ariizumi et al. 2000b; Taylor et al. 2005). Dectin-2 is a PRR for fungi that employ Fc receptor (FcR) chain signaling to induce internalization, activate NF-κB, and up-regulate production of TNFα and IL-1ra (Sato et al. 2006).

During fungal infection, a variety of receptors, including TLR and Dectin-1 initiate immune responses. TLR recognition of fungal ligands and subsequent signaling through the MyD88 pathway were thought to be the most important interactions required for the control of fungal infection. However, Dectin-1-deficient mice, address the role of Dectin-1 in control of fungal infection. Saijo et al. (2007) argue that Dectin-1 plays a minor role in control of *Pneumocystis carinii* by direct killing and that TLR-mediated cytokine production controls *P. carinii* and *Candida albicans*. By contrast, Taylor et al. (2005) argue that Dectin-1-mediated cytokine and chemokine production, leading to efficient recruitment of inflammatory cells, is required for control of fungal infection.

Binding assays using soluble dectin-2 receptors showed the extracellular domain to bind preferentially to hyphal (rather than yeast/conidial) components of *Candida albicans*, *Microsporum audouinii*, and *Trichophyton rubrum*. Selective

binding for hyphae was also observed using RAW macrophages expressing dectin-2, the ligation of which by hyphae or cross-linking with dectin-2-specific antibody led to protein tyrosine phosphorylation. Because dectin-2 lacks an intracellular signaling motif, Sato et al. (2006) searched for a signal adaptor that permits it to transduce intracellular signals. First, it was found that the Fc receptor (FcR) chain can bind to dectin-2. Second, ligation of dectin-2 on RAW cells induced tyrosine phosphorylation of FcR, activation of NF-κB, internalization of a surrogate ligand, and up-regulated secretion of tumor necrosis factor α and interleukin-1 receptor antagonist. Finally, these dectin-2-induced events were blocked by PP2, an inhibitor of Src kinases that are mediators for FcR chain-dependent signaling. It is suggested that dectin-2 is a PRR for fungi that employs signaling through FcR to induce innate immune responses (Sato et al. 2006). Dennehy and Brown (2007) argue that collaborative responses induced during infection may partially explain some apparently contradictory results. It seems that Dectin-1 is the first of many pattern recognition receptors that can mediate their own signaling, as well as synergize with TLR to initiate specific responses to infectious agents (Dennehy and Brown 2007).

35.9 The DC Immunoreceptor and DC-Immunoactivating Receptor

The dendritic cell (DC) immunoreceptors (DCIR) and DC-immunoactivating receptors (DCAR) represent a subfamily of cell surface C-type lectin receptors, whose multifunctional capacities range from classical Ag uptake and immunoregulatory mechanisms to the involvement in DC ontogeny.

35.9.1 Dendritic Cell Immunoreceptor (DCIR) (CLECsF6): Characterization

DCIR was identified by screening a nucleotide database for molecules homologous to the Group II C-type lectin hepatic asialoglycoprotein receptors, which also contain a single CRD at the C-terminal end (Bates et al. 1999). The DCIR (official gene symbol *Clec4a2*, called *Dcir*) is a type II C-type lectin expressed mainly in DCs that has a CRD in its extracellular region of the protein. DCIR mRNA was found to be highly expressed in human peripheral blood leukocytes, and at lower levels in lymph node, spleen, bone marrow and thymus, while mouse DCIR was found to be expressed at highest levels in spleen and lymph node. The term "DC immunoreceptors" is applied to a distinct set of signaling pattern-recognition receptors (PRR) described by Kanazawa et al. (2004b) and Kanazawa (2007), who reviewed their signaling mechanisms, carbohydrate recognition, and other features that contribute to the function of DC to control immunity.

DCIR is a type II membrane glycoprotein of 237 aa with a single CRD, closest in homology to those of the macrophage lectin and hepatic asialoglycoprotein receptors. The intracellular domain of DCIR contains a consensus ITIM. The gene encoding human DCIR was localized to chromosome 12p13, in a region close to the NK gene complex. The DCIR mRNA is predominantly transcribed in hematopoietic tissues. A closer look at protein expression on cells, revealed that DCIR was expressed on APCs such as $CD14^+$ monocytes, $CD19^+$ B cells, macrophages, neutrophils as well as myeloid and plasmacytoid DCs (pDCs), but not on $CD3^+$ T cells nor on $CD56^+$ or $CD16^+$NK cells (Bates et al. 1999; Kanazawa et al. 2002; Richard et al. 2002). DCIR acts as an inhibitory receptor via an ITIM in its cytoplasmic tail that transduces negative signals into cells. In contrast, DCAR is a molecule that forms a putative pair with DCIR. While both molecules share the highly homologous extracellular lectin domain, DCAR lacks the ITIM in its short cytoplasmic tail and acts as an activating receptor through association with the Fc receptor γ chain. Dectin-2 and BDCA-2 are highly related to DCAR by similarities of their amino acid sequence, molecular structure and chromosomal localization.

The DCIR was strongly expressed by DC derived from blood monocytes cultured with GM-CSF and IL-4. DCIR was mostly expressed by monocyte-related rather than Langerhans cell related DCs obtained from $CD34^+$ progenitor cells. The DCIR expression was down-regulated by signals inducing DC maturation such as CD40 ligand, LPS, or TNF-α. Thus, DCIR is differentially expressed on DC depending on their origin and stage of maturation/activation. DCIR represents a novel surface molecule expressed by Ag presenting cells, and of potential importance in regulation of DC function (Bates et al. 1999). Expression of mouse DCIR mRNA was observed specifically in spleen and lymph node, slightly increased with DC maturation during in vitro culture of bone marrow cells, and was not detected in cultured NK cells. Surface expression of mouse DCIR protein is observed in splenic APCs including B cells, monocytes/macrophages, and DCs, but not in T cells. The dectin-2 α isoform showed the highest degree of homology (33.5% identity in the overall sequence and 44.8% within the CRD motif) to murine DCIR. Dectin-2 differs from DCIR in ITIM motif found in the intracellular domain of DICR. ITIM was absent from short intracellular domain (14 aa) of dectin-2. Interestingly, dectin-2 also lacked an ITIM, which was identified in the intracellular domain of dectin-1. Thus, a simplified scenario would be that dectin-1 and DCIR deliver counteracting signals into DC, whereas dectin-2 has no apparent signaling potential. Unfortunately, information with respect to the

natural ligands that are recognized by CD69, DCIR, dectin-1, and/or dectin-2 is not available.

Duck DCIR encodes an inhibitory receptor that features an ITIM in the cytoplasmic domain. While DCAR1 is a pseudogene, DCAR2 encodes an activating receptor with a positively charged residue in transmembrane region. Study suggests the presence of full-length and alternatively spliced forms of both DCIR and DCAR2. Duck DCIR and DCAR transcripts are preferentially expressed in immune and mucosal tissues including spleen, bursa of Fabricius, intestine and lung. Targeting these receptors on DCs holds promise for enhancing immune responses relevant for hepatitis B and vaccination against avian influenza (Guo et al. 2008b). Recombinant duck β-defensin, expressed in HEK293T cells significantly down-regulated DCIR mRNA, without changing the expression of TLR-7, DCAR, CD44, CD58 and cytokines (Soman et al. 2009).

DCIR as Inhibitory Receptor with an ITIM Motif: After coligation with a chimeric Fcγ receptor IIB containing the cytoplasmic portion of mouse DCIR, Kanazawa et al. (2002) detected two distinct inhibitory effects of cytoplasmic DCIR (-) inhibition of B-cell-receptor-mediated Ca^{2+} mobilization and protein tyrosine phosphorylation (-); both these effects required the tyrosine residue inside the ITIM. This report suggested that mouse DCIR expressed on APCs can exert two distinct inhibitory signals depending on its ITIM tyrosine residue (Kanazawa et al. 2002). This inhibition was completely abolished when the tyrosine of the DCIR ITIM motif was mutated to a phenylalanine (Kanazawa et al. 2002).

DCIR also called CLECSF6, is dominantly present in neutrophil membranes. The expression of this protein was down-regulated in neutrophils treated with GM-CSF, TNF-α, LPS, and IL-1α, where as anti-inflammatory stimuli, including IL-4, IL-10 and IL-13, did not affect expression, that suggests that DCIR may be down-regulated during inflammation (Richard et al. 2002). Interestingly, GM-CSF, IL-3, IL-4 and IL-13 stimulation of neutrophils resulted in accumulation of a short form of DCIR mRNA, which encodes a putative non-functional protein which has been proposed to act as an antagonist to the full-length receptor (Richard et al. 2002, 2003).

During neutrophil signaling, the peptide bearing the ITIM in its phosphorylated form associates with both SHP-1 and SHP-2. Phosphorylated SHP-1 binds the ITIM whereas phosphorylated SHP-2 does not. In addition, GM-CSF reduces the binding of SHP-2 to the ITIM of CLECSF6 while enhancing the phosphorylation level of SHP-2. GM-CSF is known to recruit SHP-2 to its receptor. Results suggest that the phosphorylation of SHP-2 by GM-CSF promotes the binding of SHP-2 to the GM-CSF receptor to the disadvantage of CLECSF6. Therefore, upon a treatment with GM-CSF, SHP-2 could move from a CLECSF6 associated signalosome with a repressor function to a GM-CSF receptor associated signalosome with an activator function. This work supports the hypothesis that CLECSF6 is involved in the control of inflammation in neutrophils (Richard et al. 2003, 2006).

DCIR Inhibits TLR8-Mediated Cytokine Production: Targeting DCIR on PDCs not only results in efficient antigen presentation but also affects TLR9-induced IFN-α production. It suggests that targeting of DCIR can modulate human PDC (Meyer-Wentrup et al. 2008). The endogenous DCIR is internalized efficiently into human moDC after triggering with DCIR-specific mAb. Collectively, DCIR acts as an APC receptor that is endocytosed efficiently in a clathrin-dependent manner and negatively affects TLR8-mediated cytokine production (Meyer-Wentrup et al. 2009). Cross-priming $CD8^+$ T cells by targeting antigens to human DCs through DCIR allows activation of specific $CD8^+$ T-cell immunity (Klechevsky et al. 2010).

DCIR As an Attachment Factor for HIV-1: DCIR also plays a role in the capture and transmission of HIV-1 by DCs (Lambert et al. 2008). Although DC-SIGN was responsible for the trans-infection function of the virus, subsequent studies demonstrated that trans-infection of $CD4^+$ T cells with HIV-1 can also occur through DC-SIGN-independent mechanisms as well (Lambert et al. 2008). It was proposed that DCIR interaction with HIV could allow the virus to gain access to nondegradative endosomal organelles and lead to fusion of viral and endosomal membranes, allowing productive infection of the cells (Lambert et al. 2008). Thus, DCIR acts as a ligand for HIV-1 and is involved in events leading to productive virus infection. In this process, the neck domain of DCIR is important for DCIR-mediated effect on virus binding and infection. Therefore, DCIR plays a role in HIV-1 pathogenesis by supporting the productive infection of DCs and promoting virus propagation (Lambert et al. 2008).

DCIR Deficiency and Autoimmune Disorders: In addition to acting as a PRR for HIV, DCIR has been shown to play a role in controlling autoimmune disease. Aged DCIR deficient mice were found to spontaneously develop joint abnormalities, had elevated levels of autoantibodies and showed higher levels of $CD11c^+$ DCs and a proportional expansion of T cell populations in their lymph nodes (Fujikado et al. 2008). The DCIR deficiency was related to development of autoimmune disorders and DCIR gene polymorphisms were associated with rheumatoid arthritis (RA). When studying DCIR expression in patients with rheumatoid arthritis, the receptor was found to be abundantly expressed in synovial fluid but was not found in

healthy controls (Eklöw et al. 2008). In these samples, the DCIR was expressed on numerous cell types and surprisingly also on $CD56^+$ NK cells and $CD4^+$ and $CD8^+$ T cells. $DCIR^+$ T cells in the synovial fluid were activated, as well as much more abundant, than those found in peripheral blood (Eklöw et al. 2008). *Dcir* expression was also high in joints of two mouse RA models. These observations suggested that DCIR has an essential role in maintaining homeostasis of the immune system by controlling DC expansion and the development of autoimmune disease. Ronninger et al. (2008) analyzed the mRNA expression from the four known transcripts of DCIR in IFN-γ-treated human leukocytes together with fine mapping across the locus. RA patients and healthy controls were genotyped for several single nucleotide polymorphisms (SNPs) in *Dcir* and flanking regions. Results revealed that IFN-γ significantly downregulates the average expression of transcripts DCIR_v1, DCIR_v2, DCIR_v3 and DCIR_v4. The expression of *Dcir* showed significant association with variations in the gene. Cells with the RA-associated allele rs2024301 exhibited a significant increase in the expression of DCIR_v4. A fifth isoform, lacking exons 2, 3 and 4, illustrated that common genetic variations might influence *Dcir* mRNA expression. It also showed that the expression is regulated by the inflammatory mediator IFN-γ, affecting all four transcripts and that this was independent of genotype (Ronninger et al. 2008).

Since the *Dcir* may have an immune regulatory role, and since autoimmune-related genes are mapped to the DCIR locus in humans, Fujikado et al. (2008) found that aged $Dcir^{-/-}$ mice spontaneously develop sialadenitis and enthesitis associated with elevated serum autoantibodies. $Dcir^{-/-}$ mice showed a markedly exacerbated response to collagen-induced arthritis. The DC population was expanded excessively in aged and type II collagen-immunized $Dcir^{-/-}$ mice. Upon treatment with GMC-SF, $Dcir^{-/-}$ mouse-derived bone marrow cells (BMCs) differentiated into DCs more efficiently than did wild-type BMCs, owing to enhanced signal transducer and activator of transcription-5 phosphorylation. These observations indicated that Dcir is a negative regulator of DC expansion and has a crucial role in maintaining the homeostasis of the immune system.

35.9.2 Dendritic Cell Immunoactivating Receptor (DCAR)

In contrast to DCIR that induces negative signals through an ITIM in its cytoplasmic tail, Kanazawa et al. (2003) identified a C-type lectin receptor, dendritic cell immunoactivating receptor (DCAR), whose extracellular lectin domain is highly homologous to that of DCIR. The DCAR is expressed in tissues similar to DCIR, but its short cytoplasmic portion lacks signaling motifs like ITIM. However, presence of a positively charged arginine residue in the transmembrane region of the DCAR may explain its association with FcRγ chain and its stable expression on the cell surface. In A20 cells co-transfected with the FcRγ chain, cross-linking a chimeric receptor consisting of the extracellular region of FcγRIIB demonstrated that signaling from DCAR takes place via ITAM motif of the adaptor. The FcRγ chain was also required for surface expression of DCAR, as it enhanced receptor expression in transduced in 293T cells. Two isoforms of DCAR have been identified, one of which lacks the stalk region, but the ligands and biological functions of these isoforms still remain undefined. Thus, DCAR introduces activating signals into APCs through its physical and functional association with ITAM-bearing γ chain and provides an example of signaling via a DC-expressed C-type lectin receptor (Kanazawa et al. 2003). The gene of the DCAR has been identified next to the DCIR gene, and this acts as a putative activating pair of DCIR through association with an ITAM-bearing FcRγ chain. Kaden et al. (2009) functionally characterized mouse DCAR1 (mDCAR1) whose expression was strongly tissue dependent. The mDCAR1 expression was restricted to the $CD8^+$ DC subset in spleen and thymus and on subpopulations of $CD11b^+$ myeloid cells in bone marrow and spleen, and not detectable on both cell types in lymph nodes and peripheral blood. The Ag delivered via mDCAR1 was internalized, trafficked to early and late endosomes/lysosomes and, as a consequence, induced cellular and humoral responses in vivo even in absence of CD40 stimulation. Results indicated that mDCAR1 is a functional receptor on cells of the immune system and provides further insights into the regulation of immune responses by CLRs.

35.10 Macrophage-Inducible C-Type Lectin (Mincle)

Matsumoto et al. (1999) reported a macrophage-inducible C-type lectin (Mincle), as a downstream target of NF-IL6 in macrophages. NF-IL6 belongs to the CCAAT/enhancer binding protein (C/EBP) of transcription factors and plays a crucial role in activated macrophages. Mincle exhibits the highest homology to the members of group II C-type lectins. Mincle mRNA expression was strongly induced in response to several inflammatory stimuli, such as LPS, TNF-α, IL-6, and IFN-γ in wild-type macrophages. In contrast, NF-IL6-deficient macrophages displayed a much lower level of

Mincle mRNA induction following treatment with these inflammatory reagents. The mouse Mincle proximal promoter region contains an indispensable NF-IL6 binding element, demonstrating that Mincle is a direct target of NF-IL6. The Mincle gene locus was mapped at 0.6 centiMorgans proximal to CD4 on mouse chromosome 6. Mincle (also called as Clec4e and Clecsf9) is an FcRγ-associated activating receptor that senses damaged cells and involved in sensing necrosis (Brown 2008). Mincle selectively associates with the Fc receptor common γ-chain and activated macrophages to produce inflammatory cytokines and chemokines. Mincle-expressing cells are activated in the presence of dead cells. SAP130, a component of small nuclear ribonucloprotein, acts as a Mincle ligand that is released from dead cells. Thus, Mincle is a receptor that senses nonhomeostatic cell death and thereby induces the production of inflammatory cytokines to drive the infiltration of neutrophils into damaged tissue (Yamasaki et al. 2008).

35.10.1 Recognition of Pathogens

Yeast *Candida albicans* is a causative agent in mycoses of the skin, oral cavity, and gastrointestinal tract (Flores-Langarica et al. 2005). Identification of receptors, and their respective ligands, that are engaged by immune cells when in contact with *C. albicans* is crucial for understanding inflammatory responses leading to invasive candidiasis. Mincle, expressed predominantly on macrophages, was shown to play a role in macrophage responses to *Candida albicans*. The carbohydrate-recognition domain of human and mouse Mincle demonstrated the recognition of whole *C. albicans* yeast cells. After exposure to the yeast in vitro, Mincle localized to the phagocytic cup. However, it was not essential for phagocytosis. In absence of Mincle, production of TNF-α by macrophages was reduced, both in vivo and in vitro. In addition, mice lacking Mincle showed a significantly increased susceptibility to systemic candidiasis. Thus, Mincle plays a novel and non-redundant role in the induction of inflammatory signaling in response to *C. albicans* infection (Bugarcic et al. 2008; Wells et al. 2008). Mincle specifically recognizes *Malassezia* species among 50 different fungal species tested. *Malassezia* is a pathogenic fungus that causes skin diseases, such as tinea versicolor and atopic dermatitis, and fatal sepsis. Analyses of glycoconjugate revealed that Mincle selectively binds to α-mannose but not mannan. *Malassezia* activated macrophages to produce inflammatory cytokines/chemokines. *Malassezia*-induced cytokine/chemokine production by macrophages from Mincle$^{-/-}$ mice was significantly impaired. Results indicate that Mincle is the specific receptor for *Malassezia* species that plays a crucial role in immune responses to this fungus (Yamasaki et al. 2009).

35.10.2 Recognition of Mycobacterial Glycolipid, Trehalose Dimycolate

Trehalose-6,6′-dimycolate (TDM; also called cord factor) is a mycobacterial cell wall glycolipid that is the most studied immunostimulatory component of *M. tuberculosis*. However, its host receptor has not been clearly identified. Mincle is an essential receptor for TDM, which acts as a mincle ligand. TDM activated macrophages produce inflammatory cytokines and nitric oxide, which are completely suppressed in Mincle-deficient macrophages. The TDM and its synthetic analog trehalose-6,6-dibehenate (TDB) are potent adjuvants for Th1/Th17 vaccination that activate Syk-Card9 signaling in APCs. Further studies established that Mincle is a key receptor for the mycobacterial cord factor and controls the Th1/Th17 adjuvanticity of TDM and TDB (Geijtenbeek et al. 2003; Ishikawa et al. 2009; Matsunaga and Moody 2009; Schoenen et al. 2010).

35.11 Blood Dendritic Cell Antigen-2 (BDCA-2) (CLEC-4C)

35.11.1 BDCA-2: A Plasmacytoid DCs (PDCs)-Specific Lectin

Dzionek et al. (2000) identified three human blood DC Ags: BDCA-2, BDCA-3, and BDCA-4 which were expressed by PDCs. BDCA-2 and BDCA-4 were expressed on CD11c^{-} CD123^{bright} PDCs, whereas BDCA-3 was expressed on small population of CD11c^{+} CD123^{-} DCs. All three Ags were not detectable on a third blood DC population, which corresponded to CD1c^{+} CD11c^{bright} CD123^{dim}. Expression of all three Ags dramatically changes once blood DCs undergo in vitro maturation. For example, BDCA-2 was completely down-regulated on plasmacytoid CD11c^{-} CD123^{bright} DCs where as expression of BDCA-3 and BDCA-4 was up-regulated on sub-types of DCs on which they were localized. BDCA-2 was rapidly internalized at 37°C after mAb labeling. The three Ags serve as markers for respective subpopulations of blood DCs in fresh blood (Dzionek et al. 2000). Thus, BDCA-2 is a marker for human PDC.

35.11.2 Characterization

Molecular cloning of BDCA-2 (CD303) revealed that BDCA-2 is a type II C-type lectin, which shows 50.7% sequence identity at the amino acid level to its putative murine ortholog, the murine DC-associated C-type lectin 2. Anti-BDCA-2 mAbs are rapidly internalized and efficiently presented to T cells, indicating that BDCA-2 could play a role in ligand internalization and presentation. Furthermore,

ligation of BDCA-2 potently suppresses induction of interferon α/β production in plasmacytoid DCs, presumably by a mechanism dependent on protein-tyrosine phosphorylation by protein-tyrosine kinases (Dzionek et al. 2001). The-BDCA-2 receptor is involved in the down-regulation of virus triggered interferon-α/β production in PDC (Dzionek et al. 2001).

BDCA-2 transcripts were weakly detected in tonsils, bone marrow, pancreas, lymph nodes, peripheral blood leukocytes, testis and ovary, (Dzionek et al. 2001; Fernandes et al. 2000). While testes from patients with testicular cancer, neoplastic and normal epithelium were negative for BDCA-2, $CD123^+$ PDCs were associated with lymphoid aggregates in tumors. It appears that expression of BDCA-2 in tissues is restricted to PDCs (Dzionek et al. 2001). The murine homolog(s) of BDCA-2 are not yet known, whereas, at least five truncated BDCA-2 mRNA species have been detected in humans (Dzionek et al. 2001; Fernandes et al. 2000). BDCA-2 contains an EPN motif in the CRD but ligand(s) for this receptor have not been identified. BDCA-2 from cell lysates was shown not to recognize mannose as carbohydrate (Fernandes et al. 2000; Arce et al. 2001). However, transfection studies on 293T and Jurkat cells and freshly isolated PDCs revealed that BDCA-2 couples with FcRγ chain. This was substantiated in Jurkat cells co-transfected with BDCA-2 and FcRγ chain, resulting into stimulation of BDCA-2 induced intracellular protein phosphorylation and Ca^{2+} influx which was not possible when BDCA-2 was expressed alone (Dzionek et al. 2001; Cao et al. 2007).

35.11.3 BDCA-2 Signals in PDC via a BCR-Like Signalosome

Human BDCA2 protein lacks an identifiable signaling motif. Signaling through BDCA-2 is dependent on the ITAM motif in FcRγ chain and downstream pathways involve Syk, SH-2 domain-containing leukocyte protein of 65 kDa (Slp65), Vav1, phospholipase C-γ (PLCγ2) and Erk1/2. It forms a complex with the transmembrane adapter Fc εRI γ. The signaling machinery in human PDCs is similar to that which operates downstream of BCR, which is distinct from the system involved in TCR signaling. BDCA2 crosslinking resulted in the activation of the BCR-like cascade, which potently suppressed the ability of PDCs to produce type I interferon and other cytokines in response to Toll-like receptor ligands (Cao et al. 2007; Rock et al. 2007).

By associating with Fc εRI γ, BDCA2 activates a BCR-like signaling pathway to regulate the immune functions of PDCs. BDCA-2 signaling induces tyrosine phosphorylation and Src kinase dependent Ca^{2+} influx. Cross-linking BDCA2 results in the inhibition of IFN-I production in stimulated PDC. PDCs express a signalosome similar to the BCR signalosome, consisting of Lyn, Syk, Btk, Slp65 (Blnk) and PLCγ2. BDCA2 associates with the signaling adapter FcR γ-chain. Triggering BDCA2 leads to tyrosine phosphorylation of Syk, Slp65, PLCγ2 and cytoskeletal proteins. Analogous to BCR signaling, BDCA2 signaling is likely linked with its internalization by clathrin-mediated endocytosis. The inhibition of IFN-I production by stimulated PDC is at least partially regulated at the transcriptional level. These results support a possible therapeutic value of an anti- BDCA2 mAb strategy, since the production of IFN-I by PDCs is considered to be a major pathophysiological factor in SLE patients (Röck et al. 2007).

Engagement of BDCA-2 Blocks TRAIL-Mediated Cytotoxic Activity of PDC: PDCs express Toll-like receptor (TLR) 9, which mediates recognition of microbial DNA during infection or self-DNA in autoimmune diseases. BDCA-2-induced signaling in PDCs inhibits up-regulation of CD86 and CD40 molecules in CpG-activated PDCs, but not in CD40L-activated PDCs. Furthermore, triggering of BDCA-2 diminished the ability of CpG- and CD40L-stimulated PDCs to process and present antigen to antigen-specific autologous memory T cells. Jähn et al. (2010) suggest that BDCA-2 represents an attractive target for clinical immunotherapy of IFN-I dependent autoimmune diseases influencing both, IFN-I production and antigen-specific T-cell stimulation by PDCs.

TLR7 and TLR9 ligands can induce the secretion of biologically active TNF-related apoptosis-inducing ligand (TRAIL) by PDCs. Accordingly PDC supernatant is endowed with TRAIL-mediated cytotoxic activity when tested on a TRAIL-sensitive Jurkat cell line. Importantly, both TRAIL secretion and cytotoxic activity of PDC supernatants are completely abolished by BDCA2 ligation. These results document a negative regulatory pathway of PDC cytotoxic activity that may be relevant in pathological situations such as tumors and autoimmune diseases (Riboldi et al. 2009).

35.11.4 Functions of BDCA-2

Regulation of IFN-α Production: PDCc are the natural type I IFN-producing cells that produce large amounts of IFN-α in response to viral stimulation. Cross-linking BDCA-2, BDCA-4, and CD4 on PDC regulates IFN-α production at the level of IRF-7, while the decrease in IFN-α production after CD123 cross-linking is due to stimulation of the IL-3R and induction of PDC maturation (Fanning et al. 2006).

Pregnancy: Dendritic cells are involved in the immune regulation during physiological pregnancy. $CD1c^+$ and BDCA-2^+ cells can influence the Th2 phenomenon which is observed during physiological pregnancy. It seems possible that lower BDCA-2^+ cells percentage and higher $CD1c^+$: BDCA-2^+ ratio can be associated with increased Th1-type immunity in patients with pre-eclampsia (Darmochwal-Kolarz et al. 2003). DCs within the decidua have been implicated in pregnancy maintenance. Ban et al. (2008) identified three DC subsets in normal human first-trimester decidua: BDCA-1^+ $CD19^-$ $CD14^-$ myeloid DC type 1 (MDC1), BDCA-3^+ $CD14^-$ myeloid DC type 2 (MDC2) and BDCA-2^+ $CD123^+$ plasmacytoid DC (PDC).

BDCA-2^+ in SLE: Type 1 IFN is thought to be implicated in the autoimmune process of SLE. Plasmacytoid DC, which are natural IFN-α producing cells, play a pivotal epipathogenic role in SLE. The phenotypic characteristics of peripheral blood DC in SLE patients show a reduced number of both BDCA-2^+ plasmacytoid DC and $CD11c^+$ myeloid DC. These alternations of the DC subset may drive the autoimmune response in SLE (Blomberg et al. 2003; Migita et al. 2005). BDCA-2-expressing pDCs are termed natural IFN α-producing cells, IFN α production could be inhibited by anti-BDCA-2/4 mAb (Blomberg et al. 2003; Wu et al. 2008).

Hematopoietic Malignancies: $CD4^+CD56^+$ hematodermic neoplasms are rare, aggressive hematopoietic malignancies usually presenting with cutaneous masses followed by a leukemic phase. Accumulating evidence suggests that these neoplasms represent malignant counterparts to the plasmacytoid DCs. BDCA-2, expressed predominantly on plasmacytoid DCs in $CD7^+$ subset of hematodermic neoplasms, and similar to non-neoplastic plasmacytoid dendritic cells, indicates a relatively more mature differentiation state. Clinical follow-up data confirm the aggressiveness of these tumors and suggests that BDCA-2 immunoreactivity may herald a significant reduction in survival (Jaye et al. 2006).

35.12 CLECSF8

Murine Clecsf8 was first identified through a differential display PCR screen of numerous cell lines for macrophage-specific genes (Balch et al. 1998). The molecule, named mouse macrophage C-type lectin, is a 219-amino acid, type II transmembrane protein with a single extracellular C-type lectin domain and expressed in cell lines and normal mouse tissues in a macrophage-restricted manner. The expression of this receptor was upregulated on these cells by IL-6, IL-10, TNF-α or IFN-γ, but was downreglated with LPS. The cDNA and genomic sequences of mouse macrophage C-type lectin indicate that it is related to the Group II animal C-type lectins. The mcl gene locus has been mapped between the genes for the interleukin-17 receptor and CD4 on mouse chromosome 6, the same chromosome as the mouse NK cell gene complex (Arce et al. 2004).

Arce et al. (2004) characterized the human orthologue of the mouse Mcl/Clecsf8. Human CLECSF8 codes for a type II membrane glycoprotein of 215 amino acids that belongs to human C-type lectin family. The cytoplasmic tail of CLECSF8 lacks consensus signaling motifs and its extracellular region shows a single CRD. The CLECSF8 gene has been localized on the telomeric region of the NK gene complex on chromosome 12p13 close to MINCLE. CLECSF8 mRNA shows a monocyte/ macrophage expression pattern. Biochemical analysis of CLECSF8 on transiently transfected cells showed a glycoprotein of 30 kDa. Cross-linking of the receptor leads to a rapid internalization suggesting that CLECSF8 constitutes an endocytic receptor. Preliminary studies suggest that Clecsf8 could be upregulated in proinflammatory settings, as has been described for Mincle and Dectin-2 (Arce et al. 2004).

35.13 Macrophage Galactose/N-acetylgalactosamine Lectin (MGL)

The hMGL is a marker of immature DCs and it functions as an endocytic receptor for glycosylated antigens (Higashi et al. 2002). Van Die et al. (2003) identified an exclusive specificity for terminal α- and β-linked GalNAc residues that naturally occur as parts of glycoproteins or glycosphingolipids. Specific glycan structures containing terminal GalNAc moieties, expressed by helminth parasite *Schistosoma mansoni* as well as tumor antigens and a subset of gangliosides, were found as ligands for MGL. Studies indicate an endogenous function for DC-expressed MGL in the clearance and tolerance to self-gangliosides, and in the pattern recognition of tumor antigens and foreign glycoproteins derived from helminth parasites. The dendritic cell-specific C-type lectin DC-SIGN is a receptor for Schistosoma 8 MGL recognition of terminal GalNAc residues (Van Die et al. 2003). The MGL has been discussed in greater details in Chap. 33

DC-SIGN Family of Receptors

36

Rajesh K. Gupta and G.S. Gupta

36.1 DC-SIGN (CD209) Family of Receptors

In the immune system, C-type lectins and CTLDs have been shown to act both as adhesion and as pathogen recognition receptors. The **D**endritic **c**ell-**s**pecific **I**CAM-3 **g**rabbing **n**on-integrin (DC-SIGN) and its homologs in human and mouse represent an important C-type lectin family. DC-SIGN contains a lectin domain that recognizes in a Ca^{2+}-dependent manner carbohydrates such as mannose-containing structures present on glycoproteins such as ICAM-2 and ICAM-3. DC-SIGN is a prototype C-type lectin organized in microdomains, which have their role as pathogen recognition receptors in sensing microbes. Although the integrin LFA-1 is a counter-receptor for both ICAM-2 and ICAM-3 on DC, DC-SIGN is the high affinity adhesion receptor for ICAM-2/-3. While cell–cell contact is a primary function of selectins, collectins are specialized in recognition of pathogens. Interestingly, DC-SIGN is a cell adhesion receptor as well as a pathogen recognition receptor. As adhesion receptor, DC-SIGN mediates the contact between dendritic cells (DCs) and T lymphocytes, by binding to ICAM-3, and mediates rolling of DCs on endothelium, by interacting with ICAM-2. As pathogen receptor, DC-SIGN recognizes a variety of microorganisms, including viruses, bacteria, fungi and several parasites (Cambi et al. 2005). The natural ligands of DC-SIGN consist of mannose oligosaccharides or fucose-containing Lewis-type determinants. In this chapter, we shall focus on the structure and functions of DC-SIGN and related CTLDs in the recognition of pathogens, the molecular and structural determinants that regulate the interaction with pathogen-associated molecular patterns. The heterogeneity of carbohydrate residues exposed on cellular proteins and pathogens regulates specific binding of DC-expressed C-type lectins that contribute to the diversity of immune responses created by DCs (van Kooyk et al. 2003a; Cambi et al. 2005).

The DC-SIGN, originally described in 1992 as a C-type lectin able to bind the HIV surface protein, gp120 (Curtis et al. 1992), is important for efficient infection with HIV (Geijtenbeek et al. 2000c). Recent advances on a broad perspective concerning DC-SIGN structure, signaling and immune function have appeared in excellent reviews (den Dunnen et al. 2009; Gringhuis and Geijtenbeek 2010; Svajger et al. 2010). Interaction of DC-SIGN with the viral envelope glycoproteins may evoke cellular signal transduction implicated in viral pathogenesis.

36.1.1 CD209 Family Genes in Sub-Human Primates

Two *CD209* family genes identified in humans, *CD209* (*DC-SIGN*) and *CD209L* (*DC-SIGNR*/*L-SIGN*/*LSECtin*), encode C-type lectins that serve as adhesion receptors for ICAM-2 and ICAM-3 and participate in the transmission of HIV and SIV respectively to target cells in vitro. The *CD209* gene family that encodes C-type lectins in primates includes CD209 (DC-SIGN), CD209L (L-SIGN) and CD209L2. The *CD209* gene family in sub-human primates showed evolutionary alterations that occurred in this family across primate species. All of the primate species, specifically, Old World monkeys (OWM) and apes, have orthologues of human *CD209*. In contrast, *CD209L* is missing in OWM but present in apes. A third family member, that has been named *CD209L2*, was cloned from rhesus monkey cDNA and subsequently identified in OWM and apes but not in humans. Rhesus *CD209L2* mRNA was prominently expressed in the liver and axillary lymph nodes. Despite a high level of sequence similarity to both human and rhesus CD209, rhesus CD209L2 was substantially less effective at binding ICAM-3 and poorly transmitted HIV type 1 and SIV to target cells relative to CD209. The Toll-like receptor (TLR) gene family shares with CD209 genes a common

G.S. Gupta et al., *Animal Lectins: Form, Function and Clinical Applications*,
DOI 10.1007/978-3-7091-1065-2_36, © Springer-Verlag Wien 2012

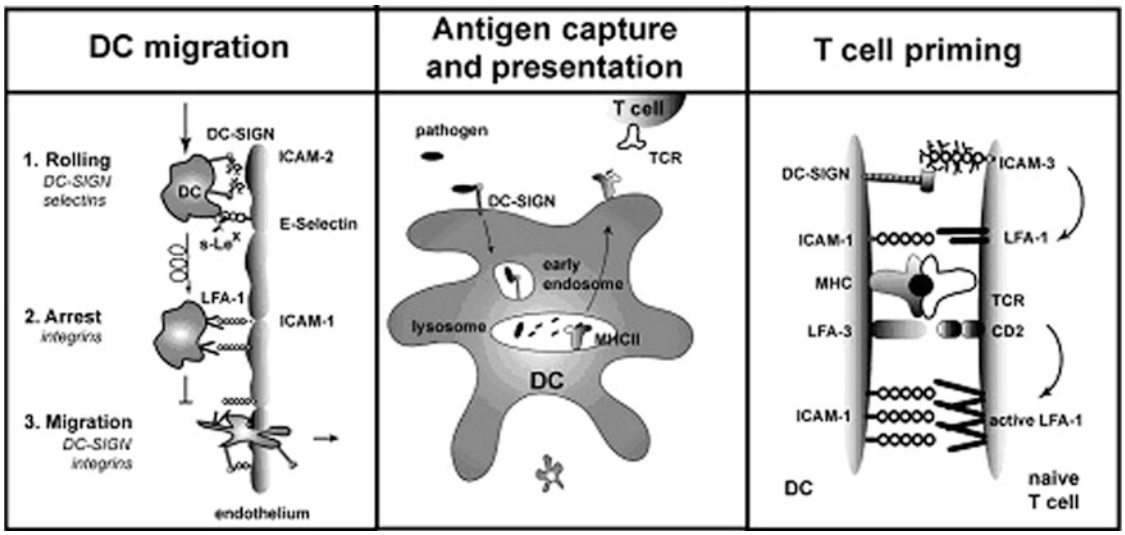

Fig. 36.1 DC-SIGN controls many functions of DC to elicit immune responses. The egress of precursor DC from blood into tissues is mediated partly by DC-SIGN. DC-SIGN facilitates rolling and transendothelial migration of DC-SIGN_ precursor DC, whereas arrest is mediated by integrin-mediated interactions. DC-SIGN also functions as an antigen receptor. DC-SIGN internalizes rapidly upon binding soluble ligand and is targeted to late endosomes/lysosomes, where antigens are processed and presented by MHC class II molecules. Moreover, initial DC-T-cell clustering, necessary for an efficent immune response, is mediated by transient interactions between DC-SIGN and ICAM-3. This interaction facilitates the formation of low-avidity LFA-1/ICAM-1 interaction and scanning of the antigen-MHC repertoire. It is becoming clear that other C-type lectins also participate in these processes. Selectins and the MR may regulate DC migration. Many other C-type lectins on DC, such as MR, DEC205, DC-ASPGR, BCDA-2, and dectin-1, are antigen receptors that recognize various distinct carbohydrate-containing antigens. It has been postulated that dectin-1 regulates T-cell priming, however its interaction with T cells is not carbohydrate-dependent (Reprinted with permission from Geijtenbeek et al. 2002a © Journal of Leukocyte Biology)

profile of evolutionary constraint (Bashirov et al. 2003b; Ortiz et al. 2008).

36.2 DC-SIGN (CD209): An Adhesion Molecule on Dendritic Cells

DC-SIGN (dendritic cell-specific ICAM-grabbing non-integrin, where ICAM is intercellular adhesion molecule) or CD209 is a type II C-type lectin expressed by DCs. DC-SIGN is specifically expressed on DCs and has been identified on monocyte-derived DCs in vitro and on DC subsets of skin, mucosal tissues, tonsils, lymph nodes, and spleen in vivo (Geijtenbeek et al. 2000a, c). DC-SIGN on DC binds the intercellular adhesion molecule (ICAM)-3 (CD50) with very high affinity. Although ICAM-3, a member of the immunoglobulin (Ig) superfamily, is known to be a ligand for β2 integrins lymphocyte function-associated antigen-1 (LFA-1; αLβ2) and $\alpha_D\beta_2$ (Bleijs et al. 2001; Geijtenbeek et al. 2002a; van Kooyk and Geijtenbeek 2002) (Fig. 36.1), these receptors did not contribute to the binding activity of ICAM-3 by DC. Many C-type lectins have been identified on DCs: (1) Type I multi-CRD lectins are represented by the mannose receptor (Sallusto et al. 1995) and DEC-205 (Kato et al. 2000); and (2) type II single-CRD lectins by DC-SIGN, dectin-1, dectin-2, Langerin, BCDA-2, DCIR, DLEC, CLEC-1, and DC-ASGPR (Geijtenbeek et al. 2000a) (Chap. 35). Within the CRD, the highly conserved EPN or QPD sequences are essential in recognizing mannose- and galactose-containing structures, respectively.

DC-SIGN contains a short, cytoplasmic N-terminal domain with several intracellular sorting motifs, an extracellular stalk of seven complete and one partial tandem repeat, and a terminal lectin or CRD (Geijtenbeek et al. 2000a; Curtis et al. 1992). The DC-SIGN has three conserved cytoplasmic tail motifs: the tyrosine (Y)-based, dileucine (LL), and triacidic cluster (EEE), which are believed to regulate ligand binding, uptake, and trafficking. The full-length porcine DC-SIGN cDNA encodes a type II transmembrane protein of 240 amino acids. Phylogenetic analysis revealed that porcine DC-SIGN, together with bovine, canis and equine DC-SIGN, is more closely related to mouse SIGNR7 and SIGNR8 than to human DC-SIGN. Porcine DC-SIGN has the same gene structure as bovine, canis DC-SIGN and mouse SIGNR8 with eight exons. Porcine DC-SIGN mRNA expression was detected in spleen, thymus, lymph node, lung, bone marrow and muscles. Porcine DC-SIGN protein was found to express on the surface of monocyte-derived macrophages and dendritic cells, alveolar macrophages, lymph node sinusoidal macrophage-like, dendritic-like and endothelial cells but not of monocytes, peripheral blood lymphocytes or lymph node lymphocytes (Huang et al. 2009). Bovine ortholog of human DC-SIGN,

within the bovine genome, exists as a single copy with a sequence similar to that of SIGNR7 (Yamakawa et al. 2008).

36.3 Ligands of DC-SIGN

36.3.1 Carbohydrates as Ligands of DC-SIGN

DC-SIGN and its close relative DC-SIGNR recognize various oligosaccharide ligands found on human tissues as well as on pathogens including viruses, bacteria, and parasites through the receptor lectin domain-mediated carbohydrate recognition. The DC-SIGN and DC-SIGNR bind to high-mannose carbohydrates on a variety of viruses. Studies have shown that these receptors bind the outer trimannose branch Manα1-3(Manα1-6)Manα present in high mannose structures. Although the trimannoside binds to DC-SIGN or DC-SIGNR more strongly than mannose, additional affinity enhancements are observed in presence of one or more Manα1-2Manα moieties on nonreducing termini of oligomannose structures. The molecular basis of this enhancement was investigated in crytstals of DC-SIGN bound to a synthetic six-mannose fragment of a high mannose N-linked oligosaccharide, Manα1-2Manα1-3 (Manα1-2Manα1-6)Manα1-6Man and to the disaccharide Manα1-2Man. The structures revealed mixtures of two binding modes in each case. Each mode features typical C-type lectin binding at main Ca^{2+}-binding site by one mannose residue. In addition, other sugar residues form contacts unique to each binding mode. Thus the affinity enhancement of DC-SIGN toward oligosaccharides decorated with Manα1-2Manα structure is due to multiple binding modes at the primary Ca^{2+} site, which provides both additional contacts and a statistical (entropic) enhancement of binding (Feinberg et al. 2007).

36.3.1.1 Lewis Antigen as Ligand

In addition to high-mannose moieties, DC-SIGN recognizes nonsialylated $Lewis^X$ (Le^x) and Le^Y glycans and binds to Le^X-expressing pathogens such as *Schistosoma mansoni* and *Helicobacter pylori* (Appelmelk et al. 2003; van Die et al. 2003). Mouse homolog of human DC-SIGN has similar carbohydrate specificity for high mannose-containing ligands present on both cellular and pathogen ligands and called mSIGNR1or SIGNR1. However, mSIGNR1 interacts not only with $Le^{x/y}$ and $Le^{a/b}$ antigens similar to DC-SIGN, but also with sialylated Le^x, a ligand for selectins. The differential recognition of Lewis antigens suggests differences between mSIGNR1 and DC-SIGN in the recognition of cellular ligands and pathogens that express Lewis epitopes (Koppel et al. 2005a). Using the known 3D structure of the Lewis-x trisaccharide, Timpano et al. (2008) identified some monovalent α-fucosylamides that bind to DC-SIGN. α-fucosylamides work as functional mimics of chemically and enzymatically unstable α-fucosides and describes interesting candidates for the preparation of multivalent systems able to block DC-SIGN with high affinity and with potential biomedical applications.

The binding partner of DC-SIGN on endothelial cells is the glycan epitope Le^Y, expressed on ICAM-2. The interaction between DC-SIGN on DCs and ICAM-2 on endothelial cells is strictly glycan-specific. ICAM-2 expressed on CHO cells only served as a ligand for DC-SIGN when properly glycosylated, underscoring its function as a scaffolding protein (García-Vallejo et al. 2008). Oligosaccharide ligands expressed on SW1116, a typical human colorectal carcinoma are recognized by DC-SIGN, and has similar carbohydrate-recognition specificities as MBP. These tumor-specific oligosaccharide ligands comprise clusters of tandem repeats of Le^a/Le^b glycans on carcinoembryonic Ag (CEA) and CEA-related cell adhesion molecule 1 (CEACAM1). DC-SIGN ligands containing Le^a/Le^b glycans are also highly expressed on primary cancer colon epithelia but not on normal colon epithelia (Nonaka et al. 2008). Fucosylated glycans similar to pathogens are also found in a variety of allergens, but their functional significance remains unclear. Results suggest that allergens are able to interact with DC-SIGN and induce TNF-α expression in monocyte-derived DCs (MDDCs) via, in part, Raf-1 signaling pathways (Hsu et al. 2010).

Structural characterization of glycolipids, in combination with solid phase and cellular binding studies revealed that DC-SIGN binds to carbohydrate moieties of both glycosphingolipid species with Galβ1-4(Fucα1-3)GlcNAc (Le^x) and Fucα1-3Galβ1-4(Fucα1-3)GlcNAc (pseudo- Le^y) determinants. These data indicate that surveying DCs in the skin may encounter schistosome-derived glycolipids immediately after infection. Crystal structure of the CRD of DC-SIGN bound to Le^x provided insight into the ability of DC-SIGN to bind fucosylated ligands. The observed binding of schistosome-specific pseudo-Le^y to DC-SIGN is not directly compatible with the model described (Meyer et al. 2005).

36.4 Structure of DC-SIGN

36.4.1 Neck-Domains

Human DC-SIGN is a type II membrane protein which contains 404 amino acids and is of 44 kDa in molecular weight. DC-SIGN consists of extracellular domain, transmembrane region and cytoplasmic region (Fig. 36.2). The extracellular portion of each receptor contains a membrane-distal CRD and forms tetramers stabilized by an extended neck region consisting of 23 amino acid repeats. Cross-linking analysis of full-length receptors expressed in

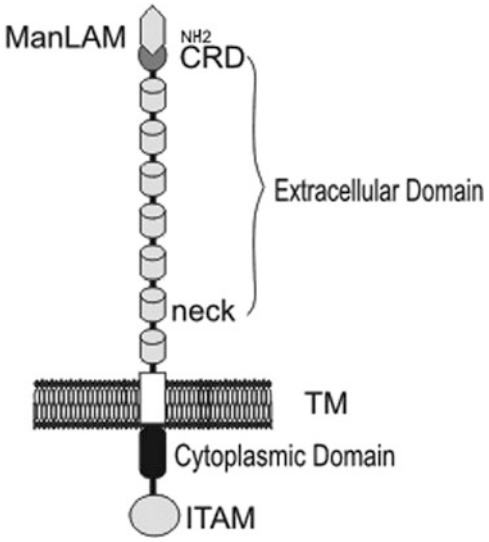

Fig. 36.2 Structure of DC-SIGN. Cytoplasmic domain, transmembrane region (TM) and extracellular domain are the three parts of DC-SIGN. The extracellular domain contains carbohydrate recognition domain (CRD) and neck domain. Cytoplasmic domain contains LL (di-leucine), EEE (tri-acidic clusters) and other internalization motifs and is connected to an incomplete ITAM. CRD recognizes certain carbohydrate-contained antigens like ManLAM and $Lewis^X$ by four amino acids (Glu^{347}, Asn^{349}, Glu^{354} and Asn^{365}) and one Ca^{2+}-binding site in it (Zhou et al. 2006)

fibroblasts confirmed the tetrameric state of the intact receptors. Alternative splicing and genomic polymorphism generate DC-SIGN mRNA variants, which were detected at the sites of pathogen entrance and transmission. Naturally occurring DC-SIGN neck variants differ in multimerization competence in the cell membrane, exhibit altered sugar binding ability, and retain pathogen-interacting capacity, implying that pathogen-induced cluster formation predominates over the basal multimerization capability. Reports highlight the central role of the neck domain in the pH-sensitive control of oligomerization state, in the extended conformation of the protein, and in CRD organization and presentation (Guo et al. 2006; Tabarani et al. 2009). Analysis of DC-SIGN neck polymorphisms indicated that the number of allelic variants is higher than previously thought and that the multimerization of the prototypic molecule is modulated in presence of allelic variants with a different neck structure. Serrano-Gómez et al. (2008) demonstrated that the presence of allelic variants or a high level of expression of neck domain splicing isoforms might influence the presence and stability of DC-SIGN multimers on the cell surface, thus providing a molecular explanation for the correlation between DC-SIGN polymorphisms and altered susceptibility to HIV-1 and other pathogens. Neck domains of DC-SIGN and DC-SIGNR are shown to form tetramers in the absence of the CRDs. Analysis indicates that interactions between the neck domains account full stability of the tetrameric extracellular portions of the receptors. The neck domains are ~40% α-helical based on circular dichroism analysis. However, in contrast to other glycan-binding receptors in which fully helical neck regions are intimately associated with C-terminal C-type CRDs, the neck domains in DC-SIGN and DC-SIGNR act as autonomous tetramerization domains and the neck domains and CRDs are organized independently. Neck domains from polymorphic forms of DC-SIGNR that lack some of the repeat sequences show modestly reduced stability, but differences near the C-terminal end of the neck domains lead to significantly enhanced stability of DC-SIGNR tetramers compared to DC-SIGN (Yu et al. 2009). The length of the neck region shows variable levels of polymorphism, and can critically influence the pathogen binding properties of these two receptors. In Colored South African population of 711 individuals, including 351 tuberculosis patients and 360 healthy controls, Barreiro et al. (2007) revealed that none of the DC-SIGN and L-SIGN neck-region variants or genotypes seems to influence the individual susceptibility to develop tuberculosis.

Surface force measurements between apposed lipid bilayers displaying the extracellular domain of DC-SIGN and a neoglycolipid bearing an oligosaccharide ligand provide evidence that the receptor is in an extended conformation and that glycan docking is associated with a conformational change that repositions the carbohydrate-recognition domains during ligand binding. The results further show that the lateral mobility of membrane-bound ligands enhances the engagement of multiple carbohydrate-recognition domains in the receptor oligomer with appropriately spaced ligands. These studies highlight differences between pathogen targeting by DC-SIGN and receptors in which binding sites at fixed spacing bind to simple molecular patterns (Menon et al. 2009).

36.4.2 Crystal Structure of DC-SIGN (CD209) and DC-SIGNR (CD299)

To understand the tetramer-based ligand binding avidity, the crystal structure of DC-SIGNR was determined with its last repeat region. Compared to the carbohydrate-bound CRD structure, the structure revealed conformational changes in the calcium and carbohydrate coordination loops of CRD, an additional disulfide bond between the N and the C termini of the CRD, and a helical conformation for the last repeat. On the basis of the current crystal structure and other published structures with sequence homology to the repeat domain, Snyder et al. (2005) generated a tetramer model for DC-SIGN/DC-SIGNR using homology modeling and proposed a ligand-recognition index to identify potential receptor ligands.

The CRD of DC-SIGN is a globular structure consisting of 2 α-helices, 12 β-strands, and 3 disulphide bridges. A loop protrudes from the protein surface and forms part of two Ca^{2+}- binding sites. One of such sites is essential for the conformation of CRD, and the other is essential for direct coordination of the carbohydrate structures. Four amino acids (Glu^{347}, Asn^{349}, Glu^{354} and Asn^{365}) interact with Ca^{2+} at this site and dictate the recognition of specific carbohydrate structures. CRD can recognize certain carbohydrate containing antigens like ManLAM and Le^{x}. Crystal structures of CRDs of DC-SIGN and of DC-SIGNR bound to oligosaccharide revealed that these receptors selectively recognize endogenous high-mannose oligosaccharides and represent a new avenue for developing HIV prophylactics (Feinberg et al. 2001). Hydrodynamic studies on truncated receptors demonstrated that the portion of the neck of each protein adjacent to the CRD was sufficient to mediate the formation of dimers, whereas regions near the N terminus were needed to stabilize the tetramers. Some of the intervening repeats are missing from polymorphic forms of DC-SIGNR. Two different crystal forms of truncated DC-SIGNR comprising two neck repeats and the CRD revealed that the CRDs are flexibly linked to the neck, which contains α-helical segments interspersed with non-helical regions. Differential scanning calorimetry measurements indicated that the neck and CRDs were independently folded domains (Feinberg et al. 2005).
