Preface

We are pleased to present a three volume treatise on "Polysaccharides: Bioactivity and Biotechnology." Polysaccharides are present throughout the plant kingdom and involved in various biological processes including defense for the plant and many useful applications for human welfare.

This work on polysaccharides is a reference work providing state-of-the-art knowledge composed by highly renowned scientists in their field. The book aims to present comprehensive, up-to-date, and well-established information about complex and astonishing structures, properties, and biotechnological applications of polysaccharides and their upcoming industrial applications. The book will be a valuable source on polysaccharides to those working in the field of industrial production and biotechnology development. Polysaccharides are a class of important biomacromolecules, with complex structures and various functional activities. Polysaccharides are extremely common and wide-spread in nature, with cellulose as the most common and abundant organic compound on the planet. It is believed that the second most common polysaccharide in the world after cellulose is chitin. Chitin is to shellfish what cellulose is to trees. This is a very timely compilation of recent developments about polysaccharides as no book is available in this format.

These polysaccharides find many uses: cf. for example the significant role of cellulose in the paper and textile industries, as a feedstock for the production of rayon (via the viscose process), cellulose acetate, celluloid, and nitrocellulose; as surgical threads (chitin), as sources of energy, dietary fibers, as a blood flow adjuvant; cosmetics, emulsion stabilizer, film former, binder, viscosity increasing agent, and skin conditioning agent; direct food additives in gums and chewing gum bases; and as vaccines. Many polysaccharides have been developed into useful products, including xanthan gum, dextran, welan gum, gellan gum, diutan gum, and pullulan.

This comprehensive and thoroughly up-to-date reference book presents the sources, identification, methods of analysis, biosynthesis, biotechnology, and applications of important polysaccharides likes starches, cellulose, chitin, gum, and microbial polysaccharides. Polysaccharides have received much attention recently because of the emergence of different biological activities, such as immunomodulatory, antibacterial, antimutagenic, radioprotective, anti-oxidative, anti-ulcer, antidepressant, antisepticemic, anticancer, and anti-inflammatory activities.

New industrial applications in pharmaceutical and medical sciences are being developed. Due to these properties and benefits, a vast body of data is being generated.

The various polysaccharides constitute important classes of biological polymers, which are dealt with in these volumes. The handbook is divided in several sections to encompass the entire spectrum of developments in this field: Part I. Biology and Biotechnology: occurrence, structure, distribution and biotechnology (bacterial polysaccharides, fungal polysaccharides, polysaccharides from lower plants, polysaccharides from higher plants including gums), biosynthesis of polysaccharides, applications in biotechnology, production by fermentation, biopolymers from marine prokaryotes, carrageenan, dextrans, polysaccharide nanocrystals, and modified gums in drug delivery. Part II. Food: structural (pectins, cellulose, xylans, gum, gumexudates, glycosamines), storage (starch, glycogens, fructans, minor polysaccharides), marine polysaccharides (alginate and brown sea weeds, carrageenan, and red sea weeds; agar, agarose, chitosan, and chitin derivatives), bacterial and synthetic polysaccharides (dextrans, cyclodextrins, gellans, xanthan, pullulan, etc.), polysaccharides from edible plant parts, and as functional foods. Part III. Methods: Extraction, identification, quantification, assays, and emerging technologies. Part IV. Bioactivity: applications in medicine, immunostimulant, polysaccharides from algal, aloe, brown seaweeds, fructus, ganoderma, medicinal mushrooms, scleroderma, and their biological activity. Most of the chapters are well illustrated, many of them in color, for the benefit of the readers. A comprehensive index section will assist in navigating through this book when searching for specific topics.

Well recognized international specialists in their respective fields of research have contributed these chapters. This book will be useful to everybody working in the field of botany, phytochemistry, pharmacy, drug delivery, molecular biology, forestry, biotechnology, and industrial/food and medical products. This work is arranged in 73 well illustrated chapters.

Because of the voluminous work for the treatise, this project was spread over almost 2 years, from concept to print. We would like to acknowledge cooperation, patience, and support of our contributors who have put their serious efforts to ensure the high scientific quality of this book with up-to-date information.

This work could not have been completed without active support of Springer team who took pains in streamlining the production process. We are particularly indebted to Drs. Tobias Wassermann, Sylvia Blago, and Stephanie Hügler for their continuous support from the very inception of the project. Our final and most heartfelt thanks we want to give to our wives Marie-Claude Mérillon and Manju Ramawat, who have supported us during the entire period of this book project.

About the Editors

Professor Dr. Kishan G. Ramawat is Former Professor and Head of the Botany Department, M.L. Sukhadia University, Udaipur, India, and can look back on longstanding research experience. He received his Ph.D. in Plant Biotechnology in 1978 from the University of Jodhpur, India, and afterwards joined the university as a faculty member. In 1991 he moved to the M.L. Sukhadia University in Udaipur as Associate Professor and became Professor in 2001. He served as the Head of the Department of Botany (2001–2004, 2010–2012), was in charge of the Department of Biotechnology (2003–2004), was a member of the task force on medicinal and aromatic plants of the Department of Biotechnology, Government of India, New Delhi (2002–2005), and coordinated UGC-DRS and DST-FIST programs (2002–2012).

Professor Ramawat had done his postdoctoral studies at the University of Tours, France, from 1983 to 1985, and later returned to Tours as visiting professor (1991). He also visited the University of Bordeaux 2, France, several times as visiting professor (1995, 1999, 2003, 2006, 2010), and in 2005 Poland in an academic exchange program (2005). Through these visits in France, Prof. Ramawat and Prof. Mérillon established a strong connection, which has resulted in productive collaborations and several book and reference work publications.

Professor Ramawat has published more than 170 well-cited peer-reviewed papers and articles, and edited several books and reference works on topics such as the biotechnology of medicinal plants, secondary metabolites, bioactive molecules, herbal drugs, and many other topics. His research was funded by several funding agencies.

In his research group, Prof. Ramawat has supervised doctoral thesis of 25 students. He is an active member of several academic bodies, associations, and editorial boards of journals.

Professeur Dr. Jean-Michel Mérillon Directeur de l'EA 3675/Faculté de Pharmacie/Université de Bordeaux is the "Directeur de l'EA 3675 (Groupe d'Etude des Substances Végétales à Activité Biologique + Polyphénols Biotech)" at the Faculté de Pharmacie, Université de Bordeaux, Institut des Sciences de la Vigne et du Vin, in Villenave d'Ornon, France. He received his M.Pharma. (1979) and Ph.D. (1984) from the University of Tours in France. He joined the University of Tours as assistant professor in 1981, and became associate professor in 1987. In 1993 he moved to the faculty of Pharmacy, University of Bordeaux, France, accepting a position as full professor. He is currently leading the "study group on biologically active plant substances" at the Institute of Vine and Wine Sciences, which comprises 25 scientists and research students. The group has been working on phenolic compounds from vine and wine for many years, mainly complex stilbenes and their involvement in health. Professor Mérillon has supervised the doctoral theses of 19 students. He is involved in developing teaching on plant biology, natural bioactive compounds, and biotechnology.

Professor Mérillon has published more than 145 research papers in internationally recognized journals, resulting in an H index of 35 (documents published between 1996 and 2015). He has co-edited books and reference works on secondary metabolites and biotechnology.

Throughout his career, Prof. Mérillon has traveled widely as a senior professor. Scientists from several countries have been and are working in his laboratory, and his research is supported by funding from the Aquitaine Regional Government, the Ministry of Higher Education and Research, and various private companies. In 2004, he founded the technology transfer unit "Polyphenols Biotech," providing support for R&D programs for SMEs and major groups from the cosmetic, pharmaceutical, agricultural, and health-nutrition sectors.

Plant Cell Wall Polysaccharides: Structure and Biosynthesis

1

Michael A. Held, Nan Jiang, Debarati Basu, Allan M. Showalter, and Ahmed Faik

Contents

Abstract

Plant cells are surrounded by cell walls consisting of complex networks of polysaccharides and glycoproteins. Cell walls play a vital role in a plant's development and its interactions with the environment. The biosynthesis of cell walls is fueled by carbon fixed by solar energy during photosynthesis. The amount of carbon fixed annually is estimated to ~2 × 10^{11} tonnes (Hall. Solar energy use through biology – past, present and future. Sol Energy 22:307–328, 1979). Thus, plant cell walls represent a valuable sustainable carbon source for human activities. Plants use complex mechanisms that require the coordinated action of hundreds of glycosyltransferases and other enzymes involved in sugar

substrate interconversion to build cell wall polysaccharides. This chapter will focus on discussing current advances in the biosynthesis and structures of these wall polysaccharides, including cellulose, a variety of hemicellulosic polymers, pectins, and structural hydroxyproline-rich glycoproteins (extensins and arabinogalactan-proteins). These polymers are organized into complex but dynamic networks that are still the subject of extensive research. Much work is still needed to determine the functions of many glycosyltransferases involved in building these polymers. In addition, how plant cells manage to secrete and organize them into such complex networks remains a mystery. Thus, the future holds exciting discoveries in the field of plant cell wall polysaccharide biosynthesis.

Keywords
Polysaccharide • Glycosyltransferase • Cellulose • Hemicellulose • Pectin • Glycoprotein

1 Introduction

Plant cell wall polysaccharides hold great promise as raw material for food, feed, and biofuel production. For plants, cell walls are important for development and disease resistance, making them targets for improvements of postharvest storage and processing of fruits. Thus, understanding how plants synthesize and remodel their cell walls is an important and expanding area of research, particularly in the light of renewable energy. Plant cell walls are complex networks comprised of physically interacting polymers such as polysaccharides (pectin, hemicelluloses, cellulose), glycoproteins (i.e., extensins), and lignin. The modification of these physical interactions underlies cell expansion and plant growth and development. Considering the complexity of plant cell wall composition and structure, it has been difficult to develop a structural model. In 1973, Keegstra and Albersheim did extensive structural and compositional analyses of primary cell walls of sycamore cells and proposed a tentative model for the primary cell wall (Keegstra et al. 1973). In this model, cellulose and xyloglucan (XyG) interconnect through hydrogen bonds to form a network that is further connected to pectic polysaccharides through XyG. Treatment with endopolygalacturonase released peptides and pectic fragments, suggesting that pectic polysaccharides and the structural proteins are covalently linked (Keegstra et al. 1973). Later studies by Carpita and Gibeaut (1993) extended Keegstra's model and proposed a more dynamic model for the primary cell wall, in which three structurally independent but interacting subnetworks are present: a subnetwork of ordered cellulose microfibrils coated with and cross-linked by hemicellulosic polysaccharides, a second gel-like subnetwork made of pectic polymers acting as "matrix" polysaccharides that surround the first subnetwork, and a third subnetwork consisting of structural proteins that hold the polymers in place. For example, extensin may act as a template to direct orderly assembly of pectin and other polysaccharides during cell wall deposition (Qi et al. 1995). During plant

Table 1 Comparison of polymer contents (% w/w) between type I and type II primary cell walls
(According to Carpita and Gibeaut 1993; Carpita 1996; Carpita and McCann 2000)

Polymer	Type I wall	Type II wall
Cellulose	30–40	30–40
Pectin	~30	2–10
Proteins	10	2–10
Xyloglucan	20	Minor
Xylan	5	20–30
Mannan	3	5

growth, extensive remodeling and modifications of these subnetworks occur, which allow the cell wall to be flexible, extensible, and yet resistant to breakage and shearing.

Primary cell walls can be classified into two main types (Carpita and Gibeaut 1993): type I walls have XyG as the major cross-linking hemicellulose, while type II walls have xylans as the major cross-linking hemicellulose (~30 % w/w). In both types, cellulose (~30 % w/w) is the major load-bearing polymer. Pectin contents differ, as it represents ~30 % (w/w) in type I walls and only 2–10 % (w/w) in type II walls (Jarvis 1984; Carpita and Gibeaut 1993). While type I walls contain ~10 % (w/w) structural proteins, type II walls contain low amounts of these proteins (2–10 % w/w) (Chen and Varner 1985; Hong et al. 1989; Carpita and McCann 2000; Fincher 2009a). Table 1 summarizes the differences between type I and type II primary cell walls.

Synthesis of cell wall polysaccharides requires sophisticated, well-coordinated biosynthetic machinery involving specialized enzymes called glycosyltransferases (GTs). By definition, a GT is an enzyme that transfers a sugar moiety (in the case of plant cell wall, the transferred sugars are mainly monosaccharides) to a nucleophilic group (i.e., alcohol group on substrate acceptor) from an activated sugar phosphate (substrate donor), such as nucleotide diphosphate-sugar (NDP-sugar) (Keegstra and Raikhel 2001; Breton et al. 2006; Lairson et al. 2008). However, biosynthesis of polysaccharides is fundamentally different from nucleic acids (DNA and RNA) and proteins, as a template is not required to synthesize complex polysaccharides. Nucleic acids and proteins do require templates that dictate the specificity in the biosynthesis of various types of molecules. In the case of polysaccharides, the biosynthesis of the various types of polymers relies on the specificity of each GT. Thus, each glycosidic linkage in a polysaccharide would require a specific GT. Considering the structural complexity of a typical plant primary cell wall, several hundreds of different GTs would be needed for its synthesis. GTs that are able to transfer more than one monosaccharide onto the same substrate acceptor (hence building a long polymer) are considered processive enzymes and are called synthases. Synthases are usually responsible for the synthesis of polysaccharide backbones (usually made up of one or two types of monosaccharide). Most of the GTs are integral membrane proteins corresponding to about 1–2 % of the predicted genes in eukaryotic genomes (Lairson et al. 2008). As of August 2014, eukaryotic and prokaryotic GTs are categorized into 95 distinct families based on amino acid sequence similarity, according to the Carbohydrate-Active enZYmes (CAZy)

database (http://www.cazy.org/, Campbell et al. 1997; Cantarel et al. 2009; Lombard et al. 2014).

Catalytic domains of GTs are globular proteins and can be organized into two main types of structural folds, GT-A and GT-B, with N-terminal and C-terminal domains serving as binding sites for substrate donors or acceptors (Bourne and Henrissat 2001). The two domains are linked via a region that serves as the active site. In a GT-B fold, both domains are shaped as a Rossmann-like fold (β/α/β), with the acceptor binding site located at the N-terminal domain, while the C-terminal domain is the NDP-sugar binding site. In a GT-A fold, however, the two domains are structurally different, with the N-terminal domain having a Rossmann-like fold and serving as the donor binding site, while the C-terminal domain does not have a Rossmann-like fold and serves as the acceptor binding site. Regardless, GTs with either GT-A or GT-B folds can catalyze transfer reactions with either an inverting or a retaining mechanism (configuration of the C-1 bond of the NDP-sugar compared to the glycosidic linkage in reaction products). Only a few conserved residues in the donor binding sites and the catalytic sites determine the sugar-nucleotide donor specificity and the catalytic mechanism, respectively (Bourne and Henrissat 2001). Despite our knowledge of the chemical composition of plant cell wall polymers, most GTs involved in their biosynthesis remain undiscovered, and we lack a significant understanding of their biosynthetic mechanisms.

In this chapter, we summarize the current knowledge on the structure and biosynthesis of the main polymers in the walls of growing plant tissues, namely, cellulose, hemicellulose, pectin, and glycoprotein (most mature tissues have additional components, such as lignins and lignans that will not be covered in this chapter).

2 Structural Cell Wall Glucans

2.1 Cellulose Structure and Biosynthesis

Cellulose is the most abundant polysaccharide produced in nature and generally serves as the major scaffolding component for plant cell wall architecture. Cellulose is composed of linear, unsubstituted β-(1,4)-linked glucan chains (Fig. 1a). Individual glucan chains are synthesized at the plasma membrane by GTs, known as cellulose synthase catalytic subunits A (CESAs), which use UDP-glucose as activated sugar-donor substrates and Mg^{2+} cofactors (Pear et al. 1996; Delmer 1999). In plants, multiple, nonredundant CESA isoforms assemble into large multiprotein complexes referred to as cellulose synthase complexes (CSCs). CESAs add glucosyl units to the growing polymer to synthesize individual β-(1,4)-glucan chains. Growing glucans are extruded across the plasma membrane, where they assemble via van der Waals forces and hydrogen bonding into paracrystalline microfibrils (Doblin et al. 2002; Haigler et al. 2014).

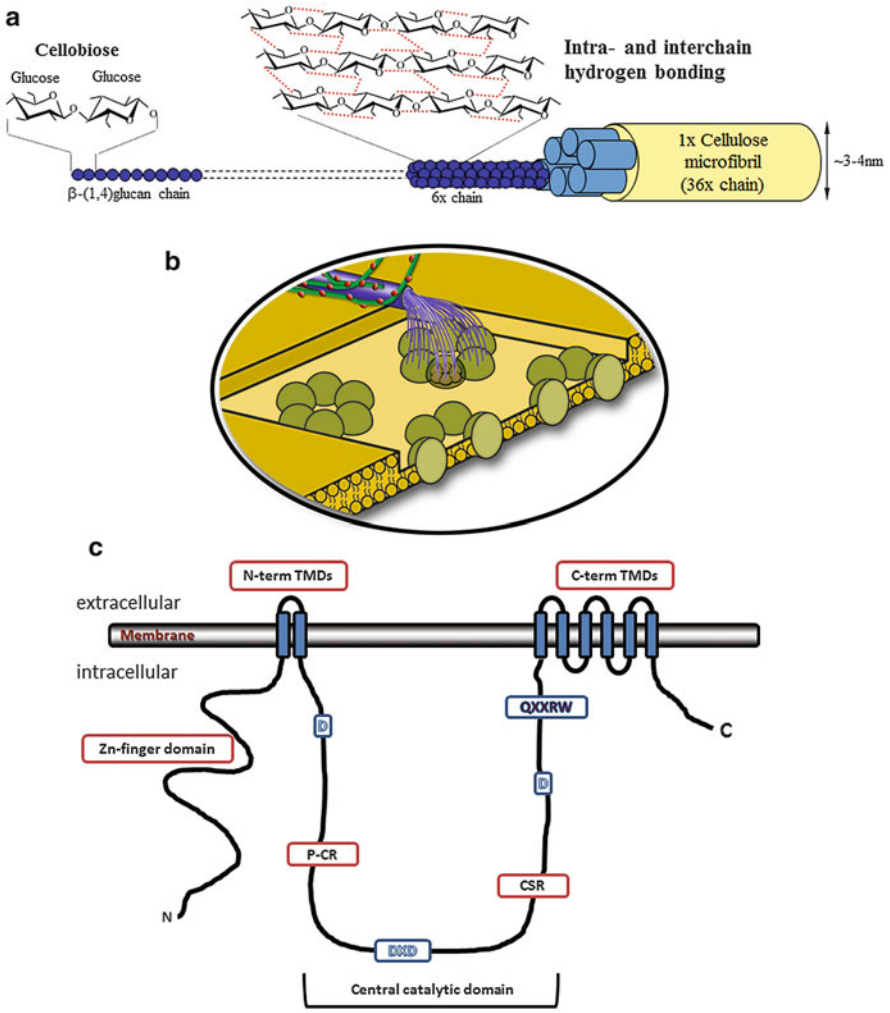

Fig. 1 Molecular features of cellulose, cellulose synthases (*CESAs*), and cellulose synthase complexes (*CSCs*). (**a**) Cellulose consists of paracrystalline microfibrils (*yellow*) containing as many as 36 individual β-(1,4)-linked glucan chains (*dark blue*). The fundamental monomer of each glucan chain is cellobiose. Extensive intra- and interchain hydrogen bonding (*red dashes*), along with van der Waals forces, promotes microfibril crystallinity. (**b**) CSCs form "rosette"-like particles (*green*) in the plasma membrane. Each lobe of the CSC contains multiple, nonredundant CESA isoforms which simultaneously synthesize β-(1,4)-glucan chains (*purple*). As the nascent glucans are synthesized and translocated outside the cell, they associate and form microfibrils which become tethered with hemicellulose (*green*/*red*). (**c**) The functional domains of CESA proteins include the Zn-finger domain, the N- and C-term TMDs, and the central catalytic domain (which possesses the plant-conserved region (*P-CR*), the class-specific region (*CSR*), and the conserved active site residues D, DxD, D, and QxxRW)

Crystallinity imparts structural rigidity and resistance to degradation. In the following sections, we will discuss cellulose biosynthesis, starting with the encoding genes and ending with the formation of a microfibril. The goals of these sections are to provide a general overview of the cellulose biosynthesis and structure and to highlight important research contributions instrumental to our understanding of the process. Many excellent reviews have been written, and readers are referred elsewhere for more detailed discussion of cellulose biosynthesis (Brown et al. 1996; Delmer 1999; Haigler et al. 2001; Williamson et al. 2002; Doblin et al. 2002; Somerville 2006; Mutwil et al. 2008; Taylor 2008; Crowell et al. 2010; Wightman and Turner 2010; Guerriero et al. 2010; Harris et al. 2010; Carpita 2011; Endler and Persson 2011; Lei et al. 2012; Slabaugh et al. 2014).

2.1.1 *CESA* Genes and Families

Genes encoding cellulose synthases were first identified in bacteria (Saxena et al. 1990; Wong et al. 1990). Attempts to use bacterial *CESA* coding sequences to find direct plant homologs were initially stymied due to the relatively low sequence similarity shared between them (Delmer 1999). A breakthrough came in the mid-1990s using gene expression profiling in cotton fibers. Cotton (*Gossypium hirsutum*) has served as a valuable model for cellulose biosynthesis and genomics, as mature fibers consist of ~90 % cellulose. Pear et al. (1996) identified two cDNA clones in cotton fibers that encoded members of the GT2 family and were loosely related to the bacterial CESA. According to the *C*arbohydrate *A*ctive En*z*ymes (CAZy) database (www.cazy.org), GT2 proteins are processive glycosyltransferases and are characterized by having conserved "D," "DxD," "D," and "QxxRW" amino acid motifs important for substrate binding and catalysis (Saxena et al. 1995; Campbell et al. 1997; Coutinho et al. 2003; Lombard et al. 2014). Other members of the GT2 family include chitin synthase (Glaser and Brown 1957; Sburlati and Cabib 1986) and hyaluronan synthase (DeAngelis et al. 1993; Jing and DeAngelis 2000; DeAngelis 1999; Tlapak-Simmons et al. 2004). Then designated *GhCelA1* and *GhCelA2* (later designated *GhCESA1* and *2*), Pear et al. (1996) showed that both genes were expressed highly during cotton fiber development and that their recombinant gene products could bind UDP-Glc substrate. Evidence for the direct involvement of *CESA* gene products in cellulose biosynthesis came later via numerous mutant analyses in *Arabidopsis thaliana* (hereafter called *Arabidopsis*) (Table 2). These reports were instrumental in determining the functional specificity of CESA isoforms in *Arabidopsis* (discussed further below). However, direct biochemical evidence of the activity of any CESA has not been achieved yet.

CESA genes are present in all plant genomes and are members of gene families (Richmond and Somerville 2000). For example, there are 10 *CesA* genes in the *Arabidopsis* genome, 10 in rice, 20 in maize, 10 in sorghum, 18 in poplar, and at least 7 in barley (Richmond and Somerville 2000; Appenzeller et al. 2004; Burton et al. 2004; Djerbi et al. 2005; Penning et al. 2009). Plant genomes also contain several clades of genes related to *CESA*s, designated *cellulose synthase-like* (*CSL*)

genes. Together, *CESA* and *CSL* genes form a large gene "superfamily" (Richmond and Somerville 2000; Holland et al. 2000; Hazen et al. 2002; Suzuki et al. 2006; Fincher 2009a). To date, CSLs have mostly been associated with hemicellulose biosynthesis.

2.1.2 *CESA* Gene Expression

Plants synthesize two types of walls during cellular development: a thin flexible primary cell wall that is produced during cell growth and elongation and a thicker secondary wall that is deposited after cell elongation ends. Synthesis of both types of walls requires coordinated deposition of multiple cell wall polymers, including those for cellulose, pectin, hemicelluloses, and lignins. Coordination is initiated at the gene expression level. In *Arabidopsis*, for example, *CESA1*, *3*, and *6* (and *CESA2* to a lesser extent) are highly co-expressed in tissues making primary walls, while *CESA4*, *7*, and *8* are highly co-expressed in cells actively making secondary walls (Brown et al. 2005; Persson et al. 2005). Not only are the *CESA* genes highly co-expressed, but they are also highly co-expressed with genes thought to be associated with the CSCs and genes needed for the biosynthesis of other wall polymers, such as xylan and mannan (Brown et al. 2005; Persson et al. 2005). This phenomenon is not restricted to *Arabidopsis*. Similar sets of co-expressed primary and secondary wall *CESA*s have been identified in other plants, including barley (Burton et al. 2004), rice (Tanaka et al. 2003; Wang et al. 2010), maize (Appenzeller et al. 2004), and poplar (Joshi et al. 2004). Together, these findings show that there are two distinct gene expression programs

for making CSCs – one for primary wall biosynthesis and one for secondary wall biosynthesis – and each CSC is likely made up of at least three individual CESA isoforms.

Coordinated expression of *CESA* gene sets is very interesting, yet we know relatively little about what controls their expression. Advances have been made regarding the transcriptional regulation of secondary cell wall biosynthesis. Expression of genes associated with the secondary cell wall program appears to be regulated by broad targeting NAC domain (Kubo et al. 2005; Zhong et al. 2006; Zhong et al. 2007a) and MYB transcription factors (Zhong et al. 2007b; Goicoechea et al. 2005; Kim et al. 2013). These transcription factors (TFs) represent "master switches" that activate expression of large sets of genes (including other TFs) necessary for secondary cell wall polysaccharide and lignin biosynthesis. While much is known regarding these master switch TFs, diversity in wall architecture suggests a finer level of regulation. This may come at the posttranscriptional level in the form of small RNA regulation and/or at the posttranslational level in the form of reversible phosphorylation events (Held et al. 2008; Nühse et al. 2004; Taylor 2007; Chen et al. 2010).

2.1.3 CSC Assembly and Protein Components

CSCs are likely assembled in the Golgi apparatus and trafficked to the plasma membrane through the *trans*-Golgi and microtubule-associated cellulose synthase (MASC/SmaCC) compartments (Haigler and Brown 1986; Paredez et al. 2006; Crowell et al. 2009; Gutierrez et al. 2009; Wightman and Turner 2010). In the plasma membrane, glucan chain polymerization and assembly are thought to provide the energy that drives CSC movement (Diotallevi and Mulder 2007). The direction of CSC movement appears to be controlled by interactions with the underlying cortical microtubules (Paredez et al. 2006; Crowell et al. 2009; Gutierrez et al. 2009; Wightman and Turner 2010). CSCs, imaged using freeze fracture electron microscopy, appear on the surface of the plasma membrane as six-membered "rosette" structures of about 24 nm in diameter (Brown and Montezinos 1976; Mueller and Brown 1980; Giddings et al. 1980; Herth 1985). Immunolabeling has confirmed that CESA proteins are indeed found in CSCs (Kimura et al. 1999). Mutational analyses and co-immunoprecipitation studies have shown that at least three individual CESA isoforms are required to form an active CSC (Taylor et al. 2003; Gardiner et al. 2003; Tanaka et al. 2003; Persson et al. 2007). In *Arabidopsis*, the primary wall CSC is composed of CESA1, 3, and 6 (with CESA2, 5, and 9 being partially redundant with CESA6), while secondary wall CSCs are composed of CESA4, 7, and 8. Current consensus holds that each lobe of the CSC contains six CESA polypeptides (Doblin et al. 2002), with a CSC having a 6×6 symmetry. Assuming that each CESA is capable of synthesizing one β-(1,4)-glucan chain, this yields microfibrils that contain ~36 glucan chains per CSC (Fig. 1a, b), which compares well with the estimated diameter of larger microfibrils of ~3–4 nm (Ding and Himmel 2006; Ding et al. 2012; Haigler et al. 2014). However, some microfibrils are narrower (~2.4 nm; Kennedy et al. 2007), leading some to question the number of CESAs per CSC, the number

of CESAs needed to produce a single glucan chain, and the number of glucan chains per microfibril (Carpita 2011; Newman et al. 2013; Olek et al. 2014).

In addition to CESAs, other accessory proteins are associated with the CSC, including cellulose synthase interacting protein 1 (CSI1; Gu et al. 2010). CSI1 is a large armadillo repeat-containing (ARM) protein and is part of CSCs involved in synthesizing primary walls (Gu et al. 2010). ARM domains have been implicated in maintaining interactions with cytoskeletal components (Ozawa et al. 1989; Coates et al. 2006; Gebert et al. 2008). As such, CSI1 likely acts as a structural component of the CSC and may mediate interactions between CSCs and cortical microtubules (Gu and Somerville 2010). The second non-CESA protein shown to be associated with a CSC is a β-(1,4)-endoglucanase, called KORRIGAN (KOR). KOR has long been implicated in cellulose biosynthesis (Nicol et al. 1998; Lane et al. 2001; Sato et al. 2001) but only recently was shown to physically interact with the CSC (Vain et al. 2014). KOR is an essential component of the CSC, as mutation of *Kor* leads to cellulose deficiency (Nicol et al. 1998; Lane et al. 2001; Sato et al. 2001). Expression of *KOR* is strongly correlated with that of primary wall *CESA*s in *Arabidopsis* (Persson et al. 2005). The precise roles of KOR are still under investigation, but putative functions include the termination of glucan synthesis and glucan release, helping to assist glucan assembly/microfibril crystallization and relieving the strain incurred during glucan polymerization and/or microfibril formation. Additionally, it appears that KOR may also play a role in the trafficking of CSCs (Vain et al. 2014). Another important protein involved in cellulose biosynthesis is called COBRA (COB). COB is a GPI-anchored plasma membrane protein and is a member of a larger gene family composed of COB and COBRA-like proteins (COBLs) (Benfey et al. 1993; Roudier et al. 2002; Roudier et al. 2005). Both *COB* and *COBL* genes are important for proper cell expansion and cellulose biosynthesis (Schindelman et al. 2001; Li et al. 2003; Hochholdinger et al. 2008; Dai et al. 2011) and are highly co-expressed with primary and secondary wall *CESA*s (Persson et al. 2005), which may suggest a direct interaction with CSCs.

Several other proteins are associated with cellulose biosynthesis, including KOBITO (KOB1) (Pagant et al. 2002), SUCROSE SYNTHASE (SUSY) (Amor et al. 1995), POMPOM1/ELP1 (POM1) (Mouille et al. 2003; Zhong et al. 2002), RADIAL SWELLING3 (RSW3) (Burn et al. 2002), FRAGILE FIBER1 (FRA1) (Zhong et al. 2002), and FRAGILE FIBER2 (FRA2) (Burk et al. 2001; Burk and Ye 2002). Although both KOBITO and POM1 are localized to the plasma membrane, direct interaction of these proteins with a CSC or their precise molecular roles in cellulose biosynthesis has yet to be confirmed. RSW3, FRA1, and FRA2 likely impact CSC trafficking and interaction with cytoskeletal components.

2.1.4 Important Protein Domains of CESAs

Since their discovery, CESAs have been analyzed in terms of their functional domains (Pear et al. 1996; Vergara and Carpita 2001). Important CESA protein domains include the *N-terminal RING-like Zn-finger domain*, *N- and C-terminal transmembrane domains* (TMDs), and the *cytosolic catalytic domain*, which contains the *plant-conserved region* (P-CR), the *class-specific region* (CSR), and the

conserved GT2 catalytic motifs (Fig. 1c). Below is a brief discussion about the characteristics of each of these domains.

N-Terminal Zinc-Finger Domain

At the N-terminus of CESA proteins is a putative zinc-finger motif (Pear et al. 1996; Kurek et al. 2002). Zn-finger motifs are typically composed of tandem arrays of evenly spaced cysteine and/or histidine residues. RING Zn-finger domains are defined by the consensus sequence **CxxC**-$X_{9–39}$-**C-$X_{1–3}$-H-$X_{2–3}$-C/HxxC-**$X_{4–48}$-**CxxC**, where X can be any amino acid (Freemont 2000). Each RING domain can coordinate two Zn ions in a tetrahedral conformation mediated by the side chains of four Cys or three Cys and one His residues (Saurin et al. 1996). CESA proteins generally contain the consensus sequence **CxxCG**-x_{14}-**CxxC**-x_4-**CxxC**-x_7-**G**-x_3-**CxxC** (Fig. 1c). The function of the Zn-finger domain is not clear. Kurek et al. (2002) showed that bacterially expressed Zn-finger domains from cotton *GhCESA1* and *GhCESA2* were able to bind zinc and dimerize in an oxidatively dependent manner. A subsequent immunological study indicated that Zn-finger domains may also be important for mediating CESA protein turnover and estimated that the half-life of CESA protein is fairly short and on the order of ~30 min (Jacob-Wilk et al. 2006). While Zn-finger domains are commonly involved in protein-protein interactions (Saurin et al. 1996), these domains in CESAs do not appear to be necessary for interactions among secondary wall CESA proteins (Timmers et al. 2009).

Central Catalytic Domain

The central catalytic domain of CESAs lies between the N- and C-terminal TMDs and is composed of four "U" motifs, which contain conserved "D," "DxD," "D," and "QxxRW" motifs (Fig. 1c) important for UDP-glucose substrate binding and catalysis (Saxena et al. 1995; Vergara and Carpita 2001). These U motifs are thought to come together spatially to form a conserved GT-A fold (Saxena et al. 1995, 2001; Charnock and Davies 1999; Lairson et al. 2008; Morgan et al. 2013; Sethaphong et al. 2013; Slabaugh et al. 2014) and are shared by all CESAs and CSLs and other GT2s (Saxena et al. 1995). The central catalytic domain is the largest domain and lies on the cytosolic side of the plasma membrane (Bowling and Brown 2008; Carpita 2011). Recent structural studies have shown that this region forms a channel through which the nascent glucan chain is polymerized and guided through the plasma membrane (Morgan et al. 2013; Sethaphong et al. 2013).

Plant-Conserved Region (P-CR) and Class-Specific Region (CSR)

Within the central catalytic domain of plant CESAs are two important sub-domains known as the plant-conserved region (P-CR) and the class-specific region (CSR) (Fig. 1c) (Pear et al. 1996; Vergara and Carpita 2001). These regions are not found in their bacterial counterparts. The P-CR is a stretch of about 125 amino acids found between the conserved "D" and "DXD" motifs in plant CESAs (Pear et al. 1996). The CSR is highly conserved among CESA orthologs, suggesting that these

domains are important for assigning functional specificity among different CESA isoforms (Pear et al. 1996; Vergara and Carpita 2001). The assembly of CSCs seems to have evolved somewhere within the *Charophyta* branch of green algae (Roberts et al. 2002). Both the P-CR and CSR also seem to have arisen in *CESA* genes around the same time, suggesting these regions may be involved in rosette formation and/or maintenance. Recent structural investigations have also hinted at their roles in mediating CESA interactions within a CSC (Sethaphong et al. 2013; Olek et al. 2014).

Transmembrane Domains (TMDs)

CESAs generally contain eight predicted TMDs. Two membrane passes are toward the N-terminus (N-term TMDs), while six are grouped near to the C-terminus (C-term TMDs) (Fig. 1c). Together, these regions flank the central catalytic domain. The TMDs are thought to form a membrane-spanning pore through which nascent glucan chains are extruded (Morgan et al. 2013; Slabaugh et al. 2014). The TMDs represent a critical interface between the lipid bilayer of the plasma membrane and each CESA protein and are potentially involved in several functions, including entry into the secretory pathway, protein topology and trafficking, glucan translocation, and maintaining the organization and interactions of CESA subunits within a CSC.

2.1.5 Advances in CESA Structure and Catalytic Mechanisms

Recently, the crystal structure of a bacterial cellulose synthase (*Rs*BcsA) was determined (Morgan et al. 2013). The catalytic subunit consisted of eight TMDs, three interfacial helices that ran parallel to the face of the plasma membrane, and a cytosolic GT2 catalytic domain containing conserved D, D×D, TED, and QxxRW motifs. Six of the TMDs form 0.8 nm wide transmembrane pore, just wide enough to accommodate the extrusion of the nascent glucan (~0.7 nm) and long enough to hold a chain of ~10 glucosyl units in length. A model was suggested whereby glucosyl units are added one at a time to the nonreducing end of the growing polymer and simultaneously translocated across the membrane through the TMD pore. Glucosyl units are apparently free to rotate 180° from their neighbor in the catalytic site to produce a β-(1,4)-linked polymer.

An in silico model of the central catalytic domain of the cotton GhCESA1 protein (Gh506) was assembled (Sethaphong et al. 2013) using crystal structures of related GT2 proteins, including SpsA (Charnock and Davies 1999) and K4CP (Osawa et al. 2009). The Gh506 protein contained the 506 amino acids of central catalytic domain, which included both the P-CR and CSR domains, but lacked structural representation of the N-terminal Zn-finger domain and the N- and C-term TMDs. Structural co-alignment of Gh506 with the *Rs*BcsA catalytic domain showed striking similarities, supporting the validity of the predicted structure (Sethaphong et al. 2013; Morgan et al. 2013). This model positions both the P-CR and CSR (lacking in the *Rs*BcsA model) at the periphery of the catalytic domain, making them attractive candidates for mediating protein-protein interactions within a CSC. More recently, an additional model for a plant *CESA* was reported.

Using both 3D structure prediction and small-angle X-ray scattering, Olek et al. (2014) provided structural data for the catalytic domain of rice CESA8. While their data were similar to that of Sethaphong et al. (2013), specifically regarding the folding of the catalytic portion of the central catalytic domain, an alternate arrangement of both the P-CR and CSR domains was reported. Further, in vitro studies indicated that the CESA catalytic domains form dimers that synthesize a single glucan chain. Formation of catalytic dimers provides a convenient explanation for the formation of cellobiose, the fundamental monomer of a β-(1,4)-linked glucan (Fig. 1a). Future work aimed at identifying the composition and stoichiometry of rosettes formed in vivo will help elucidate the number of CESAs needed to produce a glucan chain.

2.1.6 Crystallization of Cellulose Microfibrils

Crystallization is the cornerstone of cellulose structure and function, but the actual process is not fully understood. Cellulose can exist in multiple forms or allomorphs. In nature, cellulose I predominates, whereby all glucan chains are aligned in a parallel orientation (as opposed to cellulose II, which has an antiparallel arrangement). Cellulose I is composed of two distinct crystalline phases, Iα and Iβ, which differ mainly by their hydrogen bonding patterns (Atalla and VanderHart 1984; Sugiyama et al. 1991). Higher plants are enriched in cellulose Iβ, whereas bacteria and algae are rich in cellulose Iα (Sugiyama et al. 1991). For our discussion here, let's consider a 6-lobed CSC where each lobe is simultaneously producing 6 glucan chains (36 glucan chains in total). As nascent glucans traverse the plasma membrane and exit the CSC, adjacent linear chains quickly associate by hydrogen bonding and begin to form paracrystalline microfibrils. In addition to hydrogen bond formation, factors that appear to affect crystallization include the rate of polymerization (Benziman et al. 1980), van der Waals interactions among glucan chains (Haigler et al. 2014), and the physical proximity of the emerging glucans (which is related to rosette architecture and protein composition).

2.2 Mixed-Linkage Glucan (MLG) Structure

MLG is another unbranched glucose polymer consisting of β-D-glucopyranosyl units linked by both (1,3)- and (1,4)-glycosidic bonds (Fig. 2). The MLG polymer has a unit structure consisting primarily of cellotriose (G3) and cellotetraose (G4) subunits at a ratio of 2.2–2.6:1 (Gibeaut and Carpita 1993; Fincher and Stone 2004; Fincher 2009b; Fig. 2). Single (1,3)-linkages are always flanked by at least two (1,4)-linkages in plant cell wall MLG. Longer cellodextrin subunits (5–20) are found in the polymer but in decreasingly smaller amounts, and the arrangement of these subunits is thought to be random within the MLG polymer (Staudte et al. 1983; Woodward et al. 1983; Buliga et al. 1986). The subunit composition of the MLG polymer has been investigated by digestion of the MLG polymer with (1,3),(1,4)-β-D-glucan-4-glucanohydrolase from *B. subtilis*. This enzyme specifically cleaves a β-(1,4)-glycosidic bond, only if it is preceded by a

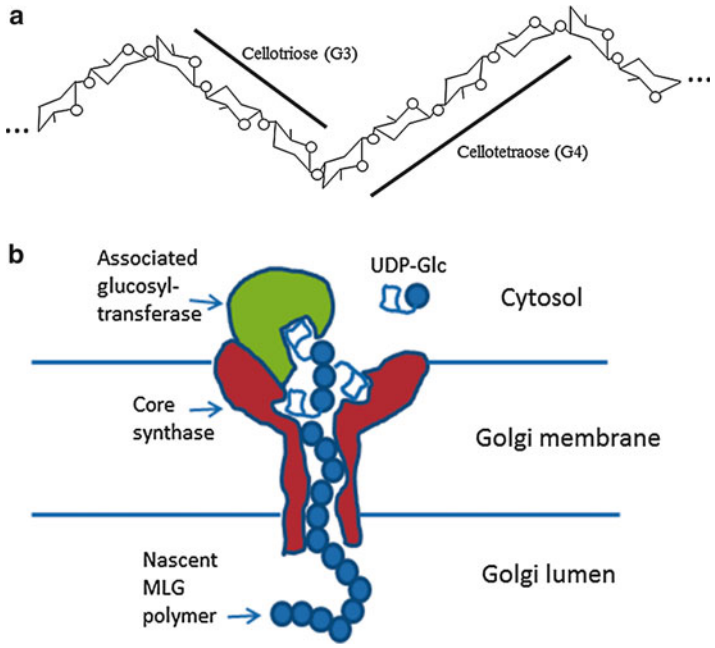

Fig. 2 Structural representation of mixed-linkage β-D-glucan (*MLG*) and the MLG synthase. (**a**) MLG is composed mostly of cellotriosyl (G3) and cellotetraosyl (G4) linked by single β-(1,3)-linkages, though longer cellodextrins are also observed. (**b**) The MLG synthase is thought to have three active sites and two GT components: a core synthase (*red*) to generate cellobiose and larger even-numbered cellodextrins and an associated GT (*green*) to add single glucosyl units from UDP-Glc to form odd-numbered subunits. Nascent polymer is extruded into the Golgi lumen prior to being packaged into vesicles for delivery to the cell wall. (Adapted from Buckeridge et al. 2004)

β-(1,3)-linkage, making this enzyme diagnostic for MLG (Anderson and Stone 1975). The oligomers released by digestion can be separated and quantified by high-pH anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) relative to authentic barley MLG standards.

MLG is found in modest amounts in the cell walls of most cereal plant tissues, but it is heavily produced at specific developmental stages. The endosperm walls of barley caryopses are composed of over 70 % MLG (Fincher et al. 1986; Fincher 2009a). MLG is also heavily secreted in cells undergoing elongation growth (Gibeaut and Carpita 1991; Gibeaut et al. 2005; McCann et al. 2007). In elongating maize coleoptiles, maximum MLG deposition coincides with peak elongation rates (McCann et al. 2007). After elongation ceases, the MLG is digested by endogenous endoglucanases, from the middle lamellae inward, leaving trace amounts in the wall. MLG is thought to serve an architectural role in the walls of elongating cells by coating cellulose microfibrils. Due to their kinked molecular shape, they are thought to provide a gel-like matrix which facilitates wall elongation (Fincher and Stone 2004).

2.2.1 MLG Biosynthesis

MLG is synthesized in the Golgi apparatus by membrane-embedded GTs using UDP-Glc as a substrate and Mg^{2+} as a cofactor (Buckeridge et al. 1999; Gibeaut and Carpita 1993; Carpita and McCann 2010). Much of what is known about MLG biosynthesis comes from in vitro studies using enriched Golgi preparations from maize. MLG composition (e.g., the mole ratio of G3:G4) is influenced by substrate donor concentration (Buckeridge et al. 1999; Henry and Stone 1982). In vitro, high levels of UDP-Glc push the ratio of G3 to G4 to as much as 10:1, whereas lower substrate levels drop this ratio closer to 1:1 (Buckeridge et al. 1999). Importantly, the ratios of all odd-numbered cellodextrins to the next even-numbered cellodextrin mirror this phenomenon. Buckeridge et al. (2001) suggested that there are multiple sites of glucosyl transfer consisting of a core synthase that generates β-(1,4)-linked cellobiosyl units and an associated GT that adds single Glc residues to each cellobiose unit to form the fundamental cellotriose unit (Fig. 2). At high substrate concentrations, all three sites are filled and G3 formation is favored. At low substrate concentrations, the associated glucosyl transferase occasionally is empty and cannot complete the formation of cellotriose and higher-ordered odd-numbered oligomers. The core synthase remains full however and can iteratively polymerize cellobiose units to form G4 (and higher-ordered even-numbered subunits). Detergent extraction experiments support these findings (Urbanowicz et al. 2004). The associated GT was shown to be more susceptible to detergent extraction with CHAPS, as evidenced by a decrease in the G3:G4 ratio. This decrease was recovered by reconstituting the CHAPS extract into the in vitro reaction and diluting the detergent concentration back to tolerable levels (Urbanowicz et al. 2004). In the same work, the topology of the MLG synthase was also determined. Intact Golgi bodies treated with proteinase K lost the preference to form cellotriosyl residues, again judged by a decrease in the G3:G4 ratio (Urbanowicz et al. 2004). These data suggested that the even-numbered forming core synthase was more membrane protected than the associated odd-numbered forming glucosyltransferase (Urbanowicz et al. 2004).

There are many similarities between MLG and cellulose: (*i*) both are unsubstituted glucose polymers; (*ii*) both polymer synthases use UDP-Glc as substrate; and (*iii*) both require divalent cation cofactors. Thus, it was reasonable to suggest that the MLG synthase components might be related to cellulose synthase components (Richmond and Somerville 2000). MLG is a cereal-specific cell wall polymer, not produced by most other plant species. Indeed, a comparison of the cellulose synthase gene superfamilies of dicots with grasses showed that there were initially two (now three) clades of cellulose synthase-like genes that were unique to grasses. These clades were dubbed the *CSLF* and *CSLH* gene families, and it was hypothesized that these clades might encode proteins that formed all or part of the MLG synthase (Richmond and Somerville 2000; Hazen et al. 2002). Subsequent heterologous expression of either the rice *OsCSLF6* gene or the barley *CSLH* gene in *Arabidopsis* (a plant that does not naturally produce MLG in its cell walls) conferred the ability to produce small amounts of MLG (Burton et al. 2006; Doblin et al. 2009). Either gene, expressed on its own, was

sufficient to produce small amounts of MLG in *Arabidopsis* cell walls, suggesting that either CSLF or CSLH can act alone to catalyze MLG biosynthesis. Recombinant expression of CSLF4, 6, and 9 was also correlated with increased MLG contents in transgenic barley (Burton et al. 2011). MLG contents varied depending on the promoter used to drive transgene expression. Additionally, individual CSLF isoforms produced MLG polymers having different G3:G4 ratios, leading the authors to speculate that each CSLF isoform produces MLG having different fine structures (Burton et al. 2011). Several lines of evidence suggest that other cofactors and/or associated proteins are required for efficient MLG biosynthesis. First, MLG was produced at very low levels in *Arabidopsis* expressing the *OsCSLF6* gene (Burton et al. 2006). It was suggested that *Arabidopsis* may lack cofactors or associated proteins necessary for normal MLG biosynthesis (Burton et al. 2006). Second, transgenic expression of *HvCSLH* in *Arabidopsis* produced variable levels of laminaribiose (Doblin et al. 2009). Laminaribiose production suggested the presence of alternating β-(1,3)- and β-(1,4)-linkages in the MLG polymer, a structural feature not found in authentic cereal MLG. It was hypothesized that HvCSLH protein was likely misregulated in the heterologous background either due to changes in its membrane environment or due to suboptimal levels of associated factors (Doblin et al. 2009).

Since CSLF and CSLH each are involved in MLG biosynthesis, it has been suggested that the two may interact to form a catalytic heterodimer (Carpita 2011). Several lines of evidence argue against this possibility. First, the expression profiles are different for *CSLF* and *CSLH* during development and across tissue types (Burton et al. 2008; Doblin et al. 2009). If CSLF and CSLH participated in heterodimer formation, one might expect that they be expressed in the same tissues at the same developmental time point. However, gene expression data do not always correlate with protein abundance. Second, both the CSLF and CSLH proteins can catalyze MLG biosynthesis independently (Burton et al. 2006; Doblin et al. 2009; Vega-Sánchez et al. 2012). While CSLF and CSLH clearly synthesize MLG individually, one cannot rule out the possibility that the MLG synthase is a multiprotein complex consisting of CSLF and/or CSLH and additional protein components. Additionally, recent structural studies of cellulose synthases should shed light on both the mechanism of glucosyl transfer and the potential for complex assembly for the MLG synthase (Morgan et al. 2013; Sethaphong et al. 2013; Olek et al. 2014).

3 Structural and Reserve Cell Wall Hemicellulosic Polymers

3.1 Xylan Structure and Biosynthesis

Xylans are a group of heteropolymers that represent the major structural hemicellulosic polysaccharides in primary and secondary cell walls of commelinid monocots (including grasses) and the secondary cell walls of dicots (Ebingerrova et al. 2005). They represent the third most abundant polymer in the biosphere, after

cellulose and chitin. Within cell walls, xylan polymers contribute to cross-linking of cellulose microfibrils and lignin (Imamura et al. 1994; Balakshin et al. 2011) and to themselves through ferulic acid residues (Wende and Fry 1997; de O Buanafina 2009). Because of their extensive cross-linking, xylan polymers have a major impact on the integrity of cell wall and the recalcitrance of plant biomass to enzymatic digestion (Faik 2013). Importantly, a recent study identified a large proteoglycan complex called "Arabinoxylan Pectin Arabinogalactan Protein 1" (APAP1) in *Arabidopsis*, which provides direct evidence for the covalent linkage between xylans, pectins, and arabinogalactan-proteins (AGPs) and confirms the importance of xylans in maintaining the integrity of plant cell walls (Tan et al. 2013).

All xylans have a common backbone of β-(1,4)-linked D-Xyl residues. This backbone can be substituted at position C2 with glucuronic acid (GlcA) or 4-*O*-methyl-glucuronic acid (MeGlcA) and/or with arabinofuranose (Ara*f*) residues at position C2 and/or C3 (Fig. 3a). Depending on the nature of these substitutions, xylans can be categorized into three basic structural types (Izdorczyk and Biliaderis 1995; Carpita and McCann 2000; Ebingerrova et al. 2005; Faik 2010; Kulkarni et al. 2012): glucuronoxylan (GX), which has an average Xyl:MeGlcA ratio of 10:1 and is found mostly in hardwoods; neutral arabinoxylan (AX), which has an Ara:Xyl ratio varying from 1:2 to 1:1 and is found mainly in cereal endosperm walls; and glucuronoarabinoxylan (GAX), which contains GlcA, MeGlcA, and Ara*f* side chains at an average Xyl:Ara:GlcA ratio of 8:3:1 (Fig. 3a). GAX is found in both primary and secondary walls of vegetative tissues in grasses (Ebringerova and Heinze 2000; Faik 2010; Faik et al. 2013). Interestingly, GX from dicots has a complex tetrasaccharide, β-D-Xyl-(1,3)-α-L-Rha-(1,2)-α-D-GalA-(1,4)-D-Xyl called sequence 1 (Johansson and Samuelson 1977; Andersson et al. 1983; Pena et al. 2007) that seems to be absent in xylans from monocots (Ratnayake et al. 2013).

Xylan synthesis is complex than previously thought. Many GTs appear to be involved in their biosynthesis, but little is known about their biochemical functions. For simplicity, xylan synthesis can be divided into three steps: (*i*) backbone synthesis, including the synthesis of the reducing end oligosaccharide in xylans from dicots; (*ii*) addition of side chains; and (*iii*) modification of the polymer. However, these processes have not been demonstrated biochemically. The first genes involved in xylan biosynthesis were discovered through several genetic studies in *Arabidopsis irregular xylem* (*irx*) mutants (Turner and Somerville 1997; Brown et al. 2005). According to their xylan phenotypes, the mutated *Arabidopsis* genes can be categorized into two major gene sets. Gene set1 includes three pairs of genes, At2g37090/At1g27600 (called *irx9*/*irx9-L*), At4g36890/At5g67230 (called *irx14*/*irx14-L*), and At1g27440/At5g61840 (called *irx10*/*irx10-l*), while gene set2 includes four genes: At2g28110/At5g22940 (called *irx7*/*irx7-L* or *fra8*/*f8h*), At5g54690 (called *irx8* or *gaut12*), and At1g19300 (called *parvus* or *gatl1*). The characterization of *Arabidopsis* mutants in gene set1 revealed that these plants have shorter xylan backbones and double mutants (such as *irx10*/*irx10L* or *irx14*/*irx14-L*) have very little GX but still have the tetra-oligosaccharide, sequence 1 (Brown et al. 2009; Wu et al. 2009, 2010a). On the other hand, the characterization of

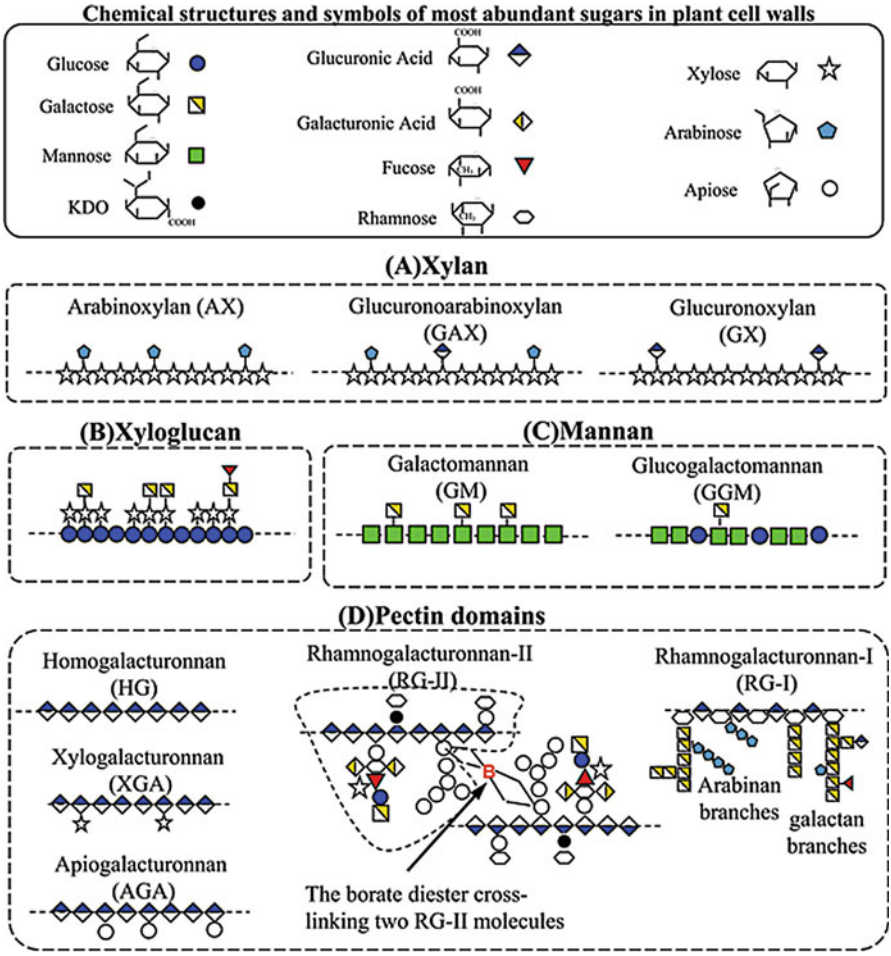

Fig. 3 Structures of hemicelluloses and pectins. *Top panel* shows the presentation of the structures and symbols of monosaccharide building blocks (monomers). Panels *A–D* represent simplified structures of xylan, xyloglucan, mannan, and pectin domains, respectively

Arabidopsis mutants in gene set2 showed that GX polymers from these plants have increased xylan backbone lengths and heterodispersity, but sequence 1 was absent in these polymers (Brown et al. 2007; Persson et al. 2007; Lee et al. 2009). Although biochemical function and the role of these proteins in xylan biosynthesis are still lacking, these observations support the following conclusions: *i*) IRX9 and IRX14 (both belong to GT43) and IRX10 (belongs to GT47) are involved in xylan backbone synthesis (Wu et al. 2010a; Chiniquy et al. 2013; Faik et al. 2013); (*ii*) IRX7/FRA8 and IRX7L/F8H (all belong to GT47) and IRX8/GAUT12 and PARVUS (both belong to GT8) are involved in the synthesis of sequence 1 in *Arabidopsis* (Pena et al. 2007); and (*iii*) sequence 1 may have a regulatory role in

GX biosynthesis in dicots. An earlier report by York and O'Neill (2008) proposed that sequence 1 could act as a primer or a terminator sequence for xylan biosynthesis in dicots. But more recently, Faik et al. (2013) proposed that sequence 1 might act as a driver of secretion of newly synthesized GX polymers to the cell surface, in addition to a terminator of the biosynthetic process. These authors hypothesized that sequence 1 is added to the newly synthesized GX in late Golgi compartments to terminate synthesis of GX polymers and allow their recruitment into secretory vesicles, which is consistent with GX phenotypes observed in mutant plants from gene set2.

Recent advances in xylan biosynthesis have shown that members of the GT43 and GT47 families are also involved in xylan backbone synthesis in grasses. For example, Zeng et al. (2008, 2010) demonstrated that GAX biosynthesis in wheat involves a synergetic/cooperative mechanism between three GT activities: a xylan glucuronosyltransferase (X-GlcAT), a xylan xylosyltransferase (X-XylT), and xylan arabinofuranosyltransferase (X-AraT). These authors used co-immunoprecipitation and proteomic analyses to demonstrate that enzymes involved in GAX biosynthesis form a protein complex containing members of the GT43, GT47, and GT75 families. Members of GT75 have been shown to possess mutase activity necessary for conversion of UDP-L-arabinopyranose (UDP-L-Ara*p*) to UDP-L-arabinofuranose (UDP-L-Ara*f*) (Konishi et al. 2007). So far, all genetic studies indicate that no cellulose synthase-like (*CSL*) genes are involved in the synthesis of the xylan backbone (Faik 2010; Carpita 2011; Doering et al. 2012; Rennie and Scheller 2014). The CSL subfamily is homologous to cellulose synthase catalytic subunit A (CESA) subfamily and both belong to the CAZy GT2 family. The CSLs have ten subgroups, CSLA through CSLJ (Richmond and Somerville 2000; Hazen et al. 2002; Farrokhi et al. 2006), and several of these CSLs are involved in hemicellulose biosynthesis, such as XyG (CSLC; Cocuron et al. 2007), mannan (CSLA; Dhugga et al. 2004; Liepman et al. 2005), and MLG (CSLF and CSLH; Burton et al. 2006; Doblin et al. 2009). Thus, xylan backbone synthesis may have a different mechanism compared to other β-glycans.

For xylan substitution, it is expected that at least four enzymes are needed to decorate the xylan backbone in dicots and monocots (Faik 2010): an α-(1,2) arabinofuranosyltransferase (α-(1,2)AraT), an α-(1,3)arabinofuranosyltransferase (α-(1,3)AraT), a β-(1,2)-xylosyltransferase (β-(1,2)XylT), and an α-(1,2)glucuronosyltransferase (α-(1,2)GlcAT). *Arabidopsis* members of the GT8 family, named Glucuronic Acid Substitution of Xylan (GUX1 and GUX2), are responsible for the addition of α-(1,2)-D-GlcA side chains onto the xylan backbone (Mortimer et al. 2010; Oikawa et al. 2010). Biochemical characterization of GUX1 and GUX2 activities showed that they strongly prefer xylohexaose as an acceptor, and the GlcA residue is almost exclusively added to the fifth Xyl residue from the nonreducing end (Rennie et al. 2012; Bromley et al. 2013). In the GT61 family, two wheat GT genes (*TaXAT1* and *TaXAT2*) and two rice genes (*OsXAT1* and *OsXAT2*) have been shown to mediate α-(1,3)arabinofuranosyl transfer onto xylan (Anders et al. 2012). Another gene from rice (*OsXAX1*) encodes a β-(1,2)XylT involved in extending Ara*f* with a Xyl residue to form β-D-Xyl-(1–2)-α-L-Ara*f* side chains

specific to AX from grasses (Chiniquy et al. 2012). However, the precise biochemical activities of XATs and XAX1 were not provided in these previous studies.

For xylan modifications, several genes have been identified in *Arabidopsis*, so far. A GX methyltransferase (*GXMT*), encoding a protein containing a domain of unknown function (DUF) 579, specifically transfers a methyl group from S-adenosylmethionine to the *O*-4 position of GlcA side chains of GX (Lee et al. 2012; Urbanowicz et al. 2012). The Trichome Birefringence-like (TBL) family member TBL29 contains a DUF231 domain and has been shown to transfer *O*-acetyl groups onto both *O*-2 and *O*-3 positions of xylose residues in the xylan backbone, hence affecting the solubility and digestibility of GX in plants mutated in these genes (At3g55990, At3g06550) (Manabe et al. 2013; Yuan et al. 2013; Xiong et al. 2013). Characterization of *Arabidopsis* mutants in *REDUCED WALL ACETYLATION* (*RWA1–4*) genes showed that these genes are required for xylan acetylation in the secondary cell wall (Lee et al. 2011). Members of a large family of acyltransferases named BAHD, a name derived from the first four biochemically characterized enzymes of this family (BEAT, benzylalcohol *O*-acetyltransferase; AHCT, anthocyanin *O*-hydroxycinnamoyltransferase; HCBT, anthranilate *N*-hydroxycinnamoyl/benzoyltransferase; and DAT, deacetylvindoline 4-*O*-acetyltransferase) (Yang et al. 1997; Dudareva et al. 1998; St Pierre et al. 1998; Fujiwara et al. 1998), have been shown to possess transferase activities that are involved in the addition of ferulic and coumaric acid esters onto arabinofuranosyl residues of xylan (Piston et al. 2010; Bartley et al. 2013).

Despite advances in identifying xylan-biosynthetic genes, it remains unknown whether their proteins form a complex that can synthesize a xylan polymer in vitro. As is so often the case, the biochemistry is lagging behind the molecular genetic studies.

3.2 Xyloglucan Structure and Biosynthesis

Xyloglucan (XyG) represents a major group of hemicellulosic polymers found mainly in the primary cell walls of dicots (Carpita and Gibeaut 1993; Faik 2013). Within the cell wall, XyG interacts with cellulose microfibrils via hydrogen bonding to form a subnetwork that reinforces the load-bearing function of cellulose in the wall (Hayashi and Maclachlan 1984; Hayashi et al. 1987). All XyG polymers have a backbone of β-(1,4)-linked D-glucose (Glc) residues similar to that of cellulose but are branched to various degrees with α-(1,6)-linked Xyl residues (Fig. 3b). Up to 75 % of the β-glucosyl residues in the backbone can be substituted with Xyl residues in a regular manner (Hayashi 1989; Fry et al. 1993; Faik et al. 1997; Ray et al. 2004; Hoffman et al. 2005). Xyl residues can be further substituted with β-(1,2)-D-galactosyl (Gal) or α-L-fucosyl-β-(1,2)-D-Gal (Fuc-Gal) side chains (Fig. 3b) (Hoffman et al. 2005; Albersheim et al. 2010). Other minor monosaccharides are also found in the side chains in XyGs. For example, Xyl residues can be substituted by α-(1,2)Ara*f* or β-Ara*f*-(1,3)-α-Ara*f*-(1,2) side chains called S and T side chains, respectively (Table 3, York et al. 1996; Ray et al. 2004; Hoffman et al. 2005).

Table 3 lists a single-letter code as a simplified nomenclature of XyG side chains where G represents unsubstituted Glc residues and X designates Glc substituted with Xyl (Fry et al. 1993; Vincken et al. 1997; Buckeridge et al. 1997; Pena et al. 2008).

Furthermore, the Gal residue in the L side chain can be substituted by another α-(1,2)-L-Gal residue to generate the J side chain as in jojoba (Hantus et al. 1997). Pena et al. (2008) described XyGs from avascular and seedless vascular land plants (liverwort, mosses, and hornworts) that contain GalA β-(1,4)-linked that extends the Xyl side chains and branched Xyl side chains (named P and Q side chains, Table 3). They also reported the presence of α-L-Ara*p* attached to the C2 of Xyl (D side chain, Table 3) or attached to the Xyl that is branched with a β-(1,4)-Gal (M side chain) or attached to a Xyl bearing a β-(1,6)Gal-(1,6)-β-Gal-disaccharide (N side chain).

Depending on the degree of substitution of Glc residues in the backbone, XyGs can be grouped into at least three types: XXXG-type, where every three Glc residues out of four are branched with Xyl residues, and XXGGG- and XXGG-types, which have only two consecutive Glc residues substituted with Xyl residues. XXXG-type XyG is mostly found in the primary cell walls of dicots (O'Neill and York 2003), whereas XXGGG- and XXGG-types are found in Poaceae (monocots) and Solanaceae with low Gal content and little or no Fuc residues (Hayashi 1989; York et al. 1996; Gibeaut et al. 2005; Hoffman et al. 2005). Members of the Poaceae and Solanaceae have low amounts of XyG in their cell wall (1–5 % w/w), which is in sharp contrast with dicots, where XyG represents up to 25 % (Pauly et al. 2001; O'Neill and York 2003; Albersheim et al. 2010). Although it is believed that XyG is not fucosylated in grasses, studies in *Festuca arundinacea*, a monocot, showed the presence of fucosylated XyG (McDougall and Fry 1994). Since *Physcomitrella* (a bryophyte) produces a XyG of XXGGG-type (~40 % of Glc residues are substituted) and *Marchantia* (a liverwort) produces a XyG of XXGG-type (~50 % of Glc residues are branched), it is believed that these branching patterns appeared evolutionarily before the XXXG-type branching pattern. It is noteworthy that XyG has not been found in *charophytes* (Popper and Fry 2003; Moller et al. 2007; Popper 2008).

For simplicity, XyG biosynthesis can be divided into three steps: *i*) "xylosyl-Glc" backbone synthesis, (*ii*) extension of xylosyl side chains, and (*iii*) modification of XyG polymers. In *Arabidopsis*, this process would require at least seven specific GT activities: a β-(1,4)-glucan synthase to synthesize the XyG backbone; three α-(1,6)xylosyltransferases to transfer Xyl residues onto the three Glc residues of the β-glucan chain (e.g., for the three X side chains in XXXG-type XyG); two β-(1,2) galactosyltransferases to extend the two X side chains with Gal residues and generate XLLG and XXLG; and an α-(1,2)fucosyltransferase to transfer Fuc residues onto XLLG and XXLG to generate XLFG and XXFG subunits, respectively (Faik et al. 1997; del Bem and Vincentz 2010). Other transferases, such as acetyltransferases, are involved in the incorporation of acetyl groups onto Gal and Glc of XyG (Kiefer et al. 1989; Gille et al. 2011).

Table 3 Single letter code nomenclature for naming XyG side chain structures (Fry et al. 1993; Pena et al. 2008)

Code letter	Structure represented
G	| β-D-Glc |
X	| α-D-Xyl-(1,6)-β-D-Glc |
L	| β-D-Gal-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
F	| α-L-Fuc-(1,2)-β-D-Gal-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
S	| α-L-Ara*f*-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
D	| α-L-Ara*p*-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
T	| α-L-Ara*f*-(1,3)-α-L-Ara*f*-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
P	D-Gal β(1,4)| | β-D-GalA-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
Q	D-Gal β(1,4)| | β-D-Gal-(1,4)-β-D-GalA-(1,2)- α-D-Xyl-(1,6)-β-D-Glc |
M	D-Gal β(1,4)| | α-L-Ara*f*-(1,2)-α-D-Xyl-(1,6)-β-D-Glc |
N	D-Gal β(1,6)| D-Gal β(1,4)| | α-L-Ara*f*-(1,2)- α-D-Xyl-(1,6)-β-D-Glc |

The in vitro synthesis of "xylosyl-Glc" backbone of XyG requires the cooperative incorporation of Glc and Xyl residues from UDP-Glc and UDP-Xyl (Ray 1980; Gordon and Maclachlan 1989; Faik et al. 1997). Members of *Arabidopsis* cellulose synthase-like C (*CSLC*) subfamily, namely, *CSLC4* (At3g28180), *CSLC5* (At4g31590), and *CSLC6* (At3g07330), have been implicated in the synthesis of the β-glucan backbone of XyG (Cocuron et al. 2007). However, direct evidence of glucan synthase activity for any members of the CSLC family is still lacking. The characterization of AtCSLC4 indicated that it is Golgi localized, with its catalytic domain on the cytosolic side of the Golgi membrane (Davis et al. 2010). *AtCSLC* homologs exist in the genomes of plants from different species, including *bryophytes* and *lycopodiophytes* (Pena et al. 2008). *Arabidopsis* genes belonging to the GT34 family have been identified to encode XyG:α-(1,6)xylosyltransferases (XXTs) (Faik et al. 2002; Cavalier and Keegstra 2006; Vuttipongchaikij et al. 2012). This GT34 family contains seven *Arabidopsis* members, but only *AtXXT*1 (At3g62720), *AtXXT2* (At4g2500), and *AtXXT5* (At1g74380) were associated with XyG biosynthesis through biochemical characterization (Faik et al. 2002; Cavalier and Keegstra 2006) or genetic studies (Vuttipongchaikij et al. 2012). A recent study using bimolecular fluorescence complementation (BiFC) and co-immunoprecipitation demonstrated that *Arabidopsis* XXT1, XXT2, XXT5, and CSLC4 proteins are able to form homo- and heterodimer complexes in Golgi membranes (Chou et al. 2012). Further, AtXXT1 and/or AtXXT2 have the capacity to incorporate the three Xyl residues onto a celloheptaose oligosaccharide (used as acceptor) in an in vitro assay (Cavalier and Keegstra 2006). Intriguingly, *xxt1*/*xxt2* double mutant plants in *Arabidopsis* have cell walls lacking detectable XyG without any growth defects (Cavalier et al. 2008). Considering the XyG content in *Arabidopsis* (up to 30 %w/w), one would expect the absence of XyG to have a major effect on the growth of these *Arabidopsis* mutants.

For GTs that extend X side chains of XyGs, *Arabidopsis* XyG fucosyltransferase (XyG-FUT) was the first GT to be identified in XyG biosynthesis (Perrin et al. 1999). These authors used a XyG-FUT enzyme assay (Camirand and Maclachlan 1986) to purify XyG-FUT activity from pea. Peptide sequence information was obtained from the pea protein preparation, which allowed the cloning of a homologous gene, called *AtFUT1* (At2g03220), from *Arabidopsis*. AtFUT1 belongs to the GT37 family and adds α-(1,2)fucosyl residues to the terminal galactosyl residue (e.g., L side chains closest to the reducing end in XXLG and XLLG subunits of XyG polymer). AtFUT1 does not act on oligosaccharides, but requires an acceptor with a minimum of three subunits (Faik et al. 2000; Shipp et al. 2008). *Arabidopsis* mutants in AtFUT1 (called *mur2*) produce XyG lacking Fuc, but with no visible phenotypes (Vanzin et al. 2002; Perrin et al. 2003), indicating that XyG fucosylation may not have an important role in plant growth. Thus, the role of fucosylated XyG in the physiology of plant growth is still unknown.

Screening of an EMS *Arabidopsis* mutant collection (called *mur* mutants) allowed for the identification of *MUR3* gene (At2g20370 from the GT47 family) that encodes a XyG galactosyltransferase (Madson et al. 2003). In an analysis of ten

Arabidopsis genes homologous to *MUR3*, a T-DNA insertion in the gene *GT18* (At5g62220) produced *Arabidopsis* plants with ~13 % less Gal in their cell walls, suggesting that this gene may also encode a XyG galactosyltransferase (Li et al. 2004). Although MUR3 can only transfer β-(1,2)-Gal onto the third Xyl residue in the repeating unit XXXG (Madson et al. 2003), the exact biochemical function of GT18 is unknown. One possible role is that GT18 is responsible for the addition of a Gal residue to the second X side chain in XyG subunit (i.e., XXXG), as the third X side chain has never been found decorated with a sugar in any XyG studied to date. More recently, an *Arabidopsis* gene from the GT47 family has been shown to catalyze the transfer of a galacturonic acid (GalA) onto Xyl residues, hence forming α-D-GalA-(1,2)-xylosyl side chains in the XyG. This type of side chain was found in XyG from *Arabidopsis* root hairs and is catalyzed by XyG-specific galacturonosyltransferase 1 (AtXUT1, At1g63450) (Pena et al. 2012).

Major post-biosynthetic modifications of XyG polymers include the addition of acetyl groups onto Gal residues in L and F side chains, as well as onto the Glc residues of the glucan backbone (Kiefer et al. 1989; Jia et al. 2005). *O*-acetylation of Gal residues in L side chains is catalyzed by two putative XyG-specific acetyltransferases: AtAXY4 (At1g70230) and AtXY4L (At3g28150) (Gille et al. 2011).

3.3 Mannan Structure and Biosynthesis

Mannans are a group of hemicellulosic polysaccharides with a β-(1,4)-glycan backbone that can consist either entirely of β-(1,4)-linked mannose (Man) residues or a combination of β-(1,4)-linked Glc and Man residues (Fig. 3c; Dhugga et al. 2004; Scheller and Ulvskov 2010). Both backbones can be substituted with α-(1,6)-linked Gal residues to produce galactomannan (GM) or galactoglucomannan (GGM, Fig. 3c; Moreira and Filho 2008). GM and GGM are minor components of primary cell walls but can represent one of the major polymers in secondary cell walls in dicot plants (Buckeridge et al. 2000b; Zhong and Ye 2009). GGM, on the other hand, is mainly found in the endosperm, as storage polysaccharides, of seeds in many plants, such as legumes and palms (Buckeridge et al. 2000a; Dhugga et al. 2004).

The first β-(1,4)-mannan synthase (ManS) was identified in guar seeds (Dhugga et al. 2004). ManS belongs to CSLA subfamily. Functional analysis of *Arabidopsis* members of the CSLA subfamily allowed the identification of CSLA2 (At5g22740), CSLA3 (At1g23480), CSLA7 (At2g35650), and CSLA9 (At5g03760) proteins as putative ManSs. Heterologous expression of these genes demonstrated their ManS activity in vitro (Liepman et al. 2005). Topology analysis of CSLA9 revealed that the protein has five transmembrane domains with the catalytic domain facing the Golgi lumen, which means GDP-mannose needs to be transported into the Golgi (Davis et al. 2010). More recently, a Golgi-localized mannan synthesis-related (MSR) gene was found to be highly and specifically expressed in fenugreek endosperm (Wang et al. 2013). In *Arabidopsis*, the

homologs MSR1 (At3g21190) and MSR2 (At1g51630) are highly co-expressed with the three ManSs, CSLA2, CSLA3, and CSLA9 (Wang et al. 2013), supporting a role, yet to be determined, in mannan synthesis (Wang et al. 2013).

Genetic studies in *Arabidopsis* revealed that mannan also plays an important role in embryo development and pollen tube growth, as an *Arabidopsis* mutant in the putative mannan synthase 7 gene (*AtCSLA7*) has an embryo lethal phenotype (Goubet et al. 2003).

4 Structure and Biosynthesis of Pectic Polymers

Pectin polymers form a gel-like matrix surrounding the "cellulose-hemicellulose" sub-network of the primary cell wall, as described in the model proposed by Carpita and Gibeaut (1993). These polymers are also found the in middle lamella (McClendon 1964; Yamauchi et al. 1986), the outer most layer of the primary cell wall that permits cell-to-cell contact and adhesion. Pectins play an important role in plant physiology, including defense, morphogenesis, and signaling (Ridley et al. 2001; Willats et al. 2001; Mohnen 2008; Peaucelle et al. 2012). Pectic polysaccharides are a source of oligogalacturonides (OGAs) released after pathogen attack, which can act as elicitors to trigger plant responses to pathogens (Lee et al. 1999; Galletti et al. 2008; Osorio et al. 2008).

Pectin polymers are a group of structurally complex polysaccharides characterized by their rich content in GalA (up to 70 %; Mohnen 2008; Atmodjo et al. 2013). This high proportion of GalA gives pectins a net negative charge. Three major groups of pectins are found in the wall: homogalacturonan (HG), rhamnogalacturonan I (RG-I), and the substituted rhamnogalacturonan II (RG-II) (Fig. 3d; Mohnen 2008; Caffall and Mohnen 2009). The most abundant group of pectins (~65 % of total pectin) is HG, which is a linear homopolymer of α-(1,4)-linked GalA residues. Many of the GalA residues of HG are methyl esterified at the C6 carboxyl position and can be acetylated at the *O*-2 and *O*-3 positions (Fig. 3d; Mohnen 2008). The second most abundant pectic polymer is RG-I (~20–35 % of total pectin), which has a backbone of the repeating unit [4)-α-D-GalA-(1,2)-α-L-Rha-(1,]$_n$. Backbone Rha residues of RG-I are decorated with oligosaccharides, including L-Ara*f*-(1,5)-α-L-Ara*f*-(1,2)-α-L-Ara*f*-(1,3)-β-Gal-(1,4), β-Gal-(1,6)-β-Gal-(1,4), β-Gal-(1,6)-β-Gal-(1,4)-β-Gal-(1,4), and α-L-Fuc-(1,2)-β-Gal-(1,4)-β-Gal-(1,4)-Rha (Fig. 3d; McNeil et al. 1980; Lau et al. 1985). RG-II polymers represent only ~10 % of total pectin but are known for their structural complexity. They have a backbone of α-(1,4)-linked GalA residues similar to HG but are substituted with at least four types of oligosaccharides (called side chains A–D, Fig. 3d): side chain A (an octasaccharide) and side chain B (a nonasaccharide) are *O*-2 linked to GalA of the HG backbone, while side chains C and D (both disaccharides) are *O*-3 linked to the HG backbone (Ishii and Matsunaga 1996; O'Neill et al. 2001; Matsunaga et al. 2004). A small proportion of RG-II contains α-D-apiose (3-*C*-hydroxylmethyl-D-erythrose, a pentose) to form a polymer called apiogalacturonan (AGA) (Hart and Kindel 1970; Duff 1965;

Longland et al. 1989; McNeil et al. 1984). Apiose residues in RG-II serve as important cross-linking points with HG side chains (Stevenson et al. 1988) and borate ions to form cyclic diesters (Ishii et al. 1999; O'Neill et al. 1996). RG-II/borate cross-linking is critical for the structural integrity of the cell wall (O'Neill et al. 2001). A *Nicotiana plumbaginifolia* mutant, *nolacH18*, illustrates the importance of borate cross-linking for cell wall integrity, as this mutant is defective in organogenesis due to the loss of cell-cell adhesion (Iwai et al. 2002). HG can also be substituted with Xyl residues to form a type of pectin polymer called xylogalacturonan (XGA) (Ovodova et al. 2000; Zandleven et al. 2006, 2007). Covalent linkages via their backbones connect HG to RG-I, RG-II, and XGA (Nakamura et al. 2002; Zandleven et al. 2007; Round et al. 2010; Atmodjo et al. 2013). Figure 3d shows a schematic presentation of HG, RG-I, RG-II, AGA, and XGA domains of pectic polymers.

Pectic polysaccharides are synthesized in the Golgi lumen and transported to the surface of plant cells (Zhang and Staehelin 1992; Mohnen 2008). According to Mohnen (2008), at least 67 different transferases, including GTs, methyltransferases (MethylTs), and acetyltransferases (AcetylTs), are predicted to be required for pectin synthesis. Recently, Atmodjo et al. (2013) proposed two models for pectin synthesis. One model, called the consecutive GT model, postulates that a set of GTs are associated to synthesize the backbone and branches of pectic polysaccharides (including both HG and RG-I) by processively adding sugars from nucleotide-sugar donors onto acceptors. This process occurs through the *cis*-, *medial*-, and *trans*-Golgi stacks. The second model, called the domain synthesis model, hypothesizes that oligosaccharides are elongated to form HG or RG-I domains, which are transferred en bloc (by oligosaccharyltransferase) onto another growing domain. Such domain transfer might occur repeatedly until a full pectin polymer is formed (Atmodjo et al. 2013).

Several biosynthetic GTs involved in pectin synthesis have been identified, including an *Arabidopsis* HG:α-(1,4)galacturonosyltransferase (HG:GalAT), named as GALACTURONOSYLTRANSFERASE 1 (GAUT1, At3g61130) (Sterling et al. 2006). GAUT1 belongs to the GT8 family and was biochemically demonstrated to catalyze the transfer of GalA, from UDP-GalA, onto the nonreducing end of endogenous and exogenous HG acceptors (Sterling et al. 2006). More recently, Atmodjo et al. (2011) showed that GAUT1 and GAUT7 (At2g38650) form a functional protein complex in the Golgi apparatus.

RG-I biosynthesis, on the other hand, requires both GalAT and rhamnosyltransferase (RhaT) activities to generate the backbone, as well as multiple GalTs and AraTs for the synthesis of the side chains. To date, in vitro synthesis of the RG-I backbone has not been achieved (Atmodjo et al. 2013), pointing out the difficulty of studying pectin biosynthetic machinery.

For side chain additions onto pectin backbones, *Arabidopsis* GALACTAN SYNTHASE 1 (GALS1) of the GT92 family has been shown to act as a β-(1,4)-galactan:β-(1,4)-GalT that transfers successive β-(1,4)-galactosyl residues, from UDP-Gal, onto β-(1,4)-galactopentose oligosaccharides, forming β-(1,4)-galactan

side chains of RG-I (Liwanag et al. 2012). A protein complex of ARABINAN DEFICIENT 1 (ARAD1, At2g35100) and its homolog ARAD2 (At5g44930) were proposed as RG-I arabinan:α-(1,5)AraTs responsible for the synthesis of pectin arabinan side chains (Harholt et al. 2012). However, the precise biochemical function of these proteins remains to be demonstrated. RHAMNOGALACTURONAN XYLOSYLTRANSFERASE 1 (RGXT1, At4g01770) and RGXT2 (At4g01750), both from the CAZy GT77 family, were identified as α-(1,3)XylTs responsible for the addition of Xyl residues during RG-II synthesis (Fig. 3d; Egelund et al. 2006). Another XylT, At5g33290 from GT47 family (called XYLOGALACTURONAN DEFICIENT 1, XGD1), shown to catalyze the transfer of β-Xyl, from UDP-Xyl, onto the C3 position of GalA residues in HG (Jensen et al. 2008).

Pectin polymers can be heavily methyl esterified and also *O*-acetylated. Methyl groups are transferred from S-adenosyl-L-methionine (SAM) donors onto the C6 carboxylate groups of GalA residues in HG by enzymes called pectin HG: methyltransferase (HG:MT) (Goubet et al. 1998). *Arabidopsis QUA2* (At1g78240) and *QUA3* (At4g00740) and Cotton Golgi-Related 3 (*CGR3*, At5g65810) may encode such HG:MTs (Mouille et al. 2007; Held et al. 2011). Methyl esterification of the C6 carboxylic acid gives HG a more neutral charge, limits Ca^{+2} binding, and likely alters its physical properties. *O*-acetyl groups, on the other hand, are transferred onto different residues and at multiple positions, depending of the species (Gille and Pauly 2012). For example, sugar beet, potato, and spinach HG polymers contain *O*-acetyl groups at the C2 and/or C3 position of the GalA residues in the HG backbone (Keenan et al. 1985; Kouwijzer et al. 1996; Ishii 1997; Perrone et al. 2002). Depending on the tissues and/or species, the degree of *O*-acetylation of pectin varies from 0 % to 90 % (Schols and Voragen 1994; Voragen et al. 1998). Acetyl-CoA was shown to be the acetyl donor for pectin acetyltransferase enzymes, which are presumably located in the Golgi apparatus (Pauly and Scheller 2000). In the RG-I backbone, GalA residues can be *O*-acetylated at the C2 and/or C3 positions in bamboo, cotton, sycamore, potato, and spinach (Komalavilas and Mort 1989; Schols et al. 1990; Lerouge et al. 1993; Ishii 1997; Kouwijzer et al. 1996; Perrone et al. 2002). Furthermore, *O*-acetylation of the C3 of Rha residues was detected in okra, *Abelmoschus esculentus* (Senkhamparn et al. 2009). In addition, *O*-acetylation of 2-*O*-methyl-fucosyl residues of RG-II side chain was also identified in sycamore (Whitcombe et al. 1995; O'Neil et al. 2004). More recently, *Arabidopsis reduced wall acetylation 2* mutant plants (*rwa2*, corresponding to the At3g06550 gene) had reduced acetylation of pectin and non-pectic polysaccharides (Manabe et al. 2011). *O*-acetylation of pectins interferes with divalent cation binding to pectin, thus affecting the solubility and gelation properties of these polymers (Pippen et al. 1950; Rombouts and Thibault 1986; Kouwijzer et al. 1996; Ralet et al. 2003, 2005). Pectin *O*-acetylation also limits enzymatic breakdown (Renard and Jarvis 1999; Schols et al. 1990; Kauppinen et al. 1995). Thus, it is not surprising that plants regulate their growth through changes in the degree of methyl esterification and acetylation of pectin during the development.

5 Hydroxyproline-Rich Glycoproteins (HRGPs)

HRGPs, which include the extensins (EXTs) and arabinogalactan-proteins (AGPs), represent the third sub-network in plant cell walls. These glycoproteins represent some of the most abundant and highly modified proteins in plants. Much of the recent work on HRGPs has focused on the biosynthesis of their carbohydrate moieties and the functional contributions of these moieties.

5.1 Structure and Biosynthesis of Extensins (EXTs)

Extensins are a family of hydroxyproline-rich glycoproteins characterized by the repeating pentapeptide sequence Ser-Hyp-Hyp-Hyp-Hyp and by the presence of short oligoarabinosides attached to the continuous Hyp residues (Showalter 1993; Kieliszewski and Lamport 1994). Single Gal residues also are attached to some of the serine (Ser) residues in EXTs. These glycoproteins are rodlike proteins that exist in a polyproline II helix stabilized by the oligoarabinosides wrapping around the protein backbone (Van Holst and Varner 1984; Shpak et al. 2001). Some EXTs contain tyrosine residues that are modified to form intramolecular isodityrosine cross-links or intermolecular di-isodityrosine or pulcherosine cross-links (Brady and Fry 1997; Brady et al. 1998; Held et al. 2004). The intramolecular cross-links cause "kinks" in the rods, while the intermolecular cross-links result in the formation of extensin networks. Such cross-links are thought to be important in regulating plant growth and development and in forming a defensive barrier to plant pathogens. It should be noted that EXT-pectin cross-links also exist, but the extent and functional significance of these cross-links are unknown (Qi et al. 1995).

Biosynthesis of EXTs consists of several steps: (1) translation of EXT mRNAs, (2) signal peptide-mediated translocation of EXT into the rough endoplasmic reticulum, (3) posttranslational modification of peptidyl-proline (Pro) residues in the EXT core protein to form hydroxyproline (Hyp), (4) glycosylation of the EXTs in the endoplasmic reticulum (ER) and possibly in the Golgi, (5) secretion of EXTs to the cell surface and integration into cell wall, and (6) formation of intramolecular and intermolecular EXT cross-links in the cell wall. EXT glycosylation is the main focus here with Fig. 4 providing an overview of the various enzymes responsible for EXT glycosylation and Table 4 listing more detailed information about these GT enzymes and their genes.

A Ser galactosyltransferase gene (*SGT1*) was recently identified in *Chlamydomonas reinhardtii*, and homologous genes subsequently were identified in *Arabidopsis* and *Nicotiana tabacum* (Saito et al. 2014). The SGT1 enzyme is found mainly in the ER. Interestingly, SGT1 is not present in the CAZy database and was initially identified by biochemical purification of proteins having serine *O*-α-galactosyltransferase activity. In contrast, at least five distinct arabinosyltransferases referred to as hydroxyproline O-β-arabinosyltransferases (HPAT1–3), reduced residual arabinose (RRA1–3), xyloglucanase 113 (XEG113), EXT arabinose deficient (ExAD), and another unknown arabinosyltransferase are responsible

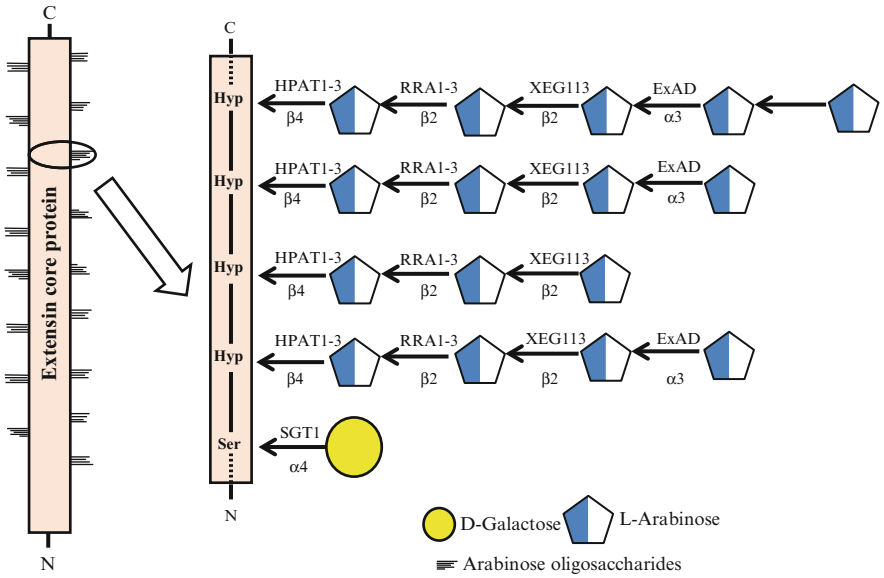

Fig. 4 Sites of action of glycosyltransferases acting on extensins are depicted within a representative extensin glycomodule sequence found in an extensin molecule

for sequential addition of 1–5 arabinosyl residues (making the oligoarabinoside) to continuous hydroxyproline residues (Velasquez et al. 2012; Saito et al. 2014). All these enzymes are thought to act in the Golgi. It should also be mentioned that the degree of EXT arabinosylation is variable, although the addition of 3 or 4 Ara residues per hydroxyproline is common. The first Ara is added directly to hydroxyproline residues in the protein backbone by the action of hydroxyproline *O*-β-arabinosyltransferase activity (HPAT1–3) (Ogawa-Ohnishi et al. 2013). At least three *Arabidopsis* genes possess this enzymatic activity, and they are related to, but not part of, the GT8 family in CAZy. The second Ara is added in a β-(1,2)-linkage by the action of one of the three RRA1–3 enzymes found in *Arabidopsis* (Egelund et al. 2007; Velasquez et al. 2011). These enzymes are members of the GT77 family and were identified from genetic mutants. The third Ara is also added in a β-(1,2)-linkage, but by the action of another GT, xyloglucanase 113 (XEG113) (Gille et al. 2009). This *Arabidopsis* enzyme is also a member of the GT77 family, and it was serendipitously identified by a novel mutant screen in which *Arabidopsis* cells were treated with a fungal endoglucanase. The fourth Ara is added in an α-(1,3)-linkage by the action of the EXT-arabinose-deficient (ExAD) enzyme (Petersen, personal communication). This enzyme is a member of the GT47 family and was identified by a genetic mutant screen similar to the one used to identify RRA1–3. An as yet unidentified GT enzyme adds the fifth Ara. It is important to keep in mind that not all EXTs exhibit hydroxyproline residues having all five Ara residues. Moreover, the anomeric nature of this fifth linkage is unknown.

Table 4 Information on the enzymes, genes, and mutants for extensin glycosylation

Enzyme abbreviation	Enzyme	GT family	Gene identifier	Mutants	Mutant phenotypes	References

Thus, at least five different GT enzymes are responsible for these five biochemically distinct arabinosyl linkages, even though two are in β-(1,2)-linkages. In other words, these various GTs are highly specific, and there are at least one or more enzymes for each sugar that is added. Moreover, since multiple genes encode at least two of these enzymes, this raises the question as to whether these genes and the enzymes they encode are redundant or nonredundant. Related to this question is whether these enzymes act on all EXT proteins or only on a subset of EXTs. Finally, another question is whether these enzymes act in a complex. To date, there is no evidence for the existence of such a complex, and the observation that EXT arabinosylation is variable may lend support to the absence of complex formation.

Genetic mutant analysis is being used to determine the functional contribution of Ser galactosylation and Hyp arabinosylation to EXT function in plants. A variety of mutant phenotypes have been observed to date (Table 4). For example, *sgt1* mutants have longer roots and larger leaves, while *hpa1–3* mutants have a variety of effects on growth and development, whereas the *rra1–3* and *xeg113* mutants demonstrate reduced root hair growth. Given the potential for redundancy at each of these glycosylation steps, it will be particularly important to examine biochemical phenotypes and correlate them to observed physiological/developmental phenotypes. Thus, increasingly more severe physiological and biochemical mutant phenotypes may be observed as redundant genes are systematically eliminated in a series of single, double, triple, etc. mutants.

5.2 Structure and Biosynthesis of Arabinogalactan-Proteins (AGPs)

AGPs are characterized by their abundance of Pro (which is modified to Hyp), alanine, serine, and threonine, by their extensive glycosylation of noncontiguous hydroxyproline residues with arabinose-/galactose-rich (AG) polysaccharide side chains, and by their ability to react with a chemical called Yariv reagent (Showalter 2001; Seifert and Roberts 2007). The AG polysaccharide side chains are composed of β-(1,3)-galactan backbones decorated with β-(1,6)-galactose side chains that are further decorated with α-L-Ara residues as well as other sugars, such as β-(methyl) glucuronic acid, α-rhamnose, and α-L-fucose, which are present in lesser amounts. Based on microscopic analyses and how the numerous Hyp-AG polysaccharides are predicted to protrude or wrap around the core protein, AGPs can exist as spheroidal or rodlike molecules. These structures are represented by the so-called wattle blossom and twisted hairy rope models of AGP structure. There are some reports that AGPs are capable of cross-linking either to one another or to other cell wall molecules, namely, pectin and arabinoxylan (Kjellbom et al. 1997; Tan et al. 2013). While definitive chemical evidence for AGP-AGP cross-linking is lacking, chemical evidence for AGP-pectin and AGP-pectin-arabinoxylan cross-linking is compelling. The extent and degree of such cross-linking reactions as well as the functional significance of such cross-linking await further investigation. It should also be noted that many AGPs encode a C-terminal glycosylphosphatidylinositol

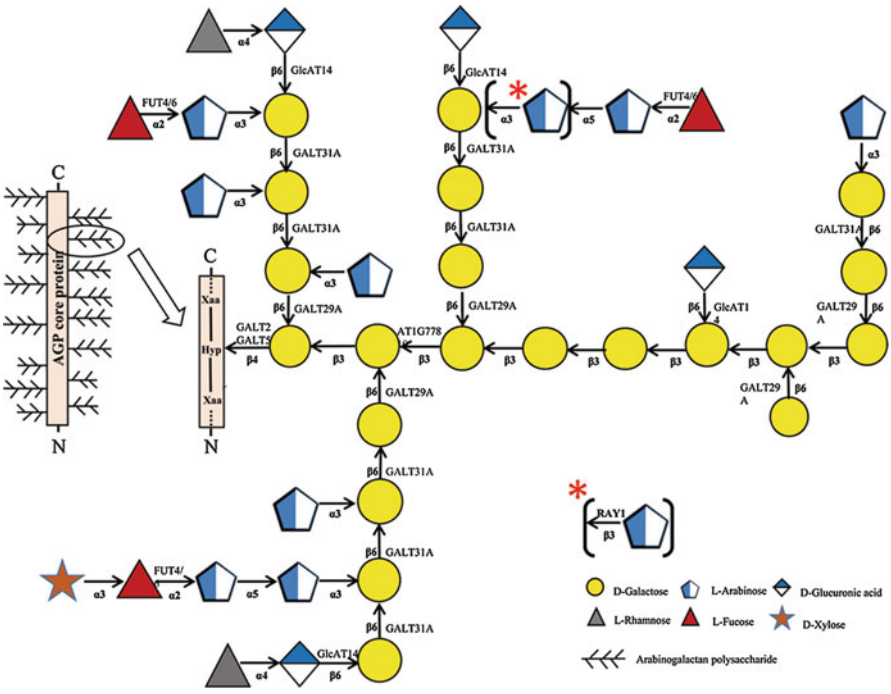

Fig. 5 Sites of action of known glycosyltransferases acting on AGPs are depicted within a representative AGP glycomodule sequence found within an AGP molecule

(GPI) anchor addition sequence, which results in a GPI anchor that serves to tether such AGPs to the outer leaflet of the plasma membrane while the rest of the molecule resides in the cell wall. Presumably, such AGPs are released from the plasma membrane to the wall by the action of specific phospholipases.

Biosynthesis of AGPs consists of several steps: (1) translation of mRNAs encoding the core protein of AGPs; (2) signal peptide-mediated translocation of AGP core proteins into the rough endoplasmic reticulum; (3) GPI anchoring of the C-terminus of the AGP core protein if specified; (4) posttranslational modification of Pro residues to form Hyp; (5) glycosylation of AGP core proteins, which likely begins in the ER but is more extensive in the Golgi; (6) secretion of AGPs to the cell wall or to the plasma membrane/cell wall (for GPI-anchored AGPs); and (7) glycosyl hydrolase-mediated hydrolysis of AGPs in the cell wall which is possible, as is the formation of AGP cross-links in the wall in some cases. AGP glycosylation is the main focus here with Fig. 5 providing an overview of the GT enzymes responsible for the various glycosylation reactions and Table 5 listing more detailed information about these GT enzymes and the genes that encode them.

Several of the GTs responsible for AGP glycosylation are known and cloned; however, many await discovery as previously reviewed (Tan et al. 2012; Knoch et al. 2014). Initial glycosylation of AGPs is catalyzed by a Hyp *O*-β-galactosyltransferase (GALT). At least two enzymes have such an activity in *Arabidopsis*, GALT2

Table 5 Information on the enzymes, genes, and mutants for AGP glycosylation

Enzyme abbreviation	Enzyme	GT family	Gene identifier	Mutants	Mutant phenotypes	References
GALT2	Hydroxyproline *O*-β-galactosyltransferase	GT31	At4g21060	*galt2-1* (SALK_117233)	Reduced root growth and root tip swelling under salt stress, reduced seed mucilage adherence	Basu et al. 2013

and GALT5 (Basu et al. 2013). These two enzymes are members of a small family that includes six members (named GALT1–6) in the GT31 family. Interestingly, GALT1 does not use AGPs as substrates, but instead catalyzes the addition of Gal to Lewis a structures (Strasser et al. 2007). GALT3, 4, and 6 remain to be examined. GALT2 was localized to the ER and Golgi, whereas GALT5 was found only in the Golgi. Both enzymes were initially identified using bioinformatics, which predicted a GALT domain as well as a novel galectin domain, and were verified using heterologous expression coupled with an in vitro Hyp-GALT biochemical assay as well as by biochemical analysis of *galt2* and *galt5* genetic mutants.

Only one GALT (At1g77810) is reported to act in the synthesis of the β-(1,3)-galactan backbone (Qu et al. 2008). At1g77810 is a member of the GT31 family. This GT was expressed in COS cells and showed that Gal was added to a synthetic β-(1,3)-galactose disaccharide; however additional supporting evidence is needed. Moreover, it is likely that several other β-(1,3)-GALTs will ultimately be identified, particularly since the GT31 family is so large (20 members, each with a GALT domain, are predicted for *Arabidopsis*).

At least two β-(1,6)-GALTs act on AGPs, GALT31A and GALT29A. The two enzymes, however, have somewhat different activities and are members of two different CAZy GT families as their names indicate. GALT31A serves to elongate β-(1,6)-galactan chains, whereas GALT29A has this activity as well as another related activity, adding β-(1,6)-Gal to the β-(1,3)-galactan backbone (Geshi et al. 2013; Dilokpimol et al. 2014). In addition, these two enzymes are reported to interact with one another based on fluorescence resonance energy transfer (FRET) analysis. Whether other AGP GTs exist in such an enzyme complex remains to be determined.

Three β-glucuronosyltransferases (GlcAT), GlcAT14A, GlcAT14B, and GlcAT14C, are responsible for the addition of glucuronic acid (GlcA) residues to AGPs (Knoch et al. 2013; Dilokpimol and Geshi 2014). All three enzymes are members of the GT14 family and are reported to add GlcA to both β-(1,6)- and β-(1,3)-galactan chains. It should be noted that GlcA imparts a negative charge to AGPs that contain them and also serves as a potential site for calcium binding; both of these properties likely have functional and physiological ramifications.

Two *Arabidopsis* α-fucosyltransferases (FUTs), FUT4 (Atg2g15390) and FUT6 (At1g14080), serve to add α-(1,2)-fucose (Fuc) residues to AGPs (Wu et al. 2010b). However, these two enzymes have different substrate specificities. Both of these enzymes are members of the GT37 family. Interestingly, heterologous expression of *FUT4* in tobacco BY2 cells (which have AGPs lacking Fuc) seems to incorporate Fuc residues and facilitate the incorporation of xylose residues on AGPs (Wu et al. 2010b; Tryfona et al. 2014). FUT6 does not produce this extra-modification of AGP. However, it should be noted that not all AGPs contain Fuc.

Finally, only one arabinosyltransferase, Reduced Arabinose Yariv1 or RAY1 (At1g70630), is reported to act on AGPs. One thing that remains puzzling about this enzyme is that it catalyzes the addition of β-linked Ara residues, whereas all the Ara residues reported in AGPs over the years are α-linked.

In summary, these 11 different enzymes are responsible for glycosylation of AGPs; however, many GTs remain to be identified. Conventional wisdom would suggest that a different enzyme would be responsible for each different sugar linkage. Some notable enzymes remain to be identified, including α-arabinosyltransferases and α-rhamnosyltransferases. In three cases, multiple genes encode two or more of these enzymes, which raises the question as to whether these genes, and the enzymes which they encode, are redundant or nonredundant. Related to this question is whether these enzymes act on all AGPs or only on a subset of AGPs. Finally, another question is whether these enzymes act in a complex. To date, there is one piece of evidence suggesting such complexes exist (i.e., GALT31A-GALT29A).

Finally, genetic mutant analysis is being used to determine the functional contribution of AGP glycosylation. To date, there appear to be a variety of functions conferred, ranging from embryo lethality to conditional effects on root growth, cell elongation, and pollen tube growth. Consequently, the sugars are important, and perhaps this will be made clearer as redundant genes are knocked out in a single plant to reveal more striking phenotypes during normal growth and development.

6 Concluding Remarks

The last decade has brought great advances in the identification of glycosyltransferases involved in plant cell wall polysaccharide biosynthesis. While strong genetic evidence is now able to associate numerous GTs with specific polysaccharides, direct biochemical evidence confirming the activities of such GTs is just beginning to catch up. This is due in large part to the complexity of wall polysaccharide synthases. The need for multiple activities to simultaneously produce a single polymer represents a clear challenge for in vitro biochemical and cell biological studies. Many, but not all, polysaccharides appear to be synthesized by multiprotein complexes. Defining the protein components of GT synthase complexes and their synergistic mechanisms is at the forefront of current molecular studies. New insights into the 3D structures of GTs are setting the stage for future advances toward defining these protein complexes (Morgan et al. 2013; Sethaphong et al. 2013; Olek et al. 2014). These kinds of structural studies will also lead to a new level of mechanistic understanding. A detailed understanding of the biosynthetic mechanisms of plant cell wall GTs will be useful toward producing designer polysaccharides and engineering plants for biofuel, food, feed, and fiber applications.

Cell Wall Evolution and Diversity

2

David S. Domozych

Contents

Abstract

Cell walls of green plants and other photosynthetic eukaryotes consist of complex polysaccharide-rich coverings that are central to cell growth, development, and defense. Most cell walls display a microarchitectural design consisting of a composite of fibrillar polysaccharides, such as cellulose, mannans, or xylans, tethered by other glycans (e.g., hemicelluloses) that are embedded in a matrix of polysaccharides and proteins. This design produces both remarkable strength and the capacity for controlled expansion. The biosynthesis and metabolism of the cell wall require a significant portion of the cell's genetic machinery and the activities of coordinated subcellular pathways that are, in turn, responsive to developmental and environmental signals. The evolution of cell walls was critical to the exploitation of, and survival in, Earth's diverse habitats.

1 Introduction

"Life is sugarcoated." While this proclamation may reflect gross optimism in human affairs, it is remarkably accurate when describing the external surfaces of cells of most of the diverse biota that occupy modern Earth's ecosystems. External to the plasma membrane of most cells exists a diverse assortment of carbohydrate-rich materials that constitute the "extracellular matrix." These include the glycocalyx of animal cells, the slimes or mucilages that constitute the extracellular polymeric substance or EPS of biofilm-forming microorganisms, the intricately designed and layered scales of unicellular flagellates, and the highly complex mineralized coverings such as frustules of diatoms, to name just a few. However, the most common and arguably the most ecologically/economically important of life's extracellular matrices are the cell walls of plants and other photosynthetic eukaryotes.

The plant cell wall consists of a load-bearing structural framework of fibrillar polysaccharides that are tethered by other glycans. This framework is embedded in a matrix composed of neutral and charged polysaccharides, various proteins, water, and in some cases, polyphenolics like lignin (Sarkar et al. 2009; Fry 2000). Production of this complex microarchitectural design requires coordinated secretion and precise insertion of the constituent polymers into the cell wall. Subsequent biochemical modulation results in structural refinements that ultimately yields a covering of remarkable strength but with the capacity to expand during specific developmental stages and in response to environmental prompts. Underlying plant cell wall biosynthesis and metabolism is a large and complex molecular machinery that constitutes an estimated 10% or more of the nuclear genome of angiosperms (Popper et al. 2011; Vidaurre and Bonetta 2012; McCann and Rose 2010). The cell wall is of profound importance to the cell in regulating cellular expansion/morphogenesis, providing physical/chemical protection, contributing to adhesion, absorption, and transport of various molecules, and serving as a conduit in signal transduction. Cell wall materials also provide humans with food, building materials, fiber, textiles, paper, gels, and important base materials for the rapidly emerging biofuel industry (Keegstra 2010; Pauly and Keegstra 2010; Meng and Raugauskas 2014).

Cell walls though are not limited to plants. Many of the biochemical constituents of the plant cell wall are also found in many green algae, most notably in the late divergent taxa of the charophyte green algae or CGA (Sørensen et al. 2010, 2011; Domozych et al. 2012; Popper et al. 2011; Fangel et al. 2012). These algae are ancestral and most closely related to modern land plants. Previous interpretations of the phylogeny of the CGA based on molecular, biochemical, and cytological data

(Leliaert et al. 2012; Graham et al. 2009; Becker and Marin 2009) suggest that the ancestors of modern-day CGA were capable of making the successful transition to land because specific features of their physiology and biochemistry allowed for a degree of preadaptation to life on land. Sørensen et al. (2011) further proposed that the ability of the CGA to produce cell walls with specific polymer arrays was a critical aspect of this preadaptation for this terrestrial invasion. Interestingly, the general architectural design of a "fibril/matrix" model cell wall is also commonly found in many taxa of the chlorophycean green algae (e.g., chlorophytes, ulvophytes Leliaert et al. 2012), the red algae (Rhodophyta), and the brown algae (Phaeophyta). Though the specific polymeric compositions of both the fibrillar and matrix components in these taxa may vary, it seems quite clear that the design of a matrix-reinforced fibrillar composite (e.g., like reinforced concrete or fiberglass) was selected by a broad spectrum of algae as the most efficacious covering for survival in a wide range of habitats (e.g., terrestrial ecosystems, shallow wetlands, marine intertidal zones), each with specific challenges. Likewise, complex underlying genetic machineries were required and evolved for the biosynthesis and metabolism of the cell wall constituents. Emerging discoveries of specific cell wall-based genes, biosynthetic pathways, and regulatory controls derived from recently sequenced algal genomes and transcriptomes are now providing new insight into the evolution of cell walls and adaptations to life in specific habitats (Ulvskov et al. 2013; Michel et al. 2010). In this review, the diversity and evolution of cell walls will be examined based on the biochemistry, molecular biology, and development of their polysaccharides and other constituents. This review focuses on taxonomic groups with distinctive cell walls and well-developed multicellularity including the green plant line (land plants and green algae; Viridiplantae), red algae (Rhodophyta), and the brown algae (Phaeophyta). An overview is provided in Fig. 1. Brief descriptions of the extracellular matrices of unicellular taxa with polymers similar to, or evolutionary lineages leading to, the aforementioned organisms are also provided. Other photosynthetic eukaryotes that are typically included in the Protista and also produce extracellular coverings are not discussed here, but detailed descriptions may be obtained elsewhere (e.g., diatoms; Kröger and Poulsen 2008).

2 The Structural Framework of the Cell Wall: Cellulose, Mannans, and Xylans

Cellulose is a β1-4 glucan polymer that constitutes the most abundant biopolymer produced annually on the planet. It is the major fibrillar component of the cell walls of plants and many algal taxa (Popper et al. 2011). The cellulose biosynthetic machinery in photosynthetic eukaryotes is an evolutionary product of lateral gene transfer derived from an ancestral bacterial endosymbiont (Niklas 2004). Cellulose is typically found in insoluble, unbranched crystalline strands called microfibrils that result from both in inter- and intrapolymer hydrogen bonding of hydroxyl

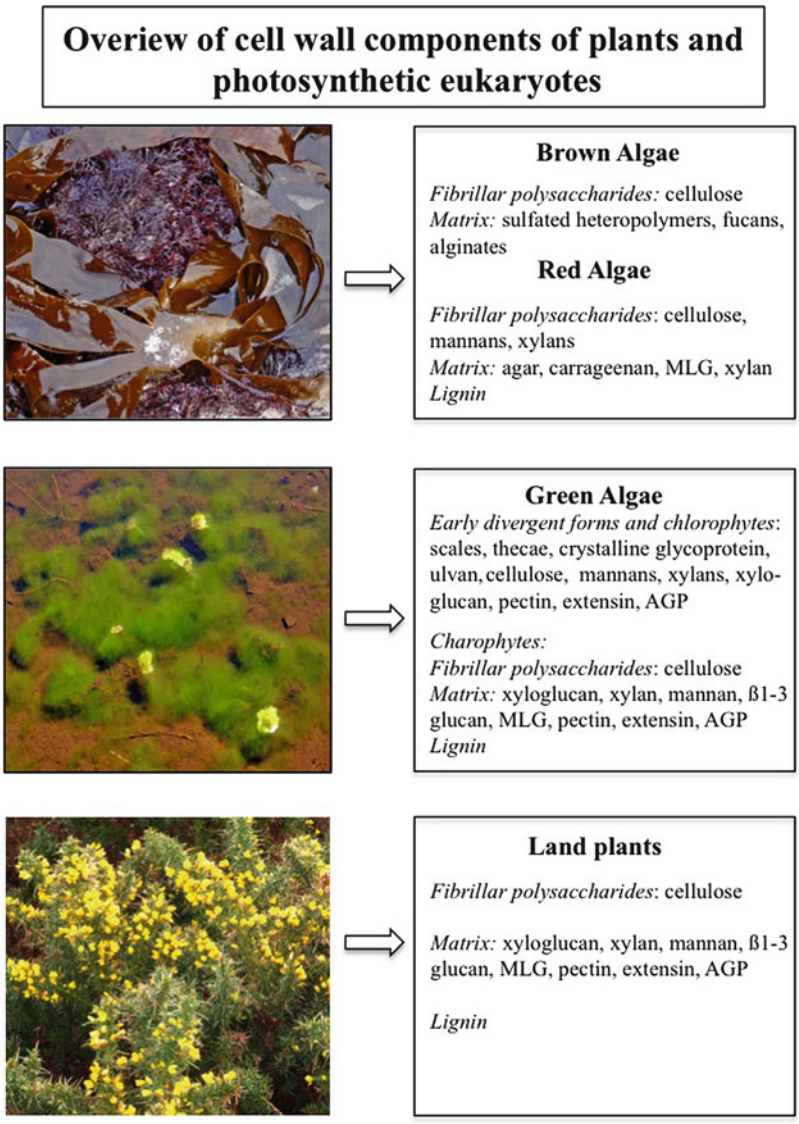

Fig. 1 Overview of the cell wall constituents of cell walls of plants, green algae, red algae, and brown algae

groups among adjacent β-1,4-glucan chains. Cellulose microfibrils are remarkably resistant to digestion and often possess tensile strength that is greater than some steels (Niklas 1992), i.e., outstanding characteristics for a polymer that serves as the load-bearing framework of the cell wall. The functional roles and dynamic actions

of cellulose are also influenced by the interconnected viscoelastic matrix of other polysaccharides and proteins that surrounds the microfibrils.

Much of our understanding of cellulose synthesis during wall development is derived from research on land plants. However, algae were some of the first organisms used in the initial identification of the cellulose biosynthetic machinery (Giddings et al. 1980; Roberts and Roberts 2007; Roberts et al. 2002). Cellulose microfibrils are typically produced in/on the plasma membrane and are then deposited or incorporated into the cell wall (McFarlane et al. 2014; Anderson et al. 2010; Lerouxel et al. 2006). More specifically, the enzyme complex responsible for its synthesis is the cellulose-synthesizing apparatus or CESA which has been classified in one supergene family that contains nine cellulose synthase-like (Csl) families and one cellulose synthase (CESA) family (Yin et al. 2009). CESA synthesis initiates in the Golgi apparatus (Gutierrez et al. 2009) and is then packaged in Golgi-derived vesicles that are transported to the plasma membrane. Here, CESA is incorporated into terminal complexes (TCs) that "weave" cellulose microfibrils (Somerville 2006; Guerriero et al. 2010). TCs function both in the polymerization of the glucan chains and the assembly of those chains into microfibrils (Roberts and Roberts 2007). Freeze fracture/etch processing followed by transmission electron microscopy (TEM)-based imaging has been critical in identifying TC structure and microfibril production. This technology has shown that in land plants and most of the late divergent taxa of the CGA, the TCs are arranged in hexameric rosettes of 25–30 nm. Each of the six components of the rosette contains six cellulose synthase units, each of which produces one β1-4 glucan chain. The 36 glucan chains produced by a single rosette associate via H-bonds to form a microfibril of approximately 2–4 nm in width and thickness. Verification of the role of TCs in the formation of cellulose was provided through labeling of TCs with a monoclonal antibody (mAb) specific for CESA using the green alga, *Micrasterias* (Nakishima et al. 2006). There is much variation in cellulose microfibril size. In many algal groups, microfibril size is much greater than that of land plants and in some red algae, microfibrils may measure from 25 nm to 68 nm (Tsekos 1999; Saxena and Brown 2005). Cellulose is probably produced on the inside of the plasma membrane and crosses to the outside via porin-based pores (Guerriero et al. 2010). The cellulose synthesis machinery also requires a pool of nucleotide sugars and is linked to activities of sucrose synthase, endo-β1-4 glucanases, and annexins (Baroja-Fernández et al. 2012; Davies 2014).

In most cellulose-producing algae, except for the CGA, variation also exists in the architecture of the TC. This, in turn, results in differences in size and arrangement of microfibrils (Tsekos 1999). For example, several chlorophycean green algae possess linear TCs that contain three rows of particles (Roberts and Roberts 2007) while in brown algae, single linear TCs with up to 100 nm subunits produce distinct ribbon-like microfibrils (Tsekos 1999). The red alga, *Erythrocladia subintegra*, produce single linear terminal complexes that measure 180 by 35 nm arranged in four rows of 30–140 particles while in the genera, *Radicilingua* and *Laurencia*, two rows of three particles each have been observed. However, these smaller complexes could represent microfibril-terminating synthesizing complexes.

In the xanthophytes, distinctly stacked or diagonally arranged linear TCs have been described (Mizuta and Brown 1992).

In land plants and many algae, cellulose microfibrils are typically laid down in layers or lamella, often as parts of a developmental phase. This most likely enhances the strength of the cell wall. That is, though cellulose microfibrils have great strength under tension but are relatively weak against shear and compressive forces, the multi-angled deposition of cellulose in lamella would allow the cell to resist forces both internal and external from various directions (Anderson et al. 2010). The orientation of cellulose microfibrils in the cell wall also correlates closely with the orientation of cortical microtubules found just underneath the plasma membrane (Taylor 2008). In land plants, this microfibril-microtubule orientation has been elegantly demonstrated using live-cell imaging of transformed cell lines (Paradez et al. 2006; Taylor 2008; Lerouxel et al. 2006; Crowell et al. 2011). Here, microtubules guide the trajectories of GFP-labeled TCs in the plasma membrane that, in turn, orient the deposition of microfibrils. However, the exact molecular mechanism behind the function of the microtubules is not yet fully defined. They may play roles in controlling the velocity of the cellulose synthesis machinery, determining the density of TCs in the plasma membrane, or targeting the insertion of CESA in the plasma membrane (Wolf and Greiner 2012; Gutierrez et al. 2009). However, other work on *Arabidopsis* demonstrated that cellulose deposition and microtubule orientation may sometimes be independent of each other (Wightman and Turner 2008). In addition, actin networks influence the rate of CESA vesicle delivery to the plasma membrane in land plants, most likely through its role in cytoplasmic streaming (Cai et al. 2011). Activity of the actin network may also control the amount of time CESA spends in the plasma membrane (Sampathkumar et al. 2013). Finally, recent work has shown that CESA is most likely recycled back into the cell by clathrin-mediated endocytosis and is possibly transported to the trans-Golgi network/early endosome (Bashline et al. 2013). This process may also require actin-mediated transport.

The interaction of cortical microtubule and actin cytoskeletal networks has also been explored in various algae. In the desmid, *Penium margaritaceum*, a band of cortical microtubules found in the central pre-division expansion zone is arranged in the same orientation as that of the innermost layer of cellulose microfibrils (Ochs et al. 2014). If the microtubules are altered using pharmacological agents (e.g., oryzalin), cellulose microfibril production is altered and the localized swelling of the cell occurs (Domozych et al. 2014b). This cortical microtubule band also serves a "marker" for expansion prior to cell division, i.e., similar to a pre-prophase band.

In red algae, cellulose synthase enzyme complexes are also most likely synthesized in the Golgi apparatus. The microfibrils that are ultimately produced at the plasma membrane are deposited in layers, but their orientation is variable. No specific correlation between cortical microtubule arrangement and microfibril positioning in the cell wall has yet been demonstrated, but it is likely that actin plays a key role in cellulose deposition (Tsekos 1999). Likewise, in some brown algae,

TC activity and microfibril production is controlled most likely by actin and not by microtubules (Bisgrove and Kropf 2001).

It is also important to note that many algal taxa produce microfibrillar wall materials that are not cellulosic (Popper et al. 2011). In coenocytic chlorophycean green algae, microfibrils may be made of β1-3 xylans, β1-4 mannans, and heteropolymeric fibrillar polysaccharides (Fernandez et al. 2010). In some red algae, microfibrillar β1-4 mannans and β1-3- or β1-4-linked xylans are produced (Craigie 1990; Rinaudo 2007).

Finally, cellulosic wall materials may also be part of other coverings that are not part of a typical cell wall. Thecate dinoflagellates (Pyrrophyta, Dinophyceae) produce an extracellular covering called the amphiesma. This complex structure consists of an outer continuous membrane, i.e., the plasma membrane, an outer plate, a single membrane-bound compartment that contains a cellulose-based theca, and an inner pellicle (Morrill and Loeblich 1983; Kwok and Wong 2003; Hohfeld and Melkonian 1992). The theca is most likely processed through the and Wong Golgi apparatus and an associated network of Golgi-derived vesicles. The amphiesma is often shed during development via a process called ecdysis (Pozdnyakov and Skarlato 2012). Much remains to be learned about the amphiesma and the cellulosic theca. However recently, Kwok and Wong (2010) demonstrated that cellulase activity was critical for coordination of cell cycle activity when amphiesma development occurs.

Our understanding of cellulose structure and synthesis in plants and algae has recently been enhanced by new technologies and the profound importance of this polysaccharide in the growing biofuel industry. For example, genomic sequencing of many algae is growing and the development of transformed cell lines expressing fluorescent protein-CESA complexes for cell wall studies of algae have recently made initial progress (Vannerum et al. 2010; Harris et al. 2010). New developments in atomic force microscopy imaging along with high-resolution light and electron microscopy imaging coupled with new probes will soon provide great insight into cellulose production (Brabham and DeBolt 2013). Similarly, chemical microarray screening employing large arrays of specific cellulose synthesis-affecting agents should soon provide insight into specific aspects of the biosynthetic machinery (Zabotina et al. 2008). All of these should soon resolve many questions about the biology and evolution of cellulose and other fibrillar wall components in plants and algae.

3 Matrix Polysaccharides

While cellulose and other fibrillar polysaccharides form the structural framework of the cell wall, other polysaccharides form a cross-connecting matrix that is critical for wall infrastructure, development, and functioning. Significant insight has been obtained concerning specific matrix polymers in flowering plants and gel-forming polysaccharides of red and brown algae (e.g., agar, carrageenan, alginates) over the past two decades. Only recently though have investigations into the chemistry and

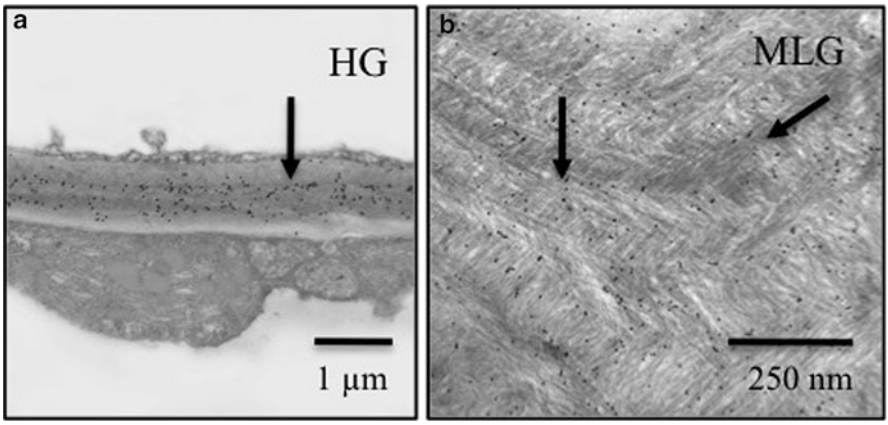

Fig. 2 TEM immunogold imaging of the cell wall of the early divergent vascular plant, *Equisetum arvense*. (**a**) Highlights the presence of homogalacturonan (*HG*) throughout the cell wall (*arrows*) using the monoclonal antibody, JIM5. (**b**) Shows MLG interspersed between layers of cellulose microfibrils (*arrows*) using the monoclonal antibody, BS-400-2

evolution of the diverse matrix polymers in early divergent green plants (i.e., algae and bryophytes) and other algal taxa begun (Franková and Fry 2013; Popper and Fry 2004, 2003).

3.1 Hemicelluloses

Hemicelluloses constitute a diverse group of polysaccharides that associate with/tether cellulose microfibrils and create a cohesive network in plant cell wall architecture. They contain a β1-4-linked glycan backbone that is substituted with varying glycan side chains. Hemicelluloses include xyloglucans, xylans, mannans, and mixed-linkage glucans (MLGs; β1-3,1-4 glucans) and β1-3 glucans. Details of their structural diversity and distribution in various taxa may be found in recent literature (Scheller and Ulvskov 2010; York and O'Neill 2008; Faik 2010; Burton and Fincher 2009; Piršelová and Matušíková 2013). Recent studies have demonstrated that hemicellulosic polymers are made in the Golgi apparatus via a variety of glycosyltransferases and are then transported to the plasma membrane for secretion to the cell wall (Driouich et al. 2012; Pauly et al. 2013). Once in the apoplast, they form associations with cellulose microfibrils. For example, in the early divergent vascular plant *Equisetum arvense*, MLGs are found interspersed with layers of cellulose microfibrils (Fig. 2). Additionally, hemicelluloses may be remodeled by endotransglycosylases (e.g., XET) and other enzymes that modify their side chains (Franková and Fry 2013). Hemicelluloses have a variety of functions including contributing to the control of expansion and differentiation of the plant cell wall (Hayashi and Kaida 2011).

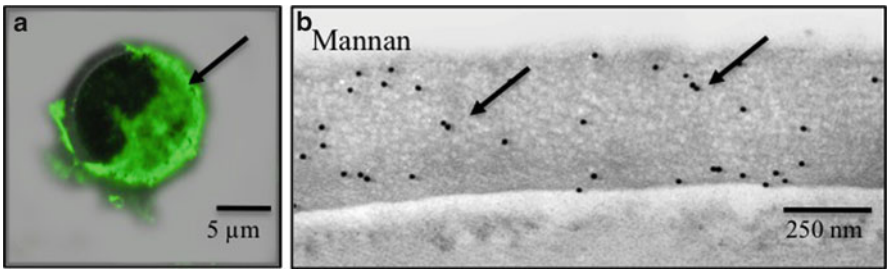

Fig. 3 (**a**) Confocal laser scanning microscope image of mannan (*arrow*) in the outer wall of the resting cyst of the chlorophyte, *Haematococcus pluvialis*. This cell was labeled with the monoclonal antibody, LM21. (**b**) TEM immunogold labeling of the mannan in the cell wall of *Haematococcus* (*arrows*) using LM21

Recently, hemicellulosic polysaccharides have been identified in several green algal groups, most notably the late divergent taxa of the CGA (e.g., mannans, xyloglucans, xylans, β1-3 glucans, and MLG; Sørensen et al. 2011). Likewise, in the chlorophyte flagellate, *Haematococcus pluvialis*, mannan is a major component of the outer layer of the cell wall of the red cyst phase (Fig. 3). When the cell enters into its flagellated green phase, the mannan is sloughed off and a new crystalline glycoprotein cell wall is deposited. In ulvophycean green algae, highly complex xylogalactoarabinans, glucuroxylorhamnans, and rhamnoxylogalactogalacturonans have been identified (Ray and Lahaye 1995). It is important to note that to date, only a few detailed investigations of hemicellulosic polysaccharides in the diverse array of green algal taxa have been undertaken. Only when sufficient data is available will insight into evolutionary trends in cell wall biochemistry be possible. A similar story may be told about the cell walls of other algal groups where significant biochemical complexity has also been noted. For example, fuco-glucuron-xylans have been found in brown algae while glucomannans and sulfated MLGs have been identified in red algae (Kloareg and Quatrano 1988; Popper et al. 2011). Currently, very little is known about the biosynthesis or metabolism of these polysaccharides.

4 Pectins

Pectins represent a group of galacturonic acid (GalA)-containing polysaccharides that are found in the cell walls of many plants and several alga taxa (Popper et al. 2011). Pectins have many functions in the wall including regulation of turgor-driven expansion, cell-cell adhesion (e.g., middle lamella of multicellular plants), absorption, and defense (Wolf and Greiner 2012; Caffall and Mohnen 2009; Yapo 2011). The most common type of pectin is the homogalacturonan (HG) which consists of alpha-1,4,-linked GalA. HG may be methyl- or acetyl-esterified at the C-6 or C-2 position, respectively. These high methyl-esterified HGs are produced in the Golgi apparatus and carried by vesicles to the PM for release. Once in the wall/apoplast, HGs can be enzymatically de-esterified, most commonly by pectin

methylesterase (PME). The release of the methyl group exposes the negative charge on the C-6 of the GalA residues which then allows for binding with cations and, more importantly, cross-linking with adjacent HG chains via divalent cations like calcium (Ca^{2+}). This cross-linking takes place in areas of ten or more de-esterified GalA residues. Cross-linking results in the formation of a stable gel, a property that is strain stiffening which in turn affects the physical properties of the wall (Braybrook et al. 2012). Pectins also consist of other GalA-containing polysaccharides, some of which represent the most complex biopolymers on the planet (Cosgrove 2005). These included substituted pectins like xylogalacturonan, apiogalacturonan, and the complex rhamnogalacturonan-II (RG-II) found to date only in land plants. Rhamnogalacturonan-I or RG-I is another type of pectin that consists of a disaccharide repeat of alpha-1,4-GalA-alpha-1,2-L-Rha. The Rha residues often contain branches of β-1,4-galactan, branched arabinans, and other arabinogalactan side chains (Harholt et al. 2010). Recent analyses of the cell walls of the CGA have shown that HG is a common cell wall constituent (Sørensen et al. 2011). Likewise, RG-I-like epitopes also appear in the cell walls of some green algae (Domozych et al. 2014a).

In higher plants, pectin synthesis initiates in the Golgi apparatus, and pectins are carried to the cell surface or cell plate by Golgi-derived vesicles (Caffall and Mohnen 2009). Recently, Atmodjo et al. (2013) described a hypothetical model for pectin synthesis called the domain synthesis model. Here, an oligosaccharide or polysaccharide primer is first synthesized. The primers are then elongated by elongation enzymes to make particular pectin domains like HG or RG-I. The domains are transferred en bloc onto the growing polysaccharide in the apoplast/cell wall. At least 16 gene families have been identified for pectin biosynthesis and modulation in late divergent land plants (e.g., angiosperms). Genes from these families have also been identified in both bryophytes and CGA (McCarthy et al. 2014).

In algae, the study of pectins and their secretion has focused the CGA especially desmids (Zygnematales) and taxa of the Charales (e.g., *Chara*). *Micrasterias*, a desmid that has been widely used as a model system for cell morphogenesis studies (Lutz-Meindl and Brosch-Salomon 2000; Meindl 1993), possesses a primary cell wall that contains HG with medium levels of methyl esterification (Eder and Lutz-Meindl 2008). The outer portion of this wall apparently has lower levels of methyl-esterified HG than the inner portion. The desmids, *Netrium digitus* (Eder and Lutz-Meindl 2010) and *Closterium acerosum* (Baylson et al. 2001), also possess HG in their cell walls, most commonly noted at expansion loci of the cell. Perhaps the most prominent example of pectin in the green algae is found in the simple cylindrical desmid, *Penium margaritaceum* (Fig. 4), This alga only produces a primary cell wall that contains a distinct Ca^{2+}-HG "lattice" in the outer wall layer (Domozych et al. 2007a, 2009), The pectin is embedded in an inner layer of cellulose microfibrils, and the interface between these two polymeric domains, the median layer, contains HG and most likely, RG-I. The large *Chara corallina* is distinguished by having some of the largest plant cells (e.g., intermodal cell). The cell walls of its vegetative thallus contain cellulose microfibrils that are cross-linked by HG that is cross-linked by Ca^{2+} (Proseus and Boyer 2007, 2008, 2012), HG and RG-I epitopes

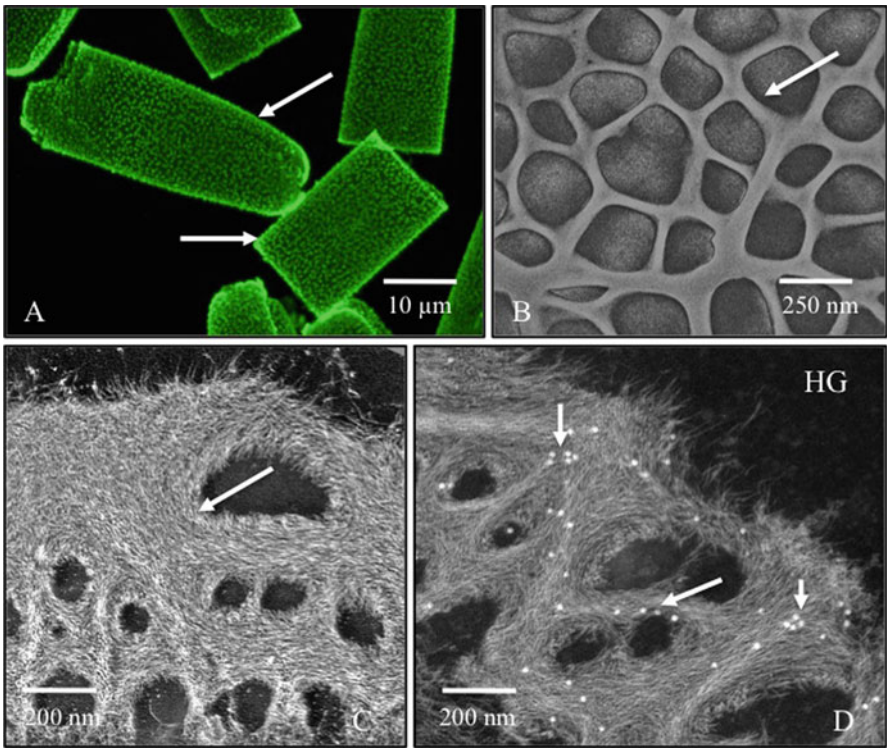

Fig. 4 (**a**) Confocal laser scanning microscope image of the HG (*arrow*) of isolated cell walls of the CGA, *Penium margaritaceum*, using the monoclonal antibody JIM5. (**b**) Shadow-cast TEM image of the outer pectin-rich wall layer of *Penium*. A distinct lattice-like covering is apparent (*arrow*). (**c**) TEM image of a partially decalcified cell wall of *Penium*. (Note that the outer layer (*arrow*) consists of tightly bound fibrils (*arrow*)). (**d**) These fibrils consist of HG as labeled (*arrows*) by the monoclonal antibody, JIM5

have also been identified in other CGA (Sorensen et al. 2011), but detailed studies of them in specific taxa have not yet begun.

The last two and a half decades have seen growing amounts of research in the synthesis and secretion of pectins in green algae. In *Micrasterias*, pectins are initially synthesized in the Golgi apparatus and are transported to the cell surface via "dark" vesicles that emerge from the peripheries of the medial-to-trans loci of a Golgi body (Lutz-Meindl and Brosch-Salomon 2000; Holzinger 2000). Interestingly, it is believed that these vesicles also carry cell arabinogalactan proteins (AGPs). The pectins are transported to expansion zones where they become part of the growing primary cell wall. In a study employing electron energy loss spectroscopy (or EELS) of thin sections of HG-carrying vesicles, notable levels of Ca^{2+} were also detected. This led to the suggestion of a regulatory role of Ca^{2+} in the gelation qualities of the HG prior to secretion (Eder and Brosch-Salomon 2008). The delivery of the HG vesicles to specific sites is mediated by actin (Pflugl-Haill et al. 2000) and a Rab GTPase,

MdRABE1, may also be involved in spatial targeting of vesicles to particular sites on the cell surface (Vannerum et al. 2012). In the desmid, *Closterium acerosum*, osmotically generated Hechtian strands may mark sites at the plasma membrane where vesicles fuse (Domozych et al. 2003). Once secreted, the pectin-modulating enzyme, PME, most likely remodels the pectin. PME activity was also described in the desmid, *Netrium* (Eder and Lutz-Meindl 2010).

In *Penium margaritaceum*, considerable cell wall expansion occurs prior to cell division at a narrow band at the central isthmus. The inner cellulose layer is first produced in a narrow 1 μm band. High-esterified HG is added here (Domozych et al. 2009, 2011 where it apparently de-esterified as it is pushed toward the polar zones. This allows for Ca^{2+} complexing and the formation of the outer HG lattice. After cell division, residual wall expansion occurs at the polar tip of expanding daughter semicells. These events can be easily monitored and quantified using live-cell labeling with mAbs with specificity toward various HG epitopes (Domozych et al. 2011). In *Penium* though, the expansion process is not always symmetrical as size and positioning of old and new cell wall may not equivalent. The expansion zone at the isthmus is highlighted by a cortical band of microtubules and microfilaments positioned around the nucleus. Interestingly, the positioning of the microtubules in this band matches the orientation of the cellulose microfibrils in the inner wall at this zone. After cell division when daughter nuclei are separated and positioned in the center of the new daughter semicells, the cortical microtubule/microfilament bands reform around each nuclei. Deviations in the repositioning of the nuclei and the surrounding cortical cytoskeletal elements may cause asymmetry in the wall development.

Pectin secretion and incorporation into the cell wall has also been well studied in charalean taxa of the CGA specifically *Chara corallina* (Proseus and Boyer 2007) where a novel pectin cycle was proposed. Turgor pressure is the driving force generated from the cell interior that fuels expansion. Newly secreted pectin added to the cell wall removes Ca^{2+} from the cell wall in localized regions. This loosens the tension in the wall and causes wall expansion. Ca^{2+} then enters the wall to reestablish cross-links that enhance the tensile strength of the cell wall.

5 The Matrix Polymers of Brown Algae

Modern brown algae (Phaeophyceae) constitute a large and diverse assemblage of primarily marine taxa displaying complex multicellular forms and in some cases, growing to 50 m or longer (e.g., *Macrocystis*). They also exhibit highly complex reproductive cycles and postfertilization developmental strategies initiating with polar expansion of the zygote (Graham et al. 2009). The cell walls of brown algae are distinct in that they contain a small amount of cellulose (e.g., 1–8 %) embedded in a thick matrix (Michel et al. 2010) primarily composed of anionic polysaccharides including alginates and fucoidans (Kloareg and Quatrano 1988). Early biochemical analyses of these and other wall constituents and their biosynthetic mechanisms have recently been complemented by molecular studies especially after the sequencing of the genome of the model taxon, *Ectocarpus siliculosus*

(Coelho et al. 2012; Cock et al. 2010; Le Bail et al. 2011). Alginate polymers primarily consist of blocks containing two uronic acids, β-1,4-D-mannuronic acid and alpha-1,4-L-guluronic acid that complex divalent cations to form gels (Michel et al. 2010). They may also bind to phlorotannins that consist of halogenated (e.g., iodine) and/or sulfated phenolic compounds (Berglin et al. 2004; Verhaeghe et al. 2008). Alginates tether cellulose microfibrils and are critical for maintaining wall architecture. Evolutionarily derived from lateral gene transfer of an *Actinobacterium*, alginates were critical to the development of the multicellular condition and inclusive morphological complexity of brown algae.

Alginates are synthesized in the Golgi apparatus and are transported in GA-derived vesicles to cell wall expansion sites at the cell surface (Schoenwaelder and Wiencke 2000; Callow et al. 1978; Nagasato et al. 2010; Nagasato and Motomura 2009). During cytokinesis, alginates are found in electron-dense vesicles at the growing septum, and vesicle movement appears to be closely associated with actin dynamics. In *Dictyota*, alginate processing is also involved in the formation of plasmodesmata (Terauchi et al. 2012). Recent investigations into the molecular genetics of alginate biosynthesis have shown that the guluronic acid residues of alginates are remodeled during development and in response to environmental conditions by mannuronate C5-epimerases (Michel et al. 2010).

Fucoidans of brown algae are alpha-L-fucose-rich polysaccharides that display considerable structural diversity. Some fucoidans are highly sulfated homofucans while others are highly substituted with xylose, galactose, mannose, and glucuronic acid (Popper et al. 2011; Jeon et al. 2011). Sulfation is a distinguishing characteristic of many marine algal polysaccharides and is associated with adhesion. Fucoidans are also produced in the GA, packaged in vesicles and delivered to wall growth zones via actin-mediated transport. In *Silvetia*, fucoidans are the dominant polysaccharide in the cytokinetic region (Nagasato et al. 2010).

Brown algae display a variety of expansion patterns including both tip-based and diffuse growth mechanisms (Bisgrove and Kropf 2001). This allows for the formation of diverse morphologies including simple filaments, flattened blades, and large cones. During expansion and morphogenesis, it is thought that interactions of transmembrane proteins with components of the extracellular matrix are key to development (Le Bail et al. 2011; Fowler et al. 2004). Additionally, tip-based growth requires specific coordination of cortical Ca^{2+} gradients, the targeted fusion of vesicles at the expansion tip, spatial regulation of the secretion of cell wall components, and regulation of actin cytoskeleton dynamics. In the well-studied *Fucus distichus*, polar growth is regulated by Rho GTPases that are associated with actin assembly at tip and vesicle secretion (Katsaros et al. 2003).

6 The Matrix of Red Algae

Red algae produce matrices rich in sulfated polysaccharides (Painter 1983; Popper et al. 2011; Kloareg and Quatrano 1988; Rinaudo 2007; Craigie 1990). The most common are sulfated galactans (sulfation percentages of 20–38 %) containing a

backbone of repeating galactose (Gal) and 3,6-anhydrogalactose-linked β1-4 and β1-3, respectively. These polysaccharides are exemplified by the commercially important agars and carrageenans. The geographic positioning of the various galactans in the red algal thallus may be critical for calcification process common to many red algae (Martone et al. 2010). Likewise, competent secretion of matrix polysaccharides of the cell wall may be critical for maintenance of anterior-posterior axis of the thallus including the production of monospores (Li et al. 2008). Matrix polymers are processed in the Golgi apparatus and unique mucilage sacs that are associated with the endoplasmic reticulum (Ramus 1972; Tsekos 1981).

6.1 Arabinogalactan Proteins

In addition to polysaccharides, the matrix of cell walls may also contain an assortment of nonenzymatic and enzymatic proteins; arabinogalactan proteins or AGPs are hydroxyproline-rich glycoproteins (HRGPs) found on plant cell surfaces, specifically the cell wall and surrounding loci (Showalter 2001; Nguema-Ona et al. 2012). AGPs have diverse functions including playing important roles in growth, development, and adhesion (Ellis et al. 2010). These nonenzymatic proteins are highly glycosylated with the carbohydrate moiety often constituting 90 % or more of the mass of the molecule. The protein component of an AGP is characterized by alanine-hydroxyproline (Ala-Hyp) repeat motif interspersed with serine (Ser). *O*-glycosylation of specific amino acid residues is common with either short arabinose oligosaccharides or large β1-3-linked galactans containing 1,6-linked side chains of Gal, arabinose, rhamnose, and glucuronic acid. Repeating Ser $(Hyp)_4$ units in the protein are sites of *O*-glycosylation with the short arabinose side chains while the larger arabinogalactosyl side chains are more commonly situated on Ser, Ala, valine (Val), or threonine (Thr). Some AGPs have glycosyl-phosphatidylinositol (GPI) for anchorage in the plasma membrane. Recently, Tan et al. (2013) showed that in *Arabidopsis*, AGP is connected to HG/RG-I pectins and hemicellulosic arabinoxylan. This, in turn, suggests that wall polymers form large macromolecular complexes of interacting polymers. AGPs have been found in all land plant groups (Nguema-Ona et al. 2012; Lee et al. 2005), and recently, AGP epitopes have been identified in green algae including the CGA (Sørensen et al. 2011). More specifically, AGP-like epitopes were identified in the cell wall of the CGA including *Closterium acerosum* (Baylson et al. 2001), pore complexes of *Pleurotaenium trabecula* (Domozych et al. 2007b), and in the primary cell wall and pores of the secondary cell wall of *Micrasterias* (Eder et al. 2008). In *Micrasterias*, AGPs are first noted in Golgi bodies and then in primary wall vesicles and a group of 160–300 nm mucilage vesicles before release to the cell wall. AGPs have also been identified in the chlorophyte, *Oedogonium* (Estevez et al. 2008). Green algal AGPs appear to have some distinct differences to those found in land plants. For example, green algal AGPs have not been shown to bind to, or be

affected by, β-Yariv reagent, an agent commonly used for isolating and quantifying to land plant AGPs (Willats and Knox 1996).

6.2 Extensin

Extensins represent a second group of HRGPs found in plants and some algae. They possess a characteristic Ser-$(Hyp)_4$ repeat motif and are also significantly *O*-glycosylated (Lamport et al. 2011; Wilson and Fry 2006). In plants, they are synthesized in the Golgi apparatus and are transported to the cell surface by Golgi-derived vesicles. Once secreted, they self-assemble to form a scaffolding in the cell wall and function in maintaining wall architecture, increasing tensile strength of wall, cell plate formation, and defense responses (Velasquez et al. 2011). In green algae, extensin-like proteins have been found in CGA (Sørensen et al. 2011) and, most prominently, in the volvocalean taxa of the Chlorophyceae (Ertl et al. 1992; Roberts et al. 1985; Roberts 1974).

The cell wall of the unicellular flagellated chlorophyte, *Chlamydomonas reinhardtii*, contains 25–30 different extensin-like HRGPs (Sumper and Hallmann 1998) that are arranged in interlocking fibrillar and granular elements (Voight and Frank 2003) to form a "crystalline cell wall." These HRGPs are also components of gametic membranes and sexual agglutinins (Imam et al. 1985; Woessner and Goodenough 1994). In the colonial flagellate, *Volvox*, HRGPs make up rod-shaped modules and are combined with hydroxyproline-free domains to form the complex ECM including the colonial matrices (Kirk et al. 1986). These extensin-like HRGPs self-assemble into their wall/matrix upon secretion. During development of the glycoprotein cell wall of *Chlamydomonas*, the first elements to emerge during wall synthesis are long fibers that constitute the innermost and outermost wall layers. The other wall layers assemble later within this primary matrix (Goodenough and Heuser 1988). Prolyl-4-hydroxylase is an important enzyme in modeling of these HRGPs (Keskiaho et al. 2007). Disruption of its activity through knockdown genetics leads to highly abnormal cell walls lacking the typical multilayered ultrastructure (Goodenough and Heuser 1988). The cell biology of cell wall development has been studied in the volvocalean unicell, *Gloeomonas kupfferi*. Here, the inner wall layer is formed in the Golgi apparatus and transported initially to the contractile vacuole. It is then released from the vacuole to the anterior cell surface where it initiates self-assembly of the glycoprotein wall (Domozych and Dairman 1993).

Cell wall proteins like extensin have also been identified in other algal taxa. In the green alga, *Botryococcus braunii*, an alga of considerable importance in the biofuel industry, the colonial habit is maintained by a retaining thick wall/sheath (Weiss et al. 2012). This ECM consists of β1-3 and β1-4 glucans, a distinct polysaccharide-containing arabinose, galactose, and a small amount of deoxyhexoses as well as an extensin-like protein. Extensin-like proteins have also been found in chlorophyte green algae such as *Codium* and *Oedogonium* (Estevez et al. 2008, 2009.

7 Other Cell Wall Features: Lignins and Mineralization

The cell walls of plants and photosynthetic eukaryotes may also contain significant amounts of constituents other than carbohydrates and proteins. Their presence is often associated with specific phases of wall development or with specific taxa. These include:

Lignin constitutes a complex group of aromatic heteropolymers that are products of oxidative combinatorial coupling of 4-hydroxyphenylpropanoids (da Costa et al. 2014; van Holme et al. 2010: Boerjan et al. 2003; Ralph et al. 2004) including p-hydroxyphenyl, guaiacyl, and syringyl subunits (Bonawitz and Chapple 2010) Lignin is most commonly found in the secondary cell walls of land plants but may also be produced in response to wounding, stress, or infection (Caño-Delgado et al. 2003; Tronchet et al. 2010). Lignin and its specific binding pattern to cellulose contribute significantly to cell wall rigidity and resistance to degradation (Ding et al. 2012; Vanholme et al. 2010). Lignin-like polymers have recently been identified in late divergent taxa of CGA (Sørensen et al. 2011) and in the red alga, *Calliarthron cheilosporioides*, an organism found in high-energy surf habitats of marine intertidal zones (Martone et al. 2010).

Significant mineral complexing is characteristic of the cell walls of many plants and algae. For example, in the early divergent vascular plant, *Equisetum*, silica binds to specific wall polymers including 1–3 glucan or callose. It is believed that silica enhances rigidity and defense against biotic and abiotic stresses (Law and Exley 2011; Currie and Perry 2009). Ca^{2+} is also a common component of cell walls especially in its cross-linking with pectins (Hepler 2005; see Sect. 4). Significant calcification though that leads to a highly mineralized cell wall is commonly found in charophytes like *Chara* (Proseus and Boyer 2008) and in red algae, especially many taxa found in coral reefs (Craigie 1990; Kloareg and Quatrano 1988). However, one of the most spectacular calcification processes in an ECM of a photosynthetic eukaryote occurs in haptophytes or prymnesiophytes (Graham et al. 2009). The covering of many taxa within this algal group is characterized not by a cell wall but by a coccosphere that is comprised of multiple plate-like coccoliths (Marsh 1999). A coccolith consists of an organic base plate to which calcite is complexed Mackinder et al. 2010). Coccolith production has major ecological significance as it is responsible for up to 89 % of the total burial flux of calcium carbonate to ocean sediments (Mertens et al. 2009). The production of the coccolith in some taxa (e.g., *Emiliania*) initiates in the Golgi apparatus and a Golgi-derived coccolith vesicle (CV). The distal portion of this vesicle consists of a distinct reticular body that is comprised of a continuously changing membranous mass containing organic material derived from the Golgi body and endoplasmic reticulum. The reticular body becomes closely associated with the CV from the time of crystal nucleation to secretion (Kayano et al. 2010; Marsh 1999; Taylor et al. 2007; Brownlee and Taylor 2004). It is thought that these features provide an important regulatory role of the reticular body in supplying the organic and inorganic materials required for calcification (Drescher et al. 2012). Likewise, the reticular body might provide a large surface area that could accommodate vast

numbers of Ca^{2+}- and perhaps bicarbonate ion pumps. This would provide a supersaturated solution of cations during calcite nucleation and growth. V- and P-type of Ca^{2+}-stimulated ATPases are also involved in the coccolith biosynthesis (Corstjens and González 2004: Corstjens et al. 2001; Araki and Gonzales 1998). Nucleation and growth of the calcite crystals are also controlled by an organic base plate scale in association with acidic polysaccharides and proteins (Hirokawa et al. 2005; Kayano et al. 2010; Shroeder et al. 2005). It is also been shown that both microtubules and microfilaments are involved in coccolith formation (Langer et al. 2010).

8 "Ancestral Precursors" of the Cell Wall?: Scales and Fused Scales

Many early divergent green algal flagellates (e.g., prasinophytes; Leliaert et al. 2012) are covered with a single layer or multiple layers of scales that sometimes number in the thousands (Moestrup and Walne 1979). Scales are composed of 90 % polysaccharide that contains the unusual 2-keto-sugar acids, Kdo (3-deoxy-2-manno-octulosonic acid), 5-*O*-methyl Kdo, and 3-deoxy-2-lyxo-heptulosaric acid (Becker et al. 1994). Additionally, scales may be associated with small amounts of protein that may be involved in adhesion of scales to the cell surface (Becker et al. 1996). Scales are also found in the early divergent clade of the CGA, the Mesostigmatophyceae, represented by *Mesostigma viride*. Here, an outermost layer of scales, typically numbering 800 per cell, overlays an inner layer of small scales. These outer scales manifest in a spectacular "basket" shape and contain glucose, 3-deoxy-lyxo-2-heptulosaric acid, and two protein components (Domozych et al. 1991). In prasinophytes and *Mesostigma*, scale synthesis occurs in the Golgi apparatus. Individual scale types may be observed being formed and maturing in Golgi cisternae. The scales are segregated into vesicles and are carried to a vacuole-like scale reservoir where they are arranged and then deposited onto the cell and/or flagellar surfaces (Moestrup and Walne, 1979; Domozych et al. 1991).

The green algal flagellates, *Tetraselmis* and *Scherffelia*, possess a cell wall-like covering, called a theca, that is derived ontogenetically from fused scales (Domozych et al. 1981; McFadden and Melkonian 1986). The theca contains no cellulose but consists of a polysaccharide containing 50 % Kdo and 15 % GalA (Vierkotten et al. 2004; Becker et al. 1995). Scale-like thecal precursors are synthesized in the Golgi apparatus and are transported to the anterior region of the cell by Golgi-derived vesicles. Here, they are released to the surface where they coalesce to form the theca. During this stage, pre-theca components are converted to complete theca by the addition of long Kdo chains substituted with sulfated GalA disaccharides that are cross-linked by Ca^{2+} (Becker et al. 1994). For scaly and thecate green algae, virtually nothing is known about the molecular genetics of the biosynthesis of the extracellular coverings.

9 Conclusions

Studies of the cell wall are currently in an exciting phase as most structural, chemical, developmental, and evolutionary features of the wall remain to be discovered. The recent emergence of new and powerful analytical tools and their application in cell wall studies are rapidly providing critical data in the deciphering of the infrastructure and dynamics of the cell wall. These include genomic and transcriptomic sequencing and analyses of a greater taxonomic array of organisms, high-throughput screening of wall polymers using the expanding library of specific monoclonal antibodies and carbohydrate-binding modules, and the dissection of the nanostructure of the cell wall with new high-resolution microscopy technologies including immuno-based probing, electron tomography, and atomic force microscopy. This new research has resulted in valuable new insight into the complex glycomics of the wall, the highly coordinated genetic machinery required for wall synthesis and metabolism that interacts with precise developmental phases and in response to environmental stress, and the interactions of constituent polysaccharides, proteins, and other constituents. This new era of research holds much promise for the elucidation of the evolution and diversity of the cell wall and its application to economic and environmental activities.

Contents

Abstract

Bacterial cell wall and membrane are associated with a variety of glycoconjugates and polysaccharides which aids in structural formation as well as performing various functions in the bacterial cell. In gram-negative bacteria, peptidoglycan is majorly present in the periplasmic space and it provides mechanical strength as well as shape to the cell. In some cases, the periplasm contains membrane-derived oligosaccharides (MDOs), which are involved in osmoregulation. The outer membrane mainly contains lipopolysaccharides (LPSs) that bind to divalent cations or chelators for structure stabilization and to increase outer membrane permeability. This LPS contains lipid A, also known as endotoxin, which has shown a powerful biological effect in mammals such as fever, septic shock, multiple organ failure, and mortality. The mucoid (slime-producing) strains contain capsular polysaccharide which

aids as virulence factor. The gram-positive bacteria lack an outer membrane and have a much thicker peptidoglycan layer along with a specialized polysaccharide known as teichoic acid. It provides cell wall integrity through complex formation with cations and also assists in cell growth regulation. The present report attempts to provide an overview of bacterial polysaccharide structure, occurrence, and their important functions, along with the biosynthesis and major inhibitors to block biosynthetic pathways.

Keywords

Peptidoglycan • Teichoic acid • Bacterial glycoproteins • Membrane-derived oligosaccharides • Lipopolysaccharides • Capsular polysaccharide

Abbreviations

ABC	ATP-binding cassette
ACP	Acyl carrier protein
CPS	Capsular polysaccharide
Gal	Galactose
Glc	Glucose
GlcNAc	*N*-Acetylglucosamine
GT	Glycosyltransferase
HMM-PBPs	High molecular mass PBPs
LAL assay	Limulus amebocyte lysate assay
LOS	Lipooligosaccharides
LPS	Lipopolysaccharides
LTA polymers	Lipoteichoic acid polymers
LDAP	L-Diaminopimelic acid
Man	Mannose
MDOs	Membrane-derived oligosaccharides
MurNaC	*N*-Acetylmuramic acid
NBD	Nucleotide-binding domain
OPGs	Osmoregulated periplasmic glucans
PBPs	Penicillin-binding proteins
PG	Lysophosphatidylglycerol
WTAs	Wall TAs

1 Introduction

In nature, mostly the carbohydrates exist as polymers rather than monomers. In this context, polysaccharides are believed to be the most abundant polymeric carbohydrate. These polymers consist of ten or more simple sugar units and composed of thousands or hundreds of thousands of simple sugars which are bonded together by glycosidic bonds so as to have molecular masses as high as 100 million atomic mass units. The main function of the polysaccharide is determined by the monomers it

contains or the manner in which they are linked together. Polysaccharides present in plants, animals, and bacteria are majorly responsible for their structural and functional roles. The most common polysaccharides are cellulose in plants and glycogen in animals. They act as storage polysaccharides while certain others provide the structural support and are known as structural polysaccharides. Among the structural polysaccharides is chitin which is generally present in invertebrate animals.

On the basis of morphological localization, bacterial polysaccharides could be divided into groups: intracellular polysaccharides which are located inside or as part of the cytoplasmic membrane or cell wall such as peptidoglycan, periplasmic glucans, lipopolysaccharide (LPS), lipooligosaccharide (LOS), and capsular polysaccharides which form a structural part of the cell wall (Chawla et al. 2009) or the extracellular polysaccharides also known as exopolysaccharides consisting of branched, repeating units of sugars or sugar derivatives. Extracellular polysaccharides are further classified as: homopolysaccharides (cellulose, dextran, pullulan, curdlan) and heteropolysaccharides (gellan, xanthan) on the basis of the sugar or its derivative a particular molecule contains. Bacteria and many other microbes including fungi and algae often secrete diverse polysaccharides as an evolutionary adaptation to help them adhere to the surface as part of the cell wall component or storage units or virulence factors and also to prevent them from drying out. Exopolysaccharides have shown wide industrial applications mainly in food and pharmaceutical products and to certain extent in textile, paper, and cosmetics, as gelling agents and medicines for wound dressings (Sutherland 1998). In context to exopolysaccharides, accumulation of polyhydroxybutyrate (PHB) has been extensively studied. This is a kind of polyesters which is synthesized by a number of microorganisms as energy reserve materials under unfavorable conditions, i.e., in the limitation of some essential nutrients under an excess availability of carbon source (Lee 1996; Khanna and Srivastava 2005). The properties of pure PHB are comparable to the commonly used petroleum-derived bulk plastics, e.g., polypropylene. It is a unique natural biopolymer, which exhibits three exceptional features (Hrabak 1992): (i) thermoplastic process ability, (ii) 100 % resistance to water and moisture, and (iii) 100 % biodegradability. It could therefore be used for applications similar to those of common plastics and would fit well into new waste disposal and management strategies. While working with PHB production, it was observed that the fermented broth containing 125 gl^{-1} of sucrose had resulted in 22.65 gl^{-1} of PHB from 29.7 gl^{-1} of dry cell weight (DCW) in 38 h at 33 °C, 200 rpm by *A. australica* using constant feed rate (100 ml/h for 15 h) in fed-batch cultivation (Gahlawat and Srivastava 2013). Recently, an attempt has been made on the usage of renewable resources such as glycerol (biodiesel by-product) in order to make the process sustainable and cost effective and ensure renewabilities. The microorganisms investigated in the present study using these categories of substrates are *Alcaligenes latus*, *Ralstonia eutropha*, and *Bacillus* sp. (data not shown). The biopolymer produced by *Bacillus* sp. will be suitable for medical use, and to develop an efficient production process, studies are continuing in author's laboratory.

In the light of the current state of the art on bacterial intracellular polysaccharides, the bacterial cell wall deserves special attention as it is important for maintaining the cell viability by protecting the cell protoplast from mechanical damage either through osmotic rupture or lysis. The bacterial cell wall is composed of various unique components which are not present in nature; it is also believed to be the most important site for the attack by antibiotics. The cell wall provides ligands for the adherence and also the receptor sites for drugs or viruses. They provide immunological distinction among the bacterial strains (Todar 2011).

Realizing the important features of bacterial cell wall, this communication attempts to elucidate varied bacterial intracellular polysaccharide characteristics which are generally present in the cell wall or in the cellular membrane, their structure, occurrence, importance, or the functional role played in the cell, and its applications for human welfare and future prospects.

2 Peptidoglycan

Peptidoglycan (murein) is a polymer consisting of sugars and amino acids that forms a mesh-like layer outside the plasma membrane of bacteria (except Archaea), which forms the cell wall. The peptidoglycan in most of the gram-negative bacteria consists of alternating residues of β-1,4-linked *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNaC). *N*-acetylmuramic acid is attached covalently to short tetrapeptide chains which are composed of L-Ala, unusual D-amino acids (D-Glu and D-Ala), and L-diaminopimelic acid (LDAP). These unusual D-amino acids do not generally occur in proteins and therefore help to protect against the attacks by most peptidases. The tetrapeptide side chains could also be linked to one another by an interpeptide bond between a free amino group on diaminopimelic acid (DAP) of one chain and free carboxy group on nearby D-Ala on the other tetrapeptide side chain of *N*-acetylmuramic acid (Fig. 1).

The assembly of peptidoglycan on the outside of the plasma membrane is mediated by a group of periplasmic enzymes, which are transglycosylases, transpeptidases, and carboxypeptidases. These enzymes are designated as penicillin-binding proteins

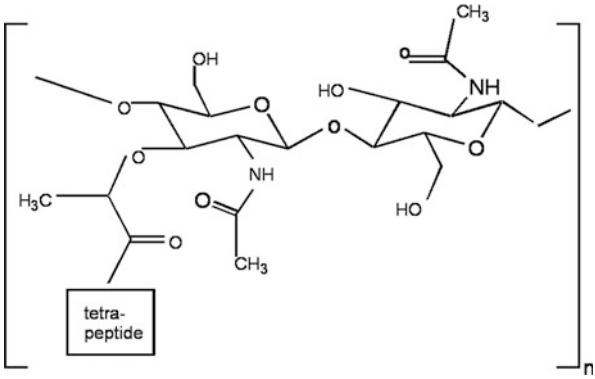

Fig. 1 Structure of peptidoglycan

(PBPs) being specific targets of the β-lactam antibiotics and are involved in the late stages of peptidoglycan synthesis which aids in the formation of a 3D mesh-like layer and a strong and rigid cell wall. Penicillin-binding proteins (PBPs) vary from species to species in number, size, amount, and affinity for β-lactam antibiotics. The high molecular mass PBPs (HMM-PBPs) mainly consist of two domain proteins that either belong to class A or class B, depending on the structure and the catalytic activity of their N-terminal domain (Heijenoort 2001). The C-terminal domain of both classes is responsible for transpeptidation activity, and β-lactam antibiotics covalently bind to its catalytic center. In class A HMM-PBPs, the N-terminal domain is responsible for their transglycosyltransferase activity, while, in the case of class B, the N terminal is involved in the interactions with other membrane proteins (Marrec-Fairley et al. 2000). It is well understood that class A HMM-PBPs are bifunctional enzymes capable of catalyzing both transglycosylation and transpeptidation.

The peptidoglycan layer is substantially thicker in the gram-positive bacteria (20–80 nm) as compared to gram-negative bacteria (7–8 nm) with the attachment of S-layer. Gram-positive bacteria are more sensitive to penicillin than gram-negative bacteria because the peptidoglycan is not protected by an outer membrane and is a more abundant molecule. In gram-positive bacteria, there are numerous different peptide arrangements among peptidoglycans. The best-studied murein is of *Staphylococcus aureus* wherein in place of diaminopimelic acid (DAP) as present in *E. coli* is diamino acid or L-lysine in position 3 of the tetrapeptide side chain, and the interpeptide bridge of amino acids connects a free amino group on lysine to a free carboxy group on D-Ala of a nearby tetrapeptide side chain. This arrangement allows a more frequent cross bonding between nearby tetrapeptide side chains. The free amino group of L-lysine is substituted with a glycine pentapeptide which then becomes an interpeptide bridge forming a link with a carboxy group from D-Ala in the adjacent tetrapeptide side chain as in the case of *S. aureus*. There are at least eight different types of peptidoglycan which exist in gram-positive bacteria and differ from species to species mainly with respect to the amino acids present in the third position of the tetrapeptide side chain and in the amino acid composition of the interpeptide bridge. The assembly of interpeptide bridge in gram-positive murein is inhibited by beta-lactam antibiotics (penicillin) in the same manner as the interpeptide bond in gram-negative murein.

Peptidoglycan forms 90 % of the dry weight of gram-positive bacteria but only 10 % for gram-negative strains. The cross-linked structure confers mechanical strength to cells and its desired shape in order to withstand internal osmotic pressure. It has sufficient plasticity to allow cell growth (elongation) and division (septation).

2.1 Biosynthesis of Peptidoglycan

The biosynthesis of peptidoglycan has been reported by various researchers in different microorganisms for both gram-positive and gram-negative bacteria (Matsuhashi 1994; Van Heijenoort 1998).

The peptidoglycan monomers are synthesized in the cytosol and are then attached to a membrane carrier bactoprenol. Bactoprenol transports peptidoglycan monomers across the cell membrane where they are inserted into the existing peptidoglycan. In the first step of the peptidoglycan synthesis, the glutamine, which is an amino acid, donates an amino group to sugar, fructose 6-phosphate. This converts fructose 6-phosphate into glucosamine-6-phosphate. In step two, an acetyl group is transferred from acetyl CoA to the amino group on the glucosamine-6-phosphate, creating *N*-acetylglucosamine-6-phosphate. In step three of the synthesis process, the *N*-acetylglucosamine-6-phosphate is isomerized, which will change *N*-acetylglucosamine-6-phosphate to *N*-acetylglucosamine-1-phosphate. In step four, the *N*-acetylglucosamine-1-phosphate, which is now a monophosphate, attacks the uridine triphosphate (UTP), which is a pyrimidine nucleotide and has the ability to act as an energy source. In this particular reaction, after the monophosphate has attacked the UTP, an inorganic pyrophosphate is released and is replaced by the monophosphate, creating UDP-*N*-acetylglucosamine. (When UDP is used as an energy source, it gives off an inorganic phosphate.) This initial stage is used to develop the precursor for the NAG in peptidoglycan. In step five, some of the UDP-*N*-acetylglucosamine (UDP-GlcNAc) is converted to UDP-MurNAc (UDP-*N*-acetylmuramic acid) by the addition of a lactyl group to the glucosamine. Also in this reaction, the C3 hydroxyl group will remove a phosphate from the alpha carbon of phosphoenolpyruvate. This creates what is called an enol derivative that will be reduced to a "lactyl moiety" by Nicotinamide Adenine Dinucleotide Phosphate (NADPH) in step six. In step seven, the UDP-MurNAc is converted to UDP-MurNAc pentapeptide by the addition of five amino acids, usually including the dipeptide D-alanyl-D-alanine. Each of these reactions requires involvement of the energy source Adenosine triphosphate (ATP). The above reactions are referred to as stage one. Stage two occurs in the cytoplasmic membrane. It is in the membrane where a lipid carrier called bactoprenol carries peptidoglycan precursors through the cell membrane. Bactoprenol will attack the UDP-MurNAc penta, creating a PP-MurNac penta, which is now a lipid. UDP-GlcNAc is then transported to MurNAc, creating lipid-PP-MurNAc penta-GlcNAc, a disaccharide and also a precursor to peptidoglycan. How this molecule is transported through the membrane is still not clear. However, once it is there, it is added to the growing glycan chain. The next reaction is known as transglycosylation. In this reaction, the hydroxyl group of the GlcNAc will attach to the MurNAc in the glycan, which will displace the lipid-PP from the glycan chain. The enzyme responsible for this reaction is transglycosylase (White 2007).

2.2 Inhibitors for Peptidoglycan Synthesis

Glycopeptides and moenomycins are best-studied groups of antibiotics which interfere with the transglycosylation reaction (Reynolds 1989) though their mode of action varies, but they have certain common features such as large molecular masses, no cell penetration, preferential in vivo action on gram-positive

microorganisms, and an accumulation of peptidoglycan precursors in intact cells and in cell-free systems. The non-penetration of such inhibitors further substantiates the localization of the polymerization reactions on the outside of the cytoplasmic membrane. Realizing this, Salton and Kim (1996) stated that there are certain antibacterial drugs such as penicillin which interferes with the production of peptidoglycan by binding itself to the bacterial enzyme such as transpeptidases or penicillin-binding protein or carboxypeptidases and thereby forming the loosely woven structure by inhibiting the cross-linking of tetrapeptide chain with another chain. Vancomycin binds or forms complex with D-Ala-D-Ala dipeptide of exported lipid II or with those of nascent peptidoglycan. It is either both mechanisms are functioning in vivo or one of them is prominent. In the first case, wherein antibiotic complexed with lipid II, the resulting segregation of the lipid substrate will lead to an arrest of the glycan chain elongation, while, in the second case, the binding with peptide subunits of growing chains can have a shielding effect by steric hindrance on both transglycosylation and transpeptidation reactions. While mutation in the gene which codes for transpeptidases or ligase leads to reduced interaction with an antibiotic, a strong and rigid 3D mesh-like layer is formed which could be due to the phenomenon known as antibiotic resistance (Spratt 1994).

In nature, human body synthesized the antibiotic lysozyme found in tears which breaks the β-1,4-linked *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNaC) in peptidoglycan primarily to destroy the bacterial cells. This phenomenon has been explored in research laboratories mainly to break the cell walls of gram-negative bacteria as lysozyme-treated bacterial cells are osmotically sensitive and easily disrupted by shearing. Homogenization followed by density gradient centrifugation separates the cytosol and inner membrane as well as outer membrane. Certain archaea have shown the presence of a similar layer of pseudopeptidoglycan or pseudomurein wherein the sugar residues are β-1,3-linked *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNaC).

3 Teichoic Acids

Teichoic acid is a major class of cell surface glycopolymers and is found within the cell wall of gram-positive bacteria such as species in the genera *Staphylococcus*, *Streptococcus*, *Bacillus*, *Clostridium*, *Corynebacterium*, and *Listeria* and appears to extend to the surface of the peptidoglycan layer. These are linear polymers of polyglycerol or polyribitol substituted with phosphates and a few amino acids and sugars linked via phosphodiester bonds. There are two types of teichoic acid: the lipoteichoic acid (LTA) polymers which contain a reducing terminal phosphatidic acid, occasionally anchored to the plasma membrane and is extended from the cell surface into the peptidoglycan layer, and the wall TAs (WTAs) which are covalently attached to peptidoglycan and extended through and beyond the cell wall. All the teichoic acids bound to peptidoglycan appear to be linked by a conserved linkage unit consisting of ManNAc-GlcNAc-1-P linked to C6 of a MurNAc residue. The chemical structure of WTAs is composed of ManNAc-(β 1→4)-GlcNAc

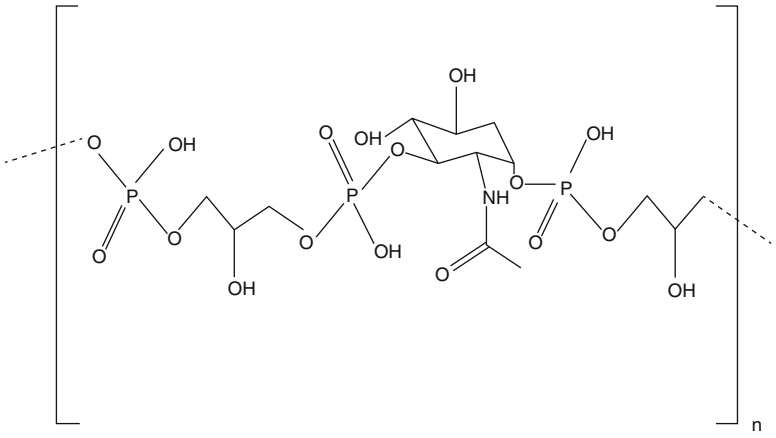

Fig. 2 Structure of teichoic acid

disaccharide with one to three glycerol phosphates attached to the C4 hydroxyl of the ManNAc residue (the "linkage unit") followed by a much longer chain of glycerol or ribitol phosphate repeats (the "main chain") (Fig. 2).

The exact function of teichoic acid in bacterial physiology is still not known though it is believed to be essential for the viability of gram-positive bacteria. There are certain evidences which elucidate the understanding of the important functions involved behind teichoic acids. The WTAs provide a channel of regularly oriented negative charges for threading positively charged substances through the complicated peptidoglycan network. The network of WTA-coordinated cations affects the overall structure of the polymers and this in turn influences the porosity and rigidity of the cell envelope. The WTA plays an important role in terms of cation homeostasis in gram-positive bacteria and provides a reservoir of ions close to the cell surface that might be required for enzyme activity (Marquis et al. 1976; Swoboda et al. 2010). In the past few years, researchers have tried to focus on the three-dimensional structure of WTAs and their bound cation group so as to elucidate the modes of cation binding to WTA polymer phosphate groups and to get an insight for designing the novel antimicrobials (Wickham et al. 2009). The other function is that wall teichoic acids (WTAs) are involved in the interaction of bacterial cells with the environment. WTAs in certain ways are involved in the regulation and assembly of muramic acid subunits on the outside of the plasma membrane. There are instances mainly for *Streptococci*, wherein teichoic acids have been involved in the adherence to the tissue surfaces. If these gram-positive bacteria lack or have defective WTAs, then there are a reduced initial adherence to artificial surfaces and also impaired ability to form biofilms. Contrary to other findings, Aly et al. (1980) mentioned in their study that impaired WTA does not exhibit reduced production of poly-*N*-acetylglucosamine (PNAG), the exopolysaccharide which is mainly involved in biofilm formation. Therefore, this suggests that WTAs played an independent role for biofilm formation. WTA is believed to be a virulent factor

and is required for host infection. Therefore, the enzymes involved in WTA biosynthesis were thought to be the targets for novel antimicrobials that could slow down colonization by gram-positive bacteria in the host cell. LTAs and WTAs have also shown to possess an important role in cell growth, division, and morphogenesis. In this context, Schirner and their coworkers indicated that in the absence of WTA expression, round and severely defective progeny is produced, while, during a defective gene expression of the biosynthesis of LTA, could hinder in septum formation and cell separation (Schirner et al. 2009). It was also suggested that the biosynthetic enzymes of WTA are associated with the machinery involved in elongation, while the biosynthetic enzymes involved for LTA might be associated with the machinery involved in septation and cell division.

3.1 Biosynthesis of Teichoic Acid

The pathway for WTA biosynthesis has been discussed here for *B. subtilis* 168 [synthesizes poly (glycerol phosphate) WTA], *B. subtilis* W23, and *S. aureus* [synthesizes poly (ribitol phosphate) WTA].

3.1.1 Biosynthesis of Poly (Glycerol Phosphate) WTA

Ward (1981) described that the pathway for the biosynthesis of poly (glycerol phosphate) WTAs was first characterized in *B. subtilis* 168. *tag* genes (also known as teichoic acid glycerol genes) were involved during biosynthesis. The pathway begins in the cytoplasm wherein the reversible enzyme TagO, which belongs to the family of phosphosugar transferases, could transfer GlcNAc phosphate to an undecaprenyl phosphate (also known as bactoprenyl phosphate) carrier which is anchored in the bacterial membrane. After catalyzing the reaction by TagO, the GlcNAc-PP-lipid is formed. Another enzyme, *N*-acetylmannosaminyl transferase (TagA), catalyzes the transfer of ManNAc from UDP-ManNAc to the C4 hydroxyl of the GlcNAc residue in order to form a β-linked disaccharide, which will now act as the substrate for the next enzyme in the pathway, TagB (Zhang et al. 2006). In order to complete the synthesis of the linkage unit, TagB, also known as glycerophosphate transferase enzyme, is involved which could transfer a single phosphoglycerol unit from CDP-glycerol to the C4 hydroxyl of ManNAc (Bhavsar et al. 2007). After the linkage unit formation, TagF (polymerizing cytidylyltransferase) could catalyze the attachment of 35 or more glycerol phosphates to the linkage unit in order to form an anionic polymer (Schertzer and Brown 2008). Once assembled, the lipid-linked WTA polymer is putatively modified by a glycosyltransferase (TagE) and then exported to the external surface of the bacterial membrane by a two-component ABC (ATP-binding cassette) transporter, TagGH (Lazarevic and Karamata 1995). The anomeric phosphate of the GlcNAc residue couples the polymer to peptidoglycan and esterified with D-alanine residues. The enzyme which could catalyze this reaction has till date not been identified though it belongs to the class of transferase enzyme.

3.1.2 Biosynthesis of Poly (Ribitol Phosphate) WTA in *B. subtilis* W23

Lazarevic and coworkers studied the pathway for the biosynthesis of poly (ribitol phosphate) WTA in *B. subtilis* W23 and reported that the genes involved were designated as *tar* genes (for teichoic acid ribitol) (Lazarevic et al. 2002). The initial three steps which were mediated by TarO, TarA, and TarB were identical to those in *B. subtilis* 168. Thereafter, pathways diverged wherein the TarF acts as primase and adds one additional glycerol phosphate unit to the 168-type linkage unit. Once the linkage unit is complete, the poly (ribitol phosphate) main chain is assembled. Lazarevic et al. proposed that the assembly of this poly (ribitol phosphate) chain requires two enzymes: TarK, which transfers a single ribitol phosphate residue to the linkage unit, and TarL, which carries out the polymerization of the ribitol phosphate chain. TarK and TarL in *B. subtilis* W23 were thus suggested to function as a primase/polymerase pair, analogous to the primase/polymerase pair (TagB/TagF) that assembles the poly (glycerol phosphate) chain in strain 168. Once the poly (ribitol phosphate) WTA polymer is assembled, the remaining steps are thought to be similar to those in strain 168. That is, the WTA polymer is glycosylated, transported through the bacterial membrane by a two-component transporter, TarGH, attached to peptidoglycan by an unidentified transferase, and esterified with D-alanine residues.

3.2 Inhibitors for Wall Teichoic Acid Biosynthesis

In the past few years, speculations are on that WTA biosynthetic pathway could be the site for the antibiotic, though still only one specific inhibitor has been reported (Swoboda et al. 2010). Swoboda and coworkers also stated that there are two distinct types of antimicrobial targets in the pathway: (1) antivirulent targets (TarO and TarA) and (2) antibiotic targets due to a mixed gene dispensability pattern. The inhibitors of the former slow down colonization and spread of infection, while inhibitors of the latter have shown to prevent bacterial growth. In this context, the inhibitors were evaluated for both target points.

Weidenmaier and coworkers were the first to suggest that the pathway for WTA biosynthesis is the site for antivirulence and had studied it for the case of *S. aureus* (Weidenmaier et al. 2004). Several researchers reported that there is a potent natural product inhibitor, the uridine-containing antibiotic tunicamycin for WTA biosynthesis (Hancock et al. 1976; Wyke and Ward 1977). Tunicamycin inhibits MraY, an enzyme, phosphosugar transferase activity (involved in the peptidoglycan biosynthetic pathway) which couples sugar phosphates to membrane-embedded lipid phosphates. Besides this, tunicamycin also inhibits TarO (Price and Tsvetanova 2007). It has been observed that tunicamycin is more selective for TarO over MraY, and due to this selectivity, it could shut off the in vitro WTA expression without affecting bacterial growth rates. Till date, researchers could not develop any other specific inhibitor or its homologue which could be used in place of tunicamycin for in vivo studies as this inhibitor is toxic to eukaryotes, so this strategy of inhibiting TarO gene involved during WTA biosynthesis could not be

worked out for treating *S. aureus* infections in humans. Therefore, there is a need to identify the nontoxic, selective inhibitors of TarO gene which are involved during the WTA biosynthetic pathway in order to cure different diseases.

The next target in the WTA biosynthetic pathway is the antibiotic target which was reported by Swoboda and coworkers (2010). Peschel and coworkers reported that *S. aureus* strains lacking WTAs are incapable of colonizing a host; however, these resistant mutants are not expected to survive in vivo (Peschel et al. 1999). But, Swoboda et al. pointed out that there are numerous other pathways that contain conditionally the essential enzymes linked to virulence factor expression. Many of these enzymes could be good antibiotic targets provided that the major mechanism for resistance involves deletion of the pathway and results in the production of avirulent organisms (Swoboda et al. 2010).

4 Bacterial Glycoproteins

Glycans are an important constituent of bacterial cell wall and of surface antigens such as lipopolysaccharides (LPSs) and capsular antigens which are attached by lipid anchors (lipid A or diacylglycerophosphates) in gram-negative bacteria (Gotschlich et al. 1981; Schmidt et al. 2003). These carbohydrate conjugates function as virulent factors which have been well documented in literature, while the structure-function relationships of bacterial cell surface lipoglycans have been elucidated. It aids in maintaining structural integrity and correct protein localization and in the induction of host responses (Beutler and Rietschel 2003).

In the past few decades, researchers thought that prokaryotes are incapable of glycosylating the proteins. But now, researchers have firmly established that there is a glycosylation of proteins in eubacteria which is due to the glycoprotein synthetic pathway being operated inside the prokaryotic cell (Power and Jennings 2003; Upreti et al. 2003). The protein glycosylation has initially been reported in Archaea and later in *Clostridia* which exhibited the glycosylated surface (S) layer proteins (Schaeffer and Messner 2001). Earlier, the presence of glycoproteins in bacteria was detected either through the formation of Schiff bases or by the specific binding of lectins. The type of glycosylation either N or O type could be distinguished by using endoglycosidases F (Endo F1, F2, F3, and D), PNGase F, or O-glycosidase in combination with the inhibitors such as bacitracin or tunicamycin which inhibits glycosylation.

4.1 Importance of Protein Glycosylation in Gram-Negative Bacteria

4.1.1 Flagellar Glycosylation and Motility

The *N*- or *O*-glycosylation of the peptide in bacteria could induce the host response by causing infection. In this context, in order to study the effect of protein glycosylation in bacteria on host's mechanism, *Campylobacter* spp. is considered

to be a prominent example as it is believed to be an agent which generally causes diarrhea. The flagellin, an immunodominant protein, is recognized as an essential constituent in flagella which could act as a virulence factor. The flagellins of *C. jejuni* and *C. coli* were found to be extensively glycosylated as reported by Guerry and coworkers (1996). In the case of *C. jejuni*, the glycoprotein structure has been revealed by Szymanski et al. wherein it was indicated that the carbohydrate structure has pseudaminic acid or its derivatives Pse5Am7Ac and Pse5Pr7Pr, which are linked to approximately 19 serine or threonine residues. These immunogenic substituents are clustered in the hydrophobic central core region, and the surface is exposed with flagella filaments (Szymanski et al. 2003). Reports suggest that adjacent to the flagellin structural genes in the genome of *C. jejuni* (NCTC 11168) lies the locus containing approximately 50 genes which represents the flagellin glycosylation machinery (Parkhill et al. 2000).

The other protein glycosylation locus (pgl) of 17 kb mediates the *N*-glycosylation of multiple proteins in *C. jejuni* and represents the first such pathway in gram-negative pathogens (Young et al. 2002). However, mutation in pgl genes affects glycosylation and also abolishes the recognition by polyclonal rabbit antiserum and by antibodies from humans which were infected with *C. jejuni*. Furthermore, insertional inactivation of pgl genes resulted in decreased adherence, invasion in vitro, and loss of intestinal colonization in mice (Szymanski et al. 2002). In addition to the nonflagellar glycoproteins PEB3, an immunoreactive surface protein (Cj0289c; Cj1670c) along with 22 periplasmic glycoproteins was identified. All the glycoproteins have a common oligosaccharide structure a-D-Galp-NAc-(1-4)-a-D-GalpNAc-(1-4)-a-D-GalpNAc [b-D-Glcp-(1-3)]-(1-4)-a-D-GalpNAc-(1-3)-b-D-Bac-(1,N)-Asn Xaa, where Bac is bacillosamine (2,4-diacetamido-2,4,6-trideoxyglucopyranose). Bacillosamine has also been found to be a constituent of LPS and capsular polysaccharide in other prokaryotes (Schaeffer et al. 2001; Schmidt et al. 2003). Szymanski and coworkers reported that PglB is a key enzyme in the pgl locus and probably acts as an oligosaccharide transferase mediating the N-linkage to the peptide backbone; however, any mutation in the pglB gene could totally abolish the glycosylation (Szymanski et al. 2003).

Motility is an important factor in *Helicobacter*-associated diseases. Flagella of gastric *Helicobacter* spp. (*H. pylori*, *H. mustelae*, and *H. felis*) exhibit two distinct flagellins, FlaA and FlaB. Mutants lacking FlaA have impaired motility and shortened flagella, while deletion of FlaB gene has shown only moderate effect (Schmidt et al. 2003).

4.1.2 Pili and Adhesions in Gram-Negative Bacteria

There are several gram-negative microorganisms wherein protein glycosylation in pili influences pathogenesis. Certain examples have been discussed here in this chapter.

In the case of *Haemophilus influenzae*, the infection is being caused through its attachment to the human epithelial cells which occurs by two related adhesions HMW1 and HMW2 being encoded by hmw1 and hmw2, and both genes are associated with hmwB and hmwC (Schmidt et al. 2003). Grass et al. described

that HMW1 is glycosylated and that HMWIC is needed for glycosylation. It was observed that the glycan moiety of HMW1 contains galactose (Gal), glucose (Glc), and mannose (Man) residues and requires the activity of phosphoglucomutase, which is involved in the lipooligosaccharide (LOS) biosynthesis pathway. Shedding of the non-glycosylated adhesins decreases the adherence to epithelial cells. Therefore, glycosylation directly modulates cellular interactions and might also influence pathogenesis (Grass et al. 2003).

In *Neisseria*, type IV pili aid in bacterial attachment to the host cell through the glycosylation of adhesins. Stimson et al. (1995) revealed that in *N. meningitidis* strain C311, there is an O-linked glycan substitution at serine residue 63 (Ser63) wherein pglA or pgtA (pilin glycosylation) gene could transfer the first a-(1, 3)-linked galactose to the diacetamido trideoxyhexose Ser63-substituent. On the other hand, certain researchers observed that strains which are deficient in pilin glycosylation could express more type IV pili along with an increased adherence to the epithelial cells but less resistance against solubilization were present (Marceau et al. 1998). Parge and coworkers deduced the structure of glycoprotein through electron density maps as a-Gal-(1, 3)-GlcNAc disaccharide which is being linked to Ser63 in *N. gonorrhoeae* strain MS11 pili (Parge et al. 1995). The homopolymeric guanosine tract identified in certain strains is basically involved in the phase variation of pglA expression which is associated with the conversion from uncomplicated gonorrhea to disseminated gonococcal infections (Banerjee et al. 2002).

4.1.3 Glycosylation of Surface and Membrane Proteins

Borrelia burgdorferi is the causative agent of Lyme disease. In this microbe, the major surface (lipo) proteins, i.e., OspA and OspB (31 and 34 kDa, respectively), are differentially expressed during the infectious cycle. However, at the time of infection, the presence of anti-Osp antibody prevents the disease by largely reducing or killing the spirochete population in the tick before transmission to the host (Schwan and Piesman 2002). In the present scenario, the human vaccine is based on OspA.

4.1.4 Pili and Adhesion in Gram-Positive Bacteria

Streptococcus parasanguis, being a gram-positive bacterium, colonizes on the tooth surface and plays a pivotal role in the development of dental plaque. Adhesion is mediated by the major fimbrial subunit Fap1, wherein 80 % of the Fap1 protein consists of dipeptide serine repeats. The glycopeptide showed the presence of Rha (rhamnose), Glc, Gal, GlcNAc, and GalNAc. The adherence properties of Fap1 are dependent on its glycan modification because monoclonal antibodies that blocked adhesion did not recognize recombinant Fap1, but were inhibited by a Fap1-derived glycopeptide and showed reduced binding to periodate-oxidized Fap1 (Stephenson et al. 2002).

4.1.5 Glycosylation of Cell Wall and Secreted Proteins

Streptococcus mutans is largely responsible for human dental caries and occasionally causes infective endocarditis in predisposed patients. An immunodominant cell

wall-associated glycoprotein of 60 kDa (IDG-60) carrying NeuNAc (*N*-acetylneuraminic acid), Man, and Gal residues has been identified by screening a genomic library of *S. mutans* strain GS-5. This protein is essential for maintaining cell wall integrity and cell shape; however, the role of the glycan modification has not been elucidated (Chia et al. 2001).

4.1.6 Molecular Mimicry of Eukaryotic Glycoproteins by Bacteria

With time, bacteria have developed glycoconjugates which are closely related to those found in mammals. *Chlamydia trachomatis* synthesizes high-mannose-type *N*-glycan on glycoprotein which is similar to the type assembled on eukaryotic glycoproteins which also produce heparin-like molecule causing infection in the eukaryotic host. *Nisseria meningitidis* produces adhesive fimbriae that contain O-glycan in a pili subunit. The assemblies of eukaryotic-like glycans by pathogenic bacteria may be a form of molecular mimicry for bacteria in order to avoid or to compromise the immune system of the host (Varki et al. 1999).

5 Membrane-Derived Oligosaccharides

Membrane-derived oligosaccharides (MDOs) were named due to the membrane origin of the phosphoglycerol substituents. These are present in the periplasmic space and are widely distributed in gram-negative bacteria. These are also known as the osmoregulated periplasmic glucans (OPGs) since the synthesis and accumulation of MDOs are inversely proportional to the osmotic strength of the environment (Bohin 2000). MDOs are a heterogeneous family of closely related, highly branched oligosaccharides containing glucose as the sole sugar. They are substituted with sn-1-phosphoglycerol, phosphoethanolamine, and 0-succinyl ester residues, giving these molecules a net negative charge. MDOs contain 6–12 glucose residues joined by K-1,2 and K-1,6 linkages, with the principal species containing eight to nine glucose units (Kennedy 1996). Several reports suggest the important functions of MDOs in *E. coli*, such as its role in cell to cell signaling, chemotaxis, lysis induction by bacteriophages, the regulation of capsular polysaccharide synthesis, and the osmoregulation of the outer membrane protein expression (Geiger et al. 1992). Bohin and coworkers stated that when *E. coli* cells were grown in low-osmolarity medium, the MDOs in the periplasmic space represent 3.5–5 % of the cell dry weight, while the cells when grown in the medium with higher osmolarity exhibit a drastic decrease in MDO content (Bohin 2000; Bohin and Lacroix 2006).

5.1 Biosynthesis of MDOs

Limited reports are available on the biosynthesis of MDOs; however, the pioneering study was reported by Dedonder and Hassid (1964). In the past decade,

researchers investigated the synthesis of cyclic glucans in *Rhizobiaceae* and established that membrane-bound glucosyltransferase system catalyzes an essential step in the biosynthesis of MDOs wherein glucose residues are transferred from UDP-glucose to octyl β-D-glucoside (acceptor) with the formation of β 1→2-linked polyglucose chains linked to the acceptor molecule (Weissborn and Kennedy 1984). It was also reported that any mutation in the mdoA locus leads to the loss of membrane-bound glucosyltransferase activity and thereby prevents the formation of MDO chains in vivo. Besides the membrane fraction, a soluble protein identified as acyl carrier protein (ACP) from the cytosolic fraction is also required during the process of biosynthesis. Jackson and Kennedy (1983) proposed a two-step model wherein phosphoglycerol transferase I, an enzyme of the inner membrane, catalyzes the transfer in vitro phosphoglycerol residues from phosphatidylglycerol to nascent MDOs (membrane-linked newly synthesized glucans) or to the synthetic β-glucoside acceptors such as arbutin. Then, the periplasmic phosphoglycerol transferase II would transfer those residues from one molecule of OPG (potentially still an acceptor in the first step) to another already liberated in the periplasmic space. The sn-1,2-diglyceride that is the product of this reaction is normally phosphorylated by the enzyme diglyceride kinase in a salvage reaction, leading to the formation of phosphatidic acid, which then can be used for the synthesis of cellular phospholipids (Jackson et al. 1984).

5.2 Inhibitors of MDO Biosynthetic Pathway

The membrane-bound transglucosylase system is inhibited in a dose-dependent manner by antibiotics such as bacitracin and amphomycin. These antibiotics generally function in a cell-free transglucosylase enzyme system by forming specific complex with polyisoprenyl phosphate derivatives (Banerjee 1989).

6 Lipopolysaccharides

A lipopolysaccharide (LPS) or lipoglycan molecule is made up of a lipid and a polysaccharide which are joined together by a covalent bond. LPSs are present in the outer membrane of the gram-negative bacteria. The low molecular weight form of bacterial polysaccharides is known as lipooligosaccharides (LOSs). The toxicity of LPS was discovered by Richard Friedrich Johannes Pfeiffer and termed as endotoxin. It was reported that endotoxins are toxins released by the bacteria into the environment and are kept within the bacterial cells and are released only after bacterial cell wall destruction (Parija 2009). Researchers used the term endotoxin as a synonym with LPS. The important function of LPS is to provide structural integrity to bacteria and its membrane protection from certain kinds of chemical attack. LPS also aids in membrane stabilization by increasing the negative charge on the cell membrane. This molecule is also believed to be a molecule of life for the

gram-negative bacteria since any sort of mutation or removal could lead to its death. LPS could also illicit a strong response from normal animal immune system. Besides its pathogenic nature, the nonpathogenic aspects have also been studied such as surface adhesion, bacteriophage sensitivity, and interactions with predators such as amebae.

Lipopolysaccharide (LPS) comprises of three parts: (i) "O" antigen, (ii) core polysaccharide, and (iii) lipid A.

6.1 "O" Antigen

It is also named as "O" antigen, "O" polysaccharide, or "O" side chain of the bacteria; it is basically a repetitive unit of glycans and forms a polymer. It is exposed on the very outer surface of the LPS molecule and is attached to the core oligosaccharide in a bacterial cell. The composition of "O" chain varies from strain to strain. Rittig et al. (2004) mention two types of LPS, smooth and rough on the basis of the presence or the absence (or reduced form) of "O" chain respectively. It was also observed that bacteria with rough LPS are more hydrophobic and have a more penetrable cell membrane for hydrophobic antibiotics (Tsujimoto et al. 2003).

6.2 Core Polysaccharide

The core generally contains the oligosaccharide component that attaches itself to lipid A. The sugars commonly present are heptose and 3-deoxy-D-mannooctulosonic acid (also known as KDO, ketodeoxyoctulosonate) (Hershberger and Binkley 1968). In most of the bacteria, a noncarbohydrate component is also present in the LPS core such as phosphate, amino acids, and ethanolamine substituents. In the case of *Neisseria meningitidis*, the inner core is composed of 3-deoxy-D-manno-2-octulosonic acid (KDO) and heptose (Hep) moieties.

6.3 Lipid A

Generally, the lipid A moiety is a much conserved component of the LPS. It is a phosphorylated glucosamine disaccharide decorated with multiple fatty acids. These hydrophobic fatty acid chains anchor the LPS into the bacterial membrane, and the rest of the LPS projects from the cell surface. The lipid A domain is mainly responsible for much of the toxicity of gram-negative bacteria. When bacterial cells are lysed by the immune system, fragments of membrane containing lipid A are released into the circulation, causing fever, diarrhea, and possible fatal endotoxic shock (also called septic shock) (Tzeng et al. 2002).

6.4 Lipooligosaccharides (LOSs)

These are the glycolipids which are present in the outer membrane of certain types of gram-negative bacteria such as *Neisseria* spp. and *Haemophilus* spp. It is basically a low molecular weight lipopolysaccharide. LOS helps in maintaining the structural integrity and functionality of the outer membrane in gram-negative microorganisms. Lipooligosaccharides act as immunostimulators and immunomodulators; therefore, its important role in the pathogenesis of certain bacterial infections has been reported (Moran et al. 1996). In certain bacterial strains, LOS molecules display molecular mimicry and antigenic diversity, aiding in the evasion of host immune defenses and thus contributing to the virulence of these bacterial strains. In contrast to lipopolysaccharides, lipooligosaccharides lack "O" antigens and possess only a lipid A-based outer membrane-anchoring moiety and an oligosaccharide core (Kilár et al. 2013).

6.5 LPS Modifications

With time, the host system could manage the toxic effects of gram-negative bacteria which are generally present in the small intestine. In the past few years, it has been reported that a specific enzyme in the host's intestine, i.e., alkaline phosphatase, could detoxify the toxic effect caused by lipopolysaccharide through the removal of two phosphate groups being present on the LPS carbohydrates (Bates et al. 2007). The other route for detoxification could be the addition of more specific sugars using glycosyltransferases in order to modify the structure of LPS.

6.6 Biosynthesis of Lipopolysaccharides

It has been observed that in *Salmonella* all *wbaP* (*rfbP*) genes encode for an enzyme (glycosyltransferase) that transfers Gal-1-P to undecaprenol-P as an initiating step of "O" units, and all have sequences that are readily aligned. It has also been reported that in certain *Salmonella* strains like from group D and group B strains, gene *wbaV* (*rfbV*) encodes for tyvelose transferase and an abequose transferase respectively, and each could carry out functions in the presence of appropriate precursors.

The genes for saccharide processing (including export, polymerization, and assembly of complex polysaccharides such as LPS) commonly occur in families of homologous genes that perform same general functions. Two genes with the same name may have specificity for different oligosaccharides and are distinguished by including the species or some other relevant information as subscript.

Most "O"-antigen gene clusters have genes currently known as rfc, rfbX and cld, or rol. Each could be recognized by the topological features of the encoded protein

although there is a certain sequence similarity for the proteins in the first two families. The wzy genes are generally found within the "O"-antigen gene cluster (Reeves et al. 1996).

6.7 Functions of Lipopolysaccharides

6.7.1 Biological Effects of Lipopolysaccharides on Hosts

Lipopolysaccharides in gram-negative bacteria usually act as a candidate target for new antimicrobial agents. LPS generally acts as endotoxin as it binds to the cell receptor (CD14/TLR4/MD2) complex in monocytes, dendritic cells, macrophages, and B cells, which thereby promotes the secretion of proinflammatory cytokines, nitric oxide, and eicosanoids (Abbas 2006). The TLR4 as the LPS receptor was demonstrated by Bruce Beutler, a noble laureate for this work in the year 2011 in Physiology or Medicine (www.nobleprize.org/nobel_prizes/medicine/laureates/2011/press.html). LPS also acts as an exogenous pyrogen or as the external fever-inducing substance. The functions of LPS are under experimental research for several years as it activates many transcription factors. LPS produces different types of mediators which are involved in septic shock. In this context, Warren et al. (2010) observed that humans are more sensitive to LPS as compared to other animals and reported that a minimal dose of 1 μg/kg induces shock in humans, wherein mice could tolerate a dose which is a thousand times higher compared to the humans' minimal dosage. This difference could be due to the level of circulating natural antibodies (Reid et al. 1997).

Endotoxins could aggravate the pathogenic effect by *Neisseria meningitidis*, a gram-negative microorganism, and could cause meningococcal disease, including meningococcemia, Waterhouse-Friderichsen syndrome, and meningitis.

Certain portions of LOS in some bacteria have shown similarity in terms of their chemical structure with the human host cell surface molecules. It is termed as **molecular mimicry**. Moran and coworkers observed and reported that in the case of certain strains of *Neisseria meningitidis*, the terminal tetrasaccharide portion of the oligosaccharide (lacto-*N*-neotetraose) is the same tetrasaccharide as that found in paragloboside, a precursor for ABH glycolipid antigens found on human erythrocytes. Furthermore, the terminal trisaccharide portion (lactotriaose) of the oligosaccharide from the pathogenic *Neisseria* spp. is also present in the lactoneoseries of glycosphingolipids from human cells. Besides this, the presence of these human cell surface mimics may also act as a camouflage from the immune system and could abolish the immune tolerance when infecting hosts with certain human leukocyte antigen (HLA) genotypes, such as HLA-B35 (Moran et al. 1996).

6.7.2 Effect of LPS Variation on Immune Response

The outer carbohydrate portion or "O" antigen is believed to be the most variable portion of the LPS molecule, and this thereby imparts the antigenic specificity. In contrast, lipid A portion is the most conserved part in LPS, but this portion could also vary in number and nature of acyl chains present within or different genera. These variations in lipid A could impart antagonistic properties to LPS like in the case of

Rhodobacter sphaeroides, wherein diphosphoryl lipid A (RsDPLA) is a potent antagonist of LPS in human cells but is an agonist in hamster and equine cells. In the normal human blood serum, anti-LOS antibodies are present which are bactericidal, while the patients who are suffering from infections arising out of serotypically distinct strains possess anti-LOS antibodies that differ in their specificity primarily within the structure of the oligosaccharide portion of the LOS molecule (Yamasaki et al. 1994). During infection, the variation in the antigenicity of LOS was observed which could be due to the ability of bacteria to synthesize more than one type of LOS molecule through sialylation, which might lead to an increase in resistance to complement-mediated killing (Yamasaki et al. 1994) or can down-regulate the complement activation (Moran et al. 1996) or even it can evade the effects of bactericidal antibodies.

6.7.3 Health Effects of Lipopolysaccharide on Host

The presence of endotoxins in the blood is called endotoxemia. It could lead to septic shock, if the immune response is severely pronounced (Opal 2010). Endotoxemia in the intestine could lead to the development of alcoholic hepatitis (Ceccanti et al. 2006). It has also been reported that gonococcal LOS can cause damage to the human fallopian tubes.

The molecular mimicry of some LOS molecules is thought to cause autoimmune-based host response. The bacteria's mimicry to the host structures via LOS is found with *Helicobacter pylori* and *Campylobacter jejuni*, the organisms which cause gastrointestinal disease in humans, and *Haemophilus ducreyi* which causes chancroid. Certain *C. jejuni* LPS serotypes (attributed to certain tetra- and pentasaccharide moieties of the core oligosaccharide) have also been implicated with Guillain-Barré syndrome and a variant of Guillain-Barré called Miller Fisher syndrome (Moran et al. 1996).

An increase in the endotoxin load due to an increased population of endotoxin-producing bacteria in the intestinal tract is associated with obesity-related patients. This clearly shows that the presence of a high level of endotoxin from *Escherichia coli* could induce obesity as has been observed by Cani and coworkers through experimental studies wherein they injected purified endotoxin from *Escherichia coli* into germ-free mouse models (Cani et al. 2007). It has also been reported that endotoxin is associated with obesity because it induces an inflammation-mediated pathway. Recently, it was observed that *Enterobacter cloacae* B29 could also contribute toward the obesity and insulin resistance in human patients (http://www.nature.com/ismej/journal/vaop/ncurrent/full/ismej2012153a.html).

Endotoxins could be detected through the standard assay known as limulus amebocyte lysate (LAL) assay utilizing the blood from the horseshoe crab (Iwanaga 2007).

7 Capsular Polysaccharide

The capsular polysaccharide constitutes the outermost layer of the bacterial cell and mediates its direct interaction with the environment. Due to these interactions, polysaccharide capsules have been implicated as an important virulence factor for

many bacterial pathogens. The capsular polysaccharide is mainly found in gram-negative bacteria such as in *E. coli*, *Neisseria meningitidis*, *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Salmonella*. In certain gram-positive bacteria, these capsular polysaccharides were also observed such as in the case of *Bacillus megaterium* (could synthesize a capsule composed of polypeptide and polysaccharides), *Streptococcus pyogenes* (synthesizes hyaluronic acid capsule), *Streptococcus pneumoniae*, *Streptococcus agalactiae*, and *Staphylococcus epidermidis*. Besides this, the capsular polysaccharide was also observed in yeast particularly in *Cryptococcus neoformans* which has a capsular polysaccharide similar to that of bacteria. Generally, it is very difficult to distinguish between the capsular polysaccharide (CPS) and other surface polysaccharides, such as the "O"-antigenic moieties of lipopolysaccharide (LPS), as CPS is found to be associated with LPS (Whitfield 1988). The capsule could be identified either through India ink staining or through serological methods wherein the capsular material acts as antigen and is mixed with specific anticapsular sera. When it was observed under a microscope, the capsule appears swollen due to an increased refractivity. This phenomenon is known as Quellung reaction.

Capsular polysaccharides are the hydrated molecules that have more than 95 % water. These molecules are linked to the bacterial cell surface via covalent attachment to either phospholipids or lipid-A molecules, while, in certain cases, it was observed that CPS may be associated directly with the cell without any membrane anchor (Whitfield 1988; Whitfield and Valvano 1993). The capsular polysaccharide could either be homo- or heteropolymers composed of repeating monosaccharides joined by glycosidic linkages (Roberts 1996). The two monosaccharide units may be joined in a number of configurations which may lead to a large structural diversity in CPS among species, while chemically identical capsular polysaccharides may also be synthesized by different bacterial species. It was identified that certain CPS or K antigen is associated with certain infections. The *Escherichia coli* K1 antigen, a homopolymer of α2,8-linked *N*-acetylneuraminic acid, is the major cause of neonatal meningitis (Robbins et al. 1974). The capsular polysaccharide of *Neisseria meningitidis* group B is identical to the K1 polymer of *E. coli* (Grados and Ewing 1970).

The bacterial capsular polysaccharide could perform a number of functions such as prevention of desiccation, adherence, resistance to nonspecific host immunity, and resistance to specific host immunity and thereby mediating the diffusion of molecules through the cell surface (Whitfield 1988; Roberts 1996). The encapsulated bacteria could sustain or survive outside the host and thereby promotes the transmission of pathogenic bacteria from one host to another; it could be due to the formation of hydrated gel around their cell surface which protects the cell from the effects of desiccation. Capsular polysaccharide promotes biofilm formation as this molecule has the tendency to adhere the bacterial cell either to the surface or with other bacterial cells which facilitates the colonization (Costerton et al. 1987).

During the invasive bacterial infections, interactions between the capsular polysaccharide and the host's immune system can decide the outcome of the infection

(Roberts et al. 1989; Roberts 1996). In the absence of specific antibody, the presence of capsule confers resistance to the nonspecific host defense mechanisms. These responses include the activation of the complement cascade via the alternative pathway and of the C3b-mediated opsonophagocytosis by polymorphonuclear leukocytes. Both these responses provide protection in the preimmune host when specific antibodies are absent. The alternative pathway is initiated by the binding of C3b to the bacterial cell surface. The bound C3b is activated by factor B and thereby forms C3convertase C3bBb. This now allows the binding of more C3 and the formation of membrane attack complex on the outer membrane of the bacteria which leads to lysis and death (Finne 1982; Roberts 1996). This phenomenon could be inactivated by capsule which could provide a cell permeability barrier to complement components, thereby masking the C3b deposited on cell surface structures from C3b receptors on the phagocyte cell surface that could otherwise be potent activators of the alternative pathway (Howard and Glynn 1971). The net negative charge is being conferred on to the cell surface by the capsular polysaccharide in order to confer resistance toward phagocytosis. The net charge is directly proportional to the conferred resistance toward phagocytosis.

In most of the cases, capsular polysaccharides could elicit an immune response while certain are poorly immunogenic. The poor immunogenicity has been observed in *E. coli* KI capsule, *E. coli* K5 capsule, and *Neisseria meningitidis* serogroup B primarily due to the presence of NeuNAc in the capsules which is similar to desulfoheparin (Bhattacharjee et al. 1975). These capsules are structurally similar to the polysaccharides encountered on host tissue; therefore, these capsules are poorly immunogenic and thereby elicit a poor antibody response in the host (Wyle et al. 1972). *Burkholderia pseudomallei* is believed to be the causative agent of melioidosis which is due to direct inoculation into wounds and skin abrasions or due to the inhalation of a contaminated material. This disease is present as an acute pneumonia or as an acute septicemia, a more severe form of disease. The chronic and the subclinical forms generally remain undetected until activated by a traumatic event or decrease in immunocompetence (Ip et al. 1995). *B. pseudomallei* is resistant to a large number of antibiotics; even with the aggressive antibiotic therapy, the mortality rate remains high and the incidence of relapse is common (Currie et al. 2000). Reckseidler-Zenteno reported that certain cell-associated antigens were identified in *B. pseudomallei*. The cell-associated antigens include capsular polysaccharides and lipopolysaccharides (Reckseidler-Zenteno 2012). The capsular polysaccharide produced by *B. pseudomallei* is determined to be an unbranched polymer of repeating tetrasaccharide units with a structure -3)-2-O-acetyl-β-D-Galp-(1-4)-α-D-Galp-1-3)- β-D-Galp-(1-5)- β-D-KDOp-(2- (Masoud et al. 1997). The exact role of CPS in terms of virulence was not known but the sera of patients suffering with melioidosis have shown the presence of antibodies against CPS. The two other CPS structures were also identified: a branched 1,4-linked glucan polymer (CP-1a) and a triple-branched heptasaccharide repeating unit composed of rhamnose, mannose, galactose, glucose, and glucuronic acid (CP-2) (Perry et al. 1995). The genes involved in the synthesis of these capsules and the role of these capsules in virulence had not been identified.

7.1 Biosynthesis of Capsular Polysaccharide

The capsular polysaccharide is produced by many gram-negative bacteria by one of the two assembly systems, i.e., either by Wzy-dependent pathway or ATP-binding cassette (ABC)-transporter-dependent pathway (Cuthbertson et al. 2009; Willis and Whitfield 2013).

Among the gram-negative bacteria, the capsular K antigens of *E. coli* are widely studied, and the capsule system is differentiated into four groups based on assembly system, key genes organization, and regulatory features (Whitfield 2006). The Wzy-dependent pathway is used for groups 1 and 4 capsules wherein the isolates are associated with gastrointestinal infections. In this pathway, the initial synthesis took place in the cytoplasm wherein the repeating units of polyprenol-linked CPS are synthesized which are then flipped by a Wzx protein across the inner membrane and further polymerized into the full length CPS by a Wzy protein. The CPS chains are assembled into a capsular structure onto the cell surface, but how it is retained in the cell surface is not entirely clear though it is a multifactorial process. The similar process exists in genera such as *Klebsiella* and *Erwinia*.

The capsular system of groups 2 and 3 in *E. coli* requires ABC-transporter-dependent assembly. This system is found in mucosal pathogens which include *Campylobacter jejuni*, *N. meningitidis*, *H. influenzae*, *Mannheimia haemolytica*, etc. These bacteria caused variety of diseases in humans like septicemia, meningitis, urinary tract infections, gastrointestinal infections, and otitis media (Agrawal and Murphy 2011). The CPS assembled by the ABC-transporter-dependent pathway is in the presence of phospholipids at the reducing end of the polysaccharide chain. Willis and Whitfield (2013) reported that the terminal lipid is attached to the repeating units of polysaccharide chain in *E. coli* K1 and K5 to the cell surface. The phospholipid is lyso-phosphatidylglycerol (PG) which is attached to the CPS chain via a novel β-linked poly-3-deoxy-D-manno-oct-2-ulosonic acid (kdo) linker. The amount of CPS associated with the cell is very difficult to measure since the linkage between the lipid and CPS is unstable; however, other mechanisms are also there which allow the CPS to link to the cell membrane such as the ionic interactions between CPS and the core region of LPS as observed in *E. coli* K1 (Jimenez et al. 2012).

In the ABC-transporter-dependent pathway, CPS is synthesized in the cytoplasm wherein the repeating units of polysaccharide structure are assembled through the action of glycosyltransferase (GT) wherein GTs catalyze the transfer of specific sugars from an activated donor to the non reducing end of the growing CPS glycan (DeAngelis 1999) and are exported across the inner membrane via an ABC transporter comprising of two identical nucleotide-binding domain (NBD) polypeptides (KpsT in *E. coli*) and two integral membrane polypeptides (KpsM). In order to complete the transportation from the periplasm toward the cell membrane, it requires two other characteristic components: a member of the polysaccharide co-polymerase (PCP-3) family (KpsE) and an outer membrane polysaccharide (OPX) protein (KpsD). These proteins are thought to form protein complex, enabling synthesis and translocation from the cytoplasm to the cell surface in a coordinated process.

KpsE, being a PCP family protein, is anchored to the inner membrane with N- and C-terminal transmembrane helices. KpsE interacts with KpsD, the OPX family protein, and this interaction is specific for the cognate pairs of KpsED homologues. In *E. coli* group 1 CPS form, the OPX protein forms an octameric outer membrane channel which could facilitate the CPS efflux. The OPX protein of CPS group 1 is mainly located in the periplasm wherein it interacts with the periplasmic domain of its cognate PCP-2a protein. The KpsD and its homologues possess a motif shared by all the OPX proteins, but they do not form stable multimers in the outer membrane so their 3D structures may differ from group 1 OPX protein. The efflux pump is organized in a tripartite and aids in the CPS export system. Here, the efflux pump is connected to an outer membrane channel such as ToIC via an adaptor protein in order to create a contiguous channel from the cytosol to the exterior of the cell (Willis and Whitfield 2013).

A lot more studies need to be carried out to understand the complete mechanism for CPS biosynthesis, since there is a need to understand the mechanism as to how the substrate for the polymerizing CPS synthases is synthesized, how the ABC transporter recognizes the CPS for export, and how is the polymer transported across the two membranes and the periplasmic space.

8 Future Outlook

The cell-bound polysaccharides as discussed in this communication are evolved in the prokaryotes to perform both structural and functional roles in cell growth and division. In this context, in the past few years, the entire genome of the bacteria is available, and a survey of open reading frames indicates that proteins involved in carbohydrate metabolism, carbohydrate-binding proteins, and cell wall assembly proteins constitute the major families of the expressed genes. Therefore, the genes encoding different enzymes or precursors which are responsible during the biosynthetic pathway of these cell-bound polysaccharides in bacteria which act as virulence factors to cause pathogenesis in host cell could be a good target for the development of antibiotic drugs. The structure and function of polysaccharides and the biosynthetic pathways involved in their synthesis would provide an important clue for designing the therapy to combat the infectious diseases caused by the bacteria. Till date, the mechanisms involved in biosynthetic pathways are not completely explored, and certain precursors are still not known thereby it remains a highly challenging problem which could prove to be a promising area for future work.

Acknowledgments The authors, S. M. and V. S., would like to thank the Department of Biotechnology (DBT, India) for providing them assistance in the form of a grant. S. M. and V. S. are the recipients of the DBT-RA.

Contents

Abstract

Freshwater and marine algae cover a wide group of various organisms living in diversified, terrestrial, or water habitats. Various environment conditions are important factors for the formation of many defense mechanisms to survive unfavorable climate leading to a wide scale of chemical compounds created by algae. Many of them show interesting and important biological activities with health benefits, which are the reason of algae being in the focus of scientists worldwide. Generally, algae can be considered as an abundant source of many nutrients, besides the polysaccharides, responsible for their different physico-chemical properties with health beneficial effects. Fundamental seaweed polysaccharides with economic impact are presented by alginates, agars, carrageenans, ulvanes, and fucoidans used as a raw material mostly in the food and pharmaceutical industry. From medicinal point of view, especially sulfate polysaccharides are an important source of bioactive natural compounds

exhibiting anticoagulant, antithrombotic, antitumor, antimicrobial, antimutagenic, anti-inflammatory, immunomodulatory, and antiviral activities. Thus, significant attention of this chapter has been focused on sulfate polysaccharides derived from algae with anticoagulant activities.

Keywords
Freshwater algae • Seaweed • Sulfate polysaccharides • Anticoagulants • Heparin

1 Introduction

Increasing interest in healthy human food across the world introduces also a rising consumption of algae due to the presence of many bioactive compounds. Algae represent a wide group of very diverse organisms formed by more than thirty thousand of species of microscopic or huge dimensions both freshwater algae and seaweed. According to the scientific classification, algae belong to the domain Bacteria with prokaryotic cells and Eucarya with eukaryotic cells. They are able to colonize different types of habitats from terrestrial types to rivers, lakes, seas, oceans, and hot springs, and they live in all biogeographic areas from tropic to polar areas. Various environment and living conditions of algae are responsible for enormous algal diversity resulting in different dimension, shapes, colors, and heterogeneous chemical composition (Dawczynski et al. 2007; Marsham et al. 2007; Ogbonda et al. 2007). Frequently, general classification according to their pigments as red (Rhodophyta), brown (Phaeophyta), green (Chlorophyta), and blue-green (Cyanophyceae) algae is used. Microalgae cover unicellular green and red algae as well as cyanobacteria (known as blue-green algae) and also diatoms and dinoflagellates. Macroalgae are represented by three groups of brown (Phaeophyceae), red (Rhodophyceae), and green (Chlorophyceae) seaweed.

Different biomes of algae together with many abiotic and biotic factors, such as geographic location, water temperature, light intensity, a level of nutrition in water, algal species, the time of harvest, and stage of life cycle, predominantly determine their different structure and significantly affect the occurrence of miscellaneous compounds in various concentration in algae. The high nutritional value of algae results from the content of proteins with essential amino acids, minerals, essential fatty acids, and vitamins. Many other compounds present in algal biomass possessing health beneficial impacts on human body, such as phenolic compounds, are secondary metabolites evolved as protective agents toward unfavorable environmental conditions (Dawczynski et al. 2007; El Gamal 2010; Marsham et al. 2007; MacArtain et al. 2007; Mišurcová 2011, Mišurcová et al. 2011a, b, 2014).

Among the fundamental compounds, i.e., polyphenols, vitamins, minerals, and proteins, algal polysaccharides have been in the focus of researches due to many important beneficial impacts on human health. Algal polysaccharides are located mostly in algal cell walls as structural compounds. Their structure and composition were found crucial for their activities on signaling pathway regulating defense of

algal cells of unicellular organisms or plant tissue of multicellular algae against the environmental surroundings (Jaulneau et al. 2010; Patron and Keeling 2005; Aquino et al. 2011; Rodrigues et al. 2012). Polysaccharides do not participate on the nutritional value of algae. Therefore, algal polysaccharides are considered as a source of dietary fiber resistant to enzymatic hydrolysis of intestinal microflora of human digestive tract (Jiménez-Escrig and Sánchez-Muniz 2000; Warrand 2006; Kim 2011). Polysaccharides of seaweed have been widely investigated for their chemical properties and important biological effects in recent years. Chemical composition of algal polysaccharides is responsible for their different functions. Exceptionality and variety of algal polysaccharides functions are based on the ability to bind sulfate groups to hydroxyl groups of sugar molecules so their biological activities are caused mainly by their diverse composition and the extent of sulfation (Percival 1979 ; Athucorala et al. 2007; Costa et al. 2010; Damonte et al. 1994; De Zoysa et al. 2008). Generally, acidic sulfated polysaccharides, such as alginic acids and carrageenans, are able to reduce cholesterol absorption in the gut due to their production of indigestible ionic colloid and in the case of neutral polysaccharides agars, thanks to their water dispersibility (Jiménez-Escrig and Sánchez-Muniz 2000). Further, algal polysaccharides are in the focus of many researches as they are an important source of bioactive natural compounds with specific biological functions; they show many health benefits provided by their anticoagulant, antioxidant, antiproliferative, antitumoral, anti-inflammatory, and antiviral properties (Mišurcová et al. 2012; Costa et al. 2010). This chapter gives details on the characterization of algal polysaccharides and their physiological function as anticoagulants.

2 Chemical Composition of Algal Polysaccharides

Different phylogenesis of many cyanobacterial and algal species determines various chemical composition and structure of polysaccharides that are extensively studied for their different physiological functions. Polysaccharide composition of algae has been described in many research papers. Common feature evaluated from these investigations is their enormous variability stemming from different algal species; further, cultivation methods of freshwater algae as well as different algal habitats and other environmental conditions affect their growth (Aquino et al. 2011; Rodrigues et al. 2012; Rodrigues and da Silva Bon 2011; Becker 2007; Cheng et al. 2011). Moreover, composition and proportions of algal polysaccharides vary with the morphological phase of algal life stages, and their location in algal cells determines also their functions (Usov 1998). Storage polysaccharides are the main source of energy, while structural polysaccharides have solidifying and protective functions.

2.1 Storage Polysaccharides of Algae

Fundamental energy storage polysaccharides could be divided into three groups according to their synthesis, different structures, and localization in cell bodies.

Thus, starch is a storage polysaccharide of green plant including algae, floridean starch is deposited in red algae, and glycogen is a storage polysaccharide of blue-green algae belonging to Cyanobacteria. Storage polysaccharides of freshwater blue-green and green algae are glycogen and starch, respectively. The molecules of both polysaccharides, starch and glycogen, are formed by α-(1,4)-linked glucose units with α-(1,6)-branch points, whereas length and number of branches alter in dependence on the species of organisms (Chao and Bowen 1971). The fundamental difference between starch, floridean starch, and glycogen is their distinct positions in algal cells. While starch synthesis is localized within the plastids because of relocalization of green algal branching enzymes and probably phosphoglucomutase to the plastid, floridean starch and glycogen syntheses are accumulated in the cytosol (Patron and Keeling 2005).

2.1.1 Starch

Further, studies concerning starch structure diversity among the various species of green algae have shown a highly various percentage of amylose. Green algal starch consists of about 70 % of branched polymer amylopectin, the remaining 30 % is a non-branched or slightly branched polymer of amylose. However, differences of starch structure also depend on the established cultivation conditions. Environmental factors, mainly temperature, light, and nutrient content in growth medium, are responsible for the quantitative distribution of amylose. Saturated cultures of three green algae *Chlamydomonas reinhardtii*, *Dunaliella bioculata*, and *Haematococcus pluvialis* grown on acetate and light accumulated starch with a low concentration of up to 5 % of amylose. On the other hand, nutrient-starved cells accumulated significantly a higher amount of amylose, from 15 % to 30 % (Ball and Deschamps 2009). Polymodal distribution of chain lengths within amylopectin molecules allows them to form granules in the matrix consisting of alternating, concentric, amorphous, and semicrystalline lamellae (Myers et al. 2000). Amylopectin synthesized by green plant has highly organized tandem-cluster structure while the bacteria and animals continue to produce random branched glycogen (Nakamura et al. 2005). Further, similar features between starch synthesis in Chlorophyta and glycogen synthesis in bacteria are attributable to the origin of chloroplasts from endosymbiotic cyanobacteria (Viola et al. 2001).

2.1.2 Glycogen

The main storage polysaccharide of blue-green algae is glycogen, and its production is strongly dependent on the conditions of algal cultivation, nitrate concentration, and light intensity. Higher production of glycogen may be caused by nitrate deficiency. Low nitrate concentration favors the accumulation of glycogen; however, it leads to lower biomass production (Aikawa et al. 2012).

2.1.3 Floridean Starch

The main storage polysaccharide of red seaweed is floridean starch. It has a similar structure as starch of green seaweed and plant, however, without amylose. Nevertheless, it was confirmed that some species of red algae form also amylose units

(McCracken and Cain 1981). Another difference is the imposition of granules of floridean starch outside the plastids (Shimonaga et al. 2007; Viola et al. 2001). In red algae, isoamylases and starch synthases are plastid-derived enzymes operating in the cytosol where they use uridine diphosphate (UDP) glucose as a glucan donor, resulting in cytosolic starch synthesis. Thus, starch granules in red algae are exclusively synthesized in the cytoplasm (Patron and Keeling 2005; Viola et al. 2001).

2.1.4 Laminaran

The main storage polysaccharide of brown seaweed is laminaran, also called laminarin, and its chemical structure is formed by (1,3)-β-D-glucan with β-(1,6) branching with different reducing endings that can have either mannitol or glucose residues. Laminaran contains also a large amount of neutral sugars with a low concentration of uronic acid, whose proportions vary according to different species (Rioux et al. 2007). The extent of branching predestinates different solubility of laminarans. Highly branched laminaran is soluble in the cold water, whereas a lower degree of branching enables solubility only in the warm water (Jaulneau et al. 2010; Rupérez et al. 2002). As well as previous mentioned storage polysaccharides, also laminaran content varies in dependence on the season, age of population, seaweed species, and geographic location. Seasonal changes of laminaran and mannitol in different species of brown seaweed have also been reported, concerning a different stage of the life cycle (Iwao et al. 2008; Zvyagintseva et al. 2005).

2.2 Structural Polysaccharides of Algae

Structural polysaccharides have the main function to protect algal cells and tissues. Obviously, algal structural polysaccharides are formed as miscellaneous mixtures of heterogenic compounds with sulfated and branched polysaccharides, proteins, and also inorganic ions, such as calcium and potassium.

2.3 Freshwater Algae

The cell wall of blue-green alga *Spirulina platensis* is formed by four layers marked as LI, LII, LIII, and LIV without cellulose. All layers are very weak except for the layer LII consisting of peptidoglycan that gives the cell wall its rigidity. The LI layer consists of β-(1,2)-glucan, a polysaccharide that is nondigestible by human gastrointestinal tract. LIII is possibly composed of protein fibrils, and the most external membrane layer LIV is composed of material arranged straight, parallel with the trichome axis, and which is considered to be analogous to that one present in the cell wall of gram-negative bacteria (Ciferri 1983; Mišurcová et al. 2012). It was reported that the variable sugar content is in the range of 8–14 % in biomass of *Spirulina platensis* in dependence on different parts of cell structures (Becker 2007)

and also on various species, when in algal biomass of *Spirulina maxima* a lower amount of 2.0 % of polysaccharides presented by xylose, rhamnose, and glucose was observed. The cell wall contains of 10.0 % of polysaccharides with glucose being the major representative. In external cellular wall layers, there have been established polysaccharides formed by a mixture of six neutral monosaccharides including fucose, rhamnose, xylose, mannose, galactose, and glucose, and finally, two uronic acids have been presented by glucuronic and galacturonic acids (Nie et al. 2002).

The cell walls of the freshwater green algae of *Chlorella* strains are composed of up to 80 % of polysaccharides including cellulose, and they may be constructed by three different types of structures varying among the miscellaneous strains (Rodrigues and da Silva Bon 2011). The first type of cell structure is formed by a trilaminar outer cell wall layer, the second by a thin outer monolayer, and the third is without an outer layer (Yamada and Sakaguchi 1982).

Trilaminar cell wall consists of algaenan, generally known as non-hydrolyzable macromolecular components, such as glycoproteins and glucosamine-containing biopolymers (Burczyk et al. 1999). The second cell wall type consists of an outer non-trilaminar layer and inner microfibrillar layer, which is probably composed of β-linked polysaccharides, such as cellulose, and of a little amount of pectin. The third type of cell wall consisted of one microfibrillar layer in which a bigger amount of pectin and a small amount of β-linked polysaccharides were established (Yamada and Sakaguchi 1982; Mišurcová et al. 2012). The chemical composition of the cell walls of green freshwater algae would vary depending on algal species and other types of their cell wall structure, but it has been also reported that cultivation conditions have the impact on chemical composition of the cell wall in *Chlorella variabilis* NC64A; different levels of neutral sugar, uronic acid, and amino sugar in the cell wall have been found when cultured in different nitrogen sources and concentrations (Cheng et al. 2011). Rigid cell walls of *Chlorella* species contain mannose as a major sugar component, further glucose, and glucosamine. Rhamnose, fucose, arabinose, xylose, mannose, galactose, and glucose have been determined in the wall matrix (Takeda 1996).

2.4 Seaweed

Structural polysaccharides of seaweed cell walls usually consist of an outer amorphous mucilage matrix commonly formed by linear sulfated galactan polymers (carrageenans, agars, and alginates) and of an inner rigid component from cellulose microfibrils (Arad and Levy-Ontman 2010). However, cellulose as a neutral structural polysaccharide is rarely present in the cell walls of red and brown seaweed as a pure β-(1,4) glucan; more frequently the wall contains other sugars than glucose and is also presented in lower levels than in higher plants, in a relatively small amount of 2–10 % in the majority of red algae. Moreover, its amount and configuration of microfibrils differs according to different life stage of algae. Whereas the concholices phase of red algae *Porphyra tenera*, *Bangia atropurpurea*, and *Bangia*

fuscopurpurea contains cellulose and minor amount of mannan in their cell walls, the generic phase of the same species contains (1,4)-linked β-D-mannan as the main structural polysaccharide of their cell walls (Gretz et al. 1980; Usov 2001). Further, the cell wall of red seaweed *Palmaria palmata* contains cellulose in a small amount, and in the genus *P. tenera*, it has been even replaced by insoluble mannose, galactose, and xylose (Deniaud et al. 2003; Rupérez and Toledano 2003). Galactose and glucose are determined as the main neutral sugars in cell walls of red seaweed *Chondrus crispus* (Rupérez and Toledano 2003).

The cell walls of red microalgae are without cellulose microfibrils. They are rather encapsulated within the gel matrix from sulfated polysaccharides (Arad and Levy-Ontman 2010). The main part of red and brown seaweed cell walls is represented by sulfated galactans, which are known as agar, alginate, and carrageenan; fucans described as fucoidin, fucoidan, ascophylan, sargassan, and glucuronoxylofucan; and also cellulose. However, their amounts and distribution are variable due to enormous algal diversity and also during different stages of their live cycles (Popper and Tuohy 2010; Percival 1979).

2.4.1 Cellulose

The main structural polysaccharide of some algal species as well as terrestrial plants is cellulose. Its linear molecules are formed by the condensation of D-glucose units through β-(1,4) glycosidic bonds. The hydrogen bonding patterns in cellulose are considered as one of the most important factors on its physical and chemical properties including the solubility, crystallinity, and hydroxyl reactivity. Several different crystalline structures are known in dependence on the location of hydrogen bonds between and within cellulose fibrils. Cellulose I with structures I_α and I_β is natural and I_α occurs in bacteria and some algae and the latter in higher plants (Nishiyama et al. 2003; Kroon-Batenburg and Kroon 1997). Cellulose obtained from algal species is substantially different from cellulose in higher plant; it has a porous or spongy structure.

2.4.2 Alginate

Alginates without sulfate groups are constituents located in the cell wall and in the matrix of brown seaweeds together with fucans and heteroglycans rich in sulfated L-fucoses. Alginates consist of two chain-forming heteropolysaccharides made up of blocks of β-(1,4)-linked D-mannuronic (M) and α-(1,4)-linked L-guluronic (G) acids, and their structure varies in dependence on the monomer position in the chain, forming either homopolymeric (MM or GG) or heteropolymeric (MG or GM) blocks (Rioux et al. 2007; Miller 1996). The alginate composition is significantly dependent on the algal species, diverse location, various season, as well as different parts of thallus from which the extraction of alginate is made, i.e., the stipe has other mechanical requirements in comparison with the fronds. Thus, a higher content of guluronate has been required in plant parts with higher rigidity. Physical properties of alginates as well as formation of gels depend on the relative proportion of these blocks. The ability of alginates to form gels in the presence of divalent

calcium ions is one of their main biofunctional properties and has a great industrial significance (Larsen et al. 2003). The evaluation of the M/G ratio is fundamental for the detection of gel properties. High M/G ratio is the signature of alginate giving elastic gels, while low M/G ratio provides brittle gels (Fenoradosoa et al. 2010).

3 Sulfated Polysaccharides

From a wide scale of different algal polysaccharides, sulfated polysaccharides are the most important from biological activity point of view. They are observed in all groups of algae in contrast to terrestrial plants. Their occurrence in marine algae is connected with a possible correlation with salt stress, and these compounds are also related to mechanical, ionic, and osmotic regulation, helping the survival of algae in the marine environment (Aquino et al. 2011; Rodrigues et al. 2012). The nomenclature of algal sulfated polysaccharides has been often based on the name of algal species, such as spirulan, furcellaran, ulvan, fucan, etc. Generally, sulfated polysaccharides, naturally occurring glycosaminoglycans, are a class of compounds containing hemiester sulfate groups in their sugar residues (Shanmugam and Mody 2000). Red algae produce sulfated galactans consisting entirely of the β-galactose or α-galactose units. The first always belongs to D-series, while the latter is either D-series in carrageenans or L-series in agars (Usov 1998). Sulfated glucans, sulfated galactans, and sulfate arabinogalactans are produced by green algae, and spirulan is known as sulfated polysaccharides of blue-green algae (Aquino et al. 2011; Costa et al. 2010; Shanmugam and Mody 2000).

3.1 Red, Green, and Blue-Green Algae Sulfated Polysaccharides

Sugar presentations of sulfated polysaccharides of some red and green seaweed and of some blue-green algae are shown in Table 1. It is evident that sugar composition as well as the extent of sulfation is very miscellaneous not only across the algal species but also within the same algal strains. While the abundant galactose residues have been established in red seaweeds, rhamnose and glucose residues and uronic acids have been determined in higher amounts in most green seaweeds. Different localities of *Ulva conglobata* affect the composition of their sulfated polysaccharides, especially in the amount of sulfate (Mao et al. 2006). Apparently, the separation processes are also responsible for the different amounts and distribution of neutral sugar and amounts of sulfate in polysaccharide molecules. Mostly hot or cold water is used for the extraction of sulfate polysaccharides from seaweeds. While in species, i.e., *Codium dwarkense*, *C. tenue*, *Avrainvillea erecta*, cold water extraction has been more effective than hot water extraction on the sulfate amounts, in the second seaweed group presented by *Udotea indica* and *Halimeda gracilis*, significant differences in chemical composition of sulfated polysaccharides in hot or cold water extracts have not been observed (Shanmugam et al. 2002).

Table 1 Chemical composition of sulfate polysaccharides of some blue-green algae and some red and green seaweeds

Two main sulfated polysaccharides of red seaweed are agar and carrageenan known as hydrocolloids. They are widely used as texturing agents for many applications in food industry, such as gelling, thickening, and stabilizing agents in different food production and also in many nonfood applications (Lahaye 2001; Sartal et al. 2011). Structural variability of these sulfated galactans occurs among diverse algal species. It is based on different environmental conditions, the season of the collection, and on the extraction methods. Furthermore, various hydroxyl groups may be substituted by sulfate ester, methyl groups, pyruvic acid acetal, or additional monosaccharides. However, the major structural variation is the sulfation pattern (Pomin and Mourão 2008; Usov 1998).

3.1.1 Agar

Generally, agar consists of two major polysaccharides, neutral agarose as a gelling fraction and charged acid agaropectin as a non-gelling fraction. Its molecule is composed of a linear chain of alternating 3-linked β-D-galactopyranosyl and 4-linked of 3,6-anhydro-α-L-galactopyranosyl residues. This backbone may be substituted in varying percentages of half-ester sulfate, methoxyl, or pyruvate groups, and the character of backbone modification may strongly influence gelling properties, i.e., a high content of 3,6-anhydrogalactose and low sulfate content are necessary for a gelling ability (Miller et al. 1993; Usov 1998). Agar is localized in extracellular matrix and is secreted by the Golgi apparatus, and its composition has been documented as very changeable in dependence on the season, seaweed species, different life phases of algae, and also the extraction methods (Praiboon et al. 2006).

3.1.2 Carrageenan

Other sulfated galactan is carrageenan extracted from red seaweed, especially species belonging to the family Gigartinaceae. This galactan consists of linear chains of repeating disaccharide units with alternating 3-linked β-D-galactopyranose (G-units) and 4-linked α-D-galactopyranose (D-units) or 3,6-anhydro-α-D-galactopyranose (DA-units). Furthermore, they usually contain more sulfate than agars in the range of 22–35 % (Jiao et al. 2011; Shanmugam and Mody 2000). Their classification into fifteen different groups, i.e., kappa, iota, lambda, gamma, theta, epsilon, and mu (κ, ι, λ, γ, τ, ε, and μ), is based on the presence and localization of sulfate esters and on the presence of the 3,6-anhydro-D-galactose linked in (1,4) (Shanmugam and Mody 2000; Usov 1998; Lahaye 2001). The main copolymers from industrial point of view are kappa, iota, and lambda carrageenans showing a different ability to form gels with dissimilar characteristics. Thus, κ-carrageenan forms strong rigid gels, ι-carrageenan forms soft elastic gels, and λ-carrageenan does not form any gels but produces the highest viscosities in the water (Sartal et al. 2011). While the main repeating dimer structure of κ-carrageenan is G4S-DA, in ι-carrageenan, it is repeating disaccharide structure of G4S-DA2S, and finally, λ-carrageenan consists of G2S-D2S,6S of dimer structure (De Ruiter and Rudolph 1997; Lahaye 2001). Variations in carrageenan structures occur not only between different species of the Gigartinaceaes but also within the same species in dependence on different life stages.

3.1.3 Furcellaran

Furcellaran, known as Danish agar, is extracted from red seaweed of genus *Furcellaria*. Besides agar and carrageenan, furcellaran is further anionic sulfated polysaccharide that is considered to be a copolymer of β- and κ-carrageenan. The composition of furcellaran extracted from red seaweed *F. lumbricalis* consists mainly of 3-linked β-D-galactopyranose, 4-linked 3,6-anhydro-α-D-galactopyranose, and 3-linked β-D-galactopyranose 4-sulphate (Laos and Ring 2005; Laos et al. 2005). Hydroxyl groups in polysaccharide chain may be substituted by sulfate, methyl groups, and other sugar monomers, such as xylose and glucose. Furcellaran can be commercially used as a gelling agent for its ability to form gels in the presence of specific gel-promoting cations, especially K^+ and Ca^{2+} (Laos et al. 2005).

3.1.4 Porphyran

Porphyran as the main polysaccharide of red alga *Porphyra umbilicalis* has been established by structural analysis. It has been observed that it consists of D- and L-galactose residues in the amount of 24–45 %; 3,6-anhydro-L-galactose has been present in the amount of 5–19 %, 6-*o*-methyl-D-galactose in the amount of 3–28 %, and ester sulfate in the amount of 6–11 %. Further, the ester sulfate seems to occur always as 1,4-linked L-galactose 6-sulfate, even if its content is variable. 3,6-anhydro-L-galactose and L-galactose 6-sulfate have been interchangeable between the polysaccharides, and D-galactose and 6-*o*-methyl-D-galactose have been related in a similar way. Moreover, 3,6-anhydro-L-galactose and L-galactose 6-sulfate introduce approximately a half of sugar units, and D-galactose together with 6-*o*-methyl-D-galactose form the other half of sugar units (Rees and Convay 1962).

3.1.5 Ulvan

The cell wall matrix of green seaweed contains highly sulfated complex of heteropolysaccharides named ulvans whose molecules consist of different sugar residues in dependence on the seaweed strain mainly of the order Ulvales (*Ulva* and *Enteromorpha* sp.). Ulvans are water-soluble polysaccharides consisting mainly of rhamnose, xylose residues, iduronic and glucuronic acids, and sulfate groups. These sulfated galactans tend to be more complex and heterogeneous in the structure than sulfated galactans from red seaweed (Jiao et al. 2011). The main ulvan constituents are sulfated rhamnose residues linked to uronic acids resulting in repeated disaccharide unit β-D-glucuronosyl-(1,4)-α-L-rhamnose 3-sulfate, called aldobiouronic acid (Jaulneau et al. 2010; Lahaye et al. 1997). Also other neutral sugars, such as xylose, mannose, galactose, and glucose, participate in different amounts on the composition of sulfated polysaccharides of green seaweed (Mao et al. 2006, 2009; Zhang et al. 2008; Shanmugam et al. 2002).

3.1.6 Spirulan

Calcium spirulan (Ca-SP) and sodium spirulan (Na-SP) are sulfated polysaccharides obtained from hot water extracts of blue-green alga *Spirulina platensis*.

They are composed of rhamnose, 3-*o*-methylrhamnose (acofriose), 2,3-di-*o*-methylrhamnose, 3-*o*-methylxylose, uronic acids, sulfate, and calcium or sodium ions. The backbone consists of 1,3-linked rhamnose and 1,2-linked 3-*o*-methylrhamnose units with some sulfate substitution at the 4-position; the polymer is terminated at nonreducing end by 2,3-di-*o*-methylrhamnose and 3-*o*-methylxylose residues (Yamamoto et al. 2003; Lee et al. 2000). In Ca-SP molecules, there are two types of disaccharide repeating units, *o*-rhamnosyl-acofriose and *o*-hexuronosyl-rhamnose (aldobiuronic acid). Component sugar analysis of Ca-SP determines 52.3 of % rhamnose and 32.5 % of 3-*o*-methyl-6-deoxyhexose, together with 4.4 % of 2,3-di-*o*-6-deoxyhexose, 4.8 % of 3-*o*-methylpentose, and trace amounts of other sugars (Lee et al. 1998). Ca-SP has been found as an antiviral agent as well as an anticoagulant with heparin cofactor II-dependent antithrombin activities but also as a potent inducer of tissue-type plasminogen activator (t-PA) production (Lee et al. 1998; Hayakawa et al. 1997). However, Ca-SP has a very low anticoagulant activity in comparison with Na-S, which has been studied for its strong antithrombin activity (Yamamoto et al. 2003).

3.2 Brown Algae Sulfated Polysaccharides

Fucans that include polydisperse molecules based on sulfated L-fucose and also heterofucans called fucoidans are observed in brown seaweeds. The chemical compositions of sulfated polysaccharides of some brown seaweed species are expressed in Table 2. Evidently, fucose is the neutral sugar abundantly presented in sulfate polysaccharides of brown seaweeds, in which different extent of sulfation has been observed. Other sugar residues, such as xylose, mannose, glucose, and galactose, participate on the composition of sulfated polysaccharides of brown seaweeds in different amounts. Galactose and xylose sugar residues occur in higher amounts following the fucose residues, the former especially in species of *Laminaria*, and in *Fucus* alternating galactose and xylose residues (Ushakova et al. 2009; Dürig et al. 1997; Rupérez and Toledano 2003). However, in *Panina* species, xylose has been the second most abundant sugar residue, and even in *Sargassum polycystum*, *Turbinara ornate*, and *Undaria pinnatifida*, galactose has been contained in higher amounts of 13.7 %, 25.6 %, and 6.4 % in relation to fucose which is 20.3 %, 30.3 %, and 7.1 %, respectively (Thuy et al. 2015; Rupérez and Toledano 2003).

3.2.1 Fucoidans

Cell walls of several orders of brown seaweed, particularly Fucales and Laminariales, consist mainly of fucoidans, which are composed from variable amounts of saccharide units, such as fucose, xylose, glucuronic acid, galactose, and mannose with a different degree of sulfation (Berteau and Mulloy 2003). Their various structures derived from different sugar distribution and diverse sulfate group contents have been described as fucoidin, fucoidan, ascophyllan, sargassan,

and glucuronoxylofucan (Percival 1979). Depending on their chemical composition, fucoidans could be further divided into xylofucoglycuronans and glycouronogalactofucans consisting of α-(1,3)-linked sulfated L-fucose as a fundamental subunit and a branch unit of α-D-galactose, D-mannose, D-xylose, and glucuronic acid (Jiménez-Escrig and Sánchez-Muniz 2000; Karmakar et al. 2009; Jiao et al. 2011). Contents, chemical composition, and the structure of fucans are changeable in dependence on different environmental conditions, time of collection, seaweed life stage, and extraction procedures (Silva et al. 2005). Besides, the extent of fucoidan content changes is variable and dependent on the seaweed species. Thus, fucoidans have been classified into two groups derived either from *L. saccharina*, *L. digitata*, *Analipus japonicus* or from *Ascophyllum nodosum* and *Fucus* sp.; and their central chains are composed of (1,3)-linked α-L-fucopyranose residues and of (1,3)- and (1,4)-linked α-L-fucopyranose residues, respectively (Jiao et al. 2011; Ushakova et al. 2009).

Different structures of fucoidans have been reported by Silva et al. (2005) who analyzed the chemical composition of heterofucan obtained from brown algae *Padina gymnospora*. The fraction (18 kDa) of heteroglycans consists of 3- or 4-linked β-D-glucuronic acid with minor amounts of 3- or 4-linked galactose units, where almost 50 % of 3-linked glucuronic acid units are branched at C-2 and the branches of galactoses are at C-6, C-2, or C-3 on disubstituted galactose. The fucose chains are formed by 3- or 4-linked fucose units and minor amounts of 4-linked fucose are branched at C-2 with the chains of xylose and/or fucose. Furthermore, for *F. vesiculosus*, two possible structures have been determined. In the first case, fucoidan has been presented as a polymer consisting of α-(1,2)-linked fucose with sulfate branches in the position of 4, whereas in the second structure, fucoidan possesses α-(1,3)-linked fucose with sulfate branches in the same position of 4 (Percival and McDowel 1967; Pomin and Mourão 2008). Fucoidan from a commercial source extracted from *F. vesiculosus* has α-(1,3)-linkages between fucose units, and the ending fucose units have been observed to hold branching with α-(1,2)-linkages or α-(1,4)-linkages (Patankar et al. 1993).

4 Biological Activities of Algal Polysaccharides

Importantly, algae are known as a great source of enormous compounds necessary to protect themselves from the exposure of external environmental factors, such as pollution, mechanical stress, and UV radiation. Both freshwater algae and seaweed have been found as producers of many bioactive compounds. Among these, structurally diverse polysaccharides stimulate human health because of their antimicrobial, antiviral, antimutagenic, anticancer, blood anticoagulant, immunomodulating, and anti-inflammatory activities, as well as hypolipidemic and hypocholesterolemic effects (Ye et al. 2008; Holdt and Kraan 2011; Costa et al. 2010). Polysaccharides have been considered as a dietary fiber from the nutrition point of view. Although dietary fiber does not belong between nutrients, it forms a very important part of diet, and its low intake in some Western countries is one of the reasons leading to

the growth of the number of incidence and mortality due to cardiovascular diseases and colorectal cancer. Generally, the main physiological functions of different parts of dietary fiber are based on their solubility or insolubility in water and degradability or fermentability by intestinal microflora that was reported earlier (Mišurcová et al. 2012). Besides, the important algal polysaccharides performing biological activities are sulfated polysaccharides that have been developing as a new generation of nutraceuticals and drugs (Holdt and Kraan 2011; Shi et al. 2007; Blunt et al. 2010; Bouhlal et al. 2010; Kim 2011).

4.1 Anticoagulant Activity

The human blood coagulation system is the process leading to the arrest of bleeding (hemostasis) and includes the transformation of liquid blood into a solid state in order to reduce the loss of blood from injured blood vessels. This process covers three mechanisms such as formation of prothrombinase, conversion of prothrombin into the thrombin which is a key protein of coagulating cascade, where thrombin activates a series of coagulant factors, and, finally, conversion of soluble fibrinogen into insoluble fibrin (Fig. 1).

The blood coagulation system consists of cellular elements (blood platelets, white cells, to some extent red cells, and microvascular remnants or microparticles), coagulation enzymes, proteins cofactors, and a number of anticoagulant proteins (Spronk et al. 2003). The mechanism of blood coagulation is based on the enzyme cascade divided in the intrinsic, extrinsic, and common pathway, where a series of coagulation factors promote the formation of the end product fibrin (Spronk et al. 2003; Wijesekara et al. 2011). As it can be concluded from Fig. 1, during the intrinsic pathway activated Stuart-Prower factor (X) can also be activated by the extrinsic pathway. Firstly, the intrinsic cascade begins with the formation of primary complex of collagen by high molecular weight kininogen (HMWK), prekallikrein, and Hageman factor (XII). During the activation, the single-chain protein of the native Hageman factor is divided into two chains of different molecular weights (28 and 58 kDa). However, both chains remain linked by a disulfide bond. The 28 kDa light chain contains the active site, and this molecule is called as activated Hageman factor (XIIa), which can activate plasma thromboplastin antecedent (PTA) or antihemophilic factor – C (XI). Further, HMWK, known as Fitzgerald factor, binds to the factor XI, and in the presence of Ca^{2+} ions, it facilitates the activation process of factor XIa. This factor XIa activates Christmas factor, plasma thromboplastin component (PTC), or antihemophilic B factor (factor IX) in the reaction requiring Ca^{2+} ions, factor VIII, and phospholipids. Antihemophilic factor VIII is obviously an essential factor for this step of coagulation cascade, and its deficiency is associated with hemophilia A, while the deficiency of factor IX is connected with hemophilia B (Adelson et al. 1963). Activated IXa factor further activates Stuart-Prower factor (X) to factor Xa; and factor X is the first molecule of the common pathway of coagulation cascade. The extrinsic pathway could be considered as an alternative

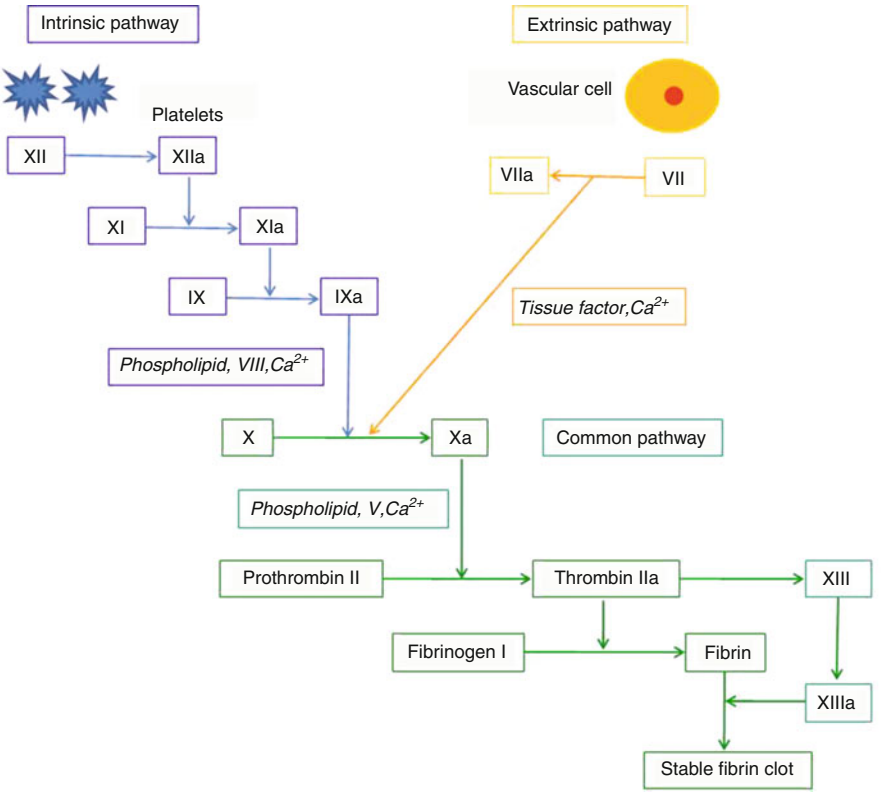

Fig. 1 The scheme of coagulation cascade

way of the activation of factor X in the cooperation with two main components – tissue factor (TF) and factor VII. Blood coagulation factor VII, formerly known as proconvertin, belongs to the serine protease enzyme class, and its main role in extrinsic pathway is to initiate the coagulation process in conjunction with TF.

TF is constitutively present on cell membranes within and around the vessels and serves as the cell surface receptor for serine protease factor VIIa. Carboxylated GLA domain of factor VIIa binds to negatively charged phospholipids in the presence of calcium. Binding of VIIa to negatively charged phospholipids greatly enhances the protein-protein binding of VIIa to TF. Upon a vessel injury, tissue factor, normally found outside of blood vessels, is exposed to the blood where it forms a catalytic complex with factor VIIa activating factor IX and catalyzing the conversion of inactive protease factor X into active protease factor Xa (Spronk et al. 2003; Mirzaahmadi et al. 2011).

Both intrinsic and extrinsic pathways lead to the activation of factor X into factor Xa (the common pathway) which combines with its cofactor – activated proaccelerin (factor Va) – in the presence of calcium and phospholipid to produce thrombin for the conversion of fibrinogen to fibrin. Fibrin monomers spontaneously

polymerize and form an insoluble gel (clots) which is held together by noncovalent and electrostatic forces and is stabilized by fibrin-stabilizing factor XIII catalyzing the formation of peptide bonds between fibrin monomers. Clots together with aggregated platelets (thrombi) block damaged blood vessel and prevent further bleeding (Chatterjee et al. 2010).

Hemostatic abnormalities can lead to serious health problems, such as excessive bleeding or thrombosis. Thus, the human coagulation mechanism has to be strictly regulated by the inactivation of procoagulant enzymes, fibrinolysis, and hepatic clearance of activated clotting factors (Kalafatis et al. 1997) via tissue pathway inhibitor (TFPI), heparin-antithrombin pathway, and protein C pathway (Esmon 2005). The first inhibitor process TFPI inactivates factor VIIa bound to tissue factor (TF). The second antithrombin (ATIII)-heparin mechanism inactivates factor Xa, thrombin, factor IXa, and factor VIIa bound to cell surface tissue factor (Rao et al. 1995). The latter protein C pathway is based on the activation of protein C by the thrombin-thrombomodulin complex on endothelium. This natural anticoagulant system exerts its anticoagulant effect by regulating an activity of factors VIIIa and Va, cofactors in tenase, and prothrombinase complexes, respectively (Dahlbäck and Villoutreix 2005; Esmon 2003).

Heparin, a highly sulfated glycosaminoglycan, is naturally produced by basophils and mast cells; in medicine it is principally used as an anticoagulant to treat and prevent blood clots in the veins and arteries. Heparin molecule possesses a specific local structure, and it is composed of pentasaccharide sequence with a specific pattern of sugar residues along with a sulfation pattern required to induce a conformational activation of antithrombin. Heparin has also an additional anticoagulant mechanism in which polysaccharide brings antithrombin and thrombin in a ternary complex in which both the inhibitor and proteinase are bound to the same polysaccharide chain (Pereira et al. 2002; Streusand et al. 1995). The heparin usage is limited due to several side effects, i.e., a serious side effect resulting in degradation of platelets causing thrombocytopenia (Bick and Frenkel 1999; Castelli et al. 2007).

4.2 Anticoagulant Activity of Algae

Therefore, the requirement of finding alternative sources of anticoagulants has arisen. Heparin-like substances extracted from seaweed have been greatly studied in vitro as potential blood anticoagulants. So far, about 150 species across three major divisions of marine red (Rhodophyta), brown (Phaeophyta), and green (Chlorophyta) algae have been reported to have blood anticoagulant activities. Examples of anticoagulant activities of some algal species across three major divisions of green, red, and brown seaweed as well as blue-green algae are shown in Table 3.

Generally, anticoagulant activity of sulfated polysaccharides has been usually measured by different in vitro method, such as activated partial thromboplastin time (APTT), prothrombin (PT), and thrombin (TT) times. The first assay indicates the

precise anticoagulant potency of analyzed polysaccharides, and it is expressed as international units (IU) per mg of polysaccharide using the non-fractionated heparin (HEP, 193 IU/mg). The latter assays (PT, TT) have been performed by using normal human plasma in which algal polysaccharide extract is added and clotting time is recorded after the clotting induction by addition of thrombo reagent (Rodrigues et al. 2011; Padmanaban et al. 2013; Mao et al. 2008). The mechanism of anticoagulant activities of algal sulfated polysaccharides in the clotting cascade could be identified by all assays, APTT, PT, and TT as well. APTT assay could identify the mechanism of anticoagulant activities of algal sulfated polysaccharides in the intrinsic pathway of clotting cascade by inhibiting factors XII, XI, X, IX, VIII, and prothrombin; the PT assay could identify the mechanism of ulvans, fucans, and galactans in extrinsic pathway by inhibiting factors X, V, and prothrombin; and TT assay could be helpful to investigate the effect of sulfated

polysaccharides on thrombin-accelerated clot formation in platelet poor plasma (Padmanaban et al. 2013; Mao et al. 2008). Anticoagulant activity of algal polysaccharides varies depending on their chemical composition and particularly on different contents and positions of sulfate radicals, molecular weight, and sugar position. Moreover, the influence of the extractive methods used for the isolation of algal polysaccharides on anticoagulant activity has been confirmed. Leite et al. (1998) investigated the anticoagulant activity of acidic polysaccharide extracts from brown alga *Spatoglossum schröederi*. Polysaccharide extracts were obtained by ion-exchange chromatography using different salt molarities (0.15–3.0 M NaCl) and lower concentrations from the range of 0.5–0.7 and 1.0–1.5 M of salt resulting in higher content of alginic acid and xylose in obtained extract, respectively, while the extracts enriched with sulfated xylofucan were obtained with using higher concentrations (2.5–3.0 M) of salt. Anticoagulant activities of all polysaccharide fractions were low (0–22.4 IU/mg) in comparison with heparin activity of 150.0 IU/mg. However, all acidic polysaccharide fractions showed the ability to stimulate the synthesis of antithrombotic heparin sulfate produced by the rabbit aorta endothelial cells in culture to the same amount of heparin Leite et al. (1998). Neutral polysaccharides are usually extracted with cold or hot water, due to low or very high molecular weight, respectively. Higher anticoagulant activity of green algae *Codium* spp. and *Udotea* spp. has been reported in the fraction obtained by cold or hot water extraction, respectively (Shanmugam and Mody 2000). Finally, it has been also reported that polysaccharides isolated by proteolytic digestion from green seaweed *Caulerpa cupressoides* have a low anticoagulant potential in relation with polysaccharide extract obtained by ion-exchange chromatography (Rodrigues et al. 2011). Further, the strength of anticoagulant activity is also influenced by algal genus. Generally, sulfated polysaccharide extracts of brown seaweeds exhibit higher anticoagulant activity than red and green algae extracts. However, in comparative analysis, it has been observed that red seaweed *Gelidium* contained higher content of total saccharides and total sulfate content than brown seaweed *Sargassum* and green seaweed *Ulva*, and their anticoagulant activities are in correlation with sugar and sulfate contents. So, the extract from red seaweed *Gelidium* exhibits the highest anticoagulant activity, followed by the extract from brown seaweed *Sargassum*, while the extract from green seaweed *Ulva* has showed the lowest anticoagulant activity (Padmanaban et al. 2013).

4.2.1 Blue-Green Algae

Calcium spirulan (Ca-SP) is sulfated polysaccharide extracted from blue-green alga *Spirulina platensis*. It has been reported that Ca-SP exhibits anticoagulant activity by potential inhibition of thrombin mediated by heparin cofactor II (HCII), however, in a different mechanism from that of heparin (Hayakawa et al. 2003). Heparin cofactor II is a plasma serine protease inhibitor which selectively inhibits thrombin. Its ability to inhibit α-thrombin is accelerated by a variety of sulfated polysaccharides in addition to heparin and dermatan sulfate. The mechanism of activation of HCII is based on the fact that binding of either heparin or dermatan sulfate to HCII

displaces the N-terminal acidic domain of the inhibitor, which normally occupies the glycosaminoglycan-binding site. Then, N-terminal acidic domain binds to anion-binding exosite I of thrombin, facilitating proteolytic attack on the reactive site of peptide bond of HCII resulting in a significant decrease of the rate of α-thrombin inhibition in the presence of either heparin or dermatan sulfate. Hayakawa et al. (2000) has suggested that the stimulatory effect of Ca-SP is not mediated through N-terminal acidic domain of HCII, but the anion-binding exosite I of α-thrombin is essential for the rapid inhibition of the reaction by HCII in the presence of Ca-SP. The allosteric activation of HCII by Ca-SP has been observed through Arg^{103} – Leu mutant bound to Ca-SP-Toyopearl with the normal affinity and inhibited α-thrombin in a manner similar to native rHCII.

Moreover, sodium spirulan (Na-SP) isolated from blue-green alga *S. platensis* has been observed as a strong anticoagulant agent in the blood coagulation-fibrinolytic system. Not only because it activates heparin cofactor II, physiologic inhibitor of thrombin, but it also exhibits fibrinolytic property through varying effects on the endothelial fibrinolytic protein secretion, where it stimulates the release of anticoagulant heparan and dermatan sulfate proteoglycans from the vascular endothelial cell layers (Yamamoto et al. 2003).

4.2.2 Green Algae

The mechanism of anticoagulant activity of green algal sulfated polysaccharides has been assigned to common pathway, primarily heparin cofactor II (HCII)-mediated anticoagulant action (Shanmugam and Mody 2000). According to Wijesekara et al. (2011), sulfated arabinan and sulfated arabinogalactan extracted from two green algae species *Codium dwarkense* and *C. tomentosum* have been the most active coagulants; the former shows higher coagulant activity, while the latter is relatively less active. Further, it has been reported that the coagulant activity is directly proportional to sugar and sulfate contents of proteoglycan and inversely proportional to protein content of proteoglycans. Thus, proteoglycans with 18.4 % content of sulfate show the greatest anticoagulant activity, followed by sulfated polysaccharides with the content of 10.2 % and 7.5 % of sulfate (Wijesekara et al. 2011). Further, highly sulfated galactan (13.1 % of sulfate) containing mainly galactose with a small amount of glucose from green algae *C. cylindricum* has been found as an anticoagulant with the similar activity compared with heparin, but weaker than heparin (Matsubara et al. 2001). Anticoagulant activity of sulfated polysaccharides isolated from green seaweed *Monostroma nitidum* has also been described. Among two sulfated polysaccharides of *M. nitidum* with different structure of their molecules, different extent of anticoagulant activities has been evaluated. Evidently, both polysaccharide fractions exhibit high anticoagulant activities; however, differences between them are directly due to their structural feature discrepancy, and sulfated polysaccharide with a lower molecular size and higher sulfate content show notably higher anticoagulant activity (Mao et al. 2008). Further, sulfated polysaccharide composed mainly of (1,2)-linked L-rhamnose residues with sulfate groups substituted at positions C-3 and/or C-4 isolated from marine green algae *M. latissimum* show high anticoagulant activities proved by APTT and

TT assays. Anticoagulant property of this sulfate polysaccharide has been mainly attributed to powerful potentiation of thrombin by HP II (Mao et al. 2009). The influence of different concentrations of extraction solutions (0.50, 0.75, and 1.00 M NaCl) used for the elution of sulfated polysaccharides of three species – *Caulerpa cupresoides*, *C. racemosa*, and *C. prolifera* – has been confirmed. Dissimilarity in the presence of sulfate groups in chemical structures of their sulfated polysaccharides obtained by ion-exchange chromatography has been observed. Lower content of sulfate groups has been established in *C. cupressoides*, followed by *C. racemosa*, and higher content has been determined in *C. prolifera* which is in accordance with the extent of their anticoagulant activities of 17.37, 22.17, and 25.64 IU/mg, respectively, in comparison with heparin activity of 193 IU/mg (Rodrigues et al. 2012). Green seaweed *Ulva conglobata* collected from three various locations in China (coasts of Quigdao, Yantai, and Rizhao) exhibited different polysaccharide compositions with major representation of rhamnose 71.90, 72.26, and 63.77 mol%, respectively; variable contents of glucose and fucose; and trace amounts of xylose, galactose, and mannose. Their sulfate ester contents were 35.20 %, 23.04 %, and 28.06 %, respectively. The highest anticoagulant activity was established in hot water extract from *U. conglobata* collected from the coast of Quigdao in comparison with extracts from the other locations. Polysaccharide extract from the coast of Rizhao possessed higher content of sulfated ester and lower content of rhamnose than extract from the coast of Yantai, the former showing lower anticoagulant activity than the latter (Mao et al. 2006). The extent of anticoagulant activity of algal polysaccharides varied in dependence on different sugar residues and their proportion, as well as on sulfation content and structural features.

4.2.3 Red Seaweed

Anticoagulant activity has been studied in over 40 species of red algae. Generally, the mechanism of anticoagulant activity of galactan sulfate of red seaweed could be realized through the inhibition of thrombin and could be either directly, even though the mechanism has been still unknown, or indirectly via HCII. Anticoagulant activity of sulfated galactans depends on the nature of sugar residue, sulfate content, and the position of sulfate groups. Furthermore, carrageenans with high molecular weight and high sulfate content have shown higher anticoagulant activity than low molecular weight and low sulfate content (Wijesekara et al. 2011).

The mechanism of anticoagulant activity of carrageenans and other sulfated galactans is exhibited via thrombin inhibition. Carrageenans appear to inhibit amidolysis of thrombin directly and via ATIII; however, only ATIII potentiated Xa amidolysis has been observed (Shanmugam and Mody 2000). Anticoagulant properties of three types, κ-, ι-, and λ-carrageenans with different sulfate amounts of 17.89 %, 27.20 %, and 33.38 %, respectively, were established by APTT and PT assays and compared with unfractionated heparin from bovine lung. The compounds may act only on intrinsic pathways of the blood coagulation system, not on extrinsic pathways which could be confirmed by very low results of PT assay in the case of κ- and ι-carrageenans. Only λ-carrageenan showed similar anticoagulant activity of 120 s at 20 μg, as heparin did. All types of analyzed carrageenans had

very low anticoagulant activity when compared to heparin by APTT assay. While κ- and ι-carrageenans exhibited the anticoagulant activity of 132.2 and 240 s at the concentration of 100 μg, λ-carrageenans displayed elevated anticoagulant activity of 240 s at 20 μg, and heparin showed the anticoagulant activity of 250 s at 2.5 μg (Silva et al. 2010).

Moreover, the strength of anticoagulant activity between different types of carrageenans appeared to be due to various amounts of sulfate content. λ-carrageenan showed greater antithrombotic activity than κ-carrageenan, although it also showed higher toxicity which is dependent on the molecular weight (Shanmugam and Mody 2000).

The extent of anticoagulant activity of carrageenans seemed to be influenced also by a different composition of polysaccharides extracted from red seaweed in various stages of their life cycle. Anticoagulant activity of carrageenans of λ-type and the mixture of κ-/ι-type extracted from cystocarpic (reproductive) and sterile plants of *Chondrus pinnulatus* harvested on the Russian Pacific coast had extremely high values exceeding 600 s established by APTT assay in contrary to that from sterile plants. Since molecular weights of cystocarpic plant carrageenans were almost twice higher (420 and 389 kDa) than molecular weights of carrageenans from sterile plants (290 and 220 kDa), high anticoagulant activity may be caused by high molecular weight of this polysaccharide (Yermak et al. 2006).

Sulfated galactans and carrageenan were extracted from red algae *Corallina* collected at the Lebanese coast in the yields of 2.5 % and 10 %, and their anticoagulant activities were determined by ATPP assay. Carrageenans exhibited more powerful anticoagulant activity from 78.4 to 120 s at doses of 0.05 and 0.5 μg, respectively, than sulfated galactans that reached 104.3 s at their highest dose of 5 μg, but only λ-carrageenan was used for analyses (Sebaaly et al. 2014).

Further, it was reported that 2,3-di-*o*-sulfated D-galactan from red seaweed *Botryocladia occidentalis* exhibited anticoagulant activity comparable to heparin, which appeared to be due to the inhibition of thrombin and factor X. Furthermore, 2,3-di-*o*-sulfated galactose has an amplifying effect on the anticoagulant activity of sulfated galactans. From the three fractions with sulfate contents of 0.69 %, 1.47 %, and 2.08 % eluted by using different concentrations of NaCl 1.0, 2.2, and 3.0 M, respectively, the fraction with the sulfate content of 1.47 % showed the highest anticoagulant activity of 150 IU/mg by APTT assay, while the fraction with the highest sulfate content showed a lower anticoagulation effect of 130 IU/mg and the fraction with the lowest sulfate content showed even no effect. Finally, desulfation had the abolish effect on the anticoagulant activity of the sulfated galactans (Farias et al. 2000). The proportion and/or distribution of 2,3-di-sulfated galactose along the polysaccharide chain modulated the interaction of polysaccharides with specific proteases in the coagulation system. It was reported that 2,3-di-sulfated galactose obtained from *B. occidentalis* inhibited intrinsic tenase and prothrombinase complexes crucial for factor Xa and thrombin generation, respectively (Jiao et al. 2011). Porphyran derivate obtained from red seaweed *Porphyra haitanensis* with fully sulfated modification showed the highest anticoagulant activities by APTT, TT, and PT assays 396.47 s, 311.70 s, and 298.03 s, respectively, in a dose of 100 μg/ml.

Besides the degree of sulfation, distribution of sulfated group was also an important factor influencing the anticoagulant activity of porphyran, which has a linear backbone of alternating 3-linked β-D-galactosyl units and 4-linked α-L-galactosyl 6-sulfate or 3,6-anhydro-α-L-galactosyl units. In the case of alkali treatment of porphyran, 6-*o*-desulphatation in (1,4)-linked residue was carried out, nevertheless almost without any change of anticoagulant activity. Moreover, 6-*o*-sulfated derivate showed a lower anticoagulant effect than 2,2′,4-*o*-sulfated derivate. From these results, it could be concluded that sulfate groups at C-6 were not necessary for the anticoagulant activity, whereas an increase in the overall molecular weight and position of sulfate groups at C-2, C-3, and C-4 was a dominant factor for the anticoagulant effect of porphyran (Zhang et al. 2010).

4.2.4 Brown Seaweed

Anticoagulant activity of fucoidans, like heparin, is based on the inhibition of thrombin activity by influencing directly the enzyme or through the activation of thrombin inhibitors, including antithrombin III (ATIII) and heparin cofactor II (HCII). Some fucoidans activate only antithrombin, whereas others interact with both inhibitors (Cumashi et al. 2007). Almost all fucoidans exhibit anticoagulant activity that may be related to the content and position of the sulfate group, molecular weight, and sugar position (Berteau and Mulloy 2003).

It has been documented that fucans with high sulfate and low uronic acid content show higher anticoagulant activity than those with high uronic acid and low sulfate content (Wijesinghe and Jeon 2012; Cumashi et al. 2007; Shanmugam and Mody 2000). It has been reported that anticoagulant activity of the fucoidans does not depend on the content of neutral sugar residues in their molecules or on the structure of the main chain. However, the degree of sulfation of their molecules has been reported as an important factor to affect their anticoagulant activities (Ushakova et al. 2009). Thus, it has been documented that higher content of sulfate groups is related to higher anticoagulant activity in native fucoidans (e.g., *Hizikia fusiformis*, *Ecklonia kurome*), and furthermore, the position of the sulfate groups on sugar residues is a very important factor of influence on the anticoagulant activity of fucoidans, relating to the concentration especially of C-2 sulfate and C-2,3 disulfate (Li et al. 2008). The structural analysis has established that a central core of fucan obtained from brown algae *Padina gymnospora* is composed of 3- or 4-linked β-D-glucuronic acid with minor amounts of 3- or 4-linked galactose units. High content of nonreducing fucose and xylopyranose terminal residues indicates that these heteroglycans are highly branched polymers. Subsequent desulfation of this heteroglycans fraction obtained by solvolysis in dimethyl sulfoxide caused the reduction of the sulfate groups by about 76 % due to the removal of 3,4-disubstituted fucosyl residues mostly sulfated at C-3, resulting in an abolishment of its anticoagulant activity. Thus, the presence of (1,4)-linked 3-*o*-sulfated fucose could be related to higher anticoagulant activity (Silva et al. 2005). Moreover, sulfated fucan obtained from brown seaweed *Laminaria brasiliensis* shows a strong anticoagulant activity of 30.0 IU/mg; however, desulfation of this fucan totally abolishes its anticoagulant activity (Pereira et al. 1999). According to

Ushakova et al. (2009), fucoidans originated from brown seaweeds *L. saccharina*, *L. digitata*, and *Fucus distichus* contained the highest amount of sulfate in the range of 27.5–34.8 % and the lowest amount of uronic acid and showed the highest anticoagulant activity by APTT assay in the amounts of 33.0, 24.2, and 26.9 U/mg, respectively, and by PT assay in the amounts of 40.8, 33.2, and 33.0 s, respectively; and, finally, anticoagulant activities performed by TT assay were in the amounts of 72.8, 36.0, and 29.0 s, respectively. In accordance with the previous author, in brown seaweeds, *L. saccharina*, *L. digitata*, and *F. distichus* have been established as the highest anticoagulant activities of 33.0, 24.2, and 26.9 U/mg, respectively. In other brown seaweeds, such as *F. serratus*, *F. evanescens*, *F. spiralis*, and *Ascophyllum nodosum*, lower anticoagulant activities have been determined in the amounts of 19.1, 15.1, 16.6, and 13.4 U/mg, respectively. On the other hand, sulfated polysaccharide of *Cladosiphon okamuranus* with the highest content of 23.4 % of uronic acids and the lowest content of sulfate groups of 15.1 % has showed almost no anticoagulant effect (Cumashi et al. 2007). Analyses of anticoagulant activities of fucoidans have demonstrated that native fucoidans interact with ATIII like heparin and promoted thrombin activation followed by the formation of a complex with thrombin and ATIII. However, in contrast to heparin, they may directly inhibit thrombin (Ushakova et al. 2009). Molecular weight is also important for the anticoagulant activity of fucoidans because of long enough sugar chain, and suitable conformation is needed to bind thrombin. A slight decrease in molecular weight of sulfated fucan dramatically reduces its effect on thrombin inactivation mediated by HCII. Although sulfated fucan with 45 tetrasaccharide repeating units could bind to HCII, it is unable to link efficiently the plasma inhibitor and thrombin because for this action chains with 100 or more tetrasaccharide repeating units are necessary. The template mechanism may predominate over the allosteric effect in the case of linear sulfated fucan inactivation of thrombin heparin cofactor II being present. Linear sulfated fucan requires significantly longer chains than mammalian glycosaminoglycans to achieve the anticoagulant activity (Li et al. 2008; Pomin et al. 2005). Molecular size of the most active fucoidans has been approximately between 50 and 100.000 daltons, whereas fractions with higher molecular weight have exceeded 850.000 Da inclined to lower the anticoagulant activity (Shanmugam and Mody 2000).

Anticoagulant activity of 75 % fucoidan from *U. pinnatifida* consisted of 24.7 % fucose, 20.35 % galactose, no mannose, 29.07 % sulfate, 2.19 % protein, and 7 % bond ions evaluated by APTT, TT, PT, and ATIII assays. It was established that this fucoidan exhibited a very strong hemostasis effect. It prolonged APTT time from 38.8 s for control to 172.5 s at 63 mg/l; TT time was also prolonged at a higher rate in which it was 15.2 s at baseline and went up to 240.1 s at 15.6 mg/l. Further, ATIII decreased with the fucoidan treatment from 108 % for control to 89 % at 10 000 mg/l; and finally, low concentration of fucoidan had no effect on PT until the concentration of 125 mg/l of PT when it began to increase (Irhimeh et al. 2009). Also crude polysaccharide fraction of brown seaweed *Sargassum horneri* consisted of 97 % of polysaccharide and 2 % of protein showed a strong anticoagulant effect exceeding 300 s by APTT assay, whereas anticoagulant active compounds were

mainly concentrated in the fraction with molecular weight higher than 30 kDa (Athucorala et al. 2007). Brown seaweed *Dictyopteris polypodioides* growing on the Lebanese coast was collected in two different seasons in May and July. It was rich in polysaccharides whose main component was alginic acid (11 %) as well as water-soluble polysaccharides, such as fucoidan, laminaran, and mannuronan, whose amounts differed depending on the season between 3.75 % in May and 5.8 % in July. The anticoagulant activities were established in different fractions of polysaccharides composed from fucose and laminaran residues (FL), mixture of fucose, laminaran and mannuronan (FLM), and mannuronan (M). The highest anticoagulant activities of 42.5, 43.1, and 42.1 s by APTT assay in the application doses of 2.5 μg of different fractions FL, FLM, and M were determined, respectively (Karaki et al. 2013).

Laminaran is known as a storage polysaccharide of brown seaweed, and it does not naturally contain sulfate groups. However, laminarin sulfate obtained by sulfation could possess 0.6–2.2 sulfate groups per glucose unit, and its molecule consists of *o*-sulfated β-(1,3)-linked glucose residues. It has been observed that laminarin sulfate with about two sulfate units per glucose exhibits the maximum anticoagulant activity of about 30–40 % of the anticoagulant activity of heparin, and it is therapeutically effective in the prevention and treatment of cerebrovascular diseases (Miao et al. 1995; Adams and Thorpe 1957).

It has been also observed that the degree of sulfation influences the anticoagulant activity of sulfated laminarin, i.e., derivate with 2.31 degree of sulfation is less anticoagulant (26.2 USP-U/mg and 3.1 U/mg by APTT and TT assays, respectively) than derivate of laminarin with a degree of sulfation of 1.98 that shows the highest anticoagulant activity of 36.2 USP-U/mg and 14 U/mg by APTT and TT assays, respectively, while laminarin derivates with 0.3 and 0.64 degree of sulfation exhibits no effect (Hoffmann et al. 1995).

Sulfated β-aminoethyl ether derivates of laminaran, (1,3)-linked glucan of *L. digitata* containing both *o*-sulfated and N-sulfated groups have been found to show anticoagulant activity rather than isolated *o*-sulfated groups. Further, partially oxidized laminaran with a sulfate content of 15.9 % gave the activity of 26 IU/mg in APTT test, while partially reduced sulfated alginic acid with the maximum of sulfate of 13.4 % and the lowest uronic acid content of 20 % gave the highest activity of 55 IU/mg in APTT test than low sulfated one (Shanmugam and Mody 2000). The sargassan obtained from brown seaweed *S. linifolium* was composed of D-glucuronic acid, D-mannose, D-galactose, D-xylose, L-fucose, and a protein moiety. The backbone of sargassan seems to be composed of glucuronic acid, mannose, and galactose residues with partially sulfated side chains consisting of galactose, xylose, and fucose residues, and it exhibited high coagulant activity (Fattah et al. 1974).

Alginic acid is naturally a polymer of D-mannuronic and L-guluronic acids without sulfate contents. Sulfated derivate of alginic acid also shows anticoagulant activity; however, it is much lower and much more toxic than heparin. Also aminated fraction of sulfated alginic acid derivate shows anticoagulant activity in APTT assay by binding to immobilized ATIII (Shanmugam and Mody 2000).

5 Conclusion

High interest in algae is their perspective to be served as food with high nutritional value, as nutraceuticals and medicinal food for their health benefits of bioactive compounds present. Freshwater algae and seaweed are a natural source representing many other interests for medical, therapeutic, and nutritional fields in many applications in the food industry, cosmetic industry, and medicine and pharmaceutical industry by the reason of searching for new natural and less toxic bioactive compounds than synthetic products.

Recently, algal polysaccharides alongside nutritious important compounds, such as proteins, amino acids, minerals, and vitamins, are in the focus of many researches all over the world for their health beneficial activities, such as anticoagulant, antioxidant, antiproliferative, antitumoral, anti-inflammatory, and antiviral properties, as well as skin protecting and antiaging activities. Heparin has been identified and used for more than fifty years as a commercial anticoagulant. However, some of the side effects of heparin, i.e., thrombocytopenia, hemorrhagic effect, and incapacity to inhibit thrombin bound to fibrin, lead to an increasing interest in discovering new anticoagulants to replace heparin. Algal-derived sulfated polysaccharides have been found to possess anticoagulant activity similar to or higher than heparin. Thus, the results of many research studies suggest that algal sulfated polysaccharides have a promising potential to be used as anticoagulant agents and medication for thrombotic disorders.

Polysaccharides from Lower Plants: Bryophytes

5

Laura Klavina

Contents

Abstract

Bryophytes, which are considered to be the first land plants, are the second largest taxonomic group in the plant kingdom. Polysaccharides in bryophytes play a key role in the evolution of chemical diversity of vegetation, and they also function as a structural material. Additionally, polysaccharides are believed to be involved in bryophyte stress tolerance and other functions in this plant kingdom group. Despite the recent progress in bryophyte phytochemistry, bryophyte polysaccharides as a group of substances are largely neglected. Still, major differences in the polysaccharide composition in comparison with higher plants can be identified. In *Sphagnum* mosses, a unique polysaccharide – sphagnan – has been found, and its possible applications are on the way. Further, a relatively large group of carbohydrates that form bryophyte polysaccharides has been identified, and their functions in the development of bryophyte stress tolerance are discussed. Study of bryophyte polysaccharides is a challenging and

prospective field of research, with a potential of providing not only considerable new knowledge about this group of substances, their functions, evolution of chemical compounds and chemical diversity, but also new applications of bryophyte carbohydrates.

Keywords
Polysaccharides • Monosaccharide • Bryophytes • *Sphagnum* • 2-Galacturonic acid • Sphagnan

1 Introduction

The bryophytes are one of the major plant taxonomical groups in the world, and they can be found nearly everywhere globally, growing on differing substrates and in a variety of growth conditions (Goffinet and Shaw 2008; Glime 2007). There have been about 25,000 bryophyte species identified; however, this figure is rapidly changing due to the increasing application of genetic identification of species, supporting better understanding of taxonomical order and differences of their physiology, as well as discoveries of new species (Asakawa et al. 2013; Goffinet and Shaw 2008). Bryophytes are divided in three phyla – Bryophyta (mosses), Marchantiophyta (liverworts), and Anthocerotophyta (hornworts). Taking into account that bryophyte taxonomy is rapidly changing, the taxonomy given in Fig. 1 will be used in this chapter. In respect to the evolution theory, bryophytes are placed between algae and vascular plants and thus considered as the first terrestrial plants (Goffinet and Shaw 2008; Glime 2007).

Bryophyte fossils serve as an indicator of the age of bryophytes, and they date back to the upper Carboniferous. However, the fossil record cannot be considered as a strong indicator, because not many findings are unambiguous, and the possible age estimation differs from sample to sample. The molecular phylogeny of bryophytes suggests that the origin of this division dates back to Ordovician; accordingly, their evolution appears to have begun at least 400 million years ago (Goffinet and Shaw 2008; Glime 2007). Studies of bryophyte phytochemistry and their polysaccharides can be used as a tool to understand the composition of bryophytes and to explain and find new evidence about the genesis of both higher and lower plants, as bryophytes are likely to be a link between them.

The bryophyte polysaccharide studies require understanding of the evolution of chemical diversity during the development from lower plants and microorganisms to higher plants. Furthermore, polysaccharides in bryophytes function as a structural material, demonstrating the importance of cellulose and lignin as cell wall molecules (Popper and Fry 2003; Popper et al. 2004) (absent in bryophytes) in higher plants and revealing how the evolution of chemical structures has supported the biological evolution (Glime 2007). Polysaccharide studies may result not only in identification of new compounds and their combinations, providing new knowledge about this group of substances and their functions, but also in new applications

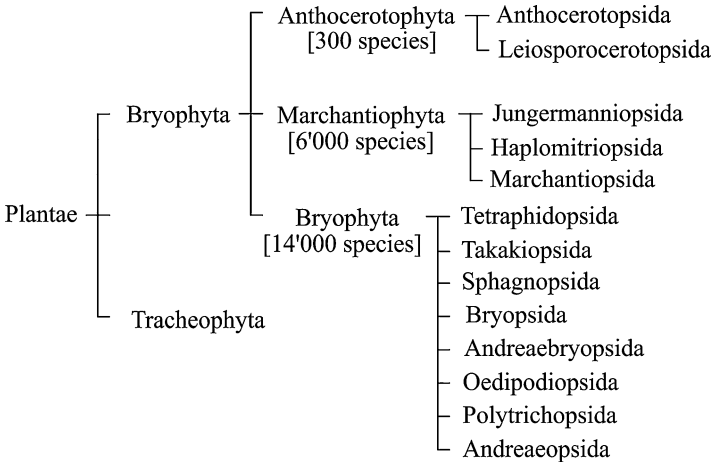

Fig. 1 Taxonomical order of the Bryophyta division (Adapted from Asakawa et al. 2013; Glime 2007)

of bryophyte carbohydrates. Studies of *Sphagnum* polysaccharides as prospective substances for food conservation can be considered exemplary in demonstrating the potential for development in this direction (Balance et al. 2008; Painter 1991).

2 Occurrence/Sources

The bryophyte habitat structure is regulated by the hydrological requirements of the species as well as the requirements in respect to the growth substrate and other aspects. For instance, the compound of 3-hydroxy-β-ionone and momilactone A and B found in bryophytes inhibit the growth of other plants, thereby enabling *Rhynchostegium pallidifolium* and *Hypnum plumaeforme* to form the species-specific dense cover of moss (Kato- Noguchi et al. 2010). Each bryophyte species has its own hydrological requirements that are partly connected with their stress tolerance. Some species are more adapted to cold or extremely cold (such as Arctic) climates, while others are able to survive heat and long-time drought. These unique adaptation skills are the reason of why bryophytes are so widespread in all ecosystems (Glime 2007) and have a wide ecological niche and higher stress tolerance than higher vegetation.

Despite the global abundance, high diversity of species, and unique chemical composition, bryophyte chemistry and their polysaccharides have not been extensively studied. One of the reasons for the low interest in bryophyte chemical composition studies is their relatively small size that usually varies between a couple of millimeters to up to a few centimeters (Zinsmeister and Mues 1990; Glime 2007). The size of bryophytes is limited due to their anatomical and physiological character, as they do not have a vascular system and strong building materials of cell walls, such as cellulose-based polysaccharides and lignin

(Goffinet and Shaw 2008; Popper and Fry 2003). Although in higher plants a significant source of polysaccharides is the reserve polysaccharides, such as starch, this by no means applies to bryophytes, in which polysaccharides can be isolated from the whole plant material and which have a low number of special bodies or structural elements responsible for the accumulation of larger quantities of polysaccharides (Balance et al. 2012; Goffinet and Shaw 2008). Due to their small size, it is complicated to harvest large quantities of sample materials necessary for extensive chemical analysis and identification of individual substances (Goffinet and Shaw 2008; Zinsmeister and Mues 1990). In most cases bryophytes tend to form tight colonies, including other bryophyte species, vascular plants, as well as small living beings, such as fungi, bacteria, ticks, spiders, etc. (Goffinet and Shaw 2008; Glime 2007). One more reason for the slow pace of research in the area of bryophyte polysaccharides that is also partially connected with their size is their complicated identification due to the unclear taxonomy (Asakawa et al. 2013; Goffinet and Shaw 2008; Glime 2007). In some occasions, identification of different bryophyte species can be done only by examining in a microscope the cross section of a leaf that in many cases is about 1 mm or less in size, making the gathering of this kind of species for chemical analysis extremely difficult (Zinsmeister and Mues 1990).

Isolation of polysaccharides from bryophytes usually is done by extensive removal of secondary metabolites by means of exhaustive extraction with low-polarity solvents (hexane, chloroform, dichloromethane, etc.), followed by extractions with more polar solvents (methanol, ethanol, acetone) and extractions with water, acid hydrolysis or autohydrolysis (Balance et al. 2008; Painter 1991). Although the extraction process of bryophyte polysaccharides is well elaborated in respect to *Sphagnum* mosses, however, the suggested approaches include an intermediate step of oxidation with $NaClO_2$, possibly resulting in the oxidation of carbohydrate functional groups (Balance et al. 2008; Painter 1991, 1983), thus potentially giving false results.

3 Brief Phytochemistry

3.1 Bryophyte Phytochemistry

Bryophyte phytochemistry is one of the most challenging and at the same time very rapidly developing field of phytochemistry, and it is closely related to developments in better understanding of the evolution of vegetation. The phytochemistry of bryophytes is also noteworthy as a new field of bioprospecting, and it is important for understanding the ecological functions of bryophytes in nature. The phytochemistry of bryophytes has been analyzed in several review articles and in a recently published book that mainly concentrates on the chemistry of liverworts (Asakawa et al. 2013; Beike et al. 2010). The interest in bryophytes is related to their wide use as medicinal plants to cure burns, bruises, snake bites, tuberculosis, neurasthenia, fractures, convulsions, scald, uropathy, and pneumonia (Asakawa et al. 2013;

Table 1 Major chemical constituent groups of bryophytes (Adapted from Asakawa et al. 2013; Ignat et al. 2011; Üçüncü et al. 2010; Iwashina 2003; Baas et al. 2000; Dembitsky et al. 1993; Zinsmeister et al. 1991; Zinsmeister and Mues 1990; Tutschek 1982)

Saboljevic et al. 2010; Singh et al. 2006; Spjut et al. 1986; Hotson 1921). Besides, the presence of biologically active compounds in bryophytes makes them resistant to microorganisms (Asakawa et al. 2013; Üçüncü et al. 2010; Basile et al. 1999). The biological diversity of bryophytes influences their chemical diversity and the close relations between the chemical composition of bryophytes and their taxonomy. The main groups of newly identified substances are terpenoids and steroids, while polyphenols and carbohydrates have also been identified (Table 1).

Only around 10 % of bryophyte species have been investigated to date, identifying more than 400 new substances, many of which are unique and possess biological activity (Asakawa et al. 2013; Beike et al. 2010). A number of different compounds have been found in bryophytes. At first, it should be noted that a high number of lipophilic compounds have been detected in liverworts, especially in

their oil bodies, and similar substances have also been identified in mosses and hornworts. Mono-, sesqui- and diterpenoids, as well as aromatic compounds, such as bibenzyls and bis(bibenzyls), have been found in bryophytes. Flavonoids and terpenoids are ubiquitous components in bryophytes and have been detected in Marchantiophyta and Bryophyta (Asakawa et al. 2013; Ignat et al. 2011; Iwashina 2003). The phytochemical content of bryophytes accounts for their taste (e.g., bitterness) and smell, as well as other characteristics (Asakawa 2007).

4 Carbohydrates in Bryophytes

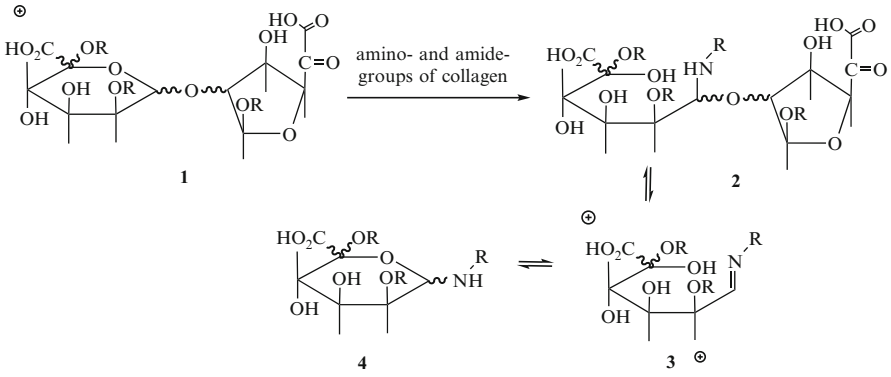
The total amount of carbohydrates and polysaccharides in bryophytes vary in a significant range, largely depending on the studied species and the method used (Judina et al. 1999; Marschall et al. 1998). One of the key groups of bryophyte mosses most abundantly studied to identify the structure-forming polysaccharides is *Sphagnum* moss, which is placed in a separate class – Sphagnopsida – represented by 120 different species and being one of the main species forming northern bogs and wetlands as well as the major precursor of raised bog peat (Glime 2007; Judina et al. 1999). The interest in polysaccharides in S*phagnum* mosses started around the year 1950, when the first short communications on this topic were published and increased after the identification of D-*lyxo*-5-hexopyranuronic acid in the year 1983 (Maass and Craigie 1964; Painter 1983). The first larger-scale investigation was conducted on 14 *Sphagnum* species, and the results showed that glucose, fructose, sucrose, fructosides, as well as short-chain fructans can be found in the water-soluble fraction of bryophytes (Maass and Craigie 1964). In later studies, D-galacturonic acid, glycuronoglycan, L-rhamnose, and D-galactose were identified as the major polysaccharides in *Sphagnum* mosses (Judina et al. 1999; Graham et al. 2010). It was concluded that the cell walls of bryophytes mostly consist of the cross-linking products of cellulosic, hemicellulosic, and pectin-like chains. Pectin-like polysaccharides in *Sphagnum* mosses have a molecular mass of up to 37,000 Da, and they may form up to 20 % of dry-moss weight (Kosonogova et al. 1994). The mentioned studies included intensive extraction, while the most efficient way of treatment was autohydrolysis in distilled water after acid hydrolysis (Painter 1983). The treatment resulted in browning and release of glycuronoglycan in a solution which also contained D-galacturonic acid (25 %), L-rhamnose (19 %), D-galactose (10 %), pentoses (6 %), glucose (7 %), as well as D-mannose (4 %). The remaining 20 % were acid-insoluble polymer-like carbohydrates, but to analyze the rest of the material, further hydrolysis had to be done. The obtained material was porous, with a yield of approximately 40 %, behaving similarly to holocellulose. After the subsequent treatment, residues of D-glucose (33 %) were found, along with other carbohydrates, such as L-fucose (4 %), D-galactose (9 %), D-mannose (23 %), and D-xylose (29 %), and some percentage of unidentified carbohydrates was also evidently present. One of the unknown carbohydrates was identified as D-*lyxo*-5-hexopyranuronic acid, which cross-links cellulose and hemicellulose, as well as other carbohydrates in the *Sphagnum* cell walls (Painter 1983; Hajek

et al. 2011). Sucrose is one of the carbohydrates that can be found in bryophyte content, and its concentration varies from 100 up to 500 μmol/g of dry weight in the *Dicranum majus*, *Hookeria lucens*, *Polytrichum commune*, and *Racomitrium lanuginosum* species (Melick and Seppelt 2002; Smirnoff 1991). Fructose and glucose in bryophytes are found in much lower concentrations than sucrose. During cold weather and in the aging process, the fructose and glucose levels decrease, while sucrose does not change greatly (Smirnoff 1991).

Even if *Sphagnum* mosses is the bryophyte group most frequently chosen for polysaccharide research, there are some studies concentrating on other bryophyte groups, such as liverworts (Suleiman et al. 1978; Marschall et al. 1998; Nagao et al. 2006). Studies on the carbohydrate content of the liverwort *Plagiochila asplenioides* reveal that there are some differences in the carbohydrate content of mosses and liverworts, and the carbohydrate composition can be used as a taxonomic characteristic (Marschall et al. 1998). The water-soluble fraction of *Plagiochila asplenioides* consists of glucose (3 μg * mg of dry weight^{-1}), fructose (6 μg * mg of dry weight^{-1}), sucrose (6 μg * mg of dry weight^{-1}), mannitol (0.93 μg * mg of dry weight^{-1}), and volemitol (10.4 μg * mg of dry weight^{-1}), which have not been found in *Sphagnum* mosses (Suleiman et al. 1978). The major neutral monosaccharide residue sequence in the cell walls of liverworts are glucose > galactose > mannose > xylose ≈ arabinose > fucose ≈ rhamnose (Popper and Fry 2003; Thomas et al. 1984). In the cell walls of liverwort *Riccardia*, residues of mannuronic acid have been found. However, due to slightly different R_f values, galacturonic acid could have been falsely perceived as mannuronic acid. The content of xyloglucan was proved by the HPLC and paper chromatography analysis of Driselase digests of the materials of the primary cell walls. These analyses showed the presence of disaccharide isoprimeverose – a product of Driselase digestion of xyloglucan. The uronic acids are present in primary cell walls as constituents of xylans, pectins, glucuronomannans, and arabinogalactan proteins (Popper and Fry 2003; Popper et al. 2003; Thomas et al. 1984). The major uronic acid found in the tested samples was galacturonic acid. Additionally, in the cell walls of leafy and thalloid liverworts and *Sphagnum*, galacturonic acid was present in a high concentration. 3-*O*-Methylrhamnose has been obtained through purification of acid hydrolysates of the alcohol-insoluble residue of *Anthoceros* (Popper et al. 2003). It has also been found to occur in primary cell walls of other bryophytes (Popper and Fry 2003). A high concentration of mannose residues has been detected in most bryophytes, liverworts, and lycopodiophytes. Despite a relatively low number of studies, the carbohydrates specific for bryophyte polysaccharides can be identified as: (a) xyloglucan, (b) uronic acids, (c) mannose, (d) mixed-linkage glucan, and e) 3-*O*-methylrhamnose (Popper et al. 2003). Xyloglucan can be found only in land plants and not in algae at the same time, while in algae and bryophytes, there are higher concentrations of glucuronic acid than in land plants, thus showing the role of bryophytes in evolution (Popper and Fry 2003). Mixed-linkage glucan is clearly detected in higher plants, while in experiments conducted on bryophytes, it has been detected only in the leafy liverwort *Lophocolea bidentata*, due to licheninase digestion (Popper and Fry

2003). As mentioned above, the primary cell walls of bryophytes contain a large amount of uronic acids, which are mainly represented as galacturonic acid and gallic acid. Bryophyte-specific carbohydrates of the primary cell walls of more advanced (desiccation-tolerant) mosses have lower concentrations of gallic acid. Still, the conclusion from the very few studies on polysaccharides in bryophytes is evident: the polysaccharide composition among bryophytes differs very much, and the few studies dedicated to interspecies comparison have proved this. In liverworts (*Mylia taylorii* and eight others), (–)-L-bornesitol, (–)-D-mannitol, (+)-D-glucose, (+)-sucrose, and (+)-trehalose have been found, and their roles in the cell wall polysaccharides discussed (Matsuo et al. 1986).

Major growth of interest in bryophyte and, specifically, *Sphagnum* moss polysaccharides happened after the discovery that the *Sphagnum* moss polysaccharides can be used for preservation of food articles (Stalheim et al. 2009; Borsheim et al. 2001; Painter 1998, 1991). This concept largely relies on the widespread use of *Sphagnum* mosses for food preservation in traditional cultures of northern countries. In the first publications on the preserving properties of *Sphagnum* mosses, sphagnan – a complex, pectin-like substance found in the living cells of mosses – is mentioned as one of the main substances responsible for this activity. The preserving as well as antimicrobial effects of sphagnan was first noticed in bog bodies, such as the Lindow (2,000 years old) and Tollund (1,400 years old) men, as well as in animal tissues and wooden artifacts, which have been found in bogs. All of the bog bodies found had a distinctive coloring characteristic of tanning caused by the Maillard reaction (Scheme 1) and reactive carbonyl groups in the sphagnan-containing residues. The highly reactive carboxyl groups in the α-ketocarboxylic acids present in sphagnan as a major component of the hyaline cell walls of *Sphagnum* mosses are undergoing the Maillard reaction with ammonia, amino acids, and polypeptides (Painter 1998). The Maillard reaction can happen without hydrolyses of the cell wall polysaccharides because of the reactive carbonyl groups



Scheme 1 Acid-catalyzed reaction of carbonyl group-containing compounds (sphagnan (*1*)) with amino groups in proteins (collagen (*2*)) and amino acids, resulting in production of glucosylamine (*3*) and brown pigment products (*4*), possibly melanoidins (the Maillard reaction)

that can be found in the *Sphagnum* moss cell walls. It is assumed that the antimicrobial activity in peat bogs is partially caused by the specific humic substance that is formed as a result of decay of *Sphagnum* mosses that still contain reactive carbonyl groups able to react with amino acids. As a result, humic substances formed in these conditions are resistant against microbial activity, especially in anoxic conditions (Painter 1991).

The second aspect responsible for antimicrobial activity could be connected with body tanning. This phenomenon is also caused by the Maillard reaction, when collagen reacts with sphagnan, causing inking in these two elements. This process, in turn, causes inactivation of proteolytic enzymes that make nitrogen within animal bodies inaccessible to microorganisms. Some studies claim that the antimicrobial activity of peat in bogs occurs due to the low pH and anoxic conditions that are caused by humic substances, although this argument cannot be considered fully true, as there have been acidophilic, anaerobic bacteria found that could easily survive in this kind of environment (Painter 1991). Nevertheless, some scientists believe that the main reason for the antimicrobial activity of sphagnan is related to its acidic properties that lower the pH level of bog waters (Stalheim et al. 2009). There have also been some investigations of a possibility that when the *Sphagnum* moss cell wall dies, synthesis of hyaline is induced as a result of water consumption in the cell, and the concentration of galacturonic acid increases, resulting in the growth of the inner cell pH levels, eventually causing the antimicrobial effect of moss (Balance et al. 2012). However, it should be noted that this theory applies to acid-sensitive bacteria only (Painter 1991; Stalheim et al. 2009). Although sphagnan has antimicrobial activity, its practical usage in food preservation is uncertain, because, even though the outer layers of products are preserved, inner spoilage is possible for the reason that soluble proteins diffuse from muscles too quickly and neutralize the active carbonyl groups, thereby causing spoilage from inside of the food product (Borsheim et al. 2001; Stalheim et al. 2009). Research conducted in the year 2001 suggests that even though *Sphagnum* moss can be used as a preservation material, there are many aspects that need to be taken into consideration to make it efficient; for example, there cannot be any air bubbles embedded in the surface of the food product, and the "skin" of the product cannot be damaged and needs to be preserved in the moss as soon as possible after the harvesting or gathering of the product (Borsheim et al. 2001).

5 Bryophyte Biology

Bryophytes are especially remarkable for their tolerance to growth conditions. They can be found in both shady and sunny places, even if they usually prefer humid environments. Bryophytes are also adapted to variable temperatures and daylight regimes; therefore, they can be found from Sahara to Arctic regions. One of the most investigated properties of bryophytes is their high tolerance in respect to long drought periods and excessive wetness regimes in comparison with the higher plants (Pence et al. 2005). Their tolerance is one of the reasons why investigation

of bryophytes and their chemical composition has been rapidly growing in the past two decades. The bryophyte cell wall composition reflects changes that happened during plant evolution, at first, events during the colonization of land and vascularization of plants. Cell walls regulate cell expansion and have a crucial role in the growth and development of plants; they also actively participate in defense against microorganisms (Matsunaga et al. 2004). It is suggested that major changes in the cell wall polysaccharide composition happened during these processes. Whereas the cell walls of vascular plants are composed predominantly of cellulose, hemicellulose, and pectin, together with such functional molecules as glycoproteins, mineral substances, enzymes, and lignin, the cell wall composition of bryophytes is much simpler (Carpita and Gibeaut 1993). Changes in the cell wall composition could have been essential for the colonization of increasingly dry land environments. Evidently, not all plants participating in these evolutionary processes are preserved; still, the studies of bryophyte cell wall polysaccharides provide information of the chemistry of land plant evolution. A major step in the evolution of tracheophytes from bryophytes was the development of supporting and conducting tissues with lignified cell walls (Niklas 1997). The attempts to identify lignin as a significant constituent of cell walls in bryophytes failed (Bland et al. 1968; Maksimova et al. 2013), although controversies in this respect exist (Balance et al. 2012). Another key factor differentiating the cell wall structures of bryophytes and vascular plants is the near absence of pectic polysaccharide rhamnogalacturonan II in bryophytes (Matsunaga et al. 2004). However, partially methyl-esterified homogalacturonan has been found in specific water-conducting cells (hydroids) in bryophytes (Ligrone et al. 2002).

One of the key reasons for studying polysaccharides in bryophytes is directly related to their extremely high resistance against many environmental factors, such as drought, heat and cold, and also pollution (Goffinet and Shaw 2008). According to some scientists, the tolerance to freezing, desiccation, and drought is considered to be characteristic mainly of lower plants (Melvin et al. 2005). Many studies have demonstrated that bryophytes can be found under very differing environmental conditions, and they are highly tolerant to cold. A hypothesis has been advanced that the key factor influencing the tolerance of bryophytes is the presence of cell wall polysaccharides and cytoplasmic monosaccharides (Proctor 2000). In contrast with higher plants, in which the desiccation/freezing tolerance is usually restricted to seeds or pollen, the stress tolerance mechanisms of vegetative tissues in bryophytes are common (Oldenhof et al. 2006). Development of freezing tolerance is mostly associated with theanderose and stachyose, the synthesis of which is supposedly promoted by the stress hormone – abscisic acid. The effect of freezing tolerance is mainly due to the carbohydrate accumulation in protonema cells that are located in bryophyte cell walls (Nagao et al. 2006). The resistance of bryophytes to freezing is mainly based on alteration of hormone balance and regulation of osmotic pressure with the help of soluble sugars. Even though it has been shown that abscisic acid increases the synthesis of soluble sugars in cases of environmental stress, such as freezing or desiccation, this account is not true for all bryophyte species. In the case of *Physcomitrella patens*, *Riccia fluitans*, and *Pallavicinia lyellii*, the increase in abscisic acid synthesis does really increase their freezing and desiccation tolerance,

while in the case of *Marchantia polymorpha*, addition of this hormone does not affect its survival. There is an evidence of an abscisic acid-independent cold-signaling pathway that leads to stress-related gene expression that causes freezing tolerance (Minami et al. 2005). As shown in some studies, the stress tolerances in different bryophytes are differing mainly due to their growth environment, and, as there are many species, they are adapted to specific niches (Oliver et al. 2005). The best example is the bryophytes from Antarctic environments, which is able to survive freeze-thaw cycles, reacting by release of sucrose (Melick and Seppelt 2002). The bryophyte freezing stress tolerance and their cold acclimation are associated not only with the expression of stress-related genes but also with the specific composition of their polysaccharides and the release mechanisms of low-molecular carbohydrates during stress conditions (Minami et al. 2005). Thus, it may be concluded that there are more than one way of how bryophytes can cope with environmental stress (Pence et al. 2005; Nagao et al. 2006). In the case of desiccation tolerance, there is an extra water source in comparison with vascular plants. The latter have two water content components – symplast water and apoplast water – while in the case of bryophytes, there is also the third one that needs to be taken in consideration – external capillary water. The importance of water content components in bryophytes varies among species. For example, symplast water dominates in most thalloid liverworts; in contrast to that, in most mosses and leafy liverworts, as well as in nearly all highly desiccation-tolerant species, external capillary water is dominating. External capillary water is the most important aspect that is responsible for the high desiccation tolerance, as the water conduction is mostly external, and although the water content in many cases is near zero, the water potential keeps the inner processes of bryophyte cells intact. Thus, in difference from vascular plants, the main water movement in bryophytes takes place in the capillary spaces between leaves and other external spaces (Proctor 2000). In *Selaginella inaequalifolia*, in turn, the synthesis of trehalose has been related to their high desiccation tolerance (Irudayaray et al. 2010).

Hornworts are thought to be the most primitive land plants (Renzaglia et al. 2000), and, for example, in cell wall material from thalli of the hornwort *Anthoceros caucasicus*, substantial amounts of unusual disaccharide α-D-glucuronosyl(-1→3)L-galactose were isolated (Fig. 2). Notably, it was not detected in other terrestrial plants, including bryophytes, liverworts, and charophytes.

Such polysaccharides could possibly be able to act as mucilaginous substances that minimize desiccation of land plants. Mucilaginous substances are present in simpler bryophytes but absent in other evolutionary more advanced bryophytes. Thus, several unique polysaccharides present in an evolutionary isolated species of bryophytes (*Anthoceros*) represent the unique role of polysaccharides in the development of primary cell walls and the process that happened in plant phylogeny during evolution. There is a consensus among scientists that the presence of such carbohydrates and their composition change due to ecological pressures in bryophytes may have been preadaptive advantages that allowed the colonization of land (Renzaglia et al. 2000).

One of the puzzling issues of the bryophyte carbohydrate research is related to identification of their localization, especially in cell walls. This issue is especially

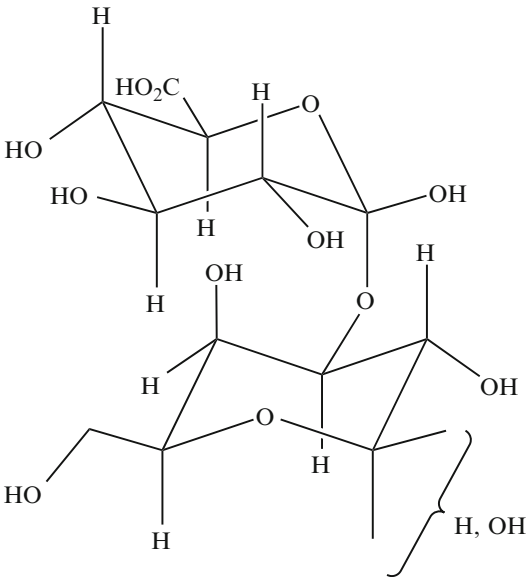


Fig. 2 Polysaccharide α-D-glucuronosyl(-1→3)L-galactose, found in hornworts only, can have an important role in their desiccation tolerance

important in respect to *Sphagnum* mosses, since these bryophytes historically have been intensively used as bandage materials to replace cotton dressings (Painter 2003; Hotson 1921). In recent studies, it has been suggested that *Sphagnum* cell walls are composed of a pectin-like polysaccharide – sphagnan (Stalheim et al. 2009; Painter 2003), which is abundant in hyaline cell walls, fibrils, papillae, chlorophyllous cell walls, and thickenings around hyaline cell pores (Balance et al. 2012). The character of localization of pectin was proved using staining with ruthenium red and by means of transmission electron microscopy of ultrathin cell walls labeled with poly-L-lysine. The presence of reactive pectin in cell walls, in the opinion of Balance et al. (2012), is the main factor influencing the possibilities of using *Sphagnum* mosses for food conservation, food tray pads, and other purposes. Thus, two major roles of polysaccharides could be identified in the constitution of bryophytes: (1) in pectin (or, probably, other similar polysaccharides in other bryophytes), as a major cell wall building material, and (2) functional polysaccharides as substances regulating the interactions of bryophytes with the surrounding environment. However, further research is needed to confirm the relevance of this hypothesis, also in respect to other bryophytes.

6 Biotechnological Approaches of Bryophyte Cultivation

Studies of bryophyte polysaccharides are hampered due to difficulties in acquiring large amounts of bryophyte biomass, considering their tiny size and mostly small populations. Often sites where bryophytes can be found (whether tropics or bogs in colder environments) cannot be easily accessed, and their cultivation cannot be

easily achieved. Nevertheless, the problem of obtaining significant quantities of bryophytes can be solved using in vitro cultures (Zinsmeister et al. 1991). Despite problems related to the identification of growth media, several cultivation experiments proved the efficiency of such an approach and feasibility to obtain cell biomass in sufficient quantities for obtaining bryophyte polysaccharides if they had a potential for application (Duckett et al. 2004). Cultivation approaches are most developed for *Sphagnum* mosses, considering their use for recultivation of bogs and as a media for plant growth (Batra et al. 2003). *Sphagnum* mosses also can be easily cultivated in greenhouses both on peat and water. In this kind of cultivation circumstances moss collection is easy and with high yields; nevertheless, there is still a need for separation of moss species as there is no possibilities to cultivate only one (Graudig et al. 2014).

7 Conclusion/Prospects

The main conclusion in respect to carbohydrates in bryophytes can be made not so much from the existing knowledge on the topic but rather from considering the roles of carbohydrates in the evolution of plant kingdom and bryophyte ecology. Carbohydrates in bryophytes illustrate a significant process in the evolution of chemical diversity and major compounds in the development from lower plants and microorganisms (bacteria, fungi) to carbohydrates in higher plants. Carbohydrates in bryophytes function as a structural material; they demonstrate the importance of cellulose and lignin as cell wall molecules (absent in bryophytes) in higher plants and show how evolution of chemical structures has supported biological evolution. The evolutionary approach also admits major gaps in the knowledge of carbohydrates in bryophytes; the number of studies is rather small, and the results obtained are controversial. For example, the issue concerning major structural carbohydrates in *Sphagnum* mosses (studied relatively much considering significance of this group of bryophytes) is still open. Furthermore, differences in carbohydrate composition among a challenging number of different bryophyte species are neglected: from ~25,000 species, carbohydrates are studied only in ~60–75 species, and the differences found are significant, leaving no doubts that examination of other species will result in finding new compounds and their combinations. Thus, the major conclusion in respect to studies of carbohydrates in bryophytes is that it is a challenging and prospective field of research, with a potential of providing not only considerable new knowledge about this group of substances, their functions, evolution of chemical compounds, and chemical diversity, but also new applications of bryophyte carbohydrates. The recent progress in bryophyte phytochemistry also supports these expectations.

Microbial Production of Extracellular Polysaccharides from Biomass Sources

6

Emrah Özcan and Ebru Toksoy Öner

Contents

Abstract

The interest in bio-based polymers, especially extracellular polysaccharides (EPSs), has increased considerably in recent years due to their useful physicochemical and rheological properties and diverse functionality. Microbial polysaccharides have many commercial applications in different industrial sectors like chemical, food, petroleum, health, and bionanotechnology. Although microbial EPS production processes are regarded as environmentally friendly and in full compliance with the biorefinery concept, EPSs constitute only a minor fraction of the current polymer market due to their cost-intensive production and recovery. For that reason, much effort has been spent to the development of cost-effective production processes by using cheaper fermentation substrates

such as low-cost biomass resources. These resources are generally either in liquid form like syrups, molasses, juices, cheese whey, and olive mill wastewater or solid-like lignocellulosic biomass and pomaces. In this chapter, after a brief description of microbial polysaccharides, submerged and solid-state fermentation processes utilizing cheap biomass resources are discussed with a special focus on the microbial production of EPSs with high market value.

EPS • Microbial exopolysaccharides • Polysaccharides • Biomass resources • Fermentation

1 Introduction

Since the beginning of the twentieth century, bio-based technologies such as the production of biomolecules like enzymes, antibiotics, metabolites, and polymers have developed to a great extent. Currently, microorganisms are used for commercial production of several products such as pesticides, fertilizers, and feed additives in the agrochemical sector, biopharmaceuticals and therapeutics in the healthcare sector, and biopolymers and biofuels in the energy and environment sectors (Toksoy Oner 2013). Globally, the market for bio-based products has been increasing significantly such that from 2005 to 2010, it increased from 77 to 92 billion € and is expected to increase up to 228 and 515 billion € in 2015 and 2020, respectively (without biofuels and pharmaceuticals) (Fava et al. 2013).

Substrates used by microorganisms for the production of bio-based products are an important cost consideration. Hence, using cheaper substrates such as wastes or by-products of food processing or agro-industry instead of synthetic media leads to a significant decrease in the production costs. In the EU, the annual amount of waste or by-products of agro-industrial, organic household, yard/forestry, and food processing reaches up to 1,000, 200, 550, and 250 million tons, respectively. In 2008, the recovery rate of waste (excluding energy recovery) was 46 % (Fava et al. 2013). Hence the use of wastes or by-products as substrate for microbial production of biotechnologically important molecules like exopolysaccharides (EPSs) has a remarkable potential for not only the recovery of waste but also for reducing the production cost (Kaur et al. 2014).

EPSs are high-molecular-weight polymers that are composed of sugar residues and are secreted by microorganisms to the surrounding environment. Many microorganisms including many species of gram-positive and gram-negative bacteria, archaea, fungi and some algae are known to produce EPSs. These natural, nontoxic, and biodegradable polymers not only protect microorganisms against environmental extremes such as Antarctic ecosystems, saline lakes, geothermal springs, or deep-sea hydrothermal vents but also play important roles in various biological mechanisms such as immune response, adhesion, infection, and signal transduction (Jones et al. 2014; Poli et al. 2011; Kumar et al. 2007; Sutherland 1998) as well as in

biofilm formation, biofouling, and quorum sensing (Garg et al. 2014; Fazli et al. 2014). Some EPSs produced by microorganisms such as cellulose are also produced by higher-order plants. But, due to their slow production rate (3–6 months) as well as their dependence on seasonal conditions and high agricultural land, controlled microbial fermentations are preferred over plants for sustainable and economical production of EPSs at industrial scale (Toksoy Oner 2013).

Due to their useful physicochemical and rheological properties and diverse functionality, the EPSs have been recognized as new biomaterials and been found to have a wide range of applications. They can be used as thickeners, bioadhesives, stabilizers, probiotics, gelling agents, emulsifiers, biosorbents, and bioflocculants not only in many industrial sectors like textiles, detergents, adhesives, microbial enhanced oil recovery (MEOR), wastewater treatment, dredging, brewing, downstream processing, cosmetology, pharmacology, and food additives but also in health and bionanotechnology sectors (Kreyenschulte et al. 2014; Toksoy Oner 2013; Donot et al. 2012; Freitas et al. 2011). However, despite these diverse industrial applications, EPSs still represent only a small fraction of the current polymer market, mostly due to the processes associated with their costly production and recovery (Kreyenschulte et al. 2014). Hence, significant effort has been devoted to the development of efficient downstream processing and cost-effective EPS production processes such as investigating the potential use of biomass resources as cheaper fermentation substrates.

In this chapter, after a brief description of microbial polysaccharides, submerged and solid-state fermentation processes utilizing cheap biomass resources are discussed with a special focus on the microbial production of EPSs with high market value.

2 Microbial Extracellular Polysaccharides

Polysaccharides are high-molecular-weight carbohydrate polymers of sugar residues that are linked by glycosidic bonds. While some polysaccharides like starch or glycogen serve for energy storage, others like chitin or cellulose function as structural support. In microorganisms, they are present either at the outer membrane as lipopolysaccharides (LPS) that mainly determine the immunogenic properties or secreted as capsular polysaccharides (CPSs) forming a discrete surface layer (capsule) associated with the cell surface or excreted as extracellular polysaccharides (EPSs) that are only loosely connected with the cell surface (Cuthbertson et al. 2009). While CPSs are responsible for pathogenicity like resistance to specific and nonspecific host immunity and adherence (Taylor and Roberts 2005), EPSs are related with adhesion, cell-to-cell interactions, biofilm formation (Mann and Wozniak 2012), and cell protection against environmental extremes (Kumar et al. 2007).

These microbial polysaccharides exhibit considerable diversity in their composition and structure. Based on their monomeric composition, they are generally classified as homopolysaccharides and heteropolysaccharides (Sutherland 1982).

Whereas homopolysaccharides consist of one type of monosaccharide connecting each other with either linear chains (pullulan, levan, bacterial cellulose, or curdlan) or ramified chains (dextran), heteropolysaccharides consist of two or more types of monosaccharides being usually present as multiple copies of oligosaccharides, containing three to eight residues (xanthan or gellan) (Purama et al. 2009; Sutherland 2007). Among the EPS producer microorganisms, bacteria are dominant for industrial or technical production. Some bacteria species such as *Xanthomonas*, *Leuconostoc*, *Sphingomonas*, and *Alcaligenes* which produce xanthan, dextran, gellan, and curdlan are the best known and most industrially used (Toksoy Oner 2013).

Dextran, curdlan, and cellulose are neutral bacterial glucans that are homopolysaccharides of glucose monomers. Dextran is produced by *Leuconostoc mesenteroides* cultures (Nasab et al. 2010a) together with levan (Siddiqui et al. 2014). Commercial applications for dextran are generally in the pharmaceutical industry, but new applications are being considered in the food and textile industries (Nasab et al. 2010a; Sarwat et al. 2008). Curdlan produced by the alkaline-tolerant mesophilic bacteria *Alcaligenes faecalis* (Matsushita 1990) can form aqueous suspensions which can form high-set gels upon heating. Curdlan can be used as a gelling agent in food and pharmaceutical industries. Curdlan is also produced by *Cellulomonas flavigena* as an extracellular storage polymer (Kenyon and Buller 2002). On the other hand, bacterial cellulose is produced by many species of bacteria, such as those in the genera *Gluconacetobacter*, *Agrobacterium*, *Aerobacter*, *Azotobacter*, *Rhizobium*, *Sarcina*, *Salmonella*, *Enterobacter*, *and Escherichia* and several species of cyanobacteria. Contrary to plant cellulose, bacterial cellulose has many desirable properties such as high purity (free of lignin and hemicelluloses), high crystallinity, high degree of polymerization, a nanostructured work, high wet tensile strength, high water holding capacity, and good biocompatibility (Hungund et al. 2013).

Pullulan from *Aureobasidium pullulans* (Özcan et al. 2014; Singh et al. 2008) and scleroglucan produced by *Sclerotium glucanicum* (Survase et al. 2007) are fungal glucans that are the most known uncharged homopolysaccharides having industrial production for a long time. Whereas the major market for pullulan is still in food industry, there are several reports for its potential applications in pharmaceutical, biomedical, and environmental remediation areas (Özcan et al. 2014). Due to its exceptionally high stability, the first application of scleroglucan was in the oil recovery; however, other applications in the cosmetic, pharmaceutical, and agriculture sectors have also been reported (Schmid et al. 2011; Survase et al. 2007).

Besides these glucan-type EPSs, levan is a linear, fructan-type homopolymer of fructose residues. It is a water-soluble, strongly adhesive, and film-forming EPS, which can be used not only in the food industry as an emulsifying, thickening, and encapsulating agent but also in medicine such as an immunomodulator and a blood plasma substitute (Kang et al. 2009; Silbir et al. 2014). Xanthan, which is after dextran, the second EPS to be approved by the FDA as a safe food ingredient, is an industrially important EPS produced by *Xanthomonas campesteris* through aerobic fermentation (Gunasekar et al. 2014; Palaniraj and Jayaraman 2011). It is a branched, anionic heteropolysaccharide composed of glucose, mannose, and

glucuronic acid monomers. Due to its exceptional rheological properties, xanthan has a considerable market. Another anionic EPS is the gellan gum that is a linear polymer of glucose, rhamnose, and glucuronic acid. Gellan produced by *Sphingomonas paucimobilis* (formerly *Pseudomonas elodea*) is gaining increasing attention due to its novel property of forming thermo-reversible gels and showing good stability over a wide pH range (3.5–8.0). Due to the diversity of its structure and properties, gellan gum has a great commercial potential for food, pharmaceuticals, and predominantly environmental bioremediation (Bajaj et al. 2007; Jin et al. 2003). Hyaluronan, composed of glucuronic acid and acetylglucosamine residues, is widely used in regenerative medicine and cosmetic applications due to its water binding and retention capacity and immune compatibility characteristics (Sutherland 2007). Another heteropolysaccharide is alginate that is an anionic polymer of glucuronic acid and mannuronic acid residues. Alginate produced by species of *Pseudomonas* and *Azotobacter* is widely used as a thickening, stabilizing, and gelifying agent in food, textile, paper, and pharmaceutical industries (Hay et al. 2014, 2009; Gaona et al. 2004).

3 Microbial EPS Production

Microbial EPS production is usually not confined to just one type of EPS as product but rather a mixture of different polymers, each being synthesized by a certain gene cluster. For example, *Pseudomonas aeruginosa* has the genetic capacity to produce three different EPSs, namely, Pel, Psl, and alginate, which are synthesized via different mechanisms (Hay et al. 2014; Franklin et al. 2011). Similarly, *L. mesenteroides* cultures can produce both dextran and levan (Siddiqui et al. 2014). Generally, the availability of the precursors encoded by the related genes has a high impact on the yield and structure of the EPS excreted by the cell (Sutherland 2007). The synthesis of homopolysaccharides is carried out in the extracellular environment through the action of specifically secreted glycoside hydrolase (sucrase) enzymes that act on sucrose and catalyze the transglycosylation reactions forming the polymer chain (Rehm 2009; van Hijum et al. 2006). On the other hand, biosynthetic pathways of heteropolysaccharides are more complex and involve five distinct steps, namely, the uptake of sugar subunits and their activation with a high-energy bond through their conversion into sugar nucleotides, assembly of the repeating monosaccharide unit on an isoprenoid lipid carrier by sequential transfer of monosaccharides from sugar nucleotides by glycosyltransferases, addition of any acyl groups, polymerization of the repeating unit, and secretion of the polysaccharide from the cell membrane into the extracellular environment (Sutherland 2007).

Recent studies on microbial EPS production use systems-based approaches to elucidate the associated biosynthesis mechanisms; to modify physicochemical and/or rheological properties of the biopolymer by changing its composition, length, or degree of branching; and also to improve the microbial productivity via strain improvement strategies. For such an approach, whole genome sequencing (WGS) projects employing next-generation sequencing (NGS) technologies play a

central role by enabling high-throughput genomic data at very high speed with a relatively low cost. Genome data was used in comparative genomic studies of EPS biosynthesis by *Bifidobacterium* (Hidalgo-Cantabrana et al. 2013), *Crocosphaera watsonii* (Bench et al. 2013), and *Salipiger mucosus* DSM 16094^T (Riedel et al. 2014) as well as in functional genomic studies for the xanthan production by *Xanthomonas campestris* (Vorhölter et al. 2008), EPS biosynthesis by *P. aeruginosa* PA01 (Franklin et al. 2011; Hay et al. 2010; Rehm 2005), alginate biosynthesis by *Azotobacter vinelandii* (Kumar et al. 2007), and levan production by the halophilic strain *Halomonas smyrnensis* AAD6^T (Ates et al. 2011, 2013).

4 Microbial Production Processes

Microbial EPS production is significantly affected by fermentation conditions such as temperature, pH, oxygen concentration, bioreactor configuration, and culture medium. Furthermore, the chemical structure of EPS such as molecular weight, monomer composition, and physicochemical and rheological properties of the final product could also change with the type and age of strain (Özcan et al. 2014). Generally, typical microbial EPS fermentations start with the growth phase followed by the production phase (Toksoy Oner 2013). During the cultivations, severe changes in rheological properties of the microbial culture such as highly viscous and non-Newtonian broth may result in serious problems of mixing, heat transfer, oxygen supply, and also instabilities in the quality of the end product (Seviour et al. 2011). Such challenges are encountered in the microbial production of pullulan (Cheng et al. 2011) and xanthan (Palaniraj and Jayaraman 2011) but not in the production of low-viscosity polymers such as levan (Küçükaşık et al. 2011) or in high-temperature processes where thermophiles are utilized as microbial producers (Nicolaus et al. 2010).

Conventional modes of operations for the fermentation processes are batch, fed batch, and continuous. In these operations, different fermenter configurations can be used such as submerged fermentation (SmF) bioreactors including pneumatically or mechanically agitated types as well as solid-state fermentation (SSF) bioreactors. The mode of operation and the fermenter design depend on the microbial system used, and since the production is highly subject to change with the physiological and biochemical requirements of the microbial strain, each process requires a specific design by avoiding generalities (Nicolaus et al. 2010). Hence, to realize the industrial production of EPSs with the desired specifications and standardization, the parameters affecting the process should be well defined via effective optimization methods such as response surface methodology (Özcan et al. 2014).

5 Biomass Resources

Almost 30 % of the cost for a microbial fermentation can be represented by fermentation medium. Using complex media is not attractive due to its high content of expensive nutrients such as yeast extract, peptone, and salts. In order to reach

high production titers at reasonable costs, the fermentation medium should be carefully designed to make the end product compatible with its synthetic petrochemical counterpart. Until the 1990s, studies were concentrated on the recovery and chemical characterization of pure EPSs, and consequently, to avoid impurities, fermentations were preferentially performed under defined culture conditions. However, recently, studies are mainly concerned about the economical aspects of microbial production, and hence a growing number of studies focus on maximizing the cost-effectiveness of the process by replacing synthetic or complex media with appropriate biomass resources as cheaper alternatives (Kaur et al. 2014; Toksoy Oner 2013).

Biomass resources are generally of two physical states, namely, liquid resources like syrups, molasses, juices, cheese whey, and olive mill wastewater and solid resources like lignocellulosic biomass and pomaces. Whereas EPS production from liquid biomass resources is realized through submerged fermentation processes, solid-state fermentation is preferred for the latter state. Furthermore some physical and chemical pretreatment methods can also be applied to biomass resources for removal of heavy metals, colored substances, and other impurities that would interfere with the fermentation or subsequent downstream processing. In Table 1, various biomass resources have been listed for some microbial EPS producers together with the EPS yields obtained after a certain fermentation period.

6 Submerged Fermentation Processes

Submerged fermentation (SmF) processes define fermentations carried out in liquid media. The scale of the process may vary from small scale like shake flasks up to large scale like fermenters. Fermenters designed for SmF can be classified according to their agitation so that they are either pneumatically agitated such as bubble column and airlift bioreactors or mechanically agitated such as stirred tank reactors (Doran 1995). Syrups, molasses, cheese whey, and olive mill wastewater are common biomass resources for microbial production of EPS via SmF.

6.1 Syrups and Molasses

Syrups and molasses have been used as substrates for fermentative production of commercial polysaccharides such as xanthan (Kalogiannis et al. 2003), pullulan (Israilides et al. 1998; Roukas 1998; Lazaridou et al. 2002; Göksungur et al. 2004), dextran (Vedyashkina et al. 2005), levan (Küçükaşık et al. 2011; Han and Watson 1992; Oliveira et al. 2007), scleroglucan (Survase et al. 2007), and gellan (Banik et al. 2007) due to their many advantages like high sucrose and other nutrient contents, low cost, and easy availability. The chemical composition of syrups and molasses includes high ion concentrations such as K^+, Na^+, Fe^{2+}, and Zn^{2+} which could be additional stress factors that trigger the formation of the EPS (Abdel-Aziz et al. 2012a). Not only crude form of syrups and molasses but also pretreated form

Table 1 Biomass resources and applied fermentation types for some microbial EPSs

EPS	Microorganism	Biomass resource	Fermentation type	Yield (time)	Reference
Curdlan	*Agrobacterium* sp. ATCC 31749	Condensed corn solubles	SmF	7.72 gL^{-1} (120 h)	West and Nemmers 2008

of syrups and molasses can be used as substrate. Some pretreatment methods for syrups and molasses are acid treatment, pH adjustment (Roukas 1998; Küçükaşık et al. 2011), activated carbon treatment (Lazaridou et al. 2002; Göksungur et al. 2004), ion exchange chromatography (Kalogiannis et al. 2003), and centrifugation followed by filtration (Oliveira et al. 2007).

X. campestris was used for producing xanthan gum using date syrup, prepared from low-quality dates, as a substrate. Fermentation was carried out with date syrup and sucrose syrup. The results showed that EPS concentration increased with an increase in fermentation time with a maximum yield of 8.9 gL^{-1} after 96 h which was much higher than that of the sucrose-containing medium (0.18 g/100 mL) (Nasab et al. 2009). The same group used date syrup, for the production of bacterial cellulose using *Gluconacetobacter xylinus*. Static batch fermentation for the purpose of cellulose production by *G. Xylinus* PTCC 1734 was studied using date syrup and sucrose solution as fermentation media. Results showed that maximum yields of bacterial cellulose after 336 h fermentation were 4.35 and 1.69 g/100 ml of date syrup and sucrose media, respectively (Nasab and Yousefi 2011). Fruit juices are also a good alternative as biomass resource like syrups. For instance, bacterial cellulose was produced by *Gluconacetobacter persimmonis* using some fruit juices as cheaper carbon sources (Hungund et al. 2013). Hungund et al. used various fruit juices including pineapple, pomegranate, muskmelon, water melon, tomato, and orange and also molasses, sugarcane juice, coconut water, and coconut milk as alternative carbon sources for bacterial cellulose production. Out of which, muskmelon juice gave the highest cellulose yield of 8.08 gL^{-1}. Survase et al. (2007) used various dilutions of coconut water, sugarcane molasses, and sugarcane juice which were not subjected to any pretreatment methods before their use for the scleroglucan production by filamentous fungi *S. rolfsii* MTCC2156, and the highest yields (23.87 gL^{-1} in 72 h) were observed using sugarcane juice. Coconut water and sugarcane juice were also used for EPS production by *Lactobacillus confusus* cultures (Seesuriyachan et al. 2011).

Muhammadi (2014) used different carbon sources such as glucose, fructose, sucrose, sugar beet, and sugarcane molasses to produce EPS by *Bacillus* strain CMG1403. The study showed that under optimum culture conditions, sugar beet and sugarcane molasses could be superior and efficient alternatives to synthetic carbon sources providing way for an economical production of EPS. Razack et al. (2013) replaced sucrose with sugarcane molasses in the optimized medium, for an enhanced production of EPS from a soil isolate, *Bacillus subtilis*. Sugarcane molasses at a concentration of 2 % gave higher EPS yield (4.86 gL^{-1}) than that obtained in medium with sucrose (2.98 g EPS/L). Sugarcane molasses was also used to produce EPS from *P. fluorescens*. Sucrose and sugarcane molasses as the carbon substrates at different concentrations (1–7 %) and different incubation times were investigated in this study. Maximum production was obtained in the medium containing 5 % sugarcane molasses and was found to be 2,843 mgL^{-1} at 48 h after which the production decreased. The EPS production using sugarcane molasses gave comparatively a higher yield than sucrose, which could be commercialized for

a cost-effective production of these viscous to plastic polymers (Sirajunnisa et al. 2012). Banik et al. (2007) used response surface methodology to optimize the production of gellan gum by *S. paucimobilis* ATCC-31461 using crude sugarcane molasses and reported a maximum yield of 13.81 gL^{-1} gellan. Abdel-Aziz et al. (2012b) stated that EPS, synthesized by the fungus *Mucor rouxii*, was found to play an important role for the protection of cells against abiotic stress such as extreme pH values or elevated temperature. An acidic pH-shock was found to be the strongest stressor for synthesizing the EPS exploiting beet molasses as an inexpensive carbon source. Beet molasses was also used as a carbon source in other studies to produce xanthan by *X. campesteris* NRRL-B-1459 (Nasab et al. 2010b) and to produce dextran by *L. mesenteroides* (Vedyashkina et al. 2005).

6.2 Cheese Whey

Whey is the major by-product of the dairy products, especially cheese, industry. The nutrient composition of whey is based on the nutrient composition of milk from which it is derived, and it is affected by many factors including how the milk was processed. The major component of whey is lactose which is about 70 % of the total solids of whey. Whey has a rich pool of nutrients and growth factors that have the potential to stimulate the growth of microorganisms. On the other hand, the suitability of whey for EPS production highly depends on the ability of the microorganism to utilize lactose (Toksoy Oner 2013).

Fialho et al. (1999) used the media containing lactose, glucose, and sweet cheese whey as substrates for the production of gellan by *S. paucimobilis* ATCC 31461. The strain was known to grow on lactose and to produce highly viscous gellan directly from lactose (Pollock 1993). Silva et al. (2009) produced xanthan by two strains of *X. campesteris* using cheese whey as carbon source. Although both strains reached comparable yields, the polymers were found to differ in their chemical characteristics such as chemical composition and ionic strength. Nasab et al. (2010a) used a combination of molasses and cheese whey for the production of dextran by *L. mesenteroides*. Results showed that maximum dextran yield was achieved in combination of molasses-whey 10 % (M-W 10 %) and no dextran was produced using only whey. The report showed that the combination of nutrients and minerals in molasses and cheese increased the EPS yield.

Not only crude whey but also partially hydrolyzed whey by protease/peptidase complex can be used for the production of EPS. Fermentation of the hydrolyzed whey using *Lactobacillus delbrueckii* ssp. *bulgaricus* RR (RR, an EPS-producing bacterium) resulted higher EPS yield than fermentation of the unhydrolyzed whey (Briczinski and Roberts 2002). Another pretreatment method for cheese whey is precipitation of protein. Rabha et al. (2012) partially precipitated the residues of milk proteins present in the whey samples in their study which is related to EPS production by *Streptococcus thermophilus* BN1 using skimmed milk, whole milk, and cheese whey as cheap culture media.

6.3 Olive Mill Wastewater

Olive mill wastewater (OMW) is the by-product of the olive oil industry. OMW is a dark-colored juice that consists of a mixture of water from the olive, machinery cooling waters, fruit washings, and remainder of the fruit (Toksoy Oner 2013). About 15 % of OMW is organic material that is composed of carbohydrates, proteins, and lipids as well as a number of other organic compounds including monoaromatic and polyaromatic molecules (Aguilera et al. 2008). OMW also comprises toxic ingredients being mainly derived from its extremely high organic load and the presence of recalcitrant organic compounds such as polyphenols with strong antimicrobial properties. Valorization of OMW produced by the olive oil industry has long been an environmental concern in the Mediterranean countries (Morillo et al. 2009). Among several conventional technological treatment methods applied, biovalorization of OMW to value-added chemicals is considered as the most cost-effective and environmentally compatible alternative (Mantzavinos and Kalogerakis 2005). OMW has been used as a suitable substrate for the production of EPS such as pullulan (Ramos-Cormenzana et al. 1995) and xanthan (Lopez and Ramos-Cormenzana 1996) due to its composition with high carbon-to-nitrogen ratio and other valuable nutrients.

Some pretreatment methods which can be applied before microbial fermentation to reduce the inhibitory effect of phenols in OMW, are filtration, clarification by centrifugation, dilution with water, and saline neutralization (Lopez et al. 2001a; Crognale et al. 2003). Lopez et al. (2001b) used OMW as a substrate to the production of xanthan using four *X. campesteris* strains. Differences among strains were found in the range of tolerance to OMW concentration and the xanthan amount obtained. *X. campestris* NRRL-B-1459 S4LII was chosen by its capability for xanthan production from 50 % to 60 % OMW as the sole nutrient source.

Morillo et al. (2006) investigated the use of a two-phase olive mill waste (TPOMW) which is a thick sludge that contains water and pieces of pit and pulp of the olive fruit as substrate for the production of EPS by *Paenibacillus jamilae* which is able to grow and produce EPS in aqueous extracts of TPOMW as a unique source of carbon. Maximal polymer yield in 100-mL batch-culture experiments (2 gL^{-1}) was obtained in cultures prepared with an aqueous extract of 20 % TPOMW (w/v). The effects of the addition of inorganic nutrients (nitrate, phosphate, and other inorganic nutrients) were also investigated, but the nutrient supplementation did not increase yield.

In addition to EPS production, some microorganisms can be used for bioremediation of OMW. The *Paenibacillus* genus having the high phenol biodegradation ability was not only proposed for the production of a metal-binding EPS that could be used as a biofilter but also for the bioremediation of OMW (Aguilera et al. 2008).

The high amount of phenols which negatively affects the microbial fermentation is the main constraint associated with the use of OMW, and dilution of OMW can be required. On the other hand, dilution of OMW limits the concentration of the used waste as culture medium (Aguilera et al. 2008). For instance, undiluted OMW was found to be a poor substrate for pullulan production by *A. pullulans* (Israilides et al. 1998).

6.4 Others

Carob which is grown on carob tree (*Ceratonia siliqua* L.) in the Mediterranean region has recently found its place in the food industry as a biomass substrate due to its very high sugar content (Turhan et al. 2010). Pretreated carob extracts with 25 gL^{-1} initial sugar content were used for pullulan production by *A. pullulans* SU-M18, and a pullulan productivity of 2.16 gL^{-1}/day was reached (Roukas and Biliaderis 1995). Carob extract can also be used for dextran production. Santos et al. used carob pod residues pretreated by milling and extracting by use of an acetate buffer to get its sugar content. Then carob extracts were used for the production of dextran by *L. mesenteroides* NRRL B512. 8.56 gL^{-1} dextran was produced within 12 h of the fermentation period in this study (Santos et al. 2005).

Waste beer yeast (WBY) being the second major by-product from the brewing industry can be used for bacterial cellulose production by *Gluconacetobacter hansenii* CGMCC 3917. Lin et al. (2014) used pretreated WBY as the only nutrient source for bacterial cellulose production. WBY hydrolysates treated by ultrasonication gave the highest bacterial cellulose yield (7.02 gL^{-1}), almost six times as that from untreated WBY (1.21 gL^{-1}). Tapioca pulp was used as a carbon source for xanthan production by *X. campestris* NCIM 2954. Maximum 7.1 gL^{-1} xanthan was produced using sulfuric acid-pretreated tapioca pulp (Gunasekar et al. 2014). Condensed corn solubles (CCS) containing changing levels of carbohydrates, proteins, vitamins, and nutrients are a by-product of the bioethanol industry (Smith et al. 2008). The use of diluted CCS was reported for the production of scleroglucan by *S. glucanicum* (Fosmer and Gibbons 2011; Fosmer et al. 2010), the poly-(3-hydroxybutyrate-*co*-3-hydroxyvalerate) by *Rhodospirillum rubrum* (Smith et al. 2008), pullulan by *Aureobasidium* sp. strain NRRL Y-12974 (Leathers and Gupta 1994), and curdlan by *Agrobacterium* sp. ATCC 31749 (West and Nemmers 2008). Mushroom hydrolysate powder (MHP) was used as a nitrogen source for mycelial biomass and EPS productions by *Pleurotus eryngii*. MHP gave higher mycelial biomass growth rate and EPS yield than those of the yeast extract (Chen et al. 2013). Waste loquat kernel is another potential biomass resource for EPS production due to its high protein and carbohydrate content Taşkın et al. 2010).

Pullulan is one of the most producing EPSs using various ranges of biomass resources. Abdel Hafez et al. (2007) produced pullulan by *A. pullulans* ATCC 42023 using molasses, cellulosic wastes, potato starchy waste, glucose syrup, sweet whey, and corn steep liquor. Maximum pullulan concentration (65.3 gL^{-1}) was obtained after 5 days of fermentation at 28 °C using 7 % corn steep liquor as the sole nitrogen source in a medium containing 20 % sucrose. Sharma et al. (2013) also used rice bran oil cake, soya bean oil cake, cotton seed oil cake, and mustard seed oil cake corn steep liquor (CSL) as agro-industrial nitrogen source for the production of pullulan by *A. pullulans* RBF 4A3. CSL was found to be the best production of 77.92 gL^{-1} pullulan under un-optimized conditions. Choudhury et al. (2012) produced pullulan using another nitrogen source, namely, de-oiled jatropha seed cake (DOJSC). Under optimized condition, 8 % DOJSC with 15 % dextrose gave 83.98 gL^{-1} of pullulan which is comparatively a higher yield than current reports.

Some animal wastes such as ram horn hydrolysates and chicken feather have been also reported to be a substrate for EPS production. Taşkın et al. (2012) investigated the usability of chicken feather hydrolysate (chicken feather peptone (CFP)) as substrate for mycelial biomass and EPS production from edible mushroom *Morchella esculenta*. Maximum 15.9 gL^{-1} biomass and 4.8 gL^{-1} EPS were obtained using CFP in this study. Kurbanoglu et al. (Kurbanoglu and Kurbanoglu 2007) used ram horn hydrolysates for xanthan production by *X. campestris* EBK-4 due to their high amino acid and mineral content.

7 Solid-State Fermentation Processes

Solid-state fermentation (SSF) defines bioprocess technologies including the growth of microorganisms on moist solid particles (Aydınoğlu and Sargın 2013). Over the last two decades, SSF has gained significant attention for the development of industrial bioprocesses, particularly due to lower energy requirement associated with higher product yields and cheap and eco-friendly process conditions (Thomas et al. 2013). The substrates used in SSF processes are often the product, by-product, or waste of agro-industrial, forestry, or food processing (Mitchell and Krieger 2006). SSF has been recently explored for the production of biopolymers such as EPS of which yields are comparable to those obtained from conventional submerged cultivation (Thomas et al. 2013). Agro-industrial wastes like lignocellulosic biomass and pomaces are common biomass resource used in SSF for production of EPS.

7.1 Lignocellulosic Biomass

Lignocellulosic biomass is a cheap and abundant substrate for EPS production in SSF, especially for microbial systems with hydrolytic capability via endoglucanases or cellobiose. Otherwise, it is utilized to a limited extend during the fermentation and hence requires pretreatments beforehand (Toksoy Oner 2013). Mikiashvili et al. (2011) investigated 14 strains of *Grifola frondosa* for lignin degradation, ligninolytic enzyme activities, protein accumulation, and EPS production. Experiments were carried out in SSF using oak sawdust as substrate. Among 14 strains, the strains MBFBL 21, MBFBL 662, and MBFBL 638 appeared to be good producers of EPS (3.5, 3.5, and 3.2 gL^{-1}, respectively). *Lentinus squarrosulus* Mont., a high-temperature-tolerant white rot fungus, is attracting attention due to its rapid mycelia growth and lignocellulolytic enzyme activity. Isikhuemhen et al. used cornstalks as carbon source to evaluate lignocellulolytic enzyme activity and EPS production of *L. squarrosulus* MBFBL 201 in SSF. The results showed that *L. squarrosulus* was able to degrade cornstalks significantly and maximum 5.13 gL^{-1} EPS could be recovered from the fermentation media (Isikhuemhen et al. 2012). Chowdhury et al. (2012) used lignocellulosic fibers of jute with 58–63 % cellulose content as a carbon source for EPS production by *Bacillus*

megaterium RB-05 cells with known cellulase activity in SSF. Considerable cellulase activity and maximum polymer yield of 0.297 g g^{-1} substrate were found after 72 h fermentation in this study.

7.2 Pomace

Pomace is also a common substrate for microorganism fermentation in SSF due to its content of pectin, crude fiber, and minerals such as K, Mg, Fe, and Mn (Shalini and Gupta 2010). Globally, about 10 million tons of grape pomace (seeds, skin, and stem) and 1 million tons of apple pomace are produced each year (Toksoy Oner 2013; Shalini and Gupta 2010). Stredansky and Conti (1999) produced xanthan by *X. campesteris* strains in SSF using agro-industry wastes or by-products, including spent malt grains, apple pomace, grape pomace, and citrus peels as solid substrate. Yields of the xanthan ranging from 32.9 to 57.1 gL^{-1} revealed a composition consistent with those of commercial xanthan analyzed by NMR spectroscopy. Xanthan was also produced by *X. campesteris* strains in SSF using potato peel as substrate in another study (Vidhyalakshmi et al. 2012). The ammonium nitrate is a nitrogen source for the production of gellan gum by *S. paucimobilis* NK2000. The production of gellan gum by *S. paucimobilis* NK2000 significantly increased using soybean pomace as a nitrogen source instead of ammonium nitrate (Jin et al. 2003). Using soybean pomace as nitrogen source also increased pullulan production by *A. pullulans* HP-2001 compared to using yeast extract as a nitrogen source (Seo et al. 2004).

7.3 Others

Moussa and Khalil (2012) used SSF for the production of dextran by *Saccharomyces cerevisiae* using date seeds. Different concentrations of date seeds were investigated, and the highest dextran production was achieved at 6 g/flask. The purified dextran was comparable to commercial ones. Seesuriyachan et al. (2010) compared the production of EPS by a lactic acid bacteria, *Lactobacillus confuses*, in SSF and SmF using coconut water and sugarcane juice as renewable wastes with agar medium. High concentrations of EPS (62 and 18 gL^{-1} of sugarcane juice and coconut water with agar, respectively) were obtained in SSF. Fang et al. (2013) used response surface methodology to optimize physical and nutritional variables for the production of antioxidant EPSs by *Bacillus licheniformis* UD061 in SSF using squid processing by-products and maize cobs as a carbon and nitrogen source. Succinoglycan is also produced using SSF. Various solid substrates such as spent malt grains, ivory nut shaving, and grated carrots were used for the production of succinoglycan by *Agrobacterium tumefaciens* in SSF. The highest succinoglycan yield in SSF was 30 g EPS/kg solid in this study (Stredansky and Conti 1999). Taşkın et al. (2010) used detoxified loquat kernel extract (DLKE) and neutralized loquat kernel extract (LKE) prepared from waste loquat kernels as main carbon

sources in the submerged and solid cultures of *M. esculenta* for the production of EPS having various biologic and pharmacologic activities, including antitumor, immunostimulating, and hypoglycemic activities. Maximum EPS concentrations using DLKE and KLE were 5.2 and 4.1 gL^{-1}, respectively, in this study.

Whereas liquid sugar beet molasses is commonly used in SmF, solid sugar beet pulp (SBP) which is another by-product of the sugar beet industry can be used in SSF as biomass resource for EPS production. SBP is the fibrous material left over after the sugar is extracted from sugar beets and is mainly composed of cellulose, hemicellulose, and pectin (Toksoy Oner 2013). Yoo and Harcum investigated the feasibility of using pretreated SBP as a supplemental substrate for xanthan gum production from *X. campestris*, and they reported a production yield of 0.89 g xanthan per gram of SBP in 4 days of fermentation time (Yoo and Harcum 1999). Söğütçü et al. (2011) used SBP to produce EPS by halophilic *Halomonas* sp. AAD6 cultures. Some pretreatment methods such as milling, dialyzing, and autoclaving were reported to increase the EPS yields in this study.

8 Conclusion/Prospects

The constant increase in population and industrialization has created enormous quantities of industrial waste biomass and associated environmental and health hazards. Hence biomass management via biorefinery approach has become an important issue for sustainable development and economic competitiveness. The utilization of biomass requires intensive research activities for the development of feasible pretreatment, fermentation, and downstream processing techniques. The most challenging part in the whole process is to combine the production stream with the suitable waste stream.

Microbial EPS production is strictly dependent on the nutritional and environmental requirements of the microbial culture. In this respect, omics technologies and systems biology tools provide ample knowledge on the genetic capabilities of the microbial producer cultures; hence, by functional and comparative genomics, the most appropriate biomass resource leading to high polymer titers can be identified. Such systems-based approaches are expected to have an ever-increasing importance in microbial EPS production and in general industrial biotechnology.

Tree Gum: Gum Kondagogu

7

Rao Beedu Sashidhar, D. Raju, and Rasineni Karuna

Contents

Abstract

Tree gums are obtained as the natural exudates of different tree species and exhibit unique properties with a wide variety of applications. Commercially, gums have a separate niche in the world market as a commodity of international trade. These biopolymers are abundant, come from renewable sources, are relatively inexpensive and nontoxic, and are amenable to both chemical and biochemical modifications that find widespread and extensive food and nonfood applications. Most gums are heterogeneous polysaccharides with complicated structures and extremely high molecular masses. Major tree exudate gums include gum arabic, gum tragacanth, gum karaya, ghatti, and gum kondagogu. Exudate gums possess a unique combination of functionalities and properties that can never be matched by any other alternative synthetic polymers, which makes their complete substitution impossible. Importantly, these biopolymers

DOI 10.1007/978-3-319-16298-0_32

are eco-friendly as they are biodeteriorable. Gum kondagogu is a naturally occurring nontoxic polysaccharide derived as an exudate from the bark of *Cochlospermum gossypium* (Bixaceae family), a native tree of India. To exploit its potential commercial applications, its morphological, structural, physico-chemical, compositional, solution, conformational, rheological, emulsifying, and metal-biosorption properties have been elucidated. Gum kondagogu is an acidic gum with high content of uronic acid and the major functional groups identified in the gum are hydroxyl, acetyl, carbonyl, and carboxylic groups. The primary structure of this biopolymer contains sugars, such as arabinose, rhamnose, glucose, galactose, mannose, glucuronic acid, and galacturonic acid. Based on the spectroscopic categorization, the probable structural feature consigned to gum kondagogu is (1 → 2) *β*-D-Gal *p*, (1 → 6) *β*-D-Gal *p*, (1 → 4) *β*-D-Glc *p* A, 4-0-Me-*α*-D-Glc *p* A, (1 → 2) *α*-L-Rha, and (1 → 4) *α*-D-Gal *p* A.

The outcome of the experimental studies carried out with gum kondagogu has established its efficacy as a proficient biopolymer for (i) bioremediation of toxic metals, (ii) green synthesis of metal nanoparticles and magnetic iron oxide nanoparticles (MNP), (iii) mercury biosensor, and (iv) nanosilver-based antibacterial agent for medical applications. Additionally, appropriate chemical modification of the functional groups present in gum kondagogu may lead to the development of novel technologies for applications in pharmaceutical and food and biotechnology industries.

1 Introduction

The term *gum* is applied to water-soluble substances and refers to natural non-starch polysaccharides and their structurally modified derivatives**.** Gums are transparent or translucent substances produced for the protection of plant when injured**.** Gums are either soluble in water or absorb water and swell to form an adhesive viscous solution. Gums are insoluble in alcohol and other organic solvents. Many trees and shrubs produce exudate gums as a means of natural defense. Injury to plant's bark causes the exudation of aqueous gum that seals the wound, averting infection and dehydration of the plant. The solution dries in contact with air and sunlight, to form hard, glass-like lumps, which can easily be collected. Gums are not normal products of plant metabolism but are produced under abnormal or unfavorable conditions. Hence, gums are called as abnormal or pathological products and the process of exudation of gum is called as *gummosis*. Gums may be harvested in nature from trees, seeds, and marine weeds, or they may be synthesized biologically. Further, gums are also considered as hydrocolloids, which are hydrophilic in nature and are found in almost every biosphere on earth. They contain a large number of hydroxyl groups arranged usually in a fairly regular manner along the backbone of the molecule, which allows for the chelation of mono- and divalent cations, thereby cross-linking the hydrocolloid chains together and forming complex macrostructures. Hydrocolloids are some of the most well-known polysaccharides with complex structures with glycosidic bonding. Most gums are heterogeneous polysaccharides with complicated structures and have extremely high molecular masses. A broad classification for gums based on their functions has been earlier described (Mocak et al. 1998; Hall 2009). The simplest interactions of hydrocolloids are with water and it is this interaction that makes these gums applicable to their use in foodstuffs. The gum hydrocolloids are effective water adsorbents and to a greater and lesser degree will be solubilized by water. Owing to the high number of hydroxyl groups, water is held within the molecular structure by hydrogen bonding and also within the voids created by the complex molecular configuration (Hall 2009). Exudate gums are among the oldest natural products used by mankind. They were being used as thickening and stabilizing agents for centuries because they provide excellent water-binding capacity. Some gums possess a natural biological activity related to the glycoproteins they contain, which results in a particular role of gums in the pharmaceutical industry.

Gums may be harvested in nature from trees, plant seeds, and marine weeds, or they may be synthesized by microbial fermentation. Major tree exudate gums include arabic, tragacanth, karaya, ghatti, and kondagogu, which are polysaccharides that contain salts of hexuronic acids and a number of neutral monosaccharides that are often esterified in highly branched structures (Roberts et al. 1998).

Table 1 Tree gums commonly used in food industries

Food	Percent used	Function
Frozen dairy desserts and mixes	0.3	Formulation aid, stabilizer/thickener
Milk products	0.02	Stabilizer/thickener
Soft candy emulsifier	0.9	Emulsifier salt, stabilizer/thickener
Other foods	0.002	Formulation aid, stabilizer/thickener

The presence of hexuronic acids or salts favors their water solubility. The contents of uronic acids in these gums vary, e.g., karaya contains 37 % of uronic acid residues, while ghatti consists of 10 % of D-glucuronic acids (Budavari 1989). The molecular weight (MW) of these gums generally ranges from 100 to 1,000 kilodalton (kDa). In addition, the exudate gums exhibit compositional heterogeneity combined with branched linkages. Gums commonly used in food industry are presented in Table. 1.

Commercially, the exudate gums have been used in food, pharmaceutical, adhesive, paper, textile, and other industries (Phillips and Williams 2001; Verbeken et al. 2003).

2 Exudate Tree Gums

2.1 Gum Arabic, Gum Tragacanth, Gum Karaya, Ghatti, and Gum Kondagogu

Compared to the gums from marine sources, the gums in this group are structurally more complex. Galacturonic acid is known to be one of the constituents of all these exudate gums. None of these gums is produced in industrialized countries. They must be imported from third-world countries. The chemical composition of these gums is complex and varies to some extent depending on the source and its age. Therefore, it is not possible to provide defined structural formulas of these biopolymers. Exudate gums are used in an overwhelming number of applications, especially in the arena of food industry and also considerably in nonfood applications (Table 2).

2.1.1 Gum Arabic

It is also known as gum arabic or Indian gum. Gum arabic is the oldest and best known of all natural gums. It is the dried gummy exudates obtained from the stem and branches of *Acacia arabica* belonging to the family Leguminosae. Gum arabic is a branched, neutral or slightly acidic, complex polysaccharide obtained as a mixed calcium, magnesium, and potassium salts of arabic acid. Arabic acid on hydrolysis gives L-arabinose, L-rhamnose, D-galactose, and D-glucuronic acid. The backbone of the polymer consists of 1,3-linked β-D-galactopyranosyl units. It is identified as a heterogeneous gum (Anderson and Stoddart 1966).

Table 2 Nonfood applications of gum

S. no.	Industry	Uses
1	Pharmaceutical	Suspending agent, emulsifier, adhesive, and binder in tabletting and in demulcent syrups
2	Cosmetic	Stabilizer in lotions and protective creams, where it increases viscosity, imparts spreading properties, and provides a protective coating and a smooth feel
3	Soap	Adhesive agent in blusher and as a foam stabilizer in liquid soaps
4	Lithography industry	Etching and plating solutions
5	Paints and insecticidal	Pigments and active components uniformly distributed throughout the product
6	Textile industry	Thickening agent in printing pastes
7	Pet food	Canned meat-containing pet foods
8	Other applications	Inks, polishes

2.1.2 Gum Tragacanth

It is the dried gummy exudation obtained by incision from stems and branches of *Astragalus gummifer* and other species of *Astragalus* belonging to the family Leguminosae. It contains two fractions of which one is soluble in water. The water-soluble portion is known as tragacanthin, constituting about 8–10 % of the gum. Water-insoluble portion is known as bassorin (60–70 %). Tragacanth on hydrolysis yields galacturonic acid, D-galactopyranose, L-arabino-rhamnose, and D-xylopyranose. It is also used as an emulsifying, suspending and thickening, and binding agent (Verbeken et al. 2003).

2.1.3 Gum Karaya

It is also known as Indian tragacanth or *Sterculia* gum. It is as dried gum exudates obtained from the tree *Sterculia urens*, *Sterculia villosa*, and *Sterculia tragacantha* belonging to the family Sterculiaceae. Karaya gum is composed of galacturonic acid, β-D-galactose, glucuronic acid, L-rhamnose, and other residues. Karaya gum has unique features such as high swelling, water retention capacity, high viscosity, inherent nature of antimicrobial activity, and abundant availability. It is neither digested nor absorbed by the body and hence it is a good bulk laxative (Anderson et al. 1982).

2.1.4 Gum Ghatti

Gum ghatti is a naturally occurring water-soluble, complex polysaccharide derived as an exudate from the bark of *Anogeissus latifolia* (Combretaceae family), a native tree of the Indian subcontinent. The gum is light yellow to amber in color, has a glassy fracture, and often occurs in rounded tears and larger vermiform masses. The gum is almost odorless, only about 80–90 % of the gum dissolves in water and forms a colloidal solution. The name, gum ghatti, has originated from its transportation through mountain passes or *ghats*. This biopolymer is a high-arabinose,

protein-rich, acidic heteropolysaccharide, occurring in nature as mixed calcium, magnesium, potassium, and sodium salt. The primary structure of this gum is composed of sugars such as L-arabinose, D-galactose, D-mannose, D-xylose, and D-glucuronic acid in a molar ratio of 48:29:10:5:10 and <1 % of rhamnose, which is present as nonreducing end groups (Kaur et al. 2009).

3 Gum Collection and Processing

Although natural exudates are sometimes harvested, virtually all exudate gum is tapped from the trees. When acacia trees lose their leaves and become dormant at the beginning of the dry season, usually by the end of October or beginning of November, superficial incisions are made in the branches and bands of bark are stripped off. After 5 weeks, gum is manually collected as partially dried tears. This collection is repeated at 15-day intervals for up to five or six collections in total, depending on the weather conditions and the health of the tree (Imeson 1992). After collection, the gum is cleaned and graded. This is traditionally done by women, who manually sort the gum according to the size of the lumps and remove foreign matter (FAO 1995). Since the 1990s, cleaning has also been performed mechanically using conveyor belts and sieving machines. Since 1995, the gum from *Acacia seyal* (talha) has been divided into three grades: super, standard clean, and siftings.

Gum karaya exudation begins immediately after wounding the *Sterculia* tree and is particularly extensive during the first days. The exudates are allowed to solidify on the tree and are then removed as large, irregular tears. The yield of gum from a mature tree is 1–5 kg per season. India is the world's leading producer of gum karaya. The best quality gum is collected from April to June, before the monsoon season, as the temperature increases. Collection may be repeated in September, although in this period gum may be less viscous and darker, due to the presence of higher amounts of foreign matter. In Senegal, the biggest African producer of gum karaya, harvesting is done from September to January and from March to July. After collection, the gum is manually or mechanically cleaned and sorted. Commercial Indian gum karaya is available in five different grades: handpicked selected, superior no. 1 and no. 2, fair average quality, and siftings (FAO 1995). The higher grades contain less foreign matter and have a lighter color. Senegalese gum is sorted in two grades, handpicked and standard, and is generally inferior to Indian gum.

Gum tragacanth exudes from wounds in *Astragalus* trees and hardens as curled ribbons or flakes, which can be collected after a few weeks. The primary source of the gum is the rather large taproots of the bush, inside of which the gum is contained in a central gum cylinder. Incisions are also made in the bark of the branches, although this usually yields gum of an inferior quality. The plants require a plenitude of rainfall prior to tapping, but dry conditions during harvesting. Rain and wind during the gum exudation may wash some gum off and lead to a decrease in quality. Tapping and collecting is carried out in the dry summer months from July to September. After collection, the gum is sorted manually into various grades

Table 3 Major suppliers of exudate gums all over the world

S. no.	Company	Products
1	Gum Arabic Co., Sudan	Gum arabic
2	Victoria Agro Exports Ltd., Nigeria	Gum arabic
3	Importers Service Corp., USA	Gum arabic, karaya, tragacanth
4	TIC Gums, USA	Gum arabic
5	Colloides Naturels International, France	Gum arabic
6	Alok International, India	Gum arabic, karaya, tragacanth
7	Natural Colloids, Singapore	Gum arabic, tragacanth
8	AEP Colloids, USA	Gum arabic, karaya, tragacanth
9	Agri products, USA	Gum arabic
10	KIC Chemicals Inc., USA	Gum arabic
11	Girijan Co-operative Corporation (GCC), AP, India	Gum karaya, gum kondagogu, gum babul

of ribbon and flake. Iranian tragacanth ribbons are sorted into five grades, while flakes are sold in seven different grades (FAO 1995). After arrival in the importing country, the gum is usually ground into powder, with particle size varying according to the desired viscosity. A list of the major producers/suppliers of exudate gums all over the world is given in Table 3.

Gum arabic is the oldest and best known of all natural gums. Its use can be traced back to the third millennium B.C., the time of the ancient Egyptians. Early Egyptian fleets shipped gum arabic as an article of commerce. It was used as a pigment binder and adhesive in paints for making hieroglyphs, and ancient inscriptions refer to it as *kami*.

Furthermore, it was used as a binder in cosmetics and inks and as an adhering agent to make flaxen wrappings for embalming mummies. Introduced in Europe through various Arabian ports, it was called gum arabic after its place of origin. During the middle age, gum arabic trade was controlled by the Turkish Empire, giving rise to the name turkey gum. The Joint FAO/WHO Expert Committee on Food Additives (JECFA) defines gum arabic as "a dried exudates obtained from the stems and branches of *Acacia senegal* (L.) Willdenow or *Acacia seyal* (Fam. *Leguminosae*)" (FAO 1999). In a wider sense, the name gum arabic is also used to denominate gums produced by other *Acacia* species, like *A. karroo*, and is sometimes referred to as gum acacia (FAO 1995).

4 Physical Properties of Gums

Physical properties of gums are the most important factors in determining their use and commercial value. Viscosity, gel-forming tendency, colloidal nature, and adhesiveness are some of the important physical properties of gums. The physical properties of various gums vary depending on botanical origin, climatic conditions, harvesting period, age of the tree, post-harvesting practices, and storage conditions. The following are details of physical properties of gums.

4.1 Viscosity

Viscosity or the "thickness" of a solution that a gum forms with water is of paramount importance in determining the quality of gum. It is said that the higher the viscosity, the better the gum particularly in the case of medicinal use.

4.2 Shape

Gums are available in two shapes, majority of them are tear shaped, excepting few, which are globular.

4.3 Color

It is a very important factor in the commercial valuation of gums. It is believed that color is mainly due to the presence of impurities. However the concrete reasons have not been researched properly. But as per the traders, good market is always there for light-colored gums. The darker the color, the commercial value decreases. Majority of the good gums are almost water white with traces of yellow. The other colors that are found among gums are amber, orange, dark brown, black, and brownish.

4.4 Colloidal Nature

This property makes gums valuable in manufacturing processes, notably in the textile, cosmetic, pharmaceuticals, and food industry. Colloidal nature exhibits swelling pressures and forms gel structures at very low concentrations and over a wide range of concentrations. They have low surface tension, do not crystallize, and act as protective colloids and stabilizing agents. In effect they prevent agglomeration.

4.5 Taste and Smell

The true gums are nearly odorless and in this sense differ markedly from some of the resins and oleoresins that are so distinctive in smell. They may be tasteless and are in fact generally devoid of any characteristic taste. But some are slightly sweet or bitter according to botanical origin. In some gums there is distinctively bitter taste which is a serious disadvantage in their application for edible purposes.

4.6 Hardness

Gums vary in hardness. Hardness is obviously governed partly by the amount of moisture present. Density also provides variable in one and the same gum according

to the amount of air that may have been incorporated in it when it was formed. Most gums break with a clear glassy fracture when properly dried and may be readily pulverized.

5 Gum Kondagogu Occurrence

Indian forests are a major source of large number of non-wood forest products. One such product is an exudate tree gum, regionally called as gum kondagogu (*Cochlospermum gossypium*) (Fig. 1), belonging to the family Bixaceae. This gum is an important non-wood forest natural product collected by tribals in the state of Andhra Pradesh and is commercially marketed by Girijan Co-operative Corporation (GCC), Hyderabad, Andhra Pradesh, India (Table 4). Three grades of gum are marketed as grades I, II, and III. The production in the state of Andhra Pradesh is in the range of 0.5–1.5 tons of gum per season. This gum is also produced

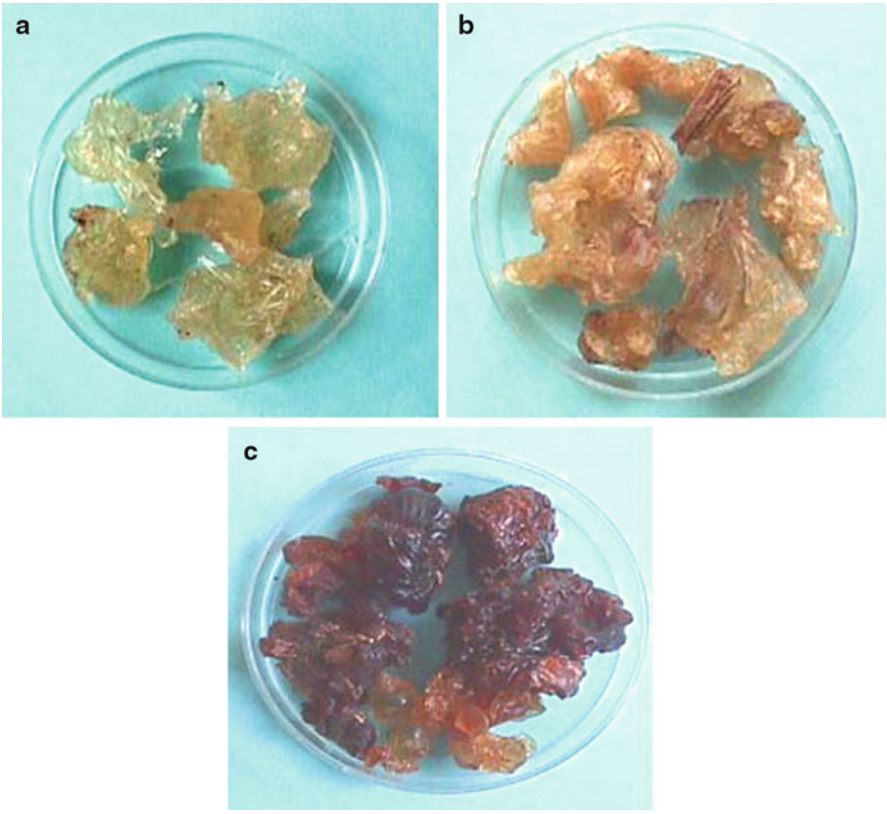

Fig. 1 Specimens of different grades of gum kondagogu. (**a**) Grade I. (**b**) Grade II. (**c**) Grade III

Table 4 Gum kondagogu collection in the state of Andhra Pradesh, India, and its export sale value

Year	Quantity in quintals	Value in rupees (in lakhs)
2000–2001	887	84.37
2001–2002	1,321	143.16
2002–2003	1,150	116.07
2003–2004	1,222	136.06
2004–2005	1,136	126.69
2005–2006	1,158	135.67
2006–2007	1,165	145.89
2007–2008	1,175	155.09

and marketed by other Indian states, namely, Rajasthan, Madhya Pradesh, and Chhattisgarh.

Gum kondagogu is trapped from the tree by blazing or stripping of the bark of the tree. The maximum amount of the gum is produced within the first 24 h of blazing and continued for several days. The gum is solidified in the form of "tears."The best quality of the gum is produced during April to June. Janaki and Sashidhar (1998) pioneered the studies on gum kondagogu in relation to its physicochemical properties and as a potential new food additive. Their investigation provided a separate identity to this gum as compared to other established tree gum such as gum arabic, gum tragacanth, and gum karaya. The physicochemical analysis revealed that gum kondagogu differs from gum karaya with respect to fiber, protein, tannin, minerals, sugar compositions, intrinsic viscosity, water-binding capacity, and pH (Janaki and Sashidhar 1998). The toxicological assessment of gum kondagogu established this gum to be nontoxic. The toxicological evaluation of gum kondagogu fed to Wistar rats did not show any adverse effects on feed consumption and utilization or clinical condition, as revealed by hematological, blood chemistry, enzymatic profile, urine analysis, organ mass, and histopathological examination, suggesting that gum kondagogu can be used in the food and pharmaceutical preparations (Janaki and Sashidhar 2000). Later, comprehensive experimental investigations were carried out in our laboratory to elucidate the morphological features, physicochemical, structural, rheological, solution, and conformational properties of this novel gum (Vinod et al. 2008a, b; Vinod and Sashidhar 2009).

5.1 Morphological Studies

Morphological analysis of gum kondagogu was carried out using scanning electron microscopy (SEM), atomic force microscopy (AFM), and transmission electron microscopy (TEM). Microscopy (SEM, TEM, and AFM) was used to provide visual evidence for the formation of multilayer interfaces around colloidal particles.

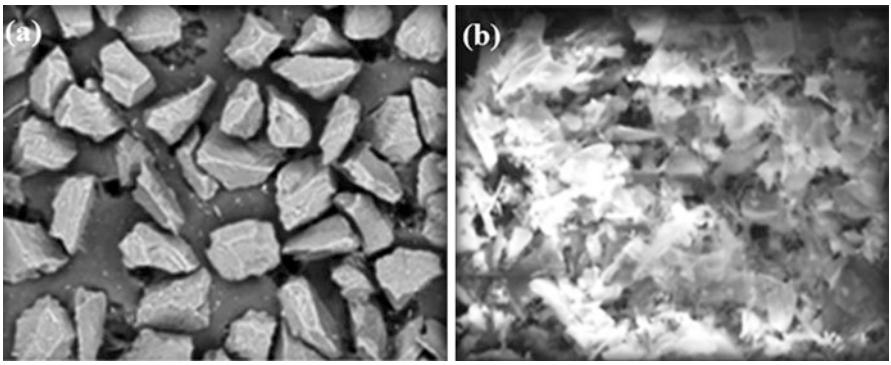

Fig. 2 (**a**) Scanning electron microscopy (SEM) of native gum shows that irregular particle size and (**b**) deacetylated gum was found to be fibrillar, indicating the loss in particulate morphology that was observed in the native form of the gum, suggesting that acetyl groups are essential for its structural integrity

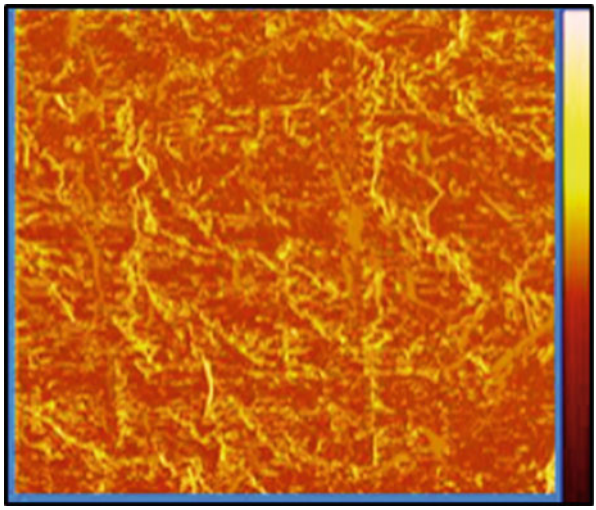

Fig. 3 Topographical phase of native gum kondagogu determined by AFM (phase image) analysis suggesting an irregular network-shaped structure for gum kondagogu

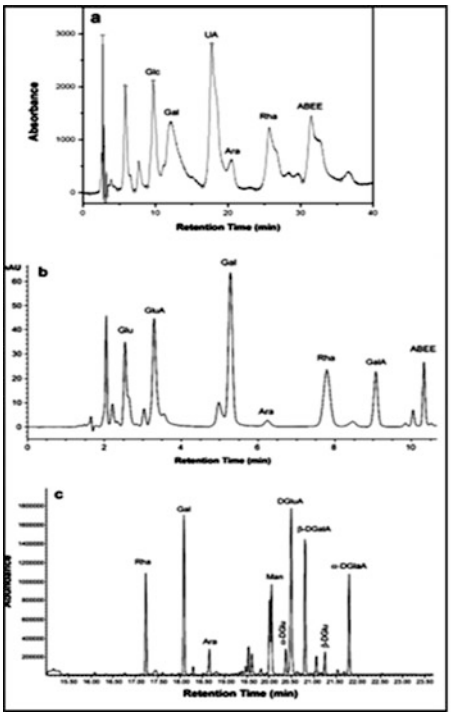
Scanning electron microscopy (SEM) of native and deacetylated gum showed that the native form of the gum had irregular particle size (Fig. 2a). Deacetylated gum was found to be fibrillar, indicating the loss in particulate morphology that was observed in the native form of the gum, suggesting that acetyl groups are essential in the structural integrity of the gum for particulate appearance in the native form (Fig. 2b). Topographic image of gum kondagogu based on AFM analysis suggested an irregularly shaped network structure, indicating the involvement of inter- and/or intramolecular aggregations (Fig. 3). The TEM analysis of gum kondagogu showed elongated chain structures with extensive branching (Vinod and Sashidhar 2010).



Sugar residue	Composition (mol %)
Rhamnose	12.85
Galactose	18.95
Arabinose	2.52
Mannose	8.30
α-D-glucose	2.48
D-glucuronic acid	**19.26**
β-D-galacturonic acid	**13.22**
β-D-glucose	2.52
α-D-galacturonic acid	**11.02**

Fig. 4 Compositional analysis of gum kondagogu: sugar profile of gum kondagogu as determined by (**a**) HPLC, (**b**) LC-MS, and (**c**) GC-MS analysis

5.2 Phytochemistry

Essentially, gum kondagogu is a biopolymer of rhamnose, galacturonic acid, glucuronic acid, β-D-galactopyranose, α-D-glucosopyranose, galactose, arabinose, mannose, and fructose with average molecular mass of 7.23×10^6 g mol^{-1} determined by static light scattering method and Berry plots. Gum kondagogu is also composed of higher uronic acid content, cruse protein, tannin, and soluble fibers.

5.3 Compositional Analysis

Composition of gum kondagogu was deciphered based on High performance liquid chromatography (HPLC), Liquid chromatography mass spectrometry (LC-MS), and Gas chromatography mass spectrometry (GC-MS) analysis. The analytical data on sugar composition suggested that gum kondagogu contains very high concentration of uronic acids [D-glucuronic acid (19.26 mol %), β-D-galacturonic acid (13.22 mol %), and α-D-galacturonic acid (11.22 mol %)] (Vinod et al. 2008a, b) (Fig. 4). The amino acids present in gum kondagogu include alanine (32.25 ± 1.44 μg g^{-1}), glycine (5.05 ± 0.55 μg g^{-1}), valine (7.24 ± 0.60 μg g^{-1}),

leucine (3.85 ± 0.22 μg g^{-1}), proline (42.45 ± 2.56 μg g^{-1}), methionine (44.24 ± 2.25 μg g^{-1}), aspartic acid (72.85 ± 3.45 μg g^{-1}), threonine (30.45 ± 1.54 μg g^{-1}), glutamic acid (34.25 ± 1.56 μg g^{-1}), tyrosine (32.89 ± 1.85 μg g^{-1}), and tryptophan (10.88 ± 0.84 μg g^{-1}). Aspartic acid, methionine, proline, glutamic acid, tyrosine, and threonine were observed to be the major amino acids in gum kondagogu. The fatty acids identified in gum kondagogu included: lauric acid ($C_{12:0}$), myristic acid ($C_{14:0}$), palmitic acid ($C_{16:0}$), stearic acid ($C_{18:0}$), oleic acid ($C_{18:1}$), linoleic acid ($C_{18:2}$), γ-linolenic acid ($C_{18:3}$), arachidic acid ($C_{20:0}$), behenic acid ($C_{22:0}$), erucic acid ($C_{22:1}$), and lignoceric acid ($C_{24:0}$). Gum kondagogu contains 84.4 % of saturated fatty acid and 15.6 % of unsaturated fatty acids. Stearic acid ($C_{18:0}$) (37.25 %) was the major fatty acids present in the gum. The unsaturated fatty acid detected includes linoleic acid (3.45 %) and γ-linolenic acid (0.54 %), oleic acid (0.50 %), palmitoleic acid (5.92 %), and erucic acid (6.02 %) (Vinod and Sashidhar 2010; Vinod et al. 2010a). Gum kondagogu is an acidic gum with high content of uronic acid, and the major functional groups identified in the gum are hydroxyl, acetyl, carbonyl, and carboxylic groups.

5.4 Structural Analysis

The structural feature of gum kondagogu was elucidated by spectroscopic methods. The purified gum kondagogu sample was studied by X-ray diffraction analysis (XRD), Fourier transform infrared spectroscopy (FTIR) (Fig. 5a, b), and nuclear magnetic resonance spectroscopy (NMR) [by1-D (^{1}H and ^{13}C) and 2-D (DQF COSY, NOESY, TOCSY, HMBC, and HSQC)]. Based on these spectroscopic studies, the probable structural feature that can be assigned to gum kondagogu was a backbone and linkages with (1 → 2) *α*-L-Rha*p* (1 → 4) α-D-Gal A (1 → 2) and pendent residue of *β*-D-Gal (1 → 4) *α*-L-Rha*p* and *β*-D-Glu A (1 → 3) *α*-D-Gal A, with branched structures composed of galactose, arabinose, rhamnose, mannose, glucose, *β*-D-glucuronic acid, *β*-D-galacturonic acid residues, and 4-*O*-methyl derivatives (Fig. 6). The backbone structure of the gum kondagogu was also assigned based on Smith degradation analysis (Vinod et al. 2008a, b; Vinod and Sashidhar 2010). Table 5 depicts the summary of proximate and physicochemical properties of gum kondagogu.

6 Biotechnological Applications of Gum Kondagogu

6.1 Bioremediation of Toxic Metal Ions from Industrial Effluents

In recent years, the presence of heavy metals in industrial wastewater and effluents is an important environmental problem due to their more rigorous discharge norms, their increased usage, and their high toxicity. One of the methods of decontamination includes green approach, which utilizes the available natural products that have low operating cost, improved selectivity for specific metals of interest, and removal of heavy metals from effluents. Gum kondagogu, a natural biopolymer, has been exploited as an efficient, environmentally friendly matrix for removal of toxic metal

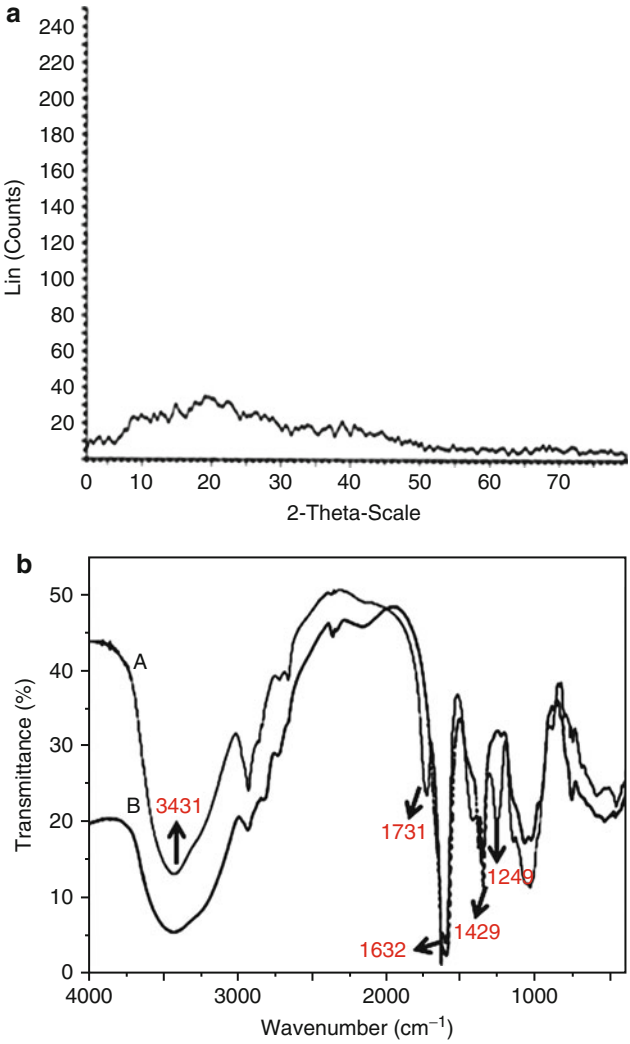


Fig. 5 (**a**) The XRD pattern of the native gum indicates a completely amorphous structure. (**b**) FTIR analysis of native and deacetylated gum kondagogu. The major functional groups identified from FTIR spectrum include 3,431 cm^{-1} (–OH), 1,731 cm^{-1} (CH_3CO–), 1,632 cm^{-1} (–COO–), 1,429 cm^{-1} (–COO), and 1,249 cm^{-1} (–CH_3CO). Absence of peaks at 1,736 and 1,227 cm^{-1} were attributed to acetyl groups; these groups were absent in deacetylated gum

pollutants from industrial effluent discharges. The biosorption of metals from wastewaters using biomass byproducts is a viable and cost-effective technology that should be included in process evaluations. The utility of this novel natural biopolymer in the bioremediation of toxic metal ions [Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, and Cr (total)] has been investigated for bioremediation of toxic metal ions present in industrial effluents.

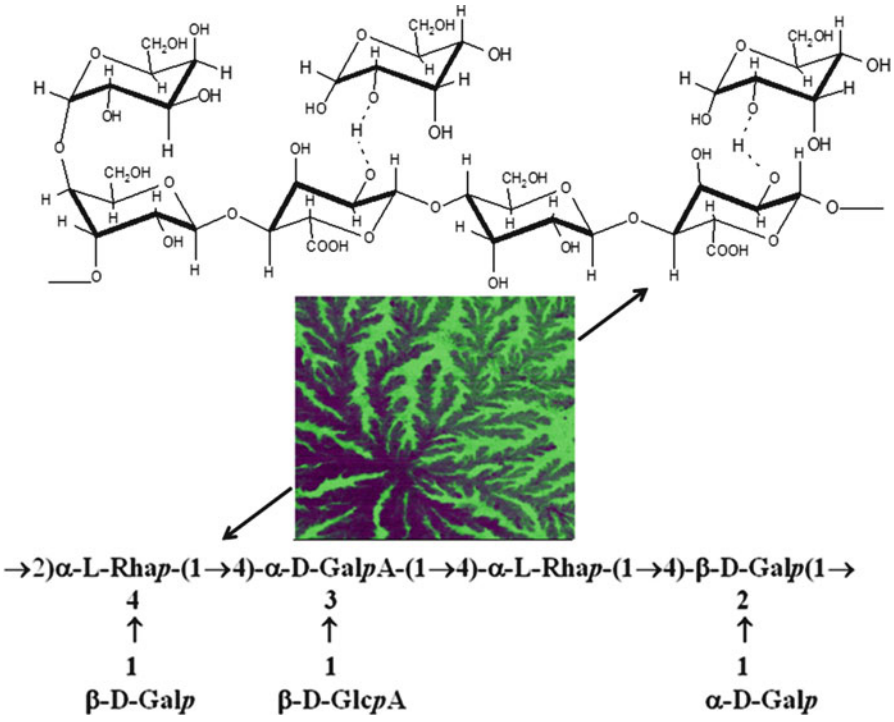

Fig. 6 The assigned structure of the gum kondagogu by NMR and GC-MS analysis. Structural assignment was carried out using acid hydrolysis, Smith degradation, and NMR studies [^{1}H, ^{13}C, 2-D NMR (TOCSY and NOESY)]. TEM analysis of native gum kondagogu showing backbone and branched network structures (Scale bar 100 nm)

The continuously increasing demand for the commodities produced by chemical industries has generated heavy metal accumulation in the ecosystem. Biosorption is a potentially attractive technology for removal of toxic heavy metals from industrial effluents. A number of technologies have been developed over the years to remove toxic metal ions from water. Newer technologies are required that can reduce heavy metal concentrations to environmentally acceptable levels at reasonable cost. One of the methods of decontamination includes green approach, which utilizes the available natural products that have low operating cost, improved selectivity for specific metals of interest, and removal of heavy metals from effluents. Among the toxic metal ions, Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Hg^{2+}, and Cr are harmful wastes produced by industry that pose a risk of contaminating groundwater and other water resources, impacting the water quality.

The study was performed on five different industrial locations (Nacharam, Cherlapally, Tank Bund, Balanagar, and Kattedan) in city zone of Hyderabad (Telangana, India). Biosorption of toxic metals was quantitatively determined by ICP-MS. The FTIR spectra were obtained using an IR spectrophotometer.

Table 5 Summary of proximate and physicochemical properties of gum kondagogu

Proximate	
Moisture (g%)	15.2 ± 1.18
Crude protein (g%)	6.3 ± 1.11
Lipid content (g%)	2.2 ± 0.14
Total fiber (g%)	80.0 ± 20.2
Volatile acidity (g%)	15.9 ± 0.35
Water-binding capacity (mL g^{-1})	35.1 ± 1.96
pH	4.9 ± 0.2
Ash (g%)	7.3 ± 0.33
Tannin (g%)	0.072 ± 0.008
Values, mean ± SD	
Physicochemical properties	
Morphology	Branched with network structures
Functional groups	–OH, –COOH, –CO, $–CH_3CO$
Structural components	Rich in rhamnose, galactose, and uronic acid (Rhamnogalacturonan type gum)
Molecular mass (Da)	$7.23 \pm 0.15 \times 10^6$
Intrinsic viscosity (dL g^{-1})	32.68
Nature of gum	Amorphous
Glass transition temperature	34.5°C
Rheological	Newtonian behavior

IR spectra of gum kondagogu and gum kondagogu–metal complexes were obtained in the spectral region of 4,000–400 cm^{-1} using resolutions of 4 cm^{-1} and 64 co-added scans.

The Langmuir isotherms of Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, and total Cr ions adsorbed on the gum kondagogu are comparatively illustrated in Fig. 7. The amount of metal ions adsorbed at equilibrium per gram of gum kondagogu (q) is represented as a function of the equilibrium metal ion concentration (C_e) as shown in Fig. 7. The uptake of metal ions by gum kondagogu varies in the range of $Cd^{2+} > Cu^{2+} > Fe^{2+} > Pb^{2+} > Hg^{2+} >$ total Cr $> Ni^{2+} > Zn^{2+}$ over the whole range of metal ion initial concentrations examined.

The effluent samples were analyzed for the bioremediation property of gum kondagogu for removal of toxic metal ions contaminants. Gum kondagogu was capable of competitively adsorbing eight metal ions from the samples of industrial effluents tested, which was observed to be in the following order: $Cd^{2+} > Cu^{2+} > Fe^{2+} > Pb^{2+} > Hg^{2+} >$ total Cr $> Ni^{2+} > Zn^{2+}$. The adsorption capacity ($\boldsymbol{q}$) of metals by gum kondagogu varied in the range of 31–37 mg g^{-1} for Fe^{2+} and a minimum of 5.5–9.3 mg g^{-1} for Hg^{2+}, in the tested effluent samples. The competitive biosorption capacity of gum kondagogu for removal of metal ions was best effective at pH 5 (Fig. 8)

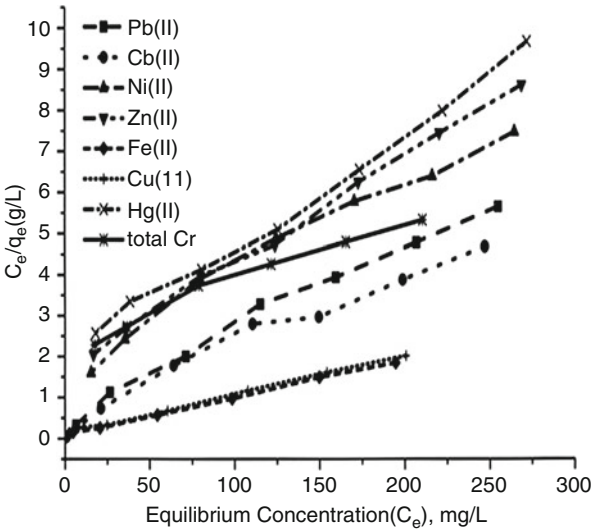

Fig. 7 Langmuir plots for metal ion (Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, and total Cr) biosorption by gum kondagogu. Conditions: initial metal ion concentrations (25–300 mg L^{-1}); gum kondagogu dose (1 mg mL^{-1}); pH 5; temperature, 25 °C; time of contact, 2 h

6.2 Nature of Metal Interaction with Gum: Analysis by FTIR

The interactions between metal ions (Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, and total Cr) and functional groups on the gum kondagogu were confirmed by FTIR analysis (Fig. 9i). The FTIR result indicates that bioremediation of metal ions by gum kondagogu occurred as a result of electrostatic interaction as well as complexation with hydroxyl, carboxylic, carbonyl, alcoholic, ester, amino, acetyl groups, and high amount of uronic acid of the biopolymer. Gum kondagogu biopolymer possesses functional groups, which can adsorb heavy metals. The major functional groups of the type include carboxylate anion (-COO), hydroxyl (-OH), and others (–C–N, –C–O, –C–H, –C = O, –NH). The wide band with maxima at 3,405 cm^{-1} was assigned to the stretching of O-H group of macromolecular association, the band at 2,925 cm^{-1} was assigned to stretching of CH_2 bond of methylene groups, and the sharp band observed at 1,708 cm^{-1} was assigned to a C-O bond of carboxylic acid. The strong peak that appears at 1,622 cm^{-1} can be attributed to C-O stretching vibration of a carboxylic acid that exists because of intermolecular hydrogen bond. The bands at 1,125 cm^{-1} and 1,127 cm^{-1} were due to the –C–O stretching of ether groups. The bands at 1,072 cm^{-1} and 1,062 cm^{-1} were assigned to the –C–O stretching of alcoholic groups. These band changes result in the absorbance band at 1,380 cm^{-1} became stronger. The C = C stretching in aromatic ring at 1,610 cm^{-1} shifts to 1,601 cm^{-1} after Cd^{2+} biosorption. The –OH and (–COO) groups in gum kondagogu were involved in Cd^{2+} biosorption. The FTIR spectra of unloaded and lead-loaded gum kondagogu in the range of 400–4,000 cm^{-1} were studied to find out which functional groups are responsible for the biosorption. The FTIR spectrum of lead-loaded gum kondagogu indicated that the peaks around 1,455 and 1,280 cm^{-1} gradually disappeared with increase of Pb^{2+} ions concentration

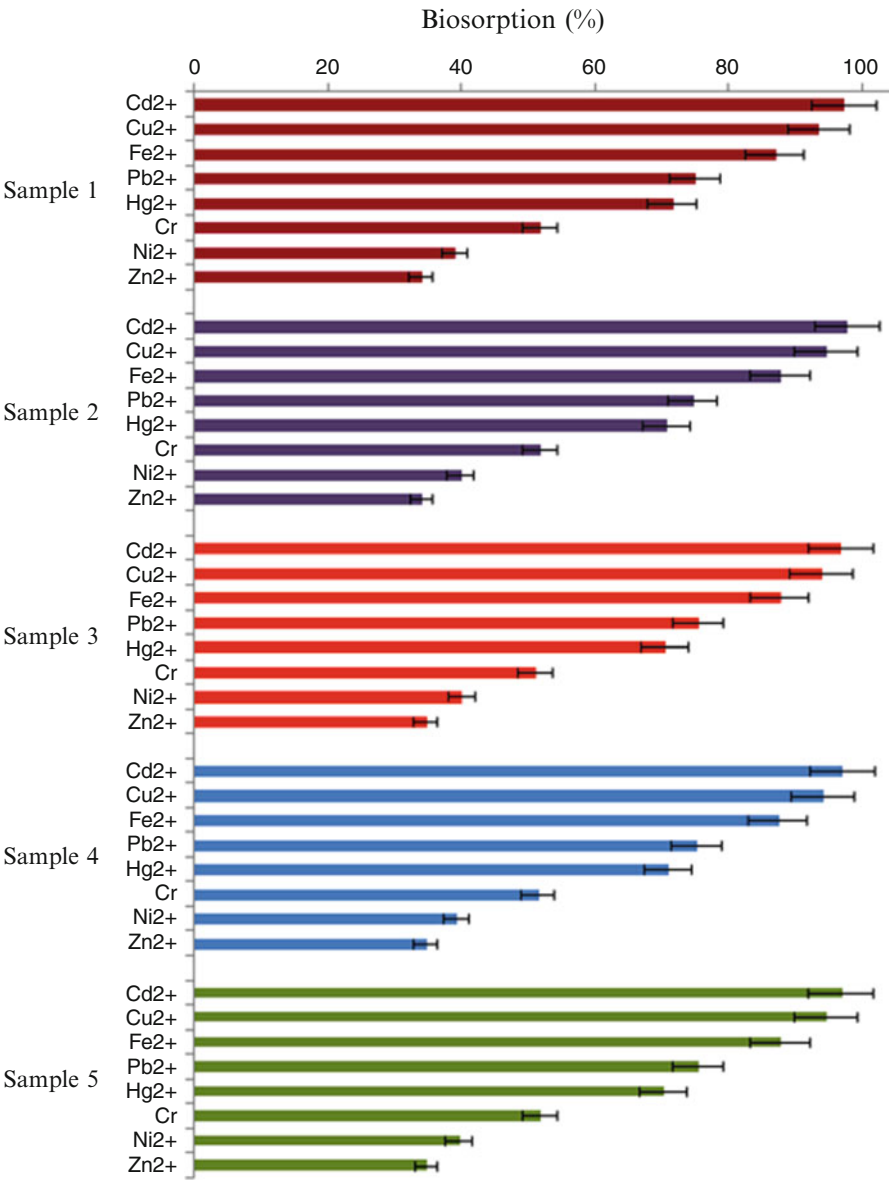

Fig. 8 Metal biosorption (%) by gum kondagogu as determined by ICP-MS in industrial effluent samples (1 Nacharam, 2 Cherlapally, 3 Tank bund, 4 Balanagar, and 5 Kattedan) Hyderabad (Telangana, India)

in solution, while the peak around 1,380 cm^{-1} was found to increase. The shift of peak at 1,455 cm^{-1} transposing to lower frequencies up to disappearance is due to the complexation of amino and hydroxyl groups with Pb^{2+}. Another shift was observed at 1,280 cm^{-1} to higher frequencies corresponding to complexation of

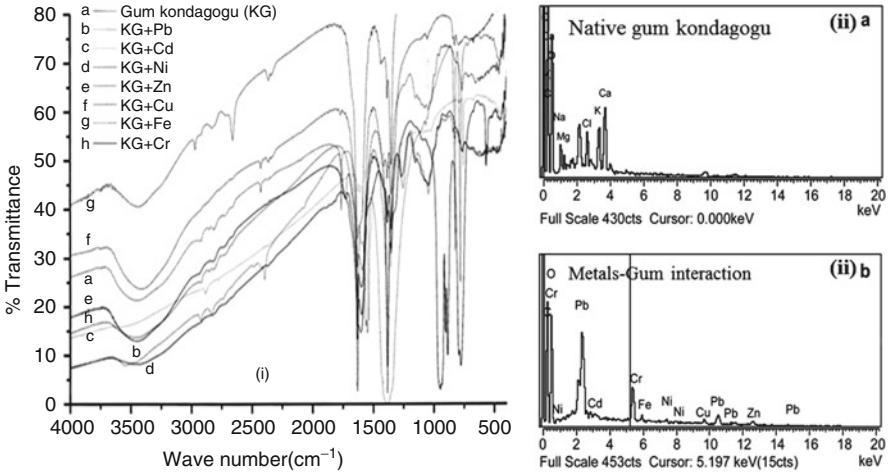

Fig. 9 (**i**) FTIR spectra of (*a*) gum kondagogu before metal biosorption, (*b*) Pb^{2+} loaded, (*c*) Cd^{2+} loaded, (*d*) Ni^{2+} loaded, (*e*) Zn^{2+} loaded, (*f*) Cu^{2+} loaded, (*g*) Fe^{2+} loaded, and (*h*) Cr loaded. (**ii**) The energy-dispersive X-ray analysis (EDXA) spectrum of native gum kondagogu presented shows that the (*a*) major elements present in gum kondagogu are Na^{+}, K^{+}, Ca^{2+}, Mg^{2+}, Cl^{-}, C, and O, respectively. (*b*) Depicts the interactions between gum kondagogu with Pb, Cd, Ni, Cr, Fe, Cu, and Zn elements respectively, suggesting the interaction of metal ions with hydroxyl, carboxyl, acetyl, and carbonyl functional groups present in gum kondagogu

oxygen from the carbonyl –C–O bond. The functional groups involved in bivalent metal biosorption included hydroxyl, carboxyl, ether, and alcoholic groups. A comparison of the spectra for native gum kondagogu with that of lead-loaded gum reveals characteristic changes of the hydroxyl groups and the acetyl groups, which shift from 3,415 cm^{-1} (–OH), amide (1,654 cm^{-1}) before lead adsorption to 3,427 cm^{-1} (–OH) and amide (1,649 cm^{-1}) after lead adsorption. Lead–gum kondagogu interaction is more evident at 3,415, 1,654, 1,550, and 1,250 cm^{-1} because of –OH, –C = O, –COOH, and –C–C vibrations. The broad stretching absorption band at 3,407 cm^{-1} shifted to 3,414 cm^{-1} after Ni^{2+} biosorption. The band intensity at 1,725 cm^{-1} clearly decreased after Ni^{2+} biosorption, i.e., there would be an interaction of Ni^{2+} with carboxylate groups. The band at 1,384 cm^{-1} appears only in the spectra at 1,082 cm^{-1}, which could be assigned to C = O from polysaccharide, while the band at 1,787 cm^{-1} was found to disappear after metal interaction. On the other hand, the band at 1,488 cm^{-1} would be attributed to the C–H bending shifted to 1,468 cm^{-1}. The appearance of new bands at 1,535 and 1,240 cm^{-1} could be assigned to –NH and C = O, respectively. The peaks at 1,725 cm^{-1} turned to a shoulder after Ni^{2+} biosorption, and this may indicate a possible Ni^{2+} interaction with C = O. A band at 1,385 cm^{-1} appears after Ni^{2+} biosorption, which could be attributed to the bending mode of C–O–H that would occur in an alcoholic group or a protonated alcoholic group or a protonated ether group. The shift of absorbance peak after Ni^{2+} biosorption provided the evidence those alcoholic groups would be one of the biosorption sites for removing Ni^{2+} metal ion.

The spectral analysis before and after metal adsorption indicated that especially the bonded –OH groups and C–O stretching were involved in Ni^{2+} biosorption. The C–O band absorption peak is observed to shift to 1,047 cm^{-1} when gum kondagogu was loaded with chromium. A broad adsorption band was observed at 3,307 cm^{-1}, which can be attributed to the bonded –OH groups present in the structure. The other prominent peaks are due to $–OCH_3$ group and aromatic compounds. However, in case of gum kondagogu, there is a remarkable shift in position and shape of the –OH group indicative of chromium binding mostly with –OH groups. These changes in FTIR spectra confirm the band shifts indicating the bonded –OH groups and/or –NH stretching and carboxyl groups (C = O) may especially play a major role in chromium biosorption on gum kondagogu. Biosorption of metal ions (Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, and total Cr) by gum kondagogu occurs as a result of electrostatic interaction and complexation with hydroxyl, carboxylic, carbonyl, alcoholic, ester, amino, uronic acid, and acetyl groups present in the biopolymer that are amenable for the interaction with metal ions at pH 5 (Vinod et al. 2010b; Vinod and Sashidhar 2011). Figure 9ii (a, b) shows the energy-dispersive X-ray analysis (EDXA) spectrum of native gum kondagogu, which contains elements such as Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, C, and O, and its interaction with Pb, Cd, Ni, Cr, Fe, Cu, and Zn metal ions, respectively, suggesting the role of hydroxyl, carboxyl, acetyl, and carbonyl functional groups in binding of metal ions.

The combination of biodegradability, high metal uptake capacity, and high uronic acid content contributes to make gum kondagogu a suitable material for toxic, heavy metal remediation by the biosorption process. The adsorption of metal ions by gum kondagogu occurs as a result of electrostatic interaction as well as complexation with hydroxyl, carboxylic, carbonyl, alcoholic, ester, amino, acetyl functional groups, and high content of uronic acid of the biopolymer. Gum kondagogu being a polyanionic polysaccharide was successfully employed as metal binder for nucleation and precipitation of heavy metals present in effluents. A schematic diagram showing the interaction of metal cation with gum kondagogu is presented in Fig. 10.

6.3 Metals Biosorption by Gum from Mixture of Toxic Metal Ions

The potential of gum kondagogu for the biosorption of toxic metals from mixture of metal in solutions was qualitatively assessed by inductively coupled plasma-mass spectrometry (ICP-MS). The aqueous mixtures of heavy metals were used for the determination of competitive metal-biosorption capacity of gum kondagogu, at three different pH (4.0, 5.0, and 6.0) points. The adsorption capacity (mg g^{-1}) of metals by gum kondagogu is presented in Fig. 11. The percent biosorption of metal ions (Cr, Fe, Ni, Co, Cu, Zn, As, Se, Cd, and Pb) by gum kondagogu from the mixed metal solutions occurred at pH 5.0 ± 0.1, as compared to other two pH values (pH 4.0 ± 0.1 and 6.0 ± 0.1). The percent biosorption of metal ions by gum kondagogu observed was highest

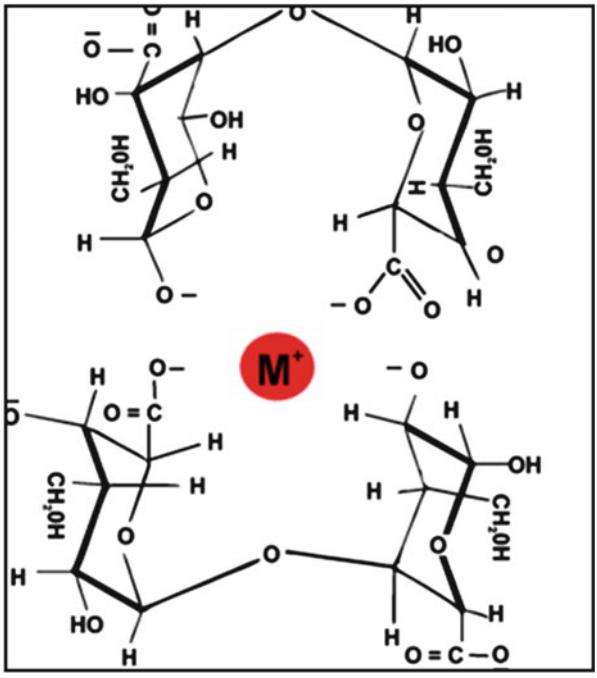

Fig. 10 Schematic diagram showing the interaction of metal cation with gum kondagogu (M^+ = metal ion)

for Cd^{2+} (97.30 ± 1.44 %) and the least for As^{2+} (16.73 ± 0.16 %) from the metal solutions.

The percent biosorption and adsorption capacity of metals by gum kondagogu follows the order $Cd^{2+} > Cu^{2+} > Fe^{2+} > Se^{2+} > Pb^{2+} >$ total Cr $> Ni^{2+} > Zn^{2+} > Co^{2+} > As^{2+}$ at pH 5.0 ± 0.1 and temperature 25 ± 2 °C. Further, to remove metal ions at pH 7.0 from wastewater, chitosan was used as a biosorbent (Gamage and Shahidi 2007). Previous studies on heavy metal biosorption showed that pH was an important factor affecting the biosorption process. The interaction of metal ions with the electron-rich functional groups located on the biopolymer may be strongly sensitive to the pH values of the environment. At very low pH values (pH 1–2), metal uptake was negligible. The optimum initial pH values for biosorption of metal ions were 5.0 ± 0.1. The pH of the adsorption medium affects the solubility of metal ions and the ionization state of the functional groups on the surface of biosorbent. The biosorption capacity of metal cations strongly depends on pH value (Yin et al. 1999; Saeed et al. 2005a). Electrostatic attraction to negatively charged functional groups might be one of the specific biosorption mechanisms. At pH 4.5–5.0, phosphate, carboxyl, and sulfate groups are active. The pH value of solution strongly influences not only the site dissociation of the biomass surface but also the solution chemistry of the heavy metals such as hydrolysis, complexation by organic or inorganic ligands, redox reactions, precipitation, and the speciation and the biosorption availability of the heavy metals (Esposito et al. 2002). The biosorption capacity of metal cations increases with increasing pH of the sorption

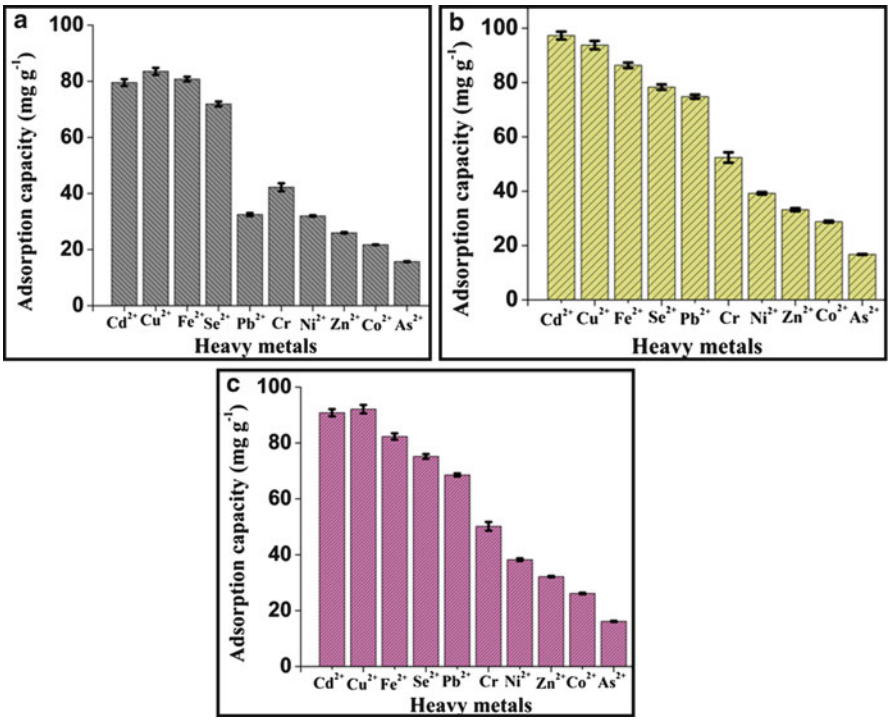

Fig. 11 Heavy metal adsorption capacity (mg g^{-1}) of gum kondagogu as determined by ICP-MS at different pH values: (**a**) pH 4.0, (**b**) pH 5.0, and (**c**) pH 6.0

system, but not in a linear relationship. At lower pH values, biomass functional groups (binding sites) would be closely associated with the hydronium ions and restrict access to binding sites by metal cations as a result of repulsive forces (Malkoc 2006). On the other hand, too high pH value can cause the formation of the metal hydroxides. The acidic groups present in gum kondagogu are responsible for metal binding. In addition, the gum also contains tannin, fibers, and proteins. Further, the pH of gum kondagogu in aqueous solution was reported to be 4.9–5.0 (Janaki and Sashidhar 1998; Vinod et al. 2008a, b). At low pH value, most of the carboxylic groups present in the gum kondagogu are protonated. With increasing pH (optimal pH 5.0), these groups get de-protonated and thus the negatively charged site formed on the gum enhances metal binding. Similar pH values (pH 5.0) were also observed for maximum biosorption of toxic metals (Cr, Fe, Ni, Co, Cu, Zn, As, Se, Cd, and Pb) by cellulose/chitin and black gram husk (Zhou et al. 2004; Saeed et al. 2005b). The high content of uronic acid (glucuronic and galacturonic) present in gum kondagogu is also responsible for metal biosorption due to negatively charged functional groups. Similar results were observed earlier, in epiphytic moss and lichen, wherein galacturonic acid was the main sugar residue involved in metal binding (Basile et al. 2008).

The native pH of gum kondagogu being 4.9–5.0 can be exploited as a natural ion exchanger to remove toxic metal from the metal-contaminated water. The observed maximum decontamination of toxic metals removed by gum kondagogu was at pH 5.0 ± 0.1 (Fig. 11). The percent adsorption of metal uptake by gum kondagogu follows the order $Cd^{2+} > Cu^{2+} > Fe^{2+} > Se^{2+} > Pb^{2+} >$ total Cr $> Ni^{2+} > Zn^{2+} > Co^{2+} > As^{2+}$ at pH 5.0 ± 0.1 and at room temperature 25 ± 2 °C.

7 Gum Kondagogu and Green Nanotechnology

7.1 Eco-friendly Synthesis of Metal Nanoparticles by Using Gum Kondagogu

There has been a remarkable research interest in the area of nanotechnology to develop reliable processes for the synthesis and stabilization of metal nanoparticles, especially noble metals owing to their potential applications in the field of biosensing and biomedical devices (Shipway et al. 2000; Yi et al. 1994; Rao et al. 2000; Sandeep Kumar et al. 2012). Numerous methodologies have been formulated in the past, to synthesize noble metal nanoparticles, such as Ag, Au, and Pt, with different compositions, sizes, and controlled monodispersity. A general method for the preparation of noble metal nanoparticles involves the treatment of metal salts with appropriate reducing agents, such as citrates, borohydrides, and other organic compounds. Many of these reducing agents have associated environmental toxicity or biological hazards. With an increasing interest in minimization or total elimination of waste and implementation of sustainable processes through the adoption of the fundamental principles of green chemistry, the development of biological and biomimetic approaches for the preparation of nanomaterials is a desirable attribute (Raveendran et al. 2003; Rao et al. 2002).

The interesting chemical composition of gum kondagogu motivated us to use this biopolymer as a template for the synthesis and stabilization of metal nanoparticles due to its (i) natural availability and low cost; (ii) nontoxicity and potential as food additive; (iii) abundance in hydroxyl, acetyl, carbonyl, and carboxylic functional groups; and (iv) metal-biosorption properties. The green route for the synthesis of metal nanoparticles using a nontoxic, renewable natural plant, gum kondagogu, as both the reducing and stabilizing agent was successfully developed. Being a natural polymer, gum kondagogu is amenable for biodegradation. The synthesis was carried out in aqueous medium without the requirement of any added chemical reducing agent, which is completely biogenic. The synthesis of metal nanoparticles by gum kondagogu is listed in Table 6 and depicted in Fig. 12.

The gum kondagogu reduced the Ag^{+} ions into Ag^{0} nanoparticles at a pH of 5.0, and mild heating (45 °C) was adequate for the complete reduction of Ag^{+} ions. In the case of $HAuCl_4$, reduction of Au^{3+} ions to Au^{0} ions occurs at a pH of 10.0 and a temperature of about 75 °C. The solution remained colorless initially for 1 h. Following the addition of 10 μL of 1 M NaOH, the solution turned into wine red color indicating the formation of Au^{0} nanoparticles. The addition of NaOH

Table 6 List of metal nanoparticles synthesized with gum kondagogu

S. no.	Metals	GK–NP size (nm)
1	Au	5.5 ± 2.5
2	Ag	7.8 ± 2.3
3	Fe	5–15
4	Pt	2.4 ± 0.7

Values, mean ± SD

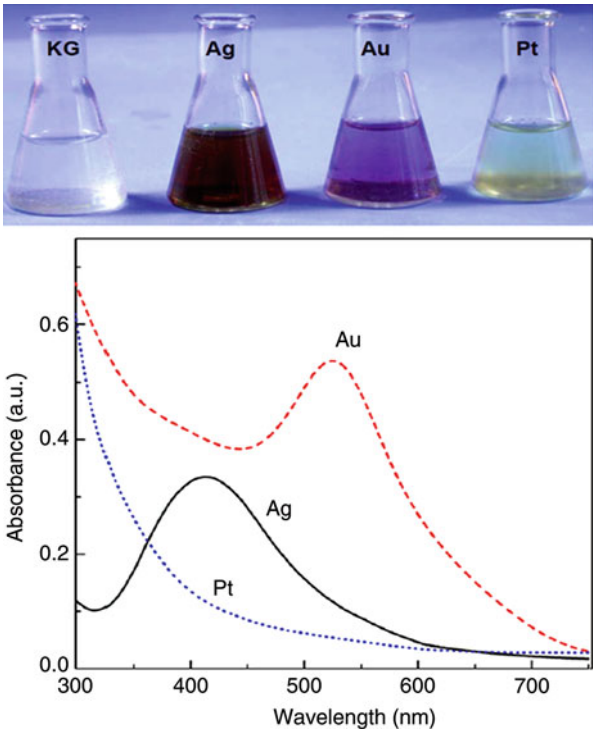

Fig. 12 Formation of striking colors of gum kondagogu – Au, Ag, and Pt nanoparticles and their specific absorption spectra

facilitates the opening of the glucose ring by the abstraction of the α-proton of the sugar ring oxygen and metal ions oxidize glucose to gluconic acid (Raveendran et al. 2003). In the case of Pt, the reduction and formation of nanoparticles occurs at a pH of 8.0 and at a temperature of 120 °C (15 psi, autoclaving).

Gum kondagogu, a natural carbohydrate biopolymer, was used for the synthesis of Ag, Au, and Pt nanoparticles in an aqueous medium. The hydroxyl functional group present in the gum network was found to be responsible for the formation of noble metal nanoparticles. The colloidal suspensions of Ag, Au, and Pt nanoparticles stabilized with the gum templates were highly stable and do not show any sign of aggregation even after storage for a period of 6 months. The Ag and Au nanoparticles formed were in the average size range of 5.5 ± 2.5 nm and 7.8 ± 2.3 nm, while Pt nanoparticles were considerably smaller in their size (2.4 ± 0.7 nm) as compared to Ag and Au nanoparticles.

7.2 Removal of Toxic Metals by Magnetic Nanoparticles Synthesized by Using Gum Kondagogu

Nanoparticles of metal oxides are proven to be a candidate material for providing better kinetics for the adsorption of metal ions from aqueous solutions (Zhong et al. 2006; Hu et al. 2008). However, for such an application, it is necessary to use a method of purification that does not generate secondary waste and involves materials that can be recycled and easily used on an industrial scale. Magnetic separation has been shown to be a very promising method for solid–liquid phase separation technique (Yantasee et al. 2007). To facilitate the recovery and manipulation of nanoparticles, magnetic nanoparticles are used as an excellent candidate for combining metal-binding and selective adsorption properties with ease of phase separation. By this means, they have the capability to treat large amounts of wastewater within a short time and can be conveniently separated from wastewater; moreover, they could be tailored by using functionalized polymers and novel molecules to impart surface reactivity. In this context, a novel magnetic nano-adsorbent based on the surface modification of magnetic iron oxide nanoparticles with GK was developed for the adsorption of toxic metal ions which is a natural, harmless, and environment-friendly polymer (Saravanan et al. 2012).

The effect of pH of the solution on the biosorption of metal cations by the GK − MNP has been investigated at pH values of 1 − 8, and the results are depicted in Fig. 13. The biosorption (%) values tend to increase with the increase in pH up to 5, and then they tend to decrease with the further increase of pH, i.e., beyond 6. The decrease in biosorption (%) at higher pH values (>6) could be probably due to the formation of metal hydroxides. A maximum biosorption of metal cations was observed at pH 5.0 ± 0.1. TEM image of the surface-modified MNPs that were synthesized by gum kondagogu is shown in Fig. 14a. The adsorption (%) of various metal cations by the GK − MNP is listed in Fig. 14b. A maximum biosorption (%) of 98.25 ± 1.42 was recorded for the Cd^{2+} ions, and a minimum biosorption of 28.5 ± 0.25 % was observed for the Hg^{2+} ions. The percent biosorption and adsorption capacity of metal cations by the GK − MNP follows the order $Cd^{2+} > Cu^{2+} > Pb^{2+} > Ni^{2+} > Zn^{2+} > Hg^{2+}$ at pH 5.0 ± 0.1 (Table 7). GK − MNP developed in the present study was found to be quite efficient in the rapid biosorption of toxic heavy metal ions as compared to the native form of GK. The biosorption (%), adsorption capacity (mg/g), and equilibrium biosorption time of the GK − MNP are found to be superior, as compared to that of the native gum (Vinod et al. 2009, 2010c).

7.3 Gum Kondagogu–Silver Nanoparticles as a Biosensor for Detection of Mercury Ions

The gum kondagogu–silver nanoparticles have potential applications as biosensors and antimicrobial agents, which have been successfully exploited in our laboratory (Kora et al. 2010; Rastogi et al. 2014). Mercury is a naturally occurring element that is found in air, water, and soil. It exists in several forms: elemental or metallic

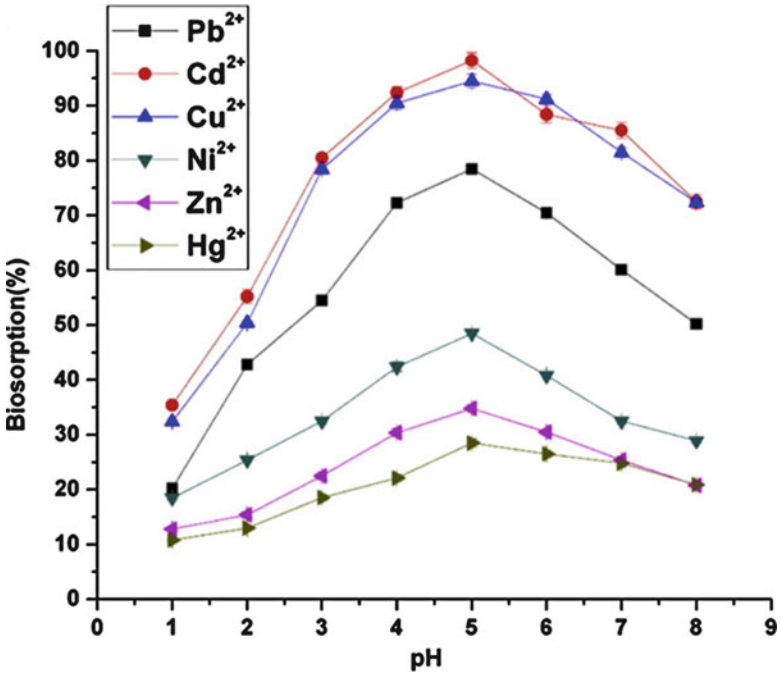

Fig. 13 The effect of pH of the solution on the biosorption of metal cations by the GK − MNP has been investigated at pH values of 1 − 8

Pb^{2+}	78.4 ± 0.54
Ni^{2+}	48.5 ± 0.54
Zn^{2+}	43.8 ± 0.28
Hg^{2+}	28.5 ± 0.25

Conditions: metal ion concentration, 100 mg/L; adsorbent dosage, 0.1 g/100 mL; agitation speed, 200 rpm; temperature, 25 ± 2 °C
[a]Value = mean ± S.D; n = 3
[b]Adsorption$(\%) = \frac{C_i - C_f}{C_i} \times 100$, where C_i and C_f are initial and final metal ion concentration, respectively

mercury, inorganic mercury compounds, and organic mercury compounds (Kim et al. 2011). Major source of mercury emissions are thermal power plant emissions, which are of great environmental hazard because their exposure can affect the human nervous system and harm the brain, heart, kidneys, lungs, and immune system (Bernhoft 2012).

Nanoparticle-based colorimetric probes have attracted lots of attention in the recent past because of their high extinction coefficients (108–1,010 M^{-1} cm^{-1}) often several orders of higher magnitude than those of organic dyes (Otsuka et al. 2001). Most of the nanoparticle-based colorimetric probes were designed by rational modification of nanoparticle surfaces with specific ligands which upon interaction with analyte can change the dispersion/aggregation state of nanoparticles accompanied by color change (Chauhan et al. 2011; Hamaguchi et al. 2010; Radwan and Azzazy 2009; Sugunan et al. 2005). Various colorimetric sensors based on functionalized gold nanoparticles have been developed in the recent past for the selective and sensitive detection of Hg^{2+} (Huang and Chang 2007; Huang et al. 2007; Lin et al. 2010; Sheng et al. 2011; Tanaka et al. 2007; Xue et al. 2008). Although these methods have led to successful development of mercury ion sensors, they suffer from the drawback of high cost of ligands (oligonucleotide probes/fluorescent dyes/selective organic molecule) used and long detection times. Apart from this, Ag NPs are preferred over Au NPs of same size due to their higher extinction coefficient (Lee et al. 2007). A simple ligand-free colorimetric protocol was developed for the facile detection of Hg^{2+} by silver nanoparticles synthesized by gum kondagogu (Rastogi et al. 2014).

A highly sensitive and selective method has been developed for the colorimetric detection of Hg^{2+} in aqueous system by using label-free silver nanoparticles (Ag NPs). Ag NPs used in this method were synthesized by gum kondagogu (GK) which acted as both a reducing and a stabilizing agent. The average size of the GK–Ag NPs was found to be 5.072.8 nm as revealed by TEM analysis, and the nanoparticles were stable at various pH conditions (pH 4–11) and salt concentrations (5–100 mM). The GK reduced/stabilized Ag NPs (GK–Ag NPs) were directly used for the selective colorimetric reaction with Hg^{2+} without any further modification. The bright yellow color of Ag NPs was found to fade in a

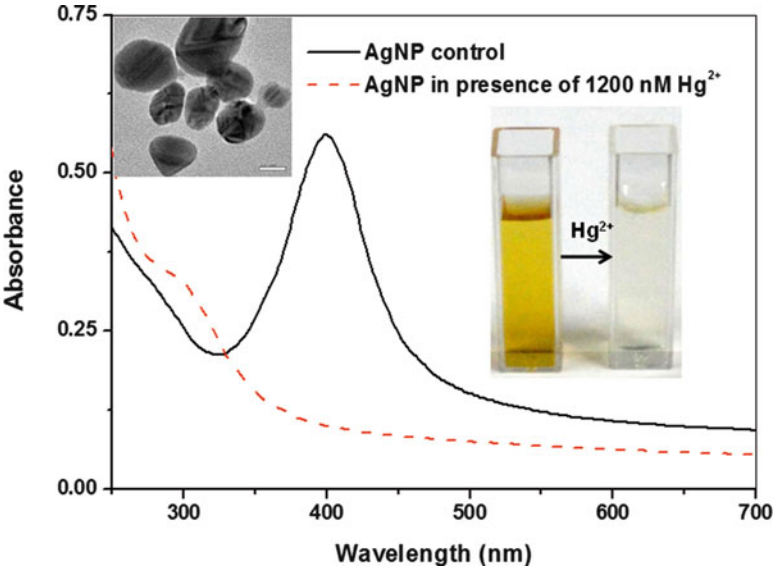

Fig. 15 UV-visible spectra of as synthesized GK–Ag NPs and Ag NPs in the presence of 1,200 nM of Hg^{2+} ions. *Inset*: TEM image of silver nanoparticles (scale: 20 nm) and photograph showing color change of Ag NPs from *yellow* to colorless after Hg^{2+} addition

concentration-dependent manner with the added Hg^{2+} ions. The fading response was directly correlated with increasing concentration of Hg^{2+}. More importantly, this response was found to be highly selective for Hg^{2+} as the absorption spectra were found to be unaffected by the presence of other ions like: Na^{2+}, K^{2+}, Mg^{2+}, Ca^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, As^{2+}, Fe^{2+}, and Cd^{2+} (Fig. 15). The metal-sensing mechanism is explained based on the turbidimetric and XRD analysis of GK–Ag NPs with Hg^{2+}. The proposed method was successfully applied for the determination of Hg^{2+} in various groundwater samples. The reported method can be effectively used for the quantification of total Hg^{2+} in samples, wherein the organic mercury is first oxidized to inorganic form by ultraviolet (UV) irradiation. The limit of quantification for Hg^{2+} using the proposed method was as low as 4.9×10^{-8} mol L^{-1} (50 nM). The proposed method has potential application for on-field qualitative detection of Hg^{2+} in aqueous environmental samples.

8 Gum Kondagogu–Silver Nanoparticles as an Antimicrobial Agent

The methodology developed in the synthesis of gum kondagogu–silver nanoparticles has been successfully exploited for its biomedical applications in our laboratory. Silver nanoparticles are of considerable interest owing to their distinctive electrical, electronic, thermal, optical, magnetic, catalytic, sensing, and

antimicrobial functionalities compared to bulk metal (Wei and Qian 2008). For antimicrobial applications, gum kondagogu–silver nanoparticles were synthesized by autoclaving 0.5 % (w/v) gum along with silver nitrate solutions (1 mM) at 121 °C under 15 psi pressure for 20 min. Under the influence of temperature and pressure, this biopolymer expands and becomes more accessible for the silver ions to interact with the available functional groups of the gum. The large number of hydroxyl and carboxyl groups on this biopolymer facilitates the complexation of silver ions. Subsequently, these silver ions oxidize the hydroxyl groups to carbonyl groups, during which the silver ions are reduced to elemental nanosilver. We have also demonstrated the potential antibacterial activity of the prepared gum nanoparticles on both Gram-positive and Gram-negative bacteria (Kora et al. 2010). As the silver nanoparticles are encapsulated with functional group rich gum kondagogu, they can be easily integrated for various medical and environmental applications.

9 Conclusion

Gum kondagogu is a dried gum exudates obtained from the tree *Cochlospermum gossypium* and other species of *Cochlospermum* belonging to the family Bixaceae. Basically it is a polymer of rhamnose, galacturonic acid, glucuronic acid, β-D-galactopyranose, α-D-glucopyranose, β-D-glucopyranose, galactose, arabinose, mannose, and fructose with sugar linkage of (1 → 2) β-D-Gal*p*, (1 → 6)-β-D-Gal *p*, (1 → 4) β-D-Glc *p* A, 4-0-Me-α-D-Glc *p* A, (1 → 2) α-L-Rha*p*, with average molecular mass of 7.23×10^6 g mol^{-1}. GK is composed of higher uronic acid content, protein, tannin, and soluble fibers. The continuously increasing demand for the commodities produced by chemical industries has generated heavy metal accumulation in the ecosystem. Biosorption is a potentially attractive technology for removal of toxic heavy metals from industrial effluents.

Gum kondagogu (*Cochlospermum gossypium*), a naturally occurring tree biopolymer, is exploited as a biosorbent to remove metal ions from aqueous solutions. The native pH of gum kondagogu being 4.9–5.0 can be exploited as a natural ion exchanger to remove toxic metal from the metal-contaminated water. The removal efficiency of toxic metals by gum kondagogu was determined quantitatively in the order $Cd^{2+} > Cu^{2+}$ $Fe^{2+} > Se^{2+} > Pb^{2+} >$ total Cr $> Ni^{2+} > Zn^{2+} > Co^{2+} > As^{2+}$ at pH 5.0 ± 0.1 and temperature 25 ± 2 °C. The biosorption (%) of various metal ions tested was found to be in the range of 97.3–16.7 %, at pH 5.0. Further, the utility of a novel natural biopolymer (gum kondagogu) obtained as an exudate gum from the tree *Cochlospermum gossypium* in the bioremediation of toxic metal ions [Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+},Ni^{2+}, Zn^{2+}, Hg^{2+}, and Cr (total)] from industrial effluents supports green chemistry principle.

Gum kondagogu has also been explored in conversion of metal ions to metal nanoparticles. The green process for the synthesis of nanoparticles using a nontoxic, renewable natural plant polymer, gum kondagogu, has been used as a reducing and a stabilizing agent for different nanoparticles like Au, Ag, Cu, Pt, Fe, etc. Being a

natural polymer, gum kondagogu is amenable for biodegradation. The synthesis was carried out in aqueous medium without the requirement of any added chemical reducing or capping agent. The gum-based magnetic nanoparticles were successfully used in biosorption of toxic metals. The biosorption of toxic metals enhanced with increasing concentration of toxic metals by using magnetic nanoparticles as compared to that of the native gum. A highly sensitive and selective method has been developed for the colorimetric detection of Hg^{2+} in aqueous system by using label-free silver nanoparticles (Ag NPs). The GK reduced/stabilized Ag NPs (GK–Ag NPs) were directly used for the selective colorimetric reaction with Hg^{2+} without any further modification. The bright yellow color of Ag NPs was found to fade in a concentration-dependent manner with the added Hg^{2+} ions. The fading response was directly correlated with increasing concentration of Hg^{2+}. This method was successfully applied for the determination of Hg^{2+} in various groundwater samples. In addition, the gum nanosilver composite material as a potential antibacterial agent was also explored, and its impeding relevance needs to be further investigated. Their efficacies in biomedical and environmental applications are waiting to be exploited.

Acknowledgment Prof. Sashidhar Rao B wishes to acknowledge the contribution of his doctoral students, Janaki B, Vinod VTP, Ms. Aruna Jyoti K, and Ms. Lori Rastogi, in accepting to work on this novel biopolymer and contribute immensely to the contemporary scientific literature.

Abstract

Chitin is the most abundant natural amino polysaccharide and is next to cellulose in abundance on the planet. Chitosan is obtained by deacetylation of chitin. Chitosan is being researched by academic and industrial scientists as an underutilized resource and as a new functional material of high potential in various fields. The purpose of this chapter is to give an overview of chitosan production, characterization, modification, and applications.

Keywords

Chitin • Chitosan • Polysaccharide • Deacetylation • Antimicrobial • Gel formation • Biopolymer • Active packaging • Metal chelation • Food additive • Biomedical • Biosorbent • Biodegradability

1 Introduction

Polysaccharides are polymeric carbohydrate molecules composed of long chains of monosaccharide units bound together by glycosidic linkages and on hydrolysis give the constituent monosaccharides or oligosaccharides. They have linear to highly branched structure. Their major role in organism is to store energy or to give structural support. Starch and glycogen are examples of storage polysaccharide and cellulose and chitin are examples of structural polysaccharides.

2 Chitin

Henri Braconnot, a French professor, discovered chitin in 1811 and named it fungine. In 1823, Odier found the same material in insects and plants and named it chitin. After cellulose, chitin is the most abundant natural polysaccharide available on the planet. Chitin is similar to cellulose in chemical structure (Fig. 1) and in biological function. Both polymers mainly serve as structural components supporting cell and body surfaces: cellulose strengthens the cell wall of plant cells, whereas chitin contributes to the mechanical strength of fungal cell walls and exoskeletons of arthropods (Rudall and Kenchington 1973).

It has been estimated that at least 1.1×10^{13} kg of chitin is present in the biosphere. However, its use has been limited because it is insoluble in most solvents and relatively difficult to isolate from natural sources in pure form under economically viable conditions. Chitin is a white, hard, inelastic, nitrogenous polysaccharide found in the exoskeleton as well as in the internal structures of invertebrates. It is a linear cationic polymer of *N*-acetylglucosamine residues with β-1,4-linkage. Chitin occurs in three polymorphic forms, α, β, and γ, but α-chitin is the most abundant (Khoushab and Yamabhai 2010). The arrangement of the chains is found to depend on the origin of the chitin. α-Chitin is present in fungal and yeast cell walls, insect cuticles, egg shells of nematodes and rotifers,

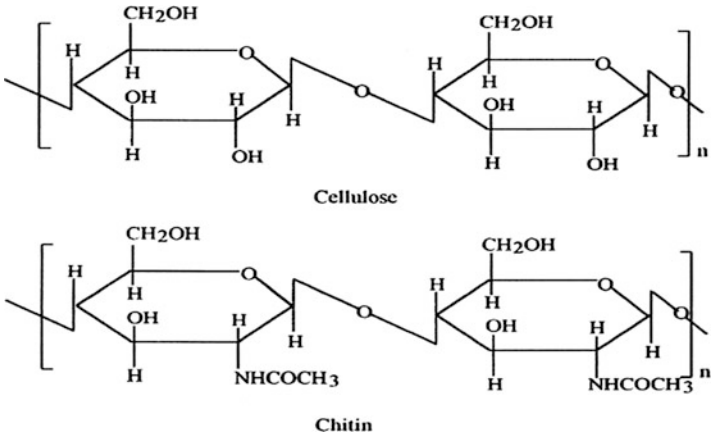

Fig. 1 Chemical structure of cellulose and chitin

the radulae of mollusks, and cuticles of arthropods. This form of chitin is also present in krill, lobster, crab tendons and shells, and shrimp shells, as well as in other marine organisms such as the harpoons of cone snails and the filaments ejected by *Phacocystis* seaweed. β-Chitin is found in the pen and cuticle of squid and the diatom *Thalassiosira fluviatilis*. In α-chitin, sheets are formed by intermolecular hydrogen bonding in parallel chains. Interchain hydrogen bonding occurs between sheets in different directions. There is also intermolecular hydrogen bonding between CH_2OH groups, which is believed to be the cause for the lack of swelling of α-chitin in water. β-Chitin has a monoclinic unit cell with polysaccharide chains attached in a parallel manner (Gardner and Blackwell 1975). In β-chitin, hydrogen bonding occurs only within sheets, not between sheets as in α-chitin. This is thought to be responsible for the swelling of β-chitin, as water can be included between the sheets. γ-Chitin is said to be a combination of α and β structure rather than a third polymorph (Robert 1992). Chitin has <10 % degree of acetylation, 7 % nitrogen content, nitrogen/carbon ratio of 0.146, and molecular weight of 1–2.5 $\times$ 10^6 Da corresponding to a degree of polymerization of ca. 5,000–10,000, which differ in the arrangement of their molecular chains.

During biosynthesis of chitin, monomers of *N*-acetylglucosamine are joined in a reaction catalyzed by the membrane-integral enzyme chitin synthase, a member of the family of glycosyltransferases. The polymerization requires UDP–*N*-acetylglucosamine as a substrate and divalent cations as cofactors. Chitin formation can be divided into three distinct steps. In the first step, the catalytic domain of chitin synthase facing the cytoplasmic site forms the polymer. The second step involves the translocation of the nascent polymer across the membrane and its release into the extracellular space. The third step completes the process as single polymers spontaneously assemble to form crystalline microfibrils of varying diameter and length (Merzendorfer 2006).

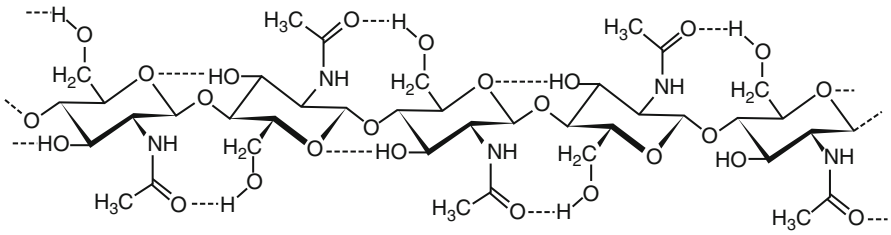

Fig. 2 Chemical structure of chitin shown with its intramolecular hydrogen bonds (*dotted lines*)

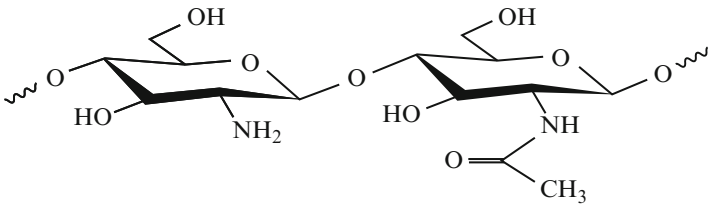

Fig. 3 Chemical structure of chitosan

In the chitin crystal structure, the chains form hydrogen-bonded sheets linked by C=O and H-N-groups. In addition, each chain has intramolecular hydrogen bonds between the neighboring sugar rings: the carbonyl group bonds to the hydroxyl group on C6. There is also a second hydrogen bond between the OH-group on C3 and the ring oxygen, similar to that in cellulose (Minke and Blackwel 1978). This extensive hydrogen bonding shown in Fig. 2 enhances the stiffness of the chitin chain.

With only one known exception, the chitin of diatoms, chitin is found in nature cross-linked to other structural components. The chitin microfibrils combine with other sugars, proteins, glycoproteins, and proteoglycans to form fungal septa and cell walls as well as arthropod cuticles and peritrophic matrices, notably in crustaceans and insects (Kozloff 1990). In animals, chitin is associated with proteins, while in fungal cell wall it is associated with glucans, mannans, or other polysaccharides. In fungal walls, it is found covalently bound to glucans, either directly or via peptide bridges (Roberts 1992). In insects and other invertebrates, the chitin is always associated with specific proteins, with both covalent and non-covalent bonding, to produce the observed ordered structures.

3 Chitosan

Chitosan is obtained by deacetylation of chitin. It consists of D-glucosamine linked to *N*-acetyl D-glucosamine by β-1,4-glycosidic bond (Fig. 3). The distribution of these subunits depends on the method of preparation of chitosan. In chitosan, degree of deacetylation ranges from 40 % to 98 % and the molecular weight ranges between 5×10^4 Da and 2×10^6 Da.

Intense research and development work is being carried out on chitosan as it is considered to be a material of great futuristic potential with immense possibilities for structural modifications to impart desired properties and functions. The presence of reactive amino groups at C2 atom and the hydroxyl group at atom C3 and C6 on chitosan is useful in a wide application in various industries. The positive attributes of excellent biocompatibility and admirable biodegradability with ecological safety and low toxicity with versatile biological activities such as antimicrobial activity and low immunogenicity have provided ample opportunities for further development.

4 Sources

Chitosan can be extracted from insects, yeast, mushroom, cell wall of fungi, and marine shellfish such as crab, lobster, krill, cuttlefish, shrimp, and squid pens (Table 1). In shellfish, chitin forms the outer protective coating as a covalently bound network with proteins and some metals and carotenoids. Shrimps are in general sold headless and

often peeled of the outer shells and tail. Crustacean shells consist of 30–40 % proteins, 30–50 % calcium carbonate, and 20–30 % chitin and also contain pigments (astaxanthin, canthaxanthin, lutein, and β-carotene). These proportions vary with species and with seasons. Shrimp, prawn, and crab wastes are the principal source of commercial chitin and chitosan production. The increase in consumption of shellfish and the expansion of aquaculture have led to a tremendous increase in the quantity of shrimp and prawn being processed and hence in the amount of waste available for chitin/chitosan production. Using mycelium waste from fermentation processes as a source of chitin and chitosan still remains a vast and as yet untapped potential source.

5 Production of Chitosan

Majority of chitosan available globally is produced by the USA, Japan, Norway, Thailand, India, Australia, and Poland. The production of chitosan involves various steps such as preparation of the chitin from the biological material followed by the deacetylation that would result in chitosan. Thus, typical production of chitosan from crustacean shell generally consists of four basic steps: demineralization, deproteinization, decoloration, and deacetylation. Demineralization and deproteinization steps are interchangeable in terms of order. The exoskeleton of crustacean is a major starting material used for commercial production of chitosan. Typical flow chart for manufacture of chitosan is given below (Fig. 4).

5.1 Demineralization

The mineral content in the exoskeleton of crustacean is not the same for all species of crustaceans. Demineralization is generally carried out using acids such as hydrochloric acid, nitric acid, acetic acid, or formic acid (up to 10 %) at room temperature with agitation to dissolve calcium carbonate as calcium chloride. However, hydrochloric acid is the preferred acid and is used at a concentration of 0.2–2 M for 1–48 h at temperatures varying from 0 °C to 100 °C. Demineralization for 1–3 h using dilute (1–8 %) hydrochloric acid at room temperature produces appreciable amounts of calcium chloride. A solid-to-solvent ratio of 1:15 (w/v) is usually used. The ash content of the demineralized shell is an indicator of the effectiveness of the demineralization process.

5.2 Deproteinization

Chitin occurs naturally in association with protein. The protein is bound by covalent bonds to chitin through aspartyl or histidyl residues, or both, thus forming stable complexes (Attwood and Zola 1967). Deproteinization of chitin is usually carried out by alkaline treatment. The shells are treated with sodium or potassium hydroxide at 65–100 °C at a minimum shell-to-alkali ratio of 1:4 for periods ranging from 1 to 12 h. Under these conditions, the protein becomes detached from the solid

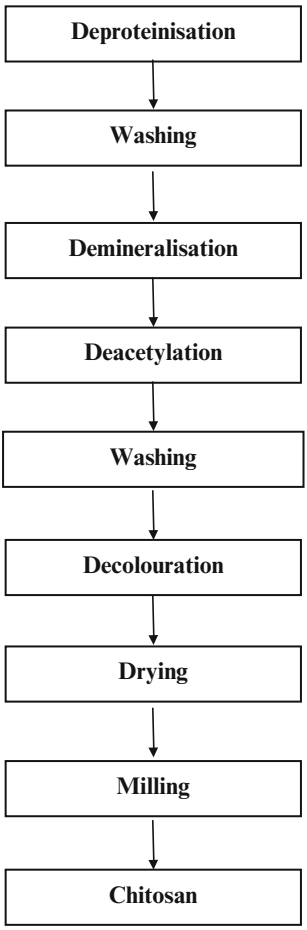

Fig. 4 Flow chart for chitosan production

component of the shrimp waste. Relatively high ratios of solid-to-alkali solution of 1/10 or 1/20 with proper agitation are used to increase the deproteinization efficiency. To prevent oxidation of the products, the process is usually carried out in a nitrogen atmosphere and in the presence of sodium borohydride ($NaBH_4$). After completion of deproteinization step, the protein hydrolysate is removed easily by separation of the solids from the protein slurry by filtration. Prolonged alkaline treatment under severe conditions causes depolymerization and deacetylation.

5.3 Decoloration

Chitin obtained after the demineralization and deproteinization of shell waste is a colored product. For commercial acceptability, the chitin needs to be decolorized or bleached to yield cream white chitin powder (No et al. 1989). The pigment in the

crustacean shells forms complexes with chitin. Fox (1973) found one 4-keto-ß-carotene and three 4, 4′-diketo-ß-carotene derivatives firmly bound to the exoskeletal chitin of red kelp crab. The level of association of chitin and pigments varies from species to species among crustacean. The residues are decolorized using solvents and/or oxidants (Acosta et al. 1993). During the process of decoloration, the chemical used should not affect the physicochemical or functional properties of chitin and chitosan. No et al. (1989) were able to prepare a near-white-colored crawfish chitin by extraction with acetone, which was dried for 2 h at ambient temperature, followed by bleaching with 0.315 % (v/v) sodium hypochloride solution (containing 5.25 % available chlorine) for 5 min with a solid-to-solvent ratio of 1:10 (w/v), based on dry shell.

5.4 Deacetylation

Deacetylation is the process to convert chitin to chitosan by removal of acetyl group. There are several critical factors that affect the extent of deacetylation including temperature and time of deacetylation, alkali concentration, prior treatments applied to chitin isolation, atmosphere (air or nitrogen), ratio of chitin to alkali solution, density of chitin, and the particle size. Considering all these as necessary conditions, the ideal process condition of deacetylation should yield a chitosan that is not degraded and is soluble in dilute acetic acid in minimal time (Muzzarelli et al. 1980). The *N*-acetyl groups cannot be removed by acidic reagents without hydrolysis of the polysaccharide, thus, alkaline methods must be employed for *N*-deacetylation (Muzzarelli 1977). Severe alkaline hydrolysis treatments are required due to the resistance of groups imposed by the trans arrangement of the C2-C3 substituents in the sugar ring. It is generally achieved by treatment with concentrated sodium or potassium hydroxide solution (40–60 %) usually at 80–140 °C for 30 min or longer using a solid-to-solvent ratio of 1:10 (w/v) to remove some or all of the acetyl groups from the polymer (No and Meyers 1989). Sodium hydroxide is the preferred alkali. After deacetylation, the chitosan is washed to completely remove alkali and is dried to give flakes. The material should be low in protein and ash. Production of chitosan by chemical processes has several disadvantages such as environmental pollution, inconsistent molecular weights, and degree of acetylation.

6 Novel Methods for Preparation of Chitosan

The conventional harsh conditions used for extraction could adversely affect the quality of the chitin. Novel methods are being developed to replace conventional demineralization and deproteinization to extract chitin from crustacean waste. The use of enzymes in the deproteinization step has been extensively studied. Shrimp waste deproteinized using *Aspergillus niger*, washed, dried, and then demineralized using acetic or lactic acid produced by fermentation from low cost biomass such as

cheese whey, has been reported (Rinaudo 2006). A number of microorganisms such as *Bacillus subtilis, Lactobacillus helveticus, Pseudomonas aeruginosa, Lactobacillus paracasei, Lecanicillium fungicola*, and *Penicillium chrysogenum* have been utilized for demineralization (Choorit et al. 2008; Oh et al. 2008). These microorganisms are responsible for the precipitation of organic salts such as calcium lactate, which is easily removed from media by wash out. Deproteinization is also carried out with the aid of proteolytic activities of some microorganisms. The calcium, magnesium, and potassium acetates obtained as by-products are suggested as possible de-iceing agents, while the calcium and potassium lactates could find applications as food preservatives. Enzymatic deacetylation by using fungal chitin deacetylase also has commercial potential.

7 Characterization of Prepared Chitosan and Its Properties

7.1 Molecular Weight

One of the most fundamental parameters characterizing a macromolecule is its molecular weight. Knowledge of the molecular weight of polysaccharides is of fundamental importance for the understanding of their applications and their role in living systems. The molecular weight of chitosan depends largely on the conditions of deacetylation and can be determined by methods such as chromatography (Bough et al. 1978), light scattering (Muzzarelli 1977), and viscometry (Maghami and Roberts 1988). Viscometry is the simplest and most popular method to determine molecular weight of chitosan. The method however has the disadvantage of not being absolute because it relies on the correlation between the values of intrinsic viscosity with those of molecular weight. Chitosan is available commercially with molecular weight ranging from 10,000 to 1,000,000 Da.

7.2 Viscosity

Viscosity of chitosan increases with increase in its molecular weight and concentration. Increasing the degree of deacetylation also increases the viscosity (Skaugrud 1991). This can be explained by the fact that high and low deacetylated chitosan have different conformations in aqueous solution. Chitosan has an extended conformation with a more flexible chain when it is highly deacetylated because of the charge repulsion in the molecule. However, the chitosan molecule has a rod-like shape or coiled shape at low degree of deacetylation due to the low charge density in polymer chain. The viscosity of chitosan solution is also affected by factors such as concentration and temperature. As the chitosan concentration increases and the temperature decreases, the viscosity increases. Chitosan viscosity decreases with an increased time of demineralization due to depolymerization (Moorjani et al. 1975). Similarly, No et al. (1999) demonstrated that chitosan viscosity is considerably affected by physical (grinding, heating, autoclaving,

ultrasonication) and chemical (ozone) treatments. Viscosity of chitosan solution stored at 4 °C is found to be relatively stable.

7.3 Solubility

Solubility characteristics of chitosan are based on its degree of deacetylation. High degree of deacetylation shows higher solubility, and low degree of deacetylation shows poor solubility (Heux et al. 2000). It has swelling characteristics due to much weaker intermolecular hydrogen bonding ascribable to the parallel arrangement of the main chains. Chitosan solubility depends on the amount of protonated amino groups in the polymeric chain and, therefore, on the proportion of acetylated and non-acetylated D-glucosamine units. Its cationic nature is unique relative to other neutral or negatively charged polysaccharides. Chitosan is a strong base possessing primary amino group with a pKa value of 6.3. The pH of solution substantially alters the charged state and properties of chitosan (Yi et al. 2005). At low pH, the amines get protonated and become positively charged and that makes chitosan a water-soluble cationic polyelectrolyte. On the other hand, as the pH increases above 6, chitosan amines become deprotonated, and the polymer loses its charge and becomes insoluble. At higher pH, precipitation or gelation tends to occur, and the chitosan solution forms poly-ion complex with anionic hydrocolloid resulting in gel formation (Kurita 1998). The soluble–insoluble transition occurs at its pKa value around pH between 6 and 6.5. Chitosan can easily form quaternary nitrogen salts at low pH values. So, organic acids such as acetic, formic, and lactic acids can dissolve chitosan. The most commonly used solvent for chitosan is 1 % acetic acid at about pH 4.0 (Rinaudo et al. 1999). Chitosan is also soluble in 1 % hydrochloric acid and dilute nitric acid but insoluble in sulfuric and phosphoric acids. Thus, solubility of chitosan is related to the degree of deacetylation, the ionic concentration, pH, the nature of the acid used for protonation, and the distribution of acetyl groups along the chain, as well as the conditions of isolation and drying of the polysaccharide. The high molecular weight of chitosan, which results in poor solubility at neutral pH and its high solution viscosity, limits its use in the food, cosmetics, agriculture, and health industry (Xia et al. 2011).

7.4 Degree of Deacetylation

Degree of deacetylation (DD) has often been cited as an important parameter that determines many physiochemical and biological properties of chitosans such as crystallinity, hydrophilicity, degradation, and cell response. Degree of deacetylation of chitosan is generally controlled by processing of the native polymer with alkali and with increasing time and temperature to obtain the highest degree of deacetylation (>90) materials. During the deacetylation reaction, the acetyl group of the chitin reacts with NaOH and produces an amine group. This is a reversible reaction, and when NaOH concentration is increased, the reaction is biased toward the forward

direction by producing more chitosan. As a result, deacetylation will increase. In the deacetylation process, acetyl groups are removed from the polymers randomly, resulting in a final polymer that has a random distribution of acetyl glucosamine and glucosamine units. The biopolymer is characterized as either chitin or chitosan according to the deacetylation which is determined by the proportion of D-glucosamine and *N*-acetyl D-glucosamine. Various methods have been reported for the determination of the degree of deacetylation of chitosan such as (1) spectroscopy (infrared, ultraviolet, or 1H, 13C, 15N nuclear magnetic resonance), (2) conventional methods (various types of titration, conductometry, potentiometry, ninhydrin assay, adsorption of free amino groups of chitosan by picric acid), and (3) destructive methods (elemental analysis or acid or enzymatic hydrolysis of chitin or chitosan) followed by colorimetric methods or high-performance liquid chromatography, pyrolysis gas chromatography, and thermal analysis using differential scanning calorimetry. Of these, 1H NMR has been found to be simple, rapid, and more precise than many of the other methods (Rinaudo 2006).

7.5 Crystallinity

One of the major physical characteristics that determine the functional properties of chitosan is the crystallinity (Trang et al. 2006). Crystallinity has been found to have an effect on metal sorption. Piron et al. (1997) found that the crystallinity of chitosan controlled the sorption rate and total uptake of uranyl, concluding that sorption was only possible in the amorphous domains and not in the crystalline domains. The crystallinity of the polymer can also control the accessibility of the amine groups (Guibal 2004). The crystallinity of chitosan is determined by X-ray diffraction (XRD) in which the pattern produced by the diffraction of X-rays through the closely spaced lattice of atoms in a crystal is recorded and then analyzed to reveal the nature of the lattice.

7.6 Complex Formation with Metals

Chitosan exhibits superior metal ion sequestering ability than chitin. It has reactive amino group and hydroxyl group and chelates many transition metal ions. Chelation is related to the amino content as well as to the distribution of the amino group. The nature of the cation is very important in the mechanism of interaction (Rhazi et al. 2002). Various processes such as adsorption, ion exchange, and chelation have been considered as the mechanisms responsible for complex formation between metal ions and chitosan. The type of interaction prevailing depends on the metal, its chemistry, and the pH. Under heterogenous conditions, at pH less than 6, chitosan acts as a poly(monodentate) ligand, while at a higher pH, it behaves as a poly(bidentate) ligand forming chelates. However, in solution, the formation of complexes in which two amino groups belonging to the same chain or different chains coordinated to the same metal ion can also take place.

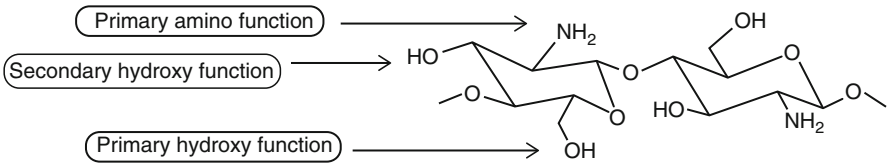

Fig. 5 Functional groups in chitosan that can be modified

8 Modifications of Chitosan

Chitosan can be modified to improve its physicochemical properties to suit various applications. Modification of chitosan is possible due to the presence of several functional groups in the polymer (Fig. 5). It has both reactive amino and hydroxyl groups that can be used to chemically alter its properties under mild reaction conditions The main goals of modifying chitosan are to provide derivatives that are soluble at neutral and basic pH values; to control hydrophobic, cationic, and anionic properties; as well as to attach various functional groups and ligands (Mourya and Inamdar 2008). Strong intramolecular and intermolecular hydrogen bonds exist in chitosan to form random orientations. The dissociation and reorganization of these hydrogen bonds by chemical modification facilitate the production of novel molecular conformations in the forms of solutions, hydrogels, fibers, films, and sponges (Tokura et al. 1996).

8.1 Acylation

A variety of acylation reactions are possible with chitosan. Acylation with long chain aliphatic carboxylic acid chlorides such as hexanoyl, dodecanoyl, and tetradecanoyl chlorides give derivatives with a high degree of acylation. *N*-acylation of chitosan with fatty acid (C6–C16) chlorides increased its hydrophobic character. Such acylated products are soluble in chloroform (Fujii et al. 1980). Chitosan with a higher degree of deacetylation is more susceptible for acylation owing to a decrease in hydrogen bonding. *N*-acyl chitosan has the ability for longer retention in body and resistance to digestible enzymes like lysozyme and chitinase and is more biocompatible than native chitosan (Hirano and Yagi 1980).

8.2 Graft Copolymerization

Graft copolymerization reaction introduces side chains and makes various molecular designs possible, thus affording novel types of tailored hybrid materials composed of chitosan and synthetic polymers. The properties of the graft copolymers can be controlled by molecular structure, length, and number of side chains attached. Grafting of chitosan allows the formation of functional derivatives by

covalent binding of a molecule, the graft, onto the chitosan backbone. The swelling behavior of chitosan at different pH has been improved by graft polymerization of vinylic monomers such as acrylic acid, acrylamide, and acrylonitrile onto chitosan (Borzacchiello et al. 2001; Mahdavinia et al. 2004). Super absorbents (absorb aqueous solutions up to hundreds of times their own dry weight) have been prepared by grafting these resins with chitosan (Nge et al. 2004) and have possible applications in infant diapers, feminine hygiene products, agriculture, and other specialized areas (Dutkiewicz 2002). Different types of chitosan graft copolymers have been prepared for use as flocculants, paper-binder strengtheners, and slow-release drug carrier. Polyethylene glycol (PEG) has been grafted onto chitosan to prepare water-soluble chitosan derivatives that have been used as carrier of anticancer drugs. Phosphorylated chitosan synthesized by grafting mono(2-methacryloyl oxyethyl) acid phosphate onto chitosan improved antimicrobial activities (Jung et al. 1999).

8.3 Carboxymethyl Chitosans

It is an amphoteric polymer, is a derivative of chitosan, and is prepared under controlled reaction conditions. It can be synthesized by reductive alkylation wherein the amino group of chitosan is reacted with the carbonyl group of aldehyde glyoxylic acid and then hydrogenated by reaction with $NaBH_4$ or $NaCNBH_3$ to give carboxymethyl chitosans. It can also be prepared by direct alkylation using monohalocarboxylic acids such as monochloroacetic acid in alkaline medium. Carboxymethyl chitosans have enhanced biological and physicochemical properties compared to chitosan and hence have promising biomedical applications (Mohan et al. 2012).

8.4 *N*-methylene Phosphonic Chitosans

These are anionic derivatives with amphoteric character and are synthesized under various conditions and proved to have good complexing efficiency for cations such as Ca^{2+} and those of transition metals (Cu (II), Cd (II), Zn (II), etc.) (Heras et al. 2001). The complexation provides corrosion protection for metal surfaces. These derivatives are also modified and grafted with alkyl chains to obtain amphiphilic properties that have potential applications in cosmetics.

8.5 Carbohydrate-Branched Chitosan

Carbohydrates can be grafted on the chitosan backbone at the C2 position by reductive alkylation: disaccharides such as cellobiose and lactose (having a reducing end group) are introduced, in the presence of a reductant, on chitosan in the open chain form. These derivatives are water soluble. Carbohydrates can also be

introduced without ring opening on the C6 position. These derivatives are important as they are recognized by the corresponding specific lectins and thus could be used for drug targeting (Morimoto et al. 2001).

8.6 Alkylated Chitosans

Alkylated chitosans are very important as amphiphilic polymers based on polysaccharides. They exhibit surface activity and increase considerably the viscosity of aqueous solution due to hydrophobic interchain interactions. Alkyl chitosans are compatible with neutral and cationic surfactants (Yang et al. 2002).

9 Chitosan Depolymerization

The main limitations in the use of chitosan in several applications are its high viscosity and low solubility at neutral pH. Low molecular weight chitosans and oligomers can be prepared by hydrolysis of the polymer chains. For some specific applications, these smaller molecules have been found to be much more useful (Rege and Block 1999). Chitosan depolymerization can be carried out chemically, enzymatically, or physically.

9.1 Chemical Depolymerization

It is mainly carried out by acid hydrolysis using HCl or by oxidative reaction using HNO_2 and H_2O_2 (Prashanth and Tharanathan 2007). It has been found to be specific in the sense that HNO_2 attacks the amino group of D-units, with subsequent cleavage of the adjacent glycosidic linkage.

9.2 Enzymatic Depolymerization

In the case of enzymatic depolymerization, low molecular weight chitosan with high water solubility is produced by several enzymes such as chitinase, chitosanase, gluconase, and some proteases (Cabrera and Cutsem 2005). Nonspecific enzymes including lysozyme, cellulase, lipase, amylase, and pectinase that are capable of depolymerizing chitosan are also used. Enzymatic methods for the hydrolysis of chitosan are performed in gentle conditions, and the molecular weight distribution of the product can be controlled (Jeon et al. 2001).

9.3 Physical Depolymerization

Physical depolymerization yielding dimers, trimers, and tetramers has been carried out by radiation (Co-60 gamma rays) but low yields have been achieved. High-pressure homogenization is a novel method employed for the depolymerization of

chitosan (Mistry et al. 2012). Chitosan has been physically modified in a variety of ways, resulting in conditioned forms such as powders, nanoparticles, gel beads, gels, fibers, and sponge (Denkbas 2006).

10 Applications of Chitosan

A lot of research is being carried out by both academic and industrial scientists on applications of chitosan. This can be seen by a number of relevant research papers and patents on the subject. Chitosan and its derivatives have varied applications in agriculture, food processing, biotechnology, chemistry, cosmetics, dentistry, medicine, textiles, veterinary medicine, and environmental sciences. The polyelectrolyte nature and the presence of reactive functional groups are responsible for the gel-forming ability, high adsorption capacity, biodegradability, and antimicrobial properties of chitosan which in turn are essential for its commercial applications.

11 Antimicrobial Activity

Chitosan displays a broad-spectrum antimicrobial activity against bacteria, molds, and yeasts. It is effective against both Gram-positive and Gram-negative foodborne microorganisms, including *Aeromonas hydrophila*, *Bacillus cereus*, *B. licheniformis*, *B. subtilis*, *Clostridium perfringens*, *Brochothrix* spp., *Enterobacter sakazakii*, *Lactobacillus* spp., *Listeria monocytogenes*, *Pseudomonas* spp., *Salmonella typhimurium*, *S. enteritidis*, *Serratia liquefaciens*, *Staphylococcus aureus*, and *Escherichia coli* O157H7; the yeasts *Candida*, *Saccharomyces*, and *Rhodotorula*; and the molds *Aspergillus*, *Penicillium*, and *Rhizopus*. The chitosan and its derivatives are effective against plant pathogenic bacteria such as *A. tumefaciens, C. fascians, E. amylovora, E. carotovora, P. solanacearum*, and *S. lutea* and fungi *A. alternata*, *B. fabae*, *F. oxysporum*, *P. digitatum*, *P. debaryanum*, and *R. solani* (Vishnukumar et al. 2005; Venugopal 2011).

The exact mechanism of antibacterial activity of chitosan is not fully understood and several factors contribute toward this. Three models have been proposed, to explain the antimicrobial action of chitosan. The most satisfactory model suggests that the antimicrobial effect of chitosan is due to its polycationic nature. In an acid environment, the NH_2 groups in the C2 position of chitosan protonates to yield NH_{3+}, which binds to negatively charged carboxylate (–COO–) groups located on the surface of the bacterial and fungal cell surfaces, causing disruption of the barrier properties of the outer membranes of the microorganisms followed by leakage of cell components (Tsai and Su 1999). This hypothesis is supported by electron microscopy studies that show binding of chitosan to outer membrane of bacteria (Raafat et al. 2008). The pH of the microenvironment in which chitosan functions determines the relative concentrations (ratios) of unprotonated and protonated amino groups. At a pH ~ pKa, 50 % of amino group are protonated. At pH 5.5, the positively charged amino group contributes 90 %, and at pH 4.5, 99 %.

The antimicrobial effectiveness of chitosan appears to be highest below pH 6.0, where the protonated form predominates and where chitosan is most soluble.

Second proposed mechanism is based on ability of chitosan to bind with microbial DNA, leading to inhibition of the mRNA and protein synthesis (Sebti et al. 2005). In this hypothesis, chitosan molecules are assumed to be able to pass through the bacterial cell wall, composed of multilayers of cross-linked murein, and reach the plasma membrane. This theory is supported by confocal laser scanning microscopy where the presence of chitosan oligomers (a chain with few number of monomer units) inside *E. coli* exposed to chitosan under different conditions has been demonstrated (Lui et al. 2001).

The third mechanism is based on ability of chitosan to chelate metals. It is well known that chitosan has excellent metal-binding capacities where the amine groups in the chitosan molecules are responsible for the uptake of metal cations by chelation; this results in reduced microbial growth and toxin synthesis (Goy et al. 2009). This mechanism is likely to be more efficient at high pH values where positive ions are bounded to chitosan, since the amine groups are unprotonated and the electron pair on the amine nitrogen is available for donation to metal ions.

The ability of chitosan to form gas-impermeable coating interferes with fungal growth. It inhibits different developmental stages such as mycelial growth, sporulation, spore viability and germination, and the production of fungal virulence factors (El- Ghaouth et al. 1992).

The derivatives of chitosan, such as *N*-trimethyl, sulfonated chitosan, and chitose oligomers, have been reported to demonstrate antibacterial activities against *Bacillus subtilis*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *S. epidermidis*, *Klebsiella pneumoniae*, and *Proteus vulgaris* to different extents (Venugopal 2011).

11.1 Factors Affecting Antimicrobial Activity

The antimicrobial activity of chitosan depends on its molecular weight, degree of deacylation, pH of solution, and, of course, the target organism.

Molecular weight: The antimicrobial activity of chitosan increases as the molecular weight increases. However, it is difficult to find a clear correlation between molecular weight and antimicrobial activity of chitosan when comparisons are between different studies. This is mainly attributed to the fact that many investigators have used an uncertain term for low MW (LMW) and high MW (HMW) chitosan without indicating exactly its MW. There are reports that conclude positive, negative, and neutral effects of MW on antimicrobial activity of chitosan (Badawy and Rabea 2011).

Degree of deacetylation: The antimicrobial activity of chitosan is directly proportional to the degree of deacetylation of chitosan. The increase in degree of deacetylation means the increased number of amino groups on chitosan. As a result, chitosan has an increased number of protonated amino groups in an acidic condition

and dissolves in water completely, which leads to an increased chance of interaction between chitosan and negatively charged cell walls of microorganisms (Sekiguchi et al. 1994).

The pH: The antimicrobial activity of chitosan is strongly affected by the pH. At lower pH, there is an increase in the number of protonated amino groups on chitosan in addition to the "hurdle effect" of inflicting acid stress on the target organisms (Badawy and Rabea 2011).

Temperature: The incubation temperature also has an effect on the antimicrobial activity of chitosan. Higher temperature (37 °C) has been shown to enhance its antimicrobial activity compared to refrigeration temperatures (Kong et al. 2010).

Cations: Antimicrobial action of chitosan is inhibited by divalent cations in the order of $Ba^{+2} > Ca^{+2} > Mg^{+2.}$ It is proposed that the cations form complexes with chitosan and consequently the reduced available amino groups of chitosan lead to the reduced bactericidal effect (Badawy and Rabea 2011).

Chitosan posses a number of characteristics that make it a suitable antimicrobial polymer for various industrial applications. These include the following: (1) easy and abundant availability, (2) long-term storage stability at the temperature of its intended application, (3) it does not decompose to and/or emit toxic products, (4) it is not toxic or irritating to handlers, and (5) it is biocidal to a broad-spectrum of pathogenic microorganisms.

12 Antioxidant Activity

Chitosan and its derivatives have been reported to have strong antioxidant activity. They control lipid oxidation by scavenging free radicals, which can be attributed to their ability to chelate metals. The antioxidant effects of chitin and chitosan are dependent on their molecular weight, viscosity, and degree of deacetylation (Venugopal 2011).

13 Chitosan as Edible Coating for Fruits and Vegetables

The edible films and coatings are used to extend shelf life and improve quality of food products. At present, edible films based on cellulose and proteins are being used for the purpose. They provide good reduction of O_2 and CO_2 partial pressure but are not so good for moisture transfer between food and the surrounding environment. Chitosan forms tough, long-lasting, flexible, semipermeable films that can be used as food wraps for extending their shelf life.

Fruits and vegetables undergo a number of physiological changes during postharvest storage. These include tissue softening, increase in sugar levels, degradation of chlorophyll, and synthesis and degradation of volatile flavor compounds. Controlling respiration rate significantly improves the storability and shelf life of fresh produce, as a certain level of respiration activity is required to prevent plant tissues from senescing and dying. In minimally processed agricultural

products, the most important quality attributes contributing to marketability are appearance, color, texture, flavor, nutritional content, and microbial quality. The marketability of these products, therefore, demands efficient control of these quality changes. Due to its barrier properties, chitosan film can prevent moisture loss and drip formation, retain color and flavor attributes, and improve microbial quality, thereby extending the shelf life of a variety of fruits and vegetables. Rather than packaging produce within a chitosan film, dipping the produce in a dilute solution of chitosan and dilute acetic acid can be performed. The technique also allows the incorporation of additives such as vitamin E, rosemary, oleoresin, calcium, and potassium to enhance the efficiency of treatment (Aider 2010). The efficacy of treatment is demonstrated in strawberries, bell peppers, cucumbers, peaches, pears, and kiwifruit (Bautista-Banosa et al. 2006).

14 Chitosan as Functional Additive in Muscle Foods

Chitosan is used as an additive in flesh foods to control flavor loss, microbial growth, and oxidation resulting in extended shelf life. When cooked flesh foods are stored, a "warmed-over" flavor develops which is perceived as loss of freshness. Chitosan is capable of preventing this flavor deterioration due to its antioxidant activity (No et al. 2007; Venugopal 2011). *N*-carboxymethyl chitosan (NCMC) and its lactate and acetate derivatives are effective in controlling the oxidation and off-flavor development in cooked meat at refrigerated temperatures. Research by the US Department of Agriculture has revealed that NCMC is useful as preservative in flesh foods. It can be sprinkled on gravies or meat products. NCMC is very useful in preserving microwavable or quickly prepared foods as well as in preventing development of the "warmed-over" flavor of institutional foods. It is advantageous to use as it is itself tasteless, blends well with foods as a colorless ingredient, and is nontoxic and nonallergenic. It is used as a glazing compound prior to flash-freezing of many flesh foods to inhibit surface oxidation and enhance shelf life. Meat and poultry processors use NCMC as a post-slaughter perfusion and as a long-term flavor and storage preservative (Flick and Martin 2000). Textural properties of surimi products can also be improved by addition of chitosan in combination with other additives (Benjakul et al. 2001; Gomez-Guillien et al. 2005).

Chitosan as coating for eggs: Chitosan coating of eggs can provide a protective barrier against moisture and CO_2 transfer from the albumen through the egg shell, thus extending the shelf life of eggs. It prevents weight loss and enhances Haugh unit and yolk index values, indicating improved albumen and yolk quality of eggs, respectively. The coated eggs can be preserved for up to 5 weeks at 25 °C, which is at least 3 weeks longer than that observed for control, uncoated eggs. Overall consumer acceptability of coated eggs did not differ from that for control and commercial eggs (Bhale et al. 2003).

Chitosan as additive in bakery and dairy products: Chitosan and chitin can be used as food additives in cookies, noodles, and bread to improve their texture. These effects are due to the ability of chitosan to control starch retrogradation.

Microcrystalline chitin has a positive effect on emulsion stability, in addition to increasing the specific loaf volume of white bread and protein-fortified breads (No et al. 2007). Maillard reaction products (MRPs) prepared from chitosan and xylose extend the shelf life of fresh noodles (Huang et al. 2007). Chitosan–lysozyme (CL) film is reported to prevent growth of *Listeria monocytogenes*, *Escherichia coli*, or *Pseudomonas fluorescens* in pre-inoculated mozzarella cheese (Duan et al. 2007).

15 Chitosan as Clearing Agent in Wines and Vinegars

Browning due to oxidation is one of the most common defects affecting white wines. It can be minimized by using adsorbents to reduce phenolic compounds. Chitosan is useful for the clarification of wine and vinegars. It exhibits high affinity to a number of phenolic compounds, particularly cinnamic acid, and prevents browning in a variety of white wines (Spagna et al. 1996).

16 Chitin as Feed Additive

Chitin has a growth-promoting effect on broiler chickens. It increases average live weight and dressed weight and decreases wastage during dressing in broiler chickens. The use of chitin as a source of dietary fiber in chicken feed promotes the growth of bifidobacteria in the guts (Hirano et al. 1990). Similarly, feeds containing chitin and glucosamine could also be used in aquaculture for improved growth of cultured fish (Kono et al. 1987). Chitin hydrolysates produced through the digestion of crustacean waste by chitinases are used as a carbon source for the cultivation of yeast that can convert chitin oligosaccharides into single-cell proteins (Carroad and Tom 1978). The yeast could be utilized as feed component.

17 Chitosan as Lipid-Lowering Agent

Chitosan is used as a dietary ingredient due to its ability to reduce serum cholesterol. It reduces lipid absorption by binding neutral lipids, such as cholesterol and other sterols, by means of hydrophobic interactions. Because of this inhibitory activity on fat absorption, chitosan acts as fat scavenger in the digestive tract and eliminates fat and cholesterol via excretion (Luo and Wang 2013). Chitosan satisfies the requirements of dietary fiber, including non-digestibility in the upper GI tract, high viscosity, and high water-binding ability in the lower GI tract. From a physiological standpoint, the prime function of a dietary fiber is to lower cholesterol levels and to promote the loss of body weight through a reduction of intestinal lipid absorption. It differs from other dietary fibers in that it possesses a positive ionic charge, which has the ability to bond chemically with the negatively charged lipids, fats, and bile acids. It is desirable that its prolonged use as fiber in diets should be

monitored to ensure that it does not disturb the intestinal flora or interfere in the absorption of micronutrients, particularly lipid-soluble vitamins and minerals, and that it does not have any other negative effects. Chitosan shows an LD_{50} (median lethal dose) of around 16 g/kg, comparable to the salt and glucose values ensuring safety for long-term use (Singla and Chawla 2001).

18 Biomedical Applications

Chitosan due its polyelectrolyte nature, gel-forming capability, biodegradability, biocompatibility, nontoxicity to living tissues, and antimicrobial and antitumor properties has extensive applications in medicine. It is used in hemodialysis membranes, artificial skin, hemostatic agents, and drug delivery systems. The property of chitosan to form gels at a slightly acid pH gives chitosan its antacid and antiulcer activities. Chitin and chitosan oligosaccharides, when intravenously injected, enhance antitumor activity by activating macrophages.

Chitosan as control release system: Chitosan has an advantage of forming covalent or ionic bonds with the cross-linking agents, building a sort of network, where the active substance is retained. Consequently, these bonds carry advantages in terms of controlled release (Estevinho et al. 2013). Depending on the cross-linker, the major interactions involved in the formation of the network are covalent or ionic bonds. Covalent cross-linking leads to the formation of hydrogels or microparticles with a permanent network structure, because irreversible chemical bonds are formed. This type of linkage allows absorption of water and/or bioactive compounds without dissolution and allows its release by diffusion. The addition of a second polymer as encapsulating agent makes possible the pH-controlled delivery (Berger et al. 2004). Cross-linking compounds used to create covalent bonds are molecules that have at least two reactive functional groups that allow the formation of linkage between polymeric chains. The most common cross-linkers used with chitosan are dialdehydes, such as glyoxal and in particular glutaraldehyde. But they are known to be toxic. For example, glutaraldehyde is known to be neurotoxic and glyoxal is known to be mutagenic. Hence, even if microparticles are purified before usage, the presence of free unreacted dialdehydes cannot be completely excluded and will induce toxic effects (Estevinho et al. 2013). Other covalent cross-linkers for chitosan such as diethyl squarate, oxalic acid, or genipin have been investigated to overcome this problem. Ionically cross-linked microparticles or hydrogels are more biocompatible and well tolerated. Ionically cross-linked chitosan hydrogels or microparticles exhibit a greater swelling sensitivity to pH changes compared to covalently cross-linked ones. This fact broadens their potential application, since dissolution can be regulated by pH conditions (Berger et al. 2004).

Chitosan with its positive charges reacts with polyanionic compounds forming polyelectrolytic complexes that can easily incorporate active substances. Tripolyphosphate, citrate, sulfate, and phosphate are used to prepare this kind of complexes. They are normally well tolerated and biocompatible with the human

organism, showing advantages in terms of applications for food and pharmaceutical industry (Berger et al. 2004; Gupta and Jabrail 2006).

Biotechnological application of chitosan: Chitin and chitosan have been found to be useful as a matrix for immobilization of various enzymes for the processing of such products as wine and sugar, the synthesis of organic compounds (Ravikumar 2000), and the construction of sophisticated biosensors for in situ measurements of environmental pollutants and metabolite control in artificial organs (Krajewska 2004).

Chitosan as drug delivery matrix: Chitosan is considered to be the drug carrier for the twenty-first century. For effective drug delivery, it is being used in the form of microspheres, microparticles, nanoparticles, granules, gels, or films. Chitosan microspheres are useful for the controlled release of antibodies, antihypertensive agents, anticancer agents, protein and peptide drugs, vaccines, and nutraceutical compounds (Dash et al. 2011).

Chitosan as wound healing agent: Due to bacteriostatic and fungistatic properties of chitosan, it is used as a wound healing agent in skin ointments. Chitosan implanted in animal tissues encourages wound healing and hemostatic activities. Biocompatible wound dressings derived from chitin are available in the form of hydrogels, xerogels, powders, composites, and films (Gavhane et al. 2013).

19 Chitosan in Water Treatment

Water gets polluted due to metal ions, inorganic anions, phenolic compounds, dyes, and radioactive isotopes. Many of these water pollutants are toxic and can enter the human food chain. The toxic heavy metal ions are discharged into the environment through different industrial activities. The high adsorption potential of chitosan is attributed to (1) high hydrophilicity due to a large number of hydroxyl groups of glucose units, (2) the presence of a large number of functional groups, (3) the high chemical reactivity of these groups, and (4) flexible structure of the polymer chain.

Chitosan and its derivatives are being successfully used in water treatment to remove lead, copper, and cadmium from drinking water, due to complex formation between the amino group and heavy metal ions (Bhatnagar and Sillanpää 2009).

Radionuclides are an important category of metals in terms of environmental impact and interest from nuclear industry. Chitosan is an excellent biosorbent to adsorb radionuclide from aqueous solution in an acid environment (Wang and Chen 2014).

Dyes are usually present in the effluents of textile, leather, paper, and dye manufacturing industries. These effluents are not only toxic to the aquatic biota but also disturb the natural equilibrium by reducing photosynthetic activity of water in streams. Some dyes are reported to cause allergy, dermatitis, skin irritation, and cancer in humans. The removal of dyes from effluents before they are released into natural water bodies is important. Chitosan-based biosorbents have an extremely high affinity for many classes of dyes (Crini and Badot 2008).

Phenol and substituted phenols cause unpleasant taste and odor in drinking water and can exert negative effects on different biological processes. The ubiquitous nature of phenols, their toxicity even in trace amounts, and the stricter environmental regulations make it necessary to develop processes for the removal of phenols from wastewaters. Chitin and chitosan derivatives can remove phenol and substituted phenols from water (Bhatnagar and Sillanpää 2009). The pH primarily affected the degree of ionization of phenol and the surface properties of chitin. The functional groups of chitosan are protonated at low pH values and resulted in a stronger attraction for negatively charged ions in the adsorption medium. Phenol being weakly acidic is partially ionized in solution. These ions are negatively charged and are attracted due to electrostatic forces by the protonated amino groups of chitosan. As the pH increases, the overall surface charge of chitosan becomes negative and adsorption decreases. The equilibrium uptake of phenol is also affected by temperature due to the enlargement of pore size or creation of some new active sites on the adsorbent surface due to bond rupture. In comparison with activated charcoal, chitosan is more efficient in the removal of polychlorinated biphenyls from contaminated water (Venugopal 2011).

Inorganic anions are also an important class of aquatic pollutants, and various inorganic anions are found in potentially harmful concentrations in drinking water sources. The removal of these pollutants from drinking water supplies is an emerging issue. In recent years, chitin and chitosan derivatives have been successfully utilized for some anion removal from water (Bhatnagar and Sillanpää 2009).

Chitosan is currently employed in domestic sewage treatment systems in conjunction with other settling aids such as alum or bentonite clay to promote coagulation and settling of colloidal and other suspended solids. The polyelectrolyte is added at the rate of 1–2 ppm but can also be employed alone without alum when the concentration is raised to around 10 ppm. Being positively charged, it is very effective at agglomerating the negatively charged sludge particles (Venugopal 2011). Chitosan is also employed as a coagulant in the treatment of wastewater from food industries. The production of surimi generates a large amount of wash water that contains sizeable amounts of proteins, showing high turbidity. Chitosan treatment of surimi wash water results in the recovery of soluble proteins. The protein recovery is further increased by adding a complex of chitosan and alginate. It is also used as coagulant to treat wastewater from milk processing plants. Recovered proteins have application in food and feed industry (Wibowo et al. 2005).

20 Chitosan Application in Agriculture

Chitin and chitosan also have potential in agriculture with regard to controlling plant diseases. They are active against soil fungi, viruses, bacteria, and other pests. Addition of chitin and chitosan alters the environmental conditions in the rhizosphere and phyllosphere to shift the microbial balance in favor of beneficial

organisms and to the detriment of plant pathogens. Fragments from chitin and chitosan are known to have eliciting activities for a variety of defense responses in host plants, including the accumulation of phytoalexins, pathogen-related (PR) proteins, proteinase inhibitors, lignin synthesis, and callose formation (El Hadrami 2010).

21 Regulations and Commercial Applications

Chitosan is used as a food quality enhancer in a number of countries. Chitosan preparations in tablet, capsule, and powder form are being used in healthcare industry. In the European market, chitosan is sold in the form of dietary capsules to assist weight loss, and in some countries, such as Japan, it is added to various foods (e.g., noodles, potato crisps, biscuits). Chitosan-fortified fruit juices and chocolates are marketed in the USA. The role of chitosan as fiber is challenged by popular fiber products such as oats, soy, and bran. In spite of some limitations, chitosan promises to offer innovative applications in diverse areas of food processing and other fields (Venugopal 2011).

In the USA, the 1994 Dietary Supplement Health and Education Act permits use of chitosan as a food supplement without premarket approval as long as no health claims are made. The use of chitin and chitosan as ingredients in foods or pharmaceutical products, however, requires standardization of identity, purity, and stability. Manufacturers should consider filing petitions with agencies such as Food Chemical Codex, US Pharmacopoeia, European Pharmacopoeia, and Japan Pharmacopoeia. These organizations establish methods to identify specific products and standards of purity for pharmaceutical and drug use. Such standards will be necessary for future expansion of the use of chitin and chitosan (Heinze et al. 2005). Chitin and chitosan have been approved for pesticide and seed treatments, as fertilizer, and as animal feed additives. The US Environmental Protection Agency has approved the use of commercially available chitosan for wastewater treatment up to a maximum level of 10 mg/L.

Chitin and chitosan products fall within the lowest level of concern for toxicological testing. Being naturally present in living organisms, chitin and its deacetylated derivative chitosan are considered safe. The available literature on chitin and chitosan suggests a low order of toxicity, based on chemical structure and animal studies. Like several high-molecular-weight food polymers of natural origin such as cellulose and carrageenan, chitin and chitosan are not expected to be digested or absorbed from the human gastrointestinal tract. To date, chitosan appears to be clinically well tolerated. The safety of chitooligomers prepared by the enzymatic depolymerization of chitosan has been reported in a short-term mice feeding study. No mutagenicity has been reported, as judged by the Ames test, mouse bone marrow cell micronucleus test, and mouse sperm abnormality test. A 30-day feeding studies did not show any abnormal symptoms and clinical signs or deaths in rats. No significant differences are reported in body weight, food

consumption, food availability, hematology values, clinical chemistry values, or organ/body weight ratios. No abnormality of any organ was found during histopathological examination (Qin et al. 2006).

22 Conclusion and Future Research Needs

Chitosan is a versatile biopolymer that has a variety of commercial applications. However, individual research reports have used chitosans from various sources with varying physicochemical properties. Hence, the question arises as to how to globally produce chitosans with consistent properties. Each batch of chitosan produced from the same manufacturer may differ in its quality. For proper quality control in the chitosan production, there is a critical need to establish less expensive and reliable analytical methods, especially for the evaluation of molecular weight and degree of deacetylation. Functional properties of chitosan vary with molecular weight and degree of deacetylation. With proper modification of chitosan, its functional properties and biological activities can be further enhanced, and more applications are being developed.

Chitosan with different structures shows different biological activities and not all the biological activities are found in one kind of chitosan. Each special type of bioactive chitosan should be developed for its potential application. Moreover, many studies carried out on chitosan and chitooligosaccharide bioactivity have not provided detailed molecular mechanisms. Hence, it is difficult to explain exactly how these molecules exert their activities. Therefore, future research should be directed toward understanding their molecular-level details, which may provide insights into the unknown biochemical functions of chitosan and chitooligosaccharide as well as help accelerate their future applications. The traditional chitosan production process is costly, thus limiting wider applications of chitosan. Simplification of chitosan production, for example, by elimination of deproteinization and/or demineralization or by reduction of reaction time required for deproteinization and demineralization, would considerably reduce production cost due to reduction in chemical usage, process time, and voluminous wastewater discharge. The typical astringent/bitter taste of chitosan limits its use as a food additive or preservative. Incorporation of L-arginine and adenosine monophosphate, both considered as GRAS, can be used to mask or minimize this effect and should be further investigated. Inherent antibacterial/antifungal properties and film forming ability of chitosan make it ideal for use as biodegradable antimicrobial packaging material. One major drawback of chitosan film is its high sensitivity to humidity, and thus, it may not be appropriate for use when it is in direct contact with moist foods. More research is needed to develop antimicrobial chitosan films that are less sensitive to humidity. Numerous researches conducted on food applications of chitosans have been done at a small or laboratory scale. Further research on quality and shelf life of foods, containing or coated with chitosan, should be conducted on scale-up with large volumes typical of commercial conditions.

This would provide a more realistic and practical information required for actual commercialization of food products containing or coated with chitosans.

Contents

Abstract

Cyclodextrins (CDs) were first isolated in 1891 as degradation products of starch from a medium of *Bacillus amylobacter*. They are cyclic water-soluble, nonreducing, macrocycle carbohydrate polymers constructed from α-(1-4)-linked D-glucopyranose units (naturally occurring α, β, and γ formed by 6, 7, and 8 glucose units), in a ring formation and present a toroidal, hollow, truncated cone shape. Their most important property is the ability to establish specific interactions – molecular encapsulation – with various types of molecules through the formation of non-covalently bonded entities, either in the solid phase or in aqueous solution, taking up a whole molecule, or some part of it, into their cavities. This process in part mimics the "lock and key" mechanism of enzyme catalysis. Complexation may cause changes in physicochemical properties of the guest molecule (e.g., solubility, stability, kinetics and bioavailability, toxicity). Their negligible cytotoxic effects promoted them to the GRAS list and led them to be widely used in many industrial products and technologies.

1 Introduction

1.1 Historical Background

Since the beginning of times, the most important discoveries happen as casual observation due to researchers' curiosity (Table 1). Cyclodextrin (CD) discovery also followed this pattern as they were first isolated in 1891 by Villiers when, in addition to reducing dextrins, beautiful crystals were observed in alcohol waste as degradation products of starch from a medium of *Bacillus amylobacter*. These substances were called "cellulosine" due to its similarity to cellulose (Villiers 1891). In the following years (early twentieth century), another prominent scientist, Schardinger, made important discoveries for CDs' science. In 1903, this author was responsible for the isolation of two crystalline products showing lack of reducing properties: dextrins A and B. In 1904, Schardinger isolated a new organism capable of producing acetone and ethyl alcohol from sugar- and starch-containing plant material (Eastburn and Tao 1994). In 1911, he described that the strain *Bacillus macerans* produces large amounts of crystalline dextrins (25–30 %) from starch. Thus, Schardinger is considered the founder of CD chemistry due to his work to characterize Villiers' "cellulosines" from 1903 to 1911, determining that they were cyclic oligosaccharides (Schardinger 1903a, b, 1904, 1911; Szejtli 1998). It is for this reason that CDs are also termed Schardinger dextrins, especially in the older literature. Since then several fractionation schemes for the production of CDs were also developed (Stella and Rajewski 1997; Matsuda and Arima 1999; Mabuchi and Ngoa 2001). The γ-dextrin was only isolated in 1935.

Pure CDs (i.e., cyclic water-soluble, nonreducing, macrocycle polymers) were prepared in the early part of the last century by Freudenberg and co-workers (Freudenberg and Meyer-Delius 1938; Freudenberg et al. 1947), who reported that CDs are constructed from α-(1-4)-linked D-glucopyranose units, in a ring formation (Saenger 1980; Uekama 1981; Szejtli 1982). In 1948, using X-ray crystallography the γ-CD structure was clarified. Immediately after, the most important property of CDs was recognized: their ability to form inclusion complexes. The general title for this class of complexes, "inclusion compounds" ("einschlussverbindung"), was first used by Schlenk in 1949. Besides the general terms ("occlusion" and "adducts"), other terms that have been used to describe these complexes are "molecular compounds," "cryptates" (Frank 1975; Szejtli 1982), and "clathrates" (Powell 1948). The term "clathrate," derived from the Latin "clathratus," meaning "enclosed or protected by cross bars of a grating," has been used to describe the cage-like structure of the hydroquinone inclusion compounds.

Table 1 Chronological order of cyclodextrin research (Cramer 1954; Bender and Komiyama 1978; Cramer 1987; Frömming and Szejtli 1994; Robyt 1998; Szejtli 1998, 2004; Loftsson and Duchêne 2007; Kurkov and Loftsson 2012)

Although Chemical Abstracts and several other reference sources use the term "clathrates" as a general descriptor for inclusion compounds, this term more appropriately describes only cage-like polymolecular inclusion compounds (Cabral-Marques 1994a). In 1961 the existence of larger natural CDs, namely, δ- (delta), ε- (epsilon), ζ- (zeta), and η- (nu) CD, was proved (9–12 glucose residues) (Hirose and Yamamoto 2001). CD chemistry was discussed in detail by Bender and Komiyama (Bender and Komiyama 1978).

1.2 Occurrence/Sources

Although discovered more than 100 years ago as previously referred, the cyclic glucooligosaccharides termed CDs (based on dextrose, which is an old name for glucose) remained laboratory curiosities until the 1970s when they began to be used commercially (Szejtli 1998). Its production results from degrading the starch by the enzyme cyclodextrin glucanotransferase (CGTases), involving excision and reconnection of single turns from the helical α-(1→4)-glucan (amylose) chain (Fig. 1) to provide cyclic α-(1→4)-linked glucooligosaccharides with six (α-CD), seven (β-CD), and eight glucose units (γ-CD) (Rendleman 1999; Lichtenthaler 2010). This intramolecular transglycosylation is called cyclization reaction (Szejtli 1998; Cheirsilp et al. 2010).

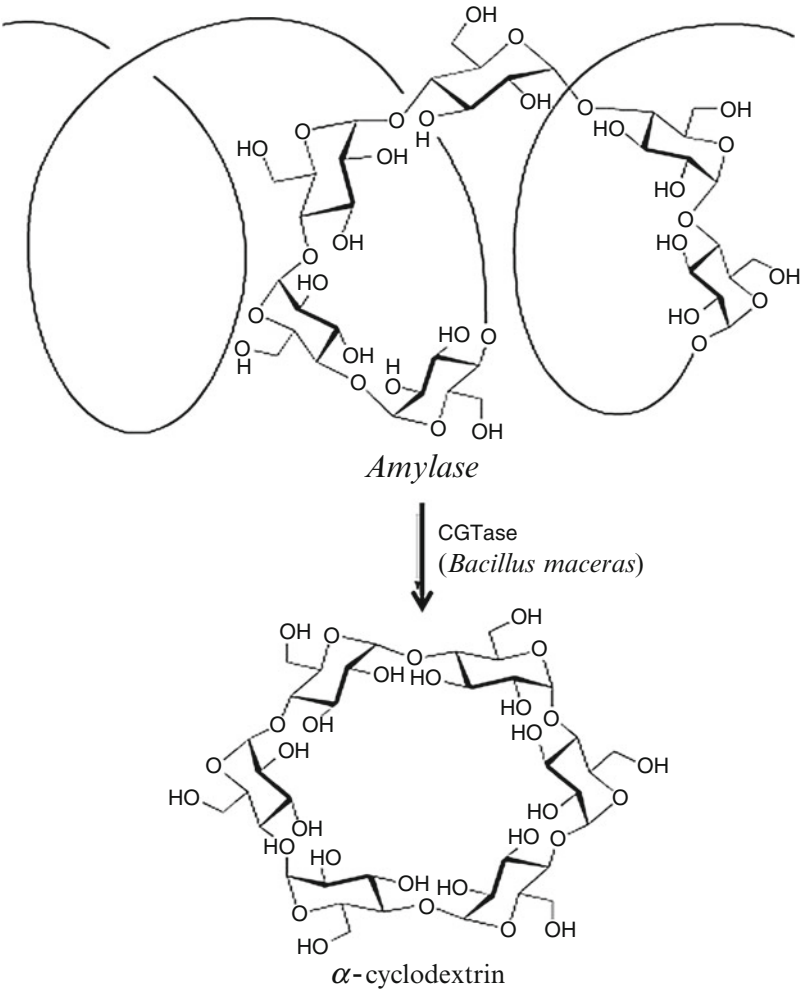

Fig. 1 Representation of a left-handed, single-stranded helix of VH-amylose (*top*) and of α-cyclodextrin (*bottom*), which de facto represents a single turn of the amylose helix excised and reconnected by *Bacillus macerans*-derived enzymes (CGTases). The close analogy allows VH-amylose to be considered as a tubular analogue of *α*-cyclodextrin (Lichtenthaler 2010)

The starch sources used to produce CDs are varied and include according to different authors the following substrates:

- Liquefied starch, maltodextrin, or long-chain maltooligosaccharides (Rendleman 1999)
- Maltodextrin and commercial soluble starch, corn, cassava, sweet potato, and waxy corn starches (Alves-Prado et al. 2008)
- Amaranth starch (Urban et al. 2012)

- Soluble and cocoyam starch (Mora et al. 2012)
- Starch such as potato, tapioca, and corn (Shahrazi et al. 2013)

CGTase is specifically active on both structures of amylose and amylopectin (Shahrazi et al. 2013). Several microorganisms and methods have been used to produce or use CGTase as described in the following:

- *Bacillus amylobacte*r in 1881 (Szejtli 1998).
- *Bacillus macerans* (Rendleman 1999).
- *Bacillus circulans* DF 9R (Rosso et al. 2002).
- *Bacillus clausii* strain E16 (Alves-Prado et al. 2008).
- *Bacillus megaterium* (Zhekova and Stanchev 2011; Sivakumar and Shakilabanu 2013).
- Alkaliphilic *Bacillus licheniformis* (Thombre and Kanekar 2013).
- CGTase was anchored on the surface of *Saccharomyces cerevisiae* and was used as an immobilized enzyme (Wang et al. 2006).
- *Escherichia coli* pAD26 cells immobilized on cotton (Kriaa et al. 2012).
- *Amphibacillus* sp. NPST-10 (Ibrahim et al. 2012).
- *Paenibacillus macerans* CCM 2012 (Urban et al. 2012).
- *Amphibacillus* sp. NRC-WN (Al-Sharawi et al. 2013).

2 Structure and Properties

2.1 Parent Cyclodextrins

The most common of these naturally occurring, ring-shaped molecules are the α- (alpha), β- (beta), and γ- (gamma) CDs formed by six, seven, and eight glucose units (Fig. 2) and cavities' diameters smaller than 0.6, 0.8, and 1.0 nm, respectively (Frank 1975; Szejtli 1982). Because of their sugar backbone, these CDs are also known as cycloamyloses: hexa- (C6A), hepta- (C7A), and octa-amylose (C8A) (Szejtli 1982) or cyclohexa-, cycloheptа-, and cyclooctaglucan and α-, β-, and γ-amylosan (French 1957).

CDs have no well-defined melting point and start to decompose at temperatures above 270 °C, and at 300 °C a sharp endothermic process is detected, which indicates that the melting is accompanied by decomposition (Szejtli 1982). Generally their solubility in water is greatly increased at higher temperatures (except for the dimethyl-β-CD which decreases). The most important characteristics of the natural CDs are summarized in Table 2 (Saenger 1980; Szejtli1998; Pitha et al. 1983; Duchêne et al. 1986; Bas and Rysanek 1987; Uekama and Otagiri 1987; Duchêne and Wouessidjewe 1990a; Salústio et al. 2011).

It is noteworthy that there are differences in the reported central cavity and outer periphery diameters of the CDs. Molecule CDs present a hydrophilic exterior, which can dissolve in water, and an apolar cavity, which provides a hydrophobic matrix, described as a "micro heterogeneous environment" (Szejtli 1989).

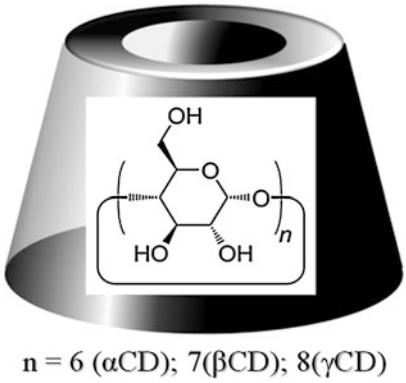

Fig. 2 Schematic cyclodextrins structure (Szejtli 1998; Salústio et al. 2011)

Table 2 Characteristics of α-, *β*-, and *γ*-CDs (Saenger 1980; Szejtli 1998; Pitha et al. 1983; Duchêne et al. 1986; Bas and Rysanek 1987; Uekama and Otagiri 1987; Duchêne and Wouessidjewe 1990; Salústio et al. 2011)

[a]Naphthalene group is too bulky for the α-CD cavity

Nuclear magnetic resonance (NMR) and X-ray diffraction indicate the C-1 chair conformation for the glucose molecule (Rao and Foster 1963). CDs are shown to have a toroidal, hollow, truncated cone structure, where the secondary OH groups on the C-2 and C-3 atoms are located on the wider side of the torus, while the primary OH groups on the C-6 are positioned on the opposite side of the torus (the narrower) and are directed "away" from the cavity except if H-bonded to include guest molecules (Saenger 1982; Szejtli 1988). The CH groups comprising H-1, H-2, and H-4 are located on the exterior of the molecule, while the polar sugar OH groups are oriented to the cone exterior, and as a consequence the external faces of CDs are hydrophilic leading to their aqueous solubility. The interior of the torus offers an environment of much lower polarity than is present in water, so it can be considered as a "hydrophobic cavity," which is lined by two rings of CH groups (H-3 and H-5), and by a ring of glucosidic oxygen-bridge atoms "ether oxygens" (O-4 and O-5) (Saenger 1982; Jones et al. 1984; Uekama and Otagiri 1987), H-6 forms the narrower rim of the truncated cone. The result of this amphipathic property is that CDs can form soluble, reversible inclusion complexes with water-insoluble compounds resulting in compound solubilization.

In all CD crystal structures, H-bonding between adjacent glucoses is found, with O-3....H-O-2 distances in the usually accepted range, 0.28–0.31 nm. H-bonding between these secondary OH groups appears to be preferred because their pKa, around 12.2 (Chin et al. 1968), is relatively low, suggesting enhanced polarization and therefore good H-bond donor and acceptor functions. This ring of H-bonds is, in general, fully established in β- and γ-CDs, but in α-CD, the curvature of the ring produces, on average, longer O-3....H-O-2′ separations, and H-bonding is weaker and can break down, as shown for the "empty" hexahydrate where four O-3....H-O-2′ hydrogen bonds are formed but two are broken. Spectroscopic data also indicate that β-CD is rigid in aqueous solution, whereas α-CD is flexible and undergoes conformational change if inclusion of a guest molecule occurs, as proposed in the "induced-fit" concept for proteins (Saenger 1982; Szejtli 1988). These interactions prevent hydration by water molecules (Szejtli 1985; Uekama and Otagiri 1987) resulting in poor aqueous solubility. In order to improve CDs' aqueous solubility, their structure has been modified via alkylation and hydroxyalkylation (Uekama and Otagiri 1987; Yoshida et al. 1988; Jicsinszky 2014).

The OH groups on C-2, C-3, and C-6 are available as points of structural modification without danger of eliminating the "central void" (MacNicol et al. 1978). The OH groups on C-6 are the most reactive, whereas the OH at C-3 are much less reactive than those at C-2.

2.2 Large Cyclodextrins

CDs with fewer than six glucopyranose residues do not exist, probably for steric reasons (Duchêne and Wouessidjewe 1990b). The existence of CDs comprising more than 8 glycosyl units was referenced in 1948 by Freudenberg and Cramer (Freudenberg and Cramer 1948). A decade later these findings were subsequently

substantiated by French and co-workers, who reported the isolation and partial characterization of large CDs with 9, 10, 11, and 12 glycosyl units in the macrocycle. However, some doubts remained concerning these CDs since they were not able to experimentally distinguish the large CDs from branched CDs (Pulley and French 1961; French et al. 1965; Szejtli 1988). During last decades, the existence of the large CDs has been fully proven. CDs containing up to 31 glycosyl units have been purified and characterized (Koizumi et al. 1999), and the existence of even larger CDs with degrees of polymerization up to several hundreds of glycosyl units has been reported (Kitamura 2000; Larsen 2002). Indeed, large CDs are not commercially exploited due to their extremely small isolation/purification yields and lack of their complexing properties (French 1957; Pulley and French 1961; French et al. 1965; Szejtli 1982).

Large CDs (Table 3) have often been designated "cycloamylose" (abbreviated CD*n*, where *n* designates the number of glucose molecules in the macrocycle) (Kitamura 2000; Larsen 2002).

2.3 Cyclodextrins Derivatives

In order to improve the physicochemical properties (i.e., better solubility, stability, and inclusion formation abilities/release behaviors of the substrate molecules) of the natural CDs, many derivatives were synthesized by various molecular manipulations (Frömming 1987; Frömming et al. 1987).

These derivatives (Table 4) usually are produced by alkylations, aminations, esterifications, or etherifications of their primary and secondary OH groups, leading also to the formation of polymeric and amphiphilic CDs (long alkyl or fluoroalkyl chains at primary and/or secondary sides of the CDs) (Bender and Komiyama 1978; Szejtli 1982; Szente et al. 1999; Sollogoub 2013). Croft and Bartsch (1983) published an interesting review of chemical methods for modifying CDs.

3 Complexation

3.1 Complexes Formation

CDs are able to form inclusion complexes with a wide variety of hydrophobic guest molecules. Thus, guest molecules can be totally or partially entrapped into CDs' cavities and in several molar ratios. The complexation process (Fig. 3) involves the insertion of the less polar part of the guest molecule into the host cavity, while the more polar and often charged group of the guest is exposed to the bulk solvent. During insertion phenomenon the water molecules are removed from the inside of CD cavity due to their thermodynamical instability. The inclusion complex formation is achieved by weak interactions such as van der Waals, hydrogen bonding, and hydrophobic effect, among others (Szejtli 1982; Cabral-Marques 1994a; Rekharsky and Inoue 1998; Sun et al. 2006). This process does not occur by means of ionic,

Table 3 Nomenclature and some properties of large cyclodextrins (Larsen 2002)

Glycosyl units	Semisystematic name	Generic name[a]	Abbreviation	Molecular weight	Aqueous[d,e] solubility (g/100 mL)	Surface[d,e] tension (mN/m^{-1})	Specific[e] rotation $[\alpha]_D^{25}$	Half-life[f] of ring opening (h)	Radius[g] of gyration (Å)

Table 4 Cyclodextrins derivatives and their release behavior (Salústio et al. 2011)

Hydrophilic derivatives		
Methylated β-cyclodextrin		
Methyl-β-cyclodextrin	Me-β-CD	
Randomly methylated-β-cyclodextrin	RM-β-CD (RAMEB)	
Dimethyl-β-cyclodextrin	DM-β-CD (DIMEB)	
Randomly dimethylated-β-cyclodextrin	RDM-β-CD	
Trimethyl-β-cyclodextrin	TM-β-CD	*Immediate release*
Acetylated dimethyl-β-cyclodextrin	DMA-β-CD	
Hydroxyalkylated β-cyclodextrin		*Enhanced dissolution and absorption of poorly water-soluble drugs*
2-Hydroxyethyl-β-cyclodextrin	2-HE-β-CD	
2-Hydroxypropyl-β-cyclodextrin	2-HP-β-CD	
3-Hydroxypropyl-β-cyclodextrin	3-HP-β-CD	
Hydroxybutenyl-β-cyclodextrin	HBen-β-CD	
2,3-Dihydroxypropyl-β-cyclodextrin	2,3-DHP-β-CD	
Branched β-cyclodextrin		
Glucosyl-β-cyclodextrin	G_1-β-CD	
Maltosyl-β-cyclodextrin	G_2-β-CD	
Glucuronylglucosyl-β-cyclodextrin	GUG-β-CD	
Hydrophobic derivatives		
Alkylated β-cyclodextrin		
2,6-di-*O*-ethyl-β-cyclodextrin	DE-β-CD	
2,3,6-tri-*O*-ethyl-β-cyclodextrin	TE-β-CD	
Acylatedβ-cyclodextrin		*Prolonged release*
2,3,6-tri-*O*-$acyl_{(C2\text{-}C18)}$-β-cyclodextrin	TA-β-CD	
2,3,6-tri-*O*-butanoyl-β-cyclodextrin	TB-β-CD	*Sustained release of water-soluble drugs*
2,3,6-tri-*O*-valeryl-β-cyclodextrin	TV-β-CD	
2,3,6-tri-*O*-octyl-β-cyclodextrin	TO-β-CD	
Ionizable derivatives		
Anionic β-cyclodextrin		
O-carboxymethyl-*O*-ethyl-β-cyclodextrin	CME-β-CD	*Delayed release* (pH-dependent release)
β-cyclodextrin sulfate	β-CD sulfate	
Sulfobutyl ether group-β-cyclodextrin (d.s.4)	SBE_4-β-CD	*Immediate release*
Sulfobutyl ether group-β-cyclodextrin (d.s.7)	SBE_7-β-CD	
Cationic β-cyclodextrin		
Trimethyl-ammonium-β-cyclodextrin	TMA-β-CD	*Prolonged release*
Drug-CD conjugate		*Delayed release* (site-specific release)

d.s. degree of substitution

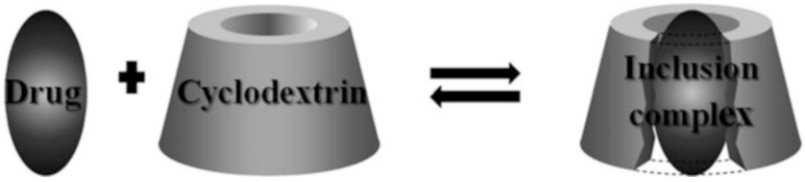

Fig. 3 Interaction of a drug molecule with a CD to form an inclusion complex (Salústio et al. 2011)

covalent, or coordinate covalent bonds (Frank 1975; Cramer 1982; Charoenchaitrakool et al. 2002). The specific association of two molecules results not by a single weak interaction but through the simultaneous cooperation of several weak interactions. Molecular mechanics calculations have also been made to investigate the solute-solvent interactions between CD and water and the molecular interactions in inclusion complexes of CDs. The essential criterion is simply that the enclosed molecule or guest must be of a suitable size and shape (i.e., the best possible filling of space) to fit into a cavity within a solid structure formed by host molecules (Powell 1948, 1954). The main binding contribution between CD and its partners is the geometrical fitting, so complexation occurs in a stereo-specific manner (Cramer 1982). The spatial requirements for the formation of a CD inclusion compound in part mimic the enzyme catalysis "lock-key" mechanism which occurs if the substrate/guest molecule is orientated properly with respect to the active centers of the host (Cramer and Hettler 1967). It is also possible to use the CD to block some reactive sites on the guest and expose others.

CD complex formation, from a pharmaceutical point of view, is equivalent to molecular encapsulation, as the drug molecules are isolated from each other and are dispersed on a molecular level in an oligosaccharide matrix, i.e., a process similar to drug encapsulation in a hydrophilic matrix (e.g., polyvinylpyrrolidine or cellulose) (Pitha et al. 1983; Szejtli 1985).

Inclusion complexes can be obtained by several techniques, such as physical mixing (Menezes et al. 2012), coprecipitation (Sapkal et al. 2007;Nieddu et al. 2014), complexation in a slurry (Fages et al. 2007; Menezes et al. 2012, 2014), complexation in paste (Gil et al. 2004; Menezes et al. 2012, 2014), extrusion (Yano and Kleinebudde 2010), dry mixing (Higashi et al. 2009), solution/suspension with solvents removal by drying methods (spray-drying, freeze-drying) (Salústio et al. 2009), sealed-heating method (Nieddu et al. 2014), and supercritical fluids (Junco et al. 2002). In order to enhance the complex efficiency of the CDs, different methods can be used such as ionization of the drug, salt formation, formation of metal complexes, addition of organic cosolvents to the aqueous complexation media, and the use of supercritical fluids, since all promote an intrinsic solubility enhancement of the drug-favoring complexation (Junco et al. 2002; Loftsson and Duchêne 2007). There are also references to the inclusion of essential oils (EO) into β-CD through a sol-gel process, which consists in the introduction of the suspension containing the EO and β-CD into a colloidal silica, under continuous stirring, at room temperature. This procedure was used to

encapsulate mint and lavender oils, which according to the authors, allowed the EOs to be much more protected against the humidity, temperature, and solar light, among other factors (Răileanu et al. 2013).

3.2 Phase Solubility Studies

Phase solubility studies are a traditional approach to determine not only the stability (also called equilibrium) constant value but also to give insight into the stoichiometry of the equilibrium. Experimentally, an excess of a poorly water-soluble guest molecule (e.g., drug, D, representing the substrate) is introduced into several vials to which a constant volume of an aqueous vehicle containing successively larger concentrations of the CD (representing the ligand) is added. Afterwards the vials are shaken at constant temperature until equilibrium is established. The supernatant is spared and the total concentration of the drug (D_t) is determined by a adequate quantification method (e.g., UV-VIS, HPLC, fluorescence). The phase solubility profile is then constructed by assessing the effect of the CD on the apparent solubility of the drug (D) as shown in Fig. 4 (Higuchi and Connors 1965; Brewster and Loftsson 2007; Cabral-Marques 2010). Several behaviors can be identified between two major types: A and B.

Thus, the following profiles may be described as:

- A-type – formation of soluble inclusion complexes
  - A_L-type – linear increase of drug solubility versus CD concentration
  - A_P-type – positively deviating from the linear profile (i.e., the solubilization is proportionally more effective at higher concentrations)
  - A_N-type – negatively deviating from the linear profile (i.e., the CD is proportionally less effective at higher concentrations)
- B-type – formation of inclusion complexes poorly soluble
  - B_S-type – complexes of limited solubility
  - B_I-type –formation of insoluble complexes

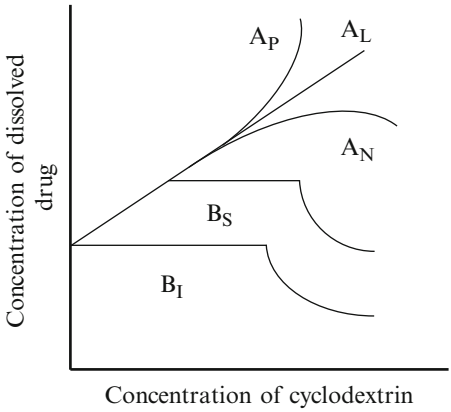

Fig. 4 Profile types in the phase solubility diagrams (Higuchi and Connors 1965)

A_L profiles indicate a linear increase in solubility in function of CD concentration, and water-soluble complexes are being formed with solubilities higher than that of the uncomplexed substrate. A_L-type relationships are first order with respect to the CD and may be of first or higher order with respect to the drug (i.e., *D•CD*, D_2•*CD*, D_3•*CD*, etc.). If the slope of the A_L isotherm is higher than the unity, higher-order complexes are assumed to be involved in the solubilization. Although a slope of less than one does not exclude the occurrence of higher-order complexes, a one-to-one complex is often assumed in the absence of other information. A_P systems suggest the formation of higher-order complexes with respect to the CD, at higher CD concentrations (i.e., *D•CD*, *D•*CD_2, *D•*CD_3, etc.). The stoichiometry of the formed complexes has historically been implied by the extent of curvature of the phase solubility profile. Thus, when an isotherm best fits to a quadratic function, the formation of a one-to-two (*D•*CD_2) complex is suggested, one best fits to a cubic function suggests a one-to-three complex (*D•*CD_3), and so forth. A_N profiles have several explanations including bulk changes imparted to the solvent by the CD at various concentrations (i.e., the CD is acting as a chaotrope or kosmotrope or is altering the bulk properties of the media by changing its viscosity, surface tension, or conductivity) and/or CD self-association at high concentrations. Equilibrium constants can be derived from the linear portion of each phase solubility profile, given by Eq. 2. To this point, intrinsic drug solubility is given as D_o and the formed complex is represented by *D•CD*.

The complexation process is most frequently a 1:1 host/guest ratio; however, 2:1, 1:2, or even higher-order associations may exist at the equilibrium, almost always simultaneously. Equilibrium established between dissociated and associated species can be expressed by the stability (association or equilibrium) constant and designed as K_s or K_a or $K_{1:1}$ (Szejtli 1998). These constants may be determined by several methods, e.g., phase solubility studies (Waleczek et al. 2003; Daletos et al. 2008), NMR, UV-VIS, HPLC (Cabral-Marques 1994a, b), TLC (Lederer and Leipzig-Pagani 1996), and static headspace method (Saito et al. 1999). The CD association with the drug (D) or guest molecules and the dissociation of the formed inclusion complexes are governed by a thermodynamic equilibrium showed by the following equations (Szejtli 1998):

$$\begin{matrix} mD + nCD \overset{K_{m:n}}{\Leftrightarrow} D_mCD_n \\ [a-mx][b-nx]\ [x] \end{matrix} \tag{1}$$

and

$$K_d = \frac{[x]}{[a-mx]^m[b-nx]^n} \tag{2}$$

Then, a dissociation constant can be defined as

$$K_d = \frac{[a-mx]^m[b-nx]^n}{[x]} = \frac{1}{K_{m:n}} \tag{3}$$

Intrinsic drug solubility is given as D_0 and a formed complex is represented by $D{\bullet}CD$.

Since

$$[D] = D_0 \tag{4}$$

$$D_t = D_0 + m[D_m CD_n] \tag{5}$$

$$CD_t = CD + n[D_m CD_n] \tag{6}$$

then the values for $[D_m{\bullet}CD_n]$, $[D]$ and $[CD]$ can be derived as

$$[D_m CD_n] = \frac{D_t - D_0}{m} \tag{7}$$

$$[CD] = CD_t - n[D_m CD_n] \tag{8}$$

where D_0 is the equilibrium solubility of the drug in the absence of CD, D_t is the total concentration of the drug (i.e., the sum of the complexed and uncomplexed forms), and CD_t is the total concentration of CD. For equilibria that are first order with respect to the CD ($n = 1$), the following equation can be obtained:

$$D_t = \frac{mKD_0^m CD_t}{1 + KD_0^m} + D_0 \tag{9}$$

A plot of D_t versus CD_t for the formation of $D_m{\bullet}CD$ should, therefore, give a straight line with the y intercept representing D_0 and the slope defined as

$$\text{slope} = \frac{mKD_0^m}{KD_0^m} \tag{10}$$

Therefore, if m is known, the K can be calculated meaning that for 1:1 complexation, i.e., $m = 1$, the following graphical approach can be applied:

$$K_{1:1} = \frac{\text{slope}}{D_0(1 - \text{slope})} \tag{11}$$

For 1:1 drug $\bullet CD$ complexes, the complexation efficiency (CE) can be calculated from the slope of the phase solubility diagram according to Eq. 12. When selecting CD or complexation conditions during formulation work, it can frequently be more convenient to compare the CE than $K_{1:1}$ values since CE is less sensitive to errors related to estimation of intrinsic drug solubility (Loftsson et al. 2005a):

$$CE = \frac{[D \bullet CD]}{[CD]} = D_0{}^* K_{1:1} = \frac{\text{slope}}{(1 - \text{slope})} \tag{12}$$

The CE is the product of the apparent solubility of the poorly soluble drug (D_0) and the apparent stability constant of the complex ($K_{1:1}$), assuming formation of 1:1 *D•CD*. The CE can be increased by either increasing the value of D_0 or the value of $K_{1:1}$ or both values simultaneously. This parameter increase can be achieved by the use of drug salts, polymers, and cosolvents. In addition, processing approaches to improve CDs, solubilizing functions should be considered, and formulation concepts such as supersaturation may further help in the optimal use and placement of CD in pharmaceutical dosage forms (Loftsson and Brewster 2012; Ciobanu et al. 2013).

4 Biology/Biotechnological Approaches

4.1 Toxicological Considerations

Due to the importance of CDs and the derivatives, their safety and toxicological profiles have been reviewed by several authors (Cabral-Marques 1994b; Irie and Uekama 1997; Thompson 1997; Del Valle 2003; Stella and He 2008; Arima et al. 2011). As CDs possess MW ranging from almost 1,000 to over 2,000 Da and hydrophilicity ($\log_{Ko/w}$ −8 to −12) with a significant number of H-donors and acceptors, they are not significantly absorbed from the gastrointestinal tract (GI) in their intact form. Natural CDs and their hydrophilic derivatives present considerable difficulties to permeate lipophilic biological membranes. Even the somewhat lipophilic randomly methylated β-CD does not readily permeate lipophilic membranes, although it interacts more readily with membranes than the hydrophilic CD derivatives (Totterman et al. 1997); for this reason some β-CD derivatives have been considered skin enhancers due to their ability to complex membrane components causing its disruption (Babu and Pandit 2004; Wang et al. 2014). Several CDs, namely, γ-CD, 2-HP-β-CD, SBE-β-CD, sulphated β-CD, and maltosyl β-CD evaluated in a number of safety studies have proven that they appear to be safe even when administered parenterally. However, these same studies proved that the natural α- and β-CDs and the methylated β-CDs are not suitable for parenteral delivery (Del Valle 2003). The α-CD and β-CD, unlike γ-CD, cannot be hydrolyzed by human salivary and pancreatic amylases even if it can be fermented by the intestinal microflora (Irie and Uekama 1997; WHO 2002). One of the target organs where the toxicity profile of several CDs can be assessed is the kidney (Antlsperger and Schmid1996).

4.1.1 α-CD

Oral administration of α-CD is, in general, well tolerated and is not associated with significant adverse effects (Lina and Bär 2004a, b). Only small fractions of α-CD are absorbed intact from the GI tract, and it is mainly excreted unchanged in the urine after IV injection (Table 5) (Brewster and Loftsson 2007). Studies in rats showed that α-CD p.o. was excreted 60 % as CO_2 (no CO_2 exhalation after p.o. to

Table 5 Safety overview of selected cyclodextrins (Brewster and Loftsson 2007)

	The pharmacokinetics in rats			Acute toxicity, LD50 rat (g/kg)		Maximum dosage in marketed products (mg/day)	
Cyclodextrin	$t_{1/2}$ after IV injection (min)	Fraction excreted unchanged in urine	Oral absorption	IV	Oral	IV	Oral
α-CD	25	≈90 %	2–3 %	0.5–0.8	>10	1.3	
β-CD	20	≈90 %	1–2 %	1	19	Not for parenteral usage	170
HP-β-CD	20	≈90 %	≤3 %	10	>2	16,000	8,000
SBE-β-CD				>15	>10	6,000–14,000	–
RM-β-CD	18	>95 %	0.5–12 %	1.5–2.1	>8	Not for parenteral usage	–
G2-β-CD	23				>5	No product	No product
γ-CD	20	90 %	<0.02 %	4	>8	No product	No product
HP-γ-CD					>2		

germ-free rats), 26–33 % as metabolite incorporation, and 7–14 % as metabolites in feces and urine, being mainly excreted in the unchanged form by the renal route after parenteral injection ($t_{1/2} = 25$ min, LD_{50} oral, rat >10,000 mg/kg, LD_{50} IV, rat between 500 and 750 mg/kg).

Some other relevant characteristics were observed after this CD administration, such as, skin irritation after IM injection, binding with some lipids, eye irritation, and slight absorption (2–3 %) after oral administration in rats. α-CD is not metabolized in the upper intestinal tract and its cleavage is only due to the intestinal flora of cecum and colon (Del Valle 2003).

4.1.2 β-CD

Due to its low aqueous solubility and side effects (e.g., nephrotoxicity), β-CD is not able to be administered by parenteral route but it can be used in p.o. because by this route is normally nontoxic. However, it must be carefully used because in high doses it may be harmful and therefore not recommended. After p.o. administration, the nontoxic effect level of β-CD was determined to be 0.7–0.8 g/kg/day in rats and about 2/g/kg/day in dogs (Bellringer et al. 1995).

It was noticed that β-CD binds cholesterol, is absorbed in small scale (1–2 %) in the upper intestinal tract after oral administration, and is less irritating than α-CD after IM injection. β-CD is not metabolized in the upper intestinal tract, but suffers bacterial degradation and fermentation in cecum and colon which may lead to gas production and diarrhea (LD_{50} oral, rat >5,000 mg\kg; LD_{50} IV, rat = 450–790 mg/kg) (Del Valle 2003). As it will be described in the Regulatory State chapter, β-CD is the most commonly used CD in pharmaceutical formulations, and, thus, it is probably the most studied in humans.

4.1.3 γ-CD

The metabolism of γ-CD closely resembles that of starch and linear dextrins (Munro et al. 2004). Only a small portion of the IV-injected γ-CD is absorbed intact from the GI tract, and it is mostly excreted unchanged in the urine. Oral administration of 8 g γ-CD or 8 g maltodextrin to humans did not reveal any differences in GI tolerance of these two oligosaccharides (Koutsou et al. 1999). The γ-CD showed to promote an insignificant irritation after IM injection and was rapidly and completely degraded by intestinal enzymes in the upper intestinal tract to glucose monomers (even using high daily doses, e.g., 10–20 g/kg). Following p.o. administration γ-CD remained intact, i.e., almost no absorption (0.1 %) was observed and it was practically not metabolized after parenteral administration (LD_{50} oral, rat $\gg$8,000 mg/kg; LD_{50} IV, rat $\approx$4,000 mg/kg) (Del Valle 2003).

Comparing the toxicological profile of the three natural CDs, γ-CD seems to be the least toxic. But its complexes normally have limited solubility in aqueous solutions and tend to self-aggregate; therefore, its complexing abilities are limited compared to those of β-CD and some water-soluble β-CD derivatives (Table 5).

4.2 Metabolism and Pharmacokinetics

4.2.1 Cyclodextrins

Regarding physicochemical and biological characteristics, CDs (ring dextrins) are very similar to water-soluble linear dextrins, but owing to their cyclic structure, they are more resistant to hydrolysis (enzymatic and nonenzymatic) than linear ones (Kurkov and Loftsson 2012). Contrary to starch, CDs are generally resistant to β-amylases, so they are not hydrolyzed from the nonreducing ends, but they cannot resist to the slow hydrolysis caused by α-amylases (hydrolysis from within the carbohydrate chain). α-CD and β-CD are not affected by the stomach acids and salivary and pancreatic enzymes during digestion, but γ-CD is digested partly by these amylases in the GI tract. The mechanism involved in the CDs' hydrolysis resistance is due to all bridge oxygens being hidden within the central cavity; this hydrolytic rate will depend on several factors, namely, the ring size and fraction of free CD (Kurkov and Loftsson 2012).

Linear dextrins as well as starch are digested mainly into glucose through a stepwise enzymatic hydrolysis process which starts when in contact with salivary α-amylase, but by p.o. administration this is overcome as in the stomach the enzyme is inactivated (Dona et al. 2010). Some nonenzymatic specific acid hydrolysis of the dextrins can occur in the stomach, but this phenomena can be delayed by the formation of complexes with food lipids (Singh et al. 2010). In the small intestine (neutral pH), where pancreatic fluid containing α-amylase is released, enzymatic hydrolysis occurs. The dextrin substrates that remained intact along the above enzymatic process are finally submitted to bacterial digestion when they reach the lower sections of the intestine.

Thus, the most important pharmacokinetic parameters for these macromolecules are urinary clearance and hepatic uptake (Nishikawa et al. 1996). As it was shown by several authors, both natural CDs and their derivatives are susceptible to bacterial digestion in the GI tract (Antlsperger and Schmid 1996; Irie and Uekama 1997; Zhou et al. 1998; Zuo et al. 2002; Van Ommen et al. 2004; Stella and He 2008).

Natural CD pharmacokinetics are very similar to each other and to the linear dextrins with similar molecular weights (MW). The insignificant amount that is absorbed from the GI tract after p.o. administration is made by passive diffusion and can be explained by the bulky and hydrophilic nature of the CDs. After absorption, CDs are eliminated by the renal route without undergoing significant metabolism. Any remaining CD is eliminated by other pathways (liver metabolism and biliary excretion) similarly to low MW dextrans.

The main elimination process is dependent on the administration route: Following p.o. administration in rats and dogs, HP-β-CD was mainly excreted via the feces, whereas after IV administration, this CD was excreted via the kidneys. In the case of humans, this excretion process mainly occurs via the kidneys (Gould and Scott 2005). The $t_{1/2}$ of the elimination phase (natural CDs) ranged approx. between 1.4 and 2 h, and the volume of distribution (V_D) was approx. 0.2 L kg^{-1}. The pharmacokinetic studies showed that over 90 % of parenterally administered CD

Table 6 The absorption of cyclodextrins and their derivatives following oral administration (Stella and He 2008)

Cyclodextrin	Species	Dose (mg/kg)	Absorption (% dose)	Reference
α-CD	Rat	200	1	Van Ommen et al. 2004
β-CD	Rat	500	0.6	Kubota et al. 1996
γ-CD	Rat	1,000	0.02	De Bie et al. 1998
G-β-CD	Rat	500	0.3	Kubota et al. 1996
HP-β-CD	Rat	40	3	Gerloczy et al. 1990
SBE-β-CD	Rat	60	1.64	CyDex (unpublished)

will be eliminated from the body within approximately 6 h and over 99.9 % within 24 h (Kurkov and Loftsson 2012). The absorption of natural CDs and their derivatives following oral administration in the rat is summarized in Table 6.

After being absorbed CDs are distributed to several organ tissues, such as the kidney, urinary bladder, liver, adrenal gland, and others (Gerloczy et al. 1990; Monbaliu et al. 1990; Antlsperger and Schmid 1996; Kubota et al. 1996; De Bie et al. 1998; Van Ommen et al. 2004). The absorption of β-CD-methylated derivatives in rats were 6.3–9.6 % for DM-β-CD and 0.5–11.5 % for M-β-CD (Mosher and Thompson 2002). The HP-β-CD oral bioavailability (itraconazoleoral solution) in humans was estimated to be less than 1 % (De Repentigny et al. 1998; Stevens 1999). The IV administration of β-CD and HP-β-CD to permanently cannulated rats resulted in a pharmacokinetic behavior of both CDs similar to that of inulin, showing a rapid distribution over extracellular fluids and elimination through glomerular filtration (Frijlink et al. 1990). CDs via IV route disappeared rapidly from systemic circulation, as they are rapidly eliminated by the kidney, almost in intact form. This makes the kidney the organ with the highest level of CDs among all tissues. Thus, renal insufficiency could result in CD accumulation. As an example, it was observed that after IV bolus administration (10 mg kg^{-1}) of M-β-CD, its concentration in the kidneys (mainly in the renal cortex) remained almost at the same level for at least 6 days (Antlsperger and Schmid 1996; Slain et al. 2001; Gould and Scott 2005; Von Mach et al. 2006; Stella and He 2008).

The β-CD steady-state volume of distribution (V_{dss}) and most of its derivatives in all animal species tested correspond well with the respective extracellular fluid volume (Table 7). Thus, it can be concluded that, after IV administration, CDs distribute mainly in the extracellular compartments without involving the deep compartments or storage pools (Kleijn et al. 2011). Methylated β-CD has a larger V_{dss} and longer $t_{½}$ compared to other CD derivatives which may be due to its ability to interact with cellular membranes and its hemolytic activity (Thompson 1997). The total plasma clearance for HP-β-CD and SBE-β-CD in all species tested is similar to the glomerular filtration rate of individual species (Davies and Morris 1993). In these cases 100 % of an IV dose was recovered in the urine within 6–12 h (Davies and Morris 1993). Most CDs disappear from tissues dramatically within the first several hours after administration. For example, the level of SBE-β-CD in most tissues decreased by more than 90 %; even in the kidney, SBE-β-CD was reduced

Table 7 Pharmacokinetic parameters of some cyclodextrins IV administered (Stella and He 2008)

Cyclodextrin	Species	Dose (mg/kg)	$T_{1/2}$ β (min)	V_{dss} (mL/kg)	Plasma clearance (mL/min/ kg)	Reference
β-CD	Rat	50	21.6	201.8	7.53	Kubota et al. 1996
G-β-CD	Rat	50	17.3	308.1	12.5	Kubota et al. 1996
HP-β-CD	Rat	200	23.9	194	7.2	Frijlink et al. 1990

[d]Methyl-β-CD with total degree of substitution (DS) of 10.4

by at least 60 % from 0.1 to 1 h following IV bolus injection of 600 mg/kg SBE-β-CD in the rat (Stella and He 2008).

4.2.2 Complexes

The partitioning of the drug in its different forms (dissolved free drug molecules, dissolved complex, solid free drug, and solid complex) depends on the solubility of the free drug and the complexed drug in the given medium, the stability constant of the CD-drug complex, the molar ratio of the components, and the volume of the liquid phase. The same complex may provoke different – enhanced or decreased – biological responses depending on the additional amount of CD or even on the volume of water consumed.

It has generally been believed that following oral administration only an insignificant amount of CD is absorbed simultaneously with the drug, i.e., only free drug molecules can enter the circulation and the increasing excess of the remaining CD will push the equilibrium towards complex formation. CD acts primarily as a carrier agent to the site of absorption transporting the more or less hydrophobic guest

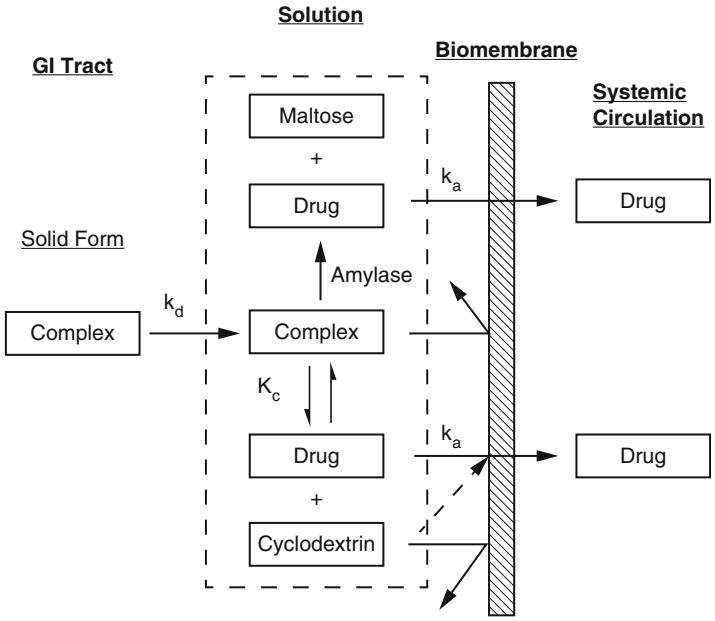

Fig. 5 Mechanism of drug absorption from CD complexes in vivo (where k_d is the rate constant of dissolution, k_a rate constant of absorption, *D* drug in the orally administered dose, *GI* concentration of dissolved drug in the gastrointestinal tract, and *B* concentration of drug in blood) (Cabral-Marques 1994c)

molecule through an aqueous milieu to the lipophilic membrane of cells in the GI tract. There the guest molecule is absorbed, since the membrane has a higher affinity for a lipophilic guest molecule than the CD itself. If the complex is very stable or the CD concentration is high, the equilibrium is greatly shifted towards complexation and absorption is considerably hindered. Some studies have indicated slow absorption of some CDs by passive diffusion across intestinal membranes, which seem to be promoted in the presence of bile salts and Ca^{2+}-chelating agents indicating absorption by the paracellular pathway. It is unclear whether GI tract absorption of drug-CD complexes may constitute a significant level of absorption under certain conditions, but in the case of pulmonary delivery where the barrier membranes are much thinner, this possibility should be considered.

In a model for in vivo drug release, the first step must be the dissolution of the solid adducts (Fig. 5). There then exists an equilibrium between the dissolved complex and the released drug. Only the dissolved, non-complexed drug can be absorbed (Cabral-Marques 1994c).

4.3 Biotechnological/Bioengineering Approaches

CD has been used in several biotechnological/bioengineering studies, some of which are described below:

It is not easy to predict drug absorption after its complexation with CD due to the large range of interacting parameters and their influence on free drug concentration.

Molecular modeling can help by making predictions and providing orientations for the development of new complexes that can be formulated in pharmaceutical dosage forms. Neutral compound complex model demonstrates the mechanism behind a possible variation (increase, decrease or no effect) in the absorption when CD is dosed as an inclusion complex. A model for predicting the CD effect on drug bioavailability, when administered as inclusion complex, was used. This model involved mass transport expressions for drug dissolution and absorption and pseudo-equilibrium *D•CD* complexation. Its predictions were compared with in vitro and in vivo experimental results allowing to predict when CD can be delivered as a preformed complex with drug to enhance bioavailability (Gamsiz et al. 2013).

Different polymers such as plasticized poly (vinyl chloride) (PVC-P), poly (ethylene oxide) (PEO), PEO/poly (propylene oxide) (PPO), and copolymers, e. g., Pluronic F68 (F68), were studied in order to obtain a novel modified biomaterial surface using CDs for increased blood compatibility. The β-CD-PEO and β-CD-F68 associations in certain feeding ratio were synergistic in producing the desired effect (Zhao and Courtney 2006).

Hydrogels have suitable properties for wound-dressing use due to its good biocompatibility and maintenance of a moist environment for better healing. The efficacy of these platforms can be improved by the use of CDs as cross-linking agents. The association hydrogels-CDs may allow the moist environment required for the healing process and the moiety with the ability to protect and modulate the release of bioactive molecules (Pinho et al. 2013). Furthermore, the development of the platforms using CD-containing polyrotaxanes is expected to provide a new paradigm for biomaterials. Thus, the CD-based biodegradable polypseudorotaxane hydrogels could be used as a promising injectable drug delivery system for sustained and controlled drug release. The polyrotaxanes with drug- or ligand-conjugated CDs threaded on a polymer chain with a biodegradable end group could be useful for controlled and multivalent targeted delivery. In the field of gene delivery, cationic polyrotaxanes consisting of multiple OEI-grafted CDs threaded on a block copolymer chain are attractive non-viral gene carries due to the strong DNA-binding ability, low cytotoxicity, and high gene delivery capability (Li et al. 2011).

The bioactive compounds from plants (polyphenolics, alkaloids, and polysaccharides) have well-documented pharmacological properties and have been widely used by the food, cosmetic, and pharmaceutical industries due to its advantages, such as high levels of biocompatibility, low toxicity and good availability. Polyphenolics are currently the major group of interest in view of their anti-inflammatory, antimicrobial, and antioxidant properties, as well as their availability in the human diet (Cowan 1999; Aridogan et al. 2002; Belščak-Cvitanović et al. 2011; Gou et al. 2011). Many studies have been published regarding the encapsulation of natural polyphenolic agents by CDs, for food and drug delivery proposes. CDs have a capacity of improving their aqueous solubility, protect them from elevated temperatures, pH, and light- or moisture-induced degradations

increasing their bioavailability. In the case of flavonoids, the CD derivatives are the best choices to achieve an efficient complexation (Pinho et al. 2014).

Monochlorotriazinyl-β-cyclodextrin (β-CDMCT) has been used as a great tool for surface modification of natural and synthetic fibers (polyester, polyamides, and polyacrylics). These materials after being grafted onto celluloses substrates can be used for fragrance release, odor adsorption (sheets and personal clothing), controlled release (antibacterial, fungicide, or insect repellents), UV protection, and stabilization of active ingredients due to CD cavities. These platforms in β-CD cavities can include an insect repellent and an insecticide. In addition this new tool was designed for the treatment of materials (such as bed nets, curtains, specific clothing, military uniforms, etc.) in order to prevent man-vector contact (Reuscher and Hinsenkorn 1996; Romi et al. 2005).

The structural CD properties make them suitable building blocks to be used in polymeric reactions, since they can be grafted to polymers (natural/synthetic) resulting in different polymer architectures (Zhang and Ma 2013).

Molecular complexation with CDs already cited play an important role in biotechnology and bioengineering area in the domain of selectivity, separation, and solubilization of various biomolecules.

4.4 Applications of CDs

Since CDs are versatile molecules that offer unique features and have negligible cytotoxic effects, they have been widely used in many industrial products, technologies, and analytical methods (Cabral-Marques 1994c; Singh et al. 2002; Del Valle 2003; Cabral-Marques 2008). Some examples of applications are the following.

4.4.1 Pharmaceuticals

CDs have been widely used in pharmaceutical industries, being in the most of the cases as auxiliary substances, improving stability, bioavailability, and organoleptic properties (e.g., palatability, masking odors) of active compounds in multiple pharmaceutical dosage forms (Del Valle 2003; Carrier et al. 2007; Miller et al. 2007; Cabral-Marques 2010). These versatile sugar molecules enabled the production and reintroduction of numerous active substances that, owing to stability, compatibility, or absorption problems, were not in use (Cabral-Marques 1994c). Shortly, the CDs' multifunctional features have been exploited in drug delivery system being potential candidates in many applications because of their ability to alter the physical, chemical, and biological properties of guest molecules through the formation of inclusion complexes (Uekama et al. 1998; Cabral-Marques 2008). All these improvements enabled their application in commercialized pharmaceutical products used in almost every drug delivery systems: α-CD (oral, parenteral), β-CD (dermal, oral, rectal, sublingual), HP-β-CD (ocular, oral, parenteral, rectal), DM-β-CD (dermal, nasal, ocular), SBE-β-CD (parenteral), and HP-γ-CD (ocular) (Cabral-Marques 2008; Tiwari et al. 2010). Among all CDs, β-CD is the most reasonably priced, thus the most used on industrial applications.

Oral delivery: The drug release in this route of administration is controlled either by dissolution, diffusion, osmotic systems, density, or pH (Tiwari et al. 2010).

CDs are particularly useful as they can be used as a way to reduce local drug irritation and increase drug absorption rate (Loftsson et al. 2005b). The hydrophilic CDs provide an enhancement of stability, solubility, dissolution rate, and wettability of poorly water-soluble drugs by means of complex formation (Carrier et al. 2007). CDs are supposed to act only as carriers and help to transport the drug through an aqueous medium to the lipophilic absorption surface in the GI tract. Buccal and sublingual routes have also been an effective way to deliver rapid-dissolving drug-CD complexes. In this case, a rapid increase in the systemic drug concentration takes place along with the avoidance of systemic and hepatic first-pass metabolism (Tiwari et al. 2010).

Pulmonary delivery: Pulmonary administration has been gaining an increased importance for therapeutic usage due to lung's anatomical and physiological characteristics like large surface area available (~100 m^2), high irrigation (5 L/min), very thin absorption membrane (0.1–0.2 μm), and relatively low enzymatic activity (Pilcer and Amighi 2010). This is normally an attractive route for treatment of local diseases (e.g., asthma, DPOC) but is also interesting for systemic delivery. However, this route is usually limited by the characteristics of drugs used, low aqueous solubility, and slow drug dissolution (Loftsson et al. 2005b). CDs are used to solve these drawbacks and to improve the pulmonary delivery of drugs either systemically or locally. Formulations of insulin delivered via pulmonary route (powders and liquids) have low bioavailability (10–15 %), and thus, to get the right dose, a high drug loading is needed in drug delivery system (Ramalhete et al. 2001). Formulations with penetration enhancers (with proven efficacy via other administration routes) such as CDs could help this matter (Cabral-Marques et al. 1991). Current DPIs (Dry Powder Inhalers) for treatment of respiratory diseases generally deliver only 10–20 % of the nominal dose to the site of action. It is possible to engineer particles by spray-drying and using CDs to improve this drawback allowing a more efficient drug delivery to the site of action, with fewer systemic effects than oral therapy (Vozone and Cabral-Marques 2002; Almeida and Cabral-Marques 2004; Drumond et al. 2014).

Nasal delivery: This is another effective route that avoids the extensive GI breakdown and hepatic first-pass metabolism. Due to nasal mucosa's good permeability, this delivery route is a novel approach for systemic delivery of high potency drugs with a low oral bioavailability. As lipophilic CDs can interact with biological barriers (without affecting their barrier function), they have the ability to enhance the drug delivery – a property which makes CDs ideal penetration enhancers for intranasal administration. Methylated CDs are the most commonly used and widely studied. They have shown in several studies very promising results being efficient absorption enhancers, namely, in the delivery of peptides and hormones (Merkus et al. 1999; Loftsson et al. 2005b; Tiwari et al. 2010).

Ocular delivery: In this type of delivery systems, the most used dosage form is the eye drop due to easy instillation in the eye. However, eye drops are a great formulation challenge due to the high probability of its inability to sustain high

local concentration of drug (Tiwari et al. 2010). By this reason CDs have been used to overcome these problems as they present possible advantages in ophthalmic use, such as increase in solubility and/or stability and reduction or avoidance of side effect of drugs (e.g., discomfort and irritation) (Torres Marques et al. 1996; Loftsson et al. 2012). One of the prerequisites for a new vehicle to be used in ophthalmic preparations is that it is not irritating to the ocular surface, because irritation causes reflex tearing and blinking, which result in a fast washout of the instilled drug (SáCouto et al. 2014). Hydrophilic CDs do not penetrate eye cornea biological barriers but enhance the ocular bioavailability of lipophilic drugs by keeping them in solution (Cabral-Marques 2008).

Rectal delivery: This route is by far the chosen one to deliver drugs to the unconscious patients, children and infants. Despite offering a relatively low area for drug absorption, which leads to an erratic release of drugs, the rectal mucosa represents a potential site for delivery of drugs with limitations by the oral route (e.g., organoleptic problems, pH degradation, high first-pass metabolism) (Tiwari et al. 2010). Beraldo et al. (2002) has shown that CDs are quite useful to solve the erratic release problems of this route.

Dermal delivery: This is the most sophisticated and more reliable form to administrate the drug through skin, either for local or systemic action (Tiwari et al. 2010). CDs have a significant safety margin in dermal application and can be used to optimize the transdermal delivery of drugs. CDs improve drugs' solubility and/or stability in topical preparations, consequently enhancing the transdermal absorption of drugs, to sustain the drug release from the vehicle and to avoid undesirable side effects associated with dermally applied drugs (Waleczek et al. 2003; Santos et al. 2004; Loftsson et al. 2005b). CDs may interact with some components of the skin and the lipids such as cholesterol and triglycerides and consequently induce a temporary change in the skin barrier function and an enhancement in the drug absorption. It was shown that DM-β-CD has higher skin permeation effect than HP-β-CD (Cabral-Marques 2008).

4.4.2 Bioconversion and Fermentation

The efficiency of bioconversion and fermentation processes is often restricted by the inhibitory or toxic influence from either the substrate or the conversion products on the biocatalyst. Another problem often found on most organic substrates is their solubility in water which complicates the amount of substrate accessible to the biocatalyst. In order to overcome process limitations such as low solubility of lipophilic substrates, CDs can be added to the bioconversion or fermentation media. In addition CDs may provide a reduction of toxicity by complexation with toxins and biocompatibility improvement (Bar 1989; Cabral-Marques 2010).

4.4.3 Environment Protection

CDs are important to environmental science in terms of remediation by complexation of organic contaminants/pollutants and heavy metals from soil, water, and atmosphere. After treating wastewaters containing environmentally unacceptable aromatic compounds (phenol, p-chlorophenol and benzene) with β-CD, the initial

levels of these aromatic hydrocarbons were significantly reduced. The same CD benefic actions may also be used in the treatment of gaseous effluent from chemical industries (Cabral-Marques 1994b; Del Valle 2003).

4.4.4 Agrochemical Industry

CDs may be used to improve a variety of properties of bactericides, insecticides, herbicides, and fungicides. Complex formation with β-CD has been reported, including examples of increased or decreased activity of pesticides (Cabral-Marques 1994b).

4.4.5 Catalysis

The CDs ability to mimetize enzymes, i.e., molecular recognition phenomenon, led them to be used in catalysis. Thus, CDs have to be modified through substituting various functional compounds or by attaching reactive groups. In addition CDs possess the ability of enantiomeric recognition. Resulting from the chelating effect of the CD catalysts, rates of reaction may be enhanced by almost 1,000-fold when compared to free solution (Del Valle 2003).

4.4.6 Analytical

The CDs are very useful in separation process due to its molecular recognition ability to discriminate positional isomers, functional groups, and homologues/enantiomeric compounds. Depending on the substrate to be separated, the choice of the CDs is essential since shape, size, and selectivity will influence separations. CDs have been used in HPLC and GC (being CDs in the stationary phase columns), in NMR (chiral shift agents), in circular dichroism (selective agents altering spectra), and also in electrochemical chemistry (to mask contaminating compounds) (Del Valle 2003). These substances serve as an ideal selector by molecular recognition and further enhance the complex forming ability and selectivity in various type of separations (Eastburn and Tao 1994; Han 1997; Loung and Nguyen 1997; Szejtli 1998; Del Valle 2003; Cabral-Marques 2010).

4.4.7 Food and Flavors

In food industry the CDs are used as multifunctional food ingredients. They can be used as carriers for molecular encapsulation forming inclusion complexes with a variety of molecules including fats, aromatic agents, flavors, and colors. The inclusion complexes improve both physical and chemical stability of sensitive ingredients leading to better conservation and, consequently, to extended food shelf life. CDs also can act as a controlled release agent of desired food constituents and can provide a promising alternative to the conventional encapsulation technologies by removing and/or masking undesirable components (e.g., removal of cholesterol from butter, eggs, milk; decreasing of juice's bitterness). In addition, CDs can protect the food ingredient throughout many rigorous food-processing methods of freezing, thawing, and microwaving (Prasad et al. 1999; Del Valle 2003; Cabral-Marques 2010).

4.4.8 Cosmetics, Toiletry, and Personal Care

Cosmetic preparations are another area where CDs have been largely used to protect molecules against physical and chemical instabilities (e.g., oxidation, decomposition, hydrolysis). By complex formation included guest molecules may increase their stability, suppress volatility (in the case of perfumes), reduce/prevent skin irritation, and improve room fresheners and detergent's action. Active ingredients are released from inclusion compounds by controlled release. In summary, it is possible to say that major benefits of CDs in the cosmetics, toiletry, and personal care products are stabilization, odor control, process improvement upon conversion of liquids to solids, absorption increase/decrease of various compounds into skin, flavor protection, enhanced water solubility, and thermal stability of oils. Moreover, CDs are used in toothpaste, lipsticks, skin creams, liquid and solid fabric softeners, paper towels, tissues, shampoos, and deodorants (Del Valle 2003; Cabral-Marques 2010).

4.4.9 Packaging and Textile Industry

Textile industry is another area in which CDs are increasingly attracting attention (Cabral-Marques 2010). Fabrics can be imbued with novel properties by means of these substances. In order to permanently transfer the versatile properties of CDs to textiles, Wacker-Chemie (the world's largest producer of γ-CDs) covalently attached reactive CD derivative with monochlorotriazinyl (MCT) substituents to the fiber. This substituted CD provided excellent textile finishing to cottons, blended materials, and woolens. Using hydrophobic tosyl derivative of β-CDs, threefold increase in the binding of fluorescent dye to the polyester fiber was attained.

CDs also play a major role in the packaging industry. Inclusion complex containing oily antimicrobial and volatile agents are coated on a water-absorbing sheet with a natural resin binder, which is used for wrapping fresh products. It was found that food-packaging bag manufactured using CD with ethylene-tetracyclo-3-dodecane copolymer and hinokitiol showed no odor and good antifungal properties after 1 week of storage at room temperature, which proved useful for food-packaging materials (Hedges 1998; Ishibashi et al. 1999; Hirose and Yamamoto 2001).

5 Current Regulatory State

Despite of being characterized as pharmacologically inactive compounds, pharmaceutical excipients are treated as active compounds in the regulatory perspective, especially when used for the first time in humans (Demerlis et al. 2009; Koo 2011; Osterberg et al. 2011). Their acceptance is often supported by previous usage in commercialized pharmaceutical products or in the food industry. This is also valid if the excipient is already being used at the same levels and administration routes as in marketed products. In these cases a full safety evaluation may not be needed (Kurkov and Loftsson 2012).

Table 8 Food approval status of Cyclodextrins (Cabral-Marques 2010)

	α-CD	β-CD	γ-CD

The regulatory status of CDs has evolved over the last years even with the skepticism within the regulatory agencies concerning their usage. Consensus seems to be building among regulators that CDs are excipients and not part of the drug substance although divergent opinions exist (Brewster and Loftsson 2007). Products containing CDs undergo rigorous evaluation, and their strengths and weaknesses are understood and agencies will become more comfortable with them and lower the barriers to their use (Davis and Brewster 2004; Loftsson et al. 2004; Stella and He 2008). Table 8 shows an overview of the food approval status of CDs by the different worldwide regulatory agencies.

Monograph for natural β-CD is listed in some pharmacopoeia sources such as the US Pharmacopoeia/National Formulary (USP/NF), European Pharmacopoeia (Ph. Eur.), and Japanese Pharmaceutical Codex (JPC). α-CD is also listed in the Ph. Eur., USP/NF, and JPC; γ-CD is referenced in the JPC and soon will be included in the Ph. Eur. and USP/NF. A monograph for HP-β-CD is available in the Ph. Eur., and a draft has been circulated for the USP/NF; SBE-β-CD can be found in the USP/NF. Other derivatives are not yet compendial but efforts are being made for their inclusion. α-CD, β-CD, and γ-CD were also introduced into the generally regarded as safe (GRAS) list of the FDA for use as a food additive in 2004, 2001,

and 2000, respectively; HP-β-CD and γ-CD are cited in the FDA's list of Inactive Pharmaceutical Ingredients. SBE-β-CD is also available in various dosage forms and listed in the FDA's compilation of Inactive Pharmaceutical Ingredients (Cabral-Marques 2010; Kurkov and Loftsson 2012).

Currently different marketed pharmaceutical products (Table 9) as well as numerous food products (Cabral-Marques 2010) can be found using different CDs: α-CD, β-CD, HP-β-CD, RM-β-CD, SBE-β-CD, γ-CD, and HP-γ-CD.

6 Conclusion/Prospects

Since the begin of nineteenth century CDs have been showing their potentialities, and up to today they have gained a great importance and different applications in distinct areas from pharmaceutical and food to chemical and environmental industries. So a prosperous future can be envisaged to CDs being one of the most adaptable and relevant excipient. All this was only possible due to their remarkable characteristics which make them a versatile compound with the ability to form inclusion complexes with guest molecules possessing a hydrophobic moiety (Tiwari et al. 2010).

Due to science evolution, the discovery of new molecules with solubility, bioavailability, and permeability limitations or other undesirable properties (stability, taste and odor, irritation potential, etc.) raises the need for CDs' usage as they can be useful tools for scientists.

CDs can be useful drug carriers in delivery systems as they are bio-adaptable particularly in parenteral applications (especially HP-β-, SBE-β-, and maltosyl-β-CDs), having the ability to control the rate and time of drug release. Peracylated CDs may serve as novel hydrophobic carriers to control the release of water-soluble drugs including peptides and proteins in various routes of administration. Amphiphilic or ionizable CDs can modify the rate or time of drug release and bind to the surface membrane of cells, which may be used for the enhancement of drug absorption across biological barriers. A combination of molecular encapsulation with other pharmaceutical excipients is effective and valuable in the improvement of carrier properties of CDs. Conjugates of a drug with CDs can be a versatile drug site-specific carrier for colon therapy; they form a new class of colon-targeting prodrugs (Uekama et al. 1998; Uekama 2004; Li and Loh 2008).

There are more than 100 different CD derivatives commercially available as fine chemicals, mainly for use in chromatography, in diagnostics, and as intermediate for further synthesis. The ideal derivative does not exist yet. It is expected that more derivatives will be developed. For organ or receptor targeting, extremely stable, bio-adaptable, and specific affinity-showing CD complexes will be needed (Cabral-Marques 2008; Kurkov and Loftsson 2012).

Despite of all the unique architecture and the chelating properties that CDs present, the usage of this excipient is not by itself a reason to achieve a successful goal without previous studies. In fact a great knowledge of the characteristics of all the compounds intended to be used (CDs, guest molecule, additives to the product)

Table 9 Commercialized pharmaceutical products containing cyclodextrins (Adapted from Szejtli 2005; Hincal et al. 2011; Kurkov and Loftsson 2012)

Cyclodextrin	Drug	Therapeutic usage	Formulation	Trade name
α-CD	Alprostadil	Treatment of erectil dysfunction	Intracavernous solution	Caverject, rigidur, dual, edex
	Alprostadil (PGE1)	Chronic arterial occlusive disease, etc	Intra-arterial infusion	Prostodin
	Alprostadil (PGE1)	IA or IV vasodilator	IV solution	Prostarmon
	Alprostadil (PGE1)	IA or IV vasodilator	IV solution	Prostavasin
	Cefotiam hexetil HCl	Antibiotic	Oral tablet	Pansporin T
	OP-1206	Buerger's disease	Tablet	Opalmon
β-CD	Benexate HCl	Anti-ulcerant	Oral capsule	Ulgut, Lonmiel
	Betahistidine	Antivertigo drug	Tablet	Betahist
	Cetirizine	Antibacterial agent	Chewing tablets	Cetrizin
	Cephalosporin	Antibiotic	Tablet	Meiact
	Chlordiazepoxide	Tranquilizer	Tablet	Transillium
	Dexamethasone	Anti-inflammatory steroid	Ointment, tablets	Glymesason, glyteer
	Dextromethorphan	Antitussive (cough suppressant)	Xyrup	Rynathisol
	Diphenhydramine, chlorotheophylline	Travel sickness	Chewing tablets	Stada travel pill
	Flunarizine	Calcium channel blocker	Tablet	Fluner
	Iodine	Throat disinfectant	Gargle	Mena-Gargle
	Meloxicam	Nonsteroidal anti-inflammatory drug	Tablet, suppository	Mobitil
	Nicotine	Nicotine replacement product	Sublingual tablets	Nicorette, nicogum
	Nimesulide	Nonsteroidal anti-inflammatory drug	Tablets	Nimedex, mesulid fast
	Nitroglycerin	Coronary dilator	Sublingual tablets	Nitropen
	Omeprazole	Proton-pump Inhibitor	Capsule	Omebeta
	PGE2	Induction of labor	Sublingual tablets	Prostarmon E
	Piroxicam	Nonsteroidal anti-inflammatory drug	Tablets	Brexin, brexidol
	Piroxicam		Suppository	Cycladol

(*continued*)

Table 9 (continued)

Cyclodextrin	Drug	Therapeutic usage	Formulation	Trade name
	Piroxicam	Analgesic for pediatric use	Liquid	
	Rofecoxib	Nonsteroidal anti-inflammatory drug	Tablet	Rofizgel
	Tiaprofenic acid	Analgesic	Oral tablet	Surgamyl
	Thiomersal	Antiseptic/ antifungal	Eye drop	Vitaseptol
HP-β-CD	Alfaxalone	Veterinary anesthetic		
	Cisapride	Gastroprokinetic agent	Suppository	Propulsid
	Hydrocortisone	Mouthwash (aphtha, gingivitis, etc.)	Liquid	Dexacort
	Indomethacin	Nonsteroidal anti-inflammatory drug	Eye drop solution	Indocid
	Itraconazole	Antifungal agent	Oral and IV solutions	Sporanox
	Mitomycin	Anticancer agent	IV infusion	Mitozytrex MitoExtra
	Telavancin	Bactericidal lipoglycopeptide	IV infusion	Vibativ
RM-β-CD	17β-Oestradiol	Hormone	Nasal spray	Aerodiol
	Chloramphenicol	Antibiotic	Eye drop solution	Clorocil
SBE-β-CD	Aripiprazole	Antipsychotic drug	IM solution	Abilify
	Amiodarone	Antiarrhythmic agent	IV	Nexterone
	Insulin	Diabetes	Nasal spray	
	Maropitant	Antiemetic drug (motion sickness in dogs)	Parenteral solution	Cerenia
	Voriconazole	Antifungal agent	IV solution	Vfend
	Ziprasidone mesylate	Antipsychotic drug	IM solution	Geodon, Zeldox
γ-CD	Minoxidil	Stimulate hair growth	Solution	Alopexy
	Sugammadex (as sodium salt)	Antidote (modified γ-CD)	IV solution	Bridion
HP-γ-CD	Diclofenac sodium salt	Nonsteroidal anti-inflammatory drug	Eye drop solution	Voltaren Ophtha
	Tc-99 Teoboroxime	Diagnostic aid, cardiac imaging	IV solution	CardioTec
SL-CD	Modified porcine (circovirus inactivated)	PCV2 vaccine	Suspension for injection	Suvaxyn PCV

and prior work are extremely necessary to try to predict and find out any possible interaction between them, just because these interactions can adversely affect the performance of these constituents, which can lead to incompatibilities, formulation problems, lack of stability, etc., and consequently have a great impact in the final commercialized product. In conclusion, the ideal scenario would be to choose the CD that has the most appropriate characteristics to include the desired guest molecule, predict all the different variables that can influence the complex formation process, and in the end be able to prepare a product with the desirable properties that can be an innovation or an improvement and at last but not the least be economically viable.

Cellulosic Biomaterials

10

Holger Wondraczek and Thomas Heinze

Contents

Abstract

Cellulose, the most abundant polymer on earth, holds a big potential for different applications in the biomedical field. This book chapter summarizes recent advances of cellulose research with respect to the new biomaterials paradigm. In this context, it is intended to give the reader an overview on the huge variety of cellulosic structures that are provided by nature or can be man-made. It highlights important examples of historical and recent cellulosic biomaterials and touches certain aspects of ongoing developments, which may form the basis for future applications.

Keywords

Structure • Biosynthesis • Bacterial cellulose • Nanomaterials • Tissue engineering • Wound treatment • Drug delivery • Cellulose derivatives

1 Introduction and Scope

Although cellulose and many of its derivatives possess unique properties including hydrophilicity, polyfunctionality, inherent biocompatibility, and last but not least, the ability to form supramolecular structures, they were typically not considered as classical biomaterials. According to the Consensus Conference on Definitions in Biomaterials Science, in 1986, which determined a biomaterial to be "a non-viable material used in a medical device, intended to interact with biological systems" (Williams 1987), only a very limited number of cellulosics were understood as biomaterials. However, in the context of the continuous development in materials science and health technology, the biomaterials paradigm has evolved to:

> A biomaterial is a substance that has been engineered to take a form which, alone or as part of a complex system, is used to direct, by control of interactions with components of living systems, the course of any therapeutic or diagnostic procedure, in human or veterinary medicine. (Williams 2009)

As a consequence of this changed understanding of what biomaterials are, cellulose and its derivatives are constantly studied for their applicability, for example, in tissue engineering, drug delivery, and diagnostics.

This chapter is not intended to exhaustively cover the published literature on cellulosic biomaterials. Instead, important concepts regarding the use of cellulose and cellulose derivatives in the field will be presented with the aim to enable the reader to further explore these concepts towards new applications in medical technology. For this purpose fundamental information on the structure, processing, and derivatization of cellulose will be provided as well as selected examples of well-known and quite recent developments of advanced cellulosic (bio)materials.

2 Sources of Cellulose

Cellulose is distributed throughout nature in plants, animals, algae, and fungi (Fig. 1). However, the majority of cellulose sources are plant fibers. Cellulose contributes approximately 40 % to the carbon fraction in plants, serving as structuring element within the complex architecture of the plant cell walls. Cellulose may occur in pure form in plants but it is usually accompanied by hemicelluloses, lignins, and comparably small amounts of extractives. Wood contains about 40–50 wt% cellulose. Comparable amounts can be found in bagasse (35–45 wt%), bamboo (40–55 wt%), and straw (40–50 wt%) and even higher in flax (70–80 wt%), hemp (75–80 wt%), jute (60–65 wt%), kapok (70–75 wt%), and ramie (70–75 wt%), whereas cotton represents a pure cellulose source containing more than 90 wt% (Hon 1996). It is an impressive amount of cellulose that is produced in one year, not only by wood fibers from trees with 1,750,000 kt world production but also in 1-year plants including bamboo (10,000 kt), cotton linters (18,450 kt), jute (2,300 kt), flax (830 kt), sisal (378 kt), hemp (214 kt), and ramie (100 kt), for instance (Eichhorn et al. 2001). In addition, several fungi and green algae produce cellulose

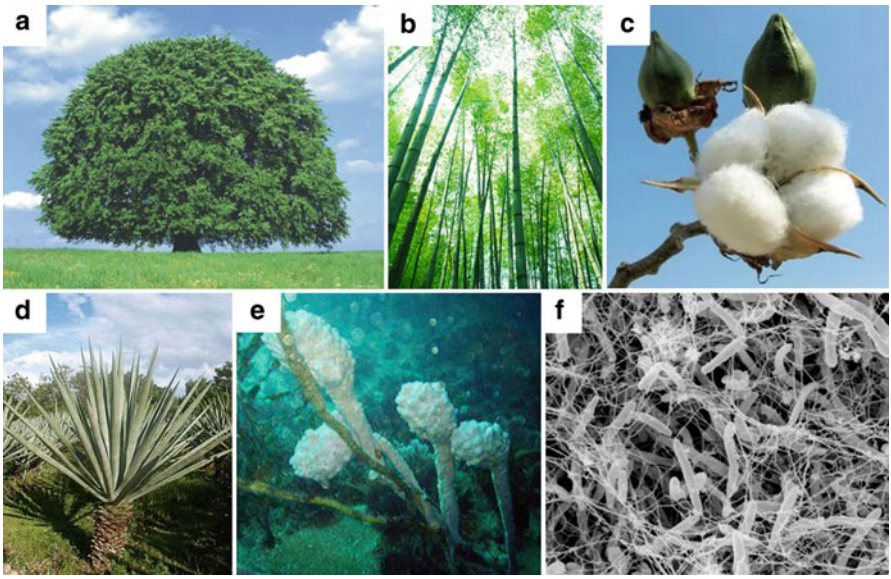

Fig. 1 Selection of important cellulose sources: (**a**) hardwood (beech tree), (**b**) bamboo, (**c**) cotton, (**d**) sisal, (**e**) tunicine, and (**f**) *Gluconacetobacter xylinus* (Reproduced from Schubert et al. (2011) with permission)

(e.g., *Valonia ventricosa*, *Chaetomorpha melagonicum*, *Glaucocystis*) and some animals such as ascidians, which are marine animals that contain cellulose in the outer membrane. Moreover, bacteria of the genera *Gluconacetobacter*, *Agrobacterium*, *Pseudomonas*, *Rhizobium*, and *Sarcina* can synthesize bacterial cellulose from glucose and various other C sources (Vandamme et al. 1998; Jonas and Farah 1998). Bacterial cellulose, which is produced directly in the form of a fibrous network, contains no lignin, pectin, hemicelluloses, and other biogenic products, is highly crystalline, and possesses high DP values.

3 Structure of Cellulose

3.1 Molecular Structure

The molecular entity of cellulose is a chain of D-anhydroglucopyranose units (AGUs) connected by glycosidic β-(1 → 4) linkages (Fig. 2). The six-membered AGU rings are in the energetically favored chair conformation with C4 and C1 out of the reference plane containing the four other ring atoms ($^4C_1$ conformation) (Rao et al. 1957). The AGUs are decorated with two secondary hydroxyl groups in positions 2 and 3 and one primary hydroxyl group in position 6, while the oxygen atom at position 4 (and 1, respectively) is part of the interunit linkage. Resulting from the β-(1 → 4) linkages, cellulose chains have a twofold helical conformation,

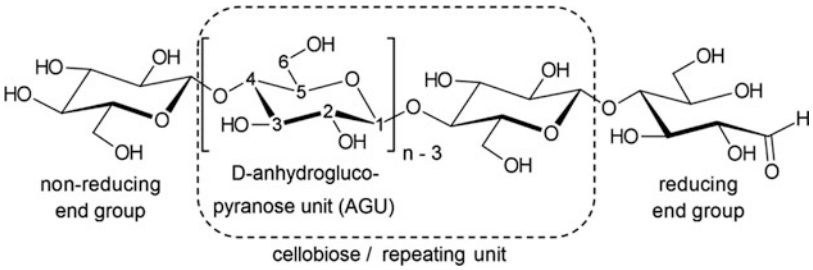

Fig. 2 Schematic drawing of the molecular structure of cellulose including conventional numbering of the C atoms of D-anhydroglucopyranose units; n = degree of polymerization (DP)

meaning that the main planes of every second AGU is turned by 180° (French et al. 2003). Thus, the structural repeating unit of cellulose molecules is cellobiose with a linear repeat length of 1.3 nm (Krässig 1993). The terminal groups of the polymeric chains are chemically different. The anomeric carbon atom of one end group is part of a glycosidic linkage, and this end group carries an additional secondary hydroxyl group in position 4. The other end group is a D-glucose unit, which is present in the cyclic hemiacetal form in equilibrium with the open-chain aldehyde form. Since the aldehyde group possesses reducing properties, the latter group is termed as reducing end group, while the other one is termed as nonreducing end group. The number of AGUs plus two for the end groups is defined as the degree of polymerization (DP) of cellulose.

Overall, cellulose has the most clearly defined molecular structure among all polysaccharides (and many synthetic polymers) in terms of chemical purity and structural identity, which is independent of the raw material cellulose is isolated from. Some minor deviations from the ideal molecular structure occur due to processing and purification steps required for isolation of cellulose from its natural sources as well as due to environmental stress and aging. For example, small amounts (4–40 mmol/kg) of oxidized functionalities like carbonyl and carboxyl groups are formed during the isolation of cellulose from wood (pulping) or cotton.

3.2 Hydrogen Bonds and Crystallinity of Cellulose

There are numerous possibilities for the formation of hydrogen bonds between the three hydroxyl groups of the AGU and the oxygens of both the ring and the glycosidic linkage. They are considered to have a strong influence on the properties of cellulose and give rise to various three-dimensional structures beyond the molecular entity. For example, the intramolecular hydrogen bonds between the OH groups of C3 and the adjacent ring oxygen of the AGUs as well as those between the hydroxyl oxygens at C6 and the adjacent OH groups at position C2 in combination with the β-glycosidic linkage are responsible for the relatively high stiffness and rigidity of cellulose molecules, on the one hand (Fig. 3) (Krässig 1993;

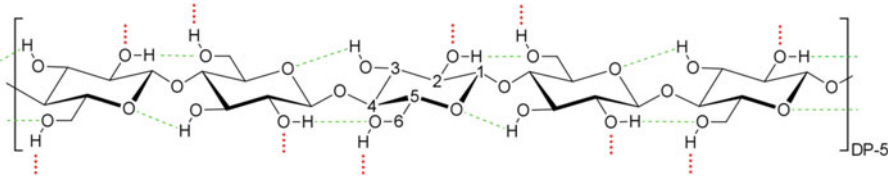

Fig. 3 Schematic representation of intra- (*green dashed*) and intermolecular (*red dotted*) hydrogen bonds of cellulose (Adapted from Tashiro and Kobayashi 1991)

Tashiro and Kobayashi 1991). On the other hand, the intermolecular hydrogen bonds, in particular between the OH groups of C6 and the oxygen of C2 of adjacent AGUs of other cellulose chains, are the main bonds stabilizing the cellulose network.

The intramolecular hydrogen bonds and the resulting chain stiffness as well as the intermolecular secondary valences cause the organization of cellulose in structures sufficiently regular to exhibit a crystalline X-ray diffraction pattern. Thus, X-ray diffraction has been extensively employed to determine the structure of cellulose including the index of crystallinity $I_C = [I_{Crystalline}/(I_{Crystalline} + I_{Amorphous})]$, for the calculation of the crystallite length and width, and for probing the inter- and intramolecular hydrogen bonds in native cellulose. As a result, cellulose polymorphism as a prominent structural feature was revealed. It was shown that native cellulose exits in two crystalline allomorphs, namely, cellulose I_α and cellulose I_β. Cellulose I_α is characterized by a one-chain triclinic unit cell with all the glycosyl linkages and the hydroxymethyl groups identically oriented and the chains organized in sheets packed in a "parallel-up" fashion. The structure of I_β differs from that of I_α in having two unique sheets containing conformationally distinct chains with different hydrogen bonding in a monoclinic unit cell (Fig. 4) (Nishiyama et al. 2003).

Besides cellulose I, several other polymorphs can be obtained from native cellulose by different treatments (Fig. 5). The most prominent and, from a technical point of view, most important one is cellulose II. It is obtained when cellulose I is either dissolved and precipitated (regeneration) or treated with a swelling agent, e.g., aqueous sodium hydroxide of >18 wt %, and washed with water (mercerization). The transformation of cellulose I to cellulose II is irreversible since cellulose II is thermodynamically more stable. The crystal structure of cellulose II is characterized by a two-chain monoclinic unit cell with antiparallel orientation of the chains.

The crystalline modification of cellulose III is obtained by treating native cellulose with liquid ammonia (below −30 °C) or an organic amine such as ethylene diamine, followed by washing with alcohol. Small differences in lattice dimensions exist between the two submodifications cellulose III_I and III_{II}. As the fourth modification reported so far, cellulose IV is formed upon treatment of cellulose III in a suitable liquid at high temperature and under tension.

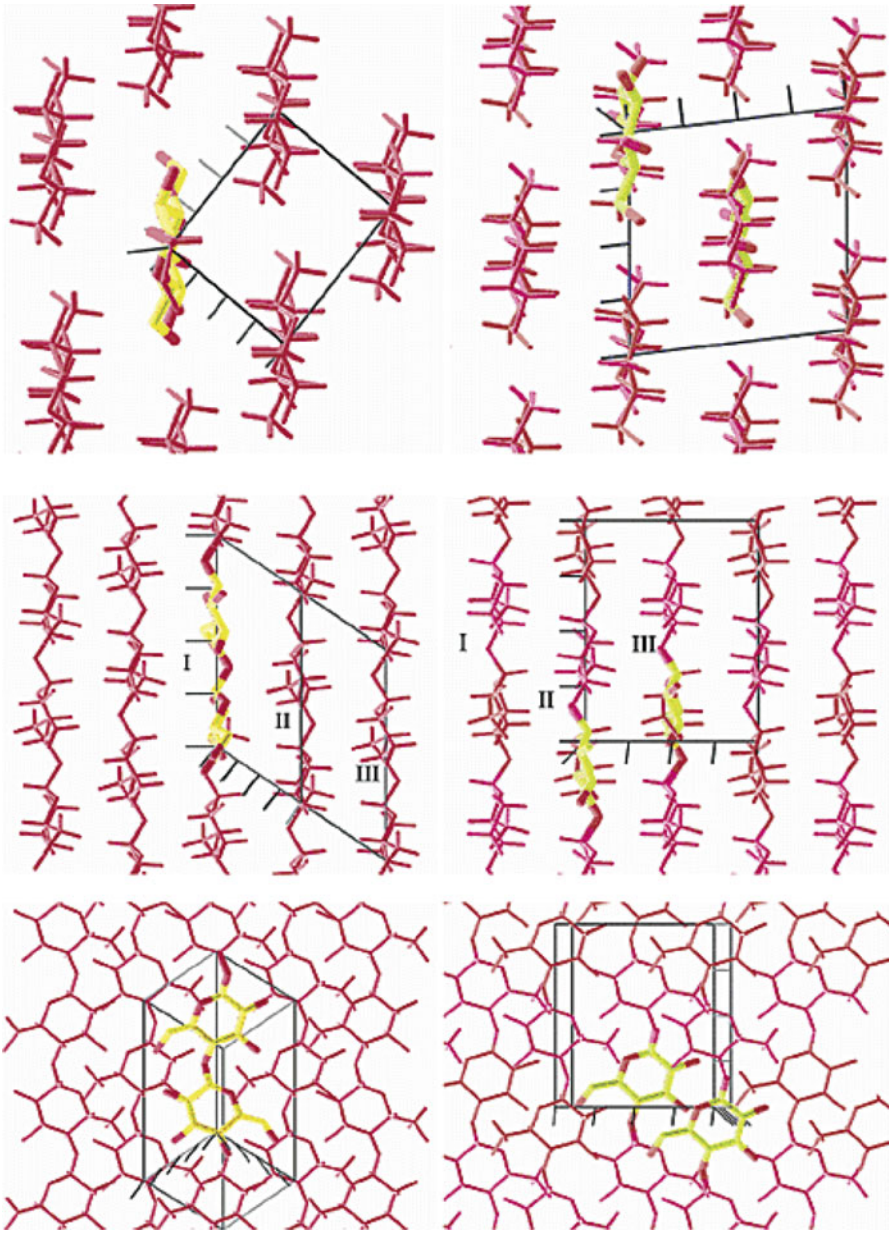

Fig. 4 Projections of the crystal structures of cellulose I_α (*left*) and I_β (*right*) down the chain axes (*top*), perpendicular to the chain axis and in the plane of the hydrogen-bonded sheets (*middle*), and perpendicular to the hydrogen-bonded sheets (*bottom*). The cellulose chains are represented by *red* skeletal models. The asymmetric unit of each structure is also represented in *thicker lines* with carbons in *yellow*. 3.3 Biosynthesis of Cellulose and Morphological Structure of Native Cellulose

3.3.1 Glucose Polymerization

The glucose polymerization toward glycans is in general accomplished by β-glycosyltransferases that catalyze the transfer of sugar residues from activated donor sugars to acceptor molecules. In the case of the cellulose synthase family, the only substrate is uridine 5′-diphosphoglucose (UDPGlc), which can be formed along two different pathways (Fig. 6) (Coleman et al. 2006). The first is the cleavage of sucrose by sucrose synthase, liberating fructose and UDPGlc. The second one relies on phosphorylation of D-glucose in position 6 by the enzyme glucokinase and the active isomerization of D-glucose-6-phosphate to α-D-glucose-1-phosphate by the enzyme phosphoglucomutase. Finally, α-D-glucose-1-phosphate is converted to alpha-linked UDPGlc.

The actual polymerization of UDPGlc toward cellulose is accomplished by the catalytic subunits, i.e., cellulose synthase (CESA), of a complex oligomeric assembly of enzymes. The precise structure and the way of working of this enzyme complex (frequently termed as terminal enzyme complex, TEC) as well as of its subunits are, almost 40 years after their discovery, not fully understood and thus still subject of intensive research efforts (Mutwil et al. 2008; Joshi and Mansfield 2007). According to the actual knowledge, the CESA proteins are tightly anchored in the cytoplasmic membrane, both in plants and in prokaryotes. It is presumed that the globular fragments of the CESAs are located at the cytoplasmic face. These

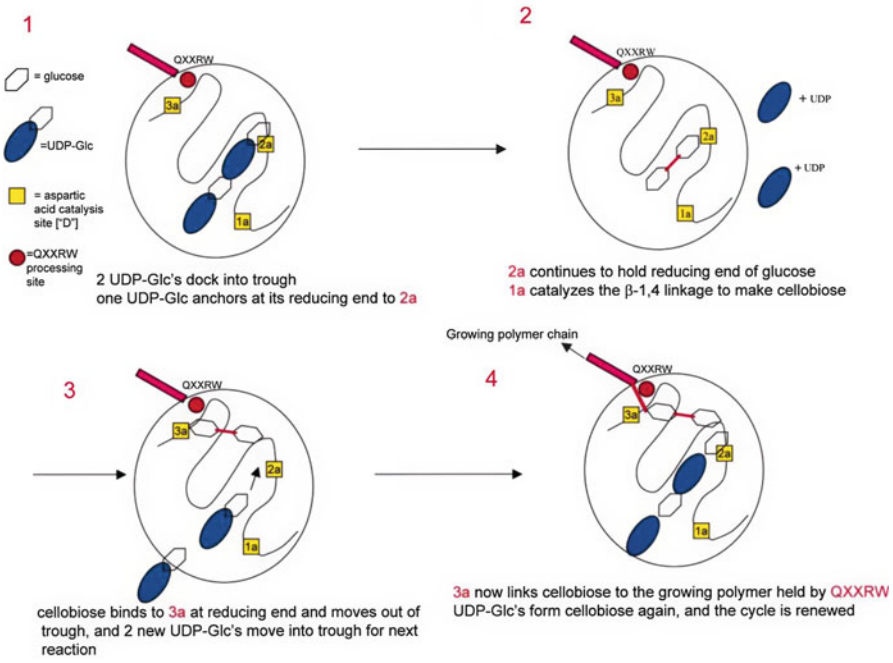

Fig. 7 Generalized model for the polymerization reactions leading to the formation of β-1,4-glucan chains in cellulose biosynthesis (Reproduced from Brown and Saxena (2000) with permission)

globular fragments contain three catalytic sites with aspartic acid residues as crucial elements, which transfer the glucopyranose units from UDPGlc to the nonreducing end of the growing glucan chains in consecutive manner. The generalized model of Brown and Saxena (2000) suggests that one catalytic site (2a) dock two UDPGlc molecules in the binding pocket (Fig. 7(1)). The second catalytic site (1a) catalyzes the formation of the β-1,4-linkage between the two glucose units under the release of two UDP molecules and thus accomplishes the synthesis of the cellobiose unit as the polymeric repeating unit (Fig. 7(2)). The third catalytic site (3a), which is in the vicinity of a Gln-X-X-Arg-Trp (QXXRW) motif, drags the reducing end of the cellobiose unit out of area 1a/2a, where subsequently two new UDPGlc molecules are bound and the next cellobiose unit is formed (Fig. 7(3)). In the next step, the QXXRW motif forces the reducing end of the cellobiose unit to the site of extrusion. Simultaneously, 3a drags the next cellobiose unit toward QXXRW and links it to the nonreducing end of the growing chain, while the 1a/2a region binds two more UDPGlc to repeat the cycle (Fig. 7(4)). Interestingly, this mechanism would require no primer for the initiation of cellulose biosynthesis, and the two UDPGlcs simultaneously docking to the binding pocket to first form cellobiose, which is then transferred to the growing chain, give an elegant explanation for the twofold helical conformation of cellulose (French et al. 2003). Moreover, this

model, based on structural data of different CESAs derived from the encoding genome, is in good agreement with experimental data, for example, from microdiffraction studies, which prove both that the reducing ends of nascent cellulose chains are directed away from the cells and the "parallel-up" packing in native cellulose I crystals (Koyama et al. 1997).

3.3.2 Morphological Organization of Cellulose

Besides the underlying molecular structure, the morphological structure of cellulose is of high importance for the apparent properties of cellulosic materials. In the case of native cellulose, the extrusion of cellulose chains and the associated hydrogen bond-based organization gives rise to a broad variety of properties, which are evolutionarily related to the physiological function of cellulose in the originating organism. In this regard, the most interesting aspect is the great diversity of the structure of the terminal enzyme complexes (TECs), along the cellulose-producing species, which implies a fundamental diversity of the supramolecular arrangement (Fig. 8). As highlighted by Brown (1996), the structure of the TEC is related, for example, to the size and shape of the microfibrils as well as to the crystallization process. Thus, the wish of many researchers to understand the diversity of the TEC complexes is not only scientifically motivated but plays also a role for the applicability of cellulosics, for example, as biomaterials. Moreover, the enormous developments in the field of genetic engineering allow nowadays to tune the properties of cellulosic materials by changing the characteristics of the cellulose source, in particular in the case of bacteria, at the very fundamental level of the structure of TECs.

In the following the role of the organization of the TECs and the resulting morphological structure of native celluloses will be discussed based on the examples of plant and bacterial cellulose.

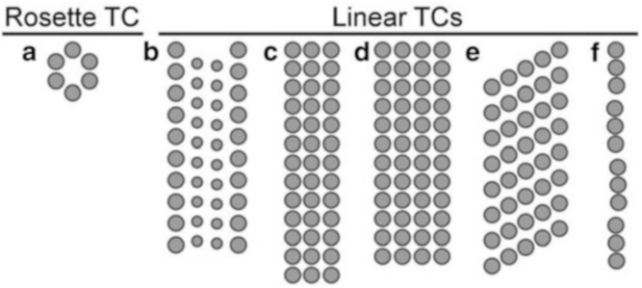

Fig. 8 Schematics of rosette and linear terminal enzyme complexes (*TCs*), for (**a**) plants (6 chains/subunits) and green algae (*Micrasterias*), (**b**) tunicate (*Metandroxarpa uedai*) (unknown number of chains/subunit), (**c**) green algae (*Valonia*) (10–12 chains/subunits), (**d**) red algae (*Erythrocladia*) (4 chains/subunits), (**e**) yellow-green algae (*Vaucheria*) (1 chain/subunit), and (**f**) bacterial (*Acetobacter*) (16 chains/subunits). Each *dark circle* represents a single subunit (Reproduced from Moon et al. (2011) with permission)

3.3.3 Plant Cellulose

For vascular plants, the ultrastructural morphology of the TECs was first described by Mueller and Brown (1980). By freeze-fracturing of rapidly frozen, untreated plant cells of *Zea mays*, they could show that the structures of the cell membranes, which are associated with the ends of individual cellulose microfibrils, have a sixfold symmetrical arrangement of transmembrane particle subunits (Fig. 9a). More recently, it was demonstrated that each subunit of these rosette TECs consists of six individual CESA proteins (Kimura et al. 1999). Interestingly, at least three different types of CESA are required to form a functional rosette complex that is capable to produce cellulose and crystallize it into cellulose I_α in the cell wall matrix (Desprez et al. 2007) (Fig. 9b).

During the coordinated action of enzymatic polymerization of cellulose by the 36 individual CESAs at the TEC, 36 highly extended cellulose chains are generated and simultaneously crystallized (Fig. 10). It has been shown that the first products of the crystallization phase are β-glucan minisheets, which each consists of six cellulose chains originating from the subunits of the TEC and holds together predominantly by van der Waals forces (Cousins and Brown 1995). The minisheets are directed to the center of the rosette complex and crystallize there to the metastable cellulose I, so-called elementary fibril, predominantly on the basis of hydrogen bond interactions (Brown and Saxena 2000). Besides the crystalline parts, the areas containing crystalline defects such as dislocations, chain ends, and twists as well as the crystal surface contribute to the less ordered amorphous cellulose. Altogether, the basic units generated by the TEC have lateral dimensions between

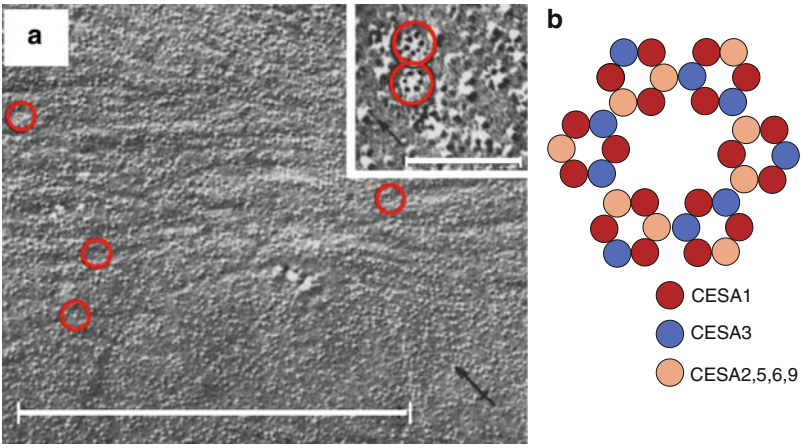

Fig. 9 Structure of terminal enzyme complexes in vascular plants: (**a**) scanning electron microscopy image of freeze-fractured cell membrane of *Zea mays* showing intermembrane particle (*circles*) possessing a symmetrical, rosette-like arrangement of six subunits (*inset*), scale bar is 1 μm; (**b**) schematic view on rosette complex visualizing the six individual CESA proteins of the rosette subunits. CESAs 1 and 3 occupy positions that are exclusively for these CESAs. CESAs 2, 5, 6, and 9 appear to be interchangeable for the other positions (Reproduced from Mueller and Brown (1980) (**a**) and Mutwil et al. (2008) (**b**) with permission)

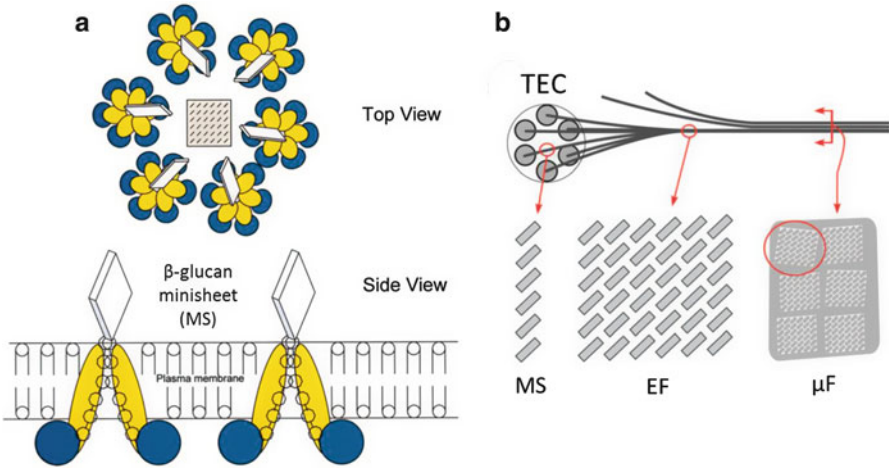

Fig. 10 Schematic model of the formation of supramolecular structures of cellulose by the terminal enzyme complex (*TEC*) in vascular plants: (**a**) spatial organization of the cellulose synthase proteins in the TEC and its impact on the formation of elementary fibrils of cellulose; (**b**) formation of the different structural levels within the TEC. *MS* denotes for the minisheet cross section believed to be formed from the rosette subunits, whereas each *gray box* represents a cellulose chain looking down the chain axis. *EF* denotes the cellulose I crystal lattice of an elementary fibril cross section formed by six minisheets. *μF* denotes the cross section of a microfibril formed by consolidation of multiple elementary fibrils (Reproduced from Brown and Saxena (2000) (**a**) and Moon et al. (2011)(**b**) with permission)

1.5 and 3.5 nm and lengths of about several 100 nm (Moon et al. 2011). Depending on the synthesizing species and the distribution pattern of the TECs on the cell surfaces, the elementary fibrils are assembled to higher structures like micro- and macrofibrils or fibrillar bands, which possess diameters/widths between 10 and 100 nm and lengths in the micrometer range.

In higher plants the fibrils and fibrillar bands represent the construction units of the cell wall. As exemplarily shown for spruce wood, in which the macroscopic fibers originate from single plant cells, the cell wall architecture is characterized by different layers, namely, the primary wall (P), the secondary wall composed of an outer (S1) and inner layer (S2), and the lumen wall (S3) (Fig. 11) (Agarwal 2006). Each of the cellulosic layers (P, S1, S2, and S3) is basically a mesh of fibrils with different density, texture, and thickness. The primary cell wall, which contains besides cellulose larger amounts of hemicelluloses, pectins, and proteins, is less than 0.1–0.2 μm and contributes only 1–4 % to the total weight of wood fiber. The different lamellae of the P-wall are characterized by the orientation of their cellulose microfibrils. In the outer lamella, the microfibrils form an irregular network, whereas in the inner lamella, they have a nearly transverse orientation. The three-layered secondary wall is in total 3–5 μm thick. The S2 layer with a thickness of 2–4 μm and 80–85 wt % of the total cellulose content is the dominant feature, whereas the S1 and S3 layers are 0.2–0.3 and 0.1 μm thick, respectively. In general, the microfibrils of the secondary cell wall are oriented parallel to each

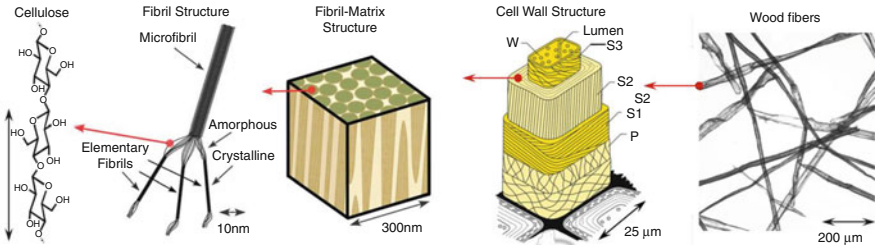

Fig. 11 Different structural levels of cellulose molecules in the plant cell wall (Adapted from Moon et al. 2011 and Agarwal 2006)

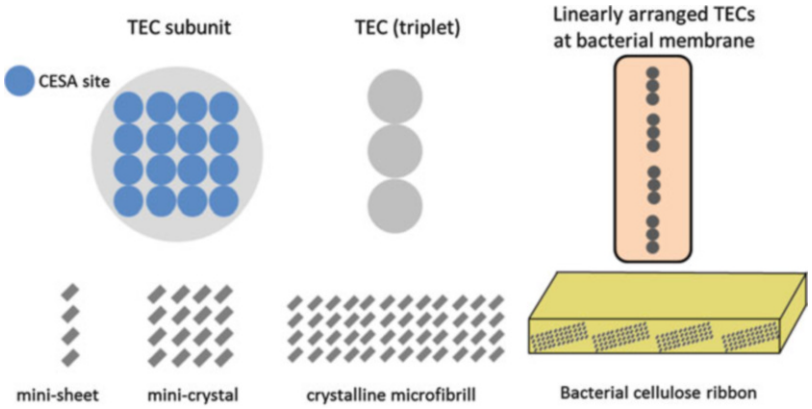

Fig. 12 Schematic representation of the structure of the terminal enzyme complex of *Acetobacter xylinum* and the related structural levels of the bacterial cellulose produced (Adapted from Brown 1996)

other, but the particular texture differs between the layers. In the S1 and S3 layers, the fibrils are tightly wound in helices at nearly transverse orientation with an angle of 60–90° with respect to the cell axis. In contrast, the microfibrils in the S2 layer are arranged in parallel extended helices possessing a comparably small angle of 5–30° to the cell axis.

3.3.4 Bacterial Cellulose

The morphological structure of cellulose formed by bacteria such as particular *Acetobacter* strains (reclassified as the genus *Gluconacetobacter*) differs remarkably, although the principal way of working of the CESA proteins is the same as in plants and consequently the molecular structure is identical. The most important difference is the alternative structure and organization of TECs of cellulose-producing bacteria. In *Gluconacetobacter xylinus*, the TECs are linear assemblies of a minimum of three massive, basket-shaped subunits (Brown 1996). It is presumed that the subunits contain at least 16 catalytic CESA sites in a not completely understood spatial distribution (Fig. 12). It was shown that the subunits

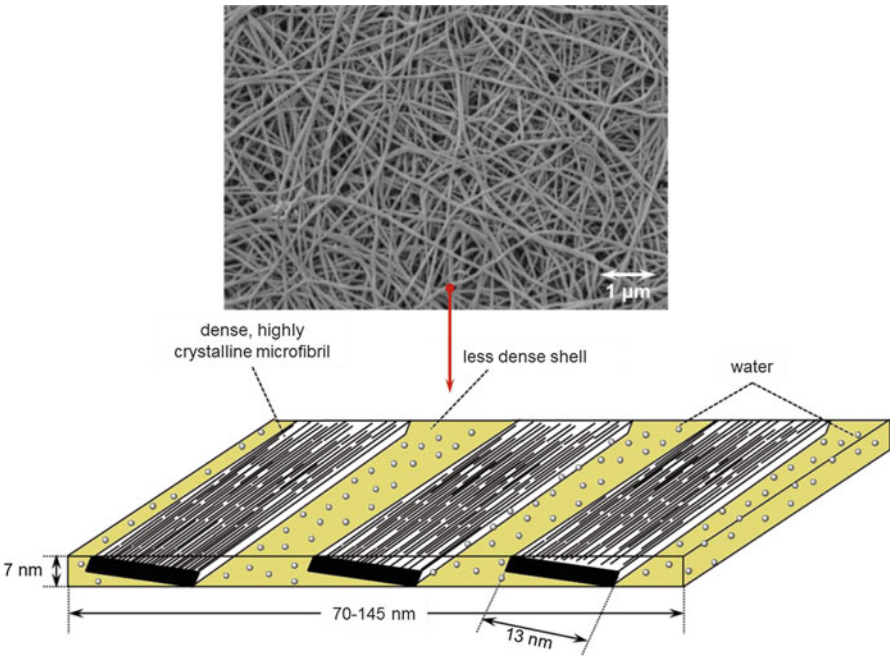

Fig. 13 Scanning electron microscopy image showing the microfibrillar ribbons of bacterial cellulose from *Acetobacter xylinum* (*top*) and model of the ribbons in the wet state as produced by the bacteria (*bottom*) (Adapted from Fink et al. 1997 and Astleya et al. 2001)

produce four-membered minisheets, which are held together predominantly by van der Waals interactions (Brown et al. 1982; Cousins and Brown 1995). These minisheets further assemble to minicrystals, which can be isolated as the smallest crystalline cellulose entity when producing cellulose with a model system consisting of individual subunits of bacterial TECs in vitro (Lin et al. 1985). In vivo, the linear arrangement of the three subunits of the TEC along the longitudinal axis of the bacteria ensures the hydrogen bond-driven consolidation of minicrystals in a highly crystalline microfibril with a rectangular cross section of about 5 × 13 nm.

As a consequence of the presence of 50–80 TECs at the membrane of each single bacterium, the microfibrils are associated into several twisted ribbons, which represent the largest morphological entities of bacterial cellulose. As exemplarily shown in Fig. 13, the ribbon structure is characterized by the dense, highly crystalline cellulose microfibrils surrounded by a shell of noncrystalline polymer chains (Astleya et al. 2001; Fink et al. 1997). The ribbon has a rectangular cross section of about 10 × 50 nm. Although Fig. 13 shows a regular arrangement of microfibrils within the ribbon, it is still debated how many microfibrils are in a single ribbon and how they are packed (Astleya et al. 2001; Fink et al. 1997; Brown et al. 1976). Thus, the arrangement shown represents merely a possibility. Overall, bacterial cellulose (BC) appears as a highly hydrated (>90 % water) network of nanoscale ribbon-like structures that can be obtained as a chemically very pure

cellulosic material by a simple washing process. The very porous structure readily permits the introduction of solutes and solids in the structure and thus makes BC an even more interesting material. Moreover, the morphological structure and thus the properties of BC can be tuned toward desired applications. For this purpose, it is possible to vary the culture conditions or to tailor the bacterial strain in terms of the density and arrangement of the TECs at the cell membrane by means of methods of genetic engineering (Lin et al. 2013).

4 Application of Native Cellulosics as Biomaterials

Historically, native cellulose materials, i.e., cellulosics in which the supramolecular and ultrastructural features formed during the biosynthesis are preserved, were not considered as biomaterials at all. However, during the last two decades, the special properties arising from the nanoscale architecture of native cellulose brought it into focus of biomaterial science and led already to different commercially available products. This section will illustrate these ongoing developments and will also include some aspects, which demonstrate that the full potential of native cellulose regarding biomaterials is far from being completely explored yet.

4.1 Bacterial Cellulose

The network of numerous nanoscale ribbons composed of highly crystalline and almost uniaxially oriented microfibrils (see Sect. 3) makes bacterial cellulose (BC) a resilient and elastic material, possessing a relatively high tensile strength (even in the wet state), an extremely hydrophilic surface, a high water binding capacity, and an excellent biological affinity. Moreover, compared to plant cellulose, BC can be obtained in a very pure form by simple washing (containing no hemicelluloses and lignin) and only a very low extent of carbonyl and carboxyl moieties is present (Schubert et al. 2011). As a consequence, BC possesses also an excellent biocompatibility as demonstrated by an in vivo study of subcutaneous BC implantation in rats (Fig. 14) (Helenius et al. 2006). Another important feature of BC is the in situ moldability, i.e., the shaping during the biosynthesis, which allows the fabrication of complex scaffold structures (Roberts et al. 1986). These properties are drawing more and more attention and BC has been explored as material for wound dressing, tissue repair, and medical implants.

4.1.1 Wound Treatment

BC is considered to recover the biological and structural functions of the skin in wound treatment, and it has been shown that it fulfills a set of requirements to be a modern wound care material (Czaja et al. 2006). It is nontoxic, non-pyrogenic, biocompatible, and able to provide barrier against infection. Due to its osmotic-diffusive properties (mainly water holding capacity and water release rate), BC is able to control fluid loss, to create and maintain a moist environment in the wound, and to absorb exudates during the inflammatory phase of wound healing. Moreover,

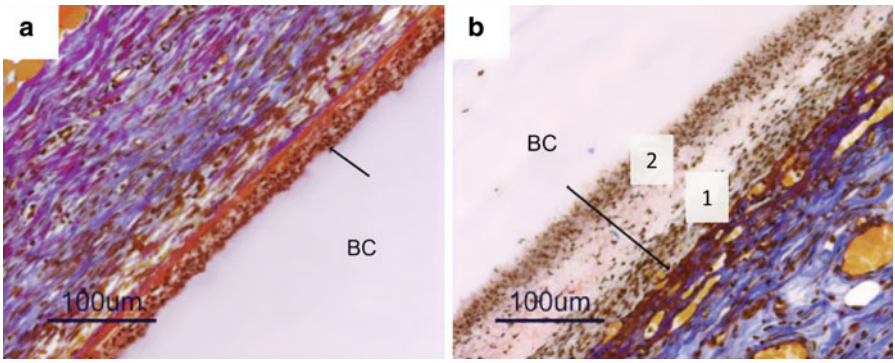

Fig. 14 Microscope images showing the interfaces of a bacterial cellulose sheet 1 week after subcutaneous implantation to rat. Ladewig's trichrome staining shows erythrocytes and muscle tissue in *yellow*/*orange*, collagen in *blue*, and nuclei in *dark blue*/*black*. *Arrows* indicate the approximate surface between the implant and the surrounding tissue: (**a**) compact side and (**b**) porous side; *1* indicates the area with fibroblasts with elongated and round regular nuclei, and *2* shows the invasive front of cells with small irregular nuclei. No foreign body reactions (i.e., fibrosis, encapsulation of the implant or giant cells) are seen. The *BC* implant integrates with the surrounding tissue. Blood vessels, with *yellow* erythrocytes inside, are present around and growing into the implant (Reproduced from Helenius et al. (2006) with permission)

Fig. 15 Never dried bacterial cellulose wound dressing applied to different wounds. The unique physical properties of bacterial cellulose allow an excellent shaping, displaying a high degree of adherence to various body contours and even moving parts (Reproduced from Czaja et al. (2006, 2007) with permission)

the unique network structure enables the introduction of (pharmaceutical) active ingredients and their release into the wound including antimicrobial agents, extracellular matrix materials (collagen, elastin, hyaluronan), or growth factors (Wei et al. 2011; Lin et al. 2011). Last but not least, BC stands out for its conformability, which enables easy and close wound coverage and allows an easy and painless release from the wound (Fig. 15).

The clinical performance of BC wound dressings has been evaluated for several skin injury treatments such as basal cell carcinoma/skin graft, severe body burns, facial peeling, sutures, dermabrasions, skin lesions, chronic ulcers, and both donor and receptor sites in skin grafts (Fontana et al. 1990). In particular, in the treatment of chronic wounds such as venous leg ulcers, bedsores, and diabetic ulcers, which

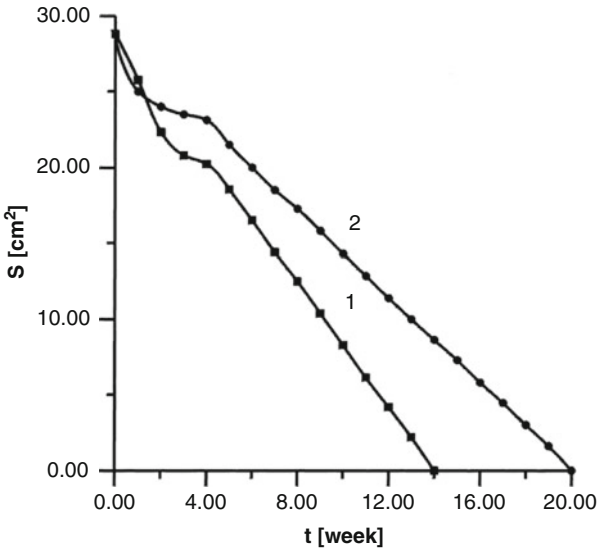

Fig. 16 Results of the comparative therapy of nonhealing venous leg ulcers. Reduction of ulcer areas (*S*) in group *1* treated with bacterial cellulose wound dressing and group *2* treated with Unna's boot (Reproduced from Kucharzewski et al. (2003) with permission)

represent a significant clinical challenge for the difficulty to heal them, BC displays a performance superior to other wound-healing materials. For example, for the therapy of nonhealing venous leg ulcers, it could be shown that a topological treatment with a BC wound dressing compared to a conventional treatment shortened the healing time and decreased the costs of treatment significantly (Fig. 16) (Kucharzewski et al. 2003). Also for the treatment of second- and third-degree burns, which represent the most traumatic and complex skin injuries, can be carried out by means of BC-based wound-healing systems (Czaja et al. 2004). It has been demonstrated that the fully biocompatible BC wound dressings protect burn wounds from excessive fluid loss and absorb wound exudates to the nano-porous structure at the same time. Thus, the entire process of healing could be significantly accelerated (Krystynowicz et al. 2000).

Beyond its use just as a wound-healing treatment, BC can be applied as a scaffold seeded with epithelial cells, thanks to its biocompatibility (see Fig. 14). In this role it could potentially be grafted as a semipermanent artificial skin, inducing epithelial recovery even after the severest epithelial damage. In cases when autografting, often the treatment of choice, is not an option, cell-seeded BC skin substitutes could be an interesting alternative, for example, for indications like large area burns or Stevens-Johnson syndrome.

The commercialization of BC for wound care products was initiated already in the 1980s by Johnson & Johnson who pioneered in investigations of the production of BC on large scale (Ring et al. 1986, 1987). Independently, the Brazilian company BioFill Produtos Biotecnologicos (Curitiba, PR, Brazil) created a new wound-healing

system based on BC (Farah 1990). At present, commercial products are distributed by Lohmann & Rauscher GmbH & Co. KG, Neuwied, Germany, under the brand Suprasorb X® and Xylos Corporation, Langhorne, PA,USA, under the brand XCell®.

4.1.2 Implantable Biomaterials

As demonstrated by the pioneering work of Roberts et al. (1986), it is possible to model BC into different shapes during its synthesis without causing significant alterations of its physical properties like mechanical strength. Going beyond the traditionally fabricated flat BC sheets gives rise to its potential application also as implantable biomaterials. In this regard, science follows two approaches for the use of BC. In the first one, BC acts as a scaffold that is surgically integrated into a biological system and is populated subsequently in vivo by cells of the surrounding tissue. The second approach is the use of BC for in vitro tissue engineering, where the cells are seeded onto the three-dimensional scaffold matrix, which enables the cells to develop into a fully functional tissue. Both approaches require the control of the macro- and microstructure of the material. For this purpose, a variety of techniques is used to direct the BC-producing bacteria to produce virtually any shape or form. Furthermore, the micro- and nanoscale structures can be controlled toward the tailoring of properties such as surface chemistry, porosity, and fiber orientation (Petersen and Gatenholm 2011). Ultimately, the ongoing research in each of these areas led to a promising array of techniques being used for structures whose application as biomaterials will be illustrated in the following.

Vascular Tissue Engineering

As shown by Klemm and coworkers, it is possible to shape BC into tubes with an inner diameter down to 1 mm, lengths of several mm, and a wall thickness of about 0.7 mm by means of a special technique involving aspects of a static culture where cellulose is growing on the oxygen-rich surface of the medium (Klemm et al. 2003). The tubes formed by this technique (brand name BASYC®) possess a smooth inner surface, which avoid the formation of blood clots since it resembles normal blood vessels. Moreover, the tensile strength of about 800 mN is compatible with normal blood vessels, and the tensile tests showed as well that the tubes withstand the blood pressure in living organisms. By implanting such a tube to rat as a replacement of a 4–6 mm-long part of the carotid artery, the excellent performance of BC in small-diameter artificial blood vessels applicable in microsurgery was impressively demonstrated (Fig. 17) (Klemm et al. 2001). It could be shown that the bacterial cellulose/carotid artery complex was covered with connective tissue and infused with small vessels in the living animal after 4 weeks after the implantation. Moreover, histological observations revealed that the inner surface of the tube was completely covered with properly oriented endothelial cells, which actively participate in the inhibition of thrombosis and serve as an anticoagulant surface (Heyligers et al. 2005).

Interesting, besides artificial blood vessels, is also the application of the same type of BC tubes for nerve surgery, which was clinically tested as well (Klemm et al. 2001). It was shown that when using the BC tubes as a protective cover for the sciatic nerve of rat, it prevented connective tissues from growing into the nerve gap

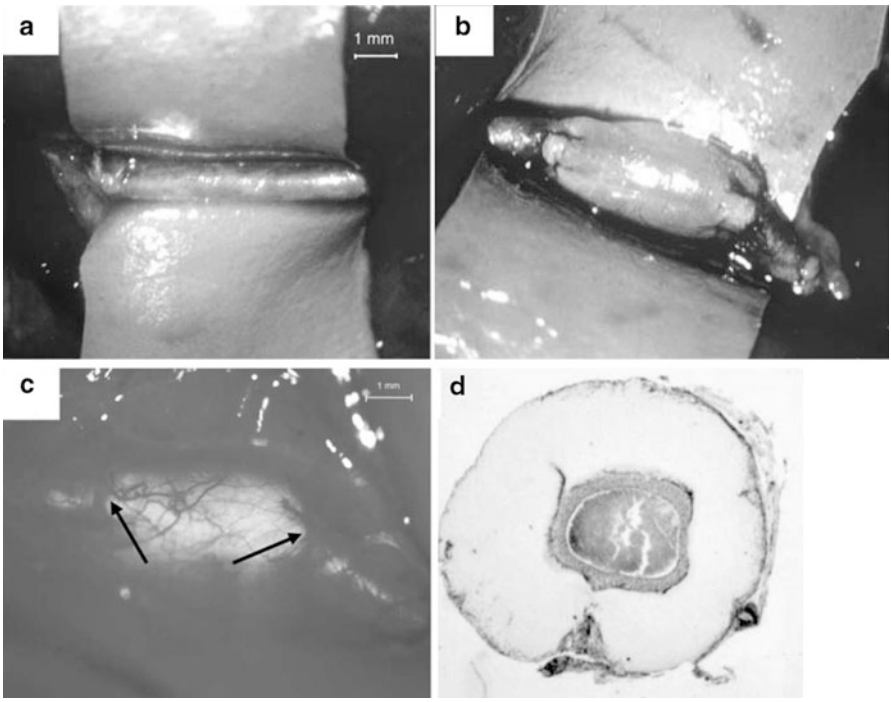

Fig. 17 Usage of a bacterial cellulose tube (BASYC®) as artificial blood vessel for the partial replacement of the carotid artery in rat. (**a**) Preparation of the carotid artery; (**b**) carotid artery with BASYC® interposition immediately after operation; (**c**) carotid artery-BASYC® complex 4 weeks postoperatively (anastomosis areas are indicated with *arrows*); (**d**) histological preparation of carotid artery-BASYC® complex in the *middle* of the region of the interposition 4 weeks after implantation (Reproduced from Klemm et al. (2001) with permission)

and thus facilitated the early regeneration of the nerve. Additionally, it was demonstrated the possibility to augment the BC tubes with a neuroregenerative compound. As a result, an accelerated innervation and improved walking ability was observed in the case of the animals treated with the drug-infused implant.

Avascular Tissues

Recently, BC has also been investigated for the guided regeneration or as scaffold for the engineering of avascular tissues like cartilage and bone. In the guided tissue regeneration, bacterial cellulose is applied as a barrier membrane to enhance the healing process. Like described above for nerve surgery, the implantation of the barrier prevents the formation of scar tissue and can even be used to actively support the regeneration. As, for example, shown in the guided regeneration of maxillofacial, cranial, and periodontal bone defects, the physical barrier prevents the fast ingrowth of fibroblast cells and thus allows the slower process of osteogenesis to occur (Mendes et al. 2009). A good performance for this kind of application was obtained when using Gengiflex® membranes, which are a

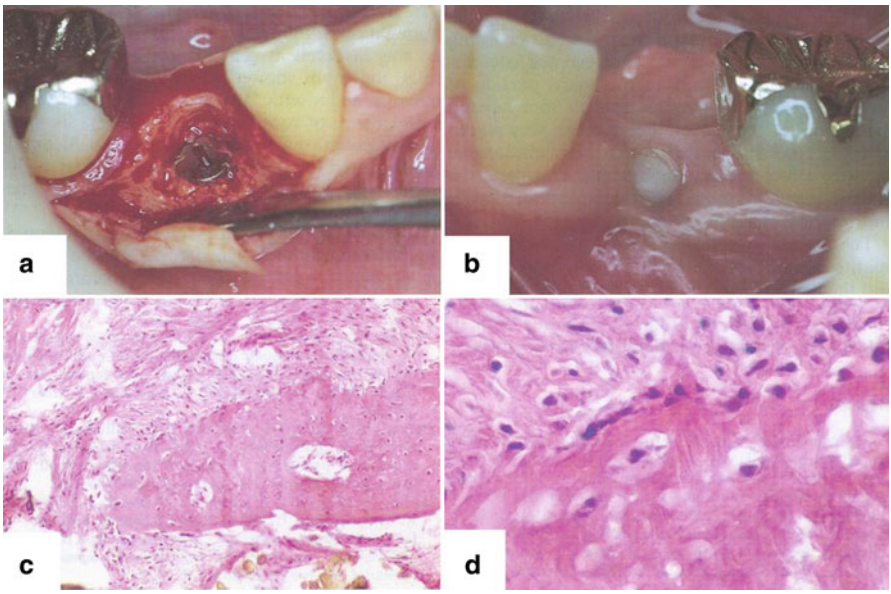

Fig. 18 Formation of bone over a titanium implant placed into an extraction socket by tissue regeneration guided by a bacterial cellulose membrane: (**a**) implant has been inserted, assuring that 4 mm are firmly anchored in healthy bone; (**b**) aspect of recently formed bone over the implant possessing osteocytes in its interior, osteoblast aligned on its surface, and continuity with young connective tissue; (**c**) histological evidence for the formation of bone tissue at the beginning of the restorative phase; (**d**) after complete healing (Reproduced from Novaes and Novaes (1993) with permission)

two-layered assembly of a pure BC (internal) layer and a chemically modified alkali cellulose (external) layer. As demonstrated by Novaes, new bone forms over a $TiAl_6V_4$ implant placed into a circumferential type defect on the buccal aspect (extraction socket) when using BC-based Gengiflex® membranes augmented with hydroxyapatite for guided regeneration (Novaes and Novaes 1993). The complete healing of the bone could be determined clinically and histologically (Fig. 18).

As an alternative to the approach of guided regeneration, BC is also discussed as scaffold for the in vitro engineering of tissue. For example, there is an ongoing research on the usage of BC as a substitute for collagen in biomimetically engineered bone constructs. In this context, the mineralization of the BC scaffolds with inorganic calcium phosphate minerals, such as hydroxyapatite, toward new hybrid materials is intensively studied since these minerals are known to increase osteoblastic differentiation of progenitor cells, increase cell alkaline phosphatase activity, and generally promote bone tissue formation (Stevens et al. 2008; Sibilla et al. 2006). Besides the ratio and morphology (in particular crystal size) of the dopant, also the porosity and nanoscale topography are key elements permitting the migration, adhesion, differentiation, and proliferation of osteogenic cells (Karageorgiou and Kaplan 2005; Dulgar-Tulloch et al. 2009). As, for example, shown by Zaborowska et al. (2010) by means of confocal fluorescence microscopy

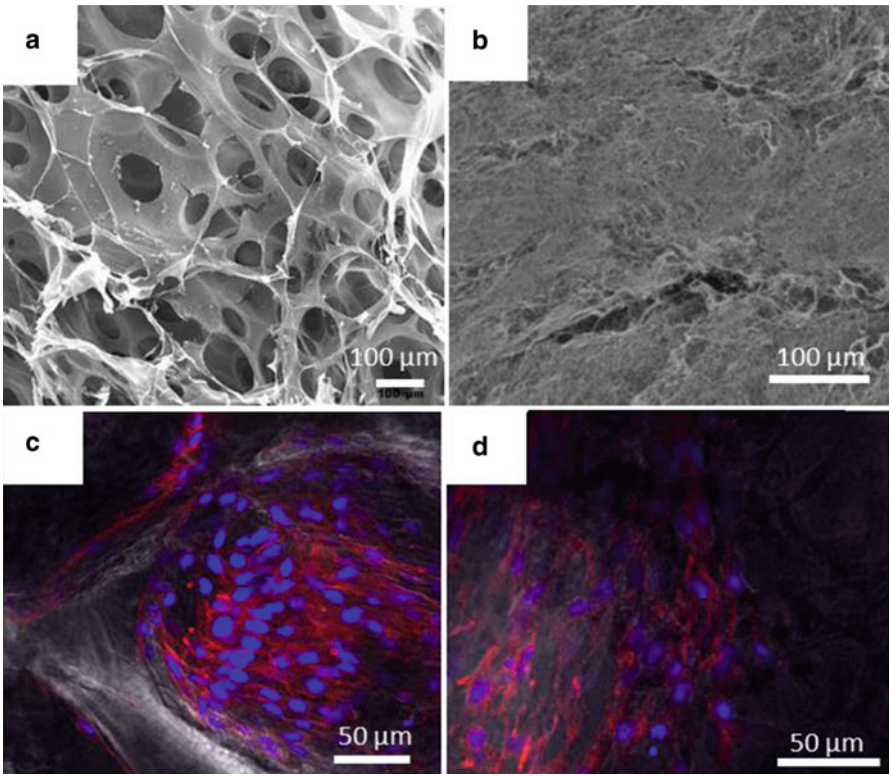

Fig. 19 (**a**) Scanning electron microscopy image showing the morphology of a bacterial cellulose scaffold material possessing highly interconnected pores of about 300–500 µm besides its nanostructure; (**b**) bacterial cellulose scaffold material without microporous morphology; (**c** and **d**) confocal fluorescence microscopy images of MC3T3-E1 osteoprogenitor cells seeded on abovementioned scaffolds. Cell nuclei are stained with DAPI (*blue*) and actin cytoskeleton is stained with rhodamine-phalloidin (*red*) (Reproduced from Zaborowska et al. (2010) with permission)

and histological studies, BC scaffolds, which possess besides their nanostructure highly interconnected pores of about 300–500 µm, are a promising material for bone tissue engineering applications. While the nanometer-sized structures have positive effects on the cell adhesion, the microporosity permits a better penetration of cells, their accumulation in clusters, and an improved osteoplastic differentiation (Fig. 19). Overall, an enhanced bone and capillary formation can be expected by such tailor-made scaffolds.

Another promising field of application is the use of BC as scaffold material for the engineering of cartilage tissue. In this context, native, phosphorylated, and sulfated BCs were evaluated using bovine chondrocytes (Svensson et al. 2005). The results demonstrated native BCs' potential utility as a cartilage scaffold, noting that it showed significantly higher chondrocyte growth than conventional tissue culture plastics and alginate. Although BC showed a chondrocyte proliferation

level of only 50 %, when compared to a collagen type II substrate it provided significant advantages in terms of mechanical properties, i.e., a Young's modulus in the same range as articular cartilage. Bodin et al. (2007) could show that BC has a high potential as meniscus implant for the regeneration of meniscal tissue after partial meniscectomy. The authors demonstrated the five times better mechanical properties of BC compared to the collagen material that have been used in clinical practice, even though natural menisci surpassed BC at higher loads. However, the ongoing research in particular on the preparation of highly ordered BC materials might help to advance even in such challenging applications (Zang et al. 2014).

4.2 Plant Cellulose

Unlike bacterial cellulose, native plant cellulose is not at all considered to be used as a biomaterial nowadays. However, from the author's point of view, micro- and nanostructured materials, which can be prepared from plant cellulose by applying specific so-called top-down approaches (Fig. 20) (Pääkkö et al. 2007), may open new perspectives in biomaterial science by using the remarkable supramolecular and ultrastructural features formed during the biosynthesis of cellulose. Therefore, some aspects of preparation, structure, and properties of such cellulosic nanomaterials will be presented in the following.

4.2.1 Microcrystalline Cellulose (MC)

MC is derived from native cellulose by acid-catalyzed depolymerization using HCl, SO_2, or H_2SO_4 at temperatures well above 100 °C (Dufresne 2008). The acidic hydrolysis occurs in the regions of low lateral order with the consequence that water-insoluble, highly crystalline residues are obtained, forming a stable suspension after vigorous stirring. The DP of the starting cellulose decreases with time and finally reaches a nearly constant value (the level-off DP) of 25–300, which can be controlled by the depolymerization conditions and especially the starting material (Steege and Philipp 1974). The dialysis, commonly applied to remove the acid, and the final spray drying result in re-agglomeration of smaller crystalline domains and, thus, MC may appear stubby to fibrillar (Bondeson et al. 2006).

Commercial MC is a fine, white, and odorless crystalline powder (commercial products are Avicel®, Heweten®, Microcel®, Nilyn®, or NOVA Gel®) and currently used in pharmaceutical (tablet binder), food (rheology control), and paper applications as well as in composite manufacturing (Samir et al. 2005).

An interesting property of MC crystallites is their ability to self-assemble into chiral nematic phases with crystal pitches in the order of the wavelength of visible light, which consequently reflect circularly polarized light of the same handedness as the chiral nematic phase. Above a critical concentration, the MC suspension changes spontaneously into a chiral nematic liquid crystalline phase and forms regularly twisted fibrillar layers, which after drying mimic the structural organization of natural helicoids (de Vries 1951; Revol et al. 1992). This phenomenon is also observed for the cellulose nanocrystallites, namely, cellulose whiskers, which are described below.

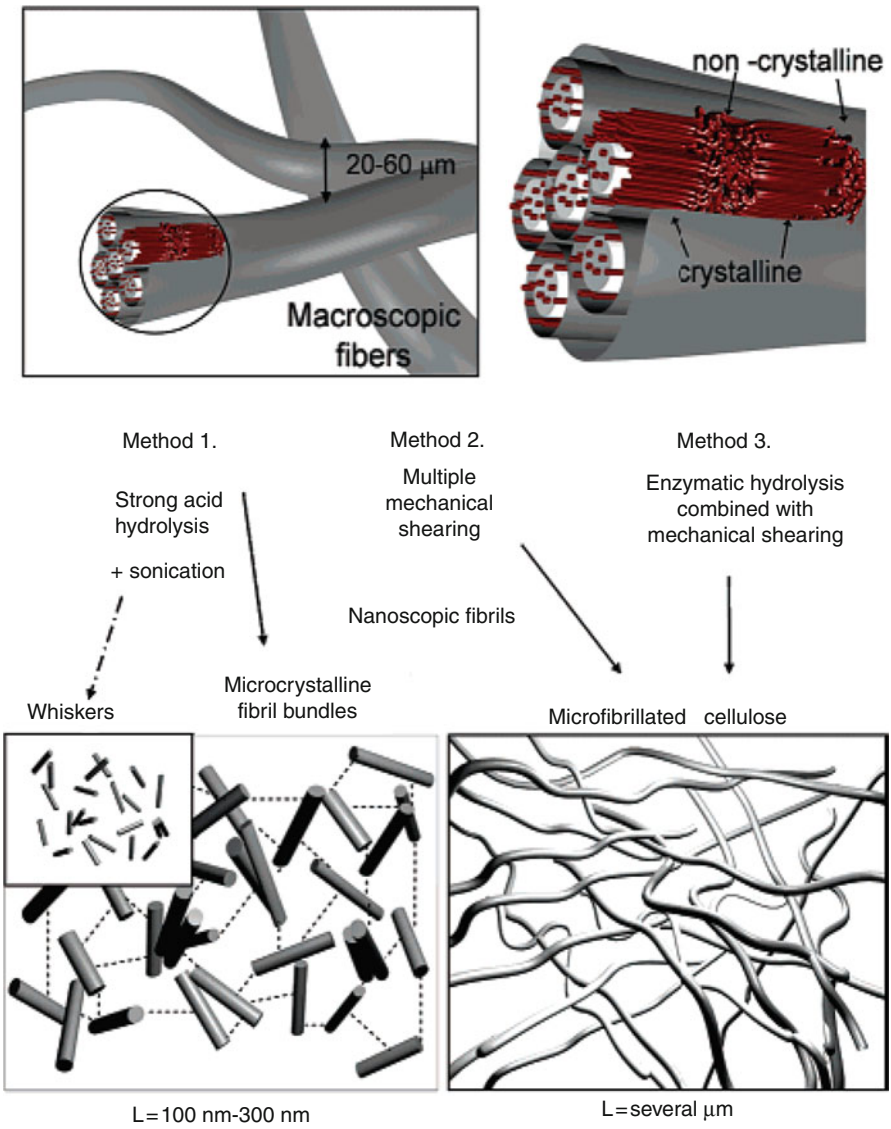

Fig. 20 Mechanical treatment and hydrolysis as top-down approaches for preparing nanoscale cellulosic materials (Reproduced from Pääkköö et al. (2007) with permission)

4.2.2 Cellulose Whiskers

A more intensive hydrolysis than that applied for the preparation of MC results in rigid rodlike cellulose crystallites, which form a stable suspension after treatment with ultrasound (Dufresne 2008). The crystals possess typical dimensions in the order of a few 100 nm in length and of a few nm in diameter (Fig. 21). They resemble a cat's whiskers in terms of straightness and the length to width ratio and

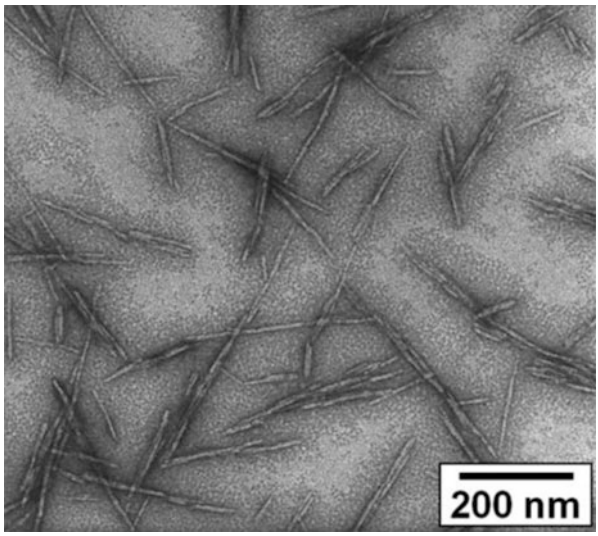

Fig. 21 Transmission electron microscopy image of cellulose nanocrystals obtained from wood pulp showing a whiskers-like structure (Reproduced from Moon et al. (2011) with permission)

are thus frequently called cellulose whiskers. The precise dimensions depend on the origin of the substrate used for preparation (in particular of its amount of amorphous regions), the hydrolysis conditions, and the ionic strength.

The fact that cellulose whiskers show no chain folding and contain only a small number of defects results in mechanical properties, making them very attractive as reinforcing dopant for both thermoplastic and thermoset polymers. The whiskers have a large modulus of elasticity (~150 GPa), strength (~7 GPa), a very low coefficient of thermal expansion (~10^{-7} K^{-1}), and last but not least they possess a comparably low density (Kroon-Batenburg et al. 1986; Nishino et al. 2004). Therefore, latex, poly(β-hydroxyalkanoate), starch, cellulose acetate butyrate, poly(vinyl chloride), poly(vinyl alcohol), polyamide 6, and several other natural and synthetic polymers were blended with cellulose whiskers, resulting in improved mechanical characteristics of the products even when the whiskers content was only a few percent (Favier et al. 1995; Dubief et al. 1999; Dufresne et al. 1999; Angles and Dufresne 2000; Grunert and Winter 2002; Chazeau et al. 2000; de Souza Lima and Borsali 2004; Correa et al. 2014). In this regard, cellulose whiskers might be an attractive material for reinforced polymeric composites. They potentially would allow to enter new fields of application by benefiting from both the proven performance of classical biomaterial plastics and the outstanding properties of the cellulosic material.

4.2.3 Micro- and Nanofibrillated Cellulose (MFC/NFC)

When wood pulp is disintegrated by applying high shear forces, the macroscopic fibers are moderately degraded and opened into their substructural micro- and nanofibrils (Fig. 22a) (Turbak et al. 1982). These individualized fibrils and fibril aggregates are highly entangled and inherently connected, forming mechanically strong networks or gels (Fig. 22b). MFC/NFCs are reminiscent of elementary fibrils

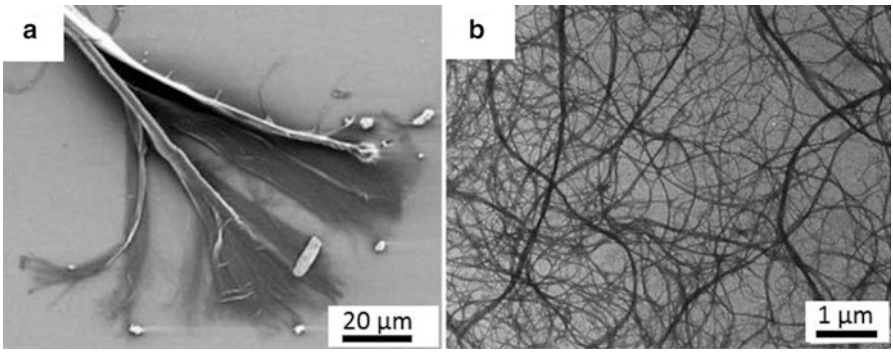

Fig. 22 (**a**) Scanning electron microscopy image visualizing the micro-/nanofibrillation of a pulp fiber by high shear forces; (**b**) transmission electron micrograph showing individualized fibrils and fibril aggregates of micro-/nanofibrillated cellulose gel (Reproduced from Johnson et al. (2009) (**a**) and Dufresne et al. (1997) (**b**) with permission)

in plant cellulose and can be applied in reinforced plastic composites similar to cellulose whiskers (Moon et al. 2011). For example, it is possible to prepare new-generation hemodialysis membranes, which combine active ion exchange with passive ultrafiltration, and the large surface area (Ferraz et al. 2012). Moreover, it is possible to prepare neat MFC/NFC films and membranes that possess properties making them comparable to bacterial cellulose in some aspects (Moon et al. 2011). Thus, there might be a potential of these native plant cellulose in biomedical applications like wound dressing, tissue repair, and medical implants as well.

5 Man-Made Cellulosics as Biomaterials

Excluding the large-scale production of pulp and paper from wood and textiles from cotton, the cellulosics processed by mankind can be classified with respect to the industrial significance into the four classical categories:

- Regenerated cellulose
- Cellulose esters of organic and inorganic acids
- Cellulose ethers
- Oxidized cellulose

While regeneration of cellulose is carried out via the state of dissolution applying either derivatizing or non-derivatizing solvents (Liebert 2010), the synthesis of cellulose derivatives is carried out exclusively under heterogeneous reaction conditions, at least in the conversions used nowadays in the industrial scale. From the authors' point of view, these established fields are mostly of historical or minor importance for the application of cellulose as a biomaterial. Therefore, this section will only include selected aspects regarding classical man-made cellulosics and give some examples of recent advances in polysaccharide science, which not

necessarily lead to actual biomaterials yet but illustrates the potential of cellulose when thinking beyond the ken.

5.1 Conventional Regenerated Cellulosics as Biomaterials

The majority of wood cellulose, which is not used in pulp and paper industry, forms the basis for the so-called regenerated cellulose. In principle, regeneration of cellulose refers to a two-step process for the shaping of cellulose into various forms including fibers, beads, sponges, and films/membranes. In the first step, cellulose needs to be dissolved. Otherwise, a shaping would not be possible since the extensive hydrogen bond network of cellulose causes its degradation before melting would occur. In the second step, the cellulose solution is solidified by precipitation using equipment convenient to obtain the desired shape. During the last century, by far the largest part of the artificial cellulose-based materials was manufactured by the viscose process invented by Cross and coworkers in the early 90s of the nineteenth century (Cross et al. 1893a, b). The most important industrial alternative to the viscose process is the dissolution of cellulose in the non-derivatizing solvent *N*-methylmorpholine-*N*-oxide (NMMO), which allows to produce products with different structural features than those from viscose (e.g., shape, degree of crystallinity, crystallite dimensions, orientation of noncrystalline chain segments) and have less environmental impact (Liebert 2010). Another prominent process used for the shaping of cellulose is based on a discovery made by the Swiss chemist Schweizer in 1857 and later on commercialized as an artificial silk process (Schweizer 1857). Schweizer found that cotton could be dissolved in a solution of copper salts and ammonia (Cuam) and then regenerated in a coagulating bath (Schweizer 1857). In addition to the application of shaping of cellulose, this solvent is very useful for the analysis of cellulose, and it was among the reagents the afterward Nobel Prize-decorated Hermann Staudinger exploited to elucidate the macromolecular structure of cellulose (Nobel laureate 1953).

The viscose, NMMO, and Cuam processes were initially invented for the preparation of fibers predominantly for textile applications. However, by specialized techniques, different geometries including flat and tubular cellulose membranes, sponges, and beads were prepared from cellulose. Membranes produced by the viscose process, namely, cellophane, were used in the early treatments of acute or reversible kidney failure by Kolff et al. (1944). For such treatments, a long cellophane tube was spirally wrapped around a cylinder and rotated in a stationary dialysis fluid bath. This kind of apparatus with its cellulose membrane as an essential part became the first system for the treatment of renal failure in widespread clinical use. Also in new designs including coil, parallel flow, and hollow fiber dialyzers, cellulose membranes were in use in the beginning. Figure 23 shows a typical hollow fiber produced by the Cuam process as it was used in hollow fiber dialyzers. However, since the 1970s, the use of membranes in the treatment of renal failure tends to move away from cellulose toward synthetic membranes, although recent clinical studies could not prove any benefit in terms of reduced mortality or

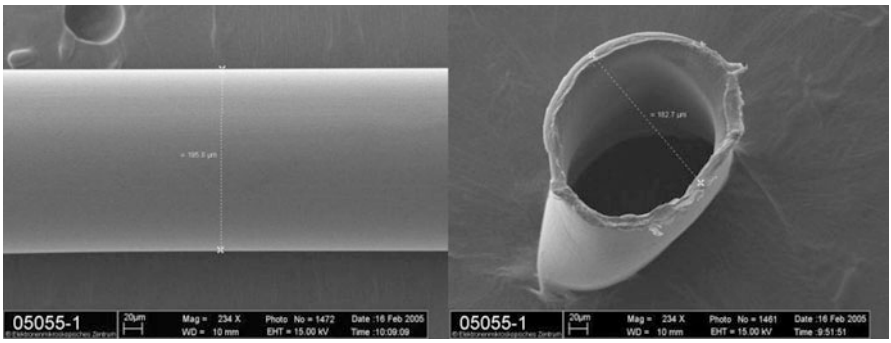

Fig. 23 Hollow fiber used for blood dialysis prepared via the Cuam process (Reproduced from Liebert (2010) with permission)

the reduction in dialysis-related adverse symptoms (Grassmann et al. 2005; Macleod et al. 2005). From the authors' point of view, this trend might change when taking into account the potential arising from the multifunctionality of cellulose in future developments. It might be possible to chemically modify cellulose membranes in a way that it not only acts as an inert phase separator but takes an active role, for example, in reducing oxidative stress or hypersensitivity reactions associated with the dialysis treatment (Yu et al. 2013; Sanchez-Villanueva et al. 2014).

A more recent use of regenerated cellulose is the application of cellulose sponges in tissue engineering approaches similar to BC as described above. For example, the formation of granulation tissue in viscose cellulose sponges with different cellulose contents and sizes was studied after subcutaneous implantation in rats (Martson et al. 1998). The sponges were studied histologically and histomorphometrically 1–16 weeks after implantation. It was shown that the implants with lower cellulose content, i.e., higher porosity and larger pore size, and smaller dimensions were invaded by more cells and filled with connective tissue more rapidly than those with the higher cellulose content and larger dimensions. A similar study by Pulkkinen et al. (2006) demonstrated the suitability of viscose cellulose sponges as a scaffold for cartilage tissue engineering. They showed that the sponges alone or with recombinant human type II collagen cross-linked inside the material were biocompatible and a significant cell proliferation could be obtained. The constructs remained soft during the observation period and were devoid of extracellular matrix composition, typical for normal articular cartilage. However, as a drawback of viscose sponges in tissue engineering approaches, the more pronounced foreign body tissue reaction, compared to BC, must be considered. It may arise from minor impurities or deviations from the idealized cellulose structure caused by the viscose process (Martson et al. 1999). Moreover, viscose is like other neat cellulosic materials as well, hardly degradable in the body of living animals or humans.

The NMMO process described above offers various possibilities for the physical modification of fibers. Thus, a variety of filled fibers possessing functional properties became accessible in recent years. For example, fibers with 33 wt % of a

superabsorbent resin without a pronounced deterioration of its textile properties could be produced, applying NMMO as solvent. Instead of using powdered organic compounds as absorbent materials, embedding into fibers provides the chance for applications of superabsorbent materials in areas which were not considered so far (Kolbe and Meister 2006). Other filled fibers are accessible in a comparable manner in particular for health-promoting applications. For example, fibers possessing antimicrobial and antifungal activities could be prepared by immobilizing about 0.04 g of silver per kg of fibers. As shown by Hipler et al. (2006), the antimicrobial activity remains constant over approx. 60 washing cycles, and the textiles made from these fibers can be applied as an excellent antimicrobial barrier dressing without causing allergic or toxic effects.

5.2 Conventional Cellulose Derivatives as Biomaterials

Chemical modifications of cellulose are generally based on the characteristic reactions of alcohols involving the hydroxyl groups at positions 2, 3, and 6 of the AGUs of the polymer. In this regard, esterification and etherification are of particular importance. Esterification is usually performed with acids in the presence of a dehydrating agent or by the reaction with acyl chlorides or acid anhydrides. The resulting esters can be classified into esters of inorganic acids, such as cellulose nitrate, sulfate, and phosphate, and esters of organic acids, such as cellulose acetate, propionate, acetobutyrate, and acetophthalate. Cellulose etherification is generally performed by Williamson ether synthesis with alkyl halides in the presence of a strong base, with alkylene oxides in weakly basic medium, and by Michael addition of acrylic or related unsaturated compounds (Wertz et al. 2010).

Like neat regenerated cellulose, its esters and ethers had historically been applied in hemodialysis. For example, hollow cellulose acetate-based fibers were introduced by Dow Chemical in the late 1960s of the last century to overcome some of the shortcomings associated with Cuam fibers like problems with leukopenia (Gotch et al. 1969). With similar intent, cellulose etherified with small amounts of tertiary amino groups, namely, N,N-dimethylaminoethyl- or benzyl moieties were used for the production of hemodialysis membranes under the brand names HEMOPHAN® and SMC®, respectively (Schaefer et al. 1987; Hoenich et al. 1997). Although these membranes showed some advantages in terms of biocompatibility, they did not become accepted in widespread clinical use and are of minor importance nowadays (Yu et al. 2013).

Another field where cellulose derivatives find a widespread application is in the controlled drug release from tablets. In such, the cellulose derivatives constitute a hydrophilic excipient system possessing a variety of different release modalities, which are dependent on the actual structure of the derivative as well as on the formulation process. It has been shown by a model system that the synergistic interactions of the heterodisperse cellulose derivatives determine the release profile of the active pharmaceutical ingredient (Staniforth and Baichwal 1993). For example, the cellulose ether hydroxypropylmethyl cellulose (HPMC) is one of the most

widely used hydrophilic matrices for drug delivery systems. It is used in tablets prepared by wet granulation (Lapidus and Lordi 1966), slugging (Huber and Christenson 1968), and direct compression (Conte et al. 1993). In such formulations, the drug release is controlled by the molecular weight of the HPMC, the drug to HPMC ratio, the particle size of both the drug and HPMC, and the solubility of the drug (Kawashima et al. 1998; Pillay and Fassihi 1999). None of the inventors considered the cellulose derivatives in such classical drug delivery applications as biomaterials. However, keeping in mind the new biomaterials paradigm, the reader will notice that they actually were used as such.

5.3 New Aspects of Man-Made Cellulosics for Biomaterials

As stated before, the constant development in cellulose science and technology gives rise to new perspectives for the use of cellulose as biomaterials. From the authors' point of view, two aspects are of major importance in this context. The first one is the development of new processing techniques for cellulose toward hybrid- and nanoscale materials. The second is related to new methods for the chemical modification of cellulose. This includes in particular the great opportunities to design novel and unconventional cellulose derivatives by homogeneous-phase chemistry. The following discussion on these two aspects is not intended to give a comprehensive review. Instead, it should give the reader an impression of what is possible even though some of the examples might not have an obvious link to biomaterial science.

5.3.1 New Cellulosic Nanomaterials

Electro-spinning of Cellulose and Cellulose Derivatives

Electro-spinning is a technique widely used for the preparation of nanofibers, which opens up a way to realize high effective surface area materials (Greiner and Wendorff 2007). The nanofibers may be produced from different polymers and found to be interesting for various application fields, namely, in biomedicine, composites, and filters, as well as in catalytic and textile products (Reneker and Chun 1996; Frenot and Chronakis 2003; Xie et al. 2008). The nanofibers regulate the water vapor and wind permeability and may improve the thermal isolation of textiles. Moreover, they may possess special properties like aerosol filtration, binding of chemical and biological contaminants, or improved surfactant release (Li et al. 2010), for which air cleaning of contaminated environments is a typical example (Scholten et al. 2011).

Cellulose dissolved in DMA/LiCl; NMMNO (Kim et al. 2006); ionic liquids, e.g., 1-butyl-3-methylimidazolium chloride (Viswanathan et al. 2006); or sodium hydroxide/water/urea (Qi et al. 2010) could be transferred to nanofibers of different morphology by electro-spinning (Fig. 24). Also conventional cellulose derivatives like cellulose acetate can be easily processed by electro-spinning. Other more specialized polysaccharide derivatives including water-soluble polyelectrolytes

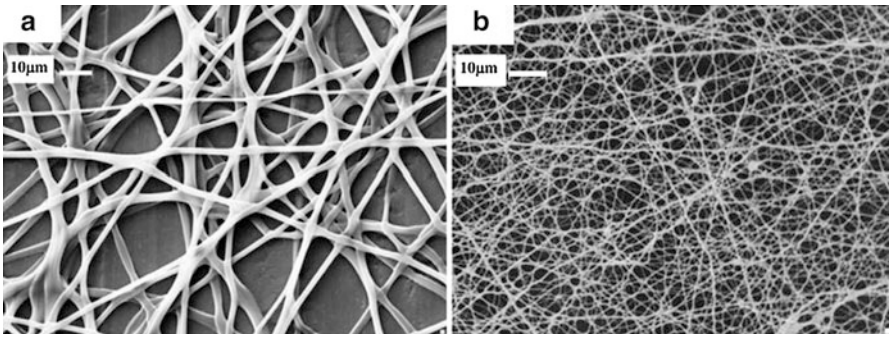

Fig. 24 Scanning electron microscopy images of electro-spun cellulose fibers (**a**) from NMMO and (**b**) from DMA/LiCl (Reproduced from Kim et al. (2006) with permission)

like 6-deoxy-6-trisaminoethyl-amino cellulose can be electro-spun by using blended solutions of polymers like polyvinyl alcohol (Römhild et al. 2013).

In the field of biomaterial science, electro-spun cellulose-based fibers are considered for applications like the immobilization and delivery of bioactive substances as well as for cell culture and tissue engineering approaches (Konwarh et al. 2013). For example, drug-loaded electro-spun cellulose acetate mats were prepared for transdermal drug delivery. It has been shown that it is possible to deliver drugs for systemic effects at a predetermined and precisely controlled rate, which is predominantly controlled by the design of the nanomaterial, i.e., the size and morphology of the fibers (Kumar 2011). In terms of tissue engineering, it has to be stated that the principal possibilities to actively control factors such as interfiber distance and alignment, surface functionalization, gradient organization, and biodegradability make electro-spinning of cellulose or its derivatives the most promising alternative to the tissue engineering approaches on basis of bacterial cellulose. However, up to now the application of electro-spun cellulosics is not quite well elaborated compared to bacterial cellulose. Nevertheless, the interested reader will find a series of references supporting the growing endeavor to bring electro-spun cellulosics to the field of tissue engineering in the recent review of Konwarh et al. (2013).

Nanospheres

Nanoscale particles can be obtained from different cellulose esters including the commercially available cellulose acetates, cellulose acetate propionate, and cellulose acetate butyrate and also from some organo-soluble cellulose ethers. For this purpose, an emulsification-solvent evaporation procedure or the low energy-consuming methods of solvent displacement may be applied (Wondraczek et al. 2013; Hornig and Heinze 2008). Comparing the methods, it could be shown that large amounts of small and very uniform nanoparticles could be obtained by the emulsification-solvent evaporation procedure, whereas the solvent displacement technique yields narrowly distributed particles of somewhat larger particle diameters (Fig. 25).

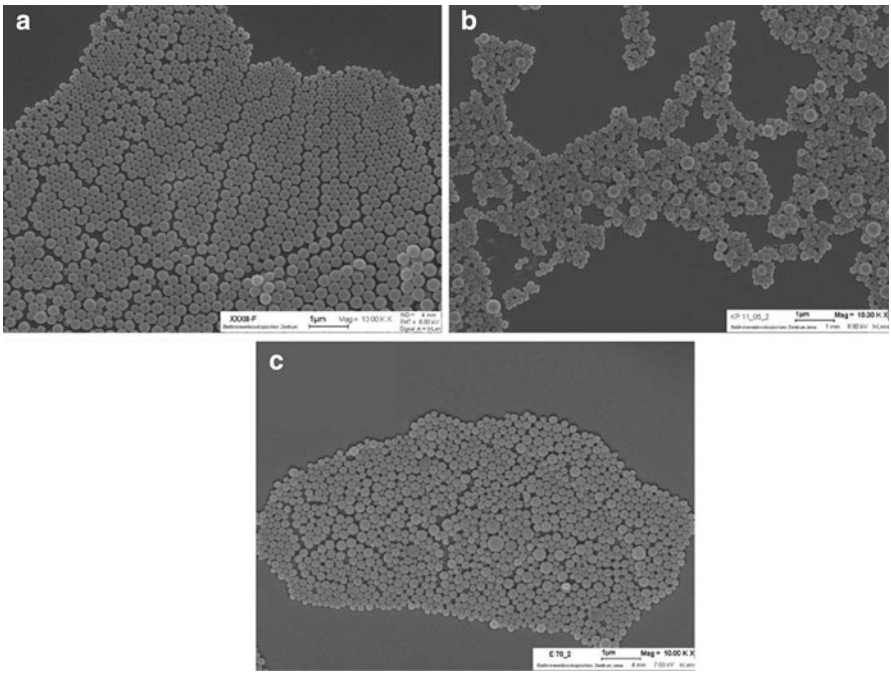

Fig. 25 Field-emission scanning electron microscopy images of the nanoparticles prepared from cellulose acetate: (**a**) by emulsification-solvent evaporation, (**b**) dialysis, and (**c**) dropping technique (Reproduced from Wondraczek et al. (2013) with permission)

It is important to point out that even spherical nanoparticles of polymers containing hydrophilic moieties like 6-deoxy-6-(ω-aminoalkyl)aminocellulose-carbamates could be prepared. Such nanoparticles are of particular interest because they possess primary amino groups that can be modified much easier than OH moieties. Thus, labeling with rhodamine B isothiocyanate is very simple and does not change the size, stability, and shape of the nanoparticles. Incorporation of the nanoparticles in human foreskin fibroblasts BJ-1-htert and breast carcinoma MCF-7 cells could also successfully be carried out without any transfection reagent (Nikolajski et al. 2012).

Although an organo-soluble cellulose derivative must be used for the technique of nanoprecipitation, even pure cellulose nanoparticles could be prepared. Using trimethylsilyl cellulose (TMSC), the formation of nanoparticles by dialysis of the organic solvent against water is accompanied by a complete removal of the TMS functions. The particle size distribution analysis shows that cellulose particles with a size of 80–260 nm are accessible in this simple manner (Kostag et al. 2010). The aqueous suspensions of the pure, spherical cellulose nanoparticles are storable for several months without any demixing. Covalent labeling of the cellulose nanoparticles with fluorescein isothiocyanate (FITC) has no influence on particle size, shape, and stability. The particles can be sterilized and suspended in biological

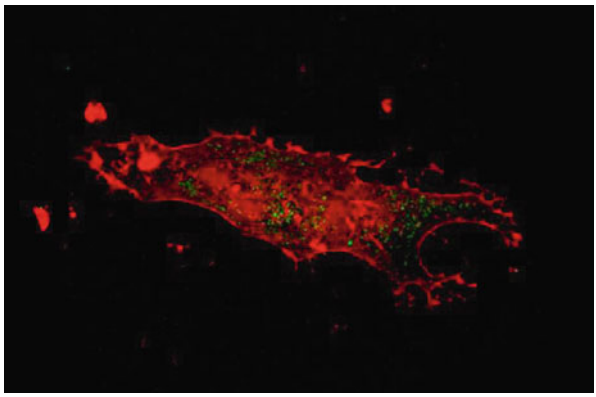

Fig. 26 Confocal micrograph overlay of 21 stacks of human fibroblasts (*red* = cell membrane) incubated with fluorescein isothiocyanate-labeled cellulose nanoparticles (Reproduced from Liebert et al. (2011) with permission)

media without structural changes. As can be seen in Fig. 26, the FITC-labeled cellulose nanoparticles can penetrate into living human fibroblasts by endocytosis without transfection reagents or attachment of a receptor molecule as studied by means of confocal LSM (Liebert et al. 2011).

5.3.2 Amino Celluloses: A Promising Example for Novel Cellulose Derivatives

From the authors' point of view, a large mostly unexplored field of applications for cellulose (also with respect to biomaterials) arises from the tailored chemical modification of cellulose under homogeneous reaction conditions. In the following, one outstanding class of such novel cellulose derivatives, namely, amino celluloses, will be explained as an example in order to stimulate the reader to think beyond the current borders of cellulosic biomaterials.

Conversion of cellulose tosylate with di- or oligoamines yields polymers of the type P–CH_2–NH–(X)–NH_2 (P = cellulose, (X) = alkylene, aryl, or oligoamine, Fig. 27). The structure of the amino celluloses can be designed in terms of different distances of the terminal NH_2 groups from the cellulose backbone (spacer effect) and different basicity and reactivity. Moreover, the di- and oligoamines provide different properties including pK_b value, charge distribution, hydrophilic/lipophilic balance, and redox-chromogenic properties (Tiller et al. 1999, 2000; Berlin et al. 2000, 2003). The chromogenic (electron mediator) properties play an important role for the inherent property of most amino celluloses that they form films on a vast amount of different materials and thus can be applied as a primer, for example, for the immobilization of antibodies for biosensor applications (Jung and Berlin 2005; Becher et al. 2004).

Due to the multifunctionality of cellulose and the stability of tosylates, a modification of the secondary OH groups prior the S_N reaction may be carried out to design the properties of the products additionally. The OH groups at positions 2 and 3 are preferably esterified to adjust the properties including the solubility of the polymer. While the amino celluloses possessing mainly OH groups at the secondary positions are water soluble, the additionally esterified polymer derivatives are soluble in organic solvents like DMAc and may form nanoparticles (see above).

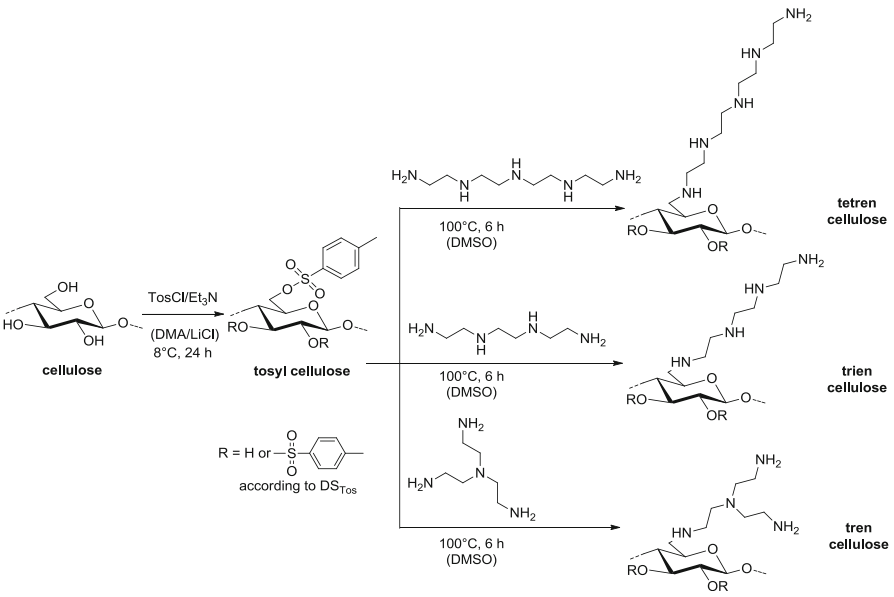

Fig. 27 Reaction path for the synthesis of 6-deoxy-6-amino cellulose ester derivatives by nucleophilic displacement of tosyl cellulose

An extremely interesting property of 6-deoxy-6-amino cellulose is the fact that they form multiple oligomeric species as it was found by using the hydrodynamic technique of analytical ultracentrifugation (Heinze et al. 2011). For every amino cellulose studied, the sedimentation coefficient distributions show between 4 and 5 discrete species with a stepwise increase in sedimentation coefficient across a range of six different solute loading concentrations (from 0.125 to 2.0 mg/ml). For example, the lowest sedimentation coefficient of the 6-deoxy-6-(2-(bis(2-aminoethyl)aminoethyl)-amino) cellulose was detected at 1.8 Svedbergs (S). Additional species sedimenting at peak maxima 2.8, 4.0, 5.1, and 6.5 S were also clearly found. It became obvious that even a fully reversible self-association (tetramerization) within this family of 6-deoxy-6-amino cellulose occurs. Remarkably, these carbohydrate tetramers are then seen to associate further in a regular way into supramolecular complexes (Fig. 28). This behavior was found for the first time for a carbohydrate, while it is well known for polypeptides and proteins like hemoglobin and its sickle cell mutation (Ferrone et al. 1985). The large self-assemblies of cationic structures render them as possibilities for mimicking the properties of histones and for their use as condensing or packing agents in DNA-based therapies (Teif and Bohinc 2011). Most importantly, however, our traditional perceptions as to what is "protein-like" and what is "carbohydrate-like" behavior may need to be reconsidered (Nikolajski et al. 2014).

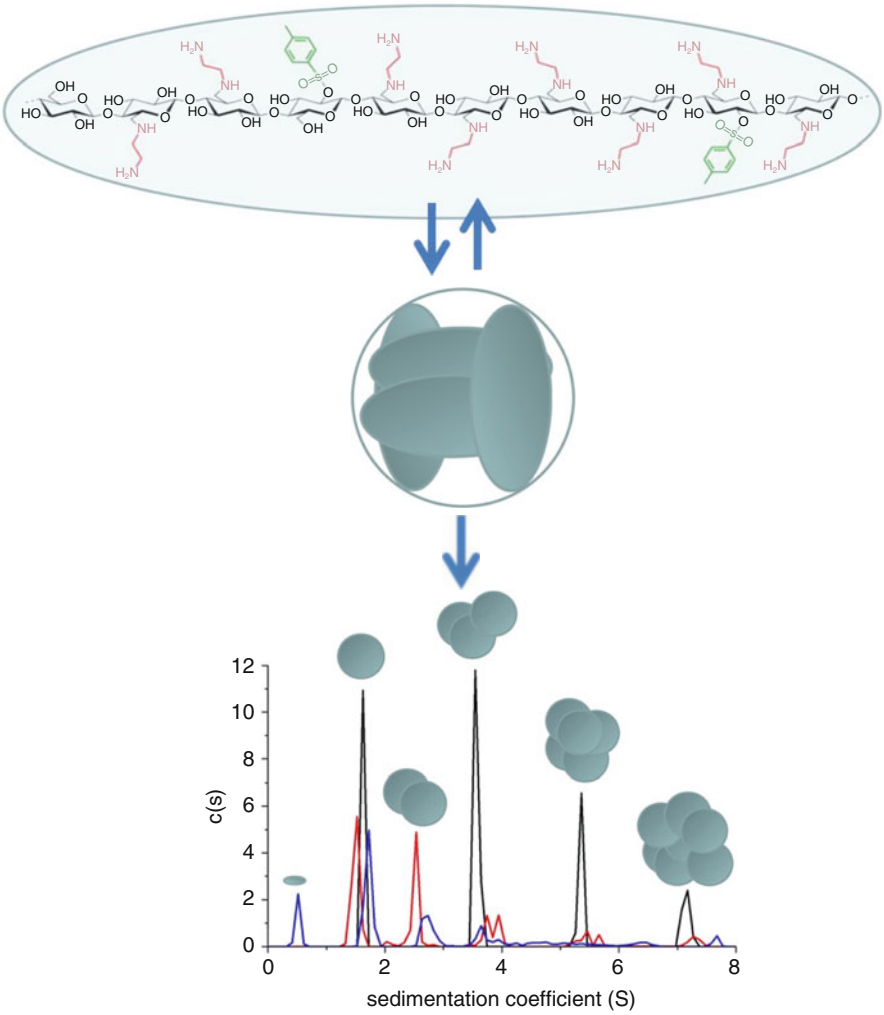

Fig. 28 Reversible tetramerization and further higher-order association of the polysaccharide 6-deoxy-6-(ω-aminoethyl)aminocellulose (AEA cellulose). *Top*: monomer unit of degree of polymerization ~10, degree of substitution at C-6 $DS_{Amine} = 0.83$, and degree of substitution at C-2 of tosyl residues $DSTosyl = 0.2$, yielding a M ~ 3,250 g/mol and s ~ 0.5 S. *Middle*: assembly into tetramers with M ~ 13,000 g/mol and s ~ 1.7 S. *Lower*: sedimentation coefficient distribution for AEA cellulose at different concentrations, 2.0 mg/ml (*black*), 1.0 mg/ml (*red*), 0.75 mg/ml (*blue*), 0.25 mg/ml (*green*), and 0.125 mg/ml (*pink*). Based on the s ~ M2/3 scaling relationship, the super-monomers associate into super-trimers, super-hexamers, and super-9-mers with evidence also for some super-dimers, although the latter were not evident at the highest loading concentration. The proportion of the super-monomers drops relative to the higher-order species showing partial reversibility even with the higher-order association (Reproduced from Nikolajski et al. (2014) with permission)

6 Conclusions

Cellulose is the most important renewable resource and a unique polymer regarding structure and properties. Based on its remarkable properties, it may serve as starting material for various biomaterials. Keeping in mind the new biomaterials paradigm, in particular the research and development in the field of micro- and nanostructured cellulosics (both native and man-made) hold a big potential for applications beneficial to human life. As shown in this book chapter, the versatile characteristics of the different cellulose-based architectures can be used to address specific functions in applications as different as drug delivery and tissue engineering. Consequently, it can be expected that the application fields of micro- and nanostructured cellulose will further be broadened, for example, by applying chemical and physical surface treatments. Moreover, it can be expected that new materials will blur the boundaries between classical biomaterials, drugs, and functional daily life materials. Last but not least, the ongoing research in somewhat exotic fields as, for example, the homogeneous functionalization of cellulose will in the future for sure open new areas of application also in biomaterial research.

Contents

Abstract

Starch is a substantial component of the human diet providing about 50 % of daily energy uptake, mostly through unrefined cereals. Starch and sucrose are the primary products of photosynthesis. Starch represents the main plant storage carbohydrate that provides energy during heterotrophic growth. Its synthesis and degradation have been studied deeply, reaching a good level of knowledge of the metabolism as a whole. Not only the enzymes involved but also the intracellular localization of the reactions, its regulation, its dependence on light–dark cycle, its evolution from ancestral bacteria, and its correlation with parameters of agronomic interest have been studied. In this work we have attempted a comprehensive review of the starch metabolism in *Arabidopsis thaliana* and other species of agronomic interest and the modular structures present in starch-related enzymes from *Arabidopsis thaliana*.

1 Introduction

Polyglucans are the most important and widespread carbohydrate storage compounds found in nature, being cellulose, glycogen, and starch the most abundant forms. These two last polysaccharides are comprised of glucose chains linked by an α-1,4 bond and branched at α-1,6. Glycogen is a homogeneous water-soluble polymer with relatively uniformly distributed branches (Roach 2002) and is found in organisms such as archaea, bacteria, and certain eukaryotes (Busi et al. 2012). Starch is the main form in which plants and algae accumulate carbohydrate storage, because cellulose, the most abundant carbohydrate in plants, complies with structural functions. Starch is present in the cytosol of Glaucophyta and Rhodophyceae (red algae) (Dauvillee et al. 2009); however, it is confined to the plastid stroma (chloroplasts in green tissues and amyloplasts in reserve organs) in green algae and higher plants. Starch is essential for the carbon economy of the different organs and tissues of the plants and it can be found in large amounts in fruits, seeds, leaves, roots, and tubers (Smith and Zeeman 2006).

Starch molecules are polymers of glucose in two configurations: amylose, which is mostly unbranched, and amylopectin, which is branched. Amylose is predominantly linear and made up of α-1,4-linked glucosyl moieties, while amylopectin is branched and contains both α-1,4 and α-1,6 linkages. These branches pack together into ordered arrays to form semicrystalline starch granules (Ball et al. 1996; Grennan 2006). Starches from different plant sources vary in size, composition, and structure of amylopectin. These factors influence the physical properties and end-uses for the different natural starches (Santelia and Zeeman 2011) (Table 1).

The structural features of the starch also determine the ability to be digested. This polysaccharide can be hydrolyzed by enzymes of the human gut and its digestion occurs in the small intestine, except for a portion named resistant starch (RS) which is degraded in the large intestine (Busi et al. 2012). RS is defined as the set of starch and products of starch degradation (oligosaccharides and other sugars)

Table 1 Amylose and amylopectin properties

Property/trait	Amylose	Amylopectin
Granule weight	15–35 %	65–85 %
Molecular mass	10^4–10^5	10^7–10^8
Average chain length	3–1,000	3–50
Ramifications	<1 %	4–6 %
Degree of polymerization[a]	10^2–10^3	10^3–10^4
Iodine affinity (g/100 mg)	19–20.5	0–1.2
λ_{max}[b]	630–660 nm	530–570 nm

[a]Molecule average size, expressed as glucose units
[b]With Lugol (I_2/KI)

that are not absorbed in the small intestine but are fermented in the colon producing short-chain fatty acids such as butyrate, and it promotes the normal function of the colonocytes. RS functions as dietary fibers, including prebiotic effect on the colon microflora, improving lipid metabolism. There are at least four mechanisms by which RS is obtained: RS1, a physically inaccessible starch, usually encapsulated on indigestible tissues (encapsulated or embedded within a lipidic or proteic matrix); RS2, starch granules highly resistant to degradation, which has two subtypes, RS2a, with lower amounts of amylose (0–30 %), which typically loses its strength after cooking, and RS2b, starches with high amylose content which retains its granular structure during processing; RS3, retrograde starch which requires cooking to be released from the granules, and the starch retrograde capacity is affected by the intrinsic biosynthetic process; and finally, RS4, chemically modified starches. Although the last mechanism is the most used to produce resistant starch, there are no reports of changes in plant that can mimic those obtained by chemical methods (Topping et al. 2003; Morell et al. 2004; Busi et al. 2012).

2 Generalities About Location, Timing, and Regulation of the Synthesis and Degradation of Starch

Starch synthesis is restricted to the Archaeplastida, which is thought to be originated via an endosymbiotic event between ancestors of cyanobacteria and a heterotrophic host (Cavalier-Smith 2009), resulting in organelles called plastids that are able to perform oxygenic photosynthesis. Recently, phylogenetic studies show that the plastidial starch pathway is highly complex and made up of genes belonging from cyanobacteria and other eukaryotes (Patron and Keeling 2005; Deschamps et al. 2008a, b) and is in sharp contrast to the lower-complexity pathway of cytosolic starch synthesis found in the Rhodophyceae and Glaucophyta (Deschamps et al. 2008a, b; Busi et al. 2012).

Phylogenetic analysis of the enzymes of the starch biosynthetic pathway strongly suggests that the pathway was originally cytosolic in the common ancestor of the Archaeplastida and then redirected to plastids via three discrete steps, leaving some enzymes involved in the metabolism of malto-oligosaccharides (MOS) and amylopectin degradation in the cytoplasm (Busi et al. 2012). The three evolutionary steps involved are (i) plastidial synthesis of unbranched MOS; (ii) glycogen synthesis (including priming steps and branching activities); and (iii) plastidial starch synthesis, resulting in the eventual loss of cytosolic starch synthesis. Interestingly, the relocation of the starch synthesis pathway to plastids coincides with the evolution of light-harvesting complexes (Deschamps et al. 2008a, b; Tetlow 2011; Busi et al. 2012).

Plants live and grow in an environment where the light period (day) is followed by dark (night). The sunlight is the only source of energy for photosynthetic CO_2 assimilation and also constitutes a source of energy for other metabolic processes that occur into the cell. During the night, plants use the storage metabolites that accumulated during the day (Smith and Stitt 2007). When the plants grow, the

accumulation of starch produced during the day (in a near-linear manner) is offset by the degradation overnight, so that most of the reserve polysaccharide is depleted before the start of the new light period. This pattern is conserved under different conditions of irradiances, day lengths, nutrients, water amount, and CO_2 levels (Gibon et al. 2009; Tschoep et al. 2009; Hummel et al. 2010; Graf and Smith 2011; Stitt and Zeeman 2012), indicating that it represents a system feature maintained and adapted to large fluctuations in environmental conditions. This balance requires adequate changes in the rates of synthesis and degradation of starch (Smith and Stitt 2007; Stitt and Zeeman 2012).

Furthermore, it has been found indirect evidence for a role of the biological clock in regulating starch breakdown. Transcripts of genes involved in starch breakdown show large and coordinated diurnal changes, which are at least driven in part by the clock (Harmer et al. 2000; Smith et al. 2004; Lu et al. 2005; Usadel et al. 2008; Stitt and Zeeman 2012; Streb and Zeeman 2012).

Usadel et al. (2008) showed the response of genes involved in starch degradation based on data from Smith et al. (2005) and Zeeman et al. (2007). Most of them (PHS1, ISA3, DPE1, PHS2, DPE2, GWD, PWD, and SEX4 among others) show a marked circadian cycle showing a minimum at the end of the dark period and a peak near the end of the light period (Harmer et al. 2000; Lu et al. 2005), which is retained in a light/dark cycle. However, this increase is weakened or abolished early in an extended night when the clock is antagonized by darkness or falling carbon. This provides a potential mechanism to decrease the rate of starch breakdown when carbon stocks are decreasing in the light period, although the impact depends on the levels of proteins involved (Usadel et al. 2008).

Finally, we should note that the redox-related signals are crucial for the regulation of starch synthesis. ADP-glucose pyrophosphorylase (ADPGlc PPase), the key regulatory enzyme of starch synthesis in the plastid, is subject to posttranslational redox regulation. It was reported that the isoforms from pea leaf chloroplasts and potato tuber are activated by thioredoxin (Ballicora et al. 2000; Geigenberger et al. 2005). In addition, various enzymes involved in starch degradation have been found to be redox regulated, which may imply a coordinated regulation of starch synthesis and degradation by redox signals (Kotting et al. 2010; Geigenberger 2011).

One example of the redox regulation of the starch breakdown is the case of the glucan, water dikinase (GWD). This enzyme catalyzes the phosphorylation of the starch granules, an essential step for the initiation of starch degradation in plant leaves and tubers (Lorberth et al. 1998; Yu et al. 2001a; Ritte et al. 2002, 2004). It was shown that a major fraction of GWD is attached to the surface of the starch granule when isolated from dark-adapted plants, whereas the protein is predominantly found in a soluble form upon isolation from illuminated plants (Ritte et al. 2000). Mikkelsen et al. (2005) showed that GWD is subject to redox activation mediated by thioredoxin f and m, which is followed by the reversible reduction of a specific intramolecular disulfide bond. It was demonstrated that the redox state of GWD affects binding of the enzyme to the starch granules in a selective and reversible manner, which would promote granule association of

GWD in the dark (Mikkelsen et al. 2005). More studies are needed to clarify the in vivo relevance of this mechanism to initiate granule degradation at the beginning of the dark period. Similar to GWD, other enzymes involved in starch degradation such as β-amylase or pullulanase have been found to be activated upon reduction (Spradlin and Thoma 1970; Dauvillee et al. 2001; Schindler et al. 2001; Wu et al. 2002) or to interact with thioredoxins (Balmer et al. 2003), but whether this affects granule binding or multi-protein complex formation was not studied yet. It was suggested that the degradation of the crystalline starch granule may involve a coordinated association of several enzymes to the surface of the granule that is triggered by a decrease in the reduction state of thioredoxins. This mechanism may link starch degradation to light and the carbon status of the leaf (Geigenberger et al. 2005).

Figure 1 presents an outline of starch synthesis and degradation, indicating the main reactions and protein involved.

3 Starch Synthesis: Enzymes Involved

Starch synthesis initiates in chloroplasts when the intermediate of the Calvin cycle fructose-6-phosphate (Fru6P) is converted into glucose-6-phosphate (Glc6P) by the action of phosphoglucose isomerase (PGI). After that, a phosphoglucomutase (PGM1) converts Glc6P into glucose-1-phosphate (Glc1P) (Caspar et al. 1985; Streb et al. 2012).

On the other hand, in non-photosynthetic plastids that accumulate starch, this polysaccharide is produced from sucrose synthesized in the leaves (Comparot-Moss and Denyer 2009). Then, sucrose is catabolized to Glc6P in the cytosol, which could be imported into the plastids via specific hexose-P translocators (Neuhaus and Emes 2000). On the other hand, part of the ATP is also generated in cytosol after sucrose breakdown, transported into plastids via an adenylate transporter and used as energy source for starch synthesis. Inside the plastid, Glc6P is converted to Glc1P by a plastidial phosphoglucomutase. It was also reported that in specific situations, different substrates such as Glc1P may be imported into the chloroplast by the same hexose-P transporter to maintain starch biosynthesis (Tetlow et al. 1996; Fettke et al. 2010).

Three functional phosphoglucomutase proteins are present in Arabidopsis (Egli et al. 2010), one plastidial (PGM1) and two cytosolic (PGM2 and PGM3). Arabidopsis mutants with reduced PGI or PGM1 activities have significantly lower levels of leaf starch (Caspar et al. 1985; Lin et al. 1988a, b; Kofler et al. 2000); however, these plants still contain small amounts of starch in their chloroplasts, showing unaltered ADPGlc levels, suggesting the presence of another pathway that could synthesize the sugar-nucleotide precursor (Vitha et al. 2000; Munoz et al. 2005; Streb et al. 2009). One possibility to explain this situation is that as mentioned above, the Glc1P is translocated to the plastid from the cytosol. However, another possible explanation is that the ADPGlc molecule could be synthesized by alternative enzymatic activities in the mutants.

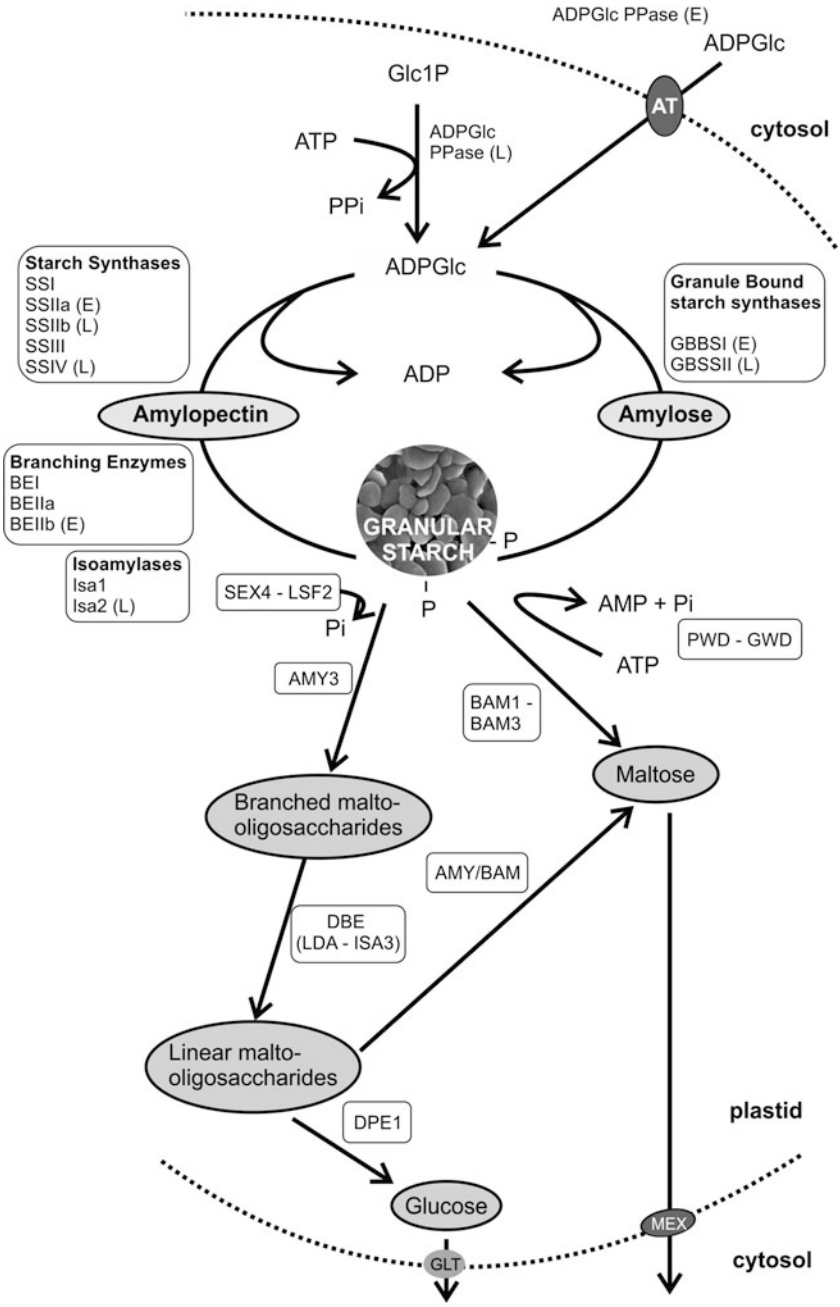

Fig. 1 Synthesis and degradation reactions of starch in plants. The scheme indicates the involvement of different isoforms in leaf (*L*) or endosperm (*E*). When not specified, the enzymes are dual localized in both compartments. All proteins concerned are listed in Tables 2, 3, 4, and 5 (AT, adenylate transporter; GLT, glucose transporter; MEX, maltose transporter)

Arabidopsis PGM2 and PGM3 single mutants present wild-type-like phenotypes; however, the loss of both cytosolic phosphoglucomutases significantly reduces the gametophyte function, probably due to a flaw on the distribution of sugars in the different metabolic pathways (Egli et al. 2010). In addition, the repression of cytosolic PGM in potato causes a significant delay in growth, a decrease in tuber number, an inhibition of sucrose synthesis in leaves, and a decrease level of sucrose and starch in tubers (Fernie et al. 2002).

The ADPGlc pyrophosphorylase (ADPGlc PPase) catalyzes the synthesis of ADPGlc from Glc1P and ATP, and this reaction constitutes the rate-limiting step for starch biosynthesis. This enzyme usually contain two catalytic (small) and two regulatory (large) subunits. Homotetrameric potato tuber ADPGlc PPase is the only PPase from plants which the 3D structure have been solved (Jin et al. 2005). The analysis of the structure show that there are two interacting domains: the N-terminal domain (catalytic) which is similar to a dinucleotide-binding Rossmann fold, whereas the C-terminal domain participates in cooperative allosteric regulation and oligomerization.

ADPGlc PPase from photosynthetic cells is tightly regulated by allosteric modulation, comprising of 3-phosphoglycerate (3PGA) activation and orthophosphate (Pi) inhibition. There is a strong evidence that the regulation by these metabolites is relevant in vivo, being the 3PGA/Pi ratio a main signal determining the starch synthesis within chloroplasts (Preiss et al. 1991; Ball et al. 1996; Preiss and Sivak 1998; Gomez-Casati et al. 1999; Gomez Casati et al. 2000; Ballicora et al. 2004). However, 3PGA can inhibit the enzymatic activity at high concentrations (Hwang et al. 2005). In contrast, whereas some ADPGlc PPases from non-photosynthetic tissues such as maize and rice endosperm and cassava roots are regulated by 3PGA/Pi, the enzymes from pea embryos, barley and wheat endosperm, and bean cotyledons are insensitive to regulation (Gomez-Casati and Iglesias 2002). In addition, as mentioned above, the small subunits of ADPGlc PPase from vascular plants are subjected to redox regulation (Ballicora et al. 2000).

All the plants analyzed contained at least three genes encoding ADPGlc PPase subunits (Deschamps et al. 2008a, b) including at least one large (L) and one small (S) subunit each. Arabidopsis mutants lacking the S or L subunit exhibit a starch-deficient phenotype (Lin et al. 1988a, b). Besides, the first maize mutant plants with altered amounts of either ADPGlc PPase S or L subunits were described almost 50 years ago. These mutant plants also showed starch-deficient phenotype, confirming a relevant function of ADPGlc PPase in starch synthesis (Tsai and Nelson 1966; Dickinson and Preiss 1969). On the other hand, transgenic plants with increased ADPGlc PPase activity triggered elevated yields in several starch-producing crops, including rice, maize, wheat, and potato (Stark et al. 1992; Greene and Hannah 1998; Huang et al. 2014).

Plant ADPGlc PPases differ in spatial and temporal expression. Cereal endosperm ADPGlc PPases are mainly located in the cytosol with only a minor amount in amyloplasts; meanwhile, they are rigorously plastidial located in other species and tissues. The differential expression of subunits in different organs results in variable degrees of sensitivity of AGPase to allosteric effectors (Wang et al. 2014).

Both cytosolic and plastidial AGPases would contribute to the production of endosperm starch (Comparot-Moss and Denyer 2009; Geigenberger 2011). Such compartmentalization requires distinctive modes of regulation and metabolic control of starch biosynthesis compared with other plants, including transport of ADPGlc and hexose-P from the cytosol into the amyloplast (Fig. 1) (Denyer et al. 1996; Thorbjornsen et al. 1996; Tetlow et al. 2003; Patron et al. 2004). Recently, it has been identified that the HvBT1 transporter in barley transports ADPGlc, the main precursor for starch biosynthesis during grain filling, from the cytosol into the amyloplasts of endospermic cells (Soliman et al. 2014). Its localization in the plastid envelop and specific expression in the endospermic barley cells indicate its significance in determining starch yield in this cereal and confirm the distinct modes of regulation between leaf and endosperm starch synthesis (Soliman et al. 2014).

Several starch synthases are thought to catalyze amylopectin synthesis, while granule-bound starch synthases (GBSS) are responsible for the biosynthesis of amylose. These enzymes are tightly bound to starch granules; for this reason they are called "granule bound" (Smith et al. 1997). *Arabidopsis thaliana* presents only one GBSS (Deschamps et al. 2008a, b), while cereals present two types of GBSS called GBSSI and GBSSII (Jeon et al. 2010). Recently, the 3D structure of the catalytic domain of rice (*Oryza sativa* japonica) GBSSI has been solved (Momma and Fujimoto 2012). It has been found that the structure was similar to those reported for the bacterial and archaeal glycogen synthases belonging to the glycosyltransferase family 5 (GT5). According to the transcripts found on the different organs, it has been shown in wheat that GBSSII is expressed predominantly in pericarp, leaf, and culm tissues, suggesting that almost all transient starch is produced by this granule-bound starch synthase (Vrinten and Nakamura 2000), whereas GBSSI (encoded by the Waxy loci (Wx) of cereals) is solely responsible or the biosynthesis of amylose in storage tissues (Smith et al. 1997). In rice it has been shown that a mutation at the Wx locus generates starch but lacking the amylose fraction, whereas a 15–30 % of amylose content is present in wild-type rice endosperm (Sano 1984). Similar results were observed in wheat (Nakamura et al. 1995). However, there is increasing evidence that GBSS is not only involved in amylose synthesis, but it is also involved in amylopectin synthesis. Studies carried out by Yoo et al. have demonstrated that there is a decreased amount of extra-long unit chains of amylopectin in Wx mutants of wheat (Yoo and Jane 2002).

SSI is one of four starch synthases present in the plastid stroma of those organisms that synthesize starch (Ball and Morell 2003). The activity of this isoform, as is the case of the other ones, depends on the organism and the tissue. For example, in developing rice endosperm, the activity of this enzyme represents the 62–66 % of the total starch synthase activity in the soluble fraction, followed by SSIII with a 26 % of the total SS activity, consistent with results obtained also in maize endosperm (Fujita et al. 2006).

SSI from barley is the only plant-soluble starch synthase of which crystallographic structures have been solved (Cuesta-Seijo et al. 2013). Unlike other SSs which present more than one isoforms in cereal species, excepting some cases like

Arabidopsis thaliana, there are no known isoforms of SSI (Deschamps et al. 2008a, b; Jeon et al. 2010). As seen on deficient SSI organisms, it was suggested that this enzyme is the major determinant for the synthesis of amylopectin, mainly involved in the biosynthesis of small outer chains (Delvalle et al. 2005).

Studies on SSI-deficient rice surprisingly shows normal seed morphology, seed weight, amount of endosperm starch, and morphology and crystallinity of endosperm starch granule. On the other hand, the structure of amylopectin is affected by this mutation. SSI prefers short glucan chains as substrate, and they propose that when the chain becomes long enough, this isoenzyme becomes inactive and actually it is entrapped inside the starch granule during the glucan deposition by others SSs (Commuri and Keeling 2001). When SSI becomes deficient, there was a reported increase of chains with degree of polymerization (DP) 6–7 and 16–19, while those of DP 8–12 decreased, indicating that SSI generates chains ranging from DP 8–12 (Fujita et al. 2006). Similar studies have been done on *Arabidopsis thaliana* and the results were in agreement with what was observed in rice. In Arabidopsis, the SSI deficiency leads to a dramatic reduction in the amount of chains with a DP of 8–12, while the ones of DP 17–20 increased (Delvalle et al. 2005). From these results it was suggested that SSI functions from early to late stages of endosperm development. In addition, the complete absence of SSI, despite being a major starch synthase isoform in endosperm, had no effect on the morphology of the starch granules, indicating that the other SS isoenzymes could partially complement SSI deficiency, leading to the modification of the length of the chains (Fujita et al. 2006). In summary, this study strongly suggested that amylopectin chains are synthesized by the coordinated actions of different SS isoforms such as SSI, SSIIa, and SSIIIa.

The second soluble starch synthase from plants, SSII, plays an essential role synthesizing the mid-length amylopectin chains. In general, SSII deficiency in different species results in increased amounts of short glucan chains (DP6 to DP11) within amylopectin, decreased abundance of DP12 to DP25 chains, and in most instances an elevated amylose to amylopectin ratio (Zhang et al. 2008). SSII deficiency in Arabidopsis showed a decreased of DP12 to DP18 chains of amylopectin, while DP6 to DP10 were significantly increased. The starch granules from *Arabidopsis* SSII mutant exhibit distorted morphology and the amount of amylose produced in leaves was increased, presumably by an increased activity of GBSS (responsible of amylose synthesis) in these mutants (Zhang et al. 2008).

In dicots only one SSII is present, in contrast to monocots that contains more than one isoform. SSII in rice presents three isoforms named osSSIIa, osSSIIb, and osSSIIc. The reason for the requirement of multiple isoforms is unknown at the present (Nakamura et al. 2005). The expression analysis of rice SSII isoforms showed that osSSIIa is expressed in endosperm, leaves, and roots, while osSSIIb is primarily expressed in leaves and osSSIIc mainly in endosperm (Jiang et al. 2004). Even though the three SSII have similar structures and the same function, it has been demonstrated that actually they are not redundant. For example, osSSIIa deficiency in endosperm leads to the increase of short chains of

amylopectin, suggesting that this isoform (and not osSSIIc) is responsible for the differences on the rice starch structure and properties. The higher content of amylopectin short chains could explain the different quality of this starch such as an easier disintegration in alkali and lower gelatinization temperature (Umemoto et al. 2002).

In maize and wheat, there are also three SSII present. In these cases, the deletion of SSIIa leads to an increase in amylose content, a decrease of longer chains of amylopectin (DP13 to DP25), and an increase of shorter chains (DP6 to DP11). Thus, it could be postulated that SSIIa has a major role, while SSIIc has a minor function in starch synthesis in endosperm (Yan et al. 2009a).

Taking in account the intron and exon arrangements of the SSII genes of both mono- and dicots, it seems that the development of the SSII genes predates the separation of these two classes (Jiang et al. 2004) and the SS gene duplication in starchy seeds species indicates that this duplication benefits storage starch synthesis in seeds (Yan et al. 2009a).

SSIII has been proposed as the responsible for the synthesis of longer amylopectin "spacers" chains extending between clusters (Maddelein et al. 1994; Wang et al. 2014) and has been proposed to perform a regulatory function in starch biosynthesis (Zhang et al. 2005; Valdez et al. 2008; Wayllace et al. 2010). However, this isoform also performs other functions that overlap with SSII to generate single-cluster chains.

Arabidopsis, wheat, and potato have only one SSIII gene (Wang et al. 2014); on the other hand, two genes are responsible for the expression of SSIII in the endosperm and leaves of rice and maize (Hirose and Terao 2004; Dian et al. 2005). The analysis of Arabidopsis *ssiii* mutants has shown that SSIII deficiency produces a starch-excess phenotype and an increase in total SS activity (Zhang et al. 2005). Loss of SSIII activity in potato tubers leads to a significant reduction of total SS activity and alterations in starch structure and physical properties (Edwards et al. 1999). Starches from SSIII-deficient maize and rice mutants show a decrease in long-branch (DP $>$ 30) proportion in addition to altered granule morphology (Gao et al. 1998). In addition, it was also documented that loss of SSIII in the maize endosperm causes decreased activity of SBEIIa and an increase in other SS activities (Boyer and Preiss 1981).

SSIII from higher plants contains two regions: an N-terminal non-catalytic SSIII-specific domain and a C-terminal domain, the catalytic domain (CD) common to all SS isoforms (Dian et al. 2005; Busi et al. 2008). It has been demonstrated that the N-terminal region of SSIII contains three starch-binding domains (SBD) that show starch-binding capacity (Palopoli et al. 2006; Busi et al. 2008; Valdez et al. 2008). These N-terminal SBDs have also a regulatory role since they modulate the catalytic properties of SSIII (Valdez et al. 2008; Wayllace et al. 2010).

Current experimental evidences provided by Gamez-Arjona et al. (2014) show that Arabidopsis SSIII exhibits a localization pattern close to the surface of the starch granule and suggest that this specific localization is mediated by its three N-terminal starch-binding domain (Gamez-Arjona et al. 2014).

Besides, we previously demonstrated the presence of protein–protein interactions between the SBDs and the catalytic domain of SSIII from *A. thaliana*. The starch-binding capacity of the SBDs and the interactions between the N- and C-terminal domains are critical in the modulation of the catalytic activity of the protein (Wayllace et al. 2010). Furthermore, it was described that the N-terminal region of maize endosperm SSIII and the central SSIII region each bind to different components of the starch biosynthetic pathway (Hennen-Bierwagen et al. 2008). Specifically, in vivo protein–protein interaction studies demonstrate that the amino terminal portion of SSIII can bind to a branching enzyme (BEIIa), whereas the SSIII central domain binds to SSI (Hennen-Bierwagen et al. 2008). Suggested potential functions for the starch synthesizing machinery complexes include substrate channeling and/or effects on the crystallization of the linear chains of amylopectin to form crystalline lamellae (Hennen-Bierwagen et al. 2008, 2009).

Meanwhile, Arabidopsis possesses just one SSIV isoform; two isoforms of SSIV exist in rice, potato and wheat, which are expressed differentially in endosperm and leaves (Dian et al. 2005; Deschamps et al. 2008a, b; Leterrier et al. 2008). Arabidopsis SSIV mutant presents just 1–2 starch granules per chloroplast and the core of these granules has a different structure from normal granules (Roldan et al. 2007). These observations indicate that SSIV is involved in starch granule initiation in Arabidopsis, granule number control, and production of short branches, although the mechanisms involved remain unclear (Roldan et al. 2007; Szydlowski et al. 2009). On the other hand, no SSIV-deficient mutant has yet been characterized in cereal plants at the present (Roldan et al. 2007; Jeon et al. 2010).

Recently, Gamez-Arjona et al. (2014) described that SSIV displays a different localization from other starch synthases. This enzyme is located in specific areas of the thylakoid membrane and interacts with fibrillin 1a (FBN1a) and 1b (FBN1b), which are mainly located in plastoglobules. The localization pattern of SSIV is mediated through its N-terminal region, which contains two long coiled-coil motifs (Gamez-Arjona et al. 2014). The localization of this isoform in specific areas of the thylakoid membrane suggests that starch granules are originated at specific regions of the chloroplast.

A summary of the enzymes involved in starch synthesis in Arabidopsis as well as in other species are shown in Tables 2 and 3.

4 Starch Degradation Pathway

Leaf starch breakdown occurs at night via the coordinated actions of a suite of enzymes constituting a network of reactions rather than a linear pathway. Many of the enzymes involved are represented by numerous isoforms. The chloroplastic starch degradation pathway is summarized and illustrated in Fig. 1 with the different *A. thaliana* isoforms implicated listed in Table 4 and the isoforms from other species in Table 5.

As it is generally known, starch is a water-insoluble polymer whose surface is inaccessible to most enzymes; thus, the starch granule surface reversible

KO knockout, *KD* knockdown, *OE* overexpression

dikinase (PWD) (Ritte et al. 2006). C6 phosphorylation overlaps the non-phosphorylated structure of the amylopectin structure, but C3 phosphorylation imposes a marked steric effect that leads to a conformational shift. C6 phosphorylation by GWD, then, promotes the local hydration of the crystalline lamella and C3 phosphorylation by PWD induces a deformation of the helix. This deformation renders the substrate more accessible to the glucan hydrolytic enzymes.

Both starch-phosphorylating enzymes are effectively the first step on the degradation pathway and so they are attractive candidates for the control of flux through

Glucan phosphorylating enzyme – 1,4 α-D-Glc + H2O + ATP → phospho-1,4-α- D-Glc + AMP + Pi				
StGWD	*Solanum tuberosum*	AFH8838	Plastidic; KD: *sex*, drastically reduced phosphate content in leaf and tuber starches	Lorberth et al. (1998)
OsGWD1	*Oryza sativa*	Os06g0498400	KO: *sex* in leaves but limited effects on vegetative growth, 20–40 % grain yield reduction	Hirose et al. (2013)
LeGWD	*Solanum lycopersicum*	ACG69788	KO: sex in leaves, pollen germination arrest, and male sterility	Nashilevitz et al. (2009)
GWD	*Triticum aestivum*	ADG27838	KD: decrease in starch phosphate content and increase in grain size and vegetative biomass	Ral et al. (2012)
Phosphoglucan phosphatase – removes a phosphate group from phosphoglucosyl residues within amylopectin				
HvSEX4	*Hordeum vulgare*	AID16302	Chloroplastic	Ma et al. (2014)
β-amylase – from the nonreducing end, catalyzes the hydrolysis of the second α(1,4)-glycosidil-bond cleaving off maltose				
PCT-BMY1	*Solanum tuberosum*	NP_001275172	KD: *sex* in leaves	Scheidig et al. (2002)
Os BAM 1-9	*Oryza sativa*	–	OsBAM2 and OsBAM3 are plastid-targeted active β-amylase	Hirano et al. (2011)
α-amylase – hydrolyzates α-1,4 linkages at random location yielding glucose, maltose, maltotriose, or limit dextrin				
OsAMY1-1	*Oryza sativa*	P17654	Chloroplastic. KO: sex. seed germination and seedling growth markedly delayed	Huang et al. (1990) Asatsuma et al. (2005)
TaAMY3	*Triticum aestivum*		Plastidic. OE: minimal effect on the overall grain weight or the starch content	Barrero et al. (2013), Whan et al. (2014)
α-1,6-glucosidase/Starch debranching enzyme – Acts on α-1,6 linkages releasing oligosaccharides				
StISA3	*Solanum tuberosum*	AAN15319	ISA-type DBE. KO: sex in leaves	Hussain et al. (2003)
OsISA3	*Oryza sativa*	AEV92948	ISA-type DBE. Plastidial. KO: sex	Yun et al. (2011)

(*continued*)

Table 5 (continued)

Name	Specie	Locus	Localization/phenotype	References
ZPU1	*Zea mays*	O81638	Pleomorphic plastids and starch granules LD/PUL-type DBE. KO: *sex* in leaves Decreased rate of starch degradation Decreased rate of cotyledon growth	Beatty et al. (1999), Dinges et al. (2003)
HvLD	*Hordeum vulgare*	O48541	LD/PUL-type DBE Amyloplastic in aleurone cells	Kristensen et al. (1999), Vester-Christensen et al. (2010)
α-Glucan phosphorylase – ((1,4)-α-D-glucosyl)(n) + Pi ↔ ((1,4)-α-D-glucosyl)(n-1) + α-D-glucose 1-phosphate				
HvPHO1	*Hordeum vulgare*	AFP19106	Plastidic. KD: not lead to any visible phenotype, no dramatic alterations in the structure of the starch	Ma et al. (2013)
HvPHO2	*Hordeum vulgare*	ACV72276	Cytosolic	Ma et al. (2013)
SP	*Zea mays*	–	Plastidic	Mu et al. (2001), Yu et al. (2001b)
TaPHO1	*Triticum aestivum*	ACC5920	Plastidic	Tickle et al. (2009)
4-α-glucanotransferase/disproportionating enzyme – transfers glucose/ α-1,4-linked glucan moiety from a donor glucan to an acceptor releasing the nonreducing end glucose/glucan moiety (reversible)				
StDPE1	*Solanum tuberosum*		KO: slightly *sex*	Takaha et al. (1993), Lutken et al. (2010)
StDPE2	*Solanum tuberosum*		Cytosolic. KO: large amounts of maltose and starch	Lutken et al. (2010)

KO knockout, *KD* knockdown, *OE* overexpression

starch degradation. Both enzymes and their expression profile possess properties consistent with modulation of their activities over the day/night cycle (i.e., redox regulation and transcript levels shows large daily changes) (Yu et al. 2001a; Smith et al. 2004; Baunsgaard et al. 2005; Kotting et al. 2005). However, recent work presented begun to tackle this point by establishing that translational control and redox activation are of limited relevance for the control of starch turnover in *Arabidopsis* leaves (Skeffington et al. 2014).

It is worth mentioning that for an efficient digestion of the starch molecule, a glucan phosphatase activity is required to avoid the accumulation of either phosphorylated starch or phosphorylated intermediates from starch breakage (Kotting et al. 2009). This role is played mainly by the starch-excess 4 (SEX4) glucan phosphatase. Primary structure of SEX4 includes an N-terminal chloroplast transit peptide, a dual-specificity phosphatase domain (DSP), and a carbohydrate-binding module (CBM) belonging to the family 48 group (Kotting et al. 2009; Vander Kooi et al. 2010). The glucan-free SEX4 crystal structure indicated that its CBM and DSP domains interact to form binding pocket that carry out two functions: glucan binding and dephosphorylation (Vander Kooi et al. 2010). SEX4 mutations lead to an important increase of starch accumulation in *A. thaliana* leaves due to a decrease in the degradation rate and an increase in the levels of soluble phospho-oligosaccharides (Zeeman et al. 1998; Sokolov et al. 2006; Kotting et al. 2009). Besides catalyzing the dephosphorylation of amylopectin, recombinant SEX4 is able to dephosphorylate crystalline maltodextrins (Hejazi et al. 2010), starch granules isolated from *A. thaliana* leaves and phospho-oligosaccharides (Kotting et al. 2009). While phosphorylation at positions C6 and C3 is performed by two different dikinases, SEX4 is able to dephosphorylate both positions but preferentially acts on C6 position (Kotting et al. 2009; Hejazi et al. 2010). Recently, the phosphoglucan-bound crystal structure of SEX4 was resolved and the authors described its possible catalytic mechanism. In addition, the identification of two DSP domain residues involved in SEX4 site-specific activity leads to the construction of a SEX4 mutant that reversed the specificity from the C6 to the C3 position (Meekins et al. 2014).

Two SEX4-homolog enzymes have also been characterized in Arabidopsis and named as LSF1 (for Like SEX4 1)and LSF2 (for Like SEX4 2) (Comparot-Moss et al. 2010; Santelia et al. 2011). Although plants lacking LSF2 possess normal levels of starch, *lsf2*/*sex4* double mutants show a more severe starch-excess phenotype respect to *sex4* alone, suggesting that LSF2 has a partial overlapping function in starch dephosphorylation. Indeed, LSF2 exclusively dephosphorylate the C3 position of amylopectin in vitro (Santelia et al. 2011); however, unlike other starch-binding enzymes, including SEX4, LSF2 does not possess a CBM. Instead, LSF2 possesses a unique DSP active site which has a dual function: a glucan binding site and phosphatase activity (Meekins et al. 2013).

LSF1 is also a chloroplast enzyme needed for efficient starch degradation: lsf1 mutants, like sex4 mutants, contain more quantities of starch in their leaves than wild type (wt) plants during the day (Comparot-Moss et al. 2010). However, genetic and transcription profile analyses as well as biochemistry studies indicate that its function would be different from SEX4 since it is mentioned as an inactive phosphatase although it shares similar primary structure to SEX4 and contains all the essential residues required for catalysis (Comparot-Moss et al. 2010). Thereby, LSF1 functions in starch metabolism, although its precise role is unknown; however, it is possible that LSF1 may recruit starch degradative enzymes to the granule surface.

As a consequence, during starch degradation, the granule surface is destabilized by phosphorylation and then simultaneously degraded by glucan hydrolytic enzymes and dephosphorylated by SEX4 and LSF2 (Stitt and Zeeman 2012). Precisely how GWD, PWD, SEX4, and LSF2 might be regulated to limit the ATP consumption of the system while permitting an appropriate flux through the starch degradation pathway remains to be discovered.

Among the hydrolytic enzymes we found β-amylases, α-amylases, debranching enzymes, disproportionating enzymes, and α-glucan phosphorylases. The five enzymes play a concerted role in the liberation and metabolism of malto-oligosaccharides in the stroma, being β-amylases and debranching enzymes the most important.

β-amylases (BAM) are exoamylases that catalyze the hydrolysis of α1-4 D-glucosidic linkages in polysaccharides, successively removing maltose units from the nonreducing ends of the chains. BAMs cannot hydrolyze nor act close to α-1,6 branch points neither can act over phosphorylated glucans. That is the reason why dephosphorylating enzymes (discussed above) as well as debranching enzymes (DBEs, discussed later) are critical for correct starch degradation. Plant genomes encode multiple β-amylase-like proteins. In Arabidopsis, there are nine genes, which have been designated BAM1 to BAM9 to provide a unifying nomenclature (Smith et al. 2004). Of all such genes, only BAM1 and BAM3 have been directly implicated in starch degradation playing a central role in the breakdown of leaf starch (Kaplan and Guy 2005). The loss of BAM2 has little effect in all genetic backgrounds assayed and no discernible function has been assigned yet (Fulton et al. 2008). Other data suggest that BAM4 facilitates or regulates starch breakdown and operates independently of BAM1 and BAM3 revealing unexpected complexity in terms of the specialization of protein function within the β-amylase gene family (Fulton et al. 2008; Li et al. 2009; Francisco et al. 2010). The complexity of β-amylase gene family was more recently exemplified by the finding of BAM7 and BAM8 as nuclear β-amylases involved in transcriptional activation (Soyk et al. 2014).

DBEs, also called isoamylases (ISAs), hydrolyze α1-6 D-glucosidic branch linkages in amylopectin and their β-limit dextrins releasing oligosaccharides into the stroma. There are two classes of DBE in higher plants, and they are referred to as pullulanase-type DBE (PUL) and isoamylase-type DBE (ISA) (Ball et al. 1996; Beatty et al. 1999). Four genes coding for DBE proteins are conserved in higher plants, one for a PUL protein and three for ISA proteins, designated as ISA1, ISA2, and ISA3 (Deschamps et al. 2008a, b). They play a dual role in the synthesis and degradation of starch in higher plants. ISA1 and ISA2 proteins exist together in a heteromeric complex, function together, and are strongly implicated in amylopectin synthesis (Fujita et al. 1999; Hussain et al. 2003; Bustos et al. 2004; Delatte et al. 2005; Utsumi and Nakamura 2006; Takashima et al. 2007; Zeeman et al. 2010). On the other hand, PU1 and ISA3 are not strongly associated within a multimer and may function as a monomer, both preferring substrates with short outer chains, such as β-limit dextrins, suggesting that their role is primarily in starch degradation. Consistently, mutating these

genes in Arabidopsis causes a sex phenotype (Delatte et al. 2006; Streb et al. 2008; Wattebled et al. 2008).

Although BAM3 and ISA3, the major enzymes that hydrolyze the α-1,4 and 1,6 linkages of the Glc polymers that constitute the starch granule, are inhibited by oxidation in vitro (Glaring et al. 2012), there is no evidence about the importance of these proteins on the modulation or control of starch degradation in vivo.

The starch degradative scenario is completed by α-amylases (an endoamylase that hydrolyze α 1–4 D-glucosidic linkages in polysaccharides containing three or more α-1,4-linked D-glucose units), α-glucan phosphorylases (act on the nonreducing end of α-1,4-linked glucose giving Glc P using polysaccharide and phosphate as substrate), and the disproportionating enzymes.

Alpha-amylases are endo-hydrolases belonging to the GH13 family (Majzlova et al. 2013). The roles and number of isoforms vary across the plant kingdom. In Arabidopsis, three isoforms have been described: AtAMY1, AtAMY2, and AtAMY3. AtAMY3 is the only plastidic alpha-amylase, whereas AtAMY1 and AtAMY2 do not have any chloroplast targeting peptide (Yu et al. 2005).

The importance of AMY3 in transitory starch catabolism was demonstrated when AMY3 knockout mutants were combined with knockout ones of debranching enzyme and/or limit dextrinase-deficient lines. AMY3 could participate in starch breakdown in wild type leaves; however, other enzymes can compensate its deficiency. In addition, neither of the three AMY proteins are required for normal rates of starch degradation, and starch degradation is normal even when all three AMY genes are disrupted (Yu et al. 2005). Recently, Streb et al. (2012) suggested that AMY3 acts on starch granules leading to short branched glucans within the chloroplast stroma. Thus, these glucans undergo a rapid conversion into maltose and glucose by debranching enzymes (Streb et al. 2012).

In Arabidopsis, α-amylase does not have a major role in starch degradation. However, in germinating cereal seeds, different amylase isoforms are secreted from the aleurone cells and play an important role in the degradation of storage starch in the nonliving starchy endosperm (Asatsuma et al. 2005; Whan et al. 2014).

Another enzyme involved in starch breakdown is α-glucan phosphorylase (PHS). This is the only phosphorolytic enzyme involved in starch metabolism and catalyzes a reversible glucosyl transfer reaction either in the direction of glucan synthesis from Glc1P in the presence of glucan primer liberating orthophosphate (Pi) or, if Pi is abundant, in the direction of glucan phosphorolysis forming Glc1P. In both cases, the nonreducing end(s) of the glucan primer act(s) as glucosyl acceptor and donor, respectively.

The metabolic function of PHS has been a great deal of debate. One widely accepted idea, according to which the physiological function of PHS1 is to degrade rather than to synthesize glucans, is based on the observations that PHS1 has a low affinity for Glc1P and that low levels of Glc1P and high levels of inorganic phosphate are found in plant cells (Kruger and Ap Rees 1983; Preiss and Sivak 1998). On the other hand, it has been demonstrated that PHS homologs are involved in starch biosynthesis in rice endosperm and potato tuber (Satoh et al. 2008; Fettke et al. 2010; Hwang et al. 2010; Nakamura et al. 2012).

In this direction, PHS plays a probed role in the capacity of the leaf lamina to endure a transient water deficit; however, it is not required for the degradation of plant starch: complete loss of the enzyme does not cause a significant change in the overall accumulation of starch during the day or its remobilization at night in healthy plants (Zeeman et al. 2004).

Finally, we have to mention the disproportionating enzymes (DPE). DPE is an α-1,4 glucanotransferase which catalyzes the cleavage of α-1,4 glucosidic bonds of polyglucans (maltotriose or larger), transferring the glucosyl groups to the nonreducing end of another glucan chain or free glucose and releasing either glucose or a glucan chain depending on the cleavage site. The *Arabidopsis* genome encodes two 4-α-glucanotransferase-like proteins: DP1 and DP2. DP1 is a chloroplastic enzyme responsible for the metabolism of the maltotriose or short malto-oligosaccharide products of starch degradation at night, presumably generated by chloroplastic β-amylolysis since DPE1 mutants accumulate maltotriose during starch breakdown at night (Critchley et al. 2001). The other DPE protein, DPE2, is cytosolic (Lutken et al. 2010). Independent mutant lines deficient in DPE2 show a decreased capacity for both starch synthesis and degradation in leaves. Thus, DPE2 is an essential component of the pathway from starch to sucrose and cellular metabolism in leaves at night despite its cytosolic localization. Probably, its role is related with the metabolization of maltose exported from the chloroplast (Chia et al. 2004; Lu and Sharkey 2006).

In summary, the main route of starch degradation in *Arabidopsis* is via GWD and PWD, which introduce some disorder at the starch granule surface, and are followed by the action of the β-amylases, debranching enzymes, and glucan phosphatases (SEX4 and LSF2). These enzymes act progressively and in combination to produce maltose, maltotriose, and longer malto-oligosaccharides (MOS) as the major products of the initial steps of starch degradation. α-amylases, DBE, PHS1, and DPE1 complement starch degradation to produce finally maltose and glucose, the two products of starch breakdown that are exported from the chloroplast to the cytosol via distinctive specific transporters (see Fig. 1). Despite its importance for productivity, we do not yet know how the rate of starch degradation is controlled.

5 Starch-Related Enzymes in *Arabidopsis thaliana* Preserve a Modular Structure

Enzymes that catalyze the reactions of glycosidic bonds share a modular organization that includes a catalytic domain and one or more carbohydrate binding module (CBM) connected by a loosely structured chain (Henrissat and Davies 1997).

Catalytic domains are often classified with an EC number according to the International Union of Biochemistry and Molecular Biology (IUBMB) recommendations and their substrate specificities (Barrett 1995), but this classification may fail to describe structural, evolutionary, and mechanistic similitude between these enzymes (Henrissat and Davies 1997). Sequence similarity classification can take into account these aspects because they are defined by the primary sequence alone

(Henrissat and Davies 2000) and could provide a more descriptive classification. CAZy classification includes these approaches (structural and mechanistic based on sequence similarity) to create a database of all known carbohydrate-associated enzymes. However, this system often grouped enzymes of different substrate specificity into a single "poly-specific" group. Nevertheless, a family can only be defined when one of its members is characterized biochemically (Valdez et al. 2008). Still, catalytic residues could be identified in both position and function for one member of a family, and then, they can easily be inferred for all members of the family (Henrissat and Davies 2000). This classification is available on the CAZy website (http://www.cazy.org) (Lombard et al. 2014).

This common modular structuration is also conserved in numerous *Arabidopsis thaliana* starch metabolism enzymes (Table 6). A batch of starch-associated enzymes were analyzed with the NCBI Conserved Domain-search tools (Marchler-Bauer and Bryant 2004; Marchler-Bauer et al. 2009, 2011), and the output was organized according to detected domain superfamily. Of the 40 proteins analyzed, we found 19 independent domains, many of them repeated in several degradation and synthesis enzymes.abcdefg

Table 6 shows that some domains tend to be exclusive of degradative (alpha-amyl_C2, CBM20, PPDK_N, PTPc, Glyco_hydro_77 and PDZ) or synthetic (alpha-amylase C, CBM 53, GT-A, LbH, phosphohexomutase, MRP-L20, RAP1, and tropomyosin_1) enzymes and others are present in both types of enzymes (AmyAc_family, CBM 48 and GT-B).

The domains present in the AmyAc_family are the most frequent glycoside hydrolase (GH) domain with the majority of enzymes acting on starch, glycogen, and related oligo- and polysaccharides (Janecek 1997; Janecek et al. 1997) catalyzing the transformation of α-1,4 and α-1,6 glucosidic linkages with retention of the anomeric center. In the *Arabidopsis thaliana* starch metabolic pathway, these modules are present in degradative enzymes such as ß-amylases (BAM1-9), pullulanase, and isoamylase (ISOA) as well as in synthesizing enzymes such as starch branching enzymes (SBE3, SBE2.2, and SBE2.1). These latter proteins also have an alpha/beta-barrel domain present in eight stranded α/ß barrel, interrupted by a calcium-binding domain, and a C-terminal Greek key beta-barrel domain (Strobl et al. 1998).

Alpha-amyl_C2 domains are associated to an O-glycosyl hydrolase (EC 3.2.1.) activity, which are found in the C-terminal end in numerous α-amylases and fold into a five-stranded antiparallel ß-sheet structure (Kadziola et al. 1998). They are actually present in three *A. thaliana* α-amylases (AMY1, AMY2, and AMY3) catalyzing the hydrolysis of α-1,4-glucosidic bonds of starch (Lloyd et al. 2005). The branching enzymes (BEs) catalyze the formation of α-1,6 branch points in either glycogen or starch by cleavage of the α-1,4 glucosidic linkage yielding a more reactive glycogen with an increased number of nonreducing ends.

The CAZy glycoside hydrolase family 77 contains a 4-α-glucanotransferase activity (disproportionating activity) that comprise the transfer of a (1 → 4)- α-D-glucan segment to a new position in an acceptor, which may be glucose or another (1 → 4)-α-D-glucan (Pazur and Okada 1968). This domain is present in the DPE1

Table 6 Summary of domains presents in *Arabidopsis thaliana* starch metabolism enzymes

Protein name	Description	Locus ID	UniProt ID	From	To	Domain	Function
AMY1	Alpha-amylase 1 (AMY1)	At4g25000	Q8VZ56	362	422	Alpha-amyl_C2	Degradation

Script curated CD-search output (Marchler-Bauer and Bryant 2004; Marchler-Bauer et al. 2009; 2011) was used to construct this table. See text for domain description. Domains that do not have a specific function annotated are annotated as "DUF" families (domain of unknown function). Protein name refers to the most common name for a specific protein. "From" and "to" refers to the domain specific position in the amino acidic sequence. "Synthesis" and "degradation" attempt to summarize the specific role of a protein in the starch metabolism, although a protein may be playing a role in both pathways

(disproportionating enzyme) of *Arabidopsis thaliana* and folds into a (β/α) 8-barrel with a strand β4-aspartic acid (catalytic nucleophile), a β5-glutamic acid (proton donor), and a β7-aspartic acid (transition-state stabilizer) critical for the catalytic machinery (Jespersen et al. 1993). At this moment, the three-dimensional structures have been solved for only five members of the family (Cantarel et al. 2009; Levasseur et al. 2013).

Glycosyltransferases (GTs) are enzymes that synthesize oligosaccharides, polysaccharides, and glycoconjugates by transferring the sugar moiety from an activated nucleotide-sugar donor to an acceptor molecule (oligosaccharide, a lipid, or a protein). Based on the stereochemistry of the donor and acceptor molecules, GTs could be classified as either retaining or inverting enzymes (Lairson et al. 2008).

It has been described that glycosyltransferases adopt two different folds, named GT-A and GT-B (Bourne and Henrissat 2001; Breton et al. 2001). The GT-A includes diverse families of glycosyl transferases that folds into two closely neighboring β/α/β Rossmann domains, one for nucleotide binding and the other for the binding of the acceptor molecule (Charnock and Davies 1999).

The GT-B fold is present in other families (GT-3 and GT-5 families) including about glycogen or starch synthases from different organisms (Gomez-Casati et al. 2013). The first protein whose structure was described in this group of GTs was the glycogen synthase from *Agrobacterium tumefaciens* (Buschiazzo et al. 2004). It was reported that the overall fold and the architecture of the active site of the protein are remarkably similar to those of glycogen phosphorylase (Buschiazzo et al. 2004). GTB proteins have distinct N- and C-terminal β/α/β Rossmann domains that face each other and have high structural homology despite minimal sequence homology. The large cleft that separates the two domains includes the catalytic center and permits a high degree of flexibility (Lairson et al. 2008).

In *Arabidopsis thaliana*, those GT-A domains are associated mainly with the starch synthesis Glc1P adenylyltransferase enzymes (APL2, APL3, GLGL, ADG2, APS1, and ADG2). Some of the mentioned GT-A present a left-handed parallel beta-helix (LbetaH or LbH) domain, which is related with enzymes showing as diverse activity as acyltransferase, ion transport, or translation initiation (Raetz and Roderick 1995). In addition, the GT-B domains are associated with both degradative enzymes such as α-glucan phosphorylase (PHS1 and PHS2) and synthesizing enzymes such as starch synthases (SS1, SS2, SS3, SS4, and GBSS1). Interestingly, the *Arabidopsis* SS3 protein presents a domain that resembles the mitochondrial ribosomal protein subunit L20 (MRP-L20) of fungi (Garcia-Cantalejo et al. 1994), but has no assigned function in the *A. thaliana* enzyme.

The PTPc domain superfamily is defined by a dual-specificity phosphatase protein that catalyzes the dephosphorylation of phosphotyrosine peptides and oligosaccharides. This domain is present in *A. thaliana* DSP4 (SEX4), LSF1, and LSF2 and mediates the reversible phosphorylation of starch at the C6 and C3 positions of glucose moieties (Comparot-Moss et al. 2010; Meekins et al. 2014). Starch phosphorylation is the only known natural modification and is the key regulatory mechanism controlling its diurnal breakdown in plant leaves (Meekins et al. 2014). The PDZ domain is present in LSF1 and it is believed that LSF1 may be

responsible for specific protein–protein interactions through this N-terminal beta-strand structure (Harris and Lim 2001).

The phosphoglucan, water dikinase (PWD1) and the α-glucan, water dikinase (GWD1, GWD2) proteins share a domain classified in the PPDK_N superfamily which is mainly characterized by enzymes showing a pyruvate phosphate dikinase, a PEP/pyruvate binding, and a reversible conversion of ATP to AMP activity (Herzberg et al. 1996). However, in these enzymes this domain are implicated in the phosphorylation of starch polymers, being the first step on the pathway of starch degradation in Arabidopsis leaves at night (Skeffington et al. 2014).

Phosphoglucomutase enzymes play an important and diverse role in carbohydrate metabolism in organisms from bacteria to humans. The *A. thaliana* phosphoglucomutase PGMC, PGMC, and PGMP (Table 6) have a phosphohexomutase domain (superfamily) that catalyze a reversible intramolecular phosphoryl transfer of Glc1P and Glc6P via a Glc1,6bisP intermediate (Levin et al. 1999).

Finally, the SBE2.1 and SS4 strikingly present some unusual domains, such as RAP1 (rhoptry-associated protein 1) (RAP-1) and a tropomyosin_1, respectively. The first domain belongs to a family that consists of several rhoptry (parasite secretory organelle)-associated proteins specific to *Plasmodium falciparum* (Moreno et al. 2001), and the second domain (tropomyosin_1) resembles to a tropomyosin-like protein.

Because the starch granule structure exposes very few chain ends, starch-associated enzymes must have a "processive" or "multiple-attack" activity that can perform many hydrolytic events without releasing the polysaccharide chain (Henrissat and Davies 1997). Some proteins are equipped with carbohydrate-binding modules (CBMs), which are able to fulfill this task. A CBM is defined as the contiguous amino acid sequence in an active enzyme involved in carbohydrate metabolism, with the ability to bind carbohydrates (Shoseyov et al. 2006). CBMs contain between 30 and 200 amino acids and may exist as simple, double, or triple repeats in a protein. These domains are located at the N- or C-terminal end of a protein and occasionally can be found in the middle of the polypeptide chain. Currently, more than 300 putative sequences in over 50 different species have been identified and the binding domains have been classified in 71 families, based on their amino acid sequence, substrate binding specificity, and structure (see CAZY http://www.cazy.org) (Boraston et al. 2004; Lombard et al. 2014). By driving the catalytic process through a strong physical association with substrates, CBMs can increase the rate of enzymatic reactions. When CBMs are present in proteins with no hydrolytic activity, they constitute an organizing subunit of catalytic domains generating cohesive multienzymatic complexes that lose enzymatic activity when CBMs are removed from the structure (Shoseyov et al. 2006).

Based on the CAZy classification, we found three carbohydrate-binding modules families, CBM53, CBM20, and CBM48 (E_set). CBM53 and CBM20 which show a starch-binding function (Mikami et al. 1999; Valdez et al. 2008). The CBM48 family is often found in enzymes containing glycosyl hydrolase, family 13, catalytic domains and is mainly described in enzymes that degrade branched substrates as glycogen (Katsuya et al. 1998; Hudson et al. 2003).

Among the CBMs, we can highlight the starch-binding domains (SBD), which have acquired the evolutionary advantage to break the structure of their substrate when compared to the CBD, due to the presence of two binding sites for the polysaccharide (Southall et al. 1999). So far, no CBM 3D structure containing such binding sites has been reported. In view of this, such domains are unable to break down the polysaccharide structure as efficiently as the SBD do (Tormo et al. 1996; Southall et al. 1999).

While SSIII has three in tandem CBM in its N-terminal domain that belongs to the CBM53 family, the degradative enzymes (LSF1, SEX4, as well as the proteins encoded by At5g39790 and At1g27070) have only one CBM in their C-terminal domain belonging to the CBM48 family. It is worth mentioning that there is a clear evolutionary relatedness of CBM48, CBM53, and CBM20. Moreover, the alignment of the amino acid sequences of CBM20 (including some mammalian proteins, such as laforin, involved in the regulation of glycogen metabolism), CBM21, CBM48, and CBM53 has revealed only subtle differences in the polysaccharide-binding sites, showing a high degree of conservation (Christiansen et al. 2009).

6 Concluding Remarks

Starch is the most important higher plant storage carbohydrate and is made up of the glucose long chains amylose and amylopectin. Plants use starch as an energy source during the night, when leaves cannot generate sugars by photosynthesis. The polysaccharide forms complex semicrystalline structures called starch granules which accumulate within the plastids. Its metabolism involves the concerted and controlled actions of many enzymes. In most cases, multiple genes encode different isoforms of each enzyme, which may have slightly different roles depending on plant species and tissue (Kotting et al. 2010).

We have attempted a comprehensive review of the existing information on the different enzymes involved in *Arabidopsis thaliana* and other species of agronomic interest. From our point of view, to address biotechnologically starch metabolism is essential to expand the knowledge of the enzymes involved in this process. Tables 2, 3, 4, and 5 brought together the main works on this subject, describing not only the native proteins but also the plant phenotypes obtained by overexpression or deletion of specific genes. Furthermore, previous work was done in vivo where different groups have obtained modified starches (quantity and quality) through the action of different carbohydrate-binding modules of degradative microbial enzymes. Indeed, we also described the existence of such modules in some starch biosynthetic enzymes in plants. Therefore, and considering the modular structure of many enzymes involved in the metabolism of this polysaccharide, we have a section dedicated to review this point.

Recent work has focused on the role of starch as a carbon storage polymer without demonstrated regulatory activities. It is more likely that regulators of starch metabolism or signals derived from starch act as integrators of plant metabolism and growth. Gibon et al. (2009) have demonstrated a strong correlation between

starch turnover, protein content, and biomass when *Arabidopsis thaliana* Col0 plants were grown at different photoperiods (Gibon et al. 2009). Although the biomass was only very weakly correlated with individual metabolites in a recombinant Arabidopsis population, a highly significant prediction was obtained when multivariate analysis was used on the entire metabolite profile. Meyer et al. (2007) confirmed the negative link between biomass and starch (except in very short days). The simplest explanation for this negative relationship would be that large accessions maximize growth at the expense of their carbon reserves. Such a strategy would be an advantage when an excess of carbon is available, but not when carbon is in small amounts (Sulpice et al. 2009).

Moreover, starch represents an important nutrient for humans and animals and a raw material for many industrial applications. For the industry, starch represents a cheap and renewable material, with differential physicochemical properties that make it increasingly exploited in the agricultural and food sectors and in manufacturing processes (Blennow et al. 2002; Delcour et al. 2010). Starch is also used as a feedstock for first generation bioethanol production (e.g., corn, sugar cane, and cassava). The use of major food crops for energy purposes has led to the study of their applications and potential applications to obtain energy from cellulose present in plant cell walls, in addition to the study of different strategies to increase the levels of starch in plants as well as the production of starches with new attributes, in accordance with the present industrial requirements (Santelia and Zeeman 2011).

Finally, the importance of a variety of renewable biofuels has been renovated due to the increase of petroleum fuel costs and the consequences resulting from greenhouse emissions (Cheng et al. 2011). This has enhanced the interest in the study of photosynthetic algae (microalgae and macroalgae) as a possible biofuel resource because some algae species have a higher rate of biomass production compared to terrestrial plants (Dismukes et al. 2008). Graham et al. (2000) have postulated that land plants evolved from green algae belonging to the Charophyceae (Graham et al. 2000). Starch biosynthesis is unique to the Archaeplastida supergroup, comprising Chloroplastida (green algae and land plants), Rhodophyceae (red algae), and a minor group called the glaucophytes. Differences in the starch biosynthetic pathways between the archaeplastidal lineages have arisen during subsequent evolution whose starting point is the ancestral bacteria capable of synthesizing glycogen (Zeeman et al. 2010). Most notably, in green plants, starch is synthesized in the plastid compartment, whereas in red algae and in glaucophytes, its synthesis occurs in the cytosol (Shimonaga et al. 2008). Plant genomes are usually large and complex, having gene redundancy, duplications, and transposable elements among other features (Derelle et al. 2006; Armisen et al. 2008; Plancke et al. 2008). Interestingly, in the last years, several nuclear and organelle algae genomes have been sequenced (Busi et al. 2014). Because these genomes have proven to be simple, and due to the genomic, molecular, and physiological characteristics of these organisms, the unicellular green algae have become highly suitable for the study of numerous biological processes related with starch metabolism, and thus, these studies could help clarify the unknown mechanisms of starch synthesis in higher plants.

Abstract

Many species of higher basidiomycetes have traditionally been used because of their medicinal properties. The positive effects associated to the consumption of those fungi have been mainly attributed to cell wall polysaccharides, which have important structural roles and are present throughout the entire life cycles of fungi.

DOI 10.1007/978-3-319-16298-0_21

One of the most consumed and studied species native of the Americas is *Agaricus subrufescens*, a mushroom prescribed in different countries for prophylaxis and noninvasive treatment of numerous health-related disorders. Prior to the process of extraction, purification, and application of these polysaccharides, one needs to be concerned with the preservation of the specimen and production of fungal biomass. Even though basidiomata (syn. fruiting bodies, mushrooms) generally yield larger volumes of biomass when compared to the mycelium, cultivation of mycelium allows a more efficient control of the process and, therefore, is the method of choice of polysaccharide production. Mycelial biomass can be produced by solid-state fermentation (SSF) or submersed fermentation (SmF). Further separation and concentration of bioactive polysaccharides can be done by means of porous membranes, such as tangential flow nanofiltration.

Agaricus subrufescens • Biological activity • Fungal biomass • Solid-state fermentation (SSF) • Submersed fermentation (SmF) • Nanofiltration • Polysaccharides

1 Introduction

For millennia, many species of higher basidiomycetes have been traditionally cultivated and used as sources of healthy food and medicines. The interest upon products obtained from fungi has increased during the recent years. Among the most noticeable, nutraceuticals, enzymes, and natural drugs occupy a privileged position. The active constituents found in fungi are polysaccharides, dietary fibers, oligosaccharides, triterpenoids, peptides and proteins, alcohols and phenols, and mineral elements such as zinc, copper, iodine, selenium, and iron, in addition to vitamins and amino acids (Lakhanpal and Rana 2005).

Polysaccharides are one of the main components of fungal cell walls. They have important structural roles and are present throughout the entire life cycles of fungi, commonly displaying different structural arrangements according to the fungal developmental stage. These compounds are structurally oriented, mainly by β-D-glucose monomers with high molar mass. Furthermore, different cross-linkages between the monomers from the main chain and its lateral branching give structural characteristics and specifications to these polysaccharides that have unique biological activities, which are normally species related (Cleary et al. 1999; Brown and Gordon 2001; Shu et al. 2003; Mantovani et al. 2008).

The term "nutraceutical" has been used to describe all components that can considerably act as potential dietary supplements for the prevention and treatment of various human diseases, without the troublesome side effects that frequently accompany treatments involving synthetic drugs. As such, a mushroom nutraceutical is a refined/partially defined extractive from either mycelium or fruiting body, which is consumed in a capsule or tablet form, as a dietary supplement (not as a

regular food) with potential therapeutic applications (Chang and Buswell 1996). Regular intake of nutraceuticals may enhance the immune response of the human body, thereby increasing resistance to diseases and in some cases causing regression of a disease state. This characteristic of mushrooms has been related mainly to the active polysaccharides that are known to modulate the function of the immune system, denominated immunomodulators.

Fungal species with medicinal value or nutraceutical potential include *Agaricus subrufescens*, *Cordyceps militaris*, *Ganoderma lucidum*, *Grifola frondosa*, *Hericium erinaceus*, *Lentinus edodes*, and *Pleurotus ostreatus* (Lakhanpal and Rana 2005). *Agaricus subrufescens* Peck (syn. *A. brasiliensis*) is a mushroom native of the Americas and has been prescribed in different countries for prophylaxis and noninvasive treatment of numerous pathological conditions. These include cancer, diabetes, arteriosclerosis, viruses, and other infectious diseases. Its wide range of medicinal applications is consensually attributed to the immunopotentiating effects of noncellulosic polysaccharide compounds, which are macromolecular constituents of the fungal cell wall isolated from both basidiocarps and mycelial fractions. A substantial body of experimental evidence has demonstrated an intrinsic relationship between the bioactivity of *A. subrufescens* polysaccharides and their structural features, such as the degree of β-glycosidic branches, the architecture of side chain groups, and chiefly the molecular weight, although their biochemical and functional mechanisms remain to be fully elucidated (Largeteau et al. 2011; Silveira et al. 2012). Several trademarks, patents, and publications have reported the medicinal properties of polysaccharides extracted from *A. subrufescens* and their pharmaceutical products. Among them are the cosmeceuticals, well documented and proved effective against various dermatologic disorders, which are cosmetics with biological properties used for the nourishment and improvement of the skin condition (Izawa and Inoue 2004; Uchiyama and Haramaki 2004; Kozuka et al. 2005; Hyde et al. 2010). In addition, polysaccharides from *A. subrufescens* are also important to activate keratinocytes, which are important for skin regeneration (Sugita et al. 2008).

Even though fungi (especially reproductive structures) may have all this potential, prior to the process of extraction, purification, and application of these structural polysaccharides, one needs to be concerned with the production of fungal biomass, from which the compounds can be eventually extracted. The traditional way to obtain the basidiocarps involves complex pre-cultivation stages that include selecting the right substrate for the right fungus, substrate composting, and the inoculum production. During the development of the fungus in this non-axenic substrate (colonization), contamination can take place. Aside from this problem, the process lags for a long period. Furthermore, it generally discards an important portion of the fungal biomass after basidiomata (syn. fruiting bodies, mushrooms) harvesting, the spent mushroom substrate, which is the mycelium that has colonized the substrate (Oei 1996; Eira 2003).

In that respect, several research groups, including Brazilian-based ones, have focused on improving the methods for mushroom cultivation. These both employ the traditional composting methodology, largely used for species of *Agaricus*, and

diversify existing techniques, utilizing methodologies such as Jun Cao (Urben et al. 2004; Mendonça et al. 2005; Colauto and Linde 2012a; Figueirêdo et al. 2013). Due to the potentially high fungal diversity, searches for new native species from different Brazilian regions, selecting and genetically modifying species, as well as focusing on strategies for biodiversity conservation, have also been a keen condition (Neves et al. 2005; Colauto and Linde 2012b; Sales-Campos et al. 2013). On another ground, the spent mushroom substrate has been evaluated as source of energy, enzymes for industrial applications, animal feed, and fertilizers and soil detoxifiers (Ribas et al. 2009; Gonçalves et al. 2010; Camassola et al. 2013).

In this context, studies involving the Brazilian native species *A. subrufescens* (strain UFSC 51, CBMAI 1449) have been broadly explored for fungal biomass production, both aiming at basidiocarps and mycelia. These studies have focused on determining the functional polysaccharide contents of the species, with nutritional and medicinal applications (Camelini et al. 2005; Angeli et al. 2009b; Cardozo et al. 2011, 2013a, b). For this purpose, the best cultivation conditions, both in solid and liquid substrates, as well as aspects related to the separation and purification of biotechnological active polysaccharides have been explored (Silveira et al. 2012; Camelini et al. 2013a, b).

Shorter cycles during fungal cultivation allow for large biomass amounts, which consequently increases polysaccharide production. Scale-up from laboratory to industry is common for microorganisms used for the production of antibiotics, enzymes, hormones, and antibodies and for plant cell micropropagation (Hölker et al. 2004). For the cultivation is fundamental to establish an ideal method for the preservation of the microorganism, maintaining its reproductive capabilities and a high productivity for both the biomass and the compound of interest.

Mycelial preservation allows the employment of the microorganism for biotechnological purposes over time. Based on the method of choice, risks of genetic modifications are considerably low during preservation, assuring, therefore, the physiological identity of the microorganism. Several methods are available for in vitro preservation of microorganisms, ranging from simple, such as water or mineral oil, to complex ones, such as cryopreservation in −196 °C liquid nitrogen. Even the simpler methods yield good results, especially when the viability and the genetic identity of the microorganism are periodically checked (Richter and Bruhn 1989; Croan et al. 1999).

Once the organism is preserved, it can be used for the production of biomass in axenic substrates that can be either solid or liquid, denominated solid-state fermentation (SSF) and submersed fermentation (SmF), respectively. These processes are broadly employed in the industrial production of fungal inoculants for mushroom cultivation; production of flavoring agents, polysaccharides, vitamins, enzymes, organic acids, and antibiotics; or consumption as fungal biomass in the mycelial form (Hölker et al. 2004; Couto and Sanromán 2006).

The SSF presents some advantages over the SmF method. Among them, the low water requirements during cultivation and the lack of dependency of a solid support for the development of the fungi are the most important. However, one

disadvantage is the difficulty to quantify and separate the fungal biomass and to extract only the polysaccharide of interest. Subsequently, this method is more appropriate for the obtainment of fungal biomass to be used in whole in the food industry (Hölker et al. 2004; Couto and Sanromán 2006).

Nevertheless, the SmF, a method of remarkable expansion over the last decades, allows for a more precise control of the process and less risk of contamination, aside from producing a "cleaner" mycelium. This more "pure" mycelium comes from a biomass that is easily separated from the substrate. Cleaner mycelium yields polysaccharides that are easier to isolate, allowing for singular applications, such as pharmaceutical formulations (Ito and Sumiya 2000; Hölker et al. 2004; Rossi et al. 2004).

The choice for this or that method is dependent upon several factors. Among them are those of economic importance, those related to the quality of the final product, and those concerned with the particular governmental regulations regarding the disposal of the solid or the liquid residual substrates (Hölker et al. 2004). The biological activity of the resulting product is also of concern when choosing the method. Some substrates may modify the chemical structure of the mycelial polysaccharides, altering its main chain, lateral chains, or the degree to which the branching is arranged and, therefore, may impair the molecule effectiveness (Wasser and Weis 1999; Silva et al. 2006; Mantovani et al. 2008; Lavi et al. 2010).

Therefore, in the face of the factors exposed above, the potentiality of polysaccharides produced and extracted from *A. subrufescens* for the production of nutraceuticals at a commercial level is dependent upon a series of events. These events, which need to be fully understood for the success of the enterprise, include the fungal preservation, the maximization of biomass production, and the establishment of a process that allows for an adequate and reliable polysaccharide obtainment. These are sine qua non conditions for the advancement of this field allowing for the viability of preclinical and clinical studies involving these molecules.

2 Preservation of Fungal Material

Preservation of microorganisms is important for research and industrial applications, especially due to the active biological substances they may produce. By preserving, one may also be maintaining the genetic and ecological functions of these organisms (Cameotra 2007).

In order to maintain the on-growing needs for fungal material that has medicinal applications, determining the best conditions for preserving mycelia is among the main interests for those cultivating *A. subrufescens* or other important fungal species. For many fungal species, mineral oil and distilled water are often used for short-term preservation periods (Richter and Bruhn 1989; Croan et al. 1999). On the other hand, lyophilization and cryopreservation in liquid nitrogen, which arrest growth and may compromise some metabolic processes, represent long-term preservation techniques (Croan et al. 1999; Colauto et al. 2012a, b).

Two of the main challenges in maintaining cultures of *A. subrufescens* are its low culture viability and the frequent changes in growth habits, mainly after subcultures (Neves et al. 2005). In addition, some techniques may not present desirable results, as is the case for lyophilization that proved to be inefficient for *A. subrufescens*, even when 10 % trehalose and 10 % skimmed milk are used.

Colauto et al. (2012a) showed that strains of *A. subrufescens* respond differently to cryopreservation with DMSO. Recoveries of near 40 % have been obtained for isolates maintained frozen at /196 °C in DMSO for about 1.5 years. The variation in the recovery percentage indicates that this species is sensitive to the formation of intracellular ice crystals or even to the quick expansion of the cellular volume. However, a long-term cryopreservation (4 years) was effective when sucrose or glucose was used as cryoprotectant, regardless of the freezing protocol (Colauto et al. 2012b). Therefore, the use of cryoprotectants that penetrate only the cellular wall as mono- and disaccharides is a potential candidate for cryopreservation of other basidiomycetes.

Another important aspect that needs to be taken into account is that many fungi are able to produce secondary metabolites, such as agaritine. This metabolite is particularly produced by species of *Agaricus* when growth is ceased or any growing impediment is imposed (Kondo et al. 2006). When such fungi are grown in culture conditions, these metabolites are introduced into the media. Agaritine, in turn, has a mutagenic activity and may be harmful to the species (Walton et al. 1997). Therefore, methods for the attenuation of the effects of such compounds are necessary. Activated charcoal (AC) has proven to be very helpful for the removal of several toxic compounds in hemicellulosic hydrolysates used for the cultivation of fungi (Mussatto and Roberto 2004; Chandel et al. 2007), and it is used in tissue culture to improve cell growth in plants cultivated in vitro (Teng 1997). AC should also provide proper conditions for the preservation and evaluation of several microbial characteristics in culture (Hays et al. 2005).

During a particular preservation period, it is important to investigate both the viability and the morphological characteristics of the mycelium (Clark and Anderson 2004; Marín et al. 2008). It is crucial to observe the genetic stability of the preserved mycelium. The polymerase chain reaction (PCR) and other protocols for DNA analysis, such as random amplified polymorphic DNA (RAPD) markers, have become important tools in evaluating the intraspecific variability in microorganisms (Atienzar et al. 2002; Neves et al. 2005) and in detecting DNA damages and mutations (Lee et al. 2000).

Agaricus subrufescens shows a reduction in mycelial growth after subculture, with difficulties for the recovery of the original state. In that respect, Camelini et al. (2012) have explored preservation and recovery techniques for its maintenance. Mycelium on solid media supplemented with activated charcoal was compared with culture under mineral oil and mycelial disks in sterile water, all intended for long-term storages at 8 °C. Mycelium viability, radial growth rate, and genetic stability (by RAPD analysis) were continuously evaluated for 12 months. The use of AC showed a 75 % viability in the initial and final periods. On the other hand, mineral oil showed a 50 % reduction in viability toward the end of the storage

period, while sterile water differed from the others insofar as viability was high until the 6th month, with a 50 % drop after the 10th month, and a complete loss of viability after the 12th month of storage. Overall, throughout the storage period, radial mycelium growth rate decreased. However, recovery results were improved when the media were supplemented with AC. RAPD profiles demonstrated high genetic homogeneity of the mycelia maintained under all methods (>99 %). The use of PDA in slant tubes supplemented with AC was the most efficient method for the preservation of *A. subrufescens* under cold storage and resulted in the longest period of successful storage (12 months). Furthermore, AC is important for further recovery of *A. subrufescens* without significant morphological and genetic changes.

Activated charcoal has been used to adsorb toxic compounds in fermentation media prepared from hemicellulosic hydrolysates used in the cultivation of fungal species (Mussatto and Roberto 2004; Chandel et al. 2007). AC has also been proved an efficient additive in the preservation of fungi in vitro. *Agaricus subrufescens* is the only species of *Agaricus* either harmed or killed by prolonged exposure to temperatures of 4 °C or lower (Wasser et al. 2002; Kerrigan 2005). Therefore, the employment of AC to detoxify secondary metabolites produced by fungi at lower temperatures has proven to be an important procedure for the preservation of fungi up to 12 months. Nevertheless, the main benefit may be related to the recovery of such fungi after exposure to preservation procedures.

The mycelium disks of *A. subrufescens* preserved under sterile water lost complete viability after 1 year (Camelini et al. 2012). However, Richter and Bruhn (1989) reported preservation success for up to 48 months at 5 °C for several basidiomycete species. Others were maintained for shorter periods, with a viability kept for at least 9 months. Smith et al. (1994) reported a viability of 95 % for 169 fungi maintained for 20 months under preservation. Richter (2008), on the other hand, showed an 88 % viability for 34 fungal cultures maintained for 20 years in sterile water.

An important constatation of the recovered mycelia of *A. subrufescens* maintained under all preservation techniques is the deformity of the colonies (non-radial growth, zoned, cottony like, etc.). These deformities, however, were not observed when the media for fungal recovery were supplemented with AC (Camelini et al. 2012). The lack of deformities and overall characteristics of the mycelia was also reported by Wasser et al. (2002) when cultivating the fungus in the absence of AC. Teng (1997) reported that the incorporation of AC in leaf cell suspension cultures increased the number of regenerated sporophytes, even in media free of growth regulators, preventing abnormal morphogenesis and, therefore, normalizing cell development.

Most fungi can be stored at temperatures between 4 °C and 12 °C and subcultured at intervals of 6–8 months. This procedure can induce senescence in fungi, i.e., a progressive loss of mycelial growth potential, culminating in mutation and complete interruption of growth, leading to fungal death (Maheshwari and Navaraj 2008).

DNA mutations in fungi can be induced by radiation (Lee et al. 2000), genotoxins (Delmanto et al. 2001), preservation (Clark and Anderson 2004), and

senescence (Maheshwari and Navaraj 2008). Morphological mutations can be detected in the dikaryotic phase, as the one found in *L. edodes* by Shimomura and Hasebe (2006). The mutant dikaryon was readily distinguishable from the normal dikaryon by its irregularly branched, short, and sparse aerial hyphae, together with a drastically slower growth.

Camelini et al. (2012) showed deformed sectional colonies and slow mycelial growth for *A. subrufescens* recovered in media without AC, independent of the method of preservation. However, the RAPD analysis showed high genetic similarity on the mycelium collected at the 4th, 8th, and 12th month for all techniques of preservation and recovery when compared to the mycelium before preservation. The greater genetic similarity of the preserved mycelium increased the homogeneity of the isolated cultures. Even though the low variability is not desirable for genetic diversity (Llarena-Hernandez et al. 2013), it is necessary for the quality control during the cultivation of *A. subrufescens* to produce polysaccharides with biotechnological industrial applications. On the other hand, the genetic distance between fruiting bodies and mycelium observed for most basidiomycetes is possibly due to the differentiation of reproductive and vegetative phases in the life cycles of these fungi. The dikaryon is the predominant vegetative structure that, under appropriate conditions, is responsible for meiosis and, therefore, mushroom formation. In the dikaryon state, the two haploid gametic types of nuclei are maintained indefinitely in paired association. A potential complication with the long-term culture of dikaryons in vegetative phase is the possibility of genetic exchange between the paired haploid nuclei. In these events, a dominant deleterious mutation in one nucleus is followed by a compensatory mutation in the other, resulting in an increasing linear growth rate of the mycelium (Kamada et al. 1993; Clark and Anderson 2004; Torralba et al. 2004).

The RAPD technique has been largely used to detect the genetic variability of pathogenic and nonpathogenic microorganisms (Steindel et al. 1993; Oborník et al. 2000; Neves et al. 2005; Gasser 2006). This method is cheap, simple to perform, and suitable to detect DNA mutations, which can be important for evaluating the genetic stability in microorganisms during in vitro storage (Mariano et al. 2007). The use of AC for the preservation and recovery of *A. subrufescens* is easy, quick, and inexpensive and does not result in significant morphological and genetic changes in the mycelium stored for periods of up to 1 year.

3 Polysaccharide Production by Solid-State Fermentation

The interest over different products obtained from microorganisms has recently increased. Among the products of significance, many fungal sub- or by-products are listed, such as enzymes, natural drugs, and nutraceuticals (Moore and Chiu 2001; Couto and Sanromán 2005; Ghorai et al. 2009; Baños et al. 2009). These additives can be obtained by either specific extraction or concentration, used primarily by the industrialized sector, or by the utilization of whole organisms or parts of their recovered biomass.

Two main processes are generally employed for the production of fungal biomass: solid-state fermentation (SSF) and submersed fermentation (SmF). For many of the biotechnological fungal products of interest, such as enzymes and secondary metabolites, SSF has been chosen (Baños et al. 2009; Saqib et al. 2010). This substrate promotes best growing conditions for the fungi as well as specific stability for the compounds they produce (Couto and Sanromán 2006; Singhania et al. 2009). Moreover, the SSF processes are cheaper, especially when the main substrate employed is composed of raw materials (Castilho et al. 2000).

For the production of edible mushrooms, which more often have been used as nutraceuticals, the substrate of choice is that of a mix of lignocellulolytic wastes, such as straw and bran, which may have passed through a composting process prior to use. Both stages are SSF based. This methodology usually presupposes long times before the fruiting bodies are obtained, considerably increasing the costs of production (Scrase 1995; Stamets 2000), and is dependent on a trustful and reliable source of spawn.

The SSF system is also employed to produce spawn on sterilized cereal grains, which in turn are used as inoculum for the production of edible and medicinal mushroom species (Scrase 1995; Smith et al. 2002). SSF is generally the method of choice for the production of spawn around the world. This is also true for *A. subrufescens* (Stamets 2000; Mendonça et al. 2005). Spawn can be produced on many different cereal grains such as rye, wheat, and rice. The rehydration of the grains is crucial for the production of spawn. Several methods can be employed to rehydrate the grains, and each will depend on the type of grain and the final desirable moisture. The grain should normally have around 45–50 % moisture content, depending on the type of grain. Higher moisture contents can potentially break the integrity of the grain cell walls, altering the fungus metabolic capabilities and increasing the risks for contamination (Oei 1996).

Inoculation of the substrate can be done by placing the mycelium (in agar) together with the grains. This substrate is then incubated observing the fungus temperature requirements. After the mycelium has grown and colonized the grains (after approximately 14 days), this mother spawn can be used to inoculate new fresh grains, known as the grain-to-grain transfer technique. For some fungi, the addition of gypsum ($CaSO_4$) and limestone ($CaCO_3$), generally on a 1:4 ratio, is suggested to have positive effects, both on the structure of the substrate and on the substrate pH stability (Scrase 1995; Oei 1996; Stamets 2000).

Even though the production of spawn is the main purpose for this application, the fungal biomass could be alternatively processed and consumed as nutraceutical, such as in the elaboration of foods obtained through biotechnological processes. The bioconversion of grain into fungal biomass is important to improve the grain nutritional quality. This bioconversion increases the grain protein contents (all the essential amino acids), the types of polysaccharides produced (glucans, chitin, etc.), vitamins, among others nutritional aspects (Moore and Chiu 2001).

One good example of this biological transformation relates to *A. subrufescens*, a species that can successfully grow on cereal grains and is an important medicinal

fungal species with confirmed biological activities. This biological activity is attributed to cell wall polysaccharides, determined by Mizuno et al. (1999) and Camelini et al. (2013a) to be glucomannans with a main chain of β-(1 → 2)-mannans and β-(1 → 3)-glucan side branches. This fungus has been properly adapted to grow in liquid substrates, with several studies proposing its experimental optimization in SmF for the production of mycelial biomass and exopolysaccharides (Lin and Yang 2006; Fan et al. 2007; Hamedi et al. 2007). Examples of experimental optimization for several fungal species in SSF for the production of industrially important products have been proposed (Prakash et al. 2008; Baños et al. 2009). However, for *A. subrufescens*, few are the citations that report the use of SSF, due probably to the barriers inherent to this methodology (Dalla-Santa et al. 2011; Camelini et al. 2013a).

Biomass separation is one of these impediments. For most fungi, it definitely represents a challenge in SSF. Biomass separation is essential for kinetic studies of fungi (Singhania et al. 2009). Some indirect methods have been proposed to estimate biomass, such as glucosamine, ergosterol, protein, and DNA contents, as well as dry weight and changes in CO_2 evolution (Ooijkaas et al. 1998). Ergosterol, a compound well recognized for its biological activity, has been used to estimate fungal biomass percentages in SSF and proved suitable to determine the mycelial growth parameters of *A. subrufescens* (Dalla-Santa et al. 2011). All of these techniques, however, are subject to their own limitations.

Some methodologies have been proposed for polysaccharide quantification, such as high-performance liquid chromatography with refractive index detection (HPLC-RI). Examples that use this technique include the work of Nie et al. (2005), who used purified tea glycoprotein as calibration standards for the determination and comparison of glycoprotein in tea samples collected from different species, varieties, and geographic locations. Vendrell-Pascuas et al. (2000) developed a method for the quantitative determination of inulin in meat processed products containing this type of additive. This method extracted the inulin with hot water, followed by a hydrolysis with inulinase and the determination of released fructose by HPLC-RI.

Following the same trend, Camelini et al. (2013a) proposed HPLC-RI with a gel permeation column to quantify the main polysaccharide of *A. subrufescens* on SSF. Those authors have shown that polysaccharide molecules from *A. subrufescens* have around 310 kDa, representing the highest-molecular-weight polysaccharide obtained from the mycelium of that fungus. In addition to the main polysaccharide, a 25 kDa molecule has been detected. This structure was successfully removed by an α-amylase, suggesting the presence of a starch fraction on the extract, interfering significantly with the sample quantification. The purified polysaccharide used as standard showed a symmetric single peak (310 kDa), suggesting that the polymer is homogeneous. The main feature of the gel column for the analysis of polysaccharides lies in that polysaccharide and its degradation products can be determined simultaneously. The calibration curve was linear over the standard polysaccharide concentration ranging from 0.187 to 3 mg/mL, with an R^2 of 0.9997, after an analytical validation of the method.

With the objective of increasing fungal polysaccharide contents, SSF has been employed for the production of nutraceuticals by the fungus *A. subrufescens* on pretreated wheat grains (Camelini et al. 2013a). Among the important factors evaluated, time of cooking, time of resting after grain cooking, consequently grain moisture, substrate pH, temperature of incubation, and initial inoculum amount are the most significant.

Wheat grains provide essential nutrients used for fungal development, such as carbon and nitrogen. According to Van der Borght et al. (2005), whole wheat grain can be a good source of soluble starch and other polysaccharides, such as arabinoxylans, glucans, cellulose, and arabinogalactan peptides, proteins (gluten and non-gluten), and lipids. Soluble starch has also been suggested as a good carbon source for biomass and exopolysaccharide production by *A. subrufescens* in SmF (Hamedi et al. 2007).

The quantity of water in a SSF must be sufficient for fungal growth and enough for the diffusion of solutes, gas, and nutrients (Gervais and Molin 2003). Camelini et al. (2013a) report that grain cooking and resting time have significant effects on the grain moisture content and on the levels of glucomannan produced by *A. subrufescens*. High moisture contents tend to increase glucomannan production. The maximum average production was achieved when the grains had moisture close to 46 %. However, the highest polysaccharide production was not observed at the highest moisture content. Wheat grains generally open at moisture contents higher than 50 %, breaking the integrity of the grain cell walls and decreasing fungal polysaccharide production. Another factor contributing significantly with the glucomannan production is the concentration of calcium sulfate and calcium carbonate. These compounds modulate the pH, showing that high concentrations had negative effects on the production of such polysaccharides.

The addition of calcium sulfate and calcium carbonate directly on the grain surface is frequently used as a regular practice in spawn production (Scrase 1995; Oei 1996). Calcium is also used as a supplement in other solid substrates for mushroom production (Royse and Sanchez-Vazquez 2003). Royse and Sanchez-Vazquez (2003) have shown $CaCO_3$ to have great and $CaSO_4$ to have average to low modulation effects on the substrate pH. However, Camelini et al. (2013a) found that both sources of calcium modulate the pH as well as the glucomannan production in fungi: $CaSO_4$ acted decreasing the pH, while $CaCO_3$ resulted in higher pH levels. Grains without any calcium source had an initial pH of 6.4, nearly the same as observed for grains supplemented with 1.5 % $CaSO_4$ and 0.5 % $CaCO_3$ (pH 6.5). In general, better results for glucomannan production were obtained when no supplement was added or when up to 0.25 % $CaCO_3$ has been added to the mix. The addition of $CaCO_3$, even in small amounts such as that depicted above, is important to maintain the physical structure of the substrate (Oei 1996). Gadd (1995) showed that calcium ions play an important role in the regulation of the apical mycelia growth as well as in the formation of hyphal branches, corroborating the positive effects promoted by this micronutrient.

Lin and Yang (2006) obtained the highest mycelium yield of *A. subrufescens* in SmF with an initial pH of 6.06 and an incubation temperature of 27 °C.

Fan et al. (2007) observed that a pH of 6.1 and a temperature of 30 °C were the best setting points for increases in exopolysaccharide production. Other results show maximal biomass yield and exopolysaccharide production to happen at pH 5.6 and 6.9, with incubation temperatures of 24.6 °C and 20 °C, respectively (Hamedi et al. 2007).

The inoculum density is also important for the submersed cultivation of *A. subrufescens*, affecting both the fungal physiology and growth (Lin and Yang 2006). As for SSF, Camelini et al. (2013a) found that both the inoculum amount and incubation temperatures had significant negative effects on the production of glucomannans. The interaction between the two factors had also a significant effect on the polysaccharide estimation. The results from those authors demonstrate that the inoculum amount necessary for the best production is around 10 %, while the best temperature is around 27 °C. In this condition, the predicted value of glucomannan production would be close to 6.89 %, which is the maximal value obtained in this study. This experiment was conducted near the best moisture content (45 %) for polysaccharide production. Adequate moisture contents are important, since water mass transfer between the fungal tissue and the substrate is related to other parameters, such as temperature and aeration (Gervais and Molin 2003). The static condition adopted in these experiments has been critical for the definition of the initial inoculum amount, allowing for a fast colonization of the grains, as well as for proper oxygen availability (aerobic metabolism) and prevention of CO_2 saturation. In high moisture content, less dry weight substrate is filled into the bottles. In addition, there is less air space between the substrate particles. Ohga (1990) demonstrated that air spaces saturated with high moisture contents may slow the gas exchange from deep within the interior of the bottle toward the surface.

Respiration also produces water, in which an endothermic evaporation phenomenon will be the major energetic factor for heat dissipation (Gervais and Molin 2003). A great limitation of the SSF system is the difficulty to remove excess heat due essentially to a low thermal conductivity. Therefore, forced air is used for temperature control (Raghavarao et al. 2003). Hence, the SSF of *A. subrufescens* on static conditions should have an incubation temperature lower than that for SmF. Smaller amounts of the initial and scale-up substrates, as those used by Camelini et al. (2013a), are more easily controlled, allowing for improved determinations of the optimum temperature parameters.

Several models of bioreactors have been employed for SSF. The majority of them are stirred-tank or aerated bioreactors. Bioreactors are classified based on the type of aeration or the mixed system employed. Four basic types are known: trays, packed bed, horizontal drum, and fluidized bed (Singhania et al. 2009). These bioreactor designs have their own advantages and disadvantages. One major limitation imposed by the SSF method is the difficulty to remove extra heat generated by the metabolism of the fungus, essentially due to the low thermal conductivity presented by solid substances. Therefore, forced air through the body of the bioreactor is essential to dissipate the extra heat and allow for a proper temperature control. Another concern relates to the effect that aeration may bring to the

cultivation. Forced air reduces humidity, which, in turn, creates potential for desiccation of the biomass, with consequent loss of viability (Raghavarao et al. 2003).

Solid-state fermentation is an inexpensive process to obtain large quantities of biomass required for the production of foods containing fungal polysaccharides. Glucomannans of *A. subrufescens* in a SSF system can be consumed as whole biomass through the elaboration of functional foods. Product recovery and purification processes are, however, expensive. Hence, the application of the proposed procedure in the elaboration of functional foods will convey a considerable reduction in the production costs, allied to an increment of the ingestion of important confirmed bioactive compounds (Mizuno et al. 1999; Couto and Sanromán 2006; Singhania et al. 2009; Silveira et al. 2012).

4 Polysaccharide Production by Submersed Fermentation

Even though basidiomata generally produce larger volumes of biomass when compared to the mycelium, and consequently larger amounts of polysaccharides, cultivation of fungal mycelium allows for a more efficient control of the process and, therefore, is the method of choice (Smith et al. 2002). In that respect, alternative approaches that increase productivity, such as submersed cultivation, have been under investigation. Such methods are preferred since they allow for a more precise control of most of the fungal growing conditions, such as nutritional and physical–chemical factors, yielding uniform, potent, and standardized polysaccharide productions (Fazenda et al. 2008), mainly for the pharmaceutical area.

There are two kinds of bioreactors for cultivation under the SmF system. From the two, aerated ones are the most utilized in the industry (Crueger and Crueger 1990). In fact, the majority of the bioreactors employed under aerobic conditions in the industrial sector are conventional stirred-tank bioreactors. The remaining are those without a mechanical agitation, such as the airlift and the bubble column bioreactors (Chisti 1989). Nevertheless, stirred tanks are not the most suitable bioreactors for the cultivation of certain microorganisms. The degree of stirring required to reach the ideal mass transfer in many cases can damage the cells. Moreover, the agitation required by these bioreactors may imply high-energy consumption. Additionally, in the majority of the bioprocesses, the cultivation must remain free of contaminants for long periods, requiring the installation of complex mechanical seals. Conventional bioreactors are then more expensive and less resistant than the ones without mechanical agitation (Nienow 1998; Garcia-Ochoa and Gomez 2009; Choy et al. 2011).

In an airlift bioreactor, the volume of the liquid is divided into two different zones. Only one of these zones receives the injection of air. The difference in terms of gas holdup between the aerated (riser) and the non-aerated zones (downcomer) creates a difference in the liquid density between these two regions and, as a result, promotes the circulation of the fluid, reducing, therefore, the potential for damages to the cells. Gas holdup and the speed of circulation of the liquid phase, whose

source and values depend on the gas flow, are among the most important parameters during the operation of a bioreactor. These parameters interfere, for example, in the liquid circulation dynamics by reducing the speed of the rising air bubbles (Chisti 1989; Chisti et al. 1995). Aside from this, liquid circulation has an effect on the turbulence, which will have a counter effect on the coefficient of heat transfer, on the gas–liquid mass transfer, and on the shearing rate force to which the microorganisms are submitted (Chisti and Moo-young 1988). The small rising air bubbles increase the oxygen transference rates, and this current, created by this ascending flow, homogenizes the overall shearing rates through the entire bioreactor, stimulating, therefore, biomass production (Kunamneni et al. 2007).

On the other hand, the formation of *pellets* can be an alternative to avoid variations in the density of the liquid media during airlift cultivations, since many microorganisms produce and excrete exopolysaccharides that increase viscosity, modifying the transference rates of oxygen to the media (Prosser and Tough 1991; Rossi et al. 2002). Rossi et al. (submitted) have shown that airlift bioreactors are suited for such cultivations, since they promote an efficient development of the fungi while reducing the counter effects produced by the shearing forces observed in other bioreactors (such as stirred tanks). Airlift bioreactors are also more suitable for the cultivation of filamentous fungi since they promote sufficient mass transfer necessary for the growth of the fungi. Aside from those benefits, one can also explore the surplus of polysaccharides extruded to the liquid media by the fungi, proving to be an extra source of such bioactive molecules (Hamedi et al. 2007).

In that respect, a pneumatic 5 L airlift bioreactor, with external circulation (Fig. 1), was employed to study the behavior of *A. subrufescens* grown under the SmF system (Camelini et al. 2013b; Rossi et al. submitted). The unit was equipped with a heat exchange device located in the downcomer. Even though it is difficult to estimate the dissolved oxygen critical concentration for fungi that grow in pellets, a value of 45 % saturation was assumed for this study. Thus, the dissolved oxygen (DO) concentration was kept above the critical level throughout the entire cultivation period while operating at specific airflow rates of 0.35 vvm. Once the temperature was stabilized, the electrode was calibrated in the culture medium and a sample run performed. The isolate was cultured in modified MNM medium (Marx 1969) with 16 g/L glucose, with temperature maintained at 25 $\pm$ 1 °C, and with pH set at 5.8 and monitored. Settings were determined as to perform a batch cultivation, which was maintained until the full exhaustion of the main carbon source. Samples were taken to determine residual glucose and total biomass. The fungus formed relatively uniform, 4 mm Ø pellets reaching a final biomass concentration of 5.5 g/L with glucose biomass (gx/gs) conversion ($Y_{X/S}$) of 36 %, obtained when 0.5 g/L of initial inoculum was employed. Average cell growth-specific velocity was 0.4/day and biomass productivity around 0.76 g/(L.day). In this condition, almost the entire carbon source was depleted at the end of the experiment, suggesting that this is the factor to be utilized whenever calculations for the production planning and culture media are to be performed. Considering an initial biomass concentration of 0.5 g/L, it is possible to perform an entire process within 1 week of operation. A reduction to 5 days is seen when the initial biomass

Fig. 1 Pneumatic (5 L) airlift bioreactor (Rossi et al. submitted)

concentration is close to 1.0 g/L, which is generally difficult to achieve in the scale-up process when employing the fungal species utilized in this study.

Cultivation periods of 5–7 days are considered exceptional when dealing with fungi from the phylum *Basidiomycota*, which may take up to 2 months when growing in solid media (Fazenda et al. 2008). On the other hand, it is important to maintain the cultivation within this period, especially when processes with controlled systems are carried out. Increasing the time of cultivation will unvaryingly create conditions where the mycelium will get fixed in the bioreactor interfaces, such as the sensor's and other gadget's prominences, potentially interfering with the overall readings (Rossi et al. 2002).

For industrial purposes, the initial quantity of inoculum can be obtained either by producing it in a second bioreactor that fed a parallel cultivation or by continuous cultivation regimes. However, inoculum concentrations above 1.0 g/L, generally chosen to reduce the time of cultivation, are not recommended, since the inoculum homogenization may be compromised otherwise. Fragmentation, which is necessary to open the clusters of biomass and stimulate small fungal growing pockets, causes the intracellular material to be extruded to the growing media. These compounds can include both genetic material and metabolic intermediaries. These may suffer intrinsic reactions upon reaching the oxygen-rich environment of the medium and produce toxic substances, which invariably interfere negatively in the fungus growing kinetics and viability (Rossi et al. submitted).

Although approaches to optimize the cultivation of *A. subrufescens* in a bubble column bioreactor have been tested, such as the one proposed by Kawagoe et al. (2004), average productivity was eight times lower (0.095 g/(L.day)) than that obtained in an airlift bioreactor (0.76 g/(L.day)), even at similar airflow rates (Camelini et al. 2013b). Aside from having a superior performance over bubble column bioreactors (Chisti 1989), the results of the former study may have been impaired by the reduced quality of the initial inoculum. High performances are more likely to be reached when the fungal inocula are less than 15 days old, and fragmentation has been done in a way as to allow for minute cores to be formed. Small fragments associated to the right conditions (type of bioreactor, pH, airflow, etc.) allow for pellets that will have a final diameter of 5 mm or less, which is fundamental to avoid oxygen limitation to the fungi. The results from Kawagoe et al. (2004) corroborate the above conclusions, since they determine that higher aeration rates are essential for better fungal growth.

Aside from the productivity aspect, production costs are important components when dealing with biotechnological products. This aspect is crucial to determine the feasibility of the process and involves all types of costs, which includes operational (production), fixed, and general industrial expenses. The costs associated with the purchase of raw materials represent anything from 30 % to 80 % of the production costs. Supplies, which are not directly related to operation, account for 15 % of those costs. The funds necessary for the physical portion of the investment, which include buildings, equipment, etc., are directly dependent on the process performed, since it may require the purchase of bioreactors, centrifuges, homogenizers, and ultrafilters, among others (Kalk and Langlykke 1986). Consequently, the price of the final product will be a direct result between the conjugations of all these costs. Cost estimates are important to determine, among all available options, including SSF and SmF, which will yield the best proceeds for the money to be invested.

Examples of such calculation costs are available in the literature. For the production of lipase from *Penicillium restrictum*, Castilho et al. (2000) showed a fivefold increase in production costs when the fungus was grown on SmF, in comparison to SSF. One alternative used by the industrial sector to overcome these higher costs observed in the SmF is the use of hydrolyzed agro-industrial residues. These include sugarcane bagasse, brewery residues, and wheat bran (Pandey et al. 2000; Mussatto and Roberto 2006; Dobrev et al. 2007). Additionally, the transformation of these compounds into microbial biomass also reduces the volumes of residues passive of conversion prior to their disposal into the environment.

5 Extraction and Concentration

Most methods available today for the extraction of polysaccharides are considerably time- and energy consuming and require a large amount of organic solvents for polysaccharide precipitation, resulting in the critical problem of solvent recovery and environmental pollution. The extraction of polysaccharides has generally been done in water using different temperatures (Table 1).

Table 1 Biological activities of polysaccharides obtained from *A. subrufescens* Peck (syn. *A. brasiliensis* Wasser) and the related species *A. blazei* Murrill sensu Heinemann

Species' given name/ material analyzed	Strain/origin	Isolated polysaccharide	Isolation/extraction method	Biological activity	References
Agaricus brasiliensis fruiting bodies	Strain KA21, Brazil	1,6-β-Glucan	Extraction in hot water (121 °C) followed by ethanol precipitation	In vivo (mice) antitumoral activity (solid sarcoma 180)	Hashimoto et al. (2006)
	Not mentioned	1,6-β-Glucan	Extraction in hot water followed by ethanol precipitation and centrifugation	In vitro antigenotoxic activity on human peripheral lymphocytes	Angeli et al. (2006)
	Not mentioned	1,4-α-1,6-β-Glucan	Subsequential extractions with ethanol at boiling point, extraction in hot water (100 °C) and ammonium oxalate, dialysis	Enhances the in vivo (mice) candidacidal activity of murine macrophages	Martins et al. (2008)
	Strain UFSC 51 (mature stages), Brazil	1,6-β-Glucan with traces of 1,3- and 1,2-β-glucans	Extraction in hot water (100 °C), ethanol precipitation, dialysis, and DEAE-cellulose column chromatography	In vitro antigenotoxic activity on HepG2 cells	Angeli et al. (2009b)
	Strains ABL 99/25, 99/28, 99/29, and 00/30, Brazil	1,6-β-Glucan	Subsequential extractions with ethanol at boiling point, extraction in hot water (100 °C) and ammonium oxalate	In vivo (mice) antitumoral (Ehrlich adenocarcinoma) activity	Pinto et al. (2009)
	Brazil	1,6-α-Fucogalactan	Chloroform–methanol extraction followed by ethanol precipitation	In vivo (mice) antinociceptive activity	Komura et al. (2010)

Following production, extraction and concentration of bioactive polysaccharides can be done by means of porous membranes (Charcosset 2006). Membrane separation has often been used in industrial and pilot scales for size-based separations, with the advantage of high-throughput screening. Furthermore, it is environmentally friendly, and it is especially suitable for isolation of molecular-weight-specific polysaccharides with particular biological activities (Xiao et al. 2007). Silveira et al. (2012) report the employment of membrane technology for the fractionating of polysaccharides from *A. subrufescens* obtained from the main current methods of fungal biomass production, fruiting bodies, and SmF mycelium, in order to determine an optimal mass separation approach for further application at the industrial level. Both the microfiltration and ultrafiltration membranes were capable of separating high-molecular-weight polysaccharides from both extracts. As expected, higher retention levels were achieved when the nominal porosity of membranes decreased, regardless of the source of extracts. All polysaccharide components were detected in the nanofiltration membrane modules, producing greater retention yields. Therefore, this system represents an efficient alternative for scaling-up processes.

Among the membrane separation systems available, tangential flow filtration, also known as cross-flow filtration, is an option. This method allows for longer nonstop operational periods, reducing the needs for constant interruptions for cleaning, guaranteeing, therefore, higher productivity and procedural confidence. The system operates based on a feeding stream mode where the liquid phase, under pressure, passes through a membrane disposed parallel to the fluid current. A percentage of the fluid goes through the membrane every time there are components in the liquid phase that are smaller than the membrane pores. The portion that passes through the membrane is denominated permeate. The current applied will be the driven force to remove materials that have not been permeated by the membrane. This current is called retentate (Van Reis and Zydney 2007).

The use of membranes presents some advantages over alternative technologies. These include the use of low temperatures, low energy consumption, and reduced environmental impact, especially due to the reduction in the use of solvents and maintenance of the compounds' intrinsic properties (Xu and Wang 2005; Mello et al. 2010; Hsieh et al. 2014).

Following the studies of Silveira et al. (2012), Camelini et al. (2013b) developed a process to separate polysaccharides extracted from *A. subrufescens* grown in airlift bioreactors. The main objectives of that study were to produce large volumes of fungal biomass; extract the polysaccharide contents, both from the biomass and the culture media; and employ tangential flow nanofiltration to concentrate and purify these bioactive substances. Dehydrated fruiting bodies, purchased at a local market, were used to compare polysaccharide amounts with those from the mycelium and the culture media (Figs. 2a, b). The nanofiltration experiments were performed in a tangential flow filtration pilot plant using a polyvinylidene fluoride (PVDF) membrane in a spiral configuration (HL2521, GE Osmonics®, Philadelphia, USA), with molecular-weight cutoff (MWCO) ranging between 150 and 300 Da and filter area of 0.9 m^2. The operating conditions used in the experiments

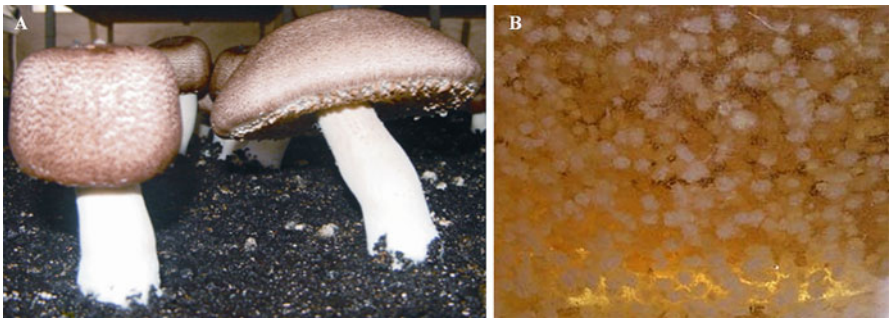

Fig. 2 *Agaricus subrufescens* (strain UFSC 51, CBMAI 1449, Brazil). (**a**) Fruiting bodies. (**b**) Mycelia growing in liquid media

followed temperatures of 35 ± 1 °C (water bath), tangential velocity of 0.68 m/s (obtained from the flow proportional to the membrane transversal area), and transmembrane pressure of 6 bar, until reaching a volumetric reduction factor (VRF) for each extract. Total and high molar mass polysaccharides as well as soluble solids were determined in the retentate for the three extracts. High molar mass polysaccharides with molecular weights of 617.93 ± 12.01 and 309.89 ± 2.22 g/mol were identified in the extracts obtained from the fruiting bodies and the mycelium, respectively. In the culture medium, two different polysaccharides were identified (20 ± 2.01 and 201 ± 3.01 g/mol). Polysaccharides were not detected in the permeate. However, there was a small amount of soluble solids in the permeate, possibly due to the polysaccharide hydrolysis into monosaccharides and due to the residual glucose and minerals from the culture media. In that respect, nanofiltration has contributed to reduce the initial extract volumes and contributed to concentrate total polysaccharides, especially those with high molar masses. Additionally, the permeate flow, the influences of temperature and pressure, and the resistance to the permeate flow during filtration were also evaluated. Nanofiltration has yielded polysaccharide increases of 85 %, 82 %, and 92 % in the extracts from fruiting bodies, mycelium, and liquid media at VRFs of 5, 6, and 7, respectively. Nevertheless, these increases were not proportional to the increases in VRF. A reduction in the permeate flow was observed during filtration, and it was compensated by increases in pressure and temperature.

Nonetheless, the membrane performance can be reduced during the processing caused by permeate flux decline as a function of time. Three phenomena can interfere with this reduction: concentration polarization, polarized gel layer, and fouling. All these factors impose high transport resistances throughout the membranes, and the extension that will affect the process depends on the membrane type and the type of fluid fed (Noble and Stern 1995; Mulder 2000). Camelini et al. (2013b) showed that the highest resistance to the permeate flux was caused by polarization due to concentration (polarized gel layer), reaching values of 88 % for the culture media. Maximal resistance caused by the membrane reached values of 40 % for the extract from the fruiting bodies. On the other hand, resistance

caused by fouling was responsible for less than 3.5 %. In conclusion, nanofiltration is efficient to concentrate these functional compounds extracted from *A. subrufescens* and can, therefore, be applied in different biotechnological areas.

Even though pressure and temperature can compensate reductions in the permeate flux, it was observed that higher pressures (6–7 bars) did not increase the flux linearly. Generally, higher pressures, while in the presence of soluble solids, cause a compacting effect over the membrane and induce the formation of a polarized gel layer, considerably increasing pore obstruction (Salgado et al. 2013). Temperature increases (25–45 °C) resulted in up to 30 % flux increases in the extracts. According to Mello et al. (2010), this result may be attributed to the effect of temperature in the viscosity of the solution. Furthermore, the temperature has an effect on the polymeric chain mobility of the membrane, making the polymeric material more flexible and, therefore, allowing for larger elements to permeate (Goosen et al. 2002). The temperature variation in the feeding process must be carefully monitored to avoid compound degradation and losses and at the same time facilitate the parameters for fluid processing and transportation (Michelon et al. 2014). As a rule of thumb, the temperature limit must be established as a function of the membrane's thermoresistance and the economic aspects related to energy consumption. In industrial processes, where time may translate into effectiveness, increasing temperatures can be a feasible and practical approach to reduce processing time. However, the use of higher temperatures will raise energy consumption and costs, aside from stimulating the degradation of thermosensitive compounds.

According to Cheryan (1998) and Chacón-Villalobos (2006), the solids present in the feed are carried to the membrane surface by convection, forming a concentration gradient. This phenomenon is responsible for altering the flow when compared to that of pure water, since it causes a counter flux of solutes toward the feeding as a function of diffusion. When the concentration of particles close to the filtering surface reaches and exceeds solubility limits, there will be jellification (gel layer) of the solution. This is caused by precipitation as a function of macromolecular saturation. This layer, so-called polarized gel layer, causes a reduction in the permeate flux (Noble and Stern 1995). When there is a deposition and accumulation of solids in the surface and/or inside the membrane pores, an irreversible phenomenon, called fouling, will occur. This phenomenon is directly related to the characteristics of the membrane and the solute–solute and solute–membrane interactions within the membrane, leading to a reduction in the effective pore size (Cheryan 1998; Mulder 2000; Van Reis and Zydney 2007).

It is important to mention that the resistance caused by polarization due to concentration can be alleviated by altering the operational conditions such as pressure, feeding temperature, and tangential velocity. In such manner, it is possible to detect higher permeate fluxes with the same feeding regime if the operational settings are altered. Fouling, on the other hand, is an irreversible phenomenon that increases the costs of operation and reduces permeation, requesting, therefore, higher working pressures and frequent chemical washings that can, potentially, reduce the membrane half-life. Furthermore, it invariably increases energy costs (Listiarini et al. 2009).

Camelini et al. (2013b) found that resistance caused by fouling alone was responsible for less than 3.5 % of the total resistance for the polysaccharide extracts. This is a remarkable result since this is the main problem faced by nanofiltration of such materials (Mänttäri et al. 2000). Inorganic and organic materials present in water typically cause fouling in nanofiltration membranes. These materials stick to the surface and pores of the membrane, resulting in the deterioration and lack of performance (reduced membrane flux) with a consequent increase in energy costs and membrane replacement (Al-Amoudia and Lovitt 2007). Therefore, reducing fouling will alleviate a second major problem associated with this technology, especially for industrial processes, which is the cleaning and recovery of the membranes.

6 Structure and Biological Activity

Polysaccharides are natural polymers found in all living organisms. In the biosphere, they represent an abundant group of macromolecules, such as cellulose and starch in plants, glycogen in animals, and glucans in fungi. These molecules, located mainly in the cell wall of fungi, may be composed of more than 75 % of carbohydrates, including predominantly glucans and mannans. In addition to acting as a sustenance element to the hyphae, some polysaccharides form an extracellular sheath around the mycelium, providing support for the adhesion of lignin-degrading enzymes, an indirect source of hydrogen peroxide, aside from protecting the cells from dehydration. Furthermore, polysaccharides may regulate extracellular glucose concentration (Gompertz et al. 2002; Da Silva et al. 2006).

The primary structure of a polysaccharide is defined by its sugar composition, the configuration of glycosidic bonds, the sequence of monosaccharides, the chain length, as well as the nature, number, and location of attached noncarbohydrate groups. Moreover, the monosaccharide polymerization can occur in different positions of the sugar units, generating a wide variety of linear or branched chains with great structural variability and different functions (Da Silva et al. 2006; Hu et al. 2013). The secondary structure of the molecule can also vary, depending on the conformation of its components, the molecular mass, and the inter- and intrachain interactions (Paulsen 2002). Modification processes, such as sulfation, naturally occurring in marine organisms and in the extracellular matrix of vertebrates, also contribute to the structural diversity of polysaccharides (Kirkwood 1974).

The structure of polysaccharides is species and strain related, and is correlated to many factors, such as location and time of collection, life cycle phase, method of cultivation, isolation, and drying. Processing may drastically affect the original chemical structure of polysaccharides altering their degree of branching, molecular weight, viscosity, and solubility, which may cause change in their biological properties. In fact, all the phases involved in the preparation of polysaccharides point toward the fact that each isolated batch is heterogeneous in nature. In this sense, the characterization of polysaccharides is necessary for ensuring their efficacy and safety and, because of its complexity, represents a challenge for industrial processing (Hu et al. 2013; Giavasis 2014).

7 An Example from the *Agaricus subrufescens* Species

In the last years, nomenclatural taxonomists have segregated *Agaricus blazei* Murrill sensu Heinemann as a different species from *A. subrufescens* Peck. In 2002, Wasser et al., based on the morphology of the fruiting bodies (size, pileal surface, type of pileal covering, presence of cheilocystidia, etc.) and the size of the spores, suggested the name *Agaricus brasiliensis* for a species of fungi collected in Brazil, very similar in nature to *A. blazei* and *A. subrufescens* (Wasser et al. 2002). In 2005, using biological and phylogenetic methods, Kerrigan showed that a cultivated specimen of *A. brasiliensis* from Brazil and a wild specimen of *A. subrufescens* from the USA (California) were in fact the same thing and, therefore, should belong to the same species name. This in turn illegitimated the name *Agaricus brasiliensis* as a later homonym (Kerrigan 2005, 2007). There are still disputes about the proper used name for this or that species within this complex, and because of this dispute, the comparison of data may be, somewhat, compromised. In this chapter, we refer to *A. subrufescens* as a synonym of *A. brasiliensis*, and, since some specimens might have been misidentified as *A. blazei*, studies on fungi coined under that name have also been considered.

Polysaccharides exhibit low toxicity to mammals and display numerous pharmacological properties. To illustrate some of these properties, Table 1 visits and presents the biological activities displayed by structurally different polysaccharides obtained from *A. subrufescens* and the related species *A. blazei*. The most common method of extraction and isolation consisted of hot water followed by ethanol precipitation. Additional fractionation using column chromatography or centrifugation has also been applied.

The main polysaccharide isolated from the fruiting body of *A. subrufescens* is the (1 → 6)-β-D-glucan, potentially with side chains. This polysaccharide is especially related to immunomodulatory, antitumoral, and antigenotoxic activities. In contrast, the majority of the mycelial polysaccharide isolated from *A. subrufescens* was found to be a (1 → 3)-β-D-gluco-(1 → 2)-β-D-mannan. This glucomannan was chemically sulfated to obtain a derivative (MI-S), which presented promising in vitro (Cardozo et al. 2011) and in vivo (Cardozo et al. 2013b) antiherpetic activities. The chain configuration of the polysaccharides has not changed after sulfation. However, the process reduced the molecular weight of the original polymer probably as a result of the sulfation conditions (acidic medium and high temperatures) (Lanteri 1978; Cardozo et al. 2013a).

The structural differences in polysaccharides obtained from the mycelium and from fruiting bodies of the same species may be related to the structural dynamic of the fungal cell wall, subjected to modifications at different stages in the life cycle, due to apical (mycelium) and lateral (fruiting bodies) growth. One good example is the glucan–glycosaminoglycan complex present in the cell walls of *A. bisporus*. In that species, the fruiting body polysaccharide has a lower number of connections, increasing flexibility and allowing reorientation of the wall, axial elongation, and insertion of new polymers, up to the maximum expansion reached by the fruiting body. On the other hand, the mycelial polysaccharides have more branched leading chains, which provide a greater rigidity of the cell wall (Mol and Wessels 1990).

8 Polysaccharides and Antiviral Activity

The antiviral activity has been displayed by polysaccharides of various sources, such as plants (Jassim and Naji 2003), lichens (Olafsdottir and Ingólfsdottir 2001), bacteria (Matsuda et al. 1999), seaweeds (Smit 2004), and fungi (Leung et al. 2006). The lists include activity against many viruses, comprising human herpesvirus types 1 (HHV-1) and 2 (HHV-2) (Eo et al. 2000; Liu et al. 2004), human immunodeficiency virus (HIV) (Jassim and Naji 2003), hepatitis B virus (Lee et al. 2002), cytomegalovirus, influenza virus (Kanekiyo et al. 2005), and coxsackievirus B3 (Lee et al. 2010).

Considering only the sulfated versions of the molecules, antiviral activity has been reported for HHV-1, HHV-2, and HHV-6 (Liu et al. 2004; Talarico et al. 2004; Zhu et al. 2004; Naesens et al. 2006), dengue virus (Qiu et al. 2007), HIV (Talyshinsky et al. 2002), cytomegalovirus, respiratory syncytial virus, influenza virus, and adenovirus (Witvrouw and De Clercq 1997). According to Ghosh et al. (2009), many of the polysaccharides studied in the last 20 years exhibited activity against more than one species of virus, showing their broad spectrum of antiviral activity. The primary mechanism of antiviral activity of sulfated polysaccharides has to do with the molecule's anionic features, allowing them to interact with the positive charges present in the viral envelope and/or on the cell surface, inhibiting the adsorption, penetration, and fusion of the virus with the host cells (Eo et al. 2000). Moreover, in vivo antiviral mechanisms via indirect stimulation of the innate and adaptive immune response have also been verified (Hayashi et al. 2008).

Table 2 summarizes studies on the in vitro antiviral activity of polysaccharides, extracts, or fractions from *A. subrufescens* and *A. blazei*. Some extracts or fractions have showed antiviral activities against western equine encephalitis (WEE) virus (Sorimachi et al. 2001), herpes simplex virus type 1 (HSV-1) (Sorimachi et al. 2001; Bruggemann et al. 2006), bovine herpesvirus 1 (BoHV-1) (Bruggemann et al. 2006), and poliovirus 1 (PV-1) (Faccin et al. 2007). However, their chemical composition was not determined, which compromises structure–activity discussions and result comparisons.

Two different polysaccharides, (1 → 6)-(1 → 3)-β-D-glucan (FR) and β-(1 → 6)-α-(1 → 4)-glucan–protein complex (PLS), were isolated from the fruiting bodies of *A. subrufescens* (Table 2). The FR was obtained through hot (100 °C) water extraction, followed by 95 % ethanol precipitation, centrifugation, and dialysis (5 kDa cutoff membrane) (Cardozo et al. 2013a). Differently, the PLS was obtained by some additional steps from the previous method, including hot (100 °C) water extraction, neutralization with NaOH to pH 7, 100 % ethanol precipitation in the presence of NaCl, centrifugation, and clarification with 30 % hydrogen peroxide, followed by a second extraction with ethanol (Gonzaga et al. 2005). Besides variances in glucan chain configuration, differences in protein content [FR = 1.76 % (w/w), PLS = 25.3 %] and molecular weight [FR = 609 kDa, PLS = 97.7 kDa] may explain the diverse antiherpetic activities displayed by these two compounds. Yamamoto et al. (2013) found an anti-HSV-1 activity

[b]Plaque assay postinfection treatment
[c]No inhibitory activity
[d]Reduced α(1,4)-glucan content
[e]Maximum tested concentration (1 mg/mL)

under simultaneous (EC_{50} = 454 μg/mL) and postinfection (83.6 % of inhibition at 800 μg/mL) treatments with PLS, using a viral plaque number reduction assay. Nonetheless, neither anti-HSV-1 nor anti-HSV-2 activity under these two treatments was found for FR at the maximum tested concentration (1 mg/mL) (Cardozo et al. 2014).

Both polysaccharides were chemically modified to produce their respective sulfated derivatives FR-S and SPLS. FR-S had had no detectable protein content and lower molecular weight (127 kDa) in comparison to the non-sulfated version (Cardozo et al. 2013a). The introduction of sulfated groups on FR resulted in a sulfated derivative (FR-S) with promising in vitro antiherpetic activity (EC_{50} < 6.74 μg/mL), acting by inhibition of HSV-1 and HSV-2 adsorption, penetration, and cell-to-cell spread (Cardozo et al. 2014). In a different way, SPLS did not demonstrate much improvement on antiviral activity after sulfation in the simultaneous treatment (EC_{50} = 346 μg/mL) and had no activity in the postinfection treatment (Yamamoto et al. 2013). The variable antiviral effects and mechanism of action demonstrated by these two polysaccharides are primarily related to their structural differences, not excluding variances related to the fungus isolate and modifications in the methodology used to determine the antiviral effects.

9 Conclusions

In the face of the factors exposed throughout this chapter, the potentiality of polysaccharides produced and extracted from *A. subrufescens* for the production of nutraceuticals and medicines at a commercial level is dependent upon a series of events. These events, which need to be fully understood for the success of the process, include the fungal preservation, the maximization of biomass production, and the establishment of a process that allows for an adequate and reliable polysaccharide obtainment. These are sine qua non conditions for the advancement of this field allowing for the viability of preclinical and clinical studies involving these molecules.

For the preservation and recovery of *A. subrufescens*, the use of activated charcoal is an easy, quick, and inexpensive method that does not result in significant morphological and genetic changes within a 1-year storage period. This method may also be suitable for the preservation of other species and lineages of filamentous fungi.

Solid-state fermentation is a feasible process to obtain large quantities of biomass required for the production of foods containing fungal glucomannans. The parameters for the production of glucomannans on wheat grains have been, over the years, optimized. Based on these results, additional research is currently in progress, aiming at a formulated product with nutritional contents and safety information.

For SmF, pneumatic systems based on airlift bioreactors, which have a simplified construction design, have shown remarkable results when utilized for the production of fungal cells such as those from *A. subrufescens*. The system proved

to be very efficient when compared to agitated tanks, even when important parameters, such as pH, were left uncontrolled. These results can be potentially improved when some parameters, such as the use of hydrolyzed residues in the culture media, are optimized. Experimental results are important to guide the planning and operational settings, in order to achieve higher productivities. Among these settings, the definition of the type and amount of culture media and inoculum is particularly important. In this respect, nanofiltration has contributed to reduce the initial extract volumes, permitting the concentration of total polysaccharides, especially those with high molar masses.

Biotechnological processes involving fungi must focus on selecting the right species for the products of interest. In addition, the method of cultivation, the identification of the compounds of interest, and the method of extraction, purification, and final processing are crucial for successful results. For species of *Agaricus*, a fair amount of studies has focused on important molecules proved to have nutraceutical and medicinal values, especially the polysaccharides, which are important components of fungal cell walls. Polysaccharides are components produced by certain species of fungi with proved antiviral, antitumoral, and immunomodulatory, among others, activities. This is a promising and very attractive field that will probably rampage in future research projects around the world, aiming at obtaining natural products that can easily and safely be employed to treat a wide range of diseases.

Starch and Nanoparticle

13

Alain Dufresne

Contents

Abstract

Nanotechnology and renewable bio-based materials are driving forces for the development of new materials that combine innovative properties and sustainability. Starch is an abundant, natural, renewable, and biodegradable polymer produced by many plants as a source of stored energy. Because of the multiscale structure of starch granules consisting of alternating crystalline and amorphous concentric layers, the controlled acid hydrolysis treatment of native starch disrupts this organization and releases crystalline platelet-like particles with nanoscale dimensions. This chapter intends to provide a comprehensive overview of their preparation, characterization, properties, and applications. The preparation and morphology of starch nanocrystals are exposed as well as strategies intended to improve the existing current methods. The properties of ensuing aqueous suspensions and reported surface chemical modifications are also presented. The preparation of polymer nanocomposites reinforced with starch nanocrystals and their properties is then reviewed.

1 Introduction

Fossil energy depletion and growing environmental concerns have brought up increasing interest in bio-based eco-efficient and high-technology materials. In this context, the development of products made of sustainable or renewable non-petroleum-based polymeric materials has become an active research area that has received much attention. This is mainly driven by the public's growing demand for more environmental friendly materials. Unfortunately, the thermomechanical performance of most renewable polymers is generally inferior compared to traditional petroleum-based polymers. The composite materials concept is one solution for creating renewable materials that match or exceed the performance of commonly used petroleum-based engineering polymers. Combining bio-based/renewable polymers with renewable reinforcements could address the property-performance gap between renewable and traditional synthetic polymers.

Starch is a natural, renewable, and biodegradable polymer produced by many plants as a source of stored energy. It is the major carbohydrate reserve in plant tubers and seed endosperm, and it is found in plant roots, stalks, crop seeds, and staple crops such as rice, corn, wheat, tapioca, and potato (Buléon et al. 1998). Starch is therefore a promising material because of its versatility, low price, availability, and numerous industrial applications. It is interesting to note that Romance languages, unlike Germanic languages and English, make a distinction between the two main sources of starch: for example, *amidon* for cereal-derived starch and *fécule* for tuber-derived starch in French (http://ec.europa.eu/agriculture/eval/reports/amidon/chap1.pdf). In 2000, the world starch market was estimated to be 48.5 million tons, including native and modified starches, but also the large volume of starch that is converted into syrups for direct use as glucose and isoglucose and as substrates in the form of very high-dextrose syrups (known as starch hydrolysates) for fermentation into organic chemicals, including ethanol (http://ec.europa.eu/agriculture/eval/reports/amidon/chap1.pdf). The value of the output is worth € 15 billion per year, explaining the interest of the industrialists and researchers seeking new properties of high-value application. The major categories to be considered while mapping the starch processing industry are food and nonfood products. The use of starch in food products includes food processing and beverages. Nonfood products of starch include paper, glue, thickening agent, and stiffening agent, among others.

Starch is biosynthesized as semicrystalline granules with varying polymorphic types and degrees of crystallinity. The amorphous regions are more susceptible to hydrolysis and, under controlled conditions, may be dissolved, leaving the rigid crystalline regions intact. It was reported that the acid hydrolysis of native starch granules releases platelet-like nanoscale highly crystalline residues. The potential of

nanotechnology and nanocomposites in various sectors of research and application is promising and attracting increasing investment. By definition, materials having at least one linear dimension in the range from approximately 1 to 100 nm are called nanomaterials. As the size of a particle is decreasing down to the nanometer scale, important changes occur. Both the specific surface area and total surface energy increase. Moreover, starch nanoparticles display a highly reactive surface with plenty hydroxyl groups. When blended with a polymeric matrix, ensuing nanocomposites show unique properties, because of the nanometric size effect, compared to conventional composite even at low filler content. Indeed, nanofillers have a strong reinforcing effect, and studies have also shown their positive impact in barrier effect. However, for decades, studies have been conducted with nonrenewable inorganic fillers. Increasing environmental concerns have led to investigating the potential uses of renewable resources for such application. It has brought two scientific fields together, viz., nanotechnologies, which allow the development of innovative and efficient materials, and biomaterial processing, with the use of renewable raw materials for more environmentally friendly and sustainable solutions.

2 Occurrence/Sources

In plants, starch accumulates in many different photosynthetic or non-photosynthetic tissues. It accumulates during the day in plant cell leaf cells and breaks down at night to achieve a more or less constant supply of sucrose to the non-photosynthetic tissues. It is therefore the major energy reserve of higher plants. The starch industry extracts and refines starches by wet grinding, sieving, and drying. After its extraction from plants, starch occurs as a flour-like tasteless and odorless white powder insoluble in cold water. This powder called native starch consists of microscopic granules with diameters depending on the botanical origin, ranging from 2 (for wheat and rice) to 100 μm (for potato), and with a density around 1.5 g cm^{-3} (Buléon et al. 1998).

2.1 Starch Composition

The composition of starch was originally determined by studying the residue of its total hydrolysis by β-amylase. It mainly consists of a combination of two glucosidic macromolecules, namely, amylose and amylopectin (Fig. 1). In most common types of starch, the amylopectin content ranges between 72 % and 82 %, while the amylose content ranges between 18 % and 28 %. However, some mutant types of starch have very high amylopectin content (99 % for waxy maize), and some very high amylose content (up to 70 % and more for amylomaize). Other trace elements associated with starches correspond to three categories of materials, viz., (i) particulate material, mainly composed of cell-wall fragments; (ii) surface components such as proteins, enzymes, amino acids, and nucleic acids, removable by extraction procedures; and (iii) internal components, mainly composed of lipids.

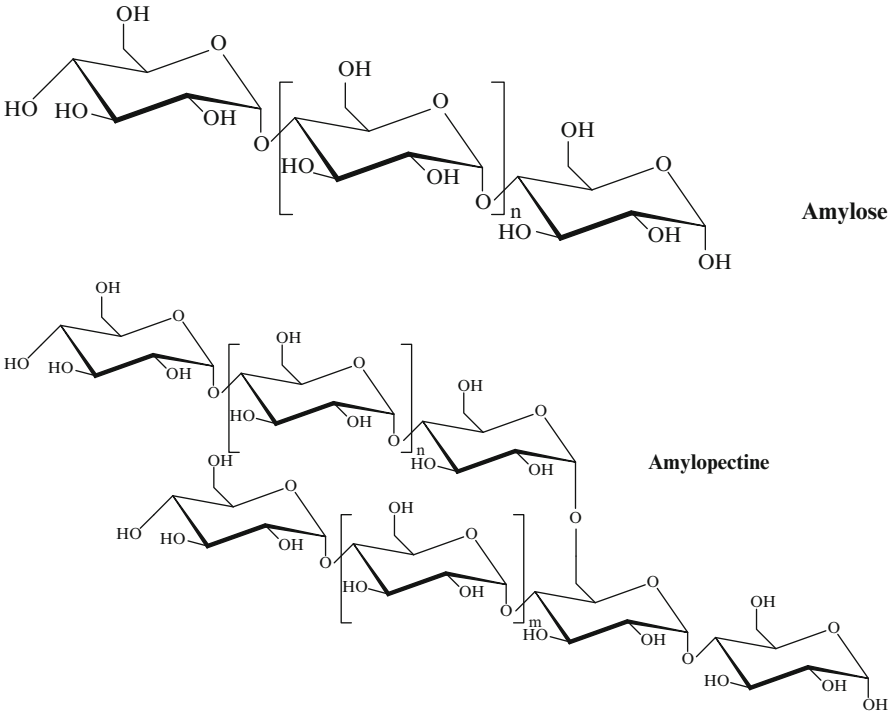

Fig. 1 Chemical structure of amylose and amylopectin

Amylose is essentially a linear polymer consisting of glucose units linked by α-(1→4) glycosidic bonds, slightly branched by α-(1→6) linkages. It has a degree of polymerization up to DP 6000 and has a molar mass of 105–106 g mol^{-1}. The chains can easily form single or double helices. Amylopectin is a highly branched polymer consisting of relatively short branches of α-D-(1→4) glycopyranose that are interlinked by α-D-(1→6) glycosidic linkages. It is a larger molecule and differs from amylose in that branching occurs, with an α-1,6 linkage every 24–30 glucose monomer units. Each amylopectin molecule contains up to two million glucose residues in a compact structure. The molecules are oriented radially in the starch granule, and as the radius increases, so does the number of branches required to fill up the space, with the consequent formation of concentric regions of alternating amorphous and crystalline structure.

2.2 Multiscale Structure of Starch Granule

As many living organisms, starch granule displays a multiscale structure as shown in Fig. 2. It consists of the (a) starch granule (2–100 μm), into which we find (b) growth rings (120–500 nm) composed of (d) blocklets (20–50 nm) made of

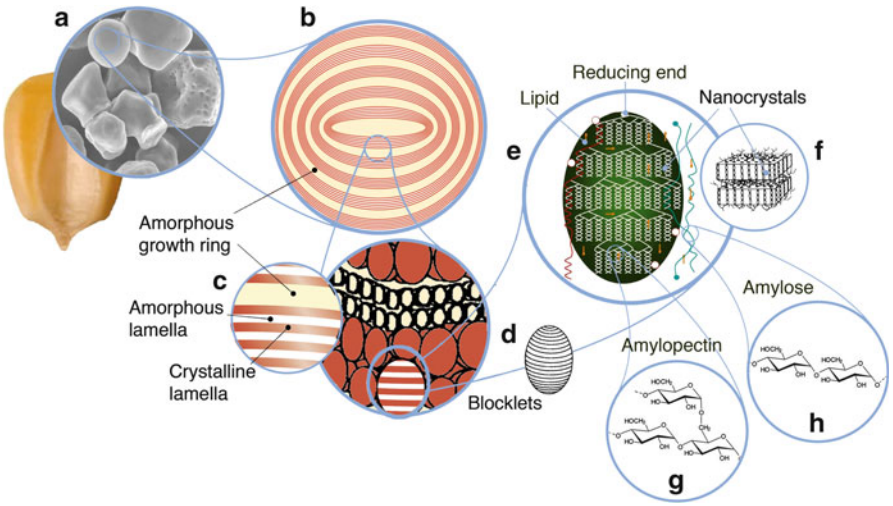

Fig. 2 Starch multiscale structure: (**a**) starch granules from normal maize (30 μm); (**b**) amorphous and semicrystalline growth rings (120–500 nm); (**c**) amorphous and crystalline lamellae (9 nm), magnified details of the semicrystalline growth ring; (**d**) blocklets (20–50 nm) constituting unit of the growth rings; (**e**) amylopectin double helixes forming the crystalline lamellae of the blocklets; (**f**) nanocrystals, other representation of the crystalline lamellae called starch nanocrystals when separated by acid hydrolysis; (**g**) amylopectin's molecular structure; (**h**) amylose's molecular structure (0.1–1 nm) (Reproduced with permissions from LeCorre et al. (2010))

(c) amorphous and crystalline lamellae (9 nm) (Gallant et al. 1997) containing (g) amylopectin, and (h) amylose chains (0.1–1 nm). The blocklet concept was developed in the 1930s (Katz 1930).

When observed under a microscope and polarized light, starch shows birefringence. The refracted characteristic "Maltese cross" corresponding to the crystalline region is typical of a radial orientation of the macromolecules. The so-called onion-like structure of starch granule that consists more or less concentric growth rings is composed of alternating hard crystalline and soft less ordered shells growing by apposition from the hilum (center of the granule). The thickness of the combined repeated crystalline and amorphous lamellae is 9 nm regardless of the starch botanical origin (Gallant et al. 1997).

Native starches contain between 15 % and 45 % of crystalline material (Zobel 1988). Depending on their X-ray diffraction pattern, starches are categorized in three crystalline types referred to as A, B, and C. A type is characteristic of cereal starches (wheat and maize starch). B type is typical of tuber and amylose-rich cereal starches. C type is characteristic of leguminous starches and corresponds to a mixture of A and B crystalline types. V type is observed during the formation of complexes between amylose and a complexing molecule (iodine, alcohols, cyclohexane, fatty acids, etc.). The appearance of starch X-ray diffraction pattern depends on the water content of granules during the measurement. The more starch is hydrated, the thinner the diffraction pattern rings up to a given limit. Water is

therefore one of the component of the crystalline organization of starch. The crystalline-to-amorphous transition occurs at 60–70 °C in water, and this process is called gelatinization.

3 Preparation of Starch Nanocrystals

Nanosize particles can be prepared from microscopic starch granules following different strategies. Consequently, ensuing nanoparticles have different properties, crystallinity, and morphology (LeCorre et al. 2010). For instance, starch nanoparticles were prepared by precipitating an aqueous gelatinized starch solution within ethanol as the precipitant (Ma et al. 2008). Nanoscale starch particles with a spherical or oval shape and diameters in the range of 10–20 nm were obtained by complex formation with other components involving mainly amylose rather than amylopectin (Kim and Lim 2009). However, the complex contained a large portion of amorphous material so that its selective removal by enzymatic hydrolysis was needed, resulting in an extremely low yield of nanoparticles.

The method for producing nanofibrillated cellulose (NFC) has also been transferred for producing starch colloids (Liu et al. 2009). Diluted slurry of high amylose corn starch was run through a Microfluidizer for several passes (up to 30). The particle size of the sample obtained from more than ten passes was below 100 nm with a yield close to 100 %, and the gel-like suspension remained stable for more than 1 month. However, the ensuing starch colloids were obtained from breaking down both amorphous and crystalline domains, rendering amorphous nanoparticles after ten passes.

Therefore, the most convenient and most investigated procedure for preparing starch nanoparticles has been acid hydrolysis yielding highly crystalline nanoparticles or starch nanocrystals.

3.1 Acid Hydrolysis Process of Starch Granules

In starch industry, acid hydrolysis process is a chemical treatment largely used to prepare glucose syrups. The preparation at room temperature of a low molecular weight acid-resistant fraction of potato starch after hydrolysis with a 15 % (w/v) sulfuric acid (H_2SO_4) suspension during 30 days was reported by Nägeli 140 years ago (Nägeli 1874). The ensuing insoluble fraction would be known as Nägeli amylodextrin. Later, Lintner reported a 40-day hydrolysis process with a 7.5 % (w/v) hydrochloric acid (HCl) suspension of potato starch at 30–40 °C to produce a high molecular weight starch suspension called “lintnerized starch” (Lintner 1886). More recently and by analogy with the acid-induced extraction of cellulose nanocrystals from cellulosic fibers, Dufresne et al. reported a method for producing a material which was called “microcrystalline starch,” consisting of agglomerated particles of a few 10 nm in diameter (Dufresne et al. 1996). This procedure consisted in hydrolyzing potato starch granules (5 wt%) in a 2.2 N HCl suspension for 15 days.

A detailed study of the HCl-induced degradation of granular starch from different origins was reported (Robin et al. 1975). The higher susceptibility to acid of amylopectin-rich waxy maize compared to other cultivars was attributed to the fact that hydrolysis severed branched molecules more readily than linear molecules. Moreover, the kinetics of lintnerization showed a two-stage profile for the hydrolysis of starch granules. For shorter times, the hydrolysis kinetics was fast, whereas for longer times, it was slow. It was explained by the fact that acid attacked amorphous areas more rapidly than the crystalline ones, less accessible to H_3O^+ ions. The critical time corresponding to fast/slow hydrolysis conditions depends on the botanical origin of starch (Singh and Ali 2000; Jayakody and Hoover 2002). The hydrolysis of the granules appeared to be governed by two factors: reactivity and accessibility. It was also reported that the hydrolysis process is faster when using HCl rather than H_2SO_4 (Muhr et al. 1984). Temperature is another parameter that catalyzes the hydrolysis reaction, but it should obviously remain below the gelatinization temperature of starch in acidic medium. The gelatinization process corresponds to an irreversible swelling and solubilization phenomenon occurring when native granules are heated above 60 °C in excess water. As for temperature, the acid concentration favors the hydrolysis kinetics. However, its upper limit is restricted (around 2.5–3 N for HCl) since above this critical acid concentration, granule gelatinization occurs (Robin 1976).

3.2 Morphology and Structure of Starch Nanocrystals

The amorphous regions of the starch granule act as structural defects which are susceptible to acid attack, and, under controlled conditions, they may be removed, releasing crystalline regions intact. The shape and dimensions of starch nanocrystal can be directly accessed by microscopic observations. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) can be used. Nevertheless, AFM is well known to overestimate the size of the nanocrystals due to the tip-broadening effect. SEM is useful to perform a rapid examination, but the resolution is simply insufficient for more detailed information. Field emission SEM (FESEM) can be used to improve the spatial resolution and minimize sample charging and damage. Transmission electron microscopy (TEM) is the best-suited method to identify individual nanocrystals and determine their morphology.

A detailed investigation on the structure of acid-hydrolyzed waxy maize starch fragments was reported (Putaux et al. 2003; Putaux 2005). TEM observation of such fragments using HCl and H_2SO_4 is shown in Figs. 3 and 4, respectively. The insoluble residue from HCl hydrolysis contains polydisperse and more or less individualized platelet nanocrystals corresponding to the lamellae formed by the association of amylopectin side branches into parallel arrays of double helices (Fig. 3). The 5–7 nm thick lamellae are still connected by α(1→6) linkages after 2 weeks of hydrolysis and can be seen edge on (Fig. 3a) but also flat on the carbon grid (Fig. 3b, c). As the hydrolysis is progressing up to 6 weeks (Fig. 3d), more α(1→6) branching points located in the interlamellar areas are severed, and the

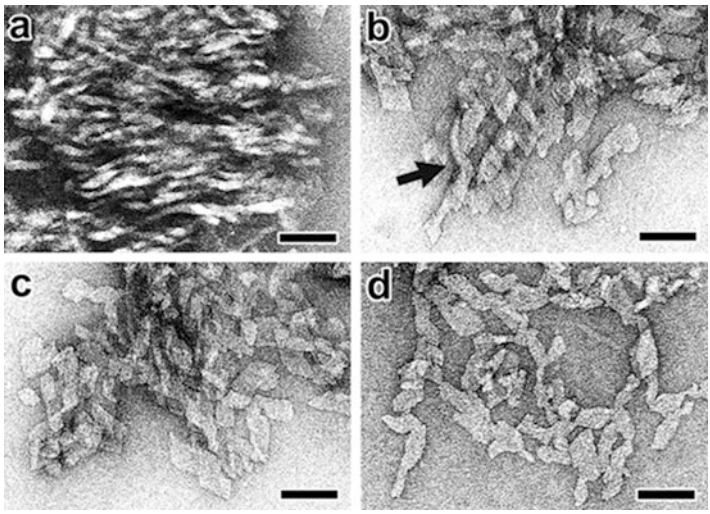

Fig. 3 TEM micrographs of negatively stained waxy maize starch samples: (**a–c**) fragments of waxy maize starch granules after 2 weeks of 2.2 N HCl hydrolysis at 36 °C. In (**a**) a lamellar organization is clearly revealed with the platelets lying parallel to the incident electron beam. In (**b**) and (**c**) parallelepipedal platelets are seen lying flat on the carbon film. The *arrow* in (**b**) indicates a pyramidal stack of crystals. (**d**) Nearly individual waxy maize starch nanocrystals obtained after 6 weeks of hydrolysis (scale bars: 50 nm) (Reproduced with permissions from Putaux et al. (2003))

platelets are thus observed in planar view. Marked 60–65° acute angles and constituting parallelepipedal blocks with a length of 20–40 nm and a width of 15–30 nm are observed.

A similar morphology was observed for H_2SO_4-hydrolyzed nanocrystals resulting from the disruption of waxy maize starch granules as shown in Fig. 4 (Angellier et al. 2004). Nanoplatelets were generally observed in aggregates of 1–5 μm (Fig. 4a) as confirmed by laser granulometry (Angellier et al. 2005a). Different organizations were also reported as observed in Fig. 4b–d. X-ray and electron diffraction showed that these nanoplatelets retain the crystalline A type of the parent granules (Putaux et al. 2003).

The influence of the botanical origin and amylose content of native starches on the morphology of starch nanocrystals was also investigated (LeCorre et al. 2011a). Starch nanocrystals were prepared from normal maize, high amylose maize, waxy maize, potato, and wheat starch, covering three botanical origins, two crystalline types, and three ranges of amylose content (0 % , 25 %, and 70 %) for maize starch. Different types of crystalline nanoparticles were obtained with a thickness ranging between 4 and 8 nm and diameter from about 50 to 120 nm depending on the source. For the same amylose content, maize, potato, and wheat resulted in rather similar size and crystallinity of nanocrystal, proving the limited influence of the botanical origin. For the same botanical origin (maize), differences in size were more significant indicating the influence of the amylopectin content, and thicker

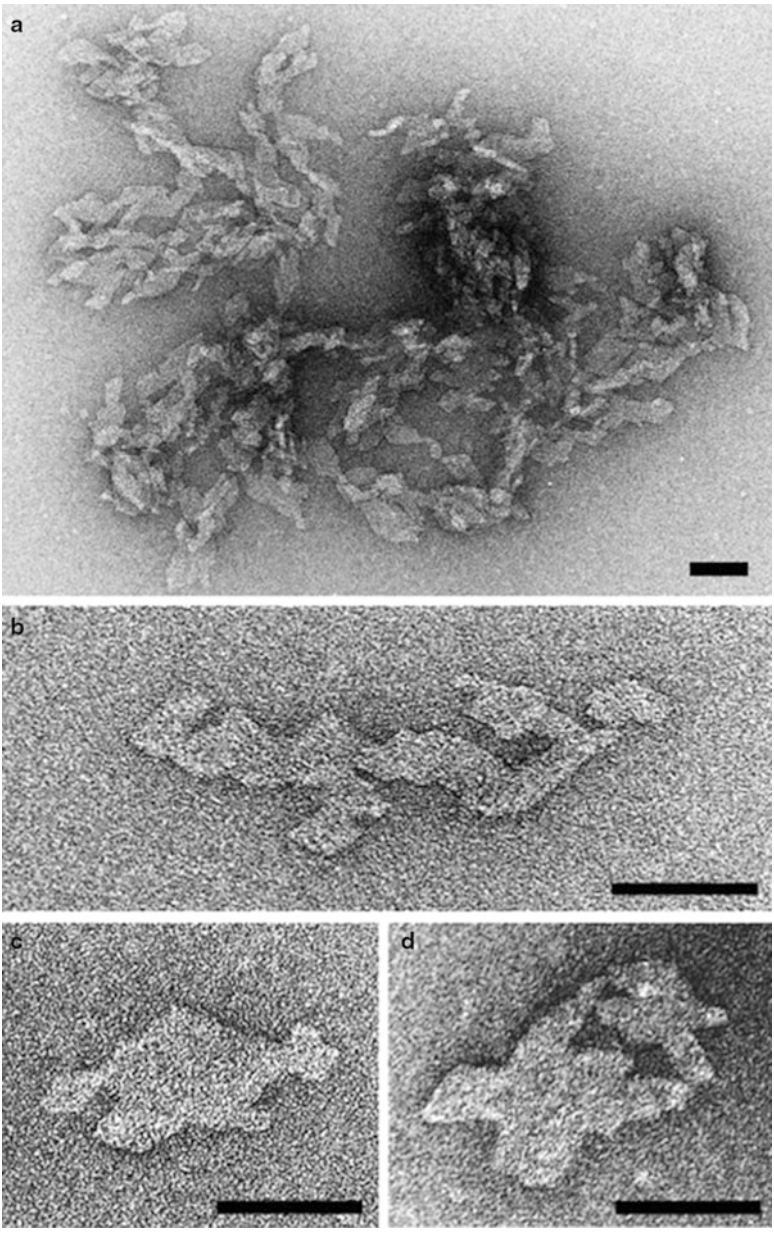

Fig. 4 TEM micrographs of negatively stained starch nanocrystals obtained by 3.16 M H_2SO_4 hydrolysis of waxy maize starch granules during 5 days, at 40 °C, 100 rpm and with a starch concentration of 14.69 wt% (optimized conditions): (**a**) aggregates of nanocrystals and (**b–d**) organizations of nanoplatelets (scale bar: 50 nm) (Reproduced with permissions from Angellier et al. (2004))

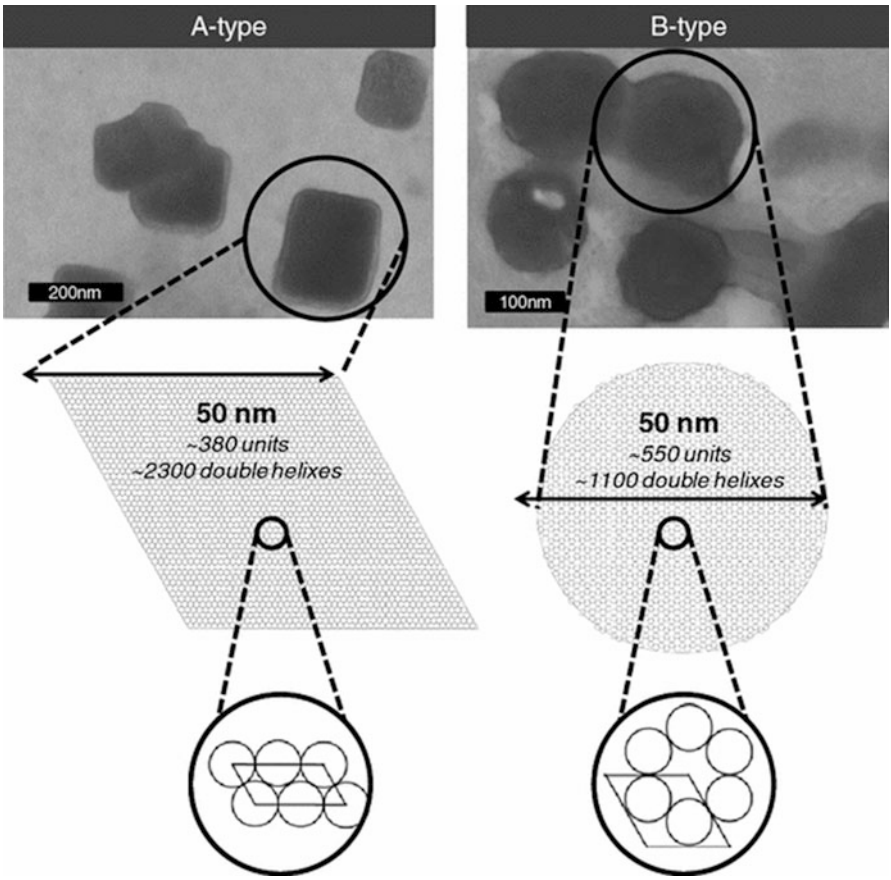

Fig. 5 Double helixes packing configuration depending on crystalline type and corresponding picture of starch nanocrystals from waxy maize starch (A type) and high amylose starch (B type) (Reproduced with permissions from LeCorre et al. (2011a))

nanocrystals were obtained for higher amylose content starches. It was also observed that nanocrystals produced from A-type starches rendered square-like particles, whereas nanocrystals produced from B-type starches rendered round-like particles (Fig. 5). This was explained by the different packing configurations of amylopectin chains for A- and B-type starches.

A detailed characterization of the molecular content of A-type nanocrystals prepared by mild sulfuric acid hydrolysis of waxy maize starch granules was reported (Angellier-Coussy et al. 2009). Two major groups of dextrins were found in the nanocrystals and were isolated. Each group was then structurally characterized using β-amylase and debranching enzymes (isoamylase and pullulanase) in combination with anion-exchange chromatography. One of these had a degree of polymerization (DP) of 14.2, which in the double-helical structure corresponds to a length of 5 nm and to the thickness of the crystalline lamellae

within the starch granule. This clearly indicated that the nanocrystals correspond to the crystalline lamellae present in native starch granules. As the nanocrystals were described by parallelepipedal blocks with a length of 20–40 nm and a width of 15–30 nm (Putaux et al. 2003), it was assumed that between 150 and 300, double-helical components are making up these crystalline domains. Further analysis indicated that roughly half of the dextrins in the nanocrystals were branched molecules, which was far more than previous investigations suggested. It was also concluded that they were equally distributed between populations of high and low molecular weights, respectively. Taking into account the length of these branches and the thickness of the platelets, it was likely that the majority of the branching points were found at the reducing-end surface of the nanocrystals, whereas the rest were located at the nonreducing side.

Because the acid hydrolysis process preferentially dissolves the amorphous domains of the starch granule leaving the crystalline zones intact, the degree of crystallinity (ratio between the mass of crystalline domains and the total mass of nanocrystal) of starch nanocrystals should be theoretically close to 100 %. However, incomplete removal of amorphous regions and less ordered surface chains may result in a lower degree of crystallinity. The values commonly reported in the literature are within the range 45–50 % (Lin et al. 2012). However, higher values such as 79 % after 10 days of hydrolysis have also been reported (Duan et al. 2011).

3.3 Acid Hydrolysis Conditions

In earlier studies on the degradation of starch granules in acidic medium, no attention was paid on the duration and yield of the process. However, these parameters should be considered before any potential application of starch nanocrystals. Long duration (40 days) and low yield (0.5 wt%) were reported for the acid hydrolysis of native starch granules (Battista 1975). The process was improved by performing periodic stirring of the suspension, and the duration of the acid hydrolysis treatment has been reduced to 15 days using a 5 wt% starch suspension and 2.2 M HCl (Dufresne et al. 1996).

The effect of five different factors on the selective sulfuric acid hydrolysis of waxy maize starch granules was investigated using a response surface methodology to comprehensively optimize the preparation of aqueous suspensions of starch nanocrystals (Angellier et al. 2004). The selected predictors were temperature, acid concentration, starch concentration, hydrolysis duration, and stirring speed. The objective of the study consisted in determining the operative conditions leading to the smallest size of insoluble residue with the shortest time and with the highest yield. The optimized preparation of aqueous suspensions of starch nanocrystals was achieved after 5 days with 3.16 M H_2SO_4 hydrolysis at 40 °C, 100 rpm and with a starch concentration of 14.69 wt% with a yield of 15.7 wt%. Ensuing nanoparticles had the same shape as those obtained from the classical procedure after 40 days of HCl treatment, with a yield of 0.5 wt%. This procedure continues to serve for most studies as the standard recipe for the preparation of starch nanocrystals. Confirming

the effect of acid concentration, it was shown that when hydrolysis was carried out with 2.2 M HCl, nanoparticles with the minimum size were obtained after 50 days, whereas this occurred just after 24 days using 3.7 M HCl (Jivan et al. 2013). It was also observed that the stronger acidity not only shortened the time required to obtain the minimum size for particles but also resulted in tinier crystals.

A further study showed that starch nanocrystals are produced from a very early stage of the acid hydrolysis treatment opening the door to new opportunities for the optimization of the process (LeCorre et al. 2011b). Microscopic observations of the insoluble residue were performed at a different stage of hydrolysis. From day 1, both granule fragments with a hollow center and starch nanoparticles were observed, indicating that starch nanocrystals were formed, at least, after 24 h of H_2SO_4 hydrolysis and that consequently, at any time including final suspension, both microscaled and nanoscaled particles can be found and coexist. It suggested that some nanocrystals might turn to sugar by the end of the batch production process explaining the low yields. This study clearly showed the need for a continuous production and extraction process of starch nanocrystals. In the same study (LeCorre et al. 2011b), differential centrifugation has been tested as an isolation process for separating these two kinds of particles but did not seem fitted for fractionation due to hydrogen bonding and different densities within starch granules.

The possibility of separating starch nanocrystals from microparticles in a continuous extraction technique was investigated (LeCorre et al. 2011c). Filtration of the hydrolyzed residues using a microfiltration unit equipped with ceramic membranes to assess the cross-flow membrane filtration potential of starch nanocrystal suspensions was therefore conducted. Contrary to frontal filtration, cross-flow filtration allowed isolation without modifying the crystalline structure of starch nanocrystals and did not favor their aggregation. The proposed microfiltration process is shown in Fig. 6.

The process parameters were monitored, and the properties of feed, permeate, and retentate were investigated. Cross-flow filtration was proved to be an efficient continuous operation for separating starch nanocrystals from the bulk suspension and non-fully hydrolyzed particles whatever the ceramic membrane pore size (0.2–0.8 μm). Analysis on permeate showed not only that collected nanoparticles were more crystalline than feed but also that mostly B-type particles were produced during the first day of hydrolysis. Based on this observation and as an attempt to establish a predictive model for the optimal parameter setting for preparing starch nanocrystals in 1 day, a statistical experimental design and a multi-linear regression method analysis were performed (LeCorre et al. 2012a).

The effect of an enzymatic pretreatment of starch granules before the acid hydrolysis aiming in reducing its duration was also investigated (LeCorre et al. 2012b). This pretreatment was performed to create pit holes at the surface of native granules without damaging the crystalline structure of starch and therefore to create pathways expected to facilitate and make more homogeneous the acid penetration during the subsequent acid hydrolysis treatment. Three amylases have been selected for the study, namely, α-amylase, β-amylase, and glucoamylase,

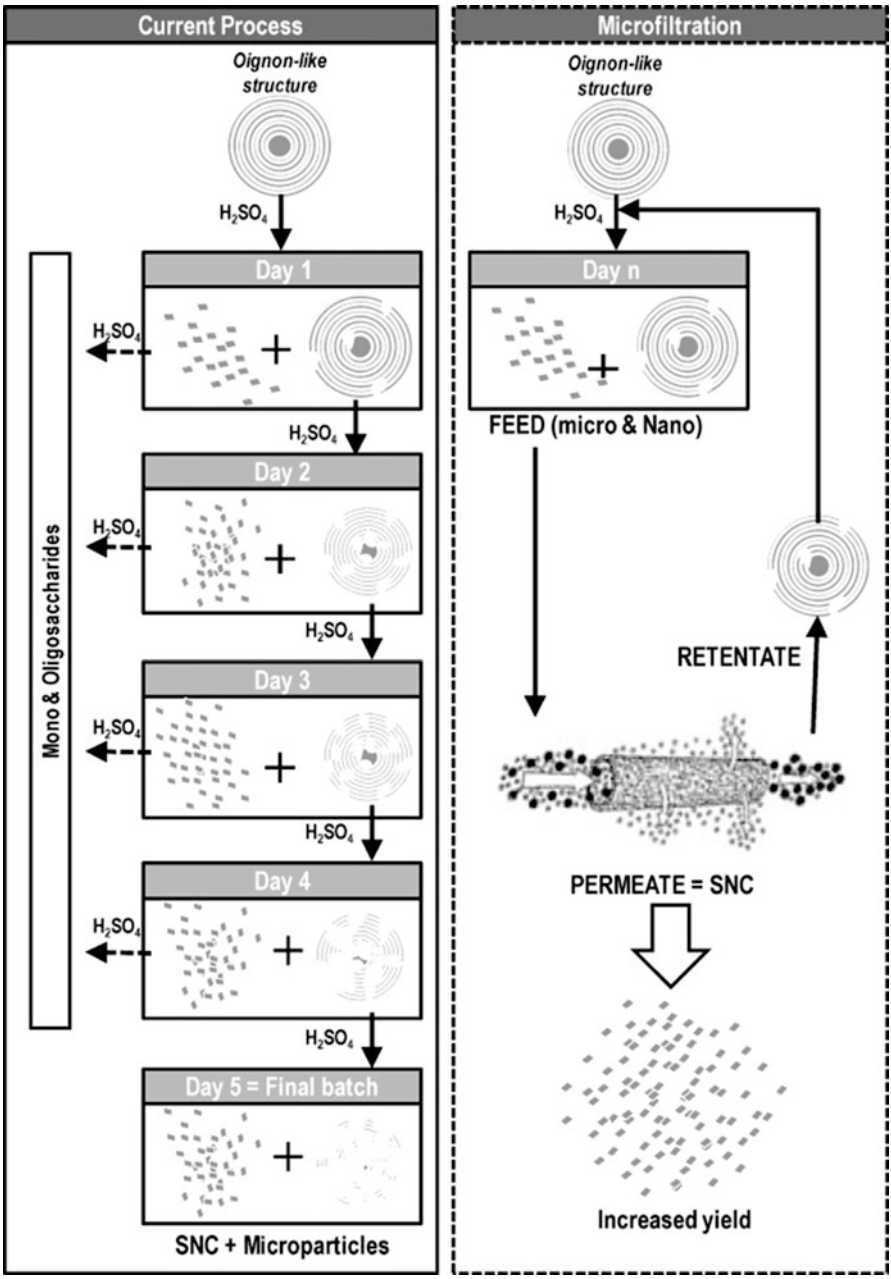

Fig. 6 Schematic comparison between the current preparation process involving the progressive production of starch nanocrystals as evidenced in LeCorre et al. (2011b) and the proposed microfiltration process (Reproduced with permissions from LeCorre et al. (2011c))

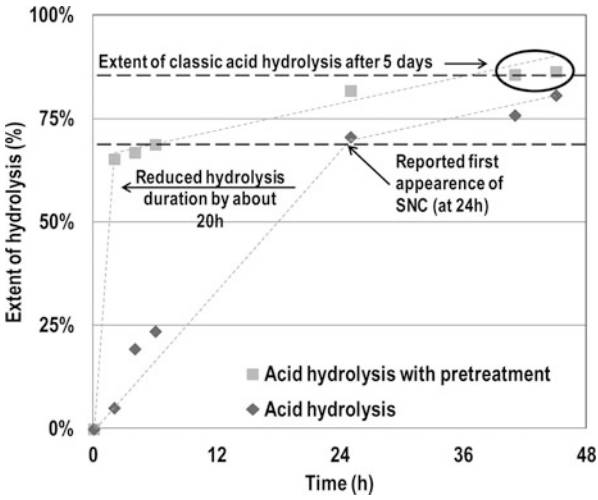

Fig. 8 Kinetics of sulfuric acid hydrolysis of non-pretreated (filled lozenges) and pretreated (*gray squares*) waxy maize starch (Reproduced with permissions from LeCorre et al. (2012b))

which correspond to three different action mechanisms. It was observed that the latter was the most efficient for producing microporous starch (Fig. 7) while keeping intact the semicrystalline structure of starch. Upon 2 h pretreatment of waxy maize starch granules, the extent of acid hydrolysis currently reached in 24 and 120 h (5 days) was reached in only 6 and 45 h, respectively, as shown in Fig. 8. Similar crystallinity and crystallite size were reported for starch nanocrystals prepared from pretreated starch in 45 h than for unpretreated starch in 120 h.

3.4 Thermal Properties of Starch Nanocrystals

The most investigated potential application for starch nanocrystals is as nanofiller for the processing of polymer bionanocomposites. However, the processing step raises the question of the potential melting of starch nanocrystals at high temperatures. A study was conducted to assess the maximum processing temperature for starch

nanocrystals in the dry state and in excess water (LeCorre et al. 2012c). The influence of the botanical origin, amylose content, and crystalline type of native starch used to produce these nanocrystals on the thermal properties of the nanoparticles was also investigated. Five types of starches (waxy maize, normal maize, high amylose maize, potato, and wheat) and their corresponding starch nanocrystals were characterized by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA).

It was shown that native starches showed as expected only one thermal transition that shifted to higher temperatures when decreasing the water content, whereas nanocrystals showed two transitions (LeCorre et al. 2012c). In excess water, the first peak was attributed to the first stage of crystallites melting (unpacking of the double helixes) and the second transition to the second stage of crystallites melting (unwinding of the helixes). B-type crystallinity starch nanocrystals gained more stability than A-type nanocrystals as they consist of more rigid crystallites. In the dry state, the peaks were attributed to crystallite melting, with a direct transition from packed helixes to unwound helixes. The presence of two peaks was attributed to the heterogeneity in crystallite quality. Limited influence of the amylose content of starch was reported.

Important information was provided from this study for the processing conditions of starch nanocrystal-based nanocomposites. It was concluded that starch nanocrystals can be used in wet processes, such as coating, keeping temperatures lower than 80–100 °C, and in dry processes at temperatures below 150–200 °C. Cross-linking of starch nanocrystals with sodium hexametaphosphate (SHMP) was found to hinder the phase transitions of the nanoparticles upon heating (Jivan et al. 2013).

3.5 Sustainability of Starch Nanocrystals

Being a bio-based material is not enough for starch nanocrystals to be sustainable. Their production and application processes need to have limited impacts on the environment, society, and economy. Indeed, sustainability was first coined by the Brundtland Commission (formally the World Commission on Environment and Development of the United Nations in 1983) and was defined as the "social and economic advance to assure human beings a healthy and productive life, but one that did not comprise the ability of future generations to meet their own needs" (Bruntland 1987). More recently, life cycle assessment (LCA) was standardized by the International Organization for Standardization (ISO) and largely contributed in assessing environmental impacts across all stages of production, use, and waste management for different materials.

The "environmentally sensitive" steps involved in the preparation of starch nanocrystals have been identified using life cycle assessment (LCA), and different scenarios have been proposed and compared according to different environmental impacts (LeCorre et al. 2013). A comparison to its main competitor, i.e., organically modified nanoclay (OMMT), was also proposed in this study. From an LCA point of view, the production of starch nanocrystal requires less energy than the

extraction of OMMT, but global warming and acidification indicators were higher than for OMMT. However, starch nanocrystals are renewable and biodegradable contrary to OMMT which contribute to nonrenewable energy and mineral depletion. Recommendations for the scaling-up of starch nanocrystal production process were made, and the main concern deals with the extensive use of land and water. It was suggested to:

1. Use noncultivated low-water-consuming naturally occurring starch sources, such as amaranth and some tubers, to limit acidification and eutrophication linked to starch cultivars.
2. Include less-water- and less-energy-consuming extraction and washing processes such as microfiltration, as described in LeCorre et al. (2011c).
3. Reach higher yield than current process.

4 Aqueous Dispersions of Starch Nanocrystals

The preparation of starch nanocrystals by acid hydrolysis treatment yields a diluted colloidal aqueous dispersion at the end of the process. The stability of this suspension depends on the dimensions of the dispersed particles and their size polydispersity and surface charge. The surface charge can be controlled through the nature of the acid used for the hydrolysis treatment. Indeed, HCl-prepared nanocrystals display an almost charge-free surface, whereas H_2SO_4 reacts with the nanocrystal surface hydroxyl groups via an esterification process inducing the grafting of anionic sulfate ester groups ($-OSO_3^-$). The presence of these randomly distributed negatively charged surface ester groups on the surface of the nanoparticle results in the formation of a negative electrostatic layer covering the nanocrystals and promotes their dispersion in water. The higher stability of H_2SO_4-prepared nanoparticles results therefore from an electrostatic repulsion between individual or aggregated nanoparticles.

Acid hydrolysis with HCl results in less stable suspensions as shown in Fig. 9 for waxy maize starch nanocrystals (Angellier et al. 2005a). It was clearly observed that the use of H_2SO_4 instead of HCl allows reducing the possibility of agglomeration of starch nanoparticles and limits their flocculation in aqueous medium. The kinetics of sedimentation of the nanoparticles was evaluated by small-angle light-scattering experiments performed on 3.4 wt% H_2SO_4-prepared starch nanocrystal aqueous suspensions (Angellier et al. 2005b). The results showed that there was no sedimentation of the nanocrystals for a period of at least 12 h. Nevertheless, the intensity of scattered light slightly was found to increase, revealing that starch nanocrystals tend to aggregate in aqueous medium but not sufficiently to induce a sedimentation phenomenon.

The dispersibility of starch nanocrystals in aqueous medium can also be controlled by adjusting the pH of the suspension. In a recent study, the effect of the pH of the dispersion on zeta potential, size distribution, and aggregation behavior of H_2SO_4-prepared starch nanocrystals was investigated (Wei et al. 2014). As the pH

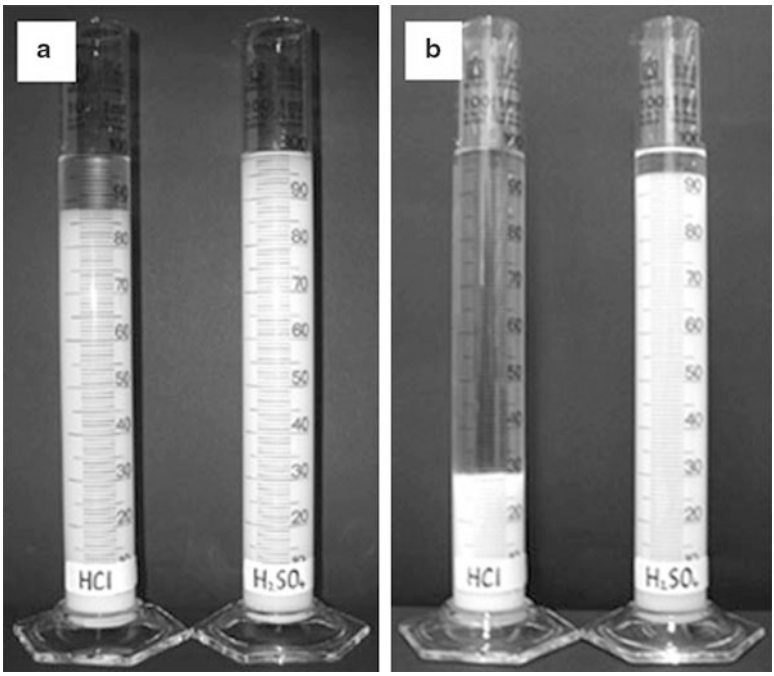

Fig. 9 Comparison of the sedimentation properties of HCl (*left* tube)- and H_2SO_4 (*right* tube)-hydrolyzed starch nanocrystals suspended in water after (**a**) 5 min and (**b**) 60 min (Reproduced with permissions from Angellier et al. (2005a))

of the dispersion increased, the zeta potential decreased, and aggregated platelet-like nanocrystals (1.5 μm) changed to monodispersed spherical-like nanoparticles (50 nm). Based on the results, it was suggested that stable starch nanocrystal aqueous suspensions could be obtained by adjusting the pH of the dispersion in the range 7.44–9.45. Improved dispersibility in water of starch nanocrystals obtained from H_2SO_4 hydrolysis of waxy maize starch was also observed upon cross-linking with sodium hexametaphosphate (SHMP) (Ren et al. 2012). The cross-linking reaction was performed in water at temperatures below the gelatinization temperature of starch and did not disrupt the crystalline structure of the nanocrystals. Stable and uniform starch nanocrystal aqueous suspensions were obtained.

The application of particles as a long-term stabilizer for the preparation of particle-stabilized emulsions, usually referred to as Pickering emulsions, is important for the development of novel food, cosmetic, and pharmaceutical products. Starch nanocrystals are surface active particles, and their food compatibility as well as complete biodegradability allows their use as particle emulsifier in food, cosmetics, and pharmaceuticals. The emulsifying ability of starch nanocrystals was investigated for oil-in-water emulsions consisting of 50 vol% paraffin liquid and equal concentration of water (Li et al. 2012). Stable emulsions were obtained when

the nanoparticle content relative to water was above 0.02 wt%. Both the size of the droplets and creaming decreased for increasing starch nanocrystal concentrations. The emulsions were very stable to coalescence over months, and the creaming was completely inhibited with 6.0 wt% starch nanocrystals, possibly because of the formation of an emulsion gel structure. When heating the emulsion above the gelatinization temperature of starch nanocrystals, it completely phase-separated.

5 Chemical Modification of Starch Nanocrystals

The high specific surface area resulting from their nanoscale dimensions coupled with the high density of surface hydroxyl groups allows targeted surface chemical modification of starch nanocrystals to introduce virtually any desired surface functionality. The reactive hydroxyl group content present on the surface of platelet-like starch nanocrystals was estimated to be ca. 14 % of the total amount available, i.e., 0.0025 mol.g^{-1} of starch nanocrystal (Angellier et al. 2005c). Different grafting strategies have been reported in the literature to graft either small molecules or polymers on the surface of starch nanocrystals as shown in Table 1. Mild reaction conditions should be applied to limit the reaction to the surface and

retain the original morphology of starch nanocrystals. The common surface chemical modifications of starch nanocrystals are schematically depicted in Fig. 10.

The surface of waxy maize starch nanocrystals was modified with alkenyl succinic anhydride (ASA) and phenyl isocyanate (PI) (Angellier et al. 2005c). The reaction was conducted in toluene/(dimethylamino)pyridine medium to avoid hydrolysis of ASA. Modified nanoparticles were characterized by Fourier transform infrared (FTIR) spectroscopy and X-ray photoelectron spectroscopy (XPS), contact angle measurements, TEM, and X-ray diffraction analysis. The lower polarity of the modified nanocrystals was also demonstrated by a simple experiment (Fig. 11). The pristine and modified nanoparticles were mixed with two immiscible solvents having both different polarities and densities (water and dichloromethane were chosen for the test) and the visual inspection of the mixture indicated with which solvent they are best wetted. It was observed that unmodified starch nanocrystals

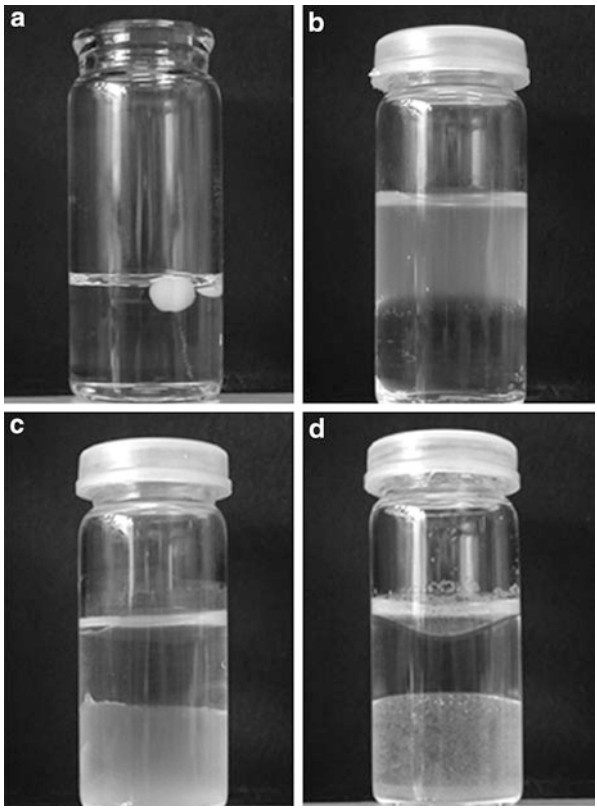

Fig. 11 Wettability tests: (**a**) a drop of an aqueous suspension of waxy maize starch nanocrystals in dichloromethane, (**b**) migration of unmodified starch nanocrystals in distilled water, migration of (**c**) ASA-modified and (**d**) PI-modified starch nanocrystals modified with (**c**) ASA and (**d**) PI in dichloromethane (Reproduced with permissions from Angellier et al. (2005c))

remained in the water medium whereas modified nanoparticles migrated towards the dichloromethane phase (Fig. 11).

The surface chemical modification of starch nanocrystals with longer chains can yield some extraordinary possibilities. Indeed, the grafted chains can act as binding sites for active agents in drug delivery systems or for low toxins in purifying and treatment systems. Moreover, for composite applications, the grafted chains may be able to interdiffuse upon heating to form the polymer matrix resulting in near-perfect stress transfer at the interface because of the covalent linkage between the reinforcement and the matrix.

Stearic acid chloride and poly(ethylene glycol) methyl ether (PEGME) were successfully grafted on the surface of starch nanocrystals (Thielemans et al. 2006). Extensive crystallization of the stearate moieties grafted to the starch nanoparticle surface, forming a crystalline hydrophobic shell around the hydrophilic starch nanocrystal, was observed. On the contrary, strong interactions between the grafted PEGME chains and the starch particle limited PEGME crystallization. These interactions caused the PEGME chains to align themselves with the nanocrystal surface. Both modifications, however, exhibit a large effect on the individualization

of the nanocrystals because of reduced hydrogen bonding and polar interactions between the individual particles.

These stearate-modified starch nanocrystals were employed as adsorbents for the removal of a wide range of dissolved aromatic compounds from water (Alila et al. 2011). The grafted stearate long chains enhanced the adsorption capacity of aromatic organic compounds on the nanometric substrate, which ranged between 150 and 900 μmol g^{-1}, and the maximum adsorption amount reached 100 mg g^{-1}. The adsorption isotherms were accurately described by the Langmuir model, and the adsorption kinetics followed a two-step process with first pure adsorption of the aromatic compounds onto the surface of the nanoparticles followed by a diffusion of the compounds into the layer of surface chains grafted onto the starch nanocrystals. Furthermore, the feasibility of using these nanoparticles in continuous flow mode processes was confirmed using a fixed-bed column setup. The fixed-bed column could also be regenerated by washing with ethanol and was found not to exhibit any loss in adsorption capacity over multiple adsorption-desorption cycles.

Even longer polymeric chains such as polycaprolactone (PCL) were grafted on the surface of starch nanocrystals using "grafting onto" (Labet et al. 2007; Habibi and Dufresne 2008) and "grafting from" (Xu et al. 2010; Yu et al. 2008; Namazi and Dadkhah 2008) approaches. Polystyrene was also grafted on starch nanocrystals using a "grafting from" strategy (Li et al. 2012). It was systematically verified that the crystalline structure of the nanoparticles was not changed after grafting and that it only occurred on the surface. The surface coating of the nanoparticles allowed dispersion in organic solvents and compatibilization with apolar polymeric matrices. Amphiphilic starch nanocrystals prepared by the graft copolymerization of starch nanocrystals with styrene were well dispersed both in polar and nonpolar solvents (Li et al. 2012). Moreover, microscopic observations of modified starch nanocrystals showed the individualization of nanoparticles. The grafting efficiency of PCL chains onto the surface of starch nanocrystals decreased with the length of the polymeric chains, as expected (Labet et al. 2007). However, the PCL content for grafted nanoparticles was higher than 50 wt% as determined from elemental analysis.

6 Starch Nanocrystal-Reinforced Polymer Nanocomposites

By adding conventional high modulus reinforcements into a polymer, usually the modulus and the strength of the composite are improved, while the ductility and the impact strength are decreased. In the case of well-dispersed nanoparticles, the modulus and strength can be improved without significant change in ductility since they do not create high stress concentrations due to their nanosize. However, to improve the mechanical properties of the host material and take advantage of this property, special care needs to be paid to the processing on the nanocomposite. Indeed, it is well known that the macroscopic mechanical properties of heterogeneous materials depend on the specific behavior of each phase and the composition (volume fraction of each phase) but also on the morphology (spatial arrangement of the phases) and the interfacial properties.

6.1 Processing of Starch Nanocrystal-Reinforced Polymer Nanocomposites

Different polymeric matrices have been associated with starch nanocrystals to prepare nanocomposite materials. Some systems reported in literature are collected in Table 2. The first investigation was performed using a copolymer of styrene and

butyl acrylate (poly(*S*-*co*-BuA)) matrix in latex form (Dufresne et al. 1996). This aqueous dispersion was mixed with the aqueous suspension of starch nanocrystals, and the mixture was freeze-dried and hot-pressed. Following works generally involved a casting/evaporation method because of its simplicity and good dispersion level of the nanoparticles in water that is preserved when processing the material in aqueous medium. Therefore, most polymeric matrices consisted of water-soluble polymers such as carboxymethyl chitosan (Duan et al. 2011), pullulan (Kristo and Biliaderis 2007), polyvinyl alcohol (PVA) (Chen et al. 2008a), gelatinized starch (Angellier et al. 2006b; Garcia et al. 2009, 2011; Viguié et al. 2007), and soy protein isolate (SPI) (Zheng et al. 2009) or polymers in the latex form (aqueous polymer dispersion) such as natural rubber (NR) (Angellier et al. 2005b, d, 2006a; Mélé et al. 2011; LeCorre et al. 2012d; Bouthegourd et al. 2011), poly(β-hydroxyoctanoate) (PHO) (Dubief et al. 1999), poly(*S*-*co*-BuA) (Dufresne et al. 1996; Dufresne and Cavaillé 1998; Angellier et al. 2005a), and waterborne polyurethane (WPU) (Yu et al. 2008; Chen et al. 2008b; Wang et al. 2010; Zou et al. 2011). However, care must be taken regarding the processing temperature to avoid gelatinization of starch nanocrystals. For instance, for the processing of thermoplastic starch reinforced with starch nanocrystals, the temperature of gelatinized starch was decreased to 40 °C before adding starch nanocrystals (Angellier et al. 2006b; Viguié et al. 2007).

To improve the nanoparticle-polymer interface and promote individualization of starch nanocrystals, in situ one-pot miniemulsion polymerization reaction of butyl methacrylate (BuMA) in the presence of starch nanocrystals was conducted (BeHaaj et al. 2013). It imparted a high degree of binding between the nanoparticles and the polymer particles. It was shown that starch nanocrystals were not sufficient to stabilize the monomer droplets, but provided a synergetic stabilization effect when used together with a cationic surfactant, reducing thus the required surfactant amount by a factor of 4. For starch nanocrystal-reinforced polycaprolactone (PCL) (Habibi and Dufresne 2008) and polylactic acid (PLA) (Xu et al. 2010), the surface chemical modification of the nanocrystals was performed to allow their dispersion in dichloromethane, a solvent for both PCL and PLA, that was used as processing liquid medium.

6.2 Mechanical Properties of Starch Nanocrystal-Reinforced Polymer Nanocomposites

To evaluate the mechanical reinforcing effect of starch nanocrystals in a polymeric matrix, mechanical measurements in both the linear (dynamic mechanical analysis – DMA) and nonlinear range (tensile tests) can be performed. In the pioneering work on potato starch nanocrystal-reinforced poly(*S*-*co*-BuA), a high reinforcing effect of the filler was observed by DMA, especially above the glass transition temperature (Tg) of the matrix (Dufresne et al. 1996; Dufresne and Cavaillé 1998). This reinforcing effect was later confirmed by most authors for different polymeric systems. For instance, Fig. 12 shows the DMA curves

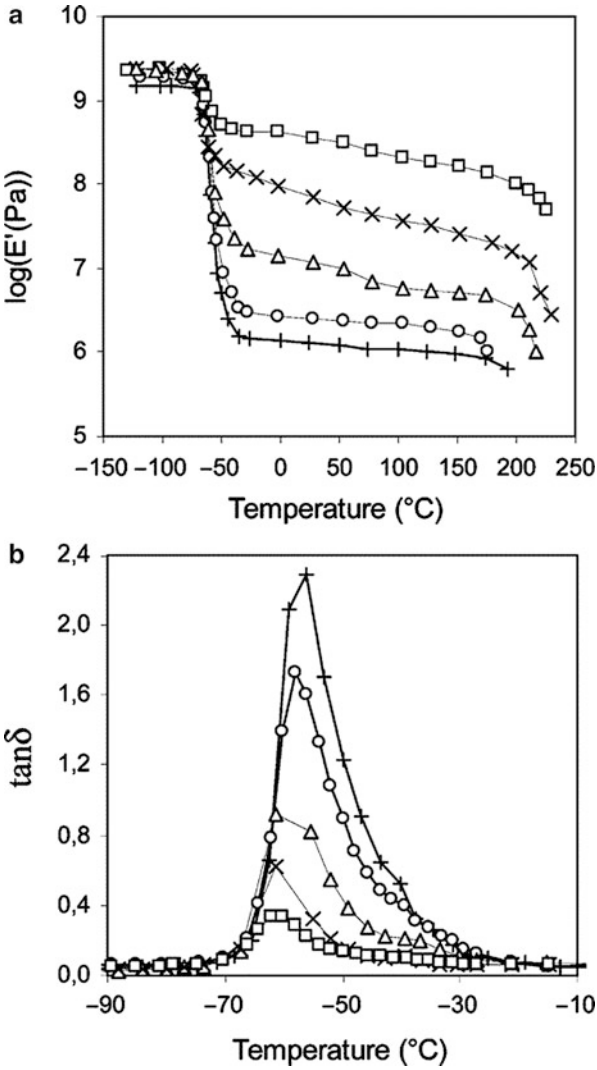

Fig. 12 Logarithm of the storage tensile modulus E′ (**a**) and tangent of the loss angle tan δ (**b**) vs temperature at 1 Hz for NR films waxy reinforced with 0 (+), 5 (○), 10 (Δ), 20 (×), and 30 wt% (□) maize starch nanocrystal (Reproduced with permissions from Angellier et al. (2005d))

obtained for waxy maize starch nanocrystal-reinforced NR (Angellier et al. 2005d). A continuous increase of the storage modulus was observed, mainly above the Tg of the matrix, when adding the nanoparticles (Fig. 12a). The evolution of the loss angle (Fig. 12b) displays a peak located in the temperature range of the glass transition of the NR matrix. A decrease of the magnitude of the peak when increasing the starch nanocrystal content is observed. It is ascribed to both the decrease of the number of mobile units participating to the relaxation process and decrease of the magnitude of the modulus drop associated with Tg.

Obviously, the magnitude of the relative reinforcing effect depends on the intrinsic mechanical properties of the neat polymer. A higher reinforcing effect is

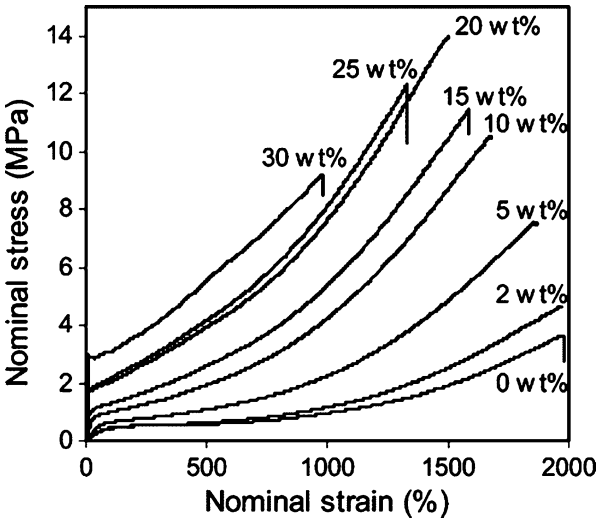

Fig. 13 Typical nominal stress vs nominal strain curves of waxy maize starch nanocrystal-reinforced NR nanocomposite films. The starch nanocrystal contents are indicated in the figure (Reproduced with permissions from Angellier et al. (2005d))

generally observed when using a soft polymer matrix (amorphous rubbery polymer) than when using a semicrystalline or amorphous glassy polymer.

Nonlinear tensile tests are more classically used to investigate the mechanical behavior of polymeric materials. The stiffness or tensile modulus can be determined from the initial slope of the stress-strain curves, and ultimate properties such as strength and strain at break correspond to the experimental data associated with the break of the sample. The introduction of starch nanocrystals within a polymeric matrix generally induces an increase of both the tensile modulus and strength, whereas the strain at break decreases. Typical stress-strain curves for waxy maize starch nanocrystal-reinforced NR are shown in Fig. 13. However, a decrease of the reinforcing capability of starch nanocrystals has been reported in some studies for higher filler contents because of self-aggregation within the polymeric matrix (Chen et al. 2008a; Zheng et al. 2009).

The reinforcing effect of starch nanocrystals to NR was compared to the one provided by other fillers such as clays, organoclays, carbon black, fly ash, and chitin nanocrystals (Angellier et al. 2005d). Starch nanocrystals were not as competitive as organoclays. They displayed a lower tensile modulus but higher ultimate properties (strength and elongation at break) than chitin nanocrystals because of the higher aspect ratio of the latter. However, starch nanocrystals presented better mechanical properties than fly ash and carbon black. It was shown that the addition of only 10 wt% starch nanocrystals to NR induced a reinforcing effect similar, in terms of stiffness, to the one observed with 26.6 wt% carbon black while maintaining a higher elongation at break.

Starch is a hydrophilic material, and therefore the performance of starch nanocrystals can be altered in moist atmosphere. The effect of moisture content was investigated for NR-based materials, and the stiffness of the nanocomposite was found to decrease when increasing the water content (Angellier et al. 2005d).

For some systems, an increase of the glass transition temperature (Tg) of the matrix when increasing the starch nanocrystal content was observed, attributed to the existence of an interphase of immobilized matrix material in contact with particle surface (Kristo and Biliaderis 2007; Angellier et al. 2006b; Viguié et al. 2007). The formation of this interphase resulted from favorable filler/matrix interactions. Interestingly, a considerable slowing down of the recrystallization (retrogradation) of the thermoplastic starch matrix upon storage in humid atmosphere was observed when adding starch nanocrystals (Angellier et al. 2006b; Viguié et al. 2007). For this system, the reinforcing effect was more significant than in NR because of strong interactions between the filler and amylopectin chains from the matrix and possible crystallization at the filler/matrix interface.

Waterborne polyurethane (WPU) was reinforced with starch and cellulose nanocrystals obtained by acid hydrolysis of waxy maize starch granules and cotton linter pulp, respectively (Wang et al. 2010). A synergistic effect was observed when adding 1 wt% starch and 0.4 wt% cellulose nanocrystals with a significant improvement in tensile strength, Young's modulus, and tensile energy at break without significant loss for the elongation at break. The mechanical performance was found to be higher than for individual filler, but it is worth noting that the total filler content was different. In the ternary system, the formation of much jammed network consisting of nanoparticles with different geometrical characteristics was suggested to play an important role in the enhancement of the cross-linked network. Moreover, strong hydrogen bonding interactions between the nanoparticles and between the nanoparticles and the hard segments of WPU matrix were suspected to improve the mechanical properties.

6.3 Effect of Chemical Modification on Mechanical Performance

Surface chemical modification of starch nanocrystals allows broadening the range of polymeric matrices that can be used in association with them through the possibility of processing composite materials from an organic solvent instead of aqueous dispersions. It consists in transforming the polar hydroxyl groups from the surface of starch nanocrystals into moieties capable of enhancing interactions with nonpolar media and polymers.

The mechanical performance of ASA- and PI-modified starch nanocrystal-reinforced NR was investigated and compared to the one of unmodified nanoparticle-based systems (Angellier et al. 2005d). The chemical modification of the nanoparticles was found to lower their reinforcing capability. This unusual behavior was ascribed to hindered interactions between chemically modified particles resulting from their coating with the grafting agents. However, it is worth noting that the nanocomposite films were obtained by casting/evaporation from an aqueous or toluene mixture, respectively, for unmodified and modified nanoparticles. On the contrary, both a higher modulus and elongation at break were reported when PCL-decorated starch nanocrystals were used in a PCL matrix,

compared to unmodified nanoparticles (Habibi and Dufresne 2008). For both systems, nanocomposite films were obtained from the same processing conditions by casting/evaporation from dichloromethane. Obviously, strong self-aggregation of the unmodified nanocrystals in dichloromethane was the source of the poor mechanical properties of the nanocomposites prepared from these particles. It was observed that the addition of 5 wt% PCL-grafted starch nanocrystals in a PLA matrix induced simultaneous enhancements of the strength and elongation at break (Xu et al. 2010). The grafted rubbery PCL component was supposed to improve the flexibility of PLA chains.

6.4 Reinforcing Mechanism of Starch Nanocrystals

A comprehensive study was performed to try to understand the reinforcing mechanism of starch nanocrystals in a non-vulcanized NR matrix through the development of a phenomenological modeling approach (Mélé et al. 2011). Nonlinear dynamic mechanical experiments highlighted the significant reinforcing effect of starch nanocrystals and the occurrence of the Mullins and Payne effects. Two models have been used to predict the Payne effect assuming the preponderance of either filler-filler (Kraus model) or matrix-filler (Maier and Goritz model) interactions. With the Maier and Goritz model, it was demonstrated that the phenomena of adsorption and desorption of NR chains on the nanofiller surface governed the nonlinear viscoelastic properties, even if the formation of a percolating network for filler contents higher than 6.7 vol% (i.e., around 10 wt%) was evidenced by the Kraus model.

6.5 Swelling Properties of Starch Nanocrystal-Reinforced Polymer Nanocomposites

The swelling process and its kinetics allow quantifying the capacity of a linear or branched polymer to dissolve or of a cross-linked polymer to swell in different liquid or vapor media. The interaction of polymeric materials with solvents can be an issue from a technological point of view because the dimensions and physical properties of the material may change with the penetration of solvent molecules into the specimen.

Obviously, the effect of starch nanocrystals which are hydrophilic by nature on the swelling property of the nanocomposite system strongly depends on the nature of the matrix (polar or apolar) and swelling liquid (hydrophilic or hydrophobic). The addition of starch nanocrystals to poly(*S*-*co*-BuA) (Dufresne and Cavaillé 1998) or NR (Angellier et al. 2005b; LeCorre et al. 2012d) was found to increase the swelling of the material by water most probably because of the hydrophilic nature of starch and hydrophobic nature of the matrix. The coefficient of diffusion of water increased as well but showing two well-defined regions. Below a critical starch nanocrystal concentration, the evolution of the diffusion coefficient was

relatively low, whereas it was more significant above it. This behavior change was assumed to be due to the establishment of a starch nanocrystal network through strong hydrogen linkages between nanoparticle clusters but also to favorable interactions between the NR matrix chains and the filler. The critical concentration was assumed to be around 20 wt% and 10 wt%, for poly(*S*-*co*-BuA) and NR, respectively.

Then, the percolation threshold is an important parameter that is assumed to govern the swelling properties of the nanocomposite. For starch nanocrystal-reinforced NR, the percolation threshold of the nanoparticles was observed around 15 wt% from electrical conductivity measurements (Bouthegourd et al. 2011). Moreover, the diffusion coefficient of water for NR-based nanocomposite films was found to be correlated with the composition of starch and to decrease when increasing the initial amylose content of native starch (LeCorre et al. 2012d). It was attributed to the presence of amorphous or less organized and therefore less bonded amylose chains in starch nanocrystals prepared from higher amylose content starch. This amorphous material was supposed to not participate to the formation of a diffusing network but to participate to the water-sorption process explaining why similar equilibrium water uptake values were reached.

For soy protein films, a slight increase of the water uptake was reported for increasing starch nanocrystal contents (Zheng et al. 2009). On the contrary, a decrease of the water uptake was observed for sorbitol-plasticized pullulan (a hydrophilic system) when adding starch nanocrystals particularly at high filler loading levels (Kristo and Biliaderis 2007). Again, it was ascribed to the formation of a three-dimensional network of nanoparticles that was able to restrict the swelling of the polar matrix. The decrease in the water uptake of PVA (Kristo and Biliaderis 2007) and carboxymethyl chitosan (Duan et al. 2011) upon starch nanocrystal addition was attributed to the crystallinity of the nanoparticles and strong interfacial interactions between both polar components in the nanocomposite film. On the contrary, for glycerol-plasticized thermoplastic starch, the composites reinforced with starch nanocrystals were found to absorb more water than the neat matrix (Garcia et al. 2009). It was ascribed to a relocalization of glycerol around the nanoparticles leading to more hydroxyl groups in the matrix able to interact with water molecules.

When using an apolar matrix and performing swelling experiments in a hydrophobic liquid medium, restriction of the liquid absorption is expected when adding hydrophilic starch nanocrystals. Indeed, swelling of the NR matrix by toluene was found to decrease when adding starch nanocrystals, and the toluene diffusion coefficient decreased strongly for low filler contents and more progressively above 10 wt% (Angellier et al. 2005b). For low nanocrystal contents, a correlation between the toluene-sorption behavior and calculated specific surface area of nanocrystals obtained from different botanical origin starches was observed (LeCorre et al. 2012d). The higher the theoretical specific surface area, the higher the toluene uptake, and the lower the diffusivity. For higher starch nanocrystal contents, this phenomenon was not observed. It was supposed to be due to aggregation at higher filler contents.

6.6 Barrier Properties of Starch Nanocrystal-Reinforced Polymer Nanocomposites

Barrier properties using bio-based materials are becoming increasingly advisable in our society to develop environmentally friendly materials for different applications such as packaging. Indeed, most materials used for food packaging are practically nondegradable petrochemical-based polymers, representing a serious environmental problem. The main reason for their use is due to their easiness of processability, low cost, and excellent barrier properties. However, given their platelet-like morphology and highly crystalline nature, starch nanocrystals were suspected, as nanoclays do, to create a tortuous diffusion pathway for penetrant molecules. Nevertheless, few reports investigated the barrier properties of starch nanocrystal-reinforced nanocomposites.

For NR films, a continuous and significant reduction of the permeability to water vapor and oxygen was reported when adding starch nanocrystals up to 30 wt% (Angellier et al. 2005b). A substantial 40 % decrease of the water vapor permeability (WVP) value was also observed for cassava starch films plasticized with glycerol when adding only 2.5 wt% of waxy maize starch nanocrystals (Garcia et al. 2009). However, when using a glycerol-plasticized waxy maize starch matrix, a close association between starch nanocrystals and glycerol-rich domains was suspected to explain the unexpected increase of the WVP value upon adding starch nanocrystals (Garcia et al. 2011). A similar decrease of the WVP value was reported for carboxymethyl chitosan films when adding starch nanocrystals as shown in Fig. 14 (Duan et al. 2011). For sorbitol-plasticized pullulan films, no significant differences were observed in WVP values when adding up to 20 wt% starch nanocrystals (Kristo and Biliaderis 2007). Nevertheless, above this critical value, a significant decrease of WVP was reported. On the contrary, a detrimental effect of starch nanocrystals on the WVP of NR films was reported (LeCorre et al. 2012d). However, it is worth noting that in this study, WVP was measured

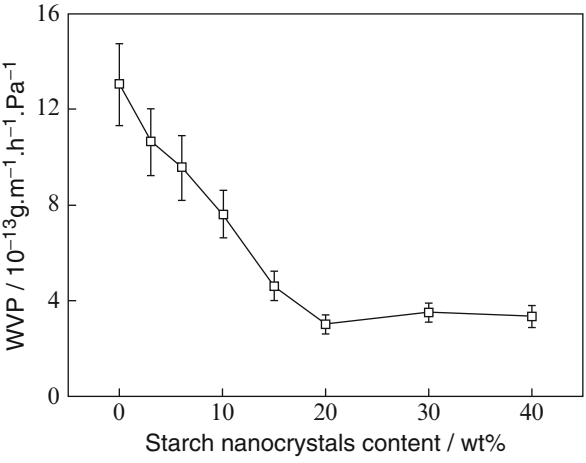

Fig. 14 Water vapor permeability of carboxymethyl chitosan nanocomposite films with different starch nanocrystal contents (Reproduced with permissions from Duan et al. (2011))

under tropical conditions (38 °C, 90 %RH), and it was suggested that the hydrophilic nature of starch nanocrystals was predominant.

Starch nanocrystals were also reported to be promising bio-nanofillers for improving barrier properties of bio-based coated papers (LeCorre et al. 2014). The nanoparticles have been introduced in a starch-based coating, and the properties of the ensuing coating color and final coated paper have been investigated. Coating colors containing starch nanocrystals showed higher viscosity but were still processable. It was shown that the nanoparticles can resist studied drying processes without melting and that their addition to the coating color decreased WVP and compensated some of the loss of mechanical properties due to the use of the water-based coating.

6.7 Drug Carrier Systems

Biomedical applications represent a niche market but with high added value for many materials. A "green" method of ionic cross-linking through Ca^{2+}, forming semi-interpenetrating polymeric networks (semi-IPN), was used to develop starch nanocrystal-reinforced pH-sensitive alginate microsphere-controlled release system for drug delivery (Lin et al. 2011). Rod-like cellulose and chitin nanocrystals were also investigated in this study. The presence of polysaccharide nanocrystals in alginate-based microspheres showed more consistent swelling patterns, higher encapsulation efficiency, and promising sustained release profiles of the drug. It was ascribed to the improvement of the stability of the cross-linked network structure and enhancement of mechanical strength, mainly for higher aspect ratio cellulose and chitin nanorods, of nanocomposite microspheres. Moreover, because of the restriction effect of rigid nanocrystals, the free diffusing routes of the drug molecules were increased and endowed the microspheres improved drug loading and sustained release profiles.

7 Conclusions

There is a growing interest in both the nonfood usage of renewable resources and nanosized particles. Polysaccharides are probably promising candidates to meet this demand since they are low-cost, abundant, and renewable materials. This chapter provides a comprehensive overview of recent advances published in the field of starch nanocrystals. This field is at the moment less reported in the literature than nanocellulose which is now growing very fast. However, there is no doubt that increasing works start to be done and will be done in the near future on starch nanoparticles. Starch consisting of crystalline and amorphous domains is a possible candidate for organic nanofillers because the amorphous domains can be removed under certain conditions such as controlled acid hydrolysis. Ensuing nanosized crystalline particles, usually known as starch nanocrystals, can be used as reinforcing nanofillers in polymer nanocomposites, thereby creating opportunities

to develop high-performance and highly durable engineering materials from a renewable resource that could be suitable for potential consumer, structural, and biomedical applications.

Polysaccharide Production by Submerged Fermentation

14

Óscar J. Sánchez, Sandra Montoya, and Liliana M. Vargas

Contents

Abstract

This chapter describes the importance of the polysaccharides obtained from different natural sources as well as their natural occurrence. An overview on the different biological activities of the polysaccharides obtained from fungi, bacteria, and algae is provided. The potential of microbial organisms, especially microfungi and bacteria, as well as macromycete fungi, during production of bioactive polysaccharides at large scale is recognized. The features of the submerged fermentation technology are disclosed considering that this cultivation technique has played and continues playing a crucial role in the industrial production of different polysaccharides with diverse biological activities. Main topics related to the production of these compounds by submerged fermentation making emphasis in the production of fungal and bacterial polysaccharides are briefly described as well. Finally, some words on the significance of the research and development on production of bioactive polysaccharide are presented.

1 Introduction

Polysaccharides are compounds widely distributed in the nature. They are present in bacteria, fungi, algae, plants, and animals. These natural biological polymers are nontoxic and have different functions, the best known of which is to be an energy reserve. They are also structural molecules as cellulose in plants, β-glucans in microorganisms (fungi and bacteria), and chitin in arthropods. In addition, these biomolecules are essential for the metabolism of living beings along with proteins and polynucleotides. They also play an important role in cellular communication, adhesion, and molecular recognition for immune system, fertilization, pathogenesis prevention, and blood coating, among others (Yang and Zhang 2009; Zong et al. 2012; Öner 2013).

Currently, people seek foods that are not only nutritive, safe, nice in sight, and with good taste but also offer health benefits like treatment and prevention of diseases. Research advances have allowed the identification of biologically active compounds of different nature in foods like peptides, carbohydrates, polyphenols, carotenoids, phytosterols, fatty acids, etc. (Mazza 2000; Webb 2007; Cheung 2008; Aluko 2012). In particular, a group of polysaccharides have gained a special interest not only because they are an important energy source in human diet but also because they exhibit special features: their chemical structures with glycosidic linkages make them resistant to the digestion; they can be used as prebiotics; they show diverse biological activities such as antitumor, anticarcinogenic, immunomodulatory, protective against mutagens, and hypoglycemic activities, among others; and they can be used in food, cosmetic, agricultural and pharmaceutical industries (Izydorczyk et al. 2005; Mantovani et al. 2008; Brown and Williams 2009; Yang and Zhang 2009; Patel et al. 2010; Lee et al. 2012; Zong et al. 2012; El Enshasy and Hatti-Kaul 2013; Öner 2013; Zhang et al. 2013).

Submerged fermentation is the most employed procedure for the production of polysaccharides. This is explained by the facility to manipulate and optimize the operating parameters during this type of fermentation (Xiao et al. 2010). Submerged fermentation has been used to cultivate different bacteria and fungi in order to obtain intracellular and extracellular polysaccharides exhibiting diverse properties and biological activities (Suárez and Nieto 2013).

The objective of this chapter is to describe the importance of the polysaccharides obtained from different natural sources and provide main topics related to the production of these compounds by submerged fermentation and their applications in food and pharmaceutical industries.

2 Polysaccharides

The polysaccharides, also named glycans, are polymers condensed from a large number of monosaccharides. These monosaccharides or simple derivatives from them can be obtained by complete hydrolysis using acids or specific enzymes. D-glucose is the predominant monosaccharide in polysaccharides although D-fructose, D- and L-galactose, D-xylose, and D-arabinose are also common. Some monosaccharide derivatives can also be found as hydrolysis products of natural polysaccharides as D-glucosamine, D-galactosamine, D-glucuronic acid, *N*-acetylneuraminic acid, and *N*-acetylmuramic acid. In these polymers, monosaccharides are linked by glycosidic bonds between the glycosyl residue of the hemiacetal and the hydroxyl residue of another monosaccharide. Polysaccharides differ from each other in their repeated monosaccharidic units, length of their chains, and degree of branching. They can be linear or branched, and with the exception of cyclic polysaccharides known as cycloamyloses or cyclodextrins, their chains have a nonreducing (terminal) end and a reducing end. The general formula of polysaccharides is $C_x(H_2O)$, where x is usually a number between 200 and 2,500 (Izydorczyk et al. 2005; Aluko 2012; Zong et al. 2012).

Polysaccharides can be divided into two classes according to the number of different monosaccharides in their structure: homopolysaccharides containing a single type of monosaccharide and heteropolysaccharides containing two or more different monosaccharidic units. The homopolysaccharides are linear or branched chains, are commonly named by the repeating monosaccharidic unit, and have the same or different glycosidic bonds as presented in Table 1. The glycosidic linkages may have α- or β-configurations in several positions. On the other hand, heteropolysaccharides can have different bond types within each monosaccharidic unit as well as different types and sequences of glycosidic linkages.

According to another classification, polysaccharides can be divided into neutral, acid, or basic. Neutral polysaccharides like amylose, cellulose, and amylopectin are composed only of glucose. Acid or anionic polysaccharides contain derivatives of acid sugars, and their structures have negative charge as pectin and alginates. To date only one cationic polysaccharide is known, the chitosan obtained by modification of the animal polysaccharide chitin. The chitosan is a polymer made of β-(1→4)-2-amino-2-desoxi-D-glucopiranose, which has positive charges at pH between 6 and 7 (Izydorczyk et al. 2005).

2.1 Overview of Biological Activity of Polysaccharides

Over the last years, different research efforts have been done to study the in vitro and in vivo biological activity of different polysaccharides obtained both from natural sources and at industrial level. Among the pharmacological activities reported for polysaccharides, antibiotic, antioxidant (Dahech et al. 2011), antimutagenic, anticoagulant, immunomodulatory (McIntosh et al. 2005;

Table 1 Main natural homopolysaccharides

Type	Polysaccharide	Repeating unit Glycosidic linkage/Monosaccharidic unit
Linear	Amylose	α-(1→4)-Glc
	Cellulose	β-(1→4)-Glc
	Xylan	β-(1→4)-Xyl
	Inulin	β-(2→1)-Fru
	Levan	β-(2→6)-Fru
	Laminarin	β-(1→3)-Glc
	Chitin	β-(1→4)-Glc-*N*-Ac
	β-Glucan	β-(1→4, 1→3)-Glc
	Curdlan	β-(1→3)-Glc
Branched	Amylopectin	α-(1→4, 1→6)-Glc
	Dextran	α-(1→2, 1→3, 1→4, 1→6)-Glc
	Levan	α-(2→1, 2→6)-Fru
	Pullulan	α-(1→6)-maltotriose
	Scleroglucan	β-(1→3, 1→6)-Glc
	Glycogen	α-(1→4, 1→6)-Glc
	Lentinan	β-(1→3, 1→6)-Glc
	Grifolan	β-(1→3, 1→6)-Glc
	Schizophyllan	β-(1→3, 1→6)-Glc

El Enshasy and Hatti-Kaul 2013), anticarcinogenic (Zong et al. 2012), antitumor (Silbir et al. 2014), hypoglycemic, and hypocholesterolemic (Belghith et al. 2012) activities may be highlighted. Different polysaccharides obtained from seaweeds like alginates, carrageenan, and ulvan have shown antibacterial, antiviral, and antifungal activities, among others. For this reason, their use has been evaluated as a dietetic supplement for a variety of fish (Peso-Echarri et al. 2012).

β-Glucans are biopolymers exhibiting a wide range of biological activities. The macromolecular structure of the β-glucans depends on the source and isolation method. Microbial β-glucans are mainly composed of a central linear chain linking D-glucose through β-(1→3) linkages and branches of several sizes originated by β-(1→6) linkages. These branches are presented at different intervals along the central chain. On the other hand, β-glucans derived from cereals are polysaccharides based on glucose with β-(1→3) and β-(1→4) linkages. Different factors like the primary structure, solubility, degree of branching, molecular weight, polymer charge, and structure in aqueous media are related to the biological activity of β-glucans. Some β-glucans obtained from microorganisms (fungi and bacteria) and cereals like oats and barley have exhibited immunomodulatory activity, which depends on the structure, molecular weight, and branching of these polymers. The (1→3)-β-glucans, especially from microbial cells, have shown their ability to stimulate the innate immunity and activate the proinflammatory response, i.e., they exhibit anti-inflammatory properties in vitro and in vivo (Kogan and Kocher 2007; Mantovani et al. 2008; Brown and Williams 2009). In several reports on β-glucans,

their immunomodulatory activity has been related to the induction of the production of tumor necrosis factor alpha (TNF-α), γ-interferon, interleukin 8 (IL-8), and nitric oxide; the activation of macrophages and lymphocytes; and the stimulation of CD8 membrane cells (El Enshasy and Hatti-Kaul 2013).

Some β-glucans having structure with β-(1→3, 1→4) linkages from cereals have presented antimicrobial, antiparasitic, hypocholesterolemic, antithrombotic, and antimutagenic activities. Those β-glucans with β-(1→3, 1→4) obtained from the yeast *Saccharomyces cerevisiae* present antiparasitic, antibacterial, antiviral, antifungal, antimutagenic, and antitumor activities, among others (Zong et al. 2012). Those ones isolated from different fungi such as *Auricularia polytricha*, *Grifola frondosa*, *Candida albicans*, *Poria cocos*, *Agaricus blazei*, *Lentinus edodes*, *Schizophyllum commune*, and *Coriolus versicolor* exhibit antitumor, immunomodulatory, and antimutagenic properties (Mantovani et al. 2008; Lin et al. 2010; Carneiro et al. 2013; Zhang et al. 2013).

The polysaccharides or polysaccharide extracts from bacteria like *Penicillium jiangxiense*, some extracts from plants like *Achyranthes bidentata*, and polysaccharides from plants like *Angelica sinensis* (Oliv.) Diels and *Panax ginseng* C. A. Meyer (ginseng), as well as the pectic polysaccharide obtained from *Angelica gigas* Nakai, have shown anticarcinogenic and antitumor properties and have been traditionally used as medicines in China. In recent years, the interest to develop drugs from polysaccharides against cancer has become evident. Some in vitro studies have shown the potential of these compounds although more in vivo tests are required to confirm the in vitro results (Aluko 2012; Zong et al. 2012; Wasser 2013).

2.2 Natural Occurrence of Bioactive Polysaccharides

2.2.1 Bacteria

Bacteria are often employed as producer of extracellular polysaccharides (exopolysaccharides) at industrial level. Bacterial β-(1→3)-D-glucans are mostly linear glucans, while β-(1→3, 1→6)-D-glucans are branched polymers and β-(1→3, 1→2)-D-glucans have cyclic structures. About 30 species of lactobacilli are exopolysaccharide producers (Badel et al. 2011). The most common are *L. casei*, *L. acidophilus*, *L. brevis*, *L. curvatus*, *L. delbrueckii bulgaricus*, *L. helveticus*, *L. rhamnosus*, *L. plantarum*, and *L. johnsonii* although their productivities are much lower than species of *Alcaligenes*, *Xanthomonas*, *Sphingomonas*, and *Leuconostoc*, which are the microorganisms most used in industry for the production of curdlan, xanthan, gellan, and dextran (McIntosh et al. 2005; Öner 2013).

The xanthan gum is a component of dietary fiber and is also employed for the formulation of liquid or solid products in the pharmaceutical industry, in the latter case as an agent for controlled release (Tungland and Meyer 2002; Pooja et al. 2014). Gellan gum is composed by repeated tetrasaccharide units of D-glucose, D-glucuronic acid, and L-rhamnose, is obtained from bacterium *Pseudomonas elodea*, and has been proved as a release vehicle of pharmaceuticals, cell

Table 2 Main bacterial bioactive polysaccharides

Name	Composition	Source	Health benefits	Reference
Curdlan	β-(1→3)-D-glucose	*Alcaligenes faecalis*	Immunomodulating and pharmacological responses include anti-tumorigenicity; anti-infective activities against bacterial, fungal, viral, and protozoal agents; anti-inflammatory activity; wound repair; protection against radiation; and anticoagulant activity	McIntosh et al. (2005), Zong et al. (2012)
Hyaluronan	Repeating units of β-(1→4)-linked disaccharides of β-D-*N*-acetyl-glucosamine-β-(1→4)-D-glucuronic acid	*Pseudomonas aeruginosa* *Pasteurella multocida*	Because of its very high immunocompatibility and water binding and retention capacity, hyaluronan is widely used in regenerative medicine and cosmetic applications	Öner (2013)
Fructan: levan type	Repeating fructofuranosyl rings connected by β-(2→6) links	*Zymomonas mobilis*, *Bacillus* spp., *Streptococcus*, *Pseudomonas*, *Xanthomonas*, *and Aerobacter*	Immunomodulator, antitumor and antioxidant agent, hypocholesterolemic, hypolipidemic, hypoglycemic, and a blood plasma substitute	Dahech et al. (2011), Belghith et al. (2012), Silbir et al. (2014)

carrier, material for guided bone regeneration, and wound dressing (Lee et al. 2012).

The curdlan is a polysaccharide produced by fermentation using the bacterium *Alcaligenes faecalis*. The effectiveness of the biological activity of curdlan, as in the case of other β-(1→3)-D-glucans (see Table 2), depends on the chemical structure, molecular weight, and conformation. Several reports on this polysaccharide suggest that the structure influences the type of biological activity, especially in the case of anti-inflammatory and antitumor activities. It has been reported that curdlans with a degree of branching less than 50 are not considered as effective antitumor agents. On the other hand, the carboxymethyl ether and sulfate and phosphate esters of curdlan show higher solubility in water and increased biological activity. Curdlan sulfates present anticoagulant and anti-HIV activities as well as inhibitory effects on the development of malaria parasites in vitro. For this reason, curdlan has been proposed for formulation of cosmetic products and as a protective agent for fish farming (McIntosh et al. 2005; Zong et al. 2012).

The levan-type EPS1 exopolysaccharide was isolated from the bacterium *Paenibacillus polymyxa* EJS-3 and is composed of fructofuranosyl residues with β-(2→6) linkages and branching due to β-(2→1) linkages. This compound showed antiproliferative activity against tumor cells. On the other hand, acetylated, phosphorylated, and benzylated modified EPS1 exhibited and improved antiproliferative activity. Other exopolysaccharide from *Rhizobium* sp. N613 (REPS) that is a β-glucan composed of a main chain of glucose linked by β-(1→4) bonds with β-(1→6) branching can significantly suppress tumor formation and improve the immune response in mice (Zong et al. 2012).

2.2.2 Fungi

The use of medicinal mushrooms for the prevention and treatment of human diseases is very old. Different bioactive compounds can be obtained from fungi such as polysaccharides, polyphenols, fatty acids, colorants, and thickeners, among others (Cheung 2008; Wasser 2013). The polymeric carbohydrates from fungi can be intracellular (intrapolysaccharides) or extracellular. They are typically glycans composed of glucose (glucans) that have different structures, molecular weights, and compositions depending on the organism from which are isolated or on the medium to which are excreted. Thus, when fungi are grown in a liquid medium, several of these compounds are released into the medium, and then they can be recovered by means of different extraction processes. Moreover, a significant amount of intrapolysaccharides makes part of the fungal biomass either within the basidioma's structure or in the mycelium (Montoya et al. 2013).

Most bioactive polysaccharides synthesized by fungi are homoglucans although some compounds can form peptidoglycan or glycoprotein complexes. The structure of the fungal cell wall is depicted in Fig. 1. It is composed of homoglucans like the chitin, β-(1→3)-glucan, β-(1→6)-glucan, α-(1→3)-glucan, heteroglucans, and other compounds as the mannoproteins (Becerra-Jiménez et al. 2011). Fungal β-glucans are typically found in the intermediate layer of the cell wall adjacent to the plasmatic membrane and have the function of maintaining the rigidity and shape of the cells. Some of the most fungal β-glucans known for their pharmacological applications are lentinan, schizophyllan, and krestin (usually abbreviated as PSK or polysaccharide K) (Mantovani et al. 2008). These polymers are β-(1→3, 1→6)-glucans as shown in Table 3. Lentinan obtained from *Lentinus edodes* has a triple-helix structure and a molecular weight between 400 and 800 kDa. Schizophyllan obtained from the fungus *Schizophyllan commune* has also a triple-helix structure and a molecular weight of about 450 kDa. PSK is a proteoglycan composed of 25–38 % protein residues and β-(1→4)-glucan with β-(1→6)-glucopyranosyl side chains, has a molecular weight of 94 kDa, and is obtained from *Coriolus versicolor* (El Enshasy and Hatti-Kaul 2013).

The pharmacological applications of the fungal polysaccharides represent a great interest for both scientific community and industry. For instance, the white-rot fungus *Ganoderma lucidum* (Reishi), known as "Lingzhi" in China, "Reishi" in Japan, and "Youngzh" in Korea, has been widely employed as a tonic to promote the longevity and health in China and other Asian countries for more than 2,000

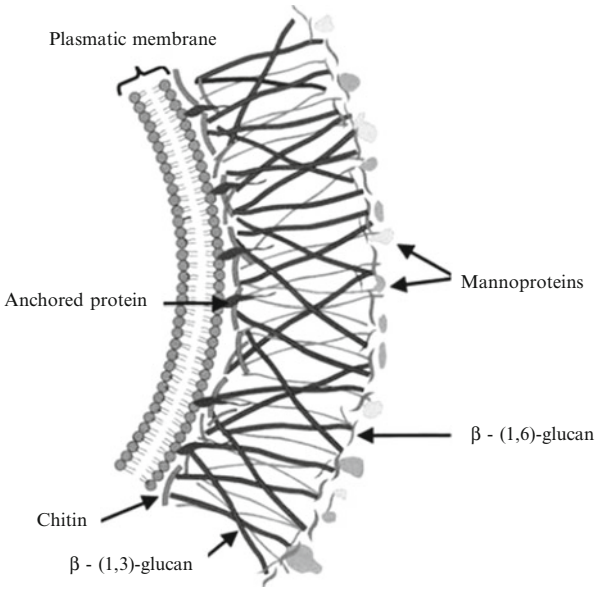

Fig. 1 Structure of the fungal cell wall (Modified from Becerra-Jiménez et al. 2011)

years ago. Bioactive compounds from the different strains of *G. lucidum* can become very diverse depending on the geographic distribution of this fungus, growth conditions, and feedstocks (substrate). According to several reports (Pan et al. 2012, 2013), the polysaccharidic extracts from *G. lucidum* present antioxidant activity and improve the immunity, so they have been suggested for the treatment of gastric cancer. The β-glucan from the macromycetes *Grifola frondosa* (known as Maitake beta-glucan or MBG) has been applied as coadjuvant for cancer treatment like chemotherapy (Lin et al. 2010).

In general, the pharmacological activities of fungal polysaccharides are strongly related to their molecular weight and degree of branching. Recently, Wang et al. (2014) researched five polysaccharide fractions obtained from the fruiting body of *Lentinus edodes*, which showed different structures to those ones reported before. The in vitro and in vivo antitumor tests indicated that the five fractions played a double role. Firstly, they regulate the immune system, and, secondly, they directly kill the cancer cells exhibiting less secondary effect than the chemotherapeutic drugs.

The nutraceutical and chemopreventive properties of the fungus *Agaricus blazei* (*Agaricus brasiliensis*) are related to the presence of β-glucans. In particular, the chemical modification of these β-glucans has been proposed in order to improve their scientific and commercial application, for instance, by increasing their solubility. The sulfation has gained special interest because the β-glucans increase their solubility avoiding granuloma formation. In recent years, several authors have reported the activity of these polysaccharides in healing wounds and burns as well as the antimutagenic, anticarcinogenic, and immunomodulatory activities (Angeli et al. 2009; Sui et al. 2010; Yamanaka et al. 2012).

Bioactive compounds	Source	Health benefits	Reference
Pullulan: α-(1→6)-linked polymer of maltotriose subunits	Synthesized by fermentation of liquefied starch, coconut by-products, beet molasses, and agro-industrial waste with *Aureobasidium pullulans* Chemical reactions	Pullulan has been used for liver and tumor target delivery of drug. Pullulan has the application of targeting drug to liver and cancer cells	Prajapati et al. (2013)
EPS2	Polysaccharide produced by a marine filamentous fungus *Keissleriella* sp. YS 4108	EPS2 exhibited profound free radical-scavenging activities	Laurienzo (2010)
Exopolysaccharides	Marine fungus *Penicillium* sp. F23-2	Three polysaccharides from *Penicillium* sp. F23-2 possessed good antioxidant properties, especially scavenging abilities on superoxide radicals and hydroxyl	Laurienzo (2010)

2.2.3 Algae

An important variety of polysaccharides such as alginates, agar, agarose, and carrageenan may be obtained from marine algae (Laurienzo 2010), some of them with pharmacological applications as can be observed in Table 4. For instance, the alginate consumption in humans has allowed the decrease of cholesterol and glucose in the blood. In addition, the alginates have shown its prebiotic activity, ability to mobilize fatty acids, immunostimulating activity, ability to reduce the blood pressure and enzymatic activity in the intestine, and preventive effect against cancer. Some alginates have been reported as coadjuvant for reparation of the intestinal mucosa. The prebiotic activity of the alginates, carrageenan, and ulvan has enabled the improvement of the intestinal microbiota in fishes as well (Peso-Echarri et al. 2012).

3 Techniques for Cultivation of Microorganisms

Although many polysaccharides can be extracted from other living organisms like plants or even animals, the microorganisms and macromycetes are the most employed source of bioactive polysaccharides. In order to produce these biopolymers at industrial level, fermentation technologies are being implemented.

Table 4 Main algal bioactive polysaccharides

Name	Composition	Source	Health benefits
Alginate	Guluronic and mannuronic acid	Marine brown algae (*Phaeophyceae*) and as capsular polysaccharides in soil bacteria	Alginate dressings for wound healing have been successfully applied for many years to cleanse a wide variety of secreting lesions, and they still remain widely used in many circumstances. Alginates have been shown to be useful also as hemostatic agents for cavity wounds
Agar/agarose	Agar (or agar-agar) is a phycocolloid, which is constructed from complex saccharide molecules (mainly β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose units). Agar and its variant agarose contain also variable amounts of sulfate, pyruvate, and uronate substituents	Agar is extracted from certain species of red algae: *Gelidium*, *Gelidiella*, *Pterocladia*, *Gracilaria*, *Gracilariopsis*, and *Ahnfeltia*	Suspending agent for radiological solutions (barium sulfate), as a bulk laxative as it gives a smooth and nonirritating hydrated bulk in the digestive tract, and as a formative ingredient for tablets and capsules to carry and release drugs
Exopolysaccharides	Soluble polymers in the culture medium (RPS)	*Spirulina platensis*	Antiviral activity

Source: Laurienzo (2010)

In principle, the organisms that contain or synthesize polysaccharides can be cultivated under controlled conditions in special fermentation systems named bioreactors. However, only a few of these organisms are suitable to be grown under such conditions, which can substantially differ from those of the ecosystems where these organisms naturally grow. The microbial organisms (mostly microfungi, yeasts, and microalgae) have the ability to quickly propagate not only in plates and flasks but also in large bioreactors with volumes of thousands of liters. This can be explained by their small sizes (from 0.5 to 10 μm) implying high surface/volume ratios that allow fast exchange of nutritional compounds and metabolites between the cytoplasm and the surrounding medium. The accumulation of very different substances inside the microbial cells enables their transformation into end or intermediate products through enzyme-catalyzed reactions. In this way, the metabolism of microorganisms tends to be very intense compared to higher macroscopic

organisms. In addition, the microorganisms have a wide range of nutritional substances and substrates for their growth. Thus, they can be cultivated using culture media that contain cheap components, e.g., agricultural or agro-industrial residues.

For specific types of polysaccharides, other organisms can be cultivated like the macrofungi (macromycetes), which have a behavior similar to their microscopic counterparts when grown in liquid fermentation media in bioreactors. If the macromycetes are cultivated on the surface of solid materials containing the nutrients required for their development, special biomass structures are formed such as the basidiomata or fruiting bodies. In the particular case of fungi, fungal cells form a filamentous structure named mycelium when liquid media are utilized. If this medium is to be stirred, the diffuse mycelium is converted into spherical cell agglomerations called pellets. When micro- or macrofungi are grown on solid materials, the fungal cells colonize the substrate taking from it the nutrients (in some cases, the solid particles are merely carriers for cells, and the nutrients are taken from the liquid medium that impregnates the solid material). For macromycetes, this growth process is named vegetative stage; after this, the macromycetes form the fruiting bodies that represent the reproductive stage of the growth cycle of the fungi. Evidently, the fructification is not possible when macromycetes are grown in liquid media. The polysaccharidic composition of the fungal biomass obtained from either liquid culture media or solid materials is quite different, and the growth rate of the latter process is usually slower.

As mentioned above, the microorganisms can be cultivated on the surface of solid substrate. This type of aerobic fermentation is called *solid-state fermentation* (SSF). SSF has been commercially implemented mainly in China, Japan, and other Asian countries for the production of different compounds like fermented foods, hydrolytic enzymes, biopesticides, and other value-added products (Pandey et al. 2000). In fact, worldwide production of the most consumed mushroom, *Agaricus bisporus*, is a special type of SSF where the fungal cells colonize previously composted solid substrates. On the other hand, some biological agents used against insects attacking economically important crops are cultivated on cereal grains in several tropical countries. For instance, the entomopathogenic fungus *Beauveria bassiana* is commercially produced in Colombia by SSF of rice grains in order to control the damage caused by the coffee berry borer (*Hypothenemus hampei*). However, SSF has not traditionally received a big attention in Western Europe and North America except for some specific cases in the food industry.

The Western microbiologic industry has been based on the utilization of liquid culture media for the growth of microorganisms. For aerobic fermentations, the microorganisms can develop on the surface of a liquid nutritive medium disposed in trays that, in turn, are located in shelves; purified air is supplied to the cultivation rooms, and the cells take the oxygen directly from the air. This type of cultivation technology is called *surface fermentation* and played an important role in the mid-twentieth century especially in Western Europe. For instance, main part of citric acid was produced by using this technology. However, the surface fermentation was abandoned due to the high risk of infection and elevated labor costs.

The *submerged fermentation* is the most used cultivation technology for the production of cell biomass and value-added products from it (metabolites) in the world. In this case, the microbial cells do not grow on the surface of the liquid medium, but they do in the bulk of the liquid, which is contained in a stainless steel vessel (fermenter). The microorganisms take the nutrients they need from the liquid medium in a solubilized way. If they are aerobic, the air should be supplied to the fermenter by pumping and sparging for the oxygen to transfer from air bubbles to the liquid medium. This technology offers several advantages: low risk of infection, hermeticity and compactness, facility of control and automation, low labor costs, higher reproducibility of the process for different production cycles, and versatility in the usage of a wide range of biological agents (bacteria, molds, yeasts, macromycetes, microalgae, plant cells, animal cells). Nevertheless, the capital costs of the submerged fermentation are higher due to the higher degree of sophistication of the bioreactors (fermenters), and the products tend to be dilute in the liquid medium at the end of fermentation. However, current trends for the development of more effective strains of microorganisms exhibiting elevated titers of the products (e.g., by the development of genetically modified microorganisms) have enabled to neutralize these drawbacks.

3.1 Features of the Submerged Fermentation

Several factors should be defined before the implementation of a submerged fermentation process at industrial scale. Among these factors, selection of the time regime of fermentation, preparation of the culture medium, selection of the process microorganism, aeration, heat transfer, type of bioreactor, process control, cell recovery and downstream operations, and treatment and final disposal of wastes should be highlighted (see Fig. 2). Some of these factors are briefly described below.

3.1.1 Time Regime of Fermentation

Submerged fermentations can be organized depending on how the liquid medium and fermented broth are supplied or removed from the fermenter. During *batch fermentation*, a series of operating procedures are periodically repeated to ensure the growth and development of process microorganisms. These procedures can include the washing and disinfection of the fermenter, fermenter filling-up with the culture medium, sterilization of such medium, inoculation of microbial cells, fermentation, and unloading of the bioreactor content at the end of cultivation process (Cardona et al. 2010). The main drawback of this regime consists in the operating and feedstock costs needed during each fermentation batch to ensure the cell biomass propagation until a concentration high enough to allow appropriate rates of cell growth and product biosynthesis. In addition, the cells are not reutilized that implies not to employ all the potential of cell biomass formed during the process. In general, the production of polysaccharides is accomplished through batch fermentation using bacterial or fungal cells.

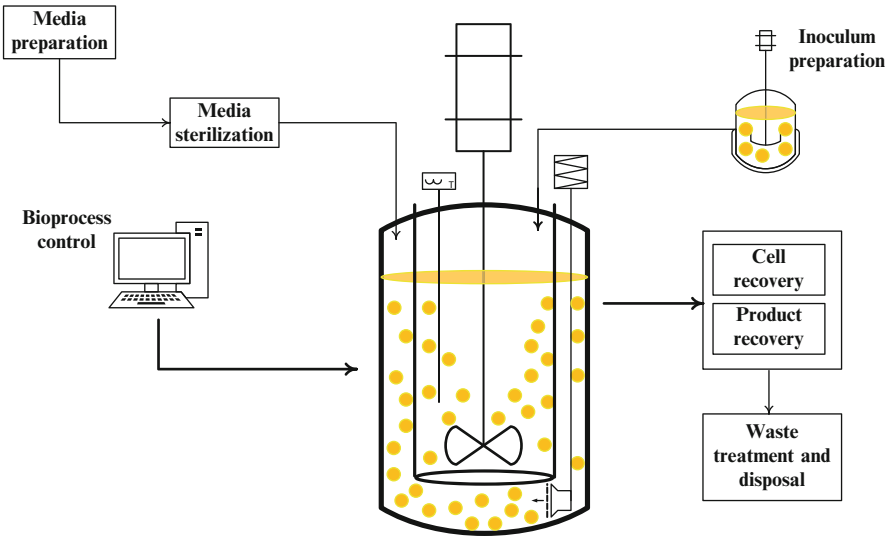

Fig. 2 Schematic diagram of the main aspects affecting the submerged fermentation

Fed-batch fermentation is one of the most employed cultivation regimes when process microorganisms present catabolic repression, i.e., when high substrate concentrations inhibit specific metabolic processes like those related to cell growth rate. For this reason, the microorganisms grow faster at low substrate concentrations. To implement such a process, conventional batch fermentation is performed through employing a less concentrated medium. Once the sugars have been consumed, the bioreactor is fed with portions of fresh medium or by adding a small amount of medium permanently until the end of fermentation. This continuous feeding of the medium can be done in a linear way (with a constant feeding rate) or according to a more complex function defining the rate with which the fresh medium is added to the fermenter, e.g., by an exponential feeding rate (Sánchez and Cardona 2008). Control of flow rate of medium feeding is quite advantageous because the inhibitory effect caused by high concentrations of substrate or product in fermentation broth is neutralized.

Continuous fermentation consists in the cultivation of cells in a bioreactor to which the fresh medium is permanently added and from which an effluent stream of culture broth is permanently removed. The microorganisms are reproduced within the bioreactor at a grow rate that offsets the cells' withdrawal with the effluent achieving the corresponding steady state. To ensure the system homogeneity and reduce concentration gradients in culture broth, continuous stirred-tank reactors (CSTR) are employed. In this way, a constant production of fermented wort can be obtained without the need of stopping the bioreactor operation in order to perform the periodic procedures typical of batch processes like filling-up and unloading. This allows a remarkably increase of volumetric productivity compared to batch or

fed-batch processes. Unfortunately, the microorganisms used to produce bioactive polysaccharides do not exhibit fast growth rates, so the continuous regime is difficult to achieve. In addition, the continuous cultivation during several months can lead to the loss of the ability to produce the target polysaccharides (genetic instability) since the microbial cells tend to form biomass under these conditions and to revert to the native strain in the case of mutants or genetically engineered microorganisms.

3.1.2 Preparation of the Culture Medium

The function of the liquid fermentation medium is to supply the nutritional substances required by the microorganisms to grow and synthesize the desired products. This depends on the metabolism type the process microorganism exhibits under the cultivation process. For instance, if the organism has a fermentative type of metabolism where there is no final electron acceptor (oxidizing agent) added to the medium and the energy source (the compound undergoing oxidation) is organic, there is no need to pump air into the fermenter and therefore the bioreactor design is simpler. The prevalent metabolism type in microorganisms producing polysaccharides is aerobic respiratory metabolism, where an energy source (mainly sugars) is oxidized to CO_2, an electron acceptor (oxygen contained in the air) is added to the medium, a nitrogen source should be present to ensure the synthesis of proteins and nucleic acids, and a series of micro- and oligoelements are also added along with the carbon source (again the sugars) to form new cell biomass. Many bacteria and fungi (micro- and macromycetes) exhibit an aerobic respiratory metabolism. In particular, the fungi utilize as energy/carbon source several plant polysaccharides like starch, cellulose, or pectin thanks to their ability to release hydrolytic enzymes (amylases, cellulases, or pectinases). In the case of the microalgae, the energy source is the sunlight, and the carbon source is the atmospheric carbon dioxide.

Metals play an important role during the metabolic processes leading to the biomass growth and biosynthesis of polysaccharides. In general, they act as cofactor of many enzymes and related proteins such as ligninases, amylases, cytochromes (electron carriers), and cellulases, among others. They also can inhibit many enzymes, so their concentration in the culture medium should be thoroughly determined.

Culture media may be synthetic or complex. In the first case, the composition of the medium is clearly established. Simple sugars are often used as energy source in these media. In the case of complex media, the exact composition is not known since materials like molasses or hydrolyzates are employed. These media are preferred because of their low cost.

3.1.3 Air Supply

The aeration levels should be defined in order to improve the fermentation process. The oxygen contained in the air is needed to oxidize the organic compounds for microorganisms with aerobic respiratory metabolism. These microorganisms exhibit high growth rates, have elevated oxygen consumption rates, and release

significant amounts of heat. As the oxygen has a low solubility in the culture broth (about 6 mg/L), high air flow rates should be used to supply the oxygen needed (between 0.5 and 2.0 vvm or volumes of air per volume of broth in a minute). The aerobic fermenters are limited by the mass transfer of oxygen to the liquid medium. For this reason, many bioreactors are provided with a stirrer with one or more impeller in order to intensify the dissolution of oxygen in the water. In addition, a sparger is mounted below the lower impeller with the same purposes. This gas–liquid system has a tendency to form foam that implies negative effect on the fermentation performance, so antifoam substances or devices are included in the fermenter.

3.1.4 Heat Transfer

All the living organisms transform the energy released by the oxidation of organic or inorganic substances, or collected from the sunlight, into other forms of useful energy, which is employed for the metabolic functions of the cell and for reproduction. These energy transformations are not 100 % efficient. Although the living matter is much more efficient than the artificial human devices (engines, turbogenerators, photovoltaic cells), some portion of energy cannot be utilized and is dissipated in the form of heat. When microbial cells grow and propagate in the culture medium, metabolic heat is produced. If this heat is not removed, the temperature of the system increases, reaching values not optimal for the growth rate or biosynthesis of the target products. High temperatures can even lead to cell death. To avoid this situation, the bioreactors are provided with some devices for heat exchange such as jackets in small fermenters (up to 1,000 L), cooling coils (up to 50–100 m^3), or external heat exchangers with recirculation of liquid medium (above 100 m^3). All these devices have pipelines inside where cooling water flows; the water is not in contact with the liquid culture medium but removes the heat through the metal walls of the pipelines by conduction and convection. The heat transfer in cylindrical tanks has been well studied, so the commercial fermenters for polysaccharide production do not present big difficulties on this matter.

3.1.5 Type of Bioreactors

One bioreactor for fermentation (fermenter) is a complex equipment that should ensure all the optimal conditions for the growth of microbial cells being, at the same time, flexible and versatile in order to be used for different purposes. Most of the bioreactors for submerged fermentation are standard apparatuses that have several internal devices and accessories to intensify the mass transfer of oxygen, ensure the homogenization of the culture broth, remove the metabolic heat, avoid the contamination with non-desired organisms, and maintain the required values of pH, temperature, and oxygen concentration, among other operating parameters. There exist in the market several commercial firms offering standard bioreactors to not only cultivate microorganisms but also macromycetes, plant cells, and animal cells.

Agitation and aeration are very important topics to be considered during the design and construction of bioreactors for submerged fermentation as mentioned above. In addition, the control (automated or not) of the bioreactor is crucial to attain the success in the fermentation industry. The different devices for process

control (probes, transducers, controllers, actuators) along with the software are quite expensive and can add up to 80 % to the main cost of the bioreactor (without control devices). However, some fermentation processes for the production of polysaccharides require a strict pH and temperature control. For this reason, an evaluation of the process viability should be performed in each case to establish if the sophistication level of a given bioreactor justifies its utilization considering the price and market of the target product.

Finally, the target product remains in the culture broth (exopolysaccharide) or inside the cells (intrapolysaccharide). A series of different unit operations are required to separate and purify these polysaccharides without loss of their biological activities. An example of a sequence of those downstream operations to recover a bioactive exopolysaccharide could be as follows: centrifugation, liquid–liquid extraction, adsorption using activated carbon, liquid chromatography, evaporation, drying, and packing. These operations are complex and difficult to design. A more detailed description of this issue is out of the objectives of this chapter.

4 Submerged Fermentation for Production of Fungal Polysaccharides

Submerged fermentation involves the development of microorganisms in a liquid medium enriched with nutrients and with high oxygen concentrations (aerobic conditions). In the case of fungal cells, the hyphal development (especially in basidiomycetes) in submerged cultures results in the uncontrolled development of the mycelium (set of hyphae). The extension of the fungal biomass has significant effects on the mass transfer, growth rate, and product secretion. The fungal mycelium can form pellets causing their proliferation in the whole culture medium and increasing the viscosity, which limits the mass transfer of oxygen. All these drawbacks limit the operation of the bioreactors (Rodriguez-Couto and Toca-Herrera 2007).

The production of extracellular polysaccharides using macromycetes by submerged fermentation is influenced by the process time, temperature, composition of the culture medium, agitation speed, initial pH, and inoculum size, among other factors. The macromycetes can grow under varied environmental conditions, e.g., at a wide range of temperature (Shu et al. 2007; Suárez and Nieto 2013). However, the submerged fermentations are usually carried out at temperature between 26 °C and 36 °C considering that the temperature increase can accelerate the fungus metabolism and diminish the solubility of oxygen in the medium. On the other hand, the aeration also influences the concentration of dissolved oxygen. This can be controlled by fixing the volume of air supplied to the culture medium during the process (Kim et al. 2008; Suárez and Nieto 2013). To accomplish the follow-up and control of all these variables demands time, efforts, and money in order to obtain the experimental data required for the comprehensive evaluation of the interaction of these variables with the production of polysaccharides.

Regarding the culture medium for polysaccharide production from fungi, different reports published in the last decade evidence the importance of the presence of vegetable oils rich in oleic acid as promoters of fungal biomass formation and, consequently, of their constituent polysaccharides (Yang et al. 2000; Hsieh et al. 2008; Hao et al. 2010). When choosing the type of vegetable oil to be used as inductor of polysaccharide production, it is necessary to take into account the fatty acid composition of the oil since several researchers have reported that important amounts of linoleic acid suppress the production of biomass and polysaccharides, while the presence of oleic promotes their production (Park et al. 2002; Hsieh et al. 2006, 2008). Soy and olive oils have been used as promoters of cell growth and polysaccharide production.

More research is needed about the control of submerged fermentation processes using macromycete fungi. For instance, Wu et al. (2006) found that it was necessary to control such variables as substrate composition, pH of the medium, temperature, and other environmental conditions to increase and maintain constant the production of cell biomass and exopolysaccharides by submerged fermentation using the macromycetes *Auricularia auricular*. Previous studies have demonstrated that the pH control plays a very important role during the development of mycelial biomass and polysaccharide production (Fang and Zhong 2002). On the other hand, some reports evidence the effect of pH on the chemical structures and molecular weight of the polysaccharides obtained from fungi. This is particularly important since other studies suggest a clear relationship between the biological properties of the polysaccharides and their molecular weights (Shu et al. 2003, 2004; Hamedi et al. 2012; Zhang et al. 2013). For instance, Shu et al. (2003) concluded that the polysaccharides found in the culture broth where *Agaricus blazei* was grown strongly depended on their molecular weight.

The dispersion of the mycelium in liquid industrial fermentations implies the homogenization and agitation of the branched hyphae. This dispersion produces a broth with a non-Newtonian behavior, and its apparent viscosity increases with the agitation speed. This reduces the transport of nutrients as well as the transfer of oxygen and heat, therefore increasing the operating costs (Prosser and Tough 1991). Thus the agitation plays a very important role regarding the mycelium integrity. If the agitation is very strong, the breakdown of mycelium is produced, and, therefore, pellets formation decreases. At the same time, the biomass formation is affected as well as the target metabolites like the polysaccharides (Cui et al. 1997; Suárez and Nieto 2013).

5 Submerged Fermentation for Production of Bacterial Polysaccharides

The submerged fermentation to obtain polysaccharides from bacteria is used universally. For example, the curdlan exopolysaccharide is obtained by submerged fermentation of *Agrobacterium* sp. or *Alcaligenes faecalis* under nitrogen-limiting conditions. For the production process of this biopolymer, critical factors such as

Table 5 Principal producers and culture conditions for lactobacillus polysaccharide production

Microorganisms	Media	Temperature (°C)	Time (h)	pH	Yield (mg/L)

the carbon source, nitrogen source, phosphate concentration, pH, and agitation rate, among other factors, should be optimized. Moreover, although the conventional nitrogen source for production of curdlan is NH_4Cl, studies with $NaNO_3$, urea, and yeast extract have been reported as well (Jiang 2013).

Badel et al. (2011) studied the main conditions for the production of dextran, levan, inulin, mutan, and reuteran from some lactobacilli species as well as their monosaccharide composition (see Table 5). The cultivation temperature varied between 32 °C and 42 °C, the process time for biopolymer production was between 18 and 72 h, and the pH lied in the range between 5 and 6. The most effective bacteria for their high yields in the production of polysaccharides were *L. rhamnosus* 9595, *L. rhamnosus* 9595 M, *L. delbrueckii bulgaricus*, and *L. helveticus*.

6 Conclusion

Bioactive polysaccharides are value-added products with important applications, especially in the pharmaceutical industry due to their key biological activities: antibiotic, antioxidant, antimutagenic, anticoagulant, immunomodulatory, anticarcinogenic, antitumor, hypoglycemic, and hypocholesterolemic activities. The world market of nutraceuticals and natural pharmaceuticals is steadily increasing. To meet the worldwide demand, especially in the developed countries, it is necessary to not only find new sources and applications of these polysaccharides

but also to improve the technology for the large-scale production of these biopolymers.

The submerged fermentation is the most developed technology in the world to produce a wide range of bio-based products. Fortunately, the organism naturally producing bioactive polysaccharides can be cultivated by fermentation using liquid culture medium. This chapter attempted to provide an overview on the features of the submerged fermentation applied to the production of bioactive polysaccharides from fungi and bacteria. The possibilities to continue the scientific research and technological development on this matter are bright and wide. Undoubtedly, the engineering approach to improve this type of technology in the case of bioactive polysaccharides has the key to reduce production costs and increase their production levels worldwide.

Acknowledgments The authors want to thank all the members of the research group on Food and Agribusiness of Universidad de Caldas (Colombia) for the knowledge generated during the last years on the theme of fermentation technologies and macromycete cultivation. The financial support for the different research projects of the Vice-rectorate for Research and Graduate Students of Universidad de Caldas and of the General Royalties System of Colombia is also acknowledged.

Abstract

Bioconversion of renewable lignocellulosic biomass to biofuel and value-added products is globally gaining significant importance. Lignocellulosic wastes are the most promising feedstock considering its great availability and low cost. Biomass conversion process involves mainly two steps: hydrolysis of cellulose in the lignocellulosic biomass to produce reducing sugars and fermentation of the sugars to ethanol and other bioproducts. However, sugars necessary for fermentation are trapped inside the recalcitrant structure of the lignocellulose. Hence, pretreatment of lignocellulosic wastes is always necessary to alter and/or remove the surrounding matrix of lignin and hemicellulose in order to improve

the hydrolysis of cellulose. These pretreatments cause physical and/or chemical changes in the plant biomass in order to achieve this result. Each pretreatment has a specific effect on the cellulose, hemicellulose, and lignin fraction. Thus, the pretreatment methods and conditions should be chosen according to the process configuration selected for the subsequent hydrolysis steps. In general, pretreatment methods can be classified into four categories, including physical, physicochemical, chemical, and biological pretreatment. This chapter addresses different pretreatment technologies envisaging enzymatic hydrolysis and microbial fermentation for cellulosic ethanol production and other bioproducts. It primarily covers the structure of lignocellulosic wastes; the characteristics of different pretreatment methods; enzymatic hydrolysis; fermentation and bioproducts; and future research challenges and trends.

1 Introduction

Conventional petroleum refineries utilize physical and chemical processes to refine crude oil to different fractions that are used for the production of several products as fuels, chemicals, and materials. However, these products have one more thing in common besides the raw material; they are produced because of their economic value. On the other hand, bioprocessing and bioproducts have gained commercial interest because of the perceived "green" advantages of using biomass rather than fossil energy for the production of chemicals and industrial products.

There are several issues influencing the current global interest in the biorefining of biomass feedstocks, more specifically lignocellulosic wastes, rather than fossil reserves, to produce a wide variety of extracts, fuels, and chemicals: the fossil fuels have finite reserves and are nonrenewable, the higher increase of the global warming when fossil fuels are burned to provide energy, and the security of supply of fossil fuels as commodities may not be reliable in the future due to the world regions they originated (Charlton et al. 2009; Anwar et al. 2014). This has led to the concept of biorefinery, which, according to American National Renewable Energy Laboratory, is defined as "a facility that integrates biomass conversion processes and equipment to produce fuels, power, and chemicals from biomass" (www.nrel.gov/biomass/biorefinery.html). Thus, biorefinery concept is analogous to today's petroleum refineries (Yang 2007; Taylor 2008; Cavka 2013).

Availability of resources seems not to be a short-term problem into biorefinery. A multitude of feedstock has been tested for biorefinery applications covering cultivated crops, agricultural wastes, forest resources, urban and industrial wastes, and algae (Kajaste 2014). Recent studies indicate that the demand for biomass to produce required biofuels and platform chemicals of the petrochemical industry can be covered without significant changes to the current agricultural land use. However, there is a clear shift from agricultural products to lignocellulosic feedstocks (plant biomass predominantly comprised of cellulose, hemicellulose, and lignin) for the production of chemicals, using different pretreatments for the achievement of specific fractionation results, depending on the desired solid or liquid by-product to obtain (Bos and Sanders 2013; Forster-Carneiro et al. 2013; García et al. 2014a).

Currently the most promising and abundant cellulosic feedstocks derived from plant residues in the USA, South America, Asia, and Europe are corn stover, sugarcane bagasse, rice, and wheat straws, respectively (Limayem and Ricke 2012; Phitsuwan et al. 2013), as they are abundant, low-cost, nonfood materials.

However, the expertise required to exploit biomass as a viable source of base commodities is also diverse and requires a multidisciplinary approach. Taking into account the emerging research trends, the concept of fractionating biomass into its core constituents, an important step in the development of biorefining technologies, has the potential to benefit a wide range of bioprocessing industries due to the ease and improved efficiency associated with working with less variable material feedstocks (FitzPatrick et al. 2010).

2 Structure of Lignocellulosic Wastes

Lignocellulosic wastes are the most abundant source of unutilized biomass. They are composed mainly of cellulose (30–50 %), hemicellulose (15–35 %), and lignin (10–20 %) (Mielenz 2001; Gírio et al. 2010). Celluloses and hemicelluloses correspond to approximately 70 % of the entire biomass and are tightly linked to the lignin through covalent and hydrogenic bonds that make the structure highly robust and resistant to any kind of hydrolysis (Knauf and Moniruzzaman 2004; Limayem and Ricke 2012). This highly recalcitrant nature is related to the presence of lignin, the degree of crystallinity of cellulose, the degree of polymerization of the polysaccharides, the available surface area, and the moisture content (Van Dyk and Pletschke 2012). In addition, other components can be found to a lesser extent, such as pectin, proteins, extractives, and ash (Jorgensen et al. 2007; Gírio et al. 2010).

These compounds are present in the cell wall and in the middle lamella of plant cell walls. In general, the plant cell wall is composed of distinct layers and can be subdivided as primary (PW) and secondary (SW) walls (Fig. 1). The distribution of

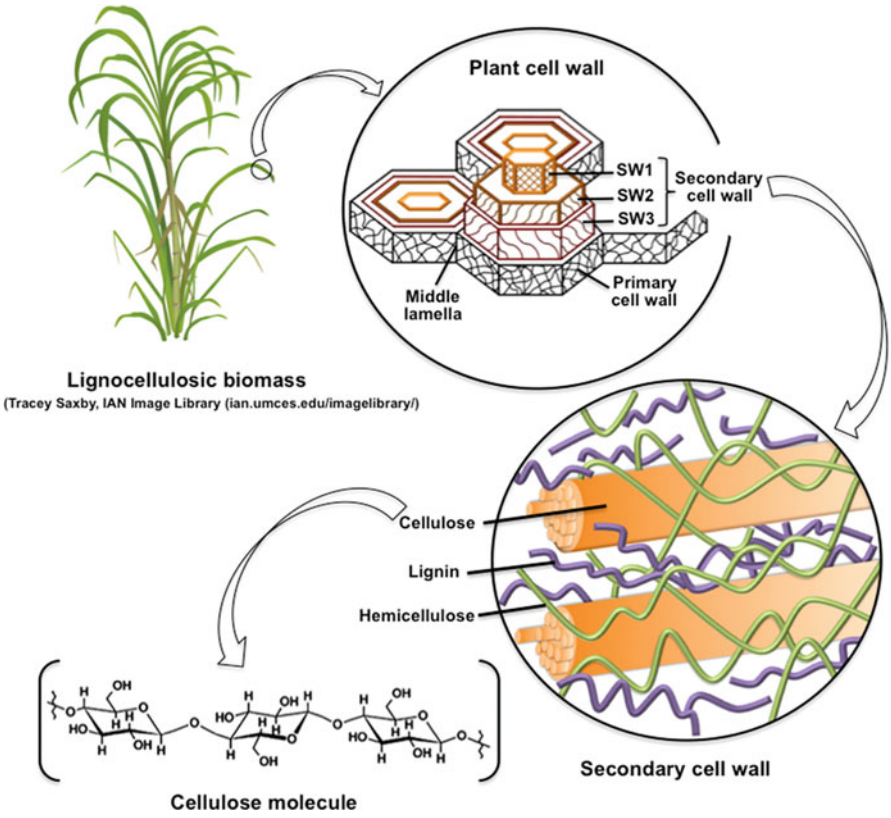

Fig. 1 Structure of the plant cell wall (Adapted from Brett and Waldron 1996; Boudet et al. 2003)

cellulose, hemicellulose, and lignin varies considerably among these layers. The PW is generally very thin and has a low cellulose content (~10 %), some lignin, but lots of pectin and hemicellulose. The SW is composed of three layers, namely, SW1, SW2, and SW3, where SW2 (which comprises the major part of the cell wall) is usually thicker than the others and contains the major portion of cellulose (about 70 %). The middle lamella, which binds the adjacent cells, is almost entirely composed of lignin (Pandey 2009; Menon and Rao 2012; Aitken 2012; Gibson 2012).

However, the composition of various lignocellulose materials varies substantially (Table 1) depending on the source and even with age, stage of growth, climatic conditions, and others (Perez et al. 2002). In sequence, the structure of the main constituents of lignocellulosic wastes will be described.

2.1 Cellulose

The most predominant component found in all plant cell walls is cellulose. It is a linear homopolymer of D-glucose monomers linked by β-1,4-glycosidic bonds that can contain over 10,000 glucose units (Cheng and Timilsina 2011). The cellulose chains are cross-linked by strong hydrogen bonds to form cellulose microfibrils. These microfibrils exhibit a crystalline region, which is very recalcitrant to degradation and a small part of amorphous cellulose, which is easier to degrade (Van Dyk and Pletschke 2012). The orientation of cellulose microfibrils in the secondary cell wall has a strong effect on the structural properties of various plant types (Abdul Khalil et al. 2012).

The cellulose microfibrils are present in the secondary cell wall usually embedded in an amorphous matrix of hemicelluloses and lignin (Cziple and Marques 2008; Huber et al. 2012). These microfibrils in the matrix are often associated in the form of bundles or macrofibrils (Menon and Rao 2012), and lignin and hemicellulose fill the spaces between cellulose microfibrils in primary and secondary cell walls, as well as the middle lamellae (Eriksson and Bermek 2009).

The high molecular weight and ordered tertiary structure makes natural cellulose insoluble in water. Although starchy materials require temperatures of only 60–70 °C to be converted from crystalline to amorphous form, cellulose requires 320 °C and a pressure of 25 MPa to change from a rigid crystalline structure to an amorphous structure in water (Deguchi et al. 2006; Limayem and Ricke 2012). Cotton, flax, and chemical pulp represent the purest sources of cellulose (up to 90 % cellulose), while wood contains approximately 50 % cellulose (Aitken 2012; Limayem and Ricke 2012).

2.2 Hemicellulose

Hemicellulose is another polysaccharide found in abundance in plant cell walls. It is a complex branched heteropolymer of sugars and sugar derivatives which form a

highly branched network. It consists of about 100–200 sugar units typically made up of different sugars including hexoses (D-glucose, D-galactose, and D-mannose), pentoses (D-xylose and L-arabinose), and/or sugar acids (uronic acids), namely, D-glucuronic, D-galacturonic, and 4-O-methyl-D-glucuronic acids (Cheng and Timilsina 2011; Limayem and Ricke 2012). Other sugars such as α-L-rhamnose and α-L-fucose may also be present in small amounts, and the hydroxyl groups of sugars can be partially substituted with acetyl groups (Gírio et al. 2010).

Xylans are the main hemicellulose components of secondary cell walls, its backbone chain is primarily composed of D-xylose residues (nearly 90 %) linked by β-1,4-glycosidic bonds (Gírio et al. 2010; Limayem and Ricke 2012). Most xylans occur as heteropolysaccharides, containing different substituent groups in the backbone chain such as acetyl, arabinosyl, and glucuronosyl residues (Michelin et al. 2013). Branch frequencies vary depending on the nature and the source of feedstocks. The hemicelluloses of softwood are typically glucomannans, while hardwood hemicellulose is more frequently composed of xylans (McMillan 1994).

The primary role of the hemicelluloses has been proposed to act as a bonding agent between lignin and cellulose. Its covalent linkage to lignin and its noncovalent interaction with cellulose may be important in maintaining the integrity of the cellulose in situ and helping to protect the fibers against degradation by cellulases (Uffen 1997; Michelin et al. 2013).

2.3 Lignin

Lignin is another highly polymerized molecule but is quite amorphous relative to cellulose and hemicellulose (Aitken 2012). It is a complex hydrophobic cross-linked aromatic biopolymer with a molecular weight of 10,000 Da (Mielenz 2001; Limayem and Ricke 2012), composed of three major phenolic components, namely, *p*-coumaryl, coniferyl, and sinapyl alcohol (Menon and Rao 2012).

Its ratio varies between different plants, wood tissues, and cell wall layers (Menon and Rao 2012). Older and more woody plants contain higher levels of lignin deposited in cell walls to provide rigidity and strength, conferring impermeability to cell walls and forming an effective physic–chemical barrier against microbial attack (Raven et al. 1999; Kumar et al. 2009; Van Dyk and Pletschke 2012) and oxidative stress. Therefore, it is the most recalcitrant component of lignocellulosic material to degradation (Himmel et al. 2007; Sánchez 2009; Michelin et al. 2013).

Lignin covalently bonds to hemicellulose and is responsible for much of the mechanical strength of wood (Aitken 2012). Forest woody biomass is primarily composed of cellulose and lignin polymers. Softwood barks have the highest level of lignin (30–60 %) followed by the hardwood barks (30–55 %), while grasses and agricultural residues contain the lowest level of lignin (10–30 % and 3–15 %, respectively) (Demirbas 2005).

3 Biorefinery Processing of Cellulose

As mentioned above, the biorefinery concept is comparable to the classical petroleum refinery and includes the conversion of biomass into fuels and chemicals with high value-added (Fig. 2). The implementation of this demands the identification of the most promising bioproducts, chemicals, and bioenergy, considering environmental and economic aspects (Cherubini and Ulgiati 2010; Ruiz et al. 2013a).

Nowadays, the application of a biorefinery process based on cellulose has increased, for example, in the pulp and paper industry (Jahan et al. 2013). Moshkelani et al. (2013) mentioned that the incorporation of a biorefinery unit into an operating kraft pulping process has significant technological, economic, and social advantages over the construction of a grassroot biorefinery. Recently, Fornell et al. (2013) performed a techno-economic analysis of a kraft pulp mill-based biorefinery producing both ethanol and dimethyl ether and concluded that the biorefinery can be self-supported in terms of fuel if the process is well integrated. Pettersson and Harvey (2012) reported black liquor gasification as an alternative technology for energy and chemical recovery in kraft pulp mills by comparing the

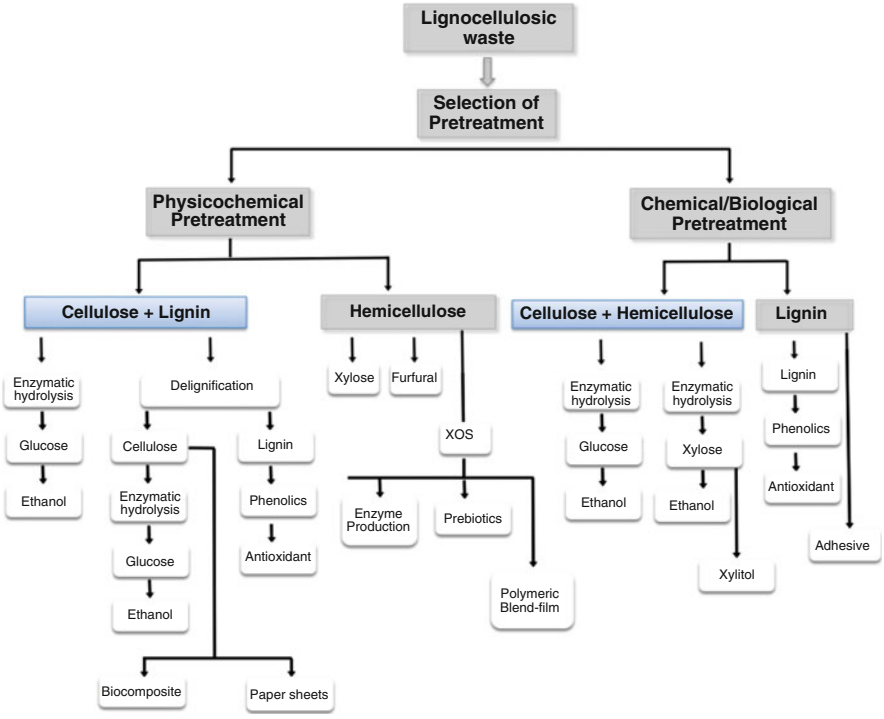

Fig. 2 Flowchart of conceptual biorefinery options for lignocellulosic wastes (Adapted and modified from Ruiz et al. 2013a)

black liquor gasification with downstream production of dimethyl ether or electricity and with recovery boiler-based pulping biorefinery for different types of mills. In a recent work, Lundberg et al. (2014) investigated the conversion of an existing Swedish kraft pulp mill to the production of dissolving pulp, with export of electricity, lignin, and hemicellulose stream suitable for upgrading, and they concluded that the profitability of this kraft pulp mill biorefinery is very dependent on the particular mill and the specific investment needs. Moreover, there are few companies that operate under the concept of biorefinery. An overview of almost all the biorefinery demonstration and pilot plants has been published in www.iea-bioenergy.task42-biorefineries.com, and new plants are continuously being built around the world, the USA being one of the main operators of biorefineries and producer of biofuels and high value-added compounds.

An important step in biorefineries of second generation is the pretreatment process. Ruiz et al. (2013a, b) reported that the pretreatment stage plays an important role in the biorefinery concept, since the pretreatment allows the fractionation of the main components of the biomass, producing substrates for conversion into biofuels and high value-added chemicals (Fig. 3).

3.1 Pretreatment Technologies

Due to the robust structure of lignocellulosic wastes, a pretreatment is required to alter its structure and chemical composition and promote fractionation (Fig. 3). According to Romaní et al. (2013a), the criteria for an effective pretreatment include: (1) avoiding size reduction, (2) preserving hemicellulose or lignin fraction, (3) limiting formation of inhibitors or sugar degradation, (4) minimizing energy input, and (5) being cost-effective. Yang and Wyman (2008) mentioned that the choice of pretreatment technology is not trivial and must take into account sugar production and solid concentrations for each pretreatment in conjunction with their compatibility with the overall process, feedstock, enzymes, and organisms to be applied and to meet the biorefinery concept. In the following sections, some different pretreatments used in second-generation processing of lignocellulosic wastes will be addressed.

3.1.1 Physical Pretreatment

Some of the important variables in the pretreatment process are residence time, temperature, and particle size. Normally, when larger chips are used, heat transfer problems lead to overcooking of the exterior (with associated formation of inhibitors) and incomplete hydrolysis of the interior. This problem can be overcome by reducing particle size before the application of the pretreatment. This size reduction process not only changes the particle size and shape, but also increases bulk density, improves flow properties, and increases porosity and surface area. This higher surface area increases the number of contact points for chemical reaction (Ruiz et al. 2011a). Also, reduction of the crystallinity of the cellulose is one of the important objectives of physical pretreatment. Chipping, grinding, and milling

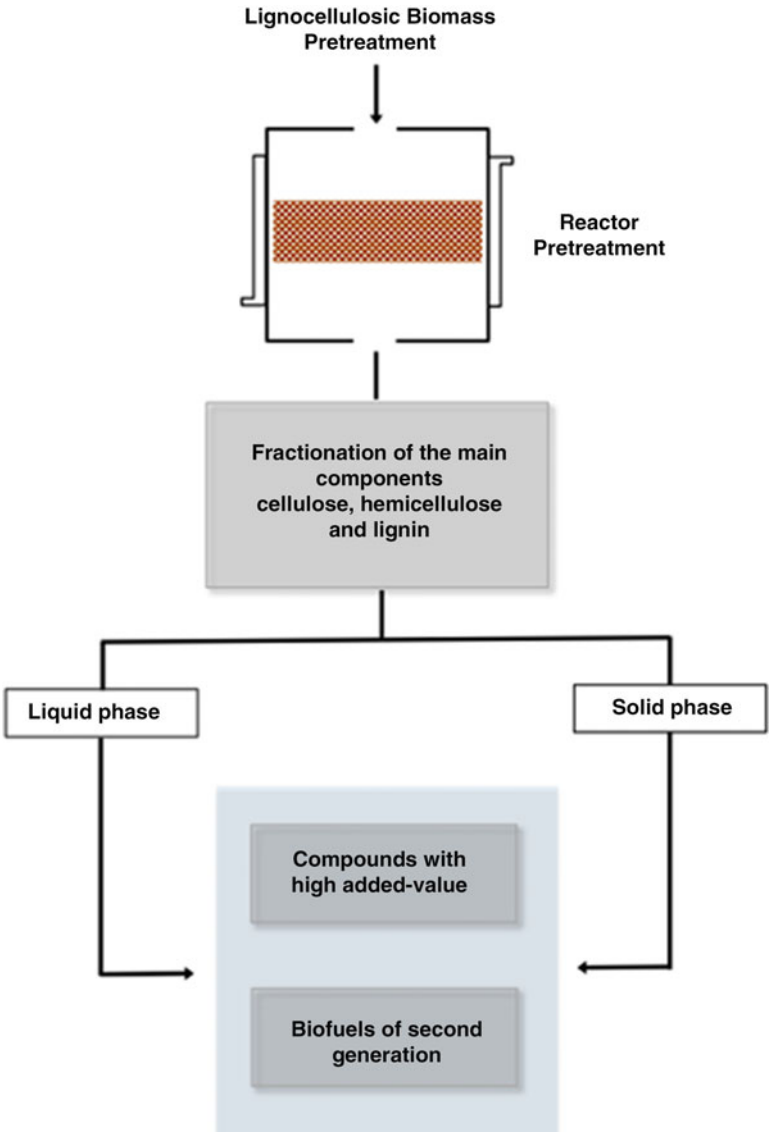

Fig. 3 Scheme for biomass fractionation

are among the different mechanical size reduction methods that have been used to enhance the digestibility of lignocellulosic wastes (Agbor et al. 2011). However, the power and energy requirement of this pretreatment is relatively high depending on the final particle size and the lignocellulosic waste characteristics. Delgenes et al. (2002) cited by Agbor et al. (2011) reported that the milling pretreatment increases biogas, biohydrogen, and bioethanol yields.

Extrusion pretreatment is a promising physical pretreatment method for lignocellulosic waste conversion to bioethanol production (Alvira et al. 2010). According to Lamsal and Brijwani (2010), the extrusion pretreatment can provide a unique continuous reactor environment for a combination of thermomechanical and chemical pretreatment of lignocellulosic wastes at higher yields. The materials are subjected to heating, mixing, and shearing, resulting in physical and chemical modifications during the process (Alvira et al. 2010). Lamsal et al. (2010) compared the particle size reduction and thermochemical extrusion pretreatment for the structural modification of wheat bran and soybean hull as raw material. They concluded that the use of chemical pretreatment in combination with extrusion did not result in improvement in hydrolysis of the lignocellulosic materials. Washing of thermomechanically treated samples was found to be very critical in maximizing the reducing sugar yields. Karunanithy et al. (2012) investigated the effect of biomass moisture content and extruder parameters such screw speed and barrel temperature on sugar recovery. They concluded that these variables were significant to the cellulose, hemicellulose, and total sugar recovery.

3.1.2 Physicochemical Pretreatment

Autohydrolysis Pretreatment

Autohydrolysis process is an environmentally friendly process in which the lignocellulosic wastes are pretreated with compressed hot water; it is based on the selective depolymerization of hemicellulose, which is catalyzed by hydronium ions generated in situ by water autoionization and by acetic acid from acetyl groups. Moreover, autohydrolysis pretreatment causes re-localization of lignin on the surface of lignocellulosic biomass. This process avoids difficult steps in chemical handling and recovery (e.g., sulfuric or hydrochloric acid) compared with dilute sulfuric acid or base pretreatment (Ruiz et al. 2012a, 2013a). Autohydrolysis process has been considered a cost-effective pretreatment, and in general, the major advantages that this process offers are as follows: (1) the process does not require the addition and recovery of chemicals different from water, (2) limited equipment corrosion problems, and (3) simple and economical operation. For that reason, autohydrolysis can be considered an environmentally friendly fractionation process.

According to Ruiz et al. (2013a), after autohydrolysis pretreatment, the cellulose shows degradation at temperatures >230 °C. It has been reported that the cellulose started to degrade in hexoses and oligosaccharides above 230 °C, and almost all cellulose was decomposed at 295 °C (Sakaki et al. 2002). An application of the solid residue (cellulose + lignin) after autohydrolysis pretreatment is used as raw material for pulp and paper marking (Ruiz et al. 2011b). Alfaro et al. (2010) reported that the cellulose pulp autohydrolysis reduces Kappa number and viscosity and decreases paper strength. Vila et al. (2011) studied the susceptibility of autohydrolysis solids to kraft processing pulp, being obtained cellulose pulps with low Kappa numbers and highly susceptible to alkaline oxygen bleaching.

Microwave Pretreatment

Microwaves as an alternative heating source have been successfully applied for extraction of numerous biologically active compounds from a wide variety of natural resources, because it is characterized as a selective, efficient, and environmental friendly process. This technique consists in a rapid delivery of energy to the total volume and subsequent rapid heating of the material structure accelerating the solubilization of compounds. Polar solvents have permanent dipole moment and can absorb microwave radiation, and water as a polar compound can absorb the microwave energy and transfer it to the sample, having as advantage over the organic solvents being a secure and ecologic reagent (Rodriguez-Jasso et al. 2011).

Budarin et al. (2010) reported the interaction between cellulose with microwave irradiation with high quality fuels produced from biomass. The substrate pretreated with microwave process has also been used for cellulose production. Zhao et al. (2010) reported that when some substrates were pretreated with microwave irradiation, the reducing sugar content and carboxymethylcellulase production were increased, and most cellulase was produced by the substrates pretreated at 450-W microwave for 3 min. Moreover, the microwave pretreatment has been used for enhancing enzymatic hydrolysis of cellulose (Peng et al. 2013).

Steam Explosion Pretreatment

This process is also considered as a hydrothermal process and has almost the same fundament of autohydrolysis. However, in this process, the high pressure steaming is followed by a rapid decompression. Steam explosion of lignocellulosic wastes has been largely studied in the last 15–20 years. This physicochemical method modifies lignocellulose material to allow the fractionation of the three polymer streams: hemicellulose into the liquor, and lignin and cellulose remaining in the insoluble fraction. Steam pretreatment of the lignocellulosic materials at temperatures of 160–220 °C generates acetic acid (from hemicellulose), which catalyzes the hydrolysis of hemicellulose resulting in its solubilization. When the process reaction is performed under high pressures followed by explosive decompression, the resulting residue is rendered highly degradable by enzymes and microorganisms.

Deepa et al. (2011) extracted cellulose nanofibers from banana fibers by steam explosion pretreatment; these nanofibers had better thermal properties over the untreated fibers. Romaní et al. (2013b) used steam exploded pretreated solids (*Eucalyptus globulus* as raw material) subjected to simultaneous saccharification and fermentation at high solids loading and reached an ethanol concentration of 51 g/L with a 91 % yield. Oliveira et al. (2013) reported the use of an industrial-scale steam explosion pretreatment of sugarcane straw for the production of bioethanol and high value-added chemicals.

Ultrasound Pretreatment

The ultrasound pretreatment is a new emerging technology that has potential as an alternative pretreatment technology. According to Yunus et al. (2010), the ultrasound pretreatment does not hydrolyze the biomass to soluble sugars. The function is to generate a pretreated substrate that is more easily hydrolyzed via increasing the

accessible surface area and affecting the crystallinity. This process has been recently reviewed by Bussemaker and Zhang (2013) for biorefinery and biofuel applications, and they commented that the ultrasonic waves create pressure differences within a solution for the enhancement of physical (mechano-acoustic) and chemical (sonochemical) processes; this ultrasonic phenomenon is generated by either piezoelectric or magnetostrictive transducers, where the transducer is attached to a vessel filled with a sonication solution and the mechanical vibrations of the piezoelectric material creates a pressure wave through the solution. This effect of ultrasound on lignocellulosic wastes has been employed to improve the extractability of hemicelluloses, cellulose, and lignin or to get clean cellulosic fiber from used paper; however, only a few attempts to improve the susceptibility of lignocellulosic materials according to biorefinery concept have been made (Bussemaker et al. 2013).

Yunus et al. (2010) studied the effect of ultrasonic pretreatment on oil palm empty fruit bunch fiber prior to acid hydrolysis, and they concluded that the exposition of this material to ultrasonication power has a marked effect on the efficiency of low temperature acid hydrolysis. García et al. (2011) reported the ultrasound pretreatment of lignocellulosic waste and showed that the application of this pretreatment improved the effectiveness of the classic pretreatments, obtaining higher yield and selectivity of the products. Nikolic et al. (2011) reported the utilization of microwave and ultrasound pretreatments in the production of bioethanol using corn as raw material, having concluded that ultrasonic and microwave pretreatments effectively increased the glucose concentration obtained after liquefaction and consequently improved the ethanol yield and productivity during the SSF process.

3.1.3 Chemical Pretreatment

Several chemical pretreatments have been studied in order to remove the hemicellulosic fraction, to cleave the bindings between the lignin and the polysaccharides, and to distort the arrangement of the cellulose crystallinity, improving the accessibility of the cellulose component to the action of hydrolytic enzymes so that an efficient hydrolysis of carbohydrates to fermentable sugars occurs (Sun and Cheng 2002; Mosier et al. 2005). Moreover, the combination of sequential chemical pretreatments is an interesting alternative for the lignocellulosic wastes being in accordance with the biorefinery concept (Ruiz et al. 2011b).

Alkaline Pretreatment

The alkaline pretreatment is one of the most studied and makes use of several reagents as sodium hydroxide, calcium hydroxide, potassium hydroxide, aqueous ammonia, and ammonia hydroxide, sometimes in mixture with hydrogen peroxide (Chen et al. 2013; Gonçalves et al. 2014). According to Chen et al. (2013) and García et al. (2014a), alkali reagent is believed to cleave hydrolyzable linkages in lignin and glycosidic bonds of polysaccharides causing a reduction in the degree of polymerization, increasing the internal surface area and decreasing crystallinity of the cellulose and disruption of the lignin structure which increases the reactivity

of the remaining polysaccharides as delignification occurs (Pedersen and Meyer 2010). Also, the alkali pretreatment is effective for agricultural residues and herbaceous crops, due to the smaller amount of lignin present in these types of materials (Galbe and Zacchi 2012). The alkaline pretreatment has as advantage the low energetic demand due to the severity of the alkaline media, where high reaction temperatures are usually not required (below 140 °C) and as disadvantage the alkali price and the difficulty of its recuperation that still involves prohibitive costs (Sun and Cheng 2002; Hamelink et al. 2005).

In a recent work, Gonçalves et al. (2014) studied the production of bioethanol using a sequential alkali pretreatment with hydrogen peroxide and sodium hydroxide, obtaining a high susceptibility of pretreated materials to enzymatic action. Selig et al. (2009) pretreated corn stover with alkaline peroxide at pH 11.5 resulting in reduction of lignin content in the pretreated solids and improvement of sugar production by cellulases. Prinsen et al. (2013) studied the modification of the lignin structure of a eucalyptus feedstock during alkaline delignification by kraft, soda–anthraquinone, and soda-O_2, indicating that soda-O_2 process produced higher lignin degradation and provides results as a pretreatment for the deconstruction of eucalyptus feedstock for subsequent use in lignocellulose biorefineries.

Acid Pretreatment

The use of acid pretreatment to catalyze the hydrolysis of lignocellulosic wastes in their sugar constituents is well known and effective. Acid pretreatment has been considered as a suitable technology for industrial-scale bioethanol production from glucose and hemicellulosic sugars (Ruiz et al. 2013c). Different types of acids have been used in these pretreatments such as: phosphoric, sulfuric, and organic acid (oxalic, citric, tartaric and acetic) (Qin et al. 2012; Avci et al. 2013; Ruiz et al. 2013c).

Castro et al. (2014) optimized the phosphoric acid pretreatment of *Eucalyptus benthamii* wood chips and produced bioethanol from this pretreated material with an ethanol yield of 240 g ethanol/kg of raw material. García et al. (2014b) produced bioethanol from the shells of *Jatropha curcas* using dilute sulfuric acid pretreatment, the cellulose conversion being above 80 %.

Organosolv Pretreatment

As alternative to conventional chemical pulping, processes utilizing aqueous organic solvents, known as organosolv, have been studied in the last 30 years. This pretreatment involves the use of organic solvents or their aqueous solutions for extracting lignin, based on the fact that lignin can be solubilized in certain solvents in a wide range of temperatures (100–250 °C) (González Alriols et al. 2009; Agbor et al. 2011). During the organosolv process, the lignin structure is broken into smaller parts and dissolved from the raw material and separated in the form of a liquor rich in phenolic compounds that represents the process effluent. This lignin can be isolated and has the advantage of being a relatively pure product with excellent properties that may be used as a precursor in the production of various commercial products according to the biorefinery concept (Ruiz et al. 2011b).

The organosolv pretreatment has been investigated due to the effective results for hemicelluloses/lignin depolymerization, increasing the cellulosic fraction digestibility (Geng et al. 2012). However, most of the used organic solvents need to be recovered for economic and environmental reasons (Alvira et al. 2010; Galbe and Zacchi 2012). The organosolv process has been developed as part of a commercial lignocellulose biorefinery technology known as the Lignol process. Lignol is a pilot plant that obtained several high value products in a cost-effective process where solvents were recovered and recycled at the end of the process (Pan et al. 2005).

Torre et al. (2013) reported that the cellulose pulp with the organosolv process is especially attractive because it can be used in boiler combustion chambers. Li et al. (2012) studied the fractionation of organosolv lignin with organic solvents and reported that this fractionation provides a way to prepare lignin with homogeneous structure and good functional properties for several potential applications. Kautto et al. (2013) reported that the organosolv pulping can be used as a pretreatment step in bioethanol production allowing, in complement to the production of bioethanol, the production of a pure lignin and other coproducts according to biorefinery concept.

Ozonolysis Pretreatment

Ozonolysis pretreatment includes using ozone gas, a powerful oxidant and soluble in water, in order to breakdown lignin and hemicelluloses and increase cellulose biodegradability; soluble compounds of smaller molecular weight such as acetic and formic acid (Balat 2011) may also be released. The lack of degradation by-products and operation at ambient conditions constitute the advantages of this pretreatment (Garcia-Cubero et al. 2009), while the disadvantages reside in the cost of ozone (Sun and Cheng 2002).

Travaini et al. (2013) pretreated sugarcane bagasse in a fixed bed reactor with ozone and studied the effect of ozone concentration and sample moisture, and they concluded that ozonolysis process is a promising pretreatment to obtain a high glucose conversion from cellulose.

Ionic Liquid Pretreatment

Ionic liquids are organic salts that exist as liquids at low temperatures, with tunable physicochemical properties, low vapor pressures, good thermal stability, and different combination of anions and cations to their synthesis (Fort et al. 2007; Lee et al. 2008). Recent studies of particular interest have indicated that both cellulose and lignin can be dissolved in a variety of ionic liquids and, perhaps more important, easily regenerated from these solutions. Thus, studies have shown ionic liquids with potential to be used as an environmentally benign pretreatment of lignocellulosic wastes (Fort et al. 2007; Zhu 2008; FitzPatrick et al. 2010).

Yuan et al. (2013) mentioned that anionic liquid-based biorefining strategy could integrate biofuel production into a biorefinery scheme in which the major components of poplar wood can be converted into value-added products. Shafiei et al. (2013) produced bioethanol from spruce wood chips using ionic liquid as pretreatment; they reported that ethanol yield was between 66.8 % and 81.5 %.

Labbé et al. (2012) investigated three ionic liquids as potential media to act on biomass and make the cellulose component more accessible to hydrolytic enzymes. The ionic liquid [emim][OAc] was the most efficient in the fractionation of lignocellulosic waste. In general terms, the treatment with ionic liquids is a useful technology for the development of the biorefinery concept (Stark 2011).

3.1.4 Biological Pretreatment

The biological or microbial pretreatment involves the use of microorganisms or enzymes. In addition, in biological pretreatment, particle size, moisture content, resident time, and temperature, besides the microbial agents used, could affect lignin degradation and enzymatic hydrolysis yield (Patel et al. 2007; Wan and Li 2010).

Unlike most of the chemical and physicochemical pretreatment methods, biological pretreatment offers as advantages low energy consumption and no chemical requirement, in addition to mild operational conditions and likely ease of integration into a consolidated bioprocessing setup (Sun and Cheng 2002; Yang and Wyman 2008; FitzPatrick et al. 2010). The disadvantages include long-time process, large space requirement, and the need for continuous monitoring of microorganism growth (Wyman et al. 2005; Taherzadeh and Karimi 2008).

Research on fungal pretreatment is mainly focused on evaluating fungi that selectively degrade lignin and hemicellulose, while utilizing little cellulose (Chen et al. 1995; Singh et al. 2008; Shi et al. 2009; Wan and Li 2010). Cellulose is more recalcitrant to fungal attack than other components. On the other hand, microbial consortium pretreatment is conducted by microbes screened from natural environment's typically rotten lignocellulosic biomass. In contrast to fungal pretreatment, which is usually conducted under sterilized conditions, in most cases, sterilization of lignocellulosic feedstocks is not necessary when using a microbial consortium for pretreatment, which is an advantage over fungal pretreatment. In enzymatic pretreatment, the most commonly used enzymes are cellulases and hemicellulases with the disadvantages of the cost of enzymes to be high and therefore its application is limited.

3.1.5 Integrated Pretreatment

Other pretreatment processes, using integrated methods, have been a target of some researches in order to improve the efficiency of fractionating, decrease the formation of inhibitors, and shorten process time (Mood et al. 2013; Zheng et al. 2014).

Thus, in literature, there are several studies with combination of alkaline and dilute acid pretreatments resulting at more effective delignification and less carbohydrate degradation, in comparison with alkali and acid pretreatment solely (Lu et al. 2009), and combinations of dilute acid and microwave pretreatments resulting in highest biomass fragmentation and swelling as well as complete hemicellulose degradation (Chen et al. 2011). Combination of biological and steam explosion pretreatment reduced the pretreatment time significantly (Taniguchi et al. 2010), while the combination of biological and dilute acid pretreatments led to enhanced enzymatic hydrolysis (Na et al. 2010). The combination

of dilute acid and steam explosion pretreatment revealed a high xylose yield, a low level of inhibitors, and an enhanced saccharification efficiency (Sun and Cheng 2002). The use of microwave-based heating, instead of the conventional heating, in alkali pretreatment, removed more lignin and hemicelluloses in shorter pretreatment time (Yuanxin et al. 2005, 2006), while the synergic effect of the combination of ultrasonic pretreatment, instead of the conventional heating pretreatment, and different ionic liquids also enhanced the saccharification ratio (Ninomiya et al. 2010).

3.2 Enzymatic Hydrolysis

After the pretreatment, the cellulose is more susceptible to enzymatic attack (Cheng and Timilsina 2011). Therefore, the enzymatic hydrolysis is the second step in the biorefinery processing of cellulose from lignocellulosic wastes. It involves cleaving the cellulose polymers to soluble monomeric sugars using a class of enzymes known as cellulases.

The cellulases are highly specific, and the enzymatic hydrolysis of cellulose is usually carried out under mild conditions of pressure, temperature, and pH (Binod et al. 2010). Most cellulases show an optimum activity at temperatures and pH in the range of 45–55 °C and 4–5, respectively (Duff and Murray 1996; Galbe and Zacchi 2002; Talebnia et al. 2010; Cheng and Timilsina 2011). Enzymes tolerant to high temperature and low pH are preferred for the enzymatic hydrolysis due to most current pretreatments making use of acid and heat. Besides, thermostable enzymes have several advantages including higher specific activity and higher stability, which improves the overall enzymatic performance.

Ultimately, improvement in catalytic efficiencies of enzymes reduces the cost of process by enabling lower enzyme dosages (Dashtban et al. 2009). A cellulase dosage of 10–30 FPU/g cellulose is often used in laboratory studies because it results in an efficient hydrolysis with high glucose yield in a reasonable time (48–72 h). However, enzymes loading may vary depending on the pretreatment, type, and concentration of raw materials (Talebnia et al. 2010). Although the cost of enzyme production is still high, a reduction in the costs may be obtained in the case less noble materials are used (Castro and Pereira Jr 2010).

Fungi and bacteria can produce cellulases for the hydrolysis of lignocellulosic wastes, and these enzymes have been mainly produced by species of *Trichoderma*, *Aspergillus*, *Schizophyllum*, and *Penicillium*. Of all these fungal genera, *Trichoderma* has been most extensively studied for cellulase production. Bacteria belonging to *Clostridium, Cellulomonas, Bacillus, Thermomonospora*, and *Streptomyces* can produce cellulases. Although many cellulolytic bacteria, particularly the cellulolytic anaerobes such as *Clostridium thermocellum* and *Bacteroides cellulosolvens*, produce cellulases with high specific activity, they do not produce high enzyme titers (Sun and Cheng 2002).

Therefore, most research for commercial cellulase production has been focused on fungi (Talebnia et al. 2010). Besides, due to the promising thermostability and

acidic tolerance of thermophilic fungal enzymes, they have good potential to be used for hydrolysis of lignocellulosic wastes at industrial scale (Dashtban et al. 2009).

The use of a mixture of cellulases from different microorganisms or a mixture of cellulases and other enzymes has been extensively studied since this can raise the rate of enzymatic hydrolysis of lignocellulosic biomass. The combination of enzymes such as cellulase, xylanases, and pectinases exhibits a significant increase in the extent of cellulose conversion (Sun and Cheng 2002; Binod et al. 2010). Tabka et al. (2006) observed that the addition of accessory enzymes, such as xylanases, feruloyl esterase, and laccase, on pretreated wheat straw could act in synergistically, improving the enzymatic hydrolysis of cellulose on pretreated material.

Currently, the use of enzymes from a cellulolytic complex in the hydrolysis of biomass is one of the more emerging applications. The lignocellulosic feedstocks contain from 20 % to 60 % of cellulose, which may be fully converted to glucose by enzymatic action. In subsequent steps, the monosaccharide can be used as a building block for obtaining a vast range of products, which range from biofuels to polymers. These technologies fall under the definition of cellulosic biorefineries, which aim to the integrated and integral use of agro-industrial wastes generated in a given production chain with value addition (Castro and Pereira Jr 2010).

The three enzymes involved in hydrolysis of cellulose to glucose by synergistic action include:

3.2.1 Endoglucanase (EG)

EG (Endo-1,4-β-D-glucanohydrolase; EC 3.2.1.4) cleaves the β-1,4-glucosidic linkages in the interior of cellulose molecule to produce cellooligosaccharides with free chain ends. It is responsible for starting cellulose hydrolysis by attacking randomly regions of low crystallinity in the cellulose fiber and making it more accessible for cellobiohydrolases (Talebnia et al. 2010; Cheng and Timilsina 2011). The EG is the cellulolytic enzyme responsible for the rapid solubilization of cellulose due to their fragmentation in oligosaccharides. It is also referred as carboxymethylcellulase (CMCase) because of the use of carboxymethylcellulose (CMC) as substrate to measure its activity (Michelin et al. 2013).

Studies have shown that many fungi produce multiple EGs. For example, *T. reesei* produces at least five EGs (EGI/Cel7B, EGII/Cel5A, EGIII/Cel12A, EGIV/Cel61A and EGV/Cel45A), whereas three EGs were isolated from white-rot fungus *Phanerochaete chrysosporium* (EG28, EG34 and EG44) (Dashtban et al. 2009).

3.2.2 Cellobiohydrolase (CBH)

CBH (1,4-β-D-glucan cellobiohydrolase; EC 3.2.1.91) is an exoglucanase that preferentially hydrolyzes β-1,4-glycosidic bonds of the cellulose, releasing cellobiose units from chain ends (Michelin et al. 2013). Cellobiose, the end product of CBHs, acts as an inhibitor, which can limit the ability of the enzymes to degrade

cellulose (Dashtban et al. 2009). Microcrystalline cellulose (Avicel) has been used as substrate to measure its activity (Michelin et al. 2013).

Although IUBMB (International Union of Biochemistry and Molecular Biology) defines the CBH as a catalyst of the hydrolysis of only the nonreducing ends of the cellulosic fiber and oligosaccharides with degree of polymerization (DP) higher than three in cellobiose, studies have shown that some CBHs can act from the reducing ends of the cellulosic chains, which increases the synergy between opposite-acting enzymes (Lynd et al. 2002; Michelin et al. 2013). For example, *T. reesei* has shown to have two CBHs acting from nonreducing (CBHII/Cel6A) and reducing (CBHI/Cel7A) ends (Zhang and Lynd 2004; Dashtban et al. 2009).

3.2.3 β-Glucosidase (BGL)

BGL (1,4-β-D-glucosidase glucanohydrolase; EC 3.2.1.21) cleaves cellobiose and other cellodextrins with a DP up to six releasing glucose units. The hydrolysis rates decrease markedly as the substrate DPs increase (Zhang et al. 2006). BGL is also inhibited by its end product (glucose).

BGLs are very amenable to a wide range of simple sensitive assay methods, based on colored or fluorescent products released from some synthetic substrates, such as *p*-nitrophenyl β-D-1,4-glucopyranoside. Also, BGL activities can be measured using cellobiose, which is not hydrolyzed by endoglucanases and exoglucanases (Ghose 1987; Zhang and Lynd 2004; Zhang et al. 2006).

BGLs have been isolated from many different fungal species including *Ascomycetes* such as *T. reesei* and *Basidiomycetes* such as white-rot and brown-rot fungi. In *T. reesei*, two β-glucosidases (BGL I/Cel3A & BGL II/Cel1A) have been isolated from culture supernatant, but the enzymes were found to be primarily bound to the cell wall. However, BGL production in *T. reesei* is very low compared to other fungi such as *A. niger* (Dashtban et al. 2009).

3.3 Fermentation and Bioproducts

3.3.1 Fermentation

Fermentation can be defined as a process performed mainly by microorganisms such as bacteria, yeast, and fungi in order to obtain a bioproduct from a suitable nutrient source. This process can be performed by solid-state or submerged cultures. Solid-state fermentation (SSF) is a complex heterogeneous three-phase (gas–liquid–solid) process defined as the growth of microorganisms, often fungi, on the surface of a porous and moist solid substrate particle in which enough moisture is present to maintain microbial growth and metabolism; submerged fermentation has been defined as fermentation in a liquid medium (Pandey 2003; Ruiz et al. 2012b).

Currently, the use of lignocellulosic wastes has been employed as nutrient source in fermentative process, and special attention has been given to cellulose present in these materials. Due to the complexity of the cellulose, several forms to lead the fermentative process were developed in order to obtain a high efficiency.

For example, for the conversion of the sugars from cellulose in molecules of interest, such as ethanol, a step of enzymatic hydrolysis of the cellulose prior to submerged fermentation is necessary, and both steps can be performed separately (SHF – separate hydrolysis and fermentation), simultaneously (SSF – simultaneous saccharification and fermentation), and semi-simultaneously (SSSF– semi-simultaneous saccharification and fermentation) (Dashtban et al. 2009; Castro and Pereira Jr 2010; Gonçalves et al. 2014).

In SHF, the hydrolysis of cellulose occurs in a separate step and after that, the sugars released are fermented to ethanol. The advantage of this method is that both steps can be carried out in each optimum condition (e.g., optimum temperature for cellulase hydrolysis is around 50 °C and for fermentation 30 °C). Besides, in this process, the cells can be recycled, since there is no raw material in suspension during fermentation. The main drawback is the accumulation of intermediate sugars (cellobiose and glucose) during the hydrolysis, which can cause inhibition of the cellulase enzymes and a reduction in the final conversion to glucose. This makes the process inefficient, and the costly addition of β-glucosidase is needed in order to promote a reduction of the inhibition of endo- and exoglucanase by its hydrolysis products (particularly cellobiose) and increase the final conversion of substrate to glucose that will be used for fermentation (Philippidis et al. 1993; Kádár et al. 2004).

In SSF, the enzymes are less susceptible to inhibition by hydrolysis products because the released glucose is fermented simultaneously. Therefore, addition of high amounts of β-glucosidase is not necessary, which reduces the costs of the process (Dashtban et al. 2009). The maintenance of low glucose concentration in the medium also promotes the continuous hydrolysis reaction and reduces the risk of contamination of the system. Besides, this process contributes to lower cost of investment at the plant since the two steps are performed in the same reactor (Castro and Pereira Jr 2010). The main drawback of SSF is the need to lead the process in suboptimal conditions of temperature and pH. The development of recombinant yeast strains (i.e., improved thermotolerance) is expected to enhance the performance of SSF (Galbe and Zacchi 2002). The semi-simultaneous saccharification and fermentation (SSSF) is a good alternative that includes a short presaccharification period before the SSF process (Gonçalves et al. 2014).

Considering the overall conversion of lignocellulosic wastes into ethanol, another alternative has been described. In this process, known as co-fermentation (CF), the fermentation of pentoses (mainly xylose from hemicellulosic fraction of the lignocellulosic wastes) and hexoses (glucose from cellulose) occurs in one reactor. The conduction of co-fermentation with concomitant hydrolysis of cellulose and/or hemicellulose fractions is called SSCF (simultaneous saccharification to co-fermentation) (Castro and Pereira Jr 2010).

Further process integration can be achieved by a process known as consolidated bioprocessing (CBP) which aims to minimize all bioconversion steps into one step using one or more microorganisms (enzyme production, hydrolysis of cellulose and hemicellulose, and fermentation of glucose and xylose happen in one reactor) and, thus, reduce product inhibition and operation costs (Limayem and Ricke 2012).

These processes are integrated within the concept of "biorefinery"-industrial installations designed to produce a wide range of bioproducts from conversion of biomass (Guo et al. 2010). A number of high value bioproducts can be obtained from lignocellulosic wastes such as bioethanol, organic acids, biohydrogen, enzymes, packaging materials, biocomposites, and others. In the sequence, some bioproducts that can be obtained from lignocellulosic wastes will be described.

3.3.2 Bioproducts

Bioethanol

In the past few years, much research has been done to find a viable alternative for ethanol production from lignocellulosic wastes (known as bioethanol, or cellulosic ethanol or second-generation ethanol) in view of fast depletion of fossil fuels and food shortages.

Ethanol is either used as fuel (pure or as an additive to gasoline) or a chemical feedstock and can be obtained from: (1) sucrose-containing feedstocks (e.g., sugar cane, sweet sorghum and sugar beet), (2) starchy materials (e.g., corn, wheat, and barley), and (3) lignocellulosic biomass (e.g., sugar cane bagasse, corncob, wood and straw) (Balat et al. 2008). The ethanol production from lignocellulose wastes has several advantages, such as: is a renewable energy source, abundant, of low cost, and noncompetitive with food crops. The use of ethanol fuel can significantly reduce the use of petroleum and reduce greenhouse gas emission. Currently, ethanol production from lignocellulosic wastes is one of the most studied and promising alternatives for reuse of these feedstocks, due to the large incentive that has been given to use of biofuels in replacement of gasoline (Mussato and Teixeira 2010).

Brazil and the USA produce ethanol from the fermentation of sucrose from sugarcane juice and starch from corn, respectively, generating wastes as the sugarcane bagasse and straw and corncob and corn straw. Therefore, a variety of widely available sugar feedstocks can be used (Sánchez 2009).

The production of fuel ethanol from lignocellulosic wastes includes an initial pretreatment (e.g., steam explosion or diluted acid) to render cellulose more accessible to the subsequent step of enzymatic hydrolysis (with cellulases), which breaks down cellulose to fermentable sugars, and finally the fermentation of the sugars to ethanol by yeast *Saccharomyces cerevisiae*. This conventional strain presents optimum temperature at 30 °C and tolerates a high osmotic pressure, low pH levels, and inhibitory products (Limayem and Ricke 2012).

Hsu et al. (2011) investigated the ethanol production by *S. cerevisiae* BCRC 21812 from reducing sugar released by hydrolysis of corncob material with cellulases (CMCase, Avicelase, and β-glucosidase) from *Streptomyces* sp. strain. Sukumaran et al. (2009) studied the saccharification of three different feedstocks, i.e., sugarcane bagasse, rice straw, and water hyacinth biomass (using cellulase and β-glucosidase) for ethanol production by *Saccharomyces cerevisiae*. The highest yield of reducing sugars was obtained from rice straw followed by sugarcane bagasse.

Intensive efforts have been done in the last years to (1) develop efficient technologies for the pretreatment of lignocellulosic wastes, since several factors have been described to affect the hydrolysis of cellulose, such as porosity (accessible surface area) of the lignocellulosic waste, crystallinity of cellulose fiber, and lignin and hemicellulose contents (McMillan 1994); (2) develop enzymes for enhanced cellulose/hemicellulose saccharification; and (3) develop suitable technologies for the fermentation of both hexose and pentose sugars (Soccol et al. 2010).

Biohydrogen

Hydrogen is considered as a clean fuel, forming water (instead of greenhouse gases) as the only combustion product. It has high energy content and can be used directly as fuel for transportation or, after purification, to produce electricity (Guo et al. 2010). Therefore, the development of renewable and cost-effective process for its production will contribute to increase the energy production and to reduce greenhouse effect (Kapdan and Kaegi 2006). Other applications of hydrogen include the use as chemical reactant in the production of fertilizers, for refining diesel and for the industrial synthesis of ammonia (Guo et al. 2010).

The use of the hydrogen as energy resource has been restricted in large part due to the high production costs, technical storage requirements, and distribution methods (Dunn 2002). Nowadays, the most part (around 88 %) of the hydrogen production derives from fossil fuels (natural gas, heavy oils or coal) (Nath and Das 2003), and up to 4 % of hydrogen production derives from water electrolysis. However, all such processes consume high energy (Guo et al. 2010).

Recently, biohydrogen gas production from lignocellulosic biomass, mainly agricultural wastes, has received more and more attention. It seems economically viable and technically feasible to produce biohydrogen from lignocellulose biomass by an integrated process involving pretreatment steps for the raw material and enzymatic hydrolysis for the yield of fermentable reducing sugars. After, the biohydrogen production can be performed by anaerobic fermentation process (Chen et al. 2008; Lo et al. 2008b, 2009b).

According to Magnusson et al. (2008), although there are several different methods of hydrogen production, biohydrogen production by dark fermentation, compared to alternative methods such as biophotolysis of water or photofermentation, is advantageous due to its higher rate of production. Besides, nonbiological methods of hydrogen production such as electrolysis and steam reformation of methane require extensive amounts of energy and also are sources of polluting emissions, such as CO_2, CO, NOx, and SOx.

The generation of biohydrogen from lignocellulosic wastes by using dark fermentation usually requires a step of pretreatment of substrate, which increases the production cost. Some investigators demonstrated a two-stage process (i.e., hydrolysis and hydrogen production) where cellulose hydrolysis can be performed by using mixed or pure microbial culture, and after, the hydrolysates (rich in reducing sugars) are used for sequential biohydrogen production by an efficient hydrogen producer. In this way, the hydrogen yield could be increased, and thus, the process

becomes more advantageous in practical applications due to a higher economical feasibility and less energy consumption (Lo et al. 2008a, 2009a).

Although pure cultures have been intensively investigated over the past years, involving species such as *Bacillus coagulans* (Kotay and Das 2007), *Thermoanaerobacterium* spp. (O-Thong et al. 2008), and *Clostridium butyricum* (Chen et al. 2005), few studies refer to the characterization of mixed cultures. In relation to mixed cultures producing biohydrogen, a wide range of species has been studied. In relation to mesophilic microorganisms, species from the genera *Clostridium* (*C. pasteurianum, C. saccharobutylicum, C. butyricum*), *Enterobacter* (*E. aerogenes*), and *Bacillus* can be cited, and in relation to thermophilic or extremophilic microorganisms, species include the genera *Thermoanaerobacterium* (*T. thermosaccharolyticum*), *Caldicellulosiruptor* (*C. saccharolyticus*), *Clostridium* (*C. thermocellum*), and *Bacillus* (*B. thermozeamaize*) (Guo et al. 2010).

Clostridium thermocellum is a thermophilic, acetogenic, anaerobic bacterium that degrades cellulose directly synthesizing a mixed product, such as acetate, hydrogen, and carbon dioxide, as well as lactate and ethanol under different growth conditions (Ng et al. 1977; Lynd et al. 1989). This bacterium expresses a suite of cellulolytic enzymes that degrades the cellulose to glucose and cellulodextrans. Of all known cellulose degrading microorganisms, *C. thermocellum* displays the highest rate of cellulose degradation (Lynd et al. 1989). Because of this characteristic and propensity to synthesize hydrogen, carbon dioxide, and acetate, *C. thermocellum* offers the potential for directly producing biohydrogen from cellulosic wastes. The high optimum growth temperature of *C. thermocellum* (60 °C) also reduces the chance of contamination by precluding the growth of predominant mesophilic microorganisms and allows for *C. thermocellum*-enriched cultures to be maintained. Besides, as the solubility of gases decreases with higher temperatures, the higher growth temperature also facilitates the efficient removal of product gases such as hydrogen and carbon dioxide.

Chen et al. (2005) reported *Clostridium butyricum* CGS5 as an efficient microorganism in converting sugars (e.g., glucose, xylose, sucrose) into hydrogen via dark fermentation. Unfortunately, *C. butyricum* CGS5, like most hydrogen-producing strains, cannot directly utilize cellulose or hemicellulose as carbon source for hydrogen production, and therefore, pretreatment and hydrolysis steps of the cellulosic feedstock were required to enable efficient cellulosic biohydrogen production.

Organic Acids

Some organic acids including citric and lactic acids can be produced by fermentation using hydrolysates rich in glucose obtained from cellulose of lignocellulosic wastes.

Currently, citric acid is produced mainly by fermentation (a small part is yet extracted from citrus fruits in Mexico and South America) submerged (SmF), in surface and in solid-state (SSF), using starch- or sucrose-based media (Jianlong 2000; Vandenberghe et al. 2000). The microorganism used is the filamentous

fungus A. niger, which can accumulate citric acid in media rich in carbohydrate but deficient in phosphate and trace elements like Fe^{+2} and Mn^{+2}.

Kumar et al. (2003) used pineapple, mixed fruit, and maosmi wastes as substrates to produce citric acid by solid-state fermentation using *Aspergillus niger* DS 1. Dhillon et al. (2011) also used different agro-industrial wastes, such as apple pomace, brewers' spent grain, citrus waste, and sphagnum peat moss to evaluate their suitability for the production of citric acid through solid-state and submerged fermentation by *A. niger* NRRL 567 and NRRL 2001.

Citric acid is used in several industrial sectors such as the food, beverage, and pharmaceutical industries. It is mainly used as an additive (antioxidant and acidulant) in the production of soft drinks, desserts, jellies, candies, and wines. It is also used as flavor enhancer and plasticizer. In pharmaceutical industry, it is used as anticoagulant (blood transfusion) and in the production of effervescent products. It is also used to adjust the pH of astringent lotions, as sequestering agent, and hair fixatives.

The food industry consumes about 70 % of the total production of citric acid (Rohr et al. 1983), due to some characteristics such as its pleasant acidic taste and its high solubility in water. Besides, it is worldwide accepted as "GRAS" (generally recognized as safe), approved by the joint FAO/WHO Expert Committee on Food Additives. The pharmaceutical industry consumes 12 %, and the rest 18 % has market for other applications (Penna 2001).

Lactic acid is another important organic acid that has attracted great attention because of its wide applications in food, chemical, and pharmaceutical industries. It is widely used as acidulant and preservative in the food industry, being used as taste-enhancing additive in soft drinks, jellies, syrups, and fruit juices. In the pharmaceutical industry, it is used for the adjustment of pH of pharmaceutical preparations and topical wart preparations. Other applications include blood coagulant and dietary calcium source. Lactic acid has been used in the manufacture of cellophane, resins, and some herbicides and pesticides. Another important application of lactic acid is in textile and tanning industries (Penna 2001).

Lactic acid has two enantiomers: D-(−) and L-(+) lactic acid. The production of optically pure D- or L-lactic acid can be obtained by fermentation when the appropriate microorganism is used (Abdel-Rahman et al. 2013).

Lactic acid is produced by fermentation and by chemical synthesis. Fermentative production offers some advantages, such as the use of cheap and renewable substrates, low production temperature, and low energy consumption. Currently, most of lactic acid produced worldwide is obtained from fermentative pathway (Abdel-Rahman et al. 2011). A racemic mixture of DL-lactic acid is usually produced by the chemical pathway.

Lactic acid can be produced from renewable materials by various microorganism species, including bacteria, fungi, yeast, microalgae, and cyanobacteria. Strains of *Lactobacillus* sp. have been common among the bacterial cultures (John et al. 2007a) and that of *Rhizopus* sp. among the fungal cultures (Tay and Yang 2002; Koutinas et al. 2007).

A major concern in lactic acid production by fermentation is to reduce the process costs with respect to substrate costs and production efficiency. Inexpensive and renewable materials can be used as substrates, including by-products of agricultural industries, food industries, and natural unutilized biomass such as starchy and lignocellulosic wastes (Nguyen et al. 2013).

Recently, lactic acid production has been studied with increased interest because of its application in the synthesis of biodegradable and biocompatible polylactic acid (PLA) polymers (Koutinas et al. 2007). L-(+) lactic acid can be polymerized to form polylactic acid (PLA). This polymer can be used in the manufacture of new biodegradable plastics. In comparison with petrochemical plastics, PLA production is considered a relatively immature technology at the industrial scale. This is mainly due to the high production cost of lactic acid – the feedstock for PLA (Abdel-Rahman et al. 2013).

Production of lactic acid from fermentation aiming the production of polylactic acid has increased, due to decreased in petrochemical resources and the problems of environmental pollution caused by the petrochemical industry. The pure polymers of poly(L-lactic acid) (PLLA) and poly(D-lactic acid) (PDLA) are relatively heat sensitive, while stereo complexes of polylactic acid produced by blending PLLA and PDLA have a melting point approximately 50 °C higher than their respective pure polymers and are more biodegradable. The ratio of L- and D-lactic acid influences the properties and the degradability of the resulting polylactic acid (Datta and Henry 2006; John et al. 2007b).

Cellulases

Cellulases, enzymes involved in cellulose hydrolysis, represent currently the third largest sale in the world market for enzymes (Singhania et al. 2010), due to their wide applications in several industry sectors, such as in extraction and clarification of fruit juices; as animal feed additive to enhance the absorption of nutrients, improving the feed value and performance of animals (Bhat 2000; Kuhad et al. 2011); in the textile industry for cotton softening and denim finishing; in the detergent industry to improve the appearance and color brightness, besides softening the garment and removing dirt particles trapped within the microfibril network (Bhat 2000); and in paper recycling (Singhania et al. 2010). However, cellulases may become the largest volume industrial enzyme, if ethanol fuel production from lignocellulosic biomass becomes a reality, since in this process, a step of enzymatic hydrolysis using cellulases is necessary.

Cellulases are relatively costly enzymes, and a significant reduction in production cost will be important for their commercial use in biorefineries. Strategies that will make the use of cellulases in biorefinery as a more economical process include the increase of volumetric productivity for commercial enzyme production, the production of enzymes using cheaper substrates, the production of enzyme preparations with greater stability for specific processes, and the production of cellulases with higher specific activity on solid substrates (Zhang et al. 2006).

Agro-industrial wastes such as wheat straw, corncobs, and sugarcane bagasse (pretreated or not) have been widely included in the nutrient media composition as

the main strategy in microbial cellulase biosynthesis and other enzymes that degrade biomass, due to their high cellulose content, wide availability, and low cost (Michelin et al. 2013).

Currently, Genencor International and Novozymes Biotech companies are the two largest producers of cellulases. Both companies have played a significant role in bringing down the cost of cellulase through active research and are continuing to bring down the cost by adopting novel technologies (Singhania et al. 2010). They reported the development of technology that has reduced the cellulase cost for the process of bioethanol production from US$5.40 per gallon of ethanol to approximately 20 cents per gallon of ethanol (Moreira 2005; Zhang et al. 2006).

A wide variety of microorganisms including fungi and bacteria have been reported to degrade cellulose by synthesizing enzymes of the cellulolytic complex. Filamentous fungi are especially interesting since they secrete these enzymes into the medium, with levels superior to those found in yeasts and bacteria. These microorganisms can degrade lignocellulosic wastes better than other microbes as they closely resemble their natural habitat.

One of the most extensively studied cellulase producers is the *Trichoderma reesei* fungus, which is capable of hydrolyzing native cellulose. It produces two cellobiohydrolases (CBHI and CBHII) and two endoglucanases (EG1 and EG2), in a rough proportion of 60:20:10:10, which together can make up to 90 % of the enzyme cocktail, while seven β-glucosidases – BGL I–VII – secreted by this fungus typically make up less than 1 % (Lynd et al. 2002; Aro et al. 2005; Herpoël-Gimbert et al. 2008). Other fungi that produce cellulases include *Aspergillus*, *Humicola*, and *Penicillium* (Singhania 2009).

Most commercial cellulases (including β-glucosidase) are produced by *Trichoderma species* and *Aspergillus species* (Zhang et al. 2006). Recently, Genencor Company has launched Accellerase®1500, a cellulase complex intended specifically for lignocellulosic biomass processing industries, which is produced with a genetically modified strain of *T. reesei*. This enzyme preparation is claimed to contain higher levels of β-glucosidase activity than all other commercial cellulases available today, to ensure almost complete conversion of cellobiose to glucose (Singhania et al. 2010).

The large market potential and the important role that cellulases play in the bioenergy and bio-based products industries provide a great motivation to develop better cellulase preparations for cellulose hydrolysis of lignocellulosic wastes.

Biocomposites

Currently, there is a wide variety of wood and non-wood resources suitable for the production of cellulose nanostructures. The use of non-wood resources such as agricultural/agro-industrial wastes is particularly interestingly due to their renewable nature (Alemdar and Sain, 2008; Lavoine et al. 2012). Besides, the shortage of natural resources such as wood and the concerns over the environmental impact of other widely used materials have encouraged researches with alternative materials (Ghaderi et al. 2014). Other advantage of non-wood materials is that the cellulose

microfibrils from wall of agricultural wastes are easier to break down than wood wall, and the fibrillation of this pulp demands less energy.

Microfibrillated cellulose (MFC) is being increasingly studied from a number of different cellulosic sources (Lavoine et al. 2012). Due to its nanometer scale, its high surface energy and its ability to form a nanoporous network, MFC has been studied for use in nanocomposites as a mechanical reinforcement (Siqueira et al. 2010) and as a dispersion stabilizer (Andresen et al. 2006).

All-cellulose nanocomposites are classified as biocomposite, a class of materials that has been recognized and studied during the past decade (Nishino et al. 2004). The matrix and reinforcement phases in these biocomposite materials are noncrystalline and undissolved cellulose, respectively (Soykeabkaew et al. 2009). These nanocomposites have promising properties, as they are a completely bio-based material and fully biodegradable. Besides, they also have remarkably high mechanical performance and transparency (Nishino et al. 2004; Gindl and Keckes 2005). These characteristics give composite materials the potential for many applications.

The use of MFC suspensions as coating slurries has several applications, such as in printing industry and, more recently, in the food packaging sector. One further possibility is the use of MFC in drug release applications (Lavoine et al. 2014). In the literature, there are diverse agricultural/agro-industrial sources, such as wheat straw and soy hulls (Alemdar and Sain 2008) and bagasse (Bhattacharya et al. 2008), that are being used to produce MFC.

4 Future Challenges and Trends of Cellulose

Recent advances in understanding the biochemical complex in cell wall structure and their biochemical characteristics offer new avenues for the development of new biological-based processes for biomass conversion to different bioproducts at industrial scale. In that sense, a huge potential exists in upgrading fuel and energy producing pathways into biorefineries in order to improve its financial performance and long-term sustainability. However, high production costs remain the bottleneck for large-scale development of this pathway. Another important issue is how extensively can biomass be utilized without causing significant and irreversible harmful environmental and social impacts.

One of the main problems during the pretreatment and hydrolysis of biomass is the variability in the content of lignin and hemicellulose. This variability depends on factors as the type of plant from which the biomass is obtained, crop age, method of harvesting, and others. This makes that no one of the pretreatment methods can be applied in a generic way for many different feedstocks (Claassen et al. 1999). The future trends for improving the pretreatment of lignocellulosic feedstocks also include the production of genetically modified plant materials with higher carbohydrate content or modified plant structure to facilitate pretreatment (Sanchez and Cardona 2008).

Therefore, the success and efficiency of the applied pretreatment must be accomplished by the proper selection of treatment conditions for raw materials that present different recalcitrance. A single pretreatment method does not provide efficient results due to its limited specificity. For this, the proper combination of pretreatment steps (firstly, for hemicelluloses solubilization and, secondly, for effective delignification) should be applied in order, not only to improve the effectiveness of the following biorefinery processing stages but also to avoid high contaminated hemicellulosic or lignin containing streams. These fractionation by-products could be properly exploited avoiding further purification steps, which are usually more expensive and require greater energy and amount of chemicals (García et al. 2014a). Thus, a number of lignocellulosic by-products and residues can be the focus of a biorefinery. The integration of the different processes outlined will certainly have a positive effect on the scientific, technological, economic, environmental, and social areas, not only for lignocellulosic materials but also for a wide range of coproducts (biofuels, chemicals, and others compounds).

Other challenges also need to be addressed including optimization of the fermentation technology in order to produce a range of bioproducts by selective fermentation of different chemicals, characterization of new enzymes or new enzymatic systems in order to lead to low-cost conversion of lignocellulosic biomass into biofuels and biochemicals, as well as logistics considerations and careful choice of raw material for the biorefinery.

Still in the context of future challenges and trends of cellulose, it is clear that different countries and regions have potential access to the dry matter as lignocellulosic wastes, for use in a commercial scale biorefinery. However, there are clearly a number of challenges that need to be addressed to the success of these processes based on renewable technologies that are expected to improve the environment and enhance the quality of life in rural areas through the diversification of the rural economy. Overall, these biorefineries will contribute to the establishment of a link between economic and social development and environmental protection.

Contents

Abstract

This chapter describes the different ways of performing sugarcane straw exploitation. This is an important agro-residue in Brazil that has a wide range of feasible applications. For these specific usages, it is essential to have an effective knowledge on the sugarcane straw fiber related to its chemical composition (lignin and carbohydrate contents) and on cellulose extraction processes. We address the recent studies on biological processes, such as alternative

pretreatment in combination with chemical processes and bleaching methods for residual lignin removal. This chapter also addresses some recent examples on the production of ethanol, bio-oil, enzymes, composites, and pulps from sugarcane straw. In addition, we discuss the development of lyocell textile fibers. The scientific and technological advances in the exploitation of sugarcane straw have a strong appeal, and the use of an agro-residue in this application is an important issue.

1 Introduction

The Brazilian industry currently has 380 sugarcane-ethanol plants that process approximately 600 million tons of sugarcane per year for the extraction of its sucrose-rich juice. Brazil is the greatest sugarcane producer in the world, with an estimated production of 587 million tons in 2013–2014 (UNICA 2013). This sizeable production leads to an accumulation of by-products, mainly sugarcane straw and bagasse. The sugarcane straw is composed of all the material removed before the cane is crushed in the harvesting and consists of plant tops and leaves (Gómez et al. 2010; Santos et al. 2012).

Significant biomass residues – either sugarcane bagasse or straw – are generated and become potential raw materials for the industry. One ton of sugarcane plant produces about 140 kg of straw and 140 kg of bagasse (in terms of dry mass), generating approximately 84 million tons of each sugarcane residue per year. The energy content of these residues can support its use for bioethanol production. Usually, the sugarcane bagasse is burned in the mills for steam and electricity generation, making the ethanol and sugar industry energetically sustainable (Ferreira-Leitão et al. 2010a; Santos et al. 2012).

In Brazil, about 50 % of the sugarcane straw is left in the field to prevent erosion and maintain moisture and soil agronomic properties. These properties are related to its carbon/nitrogen ratio and potassium, phosphorus, calcium, magnesium, and sulfur content. It also serves as weed control and preserves soil microbiota (Gómez et al. 2010; Ferreira-Leitão et al. 2010a). Moreover, as the traditional practice of burning sugarcane leaves prior to manual harvesting is being terminated (Brazilian Federal Law 2661/98 and São Paulo State Law 11241/02), the mechanized harvest will gradually take its place and higher quantities of strategically placed sugarcane straw will be available for industrial application (Gómez et al. 2010). Thus, it is

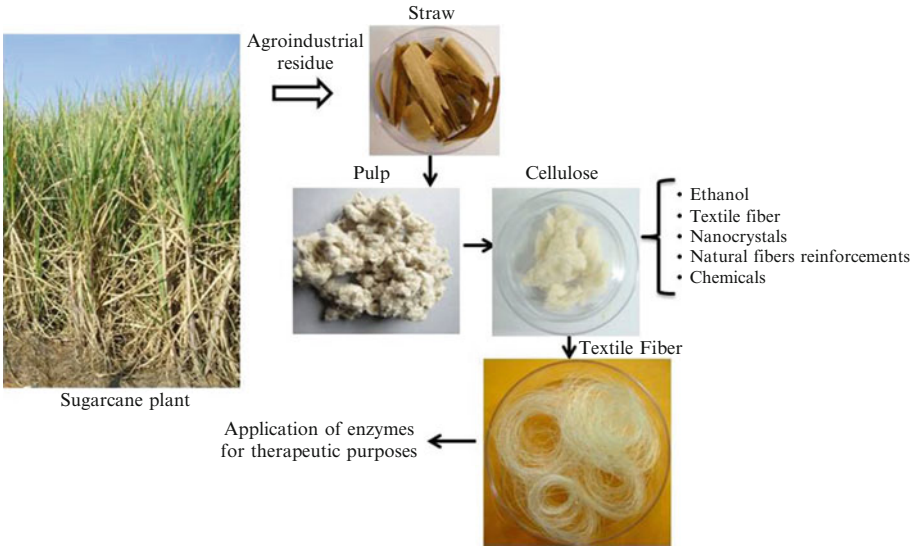

Fig. 1 Sugarcane straw and some potential applications based on its chemical composition

critical to evaluate the best applications and technologies for the use of this biomass. Figure 1 suggests some potential applications for sugarcane straw based on its chemical composition, which will be discussed in this manuscript.

2 Composition and Morphology of Sugarcane Straw

A large variation in chemical component content is observed on the sugarcane straw. Generally, it is composed of 32.4–44.4 % cellulose, 24.2–30.8 % hemicelluloses, and 12.0–36.1 % lignin. Ashes (2.4–7.8 %) and extractives (2.5–10.6 %) are also found in lesser proportions (Table 1). Dry leaves have markedly low lignin content and high ashes content in comparison with other sugarcane residues. The chemical composition varies depending on the material-collecting site, climatic conditions, stage of plant development, and variety (Gómez et al. 2010; Santos et al. 2012).

Cellulose is the most abundant component in sugarcane straw, as observed in Table 1. Cellulose is a linear homopolymer composed of glucose units linked by β-(1→4)-glycosidic bonds, forming cellobiose that is repeated several times in its chain. The interaction between the hydroxyl groups via hydrogen bonds in the chains limits the access of agents to the functional groups in the cellulose chain, which hinders both its solubilization and reactivity. Hemicellulose is a heteropolysaccharide composed of hexoses (D-glucose, D-galactose, and D-mannose), pentoses (D-xylose, L-arabinose), and acid units (acetic, D-glucuronic, and 4-*O*-methyl-D-glucuronic acid). Hemicellulose differs substantially from cellulose, as it is

(**b**) Internal part of sugarcane straw leaf showing the vegetable cell wall (2,750× magnification). (**c**) External part of sugarcane straw leaf showing the protection wall. (**d**) Fibrillar structure of sugarcane straw pulps

amorphous and has branches and lower molecular mass, which makes it easier to be hydrolyzed than cellulose. Xylan is the predominant hemicellulose in sugarcane biomass (Ferreira-Leitão et al. 2010b). Lignin is a noncarbohydrate complex aromatic macromolecule formed by radical polymerization of *p*-coumaryl, coniferyl, and sinapyl alcohols. The structure of lignin is heterogeneous and globular, with amorphous regions. Silicon is the predominant compound in sugarcane straw ashes. The sugarcane straw can contain up to 5 % m/m of sand and debris as impurities. The presence of impurities is due to the type of transport and harvesting of sugarcane (Gómez et al. 2010).

In the plant cell wall, lignin and hemicelluloses involve the cellulose elementary fibrils, providing protection against chemical and/or biological degradation (Santos et al. 2012; Aguiar and Ferraz 2011; Canilha et al. 2012). The lignin content and its distribution are responsible for the recalcitrance of lignocellulosic biomass to its chemical or enzymatic conversion (Santos et al. 2012; Canilha et al. 2012).

Sugarcane straw fibers have a common cellular morphology when compared to other lignocellulosic materials, as we can see in Fig. 2. The cell wall morphology shows a specific aspect for the internal (Fig. 2a, b) and external part of the straw leaf (Fig. 2c) and the cellulose from sugarcane straw by alkaline process (Fig. 2d).

Figure 2a presents the details of the sugarcane straw leaf cell, showing the vessel form, and in Fig. 2b, we can observe the walls of various adjacent plant cells. On the other hand, in Fig. 2c, we notice that there is a kind of globular form that seems to

involve the internal part. Visually, this external part is smoother than the internal part of the leaf. After the alkaline process, which will be presented in this work, a cellulose extraction results in fibrillar structure, as we can see in Fig. 2d.

3 Sugarcane Straw Fractionation for Cellulose Extraction

Pulping processes modify the lignocellulosic materials by disrupting the plant cell wall structure, removing, solubilizing, and/or fragmenting the lignin. The types of processes depend on the lignocellulosic material and on the purpose of the use of their fractions, which may be mechanical, physical, biological, and/or chemical (Focher et al. 1991; Wood and Saddler 1988; Kokta and Ahmed 1992).

The separation of lignocellulosic materials by a chemical process is the most widely used method in pulp and paper industries. The studied pulping processes for sugarcane straw in the literature are acetosolv (Gonçalves et al. 2008; Saad et al. 2008), ethanol/water (Moriya et al. 2007), and soda/anthraquinone (AQ) (Luz and Gonçalves 2001; Costa et al. 2013).

In the studies by Gonçalves et al. (2008) on acetosolv pulping of sugarcane straw, they used 93 % acetic acid (m/m) and 0.3 % hydrochloric acid (m/m) as catalyst and a straw/solvent ratio of 1:16 (m/v) with a 2-h cooking time at 115 ± 5 °C. In another work, a kinetic study of acetosolv pulping of sugarcane straw was performed, varying time (0–5 h) and acetic acid concentration (73–93 %). The catalyst concentration (hydrochloric acid) was defined at 0.3 % (m/m), and pulping temperature was 115 ± 5 °C. The pulp yields were 45–50 % after a 1-h treatment (Saad et al. 2008).

The ethanol/water pulping of sugarcane straw was carried out by Moriya et al. (2007). The influence of independent variables (temperature and time) on sugarcane straw cooking with solvent mixtures was studied, in order to determine the operating conditions for obtainment of pulps with high cellulose contents. An experimental 2^2 design was applied to temperatures of 185 and 215 °C and time of 1 and 2.5 h, with constant ethanol/water mixture concentration and straw/solvent ratio. The system was scaled up at 200 °C cooking temperature for 2 h with 50 % ethanol/water concentration and 1:10 (m/v) straw/solvent ratio to obtain a pulp with 3.14 cP viscosity and 58.09 kappa number. The pulp yields ranged from 45.18 % to 55.61 % (Moriya et al. 2007). At 215 °C, the pulp presented 33 % lignin content, and this amount is higher than in the pulps obtained at 185 °C and 200 °C. In organosolv pulping process, lignin reprecipitation occurs on cellulosic fibers (Xu et al. 2007).

In another method, the cellulose from sugarcane straw can be obtained by soda/AQ pulping. The pulping conditions adopted by Luz and Gonçalves (2001) were 16 % of Na_2O, 0.15 % AQ, and straw/liquor ratio of 1:12 (m/v). The pulp yield was about 35 %, presenting 83 % of cellulose content. The values for sugarcane straw pulp viscosity were low, about 5.7 cP (Luz and Gonçalves 2001). In alkaline pulping, the lignin reactions are based on two mechanisms: condensation and hydrolysis (Vallaquiran 1987). The former is undesirable, as it hinders the removal

of lignin and makes its solubilization in the pulping liquor very difficult. During hydrolysis, the alkali acts on the lignin, breaking the macromolecule into units of low molecular mass, which are soluble in the liquor. However, due to the aggressiveness of alkaline pulping reactions, the cellulose is also much degraded, decreasing the pulp yield. In order to minimize the carbohydrate degradation, AQ is utilized during treatment (Blain 1993).

Biopulping is also an alternative for the fractionation of lignocellulosic materials. This bioprocess is defined as a solid-state fermentation process carried out by white-rot fungi acting on lignocellulosic materials. Biopulping aims at minimizing some problems associated with conventional methods of chemical (pollution, low yield, and high cost) and mechanical pulping (high energy consumption, low mechanical strength pulp) (Akhtar et al.1998; Messner et al. 1998; Ferraz et al. 2008).

Biopulping of sugarcane straw has been carried out using the white-rot fungus *Ceriporiopsis subvermispora*. The results showed that this fungus is selective to lignin degradation, reducing cooking times and/or chemical loads in the subsequent pulping process (Saad et al. 2008). Manganese peroxidase was the main oxidative enzyme produced by *C. subvermispora* on sugarcane straw. Laccase and lignin peroxidase activities were not detected with the biodegradation time. Xylanase activities predominated on biodegradation time, reaching its maximum value on the 30th day. Cellulase levels were very low and did not attain the appropriate concentrations to allow determinations of filter paper activity based on the standard assay (Ghose 1987). After pretreatment with *C. subvermispora*, sugarcane straw was subjected to the acetosolv pulping process. Along with the pulping time, the viscosity for biopulps decreased (5.8–4.3 cP) after 5 h. However, for control pulps, the viscosity remained constant (~6.0 cP). The resulting pulp strength is low, but it can be used for the production of dissolving pulps or chemicals (carboxymethylcellulose, cellulose acetate, fuels) according to authors (Saad et al. 2008; Gonçalves et al. 2005). The control and biopulp yield were similar, reaching 45–50 % after 1 h. Within a 1-h reaction, the cellulose content in the biopulp was 65 %, and within 4 h, it reached 70 %. For the control pulp, the cellulose content was 60 % within a 1-h reaction, increasing to 65 % within 5-h pulping (Saad et al. 2008). The pulping kinetics showed that, for biopulps, the final lignin content was about 7.5 %, with a reduction of 40 % in the pulping time to reach 12.5 % pulp lignin. The factorial design showed that the biological pretreatment had a positive effect on the acetic acid reduction of 21.5 % during pulping process (Saad et al. 2008).

The pulping processes are not enough to extract all the lignin from the feedstock, why a stage for the bleaching of pulp is required. The treatment with sodium chlorite followed by extraction with sodium hydroxide releases chlorine, which reacts with lignin to oxidize and degrade it, thus producing substances soluble in sodium hydroxide (Machado 2000). After bleaching in a chlorite medium, the viscosity of the soda/AQ pulps decreased at 39.5 % (Luz and Gonçalves 2001). As the action of chlorite is not selective to lignin, the cellulose can be also degraded. Furthermore, during bleaching, the fibers were intensely stirred, causing the cellulose macromolecules to break and, in turn, decrease the viscosity of sugarcane straw pulps (Luz and Gonçalves 2001).

Legislative and environmental pressures have been forcing the pulp and paper mills to modify their bleaching technologies, mainly because of the chlorine used in the traditional sequences (Wang et al. 1992; Gonçalves et al. 2008). One of these modifications is the use of xylanases, which could be used together with conventional chemical sequences (Wong et al. 1997; Gonçalves et al. 2008). This enzyme degrades xylan, which constitutes a physical barrier for the action of bleaching agents on lignin. This facilitates the bleaching stage and reduces the consumption of chlorine (Viikari 1991). However, the cost of enzyme production and its low yield are major challenges in the use of these biocatalysts for industrial application. Strategies aimed at overcoming these challenges have mainly focused on hyper-producing microbial strains and using cheaper substrates (Kapoor et al. 2008; Ncube et al. 2012). Another strategy to reduce the enzyme cost is to reuse them several times in the process (Greeg and Saddler 1996; Gonçalves et al. 2008). The applicability of xylanases in sugarcane straw pulps and the possibility of recovering this enzyme were evaluated by Gonçalves et al. (2008). A commercial xylanase (Pulpzyme HC) was used for pulp treatment and was recovered and reused several times in the new pulp treatment without adding a new enzyme load. Furthermore, a combined process with fungal pretreatment of sugarcane straw (biopulping) and the acetosolv pulping was evaluated. The amount of recovered enzyme in the first treatment was approximately 7 % from the initial enzyme load. After the second treatment, no enzyme recovery was possible. Several factors interfered on xylanase recovery, such as composition, treatment medium (buffered or aqueous), and the methodology employed in the enzyme recovery (Gonçalves et al. 2008).

In addition, the chemical bleaching to remove residual lignin from the sugarcane straw pulp may be performed with hydrogen peroxide (Costa et al. 2013). With this chemical, Costa et al. (2013) evaluated a series that included three bleaching agents: sodium hydroxide (3 % m/m based dry pulp), diethylenetriaminepentaacetic acid (0.4 % m/m), and hydrogen peroxide (50 % m/m). After the bleaching stage, sugarcane straw pulps presented a reduction of 6.9 % to 1 % in the lignin content. This work used hydrogen peroxide (50 %), because cellulosic pulps should have a high level of chemical purity to obtainment of textile fibers (Costa et al. 2013).

The pulping and bleaching processes promote the isolation of fibers (cellulose-rich) from plant biomass. Therefore, the obtainment of pulps with high level of chemical purity is desired for the production of textile fibers, as the effectiveness of these two processes is an important aspect.

4 Textile Fibers

Textile fiber is a generic term for any type of natural, synthetic, or artificial material that forms the basic elements of a textile product (yarns, fabrics, knits, nonwovens, etc.), which is characterized by having a length of at least a hundred times greater than its diameter (Maluf and Kolbe 2003). In addition to the length and width or diameter of fibers, other characteristic properties – such as tensile strength, absorption, elongation, elasticity, and resistance to abrasion – are important in the

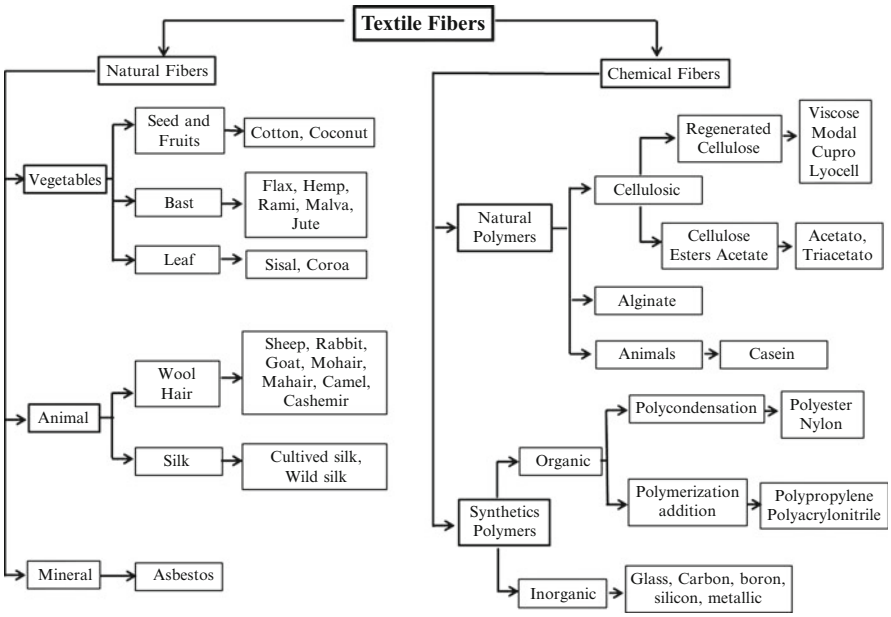

Fig. 3 Classification for textile fibers (Adapted Salem 2010)

development of a textile product. The characteristics of the fibers also play an important role in determining the machines that will be used in processing, the nature of treatments, and the products that are used (APIM 2001). Given the large amount of existing and currently in use fibers in the production of textile fibers, it is convenient to classify them (Fig. 3).

A natural or synthetic polymer should present certain essential properties or characteristics that are important to the forming process of fibers. The primary properties are known to include a high aspect ratio length, toughness and adequate strength, flexibility or malleability, cohesion "quality for spinning," reliability, and uniformity on the fibers (Ribeiro 1984; Neto Aguiar 1996). Secondary properties aim at increasing the comfort and improving maintenance: physical shape, density or specific gravity, luster, "regain," stretching, elastic recovery, resilience, thermal behavior, resistance to microorganism, chemical resistance, and resistance to environment and light. In addition, in order to qualify as a practical and economically feasible fiber, the material should have a competitive price, consistent supply, and be quantitative in terms of demand (Neto Aguiar 1996; Maluf and Kolbe 2003).

The minimal length-width ratio should be approximately 100, although the majority of fibers have a higher ratio. Fibers smaller than 1.27 cm are rarely used in yarn manufacturing. Cotton fibers, for example, have a length that varies between 1.27 and 5.08 cm. In addition, in order to be a satisfactory textile fiber, a raw material requires some properties such as toughness and resistance to equipment process. It also needs to provide adequate durability for the final product (Neto Aguiar 1996; Maluf and Kolbe 2003).

The fibers should be soft and flexible so that yarns and fabrics can be bent and have the capacity to move with the body, allowing freedom of movement. Reliability and cohesion are important to fiber properties. The fiber cohesion determines certain characteristics such as fineness, appearance, texture, volume, durability, and ease of maintenance. A yarn can consist of a single (monofilament yarn) or many fibers (multifilament yarn). Staple fibers (natural and manufactured) can be spun into yarns by twisting (staple yarns). Staple yarns have more surface texture and softness. A yarn can be made by blending several different fibers for unique properties (Neto Aguiar 1996).

When the properties or desired features are absent or only present at very low levels, selected finishes can be applied in order to introduce these features or increase those present at low levels. Therefore, several finishes may reduce or modify the undesirable characteristics of fibers due to their secondary properties (Araújo and Castro 1984; Maluf and Kolbe 2003).

Nowadays, due to the great evolution in manufacturing textile fibers that has occurred, new synthetic and natural fibers have been discovered. Particular attention is given to those obtained from polymers, concerning chemical man-made fibers from natural polymers.

Nature is the greatest source of extraction of raw materials for the manufacturing of industrial products; however, the high product demand means that the biosphere is increasingly threatened. In order to minimize the impacts, wastes from other industrial sectors, such as the agribusiness sector, have been increasingly sought after. In Brazil, among these residues, sugarcane bagasse and straw are generated on a large scale. Several processes have been reported to utilize sugarcane bagasse as raw material. These include electricity generation, pulp and paper production, and products based on fermentation. The various products from sugarcane bagasse include chemicals and metabolites such as alcohol and alkaloids, mushrooms, protein-enriched animal feed (single-cell protein), enzymes, etc. (Parameswaran 2009). One of the significant applications of the sugarcane bagasse is the production of protein-enriched cattle feed and enzymes. These applications can also be extended to the use of sugarcane straw. The textile industry is another sector that has great potential for the use of both bagasse and straw for the production of regenerated fibers, therefore reducing the use of raw material of high commercial value and contributing to the reduction of this waste in the environment (Parameswaran 2009).

4.1 Chemical Fibers from Natural Polymers: Artificial Fibers

Man-made textile fibers are those that do not occur in nature, although they may be composed of naturally occurring materials. Using the adjective “artificial” to designate some man-made fibers is not quite correct, because, in principle, they are all artificial, particularly if released before synthetic fibers. Artificial fibers are those produced from natural polymers (macromolecules) with emphasis on cellulose. The cellulosic fibers are made from cellulose that may be derived from wood

or to a lesser extent the "linters," which are short fibers covering cotton seeds. Within the cellulosic fibers, we can also consider two groups: (a) regenerated cellulose fibers, designated as such because the fibers, after its passage into spinnerets transformations, are ultimately made from cellulose. Its raw materials include viscose, modal, cupro, and lyocell. (b) Fibers derived from cellulose, so called because its passage into spinneret transformations generates acetate and triacetate (Neves 1987; APIM 2001).

The first one is the most common and a commercial man-made cellulosic fiber and is produced by viscose process. The viscose fiber is produced by the viscose process, which involves the production of cellulose xanthate solution. Cellulose xanthate is an alkali-soluble salt formed by the reaction of cellulose and carbon disulfide in the presence of strong alkali (Broughton and Brady 1995; Kennedy and Knill 2006). Extrusion of the viscose solution into a coagulating bath, containing sulfuric acid and other salts, causes the regeneration of cellulose (Cole 1992). During the viscose production process, chemical changes occur and these sulfur products arise: sulfur trioxide and hydrogen sulfide (SH_2), which saturate the bath and are released to the atmosphere. To effectively remove toxic gases into the atmosphere spinning viscose, machines have, at the top, a powerful extractor fan which takes the gases to a treatment plant (Neto Aguiar 1996). As legislation imposes ever-tighter restrictions, this is inevitably more and more costly and in some instances can limit the economic viability of the process (Cole 1992; Broughton and Brady 1995).

In recent years, there has been a great scientific and technological interest in the development of new methods of spinning cellulosic fibers, particularly in one that satisfies technical, economical, modern, and environmentally friendly demands (Navarret 2002).

4.1.1 Lyocell Fibers

Lyocell is a type of cellulose manufactured from dissolving pulp, also known as bleached wood pulp. A company known as Courtaulds Fibers, UK, was the first to develop and manufacture it in the 1980s. In 1990, Courtaulds announced a major investment in a production plant for its new cellulose-based man-made fiber, the Tencel (Cole 1992; Rosenau et al. 2001). Courtaulds developed a fiber spinning process based on the use of an amine oxide, *N*-methylmorpholine *N*-oxide (NMMO), to affect the dissolution (Cole 1992). Wood pulp and amine oxide, as a solution in water, are mixed and then passed to a continuous dissolving unit to yield a clear, viscous solution. This could be extruded onto a dilute aqueous solution of the amine oxide, which precipitated the cellulose as fiber. They are washed and dried and finally baled as staple or tow products as required by the market. The spin-bath and wash liquors are passed to solvent recovery systems (Borbély 2008). Literature data show that NMMO is highly recovered (up to 99.7 %), recycled, and reused in the process (Rosenau et al. 2001, 2003; Lim et al. 2003; Fink et al. 2001). Figure 4 shows Courtaulds' semicommercial production system.

The main disadvantage of the lyocell fiber is its relatively low surface energy, which makes it difficult for dyes to bind to it. This is not to say it is impossible to

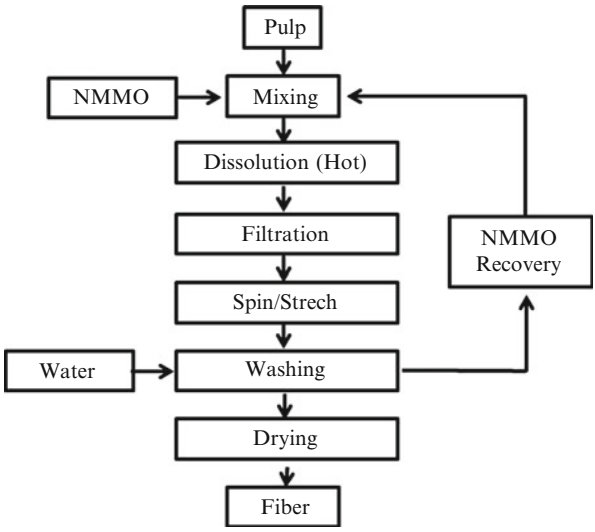

Fig. 4 Direct dissolution: Courtaulds' lyocell (Borbély 2008)

dye, but the required dyes are more expensive for this proposal. It also has a tendency to fibrillate during processing and wearing. Fibrillation is what causes the effect known as "pilling," where small balls of fiber form on the surface. The finishing processes of lyocell articles are considered different from the conventional processes of other fibers (Hall et al. 1995; APIM 2001; Borbély 2008).

Cellulase enzymes improve the appearance of lyocell fabrics and produce a more homogeneous, shorter fibrillation in a second process with mechanical agitation. This fibrillation, also called secondary fibrillation, provides a "peach skin feeling" to lyocell garments. Cellulase enzymes are well-known finishing agents that are successfully applied to remove fuzz fibers and pills from lyocell fabrics, as well as from all cellulosic-based fabrics (Morgado et al. 2000).

Renewable resources will become increasingly important as the planet's stocks of fossilized reserves are depleted and as governments realize that biomass can provide a truly sustainable, cost-effective source of energy and materials (Woodings 1995). Global trends in scientific and technological advancement in the area of new materials demonstrate the importance of using industrial and agro-industrial waste, for example, sugarcane bagasse and straw for the production processes of textile fibers. The use of this residue can minimize the environmental problems related to accumulation and reduce the use of noble raw materials (Costa et al. 2013).

4.1.2 Lyocell from Sugarcane Straw

In the studies by Costa et al. (2013), sugarcane straw cellulose was used for the production of lyocell. Sugarcane straw pulps were obtained after alkaline pulping using soda/AQ (yield of 30 %). For the removal of residual lignin, pulps were submitted to chemical bleaching. Afterward, bleached pulps were used to obtain fibers with NMMO. Fibers were obtained using 10 % (m/m) of cellulose, 80 % (m/m)

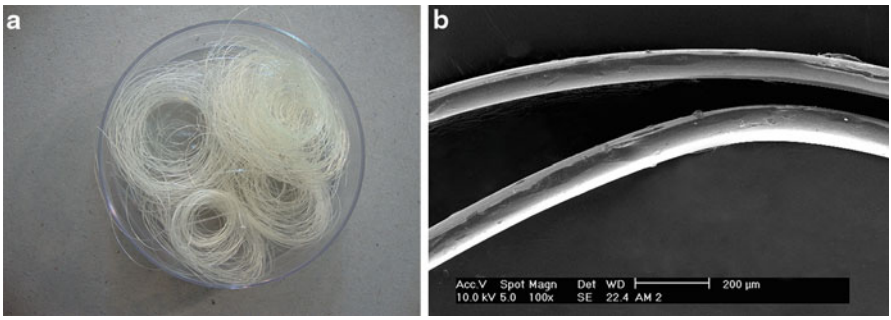

Fig. 5 Aspect of textile fiber from sugarcane straw (**a**) photo and SEM (**b**)

of NMMO, and 10 % (m/m) of water. The obtained gel was extruded with water at room temperature. The fibers showed water uptake capacity of around 73 %, and the mass loss profile was about 26 % in 30 days. Scanning electron microscopy (SEM) was used to evaluate the quality of fibers, as it allows evaluating the lack or the presence of scale, thickness, or irregularity forms along fibers (Fig. 5).

The cellulose fibers obtained from sugarcane straw, still in testing phase at laboratory scale for assessment of other important properties such as tenacity, were evaluated to confirm if they are compatible with the commercial lyocell produced from cellulose from wood pulp (Costa et al. 2013). Studies on enzyme immobilization on fibers, such as lysozyme and bromelain, for the obtainment of fibers with therapeutic properties for medical applications are under investigation. Immobilized enzymes are already being used in medical applications for clinical diagnosis and also for intra- and extracorporeal enzyme therapy. Applications in clinical analysis are mainly related to biosensors, which have been used to detect the presence of various organic compounds for many years. Glucose oxidase and catalase have been used to measure blood glucose concentration, cholesterol oxidase, and cholesterol esterase to determine cholesterol levels. In addition, enzymes can be immobilized on different prosthetic devices or used for extracorporeal therapies (e.g., artificial heart, artificial lung, artificial kidney, equipment for hemodialysis, and specific blood purification) as surface modifiers in order to increase the biocompatibility of these devices and to prevent blood clotting (Costa et al. 2004). Various methods have been developed for the immobilization of biocatalysts, which are being used extensively today. A wide range of support materials has also been employed for enzyme immobilization. The support type can be classified according to their chemical composition, as organic or inorganic supports, and the former can be further classified into natural or synthetic matrices. Immobilization techniques can be divided into different categories: physical, chemical, enzymatic, and genetic engineering methods (Costa et al. 2004).

Lysozymes are hydrolytic enzymes, characterized by their ability to cleave the β-(1,4) glycosidic bond between *N*-acetylmuramic acid and *N*-acetylglucosamine in peptidoglycan, the major bacterial cell wall polymer (Callewaert and Michiels 2010).

This enzyme is currently used as an antimicrobial agent in many types of foods, acting like "chemical condoms" or controlling microbial processes in the production of cheese, beer, and wine and antibacterial films in food packaging processes. A commercially available lysozyme is obtained by using a combination of conventional methods such as crystallization, precipitation, centrifugation, or adsorption (Wan et al. 2006). The human skin is known to produce several antimicrobial agents that form a chemical protection, such as lysozyme. Many of these agents act together to kill pathogenic microorganisms such as Gram-positive bacteria, Gram-negative bacteria, fungi, and viruses (Niyonsaba and Ogawa 2005; Zdybicka-Barabas et al. 2012).

The fibers obtained from the work carried out by Costa et al. (2013) are being tested for the immobilization of the enzyme bromelain in addition to lysozyme.

The medicinal qualities of pineapple are recognized in many traditions in South America, China, and Southeast Asia. These qualities are attributed to bromelain, a 95 % mixture of proteases. Medicinal qualities of bromelain include anti-inflammatory, antithrombotic, antiedematous, antimetastatic, fibrinolytic, and anti-cancer functions (Chobotova et al. 2010; Neetu et al. 2008; Fitzhugh et al. 2008; Kalra et al. 2008; Gupta et al. 2007). Because of its efficacy, safety, and lack of side effects after oral administration, bromelain has earned growing acceptance and compliance among patients as a phytotherapy drug. Another wide range of therapeutic benefits has been attributed to bromelain, such as inhibition of platelet aggregation, angina pectoris, bronchitis, sinusitis, surgical traumas, thrombophlebitis, pyelonephritis, and increased absorption of drugs, particularly antibiotics. Existing evidence derived from clinical observations, as well as from mouse- and cell-based models, suggests that bromelain acts systemically, affecting multiple cellular and molecular targets. In recent years, studies have shown that bromelain has the capacity to modulate key pathways that support malignancy. It is now possible to suggest that the anticancer activity of bromelain consists in the direct impact on cancer cells and their microenvironment, as well as in the modulation of the immune, inflammatory, and hemostatic systems (Chobotova et al. 2010).

The results of a study by Majid and Mashhadani (2014) showed that oral bromelain is an effective therapy to improve quality of life after the surgical removal of impacted lower third molars, with an effect on the postoperative sequelae comparable to that of preemptive diclofenac sodium. In conclusion, perioperative bromelain in a daily oral dose of 4×250 mg started 1 day before surgery and continued for 4 days showed a significant analgesic and antiedemic effect, a significant improvement in quality of life, and a limited reduction of trismus in the early postoperative period for patients who had undergone lower third molar surgery. Biochemical experiments indicate that these pharmacological properties depend only in part on the proteolytic activity, while suggesting the presence of non-bromelain protein factors (Wen et al. 2006).

5 Ethanol and Other Bioproducts from Sugarcane Straw

The application of sugarcane straw as industrial raw material for ethanol production requires its fractionation to increase the accessibility to carbohydrates. The first stage in this process is pretreatment, in which a considerable part of hemicelluloses is solubilized and cellulose is activated toward enzymatic hydrolysis. Different kinds of chemical, physical, biological, and physicochemical pretreatment methods have been proposed to disrupt the cellulose-hemicelluloses-lignin complex. Because of the intimate association between the three polymeric components of biomass, the release of carbohydrates is among the most important and urgent priorities in the research and development of new products. For new pretreatment methods, it is advisable to use cheap and easily recoverable chemicals and low-cost equipment. The use of environmentally friendly and low-energy-intensive approaches is highly desired. Reviews on the types of pretreatments applied to sugarcane biomass followed by enzymatic hydrolysis are reported in the literature (Santos et al. 2012; Canilha et al. 2012).

Ethanol produced from sugarcane residues is one of the most suitable alternatives for partial replacements of fossil fuels, because it provides energy that is renewable and less carbon intensive than gasoline. Bioethanol reduces air pollution and contributes to mitigate climate change by reducing greenhouse gas emissions. As feedstock cost is crucial, agro-industrial residues, which are less expensive than conventional agricultural feedstock, could play a central role in the production of ethanol and chemicals (Santos et al. 2012; Canilha et al. 2012).

Considering that 80 L of first-generation ethanol (from sucrose juice) are produced per ton of sugarcane and that a surplus of 36.5 L could be produced from the conversion of sugarcane residues (bagasse and straw), ethanol production could increase to almost 50 % without increasing the planted area, a topic of great environmental importance (Ferreira-Leitão et al. 2010a).

There has been an increase on the number of studies on the use of sugarcane bagasse for the production of second-generation ethanol (cellulosic ethanol). However, there are few works using sugarcane straw for this purpose. Krishnan et al. (2010) evaluated AFEX pretreatment to improve the accessibility of carbohydrates during enzymatic hydrolysis of sugarcane bagasse and leaves. The maximum glucan conversion of AFEX-pretreated bagasse and leaves by cellulases was 85 %. Supplementation with xylanases during enzymatic hydrolysis improved the xylan conversion up to 95–98 %. AFEX-treated sugarcane leaf residue was found to have a greater enzymatic digestibility compared to AFEX-treated bagasse. Co-fermentation of glucose and xylose from leaves produced 34–36 g L^{-1} of ethanol with 92 % theoretical yield (Krishnan et al. 2010).

In other work, Silva et al. (2010) verified the effectiveness of milling pretreatments on sugarcane bagasse and straw for enzymatic hydrolysis and ethanol fermentation. Glucose and xylose hydrolysis yields at optimum conditions using ball-milling pretreatment for straw were 77.6 % and 56.8 %, respectively.

Maximum glucose and xylose yields using wet disk milling were 68.0 % and 44.9 % for sugarcane straw, respectively. Ball milling decreased the cellulose crystallinity, while the defibrillation effect observed for wet disk milling samples seems to have favored enzymatic hydrolysis. Ethanol yields from total fermentable sugars using a glucose-fermenting strain reached 91.8 % for straw hydrolysates and 78 % when using a glucose-/xylose-fermenting strain (Silva et al. 2010).

Ferreira-Leitão et al. (2010b) used carbon dioxide as an impregnating agent (in comparison with sulfur dioxide) in steam pretreatment of sugarcane bagasse and leaves for ethanol production. The highest glucose and xylose yields for sugarcane leaves (97.2 % and 62.8 % respectively) were obtained after pretreatment at 220 °C for 5 min. On the other hand, Oliveira et al. (2013) evaluated the effect of temperature on steam explosion pretreatment for 15 min for sugarcane dry leaves followed by sodium hydroxide delignification. The pretreatments led to remarkable hemicellulose solubilization, with the maximum (92.7 %) for pretreatment performed at the highest temperature (200 °C). Alkaline treatment of the pretreated materials led to lignin solubilization above 80 %. All pretreatment conditions led to high enzymatic conversion of cellulose, with the maximum (80.0 %) achieved at 200 °C. The best effect of delignification was observed on the material pretreated at 180 °C, increasing its enzymatic conversion from 58.8 % to 85.1 %.

The components of sugarcane straw can also be utilized as substrates for the production of enzymes by solid-state fermentation. Singh et al. (2008) evaluated diverse fungi and bacteria to produce cellulases and xylanases during the biodegradation of sugarcane dry leaves. The total cellulose and lignin content of the substrate were significantly reduced by the microbial action. Maza et al. (2014) evaluated the production of oxidative and hydrolytic enzymes on this same agro-industrial residue. Enzymes as laccases, peroxidases, xylanases, endoglucanases, and β-glycosidases were produced in vitro by autochthonous fungi in sugarcane plantations. Hydrolytic enzymes as cellulases and xylanases are actually important to biomass enzymatic conversion, whereas laccases and peroxidases are effective for bioremediation of organopollutants (Durán and Esposito 2000; Aguiar and Ferraz 2011; Canilha et al. 2012).

Sugarcane straw can be used for bio-oil production by pyrolysis process. Bio-oil is a very complex mixture containing many organic compounds formed by the thermal degradation of plant biomass. Using two-dimensional gas chromatography coupled with time-of-flight mass spectrometry, Moraes et al. (2012) identified 123 compounds in sugarcane straw bio-oil, mainly oxygenated compounds (acids, ethers, aldehydes, ketones, and phenols) with a predominance of furfural and hexenoic acid. These compounds can be important feedstocks for the chemical industry and for energy purposes. During biomass pyrolysis, the generated solid residue, known as biochar, can present adsorptive properties. Melo et al. (2013) evaluated chromium and zinc sorption capacity by sugarcane straw-derived biochar. The authors observed higher sorption capacity in contaminated soils for biochars from highest pyrolysis temperature, which is attributed to their highest superficial area and porosity (Melo et al. 2013).

Composite materials from natural fibers have been intensely studied in recent years, and the sugarcane straw also can be used for this application. Luz et al. (2010) and Miléo et al. (2010) evaluated the use of sugarcane straw cellulose as reinforcement of polypropylene and polyurethane, respectively. These composite materials presented good mechanical and thermal properties, regardless of the matrix. Associated with that, the other important application for sugarcane straw can be the nanocrystals. The nanocrystals from cellulose can be extracted after hydrolysis, as we observed in studies with sugarcane bagasse and other agro-residues (Teixeira et al. 2011; Johar et al. 2012).

6 Conclusions and Future Perspectives

This work described potential applications for sugarcane straw. The appeal of the search for new ways to avail sugarcane straw is strong, and the economic factor has a greater impact on analyzing their processing and utilization. The economic use of sugarcane straw will depend on further research on the cost-effectiveness of collecting, loading, and transportation technologies, in addition to the cost of using this material, turning it into a higher commercial value product. In this work, we cited some products that can be obtained from sugarcane straw (ethanol, bio-oil, enzymes, enzyme support, composites, cellulose pulp, and commercial fibers). It remains to be evaluated which process can be economically viable for the obtainment of products using sugarcane straw as raw material.

Contents

Abstract

Enzymes are the key substances responsible for a variety of biotechnological processes involved in the production of useful bioproducts. Malt and microbial species (bacteria, fungi, etc.) are the main sources of endogenous hydrolyzing enzymes (EHEs). EHEs are primarily involved in the digestion of complex substrates into simpler units and the resulting formation of biological products. Based on origin and substrate specificity, EHEs are categorized into cell wall-, starch-, protein-, lipid-, nucleic acid-, polyphenol-, and thiol-hydrolyzing enzymes. The substrate specificities and reaction mechanisms of individual EHEs and groups of EHEs have been verified through isolated and purified enzymes. A number of methods have been reported for high-yield, economically feasible isolation of enzymes. The endogenous enzymes contained in microbial cells are separated from cells, cellular fragments, and organelles through several cell lysis and separation methods. Analysis of the mechanism of action has revealed that most enzymes systematically undergo biological processes through

a cascade of enzyme-specific reactions. The applications of these EHEs are involved in almost every aspect of human and animal life and are important in food, animal feed, textile, paper and pulp, fuel (energy), pharmaceutical, and chemical industries. In this chapter, we describe the origins, classes, isolation techniques, mechanisms, and applications of various EHEs with examples from updated literature.

Keywords
Endogenous hydrolyzing enzyme • Malt • Microbial species • Cell lysis • Mechanism of action

1 Introduction

Most of biochemical reactions occur spontaneously, while others depend on specific catalysts in order to reduce the magnitude of the energy difference essential for successful conversion of substrate into product (Illanes 2008). Enzymes are highly specialized catalysts that lead to increases in reaction rates and the specificity of metabolic reactions, from simple to highly complex biological reactions. Additionally, each biological reaction may be catalyzed by a specific enzyme, enabling reactions to function at rates required to sustain life. In theory, enzymes should not be consumed or altered during conversion of the substrate into product. However, in practice, the sustainability and functionality of any enzyme during reaction catalysis is strongly dependent upon the conditions adopted for substrate conversion because enzymes are primarily proteins (Shuler and Kargi 2001).

The enzymes catalyzing a biological reaction can be broadly divided into two types (exogenous hydrolyzing enzymes and endogenous hydrolyzing enzymes [EHEs]), based on their source. Generally, exogenous enzymes are expensive and ultimately increase the final cost of a bioproduct. Moreover, optimization of operational conditions, such as selection of appropriate temperature, pH, and substrate and enzyme concentrations, is a tedious job. In contrast, EHEs are attractive candidates for industrial-scale production of various bioproducts. All biological processes and metabolic pathways are driven and regulated by a group of enzymes catalyzing a cascade of reactions. These enzymes can act on the substrate both in vivo and in vitro and mediate reactions that ultimately result in improved product yields, up to severalfold. However, in the absence of a biological catalyst, the reaction rate is retarded, and biological reactions are ultimately blocked. EHEs are also advantageous in that they are encoded by the genome of a particular cell, which controls the expression level and activity of the EHE, resulting in enhanced biological activity within the same cell. Generally, EHEs are expressed within the cell when required; however, their expression can be regulated (enhanced or suppressed) depending on the cell's needs and on environmental conditions. Khattak et al. (2012) reported the presence of several EHEs from waste fermentation broth; these EHEs included starch-hydrolyzing enzymes,

cellulose-hydrolyzing enzymes, cell wall-hydrolyzing enzymes, protein-hydrolyzing enzymes, lipid-hydrolyzing enzymes, and several other important enzymes of industrial importance (Khattak et al. 2012).

Cell extracts containing EHEs can be isolated through cell disruption and further processed and utilized for various useful applications, such as development of synthetic pathways, cell-free enzyme systems, and commercialization. Cell disruption can be carried out by various methods, including chemical, enzymatic, alkaline lysis, and mechanical insults, such as ultrasonication, bead beating, and high-pressure homogenization. The obtained cellular extracts are further evaluated for extracellular and intracellular enzymes from cells and cellular fragments, respectively, through various approaches, such as filtration, centrifugation, flocculation, and flotation. Because the obtained extract possesses a lower concentration of enzymes, extracts can be further concentrated through various approaches, such as thermal methods, precipitation using different reagents, and ultrafiltration. For enhanced activity and storage to prior utilization for various purposes, enzymes can be further purified through crystallization, electrophoresis, and various chromatographic techniques.

The ease of use, cost-effectiveness, distinctive properties, and efficacy of EHEs make them attractive candidates for utilization in various industries, including breweries, food processing, and several medical and pharmaceutical industries. This chapter briefly describes the history of EHEs and then introduces various types of EHEs based on the type of substrate; discusses different techniques employed for the isolation, separation, and purification of EHEs from various sources; and describes the mechanisms of action of various EHEs.

2 History of EHEs

Hundreds of years have passed since humankind started to use enzymes for the production of beverages and baking products, as first described by ancient Egyptians. Indeed, ancient Egyptians used biological catalysts to produce beer, wine, bread (leavened bread), and cheeses, and later civilization used biological catalysts to make yogurt and other fermented milk products, pickles, vinegar, butter, and sauerkraut (Steinkraus 2002). In late eighteenth century, de Réaumur (1752) and Spallanzani reported that gastric juices secreted by the stomach are responsible for the digestion of meats (de Réaumur 1752; Modlin and Sachs 2004). In later years, a number of similar phenomena were observed, including endogenous secretions in plant extracts and saliva, which participate in the breakdown of starch into simple sugar. In 1814, glutinous (proteinaceous) secretions were reported to be responsible for the hydrolysis of starch into sugar (Segel 1993). Although the substances involved in digestion of meat, starch, and amygdalin have been identified, these early studies did not define these endogenous secretions and their mechanisms of action (Williams 1904).

After the first clear identification of endogenous enzymes made by Payen and Persoz in 1833 (Payen and Persoz 1833), it was unclear until the nineteenth century

whether the molecules responsible for the catalysis of biological processes belonged to living species or were chemical substances. The substance they obtained (referred as "diastase") was employed for the hydrolysis of starch. A second well-known enzyme obtained from an animal source in 1836 was pepsin, described by Schwann as the water-soluble factor found in gastric juice that was responsible for albumin digestion (Modlin and Sachs 2004). The next year (1837), Berzelius elucidated the details of the catalyst, which, by its mere presence, could "exert its influence and arouse affinities and relativities in the complex body thereby causing a rearrangement of the constituent of the complex body." By studying the mechanism of action of both pepsin and diastase, along with phenomenon observed during yeast fermentation, Berzelius concluded that in all three cases, only a single chemical agent (called the catalyst) is responsible for conversion of one substance into other (Segel 1993). In 1838, Charles Cagniard de Latour investigated the nature of yeast and its involvement in alcohol fermentation. His findings supported the hypothesis that fermentation was caused by a living organism (Berche et al. 2009). After additional careful studies, Louis Pasteur reported the presence of some vital force, referred to as a "fermenter," which was responsible for fermentation, thus providing a strong foundation for the vitalistic protoplasm theory (Dubos 1951).

Like most notable chemists of the time, Stahl and Liebig initially accepted the existence of a "vital force" but subsequently introduced the concept of the inorganic world, in contrast to the "vital force," in the 1850s (Goujon 2001). In their era, a clear distinction was made between organized and unorganized ferment claim to be involved in the biological process. In 1858, Moritz Traube, a student of Liebig, clearly defined this entity as a specific protein-like compound, which catalyzes all cellular activity, including fermentation, respiration, and putrefaction; later, he proposed the theory of enzyme/substrate interaction that occurs inside the cell (Rollin et al. 2013; Renneberg 2008). In 1878, Kühne introduced, for the first time, the term "enzyme," meaning "in yeast," for both the organized and unorganized ferment (Whitehurst and Oort 2009; Stead 1987). The suffix "*ase*," most commonly used as the suffix in enzyme names, was proposed by Duclaux and became the standard for enzyme nomenclature in 1883; this suffix generally indicates the substrate on which the enzyme acts (Traut 2008). The concept of the lock-and-key model was proposed by Emil Fischer in 1894 to account for the high degree of specificity of an enzyme toward a particular substrate (Segel 1993).

Moritz Traube isolated an endogenous enzyme in its active form from potatoes and proved that an enzyme from a plant extract was able to catalyze a reaction in vitro. In 1897, the concept of a cell-free enzyme system, proposed by two brothers, Hans and Edouard Buchner, provided a solid and logical background to refute Pasture's assertion of "vital force" and Liebig's "organic world" (Segel 1993). The same year, Gabriel Betrand proposed the role of heat-stable, dialyzable material, which he called "*coenzymes*," in cell-free glucose fermentation (Semenza and Turner 2005). In 1902, Henri derived a mathematical equation for the effects of substrate concentration on the enzymatic reaction rate, and Sorenson described the effects of pH on enzyme activity in 1909 (Kuby 1990). The industrial

use of endogenous enzymes began in 1913, when German chemist Otto Röhm evaluated the specific activity of pancreatic trypsin for the removal of proteinaceous stains from cloth (Aehle 2007). The same year, Michaelis and Menten reestablished the equation derived by Henri and further evaluated this equation after confirming careful control of pH. The Henri-Michaelis-Menten equation is based on the chemical equilibrium of enzyme kinetics (Kuby 1990). In 1925, Briggs and Haldane explained the steady-state concept of enzyme kinetics and modified the Michaelis-Menten equation with the more general valid assumptions of the steady state (Palmer and Bonner 2007). Today, both approaches are still applied to enzyme kinetics. In 1926, Summer obtained the enzyme urease in crystalline form and announced it to be a simple protein (Sumner 1948). However, the crystalline forms of several other enzymes were not established until the 1930s, when Northrop and his fellows crystallized pepsin, trypsin, and chymotrypsin as pure crystals (Segel 1993). In the 1940s and 1950s, hundreds of new enzymes were discovered, purified, and crystallized (Segel 1993). In 1955, the complete sequence of amino acids of insulin was reported by Sanger (Sanger 1960). In 1960, ribonuclease was sequenced, and the first chemical synthesis of an enzyme (ribonuclease) was achieved in 1969 (Segel 1993). In 1957, Kendrew discovered the three-dimensional geometry of myoglobin through X-ray diffraction analysis (Kendrew 1963). In 1963, the primary structures of two enzymes, pancreatic ribonuclease and egg white lysozyme, were reported by Smyth et al. and Canfield as containing 120 amino acids, further supporting the protein-like nature of these enzymes (Smyth et al. 1963; Canfield 1963). In 1965, the isolation of *Taq* polymerase from *Thermus aquaticus* by Thomas D. Brock set the foundation of a new era in molecular biology and biotechnology (Rollin et al. 2013). Heat-shock proteins (HSPs), identified by Tissieres et al. in 1974, are group of polypeptides expressed under stress conditions that play an important role in the stability of endogenous enzymes under stress conditions (Tissieres et al. 1974).

Currently, the most common definition of an enzyme is "a protein with catalytic activity based on the specific activation of its substrate." However, with the discovery of other catalytic biomolecules, such as catalytic RNA, the identification of ribozymes in 1982 began a new debate regarding the definition of the enzyme (Yonaha and Soda 2007). The efficiency of an enzymatic reaction was increased to a certain extent by using different advanced techniques, including immobilization, in the early 1980s (Rollin et al. 2013). In contrast to cellular extracts, a reconstituted cell-free enzyme system was employed by Welch and Scopes in 1985 for the production of bioethanol from a glucose solution. Compared to the Buchner system, the Welch and Scopes reconstituted cell-free system was evaluated as an effective system for bioethanol production, characterized by near-100 % efficiency, which was quite an achievement (Welch and Scopes 1985).

The concept of the reconstituted cell-free system, as proposed by Welch and Scopes, was the beginning of studying the activities of enzymes in a sequential manner, similar to the methods for studying particular metabolic pathways. Later, this concept was further extended to include the production of certain others biocommodities, including biofuels, biochemicals, and food (You and Zhang 2013).

Endogenous enzyme-based biotransformation systems have become an interesting tool for the production of certain other high-value biocommodities. Using a combination of selective endogenous enzymes as a single biosystem for the biotransformation of substrate into product has advantages over whole-cell systems; for example, this method is highly targeted and generally much more efficient. The best example is the cell-free enzyme system developed by Khattak et al. (2014); this system consists of both glycolytic and fermentation enzymes and can be used for bioethanol production at elevated temperatures at which conventional fermentation is impossible (Khattak et al. 2014).

3 Types of EHEs

Each cell contains genetic information encoding thousands of different endogenous enzymes, and their expression and activity in specific cell compartments usually determine which of the many possible biological reactions take place within the cell. Enzyme expression is either induced within the cell or supplied exogenously under definite circumstances. It is critical to understand the characteristics of the enzyme and its specificity to the available substrate before application in a specific biological process. Known EHEs are classified based on substrate specificity into the different categories shown in Table 1.

3.1 Starch-Hydrolyzing Enzymes

Starch, the most common storage carbohydrate in plant, is made up of D-glucopyranose linked together via α-(1→4) and α-(1→6) glycosidic bonds. Structurally, starch consists of 20–25 % amylase, a linear and helical molecule, and 75–80 % amylopectin, a branched molecule. Amylopectin provides the starch with a greater tendency to resist enzymatic hydrolysis because the residues involved in α-(1→6) glycosidic branch points constitute 4–6 % of the glucose present. Although most of the hydrolytic enzymes are specific for α-(1→4) glycosidic linkages, α-(1→6) glycosidic bonds must also be cleaved for complete hydrolysis of amylopectin to glucose. The most recently developed processes carry out the hydrolysis of starch in three steps, involving gelatinization, liquefaction, and saccharification. In gelatinization, nanogram-sized starch granules are dissolved in water or some other liquid to form a suspension. This is followed by liquefaction, which involves partial hydrolysis of starch through enzymes. Finally, glucose and maltose are formed through saccharification by enzymes.

Malt contains several starch-hydrolyzing enzymes, such as α-amylase, β-amylase, limit dextrinase, and β-glucosidase (MacGregor 1987; Bamforth 2009). Alcohol precipitates of malt extracts (known as diastase), which liquefy starch into simple sugars (Payen and Persoz 1833), have two catalytic units (Maercker 1878) classified as α-amylase (or dextrinogen) and β-amylase (or saccharogen) (Ohlsson 1926). α-Amylases from different sources, such as

Table 1 Major classes of hydrolyzing enzymes involved in the hydrolysis of longer chain into their respective constitutive subunits

Substrate	Class	Enzyme	Reference
Cell wall	1	Endoglucanase	Khattak et al. 2012

Bacillus amyloliquefaciens, *B. licheniformis*, *A. oryzae*, *A. niger*, and *B. subtilis*, act as endo-acting enzymes that randomly cleave α-(1→4) glycosidic linkages to yield α-dextrins and maltose. These molecules play an important role in the metabolism of starches and are usually produced in the beginning of the malting process, after which they are moved to and stored in the mature endosperm of seeds

(Svensson 1994). β-Amylase from malted barley is a typical exo-acting enzyme that cleaves the α-(1→4) glycosidic linkage from nonreducing ends, yielding limit dextrins, β-glucose, and β-maltose (Hoseney 1994; Svensson 1994). Glucosidases also function as exo-acting enzymes and cleave α-(1→4) glycosidic linkages in starch. Compared to β-amylase, glucosidase has the ability to bypass the side chain at α-(1→6) bonds. Glucoamylase from *A. niger* cleaves α-(1→4) and α-(1→6) glycosidic linkages from nonreducing ends to yield β-glucose. Pullulanase from *B. acidopullulyticus* cleaves α-(1→6) glycosidic linkages to yield straight-chain maltodextrins. Limit dextrinase cleaves amylopectin α-(1→6) linkages of branched dextrins to complete the hydrolysis of starch into its monomeric sugars at the end of the starch-hydrolyzing reaction (Bowles 1996).

3.2 Cellulose-Hydrolyzing Enzymes

Cellulose is an organic compound that constitutes the major portion of plant cell walls and vegetable fibers, such as cotton, ramie, and wood. It is a highly stable, water-insoluble polysaccharide consisting of chains of glucose monomers. The molecular formula of cellulose is $(C_6H_{10}O_5)_n$, producing an unbranched homopolysaccharide composed of α-D-glucopyranose units linked by (1→4) glycosidic bonds (Purves 1954). It is the most abundant biopolymer on earth and is produced at a rate of about 1×10^{11} tons per year. The enzymes responsible for cellulose hydrolysis are referred as cellulases.

Cellulases are *O*-glucoside hydrolases (GHs) that hydrolyze the β-1,4 linkages of cellulose. These enzymes are predominantly found among prokaryotes and fungi (Hildén and Johansson 2004). Several fungal species are known to produce cellulases with known catalytic abilities (Cunningham and López 1994). Cellulase genes have also been identified in the marine yeast *Aureobasidium pullulans* and *Bursaphelenchus xylophilus* (Chi et al. 2009). GHs are classified into cellulase families based on amino acid sequence similarity. Out of the 122 families of proteins identified to date, 14 correspond to cellulases. Most cellulases form complexes with other GHs; these complexes contain a catalytic module, a highly *O*-glycosylated linker, and a cellulose-binding module (CBM). The latter domain facilitates cellulose hydrolysis by holding the catalytic module in close proximity to its substrate. Cellulases are classified, depending on their enzymatic activity, in three major groups: exoglucanases, endoglucanases, and β-glucosidases. Exoglucanases catalyze the successive hydrolysis of residues from the reducing and nonreducing ends of the cellulose polysaccharide, releasing cellobiose molecules as the main product of the reaction (Aro et al. 2005). These enzymes account for 40–70 % of the total components of the cellulase system and are able to hydrolyze crystalline cellulose. Exoglucanases are monomeric proteins with molecular weights ranging from 50 to 65 kDa, although smaller variants (41.5 kDa) have been identified in some fungi. Exoglucanases have low levels of glycosylation (from 0 % to 12 %), their optimum pH is 4.0–5.0, and their optimum temperature varies from 37 °C to 60 °C, depending on the specific enzyme-substrate

combination. Endoglucanases randomly cleave internal linkages in amorphous cellulose filaments, generating randomly sized oligosaccharides and creating new chain ends that can in turn be attacked by exoglucanases (Aro et al. 2005). These are the enzymes that initiate the cellulolytic process, randomly cleaving internal linkages at amorphous regions of the cellulose fiber and creating new reducing and nonreducing ends that are susceptible to the action of cellobiohydrolases. Endoglucanases are monomeric enzymes with molecular weights ranging from 22 to 45 kDa. Endoglucanases are not glycosylated; however, they sometimes may be conjugated with relatively low amounts of carbohydrates (from 1 % to 12 %). These enzymes function best at an optimal pH of 4.0–5.0 and temperature of 50–70 °C. β-Glucosidases hydrolyze cellobiose, releasing two molecules of glucose, and thereby provide a carbon source that is easy to metabolize. These enzymes have molecular weights ranging from 35 to 640 kDa; they can be monomeric, reaching molecular weights of approximately 100 kDa, or exist as homo-oligomers, such as in the yeast *Rhodotorula minuta*. β-Glucosidases are generally glycosylated and have an optimal pH of 3.5–5.5 and temperature of 45–75 °C. The activity of a cellulase enzyme system is much higher than the sum of the activities of its individual subunits, a phenomenon known as synergism. Cellulase systems are not just simply a conglomerate of enzymes with components from all three cellulase types, but act coordinately to efficiently hydrolyze cellulose fibers (Lynd et al. 2002).

3.3 Cell Wall-Hydrolyzing Enzymes

The plant cell wall is a highly organized network of lignocellulosic material containing cellulose and cross-linked glycans. The cell wall constitutes the outermost boundary in most cell types. It is localized outside the cell membrane and provides the inner cell material with structural support and protection. The cell wall also acts as filtering mechanism and prevents the cell from expanding. Chemically, the cell wall of starch endosperm is composed of (1→3, 1→4)-β-D-glucans (75 %), arabinoxylane (20 %), cellulose (2 %), glucomannan (2 %), and traces of acetic and ferulic acids. Aleurone cells are composed of arabinoxylane (71 %), (1→3, 1→4)-β-D-glucans (26 %), and 3 % cellulose and glucomannan (Fincher 1992; Lazaridou et al. 2008). A number of cell wall-hydrolyzing enzymes are present in malt, including endoglucanase, exoglucanase, arabinofuranosidase, esterase (Bamforth et al. 2009), carboxypeptidase (Bamforth et al. 1979; Sørensen et al. 1989), xylanase (Chithra and Muralikrishna 2008), and β-glucosidase (MacGregor 1987). The cell wall-hydrolyzing enzymes are glycosyl hydrolases, which comprise one of the two main classes of carbohydrate-active enzymes (Jamar et al. 2011).

The (1→3, 1→4)-β-D-glucans are also referred as β-glucan, a linear polysaccharide composed of an unbranched chain of D-glucose residues linked together by β-(1→4) and β-(1→3) bonding with a ratio of 3.2:1–6.6:1 (Jamar et al. 2011). Based on their solubility in water, these compounds are classified as either soluble

or insoluble (Swanston and Ellis 2002). The molecular weight of β-glucan varies from 800 to 1,220 kDa (Jin et al. 2004). β-Glucans are hydrolyzed directly by β-glucan exohydrolases into glucose or indirectly by a number of enzymes involved in removal of the outer layer of the cell wall followed by hydrolysis into glucose. Enzymes participating in the breakdown of β-glucans include (1→3)-β-glucanase, carboxypeptidase, phospholipases, (1→4)-endo-β-glucanase, feruloyl esterase, and arabinofuranosidase (Jin et al. 2004).

Xylan is a major structural component of plant cell walls and is the second most abundant renewable polysaccharide in nature (after cellulose) (Collins et al. 2005). Xylan interacts with lignin and cellulose via covalent and noncovalent linkages; these interactions are important for both protecting the cellulose microfibrils against biodegradation and maintaining the structural integrity of cell walls. Due to its heterogeneity and complex nature, the complete breakdown of xylan requires the action of a variety of hydrolytic enzymes (Biely 1985; Coughlan and Hazlewood 1993). Degradation of the xylose backbone depends on xylanases, which cleave bonds within the polymer, and β-xylosidases, which release xylose units from xylobiose and xylooligomers. Four enzymes, endo-β-(1→4)-xylanase, exoxylanase, β-xylosidase, and α-arabinofuranosidase, are involved in the hydrolysis of arabinoxylan (Hrmova et al. 1997). Although exoxylanase cleaves the outer β-(1→4) xylosidic linkages, endo-β-(1→4)-xylanase attacks inner β-(1→4) xylosidic linkages in arabinoxylan polymers, separating the arabinofuranosyl residues (Egi et al. 2004). β-Xylosidase catalyzes the hydrolysis of β-(1→4) xylosidic bonding within xylo-oligosaccharides, while arabinofuranosidase cleaves the α-(1→2) and α-(1→3) linkage formed between arabinofuranose units.

3.4 Protein-Hydrolyzing Enzymes

Proteins are large biological molecules consisting of one or more chains of amino acid residues. Proteins perform several principle functions, such as catalyzing metabolic reactions, facilitating the replication of DNA, mediating stimulus responses, participating in transport, and maintaining the structures of different organelles in the cell, including the nucleus, nuclear membrane, and cell membrane. Chemically, the building blocks of proteins (i.e., amino acids) are linked together through peptide bonds. These bonds are hydrolyzed by a group of enzymes designated as peptidases, which account for about 2 % of genes within the genomes of various organisms. Peptidases are important for many biological processes, including digestion of food proteins, recycling of intracellular proteins, the blood coagulation cascade, antigen presentation, and activation of a variety of proteins, such as enzymes, peptide hormones, and neurotransmitters.

Certain proteolytic enzymes synthesized during germination are involved in the production of free amino nitrogen (FAN) and di- and tri-amino acids through their synergistic action. These enzymes can provide a greater exposed surface area for starch-hydrolyzing enzymes (Briggs 1998). All enzymes share the same substrate (polypeptides), but have different catalytic sites. The product is a modified protein

that ultimately results in seed softening and increased friability being required for the effective growth of seedlings (Wentz et al. 2004). Some of the enzymes involved in protein modification already exist in mature barley grain, while some are synthesized de novo in aleurone cells during germination (Briggs 1992). Endopeptidases and exopeptidases are two principal groups of malt proteolytic enzymes. Endopeptidases cleave the bonds between two amino acids in a protein molecule at random, producing relatively smaller peptide chains, while exopeptidases attack these smaller peptide chains and cleave the links between terminal amino acids. Therefore, exopeptidase activity ultimately leads to protein molecules being hydrolyzed into FAN or di-/tri-amino acids. Endopeptidases function at a lower optimum temperature; thus, most of these enzymes are degraded during the malting process. However, exopeptidases can withstand high temperatures and complete the protein hydrolysis process. Exopeptidases consist of two major enzymes: carboxypeptidase and aminopeptidase, both of which have different active sites. Specifically, carboxypeptidase has the ability to hydrolyze protein molecules from the carboxyl end, while aminopeptidase functions from the amino end (Lalor and Goode 2010).

3.5 Lipid-Hydrolyzing Enzymes

Lipids are a group of naturally occurring, small, hydrophobic, or amphiphilic molecules, including fats, waxes, sterols, fat-soluble vitamins, monoglycerides, triglycerides, phospholipids, and others. The amphiphilic nature of some lipids allows them to form structures, such as vesicles, liposomes, or membranes, in an aqueous environment. The principle biological functions of lipids include acting as a natural food reservoir (natural glycosides), storing energy, providing a source of hydrocarbons (waxes), functioning as a cofactor in intermediate metabolism (quinines) and structural component of cells membranes (polar glycerides), and participating in signaling (Subramaniam et al. 2011). Grain lipids consist of 65–78 % natural lipids, 7–13 % glycolipids, and 15–26 % phospholipids (Briggs 1978). Lipids in cereal grains are associated with starch granules on their surface or within the starch structure (Morrison 1988). The lipids inside starch granules alter the gelatinization properties of starch granules (Briggs et al. 1981). The hydrolysis of numerous biopolymers is governed by respective hydrolyzing enzymes in the initial stage of germination during malting. Commonly used lipid-hydrolyzing enzymes include lipases (Baxter 1982), lipoxygenases (Antrobus et al. 1997), hydroperoxide lyases, and hydroperoxide isomerases (Bamforth 2009; Bamforth et al. 2009).

Lipases are hydrolyzing enzymes that catalyze esters of long-chain aliphatic fatty acids to produce free fatty acids and glycerol. Their natural substrates are insoluble lipid compounds prone to aggregation in aqueous solution. In eukaryotes, lipases may be confined within an organelle (i.e., the lysosome) or can be found in the spaces outside cells, playing roles in the metabolism, absorption, and transport of lipids. In lower eukaryotes and bacteria, lipases can be localized either intracellularly or can be secreted, functioning to degrade lipid substrates present in the

environment. Moreover, in some pathogenic organisms (*Candida albicans*, *Staphylococcus* and *Pseudomonas* species, and *Helicobacter pylori*), lipases can even act as virulence factors. Their ability to hydrolyze insoluble fatty acyl esters makes lipases different from all other esterases. Cereals contain storage fats or oils called lipid bodies, which are hydrolyzed into free fatty acids by lipase. The hydrolysis of lipid bodies is directly related to the concentration of lipase in the aleurones and scutellums of grains, including both preexisting and newly synthesized lipases, in response to physical and chemical changes (Huang 1992). Free fatty acids produced by triglyceride hydrolysis are readily utilized as metabolic energy in the synthesis of glucose when grains containing soluble sugars are depleted or as precursors for phospholipid synthesis, which is involved in the growth of the cell membrane. In malt, the enzyme lipoxygenase can hydrolyze the dioxygenation of polyunsaturated fatty acids (linoleic and linolenic acids) into hydroperoxy acids. This hydrolyzed product is used as a precursor for the production of the stale testing aldehydes used in the wine brewing industry. Barley genetic material encodes two types of lipoxygenases secreted in embryonic tissues, LOX-1 and LOX-2. LOX-1 is already present in raw barley, and its expression increases with germination. In contrast, LOX-2 is only expressed during germination of barley grain (de-Almeida et al. 2005). Lipoxygenase is heat sensitive and loses most of its activity (96–98 %) during the kilning process. Even with the dramatic reduction in hydrolyzing activity after the kilning process, almost 30 % of malt lipids are hydrolyzed by lipoxygenase during mashing. This enzyme also plays a crucial role in senescence, wound healing, infection, and resistance against pests. Hydroperoxide lyase (HPL), which is very common in plants, is known for catalysis of the hydrolysis reaction of fatty acid hydroperoxides into oxo-acids and aldehydes. HPL is a member of the cytochrome P450 family, which plays a major role in phyto-oxylipin synthesis resulting from interactions among plant herbivores. HPLs can be divided into two groups based on substrate activity: 13-HPL (CYP74B) and 9-/13-HPL (CYP74C). Because it can change the constituents of volatile aldehydes, HPL plays an important role in determination of the characteristics of food products. The hydroxyperoxide isomerase catalyzes the conversion of hydroperoxylinoleic acid into α- or β-ketols. The localization of HPL expression changes with germination, and the enzyme is only expressed in the embryo in its dormant form during early development.

3.6 Nucleic Acid-Hydrolyzing Enzymes

Nucleic acids are the polymeric biological macromolecules essential for all known forms of life. Nucleic acids, such as DNA (deoxyribonucleic acid) and RNA (ribonucleic acid), are made up of basic repeating units called nucleotides. Each nucleotide contains three essential components: a nitrogenous base, a phosphate group, and a five-carbon sugar molecule. Each cell of a living organism contains nucleic acids in the nucleus and in some other organelles, such as mitochondria and chloroplasts (in plants only); these nucleic acids function to encode, transmit, and

express genetic information. The building blocks of nucleic acids (i.e., nucleotides) are synthesized enzymatically (5′–3′ direction) and chemically (3′–5′ direction). During synthesis, the nucleotides are sequentially added to the growing oligonucleotide chain. Different types of oligonucleotides, such as antisense oligonucleotides, small-interfering RNA, primers (for DNA sequencing and amplification), and probes (for detecting the complementary DNA or RNA via molecular hybridization technique), have several applications in a variety of biological fields and act as tools for the targeted introduction of mutations and restriction sites and for the synthesis of artificial genes or gene fragments.

Several nucleic acid-hydrolyzing enzymes are used in genetic engineering approaches; these include restriction endonucleases, nucleases, alkaline phosphatases, and RNase P. Among these, restriction enzymes or, more specifically, restriction endonucleases (REases) are the principle nucleic acid-hydrolyzing enzymes. These produce discrete DNA fragments upon cleavage, which serves as a useful feature for analyzing and recombining the DNA molecules from different origins. These characteristics have led to the development of various genetic engineering techniques and the search for additional enzymes with similar functions. REases recognize a unique short sequence (four to eight base pairs) in the DNA fragment and produce a nick at the target site (type II), vicinity (type I), or away from the site of attachment (type III), depending upon the type of enzyme. This process produces fragments with sticky ends or blunt ends. Several applications of restriction enzymes have been reported, including manipulation of DNA, insertion of genes into plasmids, distinguishing between gene alleles, digestion of genomic DNA for gene analysis, etc. Nucleases are enzymes that cleave DNA or RNA (called DNases and RNases, respectively). DNases are further classified into exonucleases, which act on the ends or terminal regions of DNA, and endonucleases, which act at nonspecific regions in the center of DNA. Exonucleases require at least two 5′ and 3′ ends and thus cannot act on circular DNA, such as plasmids. However, endonucleases can act on both linear and circular DNA molecules. Exonucleases release single nucleotides, while endonucleases produce short DNA segments. Phosphatases remove the phosphate from DNA, RNA, and proteins. Most of these enzymes act in basic buffers and are known as alkaline phosphatases. Three common types of alkaline phosphatases used in molecular cloning experiments are bacterial alkaline phosphatases (BAPs), calf intestine alkaline phosphatases (CIAPs), and shrimp alkaline phosphatases. Alkaline phosphatases are metalloenzymes containing Zn^{2+}. RNase P, which specifically cleaves at the 5′ end of RNA, is a complex ribozyme containing a 20-kDa protein and a 377-nucleotide RNA molecule possessing at least part of the enzymatic activity of the complex.

3.7 Other Hydrolyzing Enzymes

Besides the above-described enzymes, several other enzymes also catalyze hydrolytic reactions; these include glucose oxidase, galactose oxidase, cholesterol

oxidases, catalases, phytase, peroxidase, and thiol oxidase. Glucose oxidase is a flavoprotein that catalyzes the oxidation of β-D-glucose by O_2 to δ-gluconolactone and H_2O_2. Galactose oxidase is a type II (non-blue) copper protein with a molecular mass of 69 kDa that catalyzes the oxidation of a wide range of primary alcohols and polysaccharides (e.g., D-galactose) to the corresponding aldehydes. Cholesterol oxidases are bifunctional flavoenzymes that catalyze two reactions at a single active site. The first is the oxidation of cholesterol to cholest-5-ene-3-one and the isomerization of the labile cholest-5-ene-3-one intermediate to a cholest-4-ene-3-one product. Catalases or hydroperoxidases catalyze the degradation of H_2O_2 to H_2O and O_2. Phytase is involved in the hydrolysis of phytate into phytic acid, inorganic phosphate, and myoinositol during the malting process and thus decreases its total contents in the final product. Two types of phytases, 3- and 6-phytase, are known for their dephosphorylation of phytate. 3-Phytase is found in microbial species, while 6-phytase is primarily found in seeds of higher plants, including barley. Thiol oxidase belongs to the family of oxidoreductases that specifically act on the sulfur group of donors, with oxygen as the acceptor.

4 Isolation of EHEs

As mentioned earlier, enzyme-catalyzed reactions require different types of enzymes either supplied externally or induced within the biological system. Different types of EHEs have been isolated from different sources at various states of purity before being fully characterized. However, partially purified EHEs isolated from different sources tend to be analyzed more completely for elucidation of their inhibition characteristics, substrate specificity, and interaction with activators molecules during the initial characterization. The conclusions from all these preliminary studies will guide us in understanding the mechanisms through which these proteins are controlled under different conditions. Therefore, it is important to understand the basic features of techniques most commonly used for the isolation of EHEs from different sources.

4.1 Occurrence/Sources of EHEs

Malt, comprised of germinated cereal grains that have been dried in a process known as "malting," is considered an enriched source of EHEs (Khattak et al. 2012). During the malting process, cereal grains (mostly often wheat or barley) induce signals for the expression of different types of EHEs, including cell wall-hydrolyzing enzymes, starch-hydrolyzing enzymes, proteases, lipases, and phytases (Fig. 1) that mediate the internal physiological changes of seeds. Soaking of seed results in scutellum-induced gibberellin, which functions as a signal for the expression of starch-hydrolyzing enzymes; this is thought to be the first change in seeds that leads to the production of monosaccharides, including glucose and fructose, as well as disaccharides essential for the initial growth and

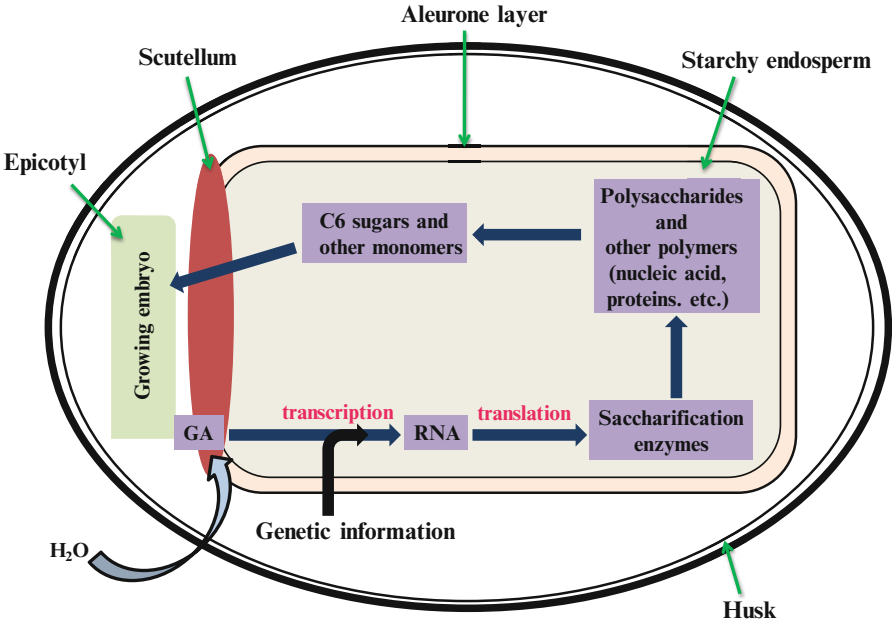

Fig. 1 The generalized scheme representation of the EHEs production in barley grain in response to external stimuli induced during malting process

development of the seed (Khattak et al. 2012). During malting, the expression of proteases involved in the hydrolysis of long-chain peptides into short-chain peptides and amino acids is also essential for seed growth (Celus et al. 2006). The expression of endogenous enzymes inside the seed is primarily involved in the hydrolysis of three major components of the grain: starch, protein, and cell wall polysaccharides (Hayes et al. 2003).

A number of cell wall-hydrolyzing enzymes, including endoglucanase, exoglucanase, arabinofuranosidase, esterase (Bamforth 2009), carboxypeptidase (Bamforth et al. 1979; Sørensen et al. 1989), xylanase (Bamforth 2009; Chithra and Muralikrishna 2008), and β-glucosidase (MacGregor 1987), have been reported to be expressed and obtained from malt. In microorganisms, fungi in particular are often studied with respect to the expression and isolation of endogenous cell wall-hydrolyzing enzymes (Aro et al. 2005; Hasegawa and Nordin 1969). Antagonistic fungi use cell wall-hydrolyzing enzymes as weapons to attack their target fungi and thus maintain stability (Aro et al. 2005). *Trichoderma* and *Aspergilli*, two industrial fungal strains, are capable of producing abundant amounts of cell wall-hydrolyzing enzymes (Durand et al. 1988; Berka et al. 1991). In the case of bacteria, *Streptomyces* strains produce cell wall-hydrolyzing enzymes capable of digesting yeast cell walls (Bacon et al. 1968). Considering the above discussion, we can conclude that endogenous cell wall-hydrolyzing enzymes can be isolated from both plants and microorganisms depending on the nature of the substrate/host.

Malt extract is also a major source of starch-hydrolyzing enzymes. Payen and Persoz (1833) found that precipitates obtained after treatment of malt extract with alcohol have the potential to liquefy starch polysaccharides into glucose (Payen and Persoz 1833). At the time of their study, malt extract was called *diastase*; the functional enzymes within the extract were later classified as α-amylase and β-amylase based on their different activities (Maercker 1878). Similarly, the existence and isolation of other starch-hydrolyzing enzymes, including limit dextrinase and β-glucosidase from malt extract, has also been reported. In recent studies, the activities of starch-hydrolyzing enzymes have been reported in agro-industrial wastes (e.g., wastes from beer fermentation broth [WBFB]), which is thought to be an enriched source of saccharification enzymes (Khattak et al. 2013a, b). Germinated barley seeds possessing abundant quantities of starch-hydrolyzing enzymes have also been processed for enzyme isolation (Sun and Henson 1990). Certain microorganisms, including thermophilic *Archaea*, bacteria (Bertoldo and Antranikian 2002), and yeast (Kelly et al. 1985), have been used for isolation of starch-hydrolyzing enzymes.

Cellulose-hydrolyzing enzymes play a pivotal role in a variety of biotechnologies, particularly biofuel production. Similar to cell wall- and starch-hydrolyzing enzymes, malt has been shown to be an enriched source of cellulose-hydrolyzing enzymes (Khattak et al. 2012). In microorganisms, fungi (Nevalainen and Palva 1978), algae (Mohapatra et al. 2003), and bacteria (Han and Srinivasan 1968) are common sources of endogenous cellulase enzymes, which can be extracted following incubation of the microorganism in its respective media.

Peptidase enzymes are encoded by about 20 % of genes in all types living organisms and play an important role in the viability of living creatures. Germinated seeds are an economical and feasible source of such EHEs. A number of proteolytic enzymes such as endopeptidases and carboxypeptidases are synthesized during seed germination. Drzymała and Bielawski (2009) also reported the isolation of endogenous carboxypeptidase from germinated triticale grains (Drzymała and Bielawski 2009). Similarly, the isolation of endogenous proteolytic enzymes from others plant sources, including barley (Sørensen et al. 1989), wheat (Baulcombe et al. 1987), and triticale (Drzymała et al. 2008), has also been reported. Microbial sources of endogenous proteolytic hydrolyzing enzymes include bacteria (Fujimura and Nakamura 1981; Pacaud et al. 1976), fungi (Kamath et al. 2010), and algae (Matsubara et al. 2000). Certain agro-industrial waste materials, including WBFB (Khattak et al. 2012), cassava wastewater (Barros et al. 2013), slaughterhouse waste, dairy industry effluent, and sewage waste (Boominadhan et al. 2009), have been utilized for the production of proteolytic enzymes through microbial species.

Lipid-hydrolyzing enzymes have been obtained from different sources, including plants, animals, and microorganisms. Based on statistical data, different organisms, including bacteria (45 %), fungi (21 %), animals (18 %), plants (11 %), and algae (3 %), contribute to total lipase production with varying degrees (Patil et al. 2011). Among microbes, fungal strains have always been considered preferable because they usually excrete endogenous enzymes, allowing for simple and inexpensive isolation of enzymes from fermentation broth (Maia et al. 1999).

Agro-industrial wastes (e.g., WBFB, waste from the fish industry, etc.) are composed of complex polysaccharides that can be exploited as economically feasible substrates for microbial growth and are responsible for endogenous enzyme production (Khattak et al. 2012; Rebah and Miled 2013). The availability and cost of these alternative media (agro-industrial waste) are the main determinants of the economics of the enzyme production process. Cereals crops (e.g., malt, wheat, and barley) can be processed for the production and isolation of endogenous lipase enzymes (Khattak et al. 2012). The lipase activity in cereal crops increases significantly, particularly during the initial stage of germination. The requirements for structural carbons and energy to initiate seed growth are met through the hydrolysis of stored food (insoluble tri-acylglycerols) by lipase (Pahoja and Sethar 2002).

Nucleic acid-hydrolyzing enzymes play an important role in certain biological processes. Complete hydrolysis of nucleic acids yields inorganic phosphate, deoxyribose sugar, and four different heterocyclic bases. As mentioned earlier, different types of nucleic acid-hydrolyzing enzymes have been isolated from different sources, including microorganisms, plants, fungi, and highly developed animals. In microorganisms, different bacterial strains (e.g., *Bacillus*, *Brevibacillus*, *Microbacterium*, *Pseudomonas*, and *Stenotrophomonas*) and fungi (e.g., *Alternaria*, *Aspergillus*, *Aureobasidium*, *Chaetomium*, *Fusarium*, *Gliomastix*, *Humicola*, *Penicillium*, *Scopulariopsis*, *Wardomyces*, and *Periconia*) are commonly used (Balestrazzi et al. 2007; Balabanova et al. 2012). Roberts (2005) reported that more than 3,000 restriction enzymes with over 250 different specificities have been isolated from various organisms (Roberts 2005). These enzymes are thought to have evolved from a common ancestor and likely became widespread via horizontal gene transfer (Jeltsch et al. 1995; Jeltsch and Pinground 1996). Evidence also exists for their evolution as self-genetic elements (Naito et al. 1995). Isolation of restriction nucleases has been reported from *Escherichia coli* (Linn and Arber 1968). Alkaline phosphatases are commonly found in the periplasmic space, external to the cell membrane in gram-negative bacteria, and are usually produced during phosphate starvation (Horiuchi et al. 1959). Additionally, RNase P has been described in several bacterial strains (Evans et al. 2006), Archaea (Hall and Brown 2002), and eukaryotes, such as yeast (Marquez et al. 2006).

Besides the abovementioned enzymes, several other enzymes have also been reported from different sources. Industrial-scale production of glucose oxidase is mainly carried out using *Aspergillus niger* or *Penicillium amagasakiense* (Crueger and Crueger 1990). Moreover, other *Penicillium* and *Aspergillus* sp., including *Penicillium notatum*, *Penicillium funiculosum*, *Penicillium piceum*, *Penicillium purpurogenum*, *Penicillium variabile*, *Penicillium chrysogenum*, and *A. fumaricus*, are also attractive candidates for industrial production of this enzyme (Leiter et al. 2004). Different fungal species, e.g., *Fusarium dendroides* (*Dactylium dendroides*), *Gibberella fujikuroi*, and *G. zeae*, as well as the basidiomycete *Polyporus circinatus*, are widely used for industrial-scale galactose oxidase production. Genes encoding galactose oxidase can also be expressed efficiently in either *Pichia pastoris* (Whittaker and Whittaker 2000) or *A. oryzae* (Xu et al. 2000). Cholesterol oxidases are produced by bacteria, including species from the

Rhodococcus, *Streptomyces*, and *Nocardia* genera. However, several *Brevibacterium*, *Proactinomyces*, *Pseudomonas*, and *Cellulomonas* species also possess enzymes with cholesterol oxidase activity and are suitable candidates for industrial production of this enzyme (Watanabe et al. 1986). Recombinant *E. coli* strains expressing bacterial cholesterol oxidase genes have been reported (Sakka et al. 1994). Different microorganisms, including bacteria (e.g., *Micrococcus*, *Bacillus*, *Microscilla*, and *Alcaligenes* spp.), fungi (e.g., *Aspergillus*, *Penicillium*, *Thermomyces*, *Thermoascus*, and *Acremonium* spp.), and yeasts (e.g., *Saccharomyces*, *Candida*, and *Mycotorula* spp.), are known for their abundant production of catalases. However, catalases from animal sources (e.g., bovine liver) are generally inexpensive, and thus, their production from microbial sources is only economical when better producer strains (preferably recombinant strains) and inexpensive technology can be used or when enzymes with special properties (e.g., functional at high or low temperatures or at alkaline or acidic pH) are produced (Takeuchi and Isobe 1999).

4.2 Methods of Cell Lysis

Obtaining endogenous enzymes from respective organisms without rupturing their cell envelopes is a difficult task. However, certain organisms excrete endogenous enzymes into the surrounding microenvironment for a variety of purposes, most commonly for cell defense. The first attempt to obtain cellular contents, specifically the proteinaceous content of the cell, was made in microbial cells, with attempts to rupture the outer cell envelope by prolonged exposure to water, followed by heating in glycerin solutions. The method was successful only in that it allowed the researchers to obtain fractions of cellular contents; however, most of the contents were altered (Buchner 1966). Over time, a number of specialized, highly efficient techniques have been reported for the rupture of enveloped cells. These techniques are briefly described below.

4.2.1 High-Pressure Homogenizer

High-pressure homogenization was the first successful cell lysis method for obtaining endogenous enzymes from yeast cells. A hydraulic press supplied by Brink and Hubner was used for applying higher pressure to cells to squeeze out the cell contents. Using this mechanical lysis method, almost 1,000 g of yeast was squeezed for a few hours, resulting in about 500 mL of liquid solution that was yellowish brown in color and contained endogenous enzymes (Buchner 1897). Dilution of the yellowish brown solution with water and hydrogen peroxide led to formation of oxygen, inducing violent foaming. Additionally, researchers concluded that the presence of catalase in the solution catalyzed the oxygen reaction. Later studies demonstrated that mixing the yellowish solution with concentrated glucose solution produced bubbles in the form of a thick layer of foam over the surface, clarifying the mechanism of carbon dioxide formation as result of a cell-free fermentation process (Buchner 1966).

4.2.2 Chemical Lysis

Chemical lysis is a well-established method for obtaining endogenous enzymes, particularly from microbial cells (Arnold 1972). Freshly prepared microbial cultures are incubated in organic solvent at room temperature for few days in order to permeabilize the microbial membrane. Addition of organic solvent, primarily toluene, induces the expression of β-fructofuranosidase, classified as a cell wall enzyme; the secretion of this enzyme primarily depends on the action of cell wall-modifying enzymes (endogenous enzymes). The addition of organic solvents (e.g., toluene and ammonium hydroxide) creates hypertonic conditions, resulting in the alteration of the membrane composition, which subsequently activates the EHEs located within the cytoplasm (Arnold 1972). Although the method is well established, certain limitations are associated with chemical lysis, particular the stability of the endogenous enzymes in the presence of endogenous peptidases (Boonraeng et al. 2000).

4.2.3 Enzymatic Lysis

Enzymatic lysis is another approach for the isolation of EHEs that has been used with a great degree of success (Salazar and Asenjo 2007). In enzymatic lysis, specific cell wall-hydrolyzing enzymes are used to digest the cell envelope. The microbial cell wall (e.g., that of yeast) is a highly dynamic structure composed of mannoprotein and fibrous β(1→3) glucans with a few β(1→6) glucan branches. The β(1→6) glucans make connections between the inner and outer cellular components of the yeast cell (Lipke and Ovalle 1998). A number of enzymes, including β(1→3) glucanase, proteases, β(1→6) glucanase, mannanase, and chitinase, can be applied directly in groups and act synergistically to digest the outer cell wall (Salazar and Asenjo 2007). This approach has a major limitation: cellular proteins released into the medium after cell wall digestion are subjected to the activity of the protease.

4.2.4 Freeze-Thawing

Rapid freeze-thawing is an uncommon method used for lysis of the yeast cell wall. A number of traditional methods, mostly mechanical methods, have been used to disrupt the cell wall; however, there are few inherent disadvantages to using these methods. For example, heat generation within a sample is commonly encountered during application of traditional techniques for cell lysis and can cause protein denaturation or aggregation. This problem can be overcome by keeping the sample at a low temperature. Liquid nitrogen is used for rapid freezing of the targeted cells, followed by grinding using a sterilized mortar and pestle prechilled with liquid nitrogen. The freeze-thawing method causes the target cells to swell and ultimately rupture due to the formation of ice crystals during freezing and subsequent contraction during thawing. However, this process takes a long time because several cycles of freezing and thawing are required. However, freeze-thawing has been shown to effectively release recombinant proteins located in the cytoplasm of bacteria and is recommended for the lysis of mammalian cells in some protocols. The fine powder obtained from this

method can be stored at −80 °C, and for experimental purposes, cell lysates can be produced by the addition five volumes of buffer solution per volume of cells (Amberg et al. 2006).

4.2.5 Ultrasonication

The process of sonication uses ultrasound pulses, i.e., high-frequency sound waves, for disruption of the cell wall. This approach to cell lysis is an alternative method that is now commonly used for rupturing the cells of bacteria, spores, and even diced tissues. The ultrasonic homogenizer is a common tool used for partial or complete disruption of the cell wall. This tool produces sound waves delivered through a vibrating probe that is immersed in the liquid cell suspension. The device consists of a piezoelectric transducer, temperature probe, horn tip, and digital system for controlling parameters, such as frequency, amplitude, and temperature. Due to the capacity for well-controlled sonication parameters and the comparatively high selectivity for cellular material release and purity, ultrasonication for disintegration of the cell wall has been described as a reliable and efficient approach (Balasundaram et al. 2009).

4.2.6 Bead Beating

Bead beating is one of the most common and frequently used approaches for obtaining cellular proteins through cell lysis. The method involves the mechanical disruption of the cell envelope of microorganisms, plants, and animals (Khattak et al. 2014). Glass beads of different sizes (0.425–0.60 mm) are used, depending on the nature of the cell, and beads are vortexed at high speeds using a vortexer. Because of the nature of this mechanical approach, localized heating within a sample can occur because of the continuous collision of beads with the wall of the container or with one another. Therefore, special measures should be taken to avoid the thermal denaturation of the cellular materials; every cycle of the agitation step must be interspersed with a cooling cycle. The beat beating procedure for cell lysis is depicted in the schematic diagram in Fig. 2. Table 2 summarizes the benefits and limitations of each approach used for the production of cell-free systems.

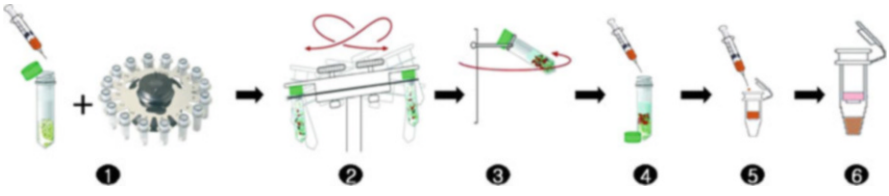

Fig. 2 Bead beating is the most common techniques employed for the cell lysis in order to obtained EHEs from cell lysate. The technique consists of (*1*) isolation of biomass from different sources in a specialized tube, (*2*) vertexing at different speed, (*3*) centrifugation and isolation of supernatant, (*4*) concentration of enzymes mixture through specialized column and obtains highly concentrated endogenous enzyme mixture

Table 2 Comparative study of different cell lysis methods employed for the rupturing of cell enveloped in order to release endogenous enzymes into the medium

Method of cell lysis	Limitations	Advantages	References
Hydraulic press	Need expensive equipment, difficulty in maintenance	Quick and ideal for large-scale lysis, effective for all cells lysis	(Buchner 1966; Goldberg 2008)
Organic solvent lysis	Possibilities of alteration in cellular materials, difficult in purification	Economical as no specialized equipment required and fast process	(Breddam and Beedfeldt 1991)
Enzymatic lysis	Can cause alteration in target protein structure, required expensive exogenous enzymes	Required nonspecialized equipment, highly specialized approach	(Lam and Wassink 1990)
Freeze grinding	Slow process, chances of contamination	Economical, obtained proteins with original activity	(Taskova et al. 2006; Yeng et al. 2013)
Centrifugation	Only effective for weal cell wall, slow process	Economically feasible	(Martz 1966; Lodish et al. 2000)
Cell bomb	Only applicable to specialized cells	Fast, ensured the protein stability and activity	(Goldberg 2008; Simpson 2011)
Ultrasonification	High ultrasound waves show negative effect on endogenous enzyme function	Really effective for large-scale cell disruption, controllable	(Liu et al. 2013; Stathopulos et al. 2004)
Beads beating	Difficulty in target proteins purification, heat produced can cause alteration in target proteins structure	Effective for all kind of cells, economical, sample, fast	(Khattak et al. 2014; Griffiths et al. 2006)

4.3 Separation of EHEs from Cell Lysates

Recent developments in the identification of new enzymes have also facilitated the improvement of recovery and separation methods. Following cell lysis, enzymes are separated from cells or cellular fragments and organelles. This process is rather sensitive due to the small size of microbial cells, which results in slight differences between the densities of cells and the components of the fermentation medium. Moreover, no effective techniques have been developed for recovery of all enzymes, and selection of an appropriate technique based on the type of enzyme and the specific microbial cells used will ensure better separation of enzymes from other constituents. A few of the techniques commonly used today are described below.

4.3.1 Filtration

The rate of filtration can be determined as a function of filter area, pressure, viscosity, and resistance offered by the filter cake medium. Generally, the flow rate becomes more uniform as the medium becomes clearer. Moreover, the cumulative filtrate volume increases linearly with time. The gradual increase in the thickness of the formed filtrate resists the flow rate across the filtration media. This limitation can be overcome to some extent by increasing the pressure applied. However, beyond certain limits, the applied pressure may cause collapsing of the filtrate cake, leading to complete blockage of the filter. The most recent developments in this area have resulted in the application of cross-flow membrane filtration and microfiltration; these techniques have unique advantages, such as enhanced efficacy, ease of operation and cleaning, improved downstream ultrafiltration purification, and, most importantly, cost-effectiveness. During the cross-flow filtration process, the input stream flows parallel to the filter area and thus prevents the accumulation of filter cake and increased resistance to filtration. Additionally, maintaining a sufficiently high filtration rate usually requires large amounts of energy in the form of high flux rates over the membranes.

4.3.2 Centrifugation

EHEs can be separated from components of lysed cells through gentle fractionation techniques, such as centrifugation; often, this method can help to preserve the functions of these enzymes. An effective and economical separation can be achieved only by sedimentation in a centrifugal field based on the molecular weight of the enzyme and the sizes of the media components. The effective operation of centrifugation technique requires a combination of high centrifugal force and short sedimentation distances. Commercially, this is achieved by using either a sieve centrifuge or a solid-wall centrifuge. Another type of centrifuge, called a decanter or scroll-type centrifuge, works with low centrifugal forces and is specifically used for the separation of cells and protein precipitates. These types of centrifuges are feasible for continuously operating processes. Tubular-bowl centrifuges are used for separation of very small-sized particles. However, these centrifuges cannot be employed for continuous operation. Separators or disk-stack centrifuges are used for continuous removal of solids from suspensions.

4.3.3 Extraction

This technique is based on the principle of liquid-liquid extraction in an aqueous two-phase system (Hustedt et al. 1985). Cellular fragments are separated in the first step, followed by subsequent purification using other methods if greater purity is required. This may involve affinity ligand binding, modified chromatography gels, etc.

4.3.4 Flocculation and Flotation

During this process, destabilized particles are induced to come together, make contact, and subsequently form larger aggregates. Separation of cells by filtration or centrifugation is limited by the small sizes and physical properties of microbial

cells and cell debris, as well as the molecular weights of the enzymes. Flocculation of cell suspensions is assisted by both filtration and centrifugation (Bajpai et al. 1991; Sitkey et al. 1992a, b). Flocculating agents are additives capable of increasing the degree of flocculation of a suspension. They can be organic or inorganic and natural or synthetic.

The flocculation of cells or enzymes by polyelectrolytes is a two-step process. In the first step, the surface charge on the suspended material is neutralized. The second step involves the linkage of these particles to form large aggregates. Flocculant selection for a specific cell separation process is a challenge because many factors can affect flocculation. These factors can have their origin in the broth (cell surface charge and size, ionic strength, pH, cell concentration, and the presence of other charged matter), the polymer (molecular weight, charge, charge density, structure, and type), and engineering parameters (mixing and mode and order of addition). The final criteria for flocculant selection should take into consideration all aspects of the flocculation process. These include the cost of the added flocculant, subsequent separation performance, process robustness, and yield. In some cases, flocculation can also provide purification by selectively removing unwanted proteins, nucleic acids, lipids, and endotoxins from the cell broth. However, in cases in which no stable agglomerates are formed, the substances can be separated by flotation. Here, the enzymes or cells are adsorbed onto gas bubbles, rise to the top of the mixture, and accumulate in froth. A typical example of flotation is the separation of single-cell protein (Mayer and Woernle 1985).

4.4 Concentration of EHEs

Protein samples separated from cell debris often contain very small concentrations of enzymes. The volume of the material to be processed is generally very large because large amounts of waste materials must be removed. Thus, there is a tremendous need to concentrate the starting material in order to achieve economic, efficient purification. However, the approaches selected must be such that they do not inactivate or denature the enzymes. Several commonly used approaches are described below.

4.4.1 Thermal Methods

Enzymes are often unstable at elevated temperatures. Thus, only a brief heat treatment can be used for concentration. Evaporators with rotating components that achieve a thin liquid film (thin-layer evaporators and centrifugal thin-layer evaporators) or circulation evaporators (long-tube evaporators) can be employed for the concentration of enzymes.

4.4.2 Precipitation

Enzymes are very complex protein molecules possessing both ionizable and hydrophobic groups, which can both interact with the solvent. Indeed, proteins can be

made to agglomerate and, finally, precipitate by changing their environment. Precipitation is actually a simple procedure for concentrating enzymes (Bell et al. 1982) and can be achieved with various reagents, such as salts, organic solvents, and polymers, or at the isoelectric point.

4.4.3 Ultrafiltration

For ultrafiltration, a semipermeable membrane is used; this membrane permits the separation of solvent molecules from larger enzymes under high osmotic pressure. This is the principle on which all membrane separation processes, including ultrafiltration, are based. Ultrafiltration and cross-flow filtration are based solely on the sieve effect. In processing enzymes, cross-flow filtration is used to harvest cells, whereas ultrafiltration is employed for concentrating and desalting.

4.5 Purification of EHEs

Enzymes can be used in the partially purified form (e.g., industrial use) or the highly purified form (e.g., analytical and medical applications). Highly purified enzymes are obtained through various techniques, such as crystallization, electrophoresis, and chromatography. Some enzyme purification techniques are described below.

4.5.1 Crystallization

Crystallization offers a cost-effective, industrial-scale method for purification. Crystallization involves the formation of solid enzyme particles of defined shapes and sizes. An enzyme can be induced to crystallize or form protein-protein interactions by creating solvent conditions that result in enzyme supersaturation. Most studies of enzyme crystallization have been focused on obtaining crystals for X-ray diffraction analysis rather than as a purification process. However, crystallization is attracting increasing interest as a purification process. Some recent advancements have been made concerning the use of self-interaction chromatography for measuring the protein osmotic second virial coefficient to predict protein crystallization behavior (Tessier et al. 2002) and the development of high-throughput screening and analysis systems for establishing robust protein crystallization conditions (Brown et al. 2003). Various enzymes have been crystallized for commercial purposes, including cellulase, glucose isomerase, subtilisin, and alcohol oxidase.

The desired characteristics of industrial-scale enzyme crystallization are product purity, process yield, ease of crystal recovery, and short overall process time. To achieve these aims, the crystallization process must be carefully designed and developed to produce crystals with relatively large sizes and the desired morphology. Many factors, including salt type and concentration, pH, temperature, the presence of variable amounts and types of impurities, mixing, and crystal seeding, can affect enzyme crystallization. Controlling the level of supersaturation throughout the crystallization process is essential for optimization of crystal size, which can be controlled by the use of precipitants, such as salt, pH, and temperature (Scopes 1993; Judge et al. 1995).

4.5.2 Electrophoresis

This involves the separation and analysis of enzymes based on their size and charge. Enzymes are separated by charge in agarose because the pores of the gel are too large to sieve proteins. This technique is mostly employed for the isolation of pure enzymes on the laboratory scale. A few limitations are associated with this approach, including generation of heat and interference caused by convection, as well as the necessity for scale-up due to these two factors.

4.5.3 Chromatography

In chromatographic techniques, enzymes are separated based on various physical properties (such as size, shape, charge, and hydrophobic interactions), chemical properties (such as covalent bonding), and biological properties (such as biospecificity). Several types of chromatographic techniques are described below.

Gel Chromatography

In gel chromatography (also called gel filtration), hydrophilic, cross-linked gels with pores of finite sizes are used in columns to separate biomolecules. Concentrated solutions are necessary for separation because the sample volume that can be applied to a column is limited. Molecules are separated according to size and shape. Molecules larger than the largest pores in the gel beads, i.e., above the exclusion limit, cannot enter the gel and are eluted first. Smaller molecules, which enter the gel beads to varying extents depending on their sizes and shapes, require longer times to pass through the column. As a result, molecules are eluted in order of decreasing molecular mass.

Ion-Exchange Chromatography

In this method, enzymes are separated based on charge. Enzymes possess positive and negative charges. The net charge is influenced by pH, and this property is used to separate proteins by chromatography on anion exchangers (positively charged) or cation exchangers (negatively charged). The sample is applied in aqueous solution at low ionic strength, and elution is best carried out with a salt gradient of increasing concentration. Because of the concentrating effect of ion-exchange chromatography, samples can be applied in dilute form. The ability to process large volumes and the elution of dilute sample components in a concentrated form make ion-exchange methods very useful. The matrix used to produce ion-exchange resins should be sufficiently hydrophilic to prevent enzyme denaturation and must have a high capacity for large molecules with a rapid equilibration. In addition, industrial applications require ion exchangers that give high resolution, allow the use of rapid flow rates, suffer small changes in volume with salt gradients or pH changes, and exhibit high regenerative capacity.

Affinity Chromatography

For affinity chromatography, the enzyme to be purified is specifically and reversibly adsorbed on an effector attached to an insoluble support matrix. Suitable effectors are substrate analogs, enzyme inhibitors, dyes, metal chelates, or antibodies. During

separation, insoluble matrix is contained in a column. The biospecific effector, e.g., an enzyme inhibitor, is attached to the matrix. A mixture of different enzymes is applied to the column. The immobilized effectors specifically bind the complementary enzyme. Unbound substances are washed out, and the enzyme of interest is recovered by changing the experimental conditions, e.g., by altering pH or ionic strength.

5 Mechanism of Action of EHEs

5.1 Cell Wall-Hydrolyzing Enzymes

Cell wall-hydrolyzing enzymes include endoglucanase, exoglucanase, arabinofuranosidases, esterase, carboxypeptidase, xylanase, and β-glucosidase (Khattak et al. 2012). The solubilization of β-glucans is the first step in cell wall hydrolysis. The enzymes involved in this process are termed "solubilases." There are two pathways that lead to the solubilization of β-glucans (Jamar et al. 2011). Specifically, β-glucans are either directly hydrolyzed into glucose by β-glucan exohydrolases or first hydrolyzed by a number of enzymes involved in removal of the outer cell wall layer and then further hydrolyzed into glucose. Enzymes involved in the hydrolysis of β-glucans include (1→3)-β-glucanase, carboxypeptidase, phospholipases, (1→4)-endo-β-glucanase, feruloyl esterase, and arabinofuranosidases (Jin et al. 2004; Georg-Kraemer et al. 2004; Kuntz and Bamforth 2007). Hydrolysis of arabinoxylan is carried out by endo-β-(1→4)-xylanase, exoxylanase, β-xylosidase, and α-arabinofuranosidases (Hrmova et al. 1997). Exoxylanase is involved in the cleavage of the outer β-(1→4) xylosidic linkages, while endo-β-(1→4)-xylanase attacks the inner β-(1→4) xylosidic linkages in arabinoxylan polymers, separating the arabinofuranosyl residues (Egi et al. 2004). β-Xylosidase catalyzes the hydrolysis of β-(1→4) xylosidic bonding, while arabinofuranosidase hydrolyzes the α-(1→2) and α-(1→3) linkage between arabinofuranose units. Arabinofuranosidases consists of two subgroups α-L-arabinofuranosidases and α-D-glucuronidases. α-L-arabinofuranosidases catalyze the cleavage of terminal arabinose residues from the side chains of xylan and other arabinose-containing polysaccharides (Saha 2000). Xylanases are also classified into debranching and nondebranching enzymes, depending on whether or not they produce free arabinose in addition to cleaving the xylan backbone (Matte and Forsberg 1992). However, the reported release of arabinose by xylanases may have been due to the presence of arabinofuranosidases as contaminants. Indeed, the synergistic activity of xylanases and arabinofuranosidases allows small amounts of contaminants to yield detectable amounts of free arabinose (Coughlan et al. 1993). α-D-glucuronidases hydrolyze the linkages between 4-*O*-methylglucuronic/glucuronic acid and xylose residues in glucuronoxylan. Despite the biodegradation of xylan, α-D-glucuronidases also show activity only toward short xylooligomers, while others can release glucuronic acid from polymeric xylan (Puls 1992). Acetyl esterase and ferulic acid esterase also influence the hydrolysis of arabinoxylane (Humberstone and Briggs 2000a, b).

5.2 Starch-Hydrolyzing Enzymes

The two basic steps in the enzymatic conversion of starch are liquefaction and saccharification. Endoamylase (EC 3.2.1.1) protects against the rapid increase in starch solution viscosity caused by the release of amylose during liquefaction (Guzman-Maldonato and Paredes-Lopez 1995). α-Amylase randomly cleaves α-(1→4) glycosidic linkages in starch until the chain lengths of the reaction products are about 10–20 glucose units. At this point, the starch fragments fail to bind to the active site of the enzyme. Hydrolysis of amylopectin produces a mixture of linear malto-oligosaccharides and fragments that contain the α-1,6-bond, which cannot be cleaved by α-amylase. Xylanases and cellulases are glycosyl hydrolases that do not act on starch, but yield improvements in starch processing. Both are involved in the cleavage of the β-1,4-glycosidic bonds in cellulose and xylans, respectively. Xylanases reduce the viscosity of starch slurries by degrading xylans, whereas cellulases positively affect starch hydrolysis when it is contaminated by cellulose fibers. Moreover, β-amylase, an exo-acting enzyme involved in the cleavage of α-(1→4) glycosidic linkages at the nonreducing end of linear chains in starches and other polysaccharides, produces β-maltose and β-glucose successively (Hoseney 1994; Svensson et al. 1985). The catalytic activity of β-amylase continues until α-(1→6) linkages are reached in starch molecules. Glucosidases are also exo-acting enzymes and hydrolyze α-(1→4) glycosidic linkages in starch molecules. The main advantage of glucosidases over β-amylase is their ability to bypass the side chain at α-(1→6) bonds (Lalor and Goode 2010).

Limit dextrinase (EC 3.2.1.41) has the ability to break the amylopectin α-(1→6) linkages of branched dextrins and complete the hydrolysis of starch, producing its monomeric sugar at the end of the hydrolyzing reaction (Bowles 1996). In short, the initial solubilization of starch is catalyzed by α-amylase, while the hydrolysis of the resulting dextrins to oligosaccharides and glucose is subsequently carried out by the synergistic action of α-amylase, β-amylase, limit dextrinase, and glucosidases (Fincher 1989; MacGregor 1996). Figure 3 represents the generalized schematic view of starch hydrolysis.

5.3 Cellulose-Hydrolyzing Enzymes

The hydrolysis of cellulose, the most abundant polysaccharide on Earth, requires the concerted activity of a number of enzymes with different substrate specificities. Cellobiohydrolases (e.g., EC 3.2.1.91; 1,4-β-D-glucan cellobiohydrolases) hydrolyze cellobiose units from the ends of long polysaccharide chains. Then, endoglucanases (e.g., EC 3.2.1.4; 1,4-β-D-glucan-4-glucanohydrolase) cleaves the middle, amorphous region of the cellulose chain, thus providing more active sites for the activity of cellobiohydrolases. Finally, the third most important hydrolyzing enzyme participating in the hydrolysis of cellulose is β-glucosidase (EC 3.2.1.21), which cleaves cellobiose to glucose. This enzyme has been available in feedstock as

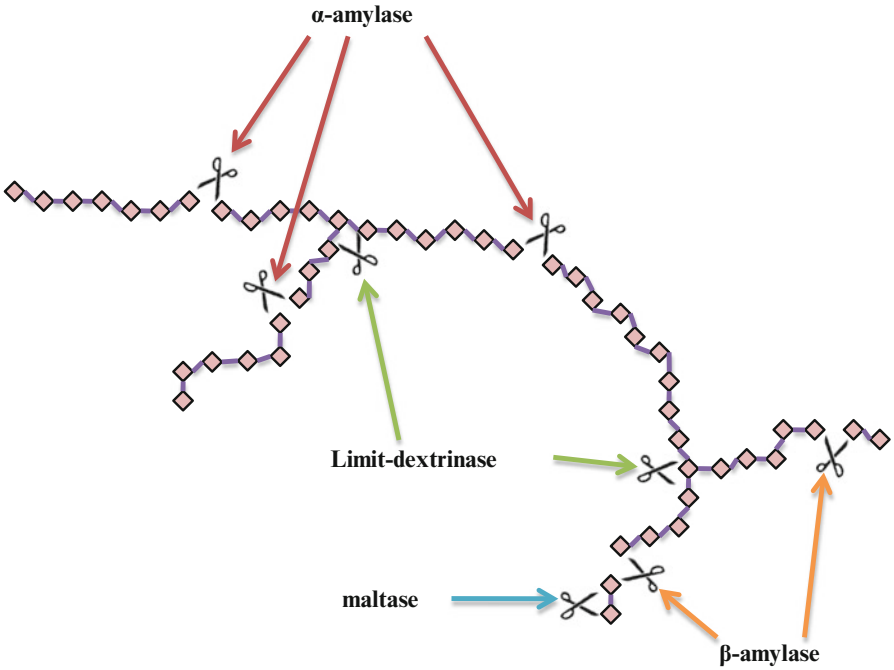

Fig. 3 Starch-hydrolyzing enzymes system consists of four major enzymes that cleave different bonding at different positions and produced glucose molecules as final product

an easily metabolizable carbon source for a number of microorganisms and is known to facilitate the production of desired products.

Another important source of cellulose readily available in complex form is hemicellulose. Hemicellulose is a heteropolymeric structure; however, the process through which hemicellulose hydrolyzes into simple sugar is well understood. Endoenzymes are the major class of hydrolyzing enzymes that cleave the main polymer chain internally, providing active sites for exoenzymes that liberate the simple sugars from the chain. Along with endo- and exoenzymes, a number of other enzymes also contribute to the hydrolysis of hemicellulose by cleaving the side chains of the polymers or oligosaccharides, producing various mono- and disaccharides depending on the type of hemicellulose being hydrolyzed. For example, the breakdown of xylan involves at least endo-1,4-β-D-xylanases (EC 3.2.1.8) and β-xylosidases (EC 3.2.1.37), which act on the main sugar chain, and, depending on the type of xylan, side-chain cleaving enzymes, such as α-glucuronidase (EC 3.2.1.131) and acetyl xylan esterase (EC 3.1.1.72). Similarly, different combinations of endoenzymes, exoenzymes, and ancillary enzymes are required for complete hydrolysis of other types of hemicelluloses into monomeric sugars.

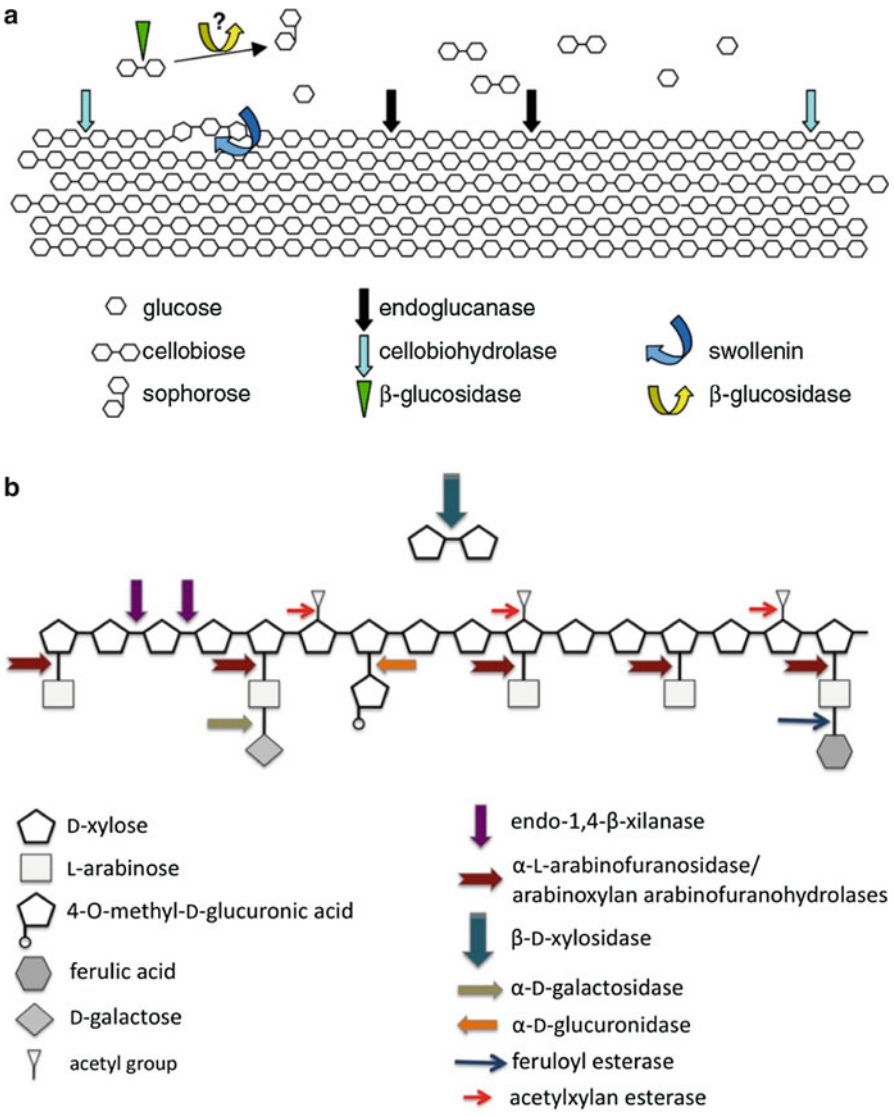

Fig. 4 Hydrolyzing enzyme system for the degradation of cell wall components. A number of hydrolyzing enzymes are participating in the degradation of (**a**) cellulose and (**b**) hemicellulose (Image taken from Aro et al. 2005)

De Vries and Visser (2001) provided a complete list of enzymes involved in the degradation of hemicellulose and their mechanisms of action (de Vries and Visser 2001). Figure 4a, b provides a complete schematic view of the cellulotic and hemicellulolytic system.

5.4 Protein-Hydrolyzing Enzymes

Certain proteolytic enzymes are involved in the production of FAN and di-/tri-amino acids. The enzymes involved in this protein modification system share the same substrate (polypeptides), but have different active sites. The final products, including, FAN, di-amino acids, and tri-amino acids, are produced as result of their synergistic action. Endopeptidases and exopeptidases are two principal groups of protein-hydrolyzing enzymes. Endopeptidases randomly cleave peptide bonds, producing relatively smaller peptide chains, while exopeptidases attack these smaller peptide chains and cleave the bonds between terminal amino acids producing FAN or di-/tri-amino acids. Exopeptidases comprise two major enzymes, carboxypeptidase and aminopeptidase, which have different active sites. Specifically, carboxypeptidase hydrolyzes proteins from the carboxyl end, while aminopeptidase hydrolyzes proteins from the amino end (Lalor and Goode 2010; Evan and Taylor 1990).

Endopeptidases hydrolyze internal, α-peptide bonds in a polypeptide chain. Endopeptidases include chymotrypsin (EC S01.001) (Graf et al. 2004), pepsin (EC A01.001) (Tang 2004), and papain (EC C01.001) (Menard and Storer 2004). Endopeptidases acting on substrates smaller than proteins are termed as oligopeptidases. Thimet oligopeptidase (EC M03.001) is an example of an oligopeptidase (Barrett and Chen 2004). Endopeptidases initiate the hydrolysis of proteins, producing new N- and C-termini, which subsequently act as substrates for exopeptidases that complete the hydrolytic process. Endopeptidases are also involved in the removal of signal peptides from secreted proteins (e.g., signal peptidase I, EC S26.001) (Dalbey 2004) and the maturation of precursor proteins, such as enteropeptidase (EC S01.156) (Sadler 2004) and furin (EC S08.071) (Creemers and Van de Ven 2004).

Exopeptidases require a free N-terminal amino group, C-terminal carboxyl group, or both and hydrolyze a bond up to three residues from the terminus. This group of enzymes is further divided into aminopeptidases, carboxypeptidases, dipeptidyl-peptidases, peptidyl-dipeptidases, tripeptidyl-peptidases, and dipeptidases.

Aminopeptidases release a single amino acid residue from the unblocked N-terminus of the substrate. This group includes aminopeptidase N (EC M01.001) (Turner 2004) and aminopeptidase C (EC C01.086) (Chapot-Chartier and Mistou 2004).

Dipeptidases hydrolyze dipeptides when both of the termini are free. They include dipeptidase A (EC C69.001) (Dudley and Steele 2004) and membrane dipeptidase (EC M19.001) (Hooper 2004).

Dipeptidyl-peptidases hydrolyze a dipeptidyl bond, i.e., release an N-terminal dipeptide from the substrate. They include dipeptidyl-peptidase I (EC C01.070) (Turk et al. 2004) and dipeptidyl-peptidase III (EC M49.001) (Chen and Barrett 2004).

Tripeptidyl-peptidases cleave a tripeptidyl bond, producing a tripeptide from the N-terminus of the substrate. Examples of tripeptidyl-peptidases are tripeptidyl-peptidase I (EC S53.003) (Sohar et al. 2004) and tripeptidyl-peptidase II (EC S08.090) (Tomkinson 2004).

Peptidyl-dipeptidases hydrolyze dipeptides from the C-terminus of the substrate. An example is peptidyl-dipeptidase A (EC XM02-001) (Corvol et al. 2004).

Carboxypeptidases hydrolyze a single residue from the unblocked C-terminus of the substrate. Examples include carboxypeptidase A1 (EC M14.001) (Auld 2004), cathepsin X (EC C01.013) (Menard and Sulea 2004), and carboxypeptidase Y (EC S10.001) (Mortensen et al. 2004).

5.5 Lipid-Hydrolyzing Enzymes

Lipid-hydrolyzing enzymes include lipase, lipoxygenase, hydroperoxidase lyase, and hydroperoxide isomerase (Khattak et al. 2012). Lipases hydrolyze esters of long-chain aliphatic fatty acids, producing free fatty acids and glycerol. Lipases are different from all other esterases due to their ability to hydrolyze insoluble fatty acyl esters (Ward 1985). The potential of lipases to act as biocatalysts is associated with their sophisticated selectivity for the modification of triglycerides. Three features are relevant: (1) regioselectivity, i.e., the position of the fatty acid on the glycerol backbone; (2) fatty acid specificity, i.e., concerning the length or unsaturation of the chain; and (3) the class of acylglycerols, i.e., mono-, di-, or triglycerides. Most lipases are 1,3 regiospecific, hydrolyzing primary alcohol 1,3 positions, and only a few lipases are able to hydrolyze the sn-2 position to allow the complete conversion of triglycerides to free fatty acids. With regard to fatty acid selectivity, lipases are able to hydrolyze fats into medium- to long-chain molecules (C4–C18, rarely up to C22), but with different efficiencies. Lipolytic enzymes possessing different selectivity can therefore be used to obtain valuable products, such as structured triglycerides with improved nutritional value, as well as an impressive range of mono-acylglycerols, di-acylglycerols, tri-acylglycerols, fatty acids, esters, and intermediates (Bornscheuer 2000). The enzyme lipoxygenase hydrolyzes the dioxygenation of polyunsaturated fatty acids into hydroperoxy acids. Hydroperoxide lyase (HPL), common in plants, is mainly involved in the hydrolysis of fatty acid hydroperoxides into oxo-acids and aldehydes. Hydroxyperoxide isomerase catalyzes the conversion of hydroperoxylinoleic acid into α- or β-ketols.

5.6 Nucleic Acid-Hydrolyzing Enzymes and Other Hydrolyzing Enzymes

Nucleic acid-hydrolyzing enzymes, called nucleases, can be regarded as molecular scissors and hydrolyze the phosphodiester bonds between the nucleotide subunits of nucleic acids. These enzymes were previously called polynucleotidases or nucleodepolymerases. Nucleases can be classified into two main categories based on the site at which they cleave: endonucleases, which act within the strand, and exonucleases, which act at the terminal end of the strand. Some nucleases have the ability to cleave the phosphodiester bond at both terminal ends and in the middle of

the nucleotide chain, therefore falling into both categories. The most well-known, highly applicable, and well-characterized nucleases are deoxyribonuclease and ribonuclease. Exonucleases have the ability to start cleavage of the nucleotides chain from either the 5′ end or the 3′ end of the nucleotide strand, depending on the encoded information. The generalized mechanism of action of nucleases and their vital roles in DNA repair are summarized in Fig. 5a, b.

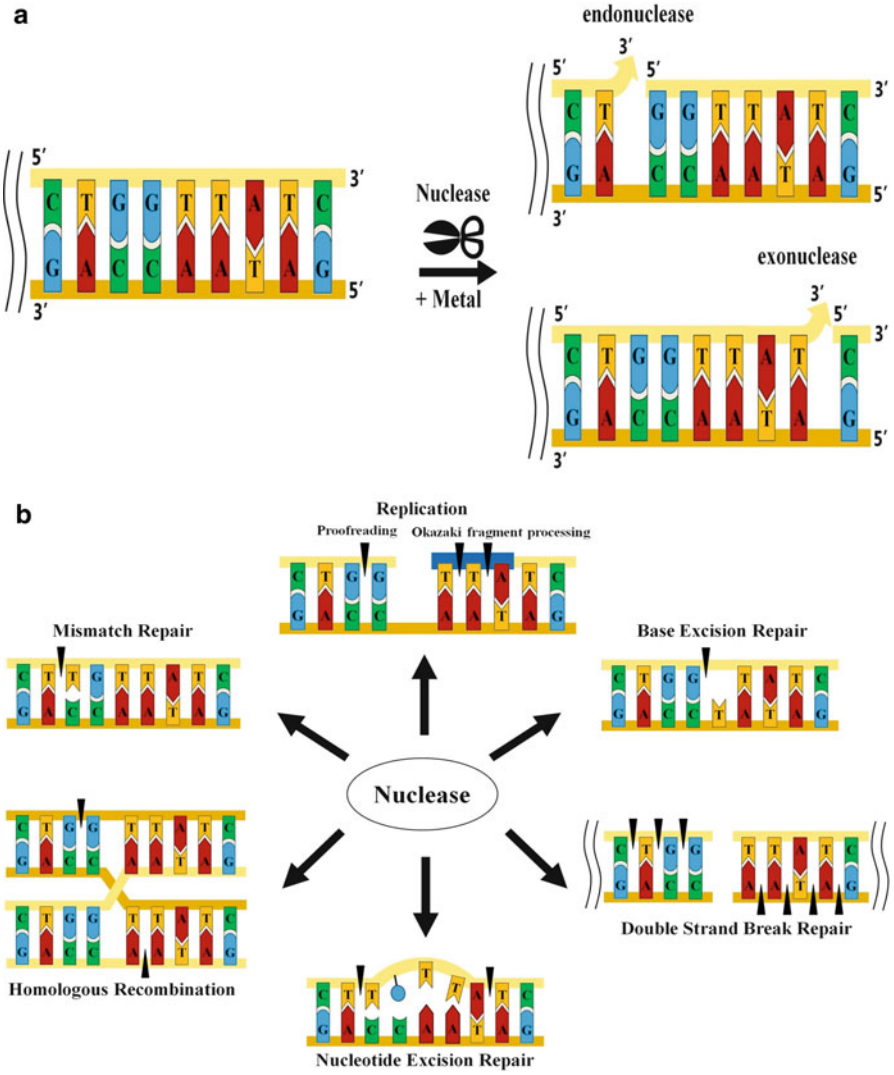

Fig. 5 Schematic diagram of the nuclease enzyme activity. The two strands of DNA are schematically drawn. (**a**) The cleavage made by the nuclease is represented by *arrows*. (**b**) The involvement of nuclease enzymes in the DNA repair system is summarized. Single-stranded region is shown in *blue* color

Beside cell wall-, starch-, protein-, and lipid-hydrolyzing enzymes, phytase, peroxidase, and thiol oxidase (Bamforth 2009) also have hydrolytic activity. Phytase hydrolyzes phytate into phytic acid, inorganic phosphate, and myoinositol (Khattak et al. 2012). Two types of phytases, 3- and 6-phytase, function to dephosphorylate phytate. 3-Phytase is produced by microbes, while 6-phytase is found in seeds of higher plants, including barley. Inorganic phosphate, a constituent of nucleotides, is also utilized by metabolic machinery during in vivo nucleotide synthesis (purines and pyramidines).

6 Applications of EHEs

Endogenous enzymes of various classes have multiple applications in day-to-day life. The major applications are in food, animal feed, textile, paper and pulp, fuel (energy), pharmaceutical, and chemical industries (Carvalho et al. 2003; Hsu and Lakhani 2002). EHEs also have numerous potential applications in advanced biosciences and engineering fields. Some of the potential applications of endogenous enzymes are described below.

6.1 Food Industry

Hydrolyzing enzymes are a vital part of various processes within the food industry. Their hydrolyzing activities are responsible for the formation of different products from the raw food materials. Starch-hydrolyzing enzymes play a significant role in the baking and brewing industries. Almost all hydrolyzing enzymes, such as α- and β-amylases, are found in raw food materials, e.g., flour and malt. Both of these amylases perform individual, but complementary, roles in food processing. Starch is initially broken down into low-molecular-weight dextrins by α-amylases; these dextrins are then further converted to maltose by β-amylase, and maltose is converted into whatever components are necessary for yeast growth (Khattak et al. 2012). Glucoamylases help to facilitate the breakdown of starches into simple fermentable sugars in the baking industry and have been shown to intensify the bread crust color through released glucose (Polaina and MacCabe 2007).

Xylanases hydrolyze hemicelluloses and are used, together with amylases, glucose oxidase, and proteases, in the bread-making process. Wheat flour contains hemicelluloses, which can be broken down to allow the redistribution of water, making the dough softer. Xylanases help to delay the formation of crumbs, thus increasing bread volume (Harbak and Thygesen 2002; Camacho and Aguilar 2003). Xylanase is recommended for making lighter cream crackers and improving the texture and regularity of the wafers. Currently, xylanases have been employed, together with cellulases, amylases, and pectinases, in order to enhance the yield of juice through the liquefaction of fruit and vegetables; achieve better recovery of aromas, important oils, mineral salts, edible dyes, and pigments; reduce viscosity;

and suppress breakdown of materials that obstruct the physiological features or chemical nature of the juice.

Cellulases have multiple applications in the food industry. For example, cellulases can be used for fruit juice and oil extraction. As mentioned earlier, along with other groups of enzymes, cellulases are used for the purification of fruits juices. An important feature of cellulases is their use in the isolation of proteins from soybeans and coconuts. The efficiency of starch isolation is increased with the activity of cellulases. Cellulases can digest ball-milled lignocelluloses, which are commonly used as food additives (Carvalho et al. 2003; Hsu and Lakhani 2002). Cellulases play a vital role in the hydrolysis of cellulosic waste, which results in the production of cello-oligosaccharides and fermentable sugars. These are essential for the digestion of cell wall components, which facilitates the release of flavor-related compounds, enzymes, and polysaccharides (Kuhad et al. 2011).

6.2 Brewing Industry

Enzymes have been used to make beverages since ancient times. Currently, the brewing industry relies on several groups of enzymes for preparing beverages using different feedstocks as substrate materials.

The traditional brewing process is mainly based on the germination and processing of barley grains. The germination period, which lasts about 7 days, involves such enzymes as α-amylase, β-amylase, and proteinases originating from barley grains. The germinated grains are then heated to develop color and flavor. These enzymes further hydrolyze the starches and proteins contained in crushed starchy cereals, resulting in the formation of simple sugars (e.g., mono- and oligosaccharides), which are fermented by yeast to produce ethanol. Amylolytic enzymes are also used for the development of low-molecular-weight carbohydrates (fermentable sugars) used by yeast cells for the production of alcoholic drinks.

Currently, a major focus in the brewing industry is immobilized enzyme technology, which can be used to effectively produce low-calorie beers and other beverages. Conventional fermentation systems produce high quantities of dextrins from starch hydrolysis, which are carried along to the final product. Immobilized glucoamylases are used to convert these dextrins to fermentable sugars for further fermentation. By passing the fermenting beer through a reactor containing immobilized glucosidase, these dextrins can be broken down into glucose, which is then almost completely transformed into alcohol. A great advantage of this technique is that the enzyme does not contaminate the product.

Glucanases obtained from microbes play a vital role in the fermentation processes of beers and wines (Singh et al. 2007; Bamforth 2009). The quality and yield of the fermented products is increased with the use of glucanases and related polysaccharides (Bamforth 2009; Bamforth et al. 2009). Enzymes including glucanase, pectinase, and hemicellulases improve the color extraction, clarification, quality, and stability of wine (Singh et al. 2007; Galante et al. 1998). Wine aroma is

also improved by β-glucosidase, which modifies glycosylated precursors. Currently, many enzymes are commercially available for use in the preparation of wine, contributing to the improvement of wine yield and quality. A number of improved enzymes, such as cellulase and pectinase, can be exogenously added during wine making in order to improve the productivity of accessible brewing processes in the near future (Bamforth 2009; Bamforth et al. 2009).

6.3 Feed Industry

The use of enzymes as feed additives is also well established. A number of enzymes from various enzyme classes are used in various applications in the feed industry. Production of feed stock using enzymes is currently an important part of agricultural business. Most of these types of enzymes are involved in the digestion of cellulose-based feeds.

Xylanases, together with certain other essential enzymes, including glucanases, pectinases, cellulases, proteases, amylases, phytase, galactosidases, and lipases, are used in the animal feed industry. These enzymes hydrolyze the arabinoxylans contained in feed components and reduce the viscosities of raw materials (Twomey et al. 2003). The addition of xylanase to feed containing maize and sorghum improves the initial digestion of nutrients in the early part of the digestive tract, improving energy utilization. Furthermore, the combined action of the remaining enzymes mentioned above produce a well-digestible food mixture. Endogenous enzymes are produced in much smaller quantities in young fowl and swine as compared to adults. Therefore, their performance as livestock is improved by the added food supplements.

Cellulases are widely used as supplements in the feeds of ruminants and monogastric animals. Additionally, cellulases are used in the pretreatment of lignocellulosic materials and in the dehulling of cereal crops. Their activities influence the digestibility of feeds in monogastric animals and ruminants (Kuhad et al. 2011). Supplementation with cellulase in feedstocks enables dairy animals to consume more feed, resulting in increased milk production. The nutritional values of agricultural wastes and grains can be improved through cellulases and xylanases (Godfrey and West 1996). These enzymes can degrade certain feed constituents and provide additional digestive enzymes, such as proteases, amylases, and glucanases.

Monogastric animals generally cannot digest and utilize plant-based feeds containing cellulose and hemicelluloses. Certain enzymes, such as xylanases and glucanases, are used in cereal-based feeds for these animals, enabling them to digest these feedstocks. β-Glucanases and xylanases are also used in the feeds of monogastric animals to promote the hydrolysis of nonstarch polysaccharides, such as β-glucans and arabinoxylans. Glucanases and xylanases decrease the viscosity of high-fiber rye- and barley-based feeds in poultry and pigs. These enzymes are effective in causing weight gain in chickens and piglets by improving the digestion and absorption of feed materials (Singh et al. 2007; Bhat 2000).

Phytase is currently the most abundant enzyme used in the feed industry. Phytase is used in cereal feeds (containing natural phosphorous bound to phytic acid) consumed by monogastric animals. The addition of phytase to these feeds results in a significant reduction in phosphorus excretion from monogastric animals (Lei and Stahl 2000; Kies et al. 2001).

6.4 Pharmaceutics and Medical Applications

The health-promoting activities of certain enzymes, their derivatives, and combinations of enzymes have facilitated the investigation of the therapeutic potential of these enzymes. For example, certain enzymes have been shown to have antimicrobial effects and have therefore become key elements in various therapeutic drugs and materials. Some of the potential therapeutic applications of EHEs are described below, and additional applications of EHEs in this industry are available in the literature.

Enzymes can be administered orally or by injection for treatment of certain diseases. Sacrosidase (β-fructofuranoside fructohydrolase from *Saccharomyces cerevisiae*) is used in the treatment of congenital sucrase-isomaltase deficiency (CSID). In this disease, patients are unable to use the disaccharide sucrose. Drugs containing sacrosidase hydrolyze sucrose, thus allowing patients with CSID to consume a more normal diet (Treem et al. 1999). Certain pancreatic enzymes, including lipases, proteases, and amylases (in the form of a mixture), have been shown to be effective in the treatment of fat malabsorption in patients with human immunodeficiency virus (HIV) (Carroccio et al. 2001). Furthermore, the same enzymatic mixture has been successfully used to treat pancreatic insufficiency (Schibli et al. 2002).

Lysozyme is a naturally occurring bactericidal agent used in a variety of food and consumer materials. This enzyme has the ability to break down the carbohydrate chains in the bacterial cell wall, thereby prohibiting the growth of bacterial cells and preventing food poisoning and other maladies. Lysozyme has also been shown to possess activity against HIV.

Chitinases are another group of enzymes that possess natural bactericidal potential. Chitin is the basic structural unit of the cell wall in a variety of pathogenic microorganisms, such as protozoa, fungi, and helminths. Chitinases effectively target chitins and possess good antibacterial activities (Fusetti et al. 2002). Certain lytic enzymes derived from bacteriophages target the cell wall of *Streptococcus pneumonia*, *Bacillus anthracis*, and *Clostridium perfringens* (Zimmer et al. 2002). These enzymes have the potential to halt the growth and activities of drug-resistant bacterial strains.

Xylanase and xylan have a few potential applications in the pharmaceutical industry. Xylanases are sometimes added in combination with a complex of enzymes (hemicellulases, proteases, and others) to produce certain medicinal products. Hydrolytic products of xylan, such as β-D-xylopyranosyl residues, can be converted into combustible liquids (ethanol), solvents, and artificial low-calorie

sweeteners. The resulting sweeteners are noncarcinogenic and are suitable for diabetic and obese individuals. A variety of commercial products containing xylitol, such as chewing gum, can be found on the market.

7 Conclusion

EHEs are involved in almost every known biological process. With the advent of novel techniques of enzyme isolation and purification, their applicability is broadening and increasing. Current approaches toward developing cell-free lysates from lysed microbial cells and their isolation, concentration, and purification have generated a great amount of interest in the potential use of EHEs in various industrial applications. Newly developing biotechnological techniques are allowing the identification of various novel applications of purified EHEs, specifically in genetic engineering. Current methods using grouped enzyme approaches for process simplification are providing insight into the broad future applications of EHEs.

Contents

Abstract

Pullulan is a microbial exopolysaccharide produced by polymorphic fungus *Aureobasidium pullulans*. Owing to its structure, consisting of α(1→4) and α(1→6) linkages, it has unique properties and hence is suitable for a variety of commercial applications in various field including food, pharmaceuticals, and biomedical. In this chapter, biosynthesis, production through microbial fermentation, and influence of fermentation conditions like pH, temperature, aeration, agitation on microbial growth, pullulan yield, pullulan purity, and molecular weight are discussed. Later, options of using various agricultural wastes as carbon source for pullulan production are considered.

Abbreviations

ATP	Adenosine triphosphate
DE	Dextrose equivalent. It is a measure of reducing sugars present in starch hydrolysate. Carbohydrate molecules like starch are polymers of monosaccharide. The extent of polymerization is indirectly measured by DE. In starch hydrolysate DE represents the amount of reducing sugar as dextrose. Dextrose equivalent of starch is 100 and that of glucose/dextrose is 100. Starch hydrolysates with DE ranging between 1 and 13 are termed as dextrins and those with DE in the range of 13–20 are called maltodextrins. DE for glucose syrup is typically greater than 20, and commercial glucose syrup has a DE of 40–42.
UDPG	Uridine diphosphate glucose

1 Introduction

Pullulan is an extracellular α-linked glucan produced by the polymorphic fungus *Aureobasidium pullulans*. It is a linear α-D-glucan. It consists of maltotriose subunits interconnected by (1→6)-α-D-glucosidic linkages (Youssef et al. 1999; Oguzhan and Yangilar 2013). The glucose units in maltotriose are linked by an α-(1→4)-glycosidic bond. Though pullulan mainly consists of repeating units of maltotriose, at random maltotetraose subunits also do appear. The maximum content of maltotetraose is estimated to be 7 % (Singh et al. 2008). Structure of pullulan was first resolved in 1960s (Leathers 2003). The structure of pullulan (Fig. 1) produced by *A. pullulans* is independent of type of strain used (Shingel 2004).

Average molecular weight of pullulan depends on the type of culture used, media composition, and fermentation type. Typically it ranges from 5×10^4 to 4×10^6 (Heald and Kristiansen 1985). From the elemental analysis, chemical formula of pullulan is elucidated as $(C_6H_{10}O_5)_n$ (Cheng et al. 2011). Bioactivity of the polymers is significantly influenced by average molecular weight and molecular weight distribution (Cheng et al. 2011).

In 1938, Bauer observed the polysaccharide production by *Aureobasidium pullulans*, and it was first isolated and characterized by Bernier (1958) from culture broths of *A. pullulans* (Singh et al. 2008). *A. pullulans* is a common plant pathogen found everywhere on the earth. It is found in fresh- and seawater, soil, dead plants, textile, and wood (Moubasher et al. 2013; Shingel 2004). As *A. pullulans* produce melanin also, it is known as black yeast. Apart from *A. pullulans*, *Tremella mesenterica*, *Cyttaria harioti*, *Cyttaria darwinii*, *Cryphonectria parasitica*, *Teloschistes flavicans*, and *Rhodotorula bacarum* also produce pullulan (Oguzhan and Yangilar 2013). Commercial production of pullulan was first started by Hayashibara Company Limited, Japan, in 1976. Hayashibara continues to be the major supplier of pullulan (Farris et al. 2014). Pullulan film was first brought to the market in 1982 (Singh et al. 2008).

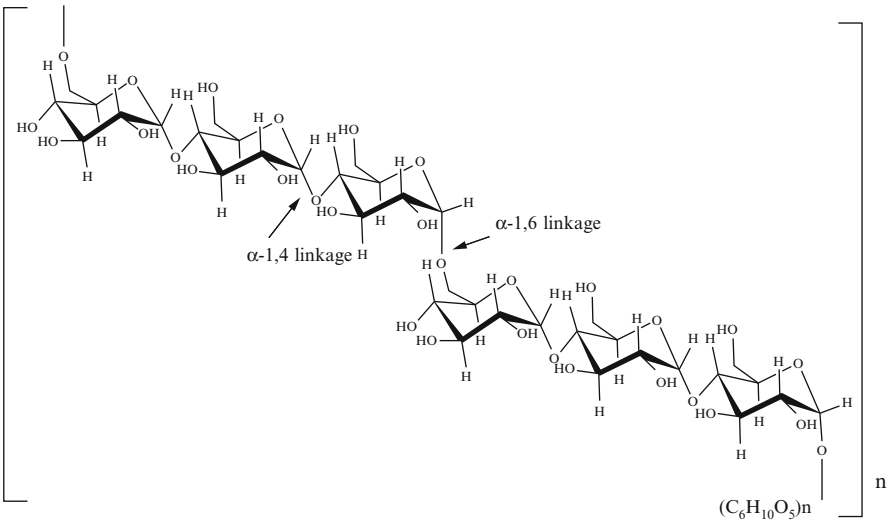

Fig. 1 Structure of pullulan

A. pullulans is an omnipresent organism. It was originally classified as Fungi Imperfecti under the family of Moniliales. Recently, it has been classified under ascomycetous yeast (Singh and Saini 2008). *A. pullulans* exists in five different morphologies. These are yeastlike cells, young blastospores, swollen blastospores, chlamydospores, and mycelia (Cheng et al. 2011; Oguzhan and Yangilar 2013). Though it has been widely accepted that pullulan yield depends on the morphology of the fungus, there is no consensus on which type of cell morphology is responsible for pullulan production (Cheng et al. 2011). Yeastlike cells (Heald and Kristiansen 1985), swollen cells (Campbell et al. 2004), and chlamydospores (Simon and Bouchonneau 1993; Singh et al. 2008) had been claimed to be the major pullulan producers by different group of scientists. Studies had shown that initial pH of the fermentation medium influenced the morphology of the organism and hence pullulan yield (Heald and Kristiansen 1985). It is also reported that higher fraction of hyphae (>3 %) results in poor pullulan yield (Simon and Bouchonneau 1993).

2 Physical Properties

Pullulan is soluble in water and insoluble in organic solvents excluding dimethylformamide and dimethyl sulfoxide (Oguzhan and Yangilar 2013;Youssef et al. 1999). It is nonhygroscopic in nature (Oguzhan and Yangilar 2013). It is edible, nontoxic, and noncarcinogenic. Its aqueous solutions are comparatively less viscous. Two distinct and useful properties, namely, structural flexibility and enhanced solubility, of pullulan result from regular alteration of 1→4 α and 1→6 α linkages (Gniewosz and Duszkiewicz-Reinhard 2008). It has good thermal stability, and it is stable up to 250 °C and decomposes only at temperature above

Table 1 Typical properties of pullulan

Parameter	Specification
Appearance	Whitish or yellowish white (Singh et al. 2008)
Solubility	Easily soluble in water; insoluble in organic solvents excluding dimethylformamide and dimethyl sulfoxide
Specific optical activity	More than +160° in 1 % solution
Molecular weight (kDa)	50–4,000
Polypeptides (%)	Maximum 0.5 %
Solution pH	5–7
Mineral residue ash (sulfated, %)	Maximum 3
Moisture (%)	Maximum 6 %
Taste and odor	Tasteless and odorless

250 °C. Some of the important properties of pullulan are listed below in Table 1 (Singh et al. 2008).

3 Biosynthesis/Elaboration of Pullulan

Polysaccharides are produced by the organisms for their self-protection. Pullulan produced by the *A. pullulans* form a highly hydrated layer around the cells in order to protect them from dehydration and from protozoans (Cheng et al. 2011). The mechanism of pullulan biosynthesis is not yet understood completely in spite of extensive research on this. Biosynthesis of pullulan occurs in cytosol and membrane and then it is secreted out forming a slimy layer on the cell surface.

Aureobasidium pullulans utilizes three enzymes, namely, α-phosphoglucose mutase, uridine diphosphate glucose pyrophosphorylase (UDPG-pyrophosphorylase), and glucosyltransferase, that are involved in the polymerization of glucose units during biosynthesis of pullulan (Cheng et al. 2011). Uridine diphosphate glucose (UDPG) is the main precursor in pullulan biosynthesis from glucose. Biosynthesis of pullulan is described here in two stages. The first stage is the synthesis of essential precursor and the second stage is polymerization of pullulan.

Figure 2 explains the synthesis of uridine diphosphate glucose in *A. pullulans*. For simplicity, the synthesis is explained using sucrose as example raw material. Sucrose is first hydrolyzed into monosaccharides by *A. pullulans*. Isomerase enzyme acts on hydrolyzed glucose units to convert it into its isomer (fructose). The fructose molecules are then phosphorylated by ATP into fructose 1-phosphate which is further converted into fructose 1,6-diphosphate by another ATP molecule. Fructose bisphosphatase enzyme then converts fructose 1,6-diphosphate to fructose 6-phosphate. Subsequently phosphoglucoisomerase converts fructose 6-phosphate into glucose 6-phosphate. Glucose 6-phosphate is transformed by α-phosphoglucose mutase into glucose 1-phosphate which is further acted by UDPG-pyrophosphorylase to convert it to UDP-glucose.

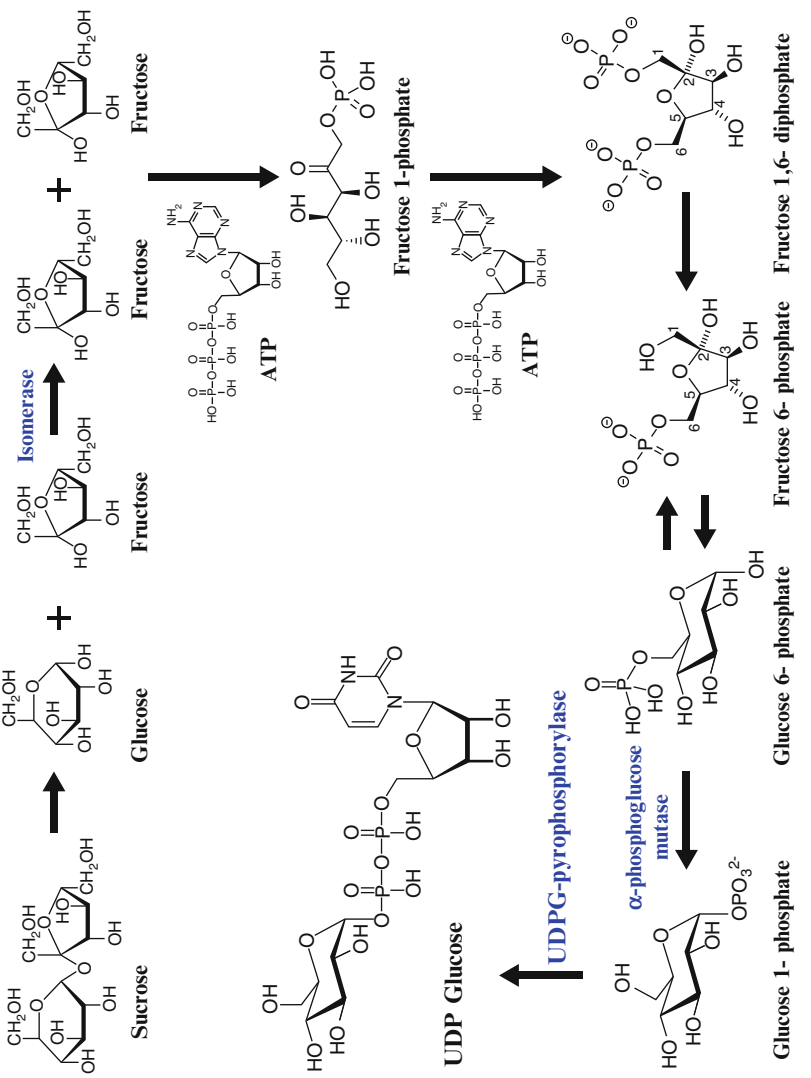

Fig. 2 Synthesis of uridine diphosphate glucose in *A. pullulans*

Polymerization of pullulan starts with the pentasaccharide from UDP-glucose molecule. Glucosyl 1-phosphate from UDP-glucose containing D glucose is attached to lipid hydroperoxide by forming a phosphoester bridge (Fig. 3). Consequently addition of other glucose subunits continues with other UDP-glucose releasing UDP. This initiates assembling of pullulan polymeric unit at α- 1, 6 carbon forming lipid-linked isomaltose unit. Chain elongation continues further with addition of glucose subunits forming isopanosyl precursor. The polymeric chain formation continues with α- 1, 4 maltotriose units linked together at α- 1, 6 position.

However, the biosynthesis of pullulan is not well understood till date. Further research on the metabolic pathway and pullulan formation will be required to increase yield and reduce cost of production of pullulan (Cheng et al. 2011; Shingel 2004).

4 Production of Pullulan

Nature of fungal strain, carbon (C) source, media composition, culture pH, fermentation temperature, dissolved oxygen concentration (Gniewosz and Duszkiewicz-Reinhard 2008), agitation rate (Lazaridou et al. 2002), and fermenter configuration influence pullulan yield (Campbell et al. 2003).

Color variant *A. pullulans* strains which do not produce melanin pigment can be used to improve pullulan yield and to simplify downstream processing steps (Singh et al. 2009). The melanin pigment produced by *A. pullulans* is black in color and has a characteristic absorption wavelength of 400–600 nm (Israilides et al. 1999). It is produced at the end of exponential phase. After released into the medium, they covalently bind to pullulan giving black-colored product. In order to reduce the overall cost of production and to improve the quality of the product, suppression of melanin pigment is very important. Several color variants had been reported in literature. A black yeast strain NG isolated from strawberry fruit produced pigment-free pullulan at pH 4.5 (Li et al. 2009). *A. pullulans* var. *melanogenium* P16 isolated from mangrove system produced pigment-free pullulan (Ma et al. 2014). *A. pullulans* RG-5 (Singh et al. 2012) and *A. pullulans* P 56 (Youssef et al. 1999) are few more examples of strains not producing melanin.

Aureobasidium pullulans produce pullulan from mono- or disaccharides like xylose, glucose, fructose, mannose, galactose, sucrose, and maltose (Thirumavalavan et al. 2009). Commercially pullulan is produced from starch hydrolysate containing 40–50 % dextrose equivalent (DE). The sugar concentration is maintained between 5 % and 15 %. Excess sugar concentration will inhibit the pullulan production (Cheng et al. 2010b; Goksungur et al. 2011). It is reported that excess sugars inhibit pullulan production by suppressing the enzymes like α-phosphoglucose mutase, UDPG-pyrophosphorylase, and glycotransferase which are responsible for pullulan production. Thus, fed-batch reactor will better suit pullulan production.

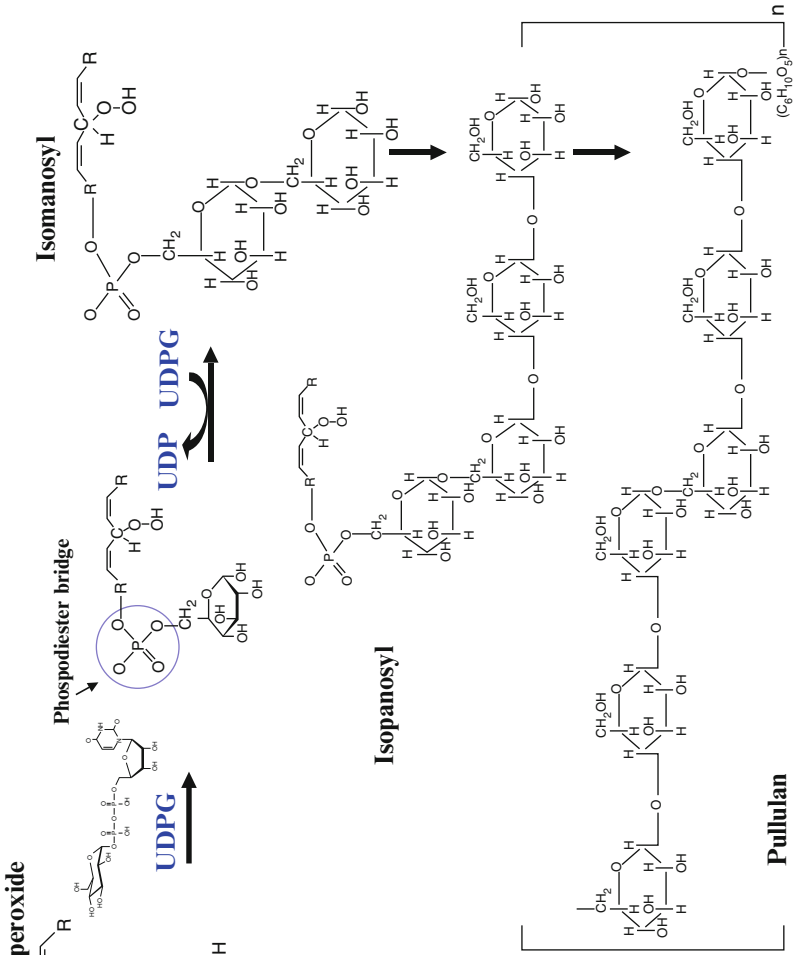

Fig. 3 Pullulan synthesis using UDP-glucose

Other micronutrients like peptone, phosphate, and basal salts are required in sufficient quantity for achieving maximum yield. Up to 70 % of starch hydrolysate used could be converted into pullulan if the fermentation conditions are maintained carefully (Kumar et al. 2012).

pH influences the morphology of the organism and in turn the pullulan yield. The pH of the medium is initially adjusted to 6.5, and during initial 24 h of fermentation, pH gradually reduces (Leathers 2003). Solution pH influences the morphology of *A. pullulans* and, in turn, morphology affects pullulan yield (Wu et al. 2009). At pH 2.5 mycelia form is observed, and at pH 4.5 yeastlike cells are obtained (Ji-Hyun et al. 2002). Optimum pH for pullulan production is between 5.5 and 7 (Wu et al. 2009). Optimum pH for biomass growth and polysaccharide production are different from this (Cheng et al. 2010a; Ji-Hyun et al. 2002). At lower pH biomass growth is high, but pullulan production is low (Israilides et al. 1999). Yeastlike morphology was maximum (60 %) at pH 6.3 while Asian palm kernel was used as solid substrate for *A. pullulans* and hence pullulan production was maximum (Sugumaran et al. 2013a). According to published reports, pullulan production was higher if the medium pH was allowed to drop naturally rather than maintained constant (Ji-Hyun et al. 2002; Sevious et al. 1992). If the pH is not controlled, fraction of high molecular weight of pullulan gradually decreases due to pullulanase activity (Ji-Hyun et al. 2002). However, if the pH goes below 2.5, it can cause severe acid stress and reduce pullulan yield (Wang et al. 2013). For maximum pullulan production, mild to moderate acid stress (pH 3.5–4.5) is preferential according to Wang et al. (2013). On the other hand, if pH is controlled at 6.5, fraction of high molecular weight pullulan is nearly constant (Ji-Hyun et al. 2002).

In addition to pH, nutritional level and dissolved oxygen also affect the morphology and hence pullulan yield (Li et al. 2009).

Temperature of the medium is to be maintained at 30 °C. Typically at 75 h the culture growth reaches a maximum. At the end of the logarithmic growth phase, when there is a depletion of nutrients, biosynthesis of pullulan begins. Maximum pullulan synthesis is obtained between 70 and 90 h (stationary phase) of cultivation. Nitrogen starvation favors pullulan synthesis. Depletion of ammonium ion concentration plays a major role in diversion of carbon source to polysaccharide production by suppressing biomass accumulation. However, *A. pullulans* also synthesizes pullulan-degrading enzyme (pullulanase) at later stages of growth. Thus, beyond stationary phase pullulan yield drops due to the action of pullulan-degrading enzymes (Campbell et al. 2003). Typically pullulan yield of about 70 % and above is achievable (Leathers 2003).

Often two-stage pH control or two stage pH and temperature control improves both cell growth and pullulan production as different conditions are required for cell growth and pullulan production. Low pH and high temperature are preferential during initial period, while relatively higher pH (~4–6.5) and low temperature will be required for pullulan production during the stationary phase later (Wang et al. 2013; Wu et al. 2010; Xia et al. 2011).

A. pullulans grows well under aerobic condition (Gniewosz and Duszkiewicz-Reinhard 2008). Aeration and agitation both stimulate the production pullulan (Survase et al. 2007). Agitation rate, impeller speed, and shear conditions influence the morphological changes of the culture and metabolite production and sometimes cause cell damage (Lazaridou et al. 2002). Strong aeration and agitation promotes yeastlike morphology which is more efficient in pullulan production. At low shear rate the amount of yeast cell is more and hence pullulan production (Wecker and Onken 1991). As the polymer accumulates, the broth becomes non-Newtonian and becomes highly viscous. This leads to increased demand for oxygen. A combination of low shear rate and low dissolved oxygen level maximizes pullulan yield (Sevious et al. 1992; Wecker and Onken 1991).

Addition of uracil is reported to improve pullulan yield. Both the time of addition and amount of uracil added affect the pullulan yield. Uracil added at zeroth hour of fermentation was utilized as a nitrogen source by the organism to stimulate the cell growth. When added after 48 h, uracil promotes pullulan production by 32 % (Sheng et al. 2014). Uracil enhances pullulan production by acting as a precursor for UDP-glucose which plays a vital role in the biosynthesis of pullulan (Sheng et al. 2014).

5 Reactors

Pullulan can be produced in batch reactor. As discussed earlier, pullulan is produced during the stationary phase and under nitrogen-limiting conditions. As excess sugar concentration can inhibit/decrease pullulan production, fed-batch fermentation is preferred over batch reactors. However, reports indicate that upon prolonged fermentation, say 7th day, further feed addition did not improve pullulan yield (Cheng et al. 2011). Continuous pullulan production is preferred for large-scale commercial production. At low dilution rate pullulan yield is increased in continuous fermenters. In order to improve the yield, various other designs of reactors had been proposed by several researchers.

Cheng et al. (2010b) had demonstrated that biofilm reactor enhances pullulan production. In this reactor 12 plastic composite tubes were employed. They were tied to the agitator of the reactor as shown in the figure. Plastic composite support employed was made of mixture of polypropylene and nutritious compounds. According to the authors, moderate leaching of nitrogen from the support maintains nitrogen level low in the reactor, favoring pullulan production, and no further addition of nitrogen is required. Another advantage of using plastic composite support, as reported by the authors, is that the cells were maintained in the stationary phase and hence the higher pullulan yield (Cheng et al. 2010b).

During the cell growth, the viscosity of the medium gradually increases. Typically in a stirred tank reactor, as the culture reaches its exponential phase, viscosity gradient appears in the radial direction. Near the agitator viscosity is lowest and near the wall it is highest (Gaidhani et al. 2003). Thus, the shear rate is maximum

near the impeller and minimum near the walls. As viscosity increases, both oxygen transfer and mixing become more difficult. This results in the formation of stagnant zones and impeller flooding in continuous stirred tank reactors. Since both oxygen transfer and mixing are influential factors of pullulan production, reactor systems with better oxygen transfer and mixing are preferential. Oscillatory baffled reactor developed by Gaidhani et al. (2005) overcomes these bottlenecks. It ensures uniform mixing with significantly lower shear strain rates. Up to 75 % higher mass transfer coefficients as compared to conventional stirred tank reactors are achievable in this reactor (Gaidhani et al. 2005). Uniform bubble size and enhanced gas holdup are considered to be responsible for improved mass transfer (Gaidhani et al. 2005).

Airlift reactor can also be used for pullulan production. In airlift reactor height to diameter ratio is high. Thus, process control is better and easy when compared with conventional reactor.

Recently, solid-state fermentation is gaining importance in bioconversion processes. Solid-state fermenters are superior to submerged fermenters as they consume less energy and less power. They are suitable for bioconversion of solid wastes into value-added products. However, there could be operational difficulties like heterogeneity in the reactor and heat and mass transfer limitations.

6 Downstream Processing

Typically purification of pullulan would require removal of cells from the culture, removal of melanin from the culture, removal of melanin pigment from the broth, precipitation of pullulan by addition of suitable solvents, resuspension of the precipitate, and final purification by ultrafiltration/chromatography.

Cell biomass can be removed by centrifugation or by cross-flow filtration (Cheng et al. 2011). The melanin pigment can be removed by activated carbon adsorption or by using a mixture of salt and alcohol (Singh et al. 2008). As pullulan is soluble in water and insoluble in most of the organic solvents, the product can be recovered from the purified supernatant by adding sufficient amount of organic solvent. Isopropyl alcohol, acetone, and ethanol are frequently employed. Upon addition of organic solvent addition, the polysaccharides begin to precipitate. The above two steps are repeated to achieve better purification. To further purify the product, pullulan solution is subjected to ultrafiltration and/or ion exchange (Kumar et al. 2012). Purified pullulan can be precipitated, dried, and mechanically ground to powder form (Cheng et al. 2011).

7 Pullulan Production from Agricultural Wastes

As stated earlier, *A. pullulans* utilize sugars like sucrose, glucose, fructose, and maltose and produce pullulan (Thirumavalavan et al. 2009). Alternatively, pullulan can also be produced from agricultural wastes like Asian palm kernel

(Sugumaran et al. 2013a), sweet potato (Wu et al. 2009), grape skin pulp (Israilides et al. 1998), hydrolyzed potato starch waste (Goksungur et al. 2011; Israilides et al. 1998), deoiled Jatropha seedcake (Choudhury et al. 2012), coconut by-products (Thirumavalavan et al. 2009), beet hydrolysate (Leduy and Boa 1977), deproteinized whey (Roukas 1999), carob pod (Roukas and Biliaderis 1995), jackfruit seed (Sugumaran et al. 2013b), etc. Pullulan yield obtained from several agricultural wastes under different formation conditions is listed below in Table 2.

Sweet potato is rich in starch content. As starch cannot be directly utilized by *A. pullulans*, saccharification pretreatment is necessary. However, since sweet potato contains β-amylase enzyme in it, external addition of saccharifying enzyme is often not required. Hydrolyzed sweet potato with a DE of 45 (containing approximately 54 % of maltose) yields 28.57 g/L (Wu et al. 2009). However, higher dextrose equivalent actually reduces pullulan yield. This is because of the fact that pullulan synthesis depends on the maltose concentration and not on glucose concentration (Wu et al. 2009).

While producing pullulan from agrowastes, the composition of saccharified intermediate affects pullulan yield. Treatment with more than one enzyme is often very useful to improve pullulan yield. While producing pullulan from hydrolyzed potato starch waste, Barnett et al. (1999) obtained maximum yield by using a two-step enzyme treatment (Barnett et al. 1999). In the first step, the starch waste was liquefied with α-amylase enzyme. For liquefaction, α-amylase was added to the starch waste, and the mixture is maintained at 65 °C and pH 6.5 for 30 min. Later the mixture was maintained at 90 °C for 2 h to complete liquefaction. Later in the second step, saccharification of the waste is carried out using an enzyme mixture consisting of pullulanase and β-amylase/amyloglucosidase. Saccharification with amyloglucosidase results in glucose-rich hydrolysate. Thus, extended saccharification to yield higher dextrose equivalent did not improve pullulan yield. On the other hand, when β-amylase was used for saccharification, maltose sugars were obtained as end product. Thus, extended period of saccharification yielded more maltose and ultimately resulted in higher pullulan yield (Barnett et al. 1999).

Israilides et al. (1998) reported that supplementation of NH_4NO_3 and K_2HPO_4 reportedly improves pullulan yield obtained from hydrolyzed potato starch from 12.9 to 30.8 g L^{-1} (Israilides et al. 1998).

Beet molasses is a sugar industry waste which is rich in sugar content. Typical beet molasses contain approximately 50 % sucrose. Thus, it is a potential substrate for pullulan production. However, it also contains high concentration of heavy metals like zinc, copper, magnesium, etc., which may inhibit pullulan production (Roukas 1998). Heavy metals can be removed by ion exchange to keep them below inhibitory concentration. Sulfuric acid pretreatment can increase polysaccharide concentration and yield by 79 % and 73 %, respectively.

Carob pod is another sugar-rich agrowaste. It contains 40–50 % sugars like glucose, fructose, sucrose, and maltose. Apart from sugar, it contains 7 % cellulose,

Table 2 Comparison of pullulan production from various agrowastes

Agrowaste	Strain	Polysaccharide concentration	Fermentation type	References
Coconut water	*A. pullulans*	38.3 g/L	Submerged fermentation	Thirumavalavan et al. 2009
Coconut milk	*A. pullulans*	58.0	Submerged fermentation	Thirumavalavan et al. 2009

Jackfruit seed	*A. pullulans* NCIM 1049	34.22 g/L	SSF	Sugumaran et al. 2013b

5 % hemicellulose, 3–4 % protein, 1–2 % pectin, etc. It may contain up to 20 % phenolic components. The kibbles obtained from carob pod after removing the seeds need to be comminuted. Sugars can be extracted from the comminuted kibbles by mixing with sufficient quantity of water. Later the sugars can be used in fermentation (Roukas and Biliaderis 1995).

Asian palm kernel is a potential feedstock for the production of pullulan. *A. pullulans* grown on solid mass of Asian palm kernel produced 18.3 g/L of pullulan (Sugumaran et al. 2013a).

Pullulan could also be produced from a mixture of deoiled Jatropha seedcake, corn steep liquor, and jaggery without addition of any further nutrients. The yield was reported as 62.25 g/L under optimized condition (Mehta et al. 2014).

Cassava is used for the commercial production of starch. Cassava residue contains up to 60 % of starch and can be effectively utilized for the production of various fermentation products. It serves as potential feedstock for the production of pullulan in solid-state fermentation (Ray and Moorthy 2007).

Sena et al. (2006) had shown that supplementation of sucrose medium with soybean oil had enhanced pullulan yield. They had achieved 25–50 % increase in pullulan yield through the addition of soybean oil (Sena et al. 2006). Similarly, supplementation of sucrose with olive oil had also reportedly improved pullulan yield (Youssef et al. 1998).

8 Applications of Pullulan

By virtue of unique structure consisting of regular alteration of α (1→4) and α (1→6) linkages, pullulan exhibits distinctive properties (Cheng et al. 2010c; Oguzhan and Yangilar 2013). Owing to its unique properties, pullulan can be used in numerous applications in food and pharmaceutical industries (Oguzhan and Yangilar 2013). It can be used as low-calorie viscosity enhancer in the food and blood plasma substitutes (Cheng et al. 2010c). It is used as starch substitute in low-calorie formulations (Gaidhani et al. 2005). It is also used as low-viscosity filler in some beverages (Leathers 2003). Pullulan functions as a prebiotic by promoting beneficial bifidobacteria growth. Thus, it can be used as a dietary fiber in humans and rats (Leathers 2003).

It has the ability to form thin fibers and thin films. Pullulan films are transparent, strong, and impermeable to oxygen, oil, and grease (Leathers 2003; Sevious et al. 1992). As the pullulan film is oxygen impermeable, it can be employed as food protective coating to protect flavor and aroma and to improve the shell life (Israilides et al. 1999). Commercial use of pullulan film is very common in various breath freshener or oral hygiene products.

9 Conclusion/Prospects

Pullulan is a commercially important microbial exopolysaccharide produced by polymorphic fungus *Aureobasidium pullulans*. Biosynthesis of pullulan involves UDPG and glucose residues. Microbial fermentation is influenced by fermentation conditions like pH, temperature, aeration, agitation on microbial growth, pullulan yield, pullulan purity, and molecular weight. In order to reduce the raw material cost, pullulan can be produced from several agricultural

wastes after proper pretreatment. Through careful control of operating conditions and choice of reactor, pullulan yield and molecular weight can be controlled.

Biosynthesis of Extracellular Matrix Components, Glycosaminoglycans, Proteoglycans, Collagens, Elastin and Structural Glycoproteins

19

Leslie Robert

Contents

Abstract

Most polysaccharides of higher vertebrates are in the extracellular matrix (connective tissues) either free or bound to proteins. Their composition and biological role will be described in decreasing order of their polysaccharide content.

Keywords

Extracellular matrix • Hyaluronan • Proteoglycans • Glycosylated collagens • Structural or matrix glycoproteins

1 Introduction

Extracellular matrix (ECM) is the macromolecular component of connective tissues (CT), which comprise also the cellular elements, essential fibroblasts, and some other cell types which produce ECM rich in carbohydrates, unevenly distributed among its macromolecular components: glycosaminoglycans (GAGs), proteoglycans (PGs), structural or matrix glycoproteins (SGPs), collagens, and elastin. All four types of macromolecular components play essential roles in tissue structure and function to be described in the next sections, in decreasing order of the importance of their carbohydrate components. The biological role of ECM components depends on their chemical composition, their quality, quantity, and type of linkage of carbohydrates. Several of these macromolecules are used since immemorial times (as collagen for leather and for other industrial purposes). The emphasis is on vertebrate – mammalian tissues, first of all human connective tissues. We have to remind here that polysaccharides and carbohydrate-rich macromolecules appeared early during evolution, from prokaryotes, bacteria, algae, etc., both in the plant and animal kingdoms. The best known among the plant polysaccharides is cellulose, a polymer of glucose, of industrial use since antiquity. These polysaccharides were also intensely studied and will be mentioned in other chapters of this book.

2 Connective Tissue Polysaccharides

Hyaluronic acid, or better hyaluronan as called by scientists specialized in its study, is a high molecular weight polysaccharide composed of alternative units of a hexosamine (*N*-acetylglucosamine) and a uronic acid (D-glucuronic acid). Its very long chains can reach several millions of molecular weight (Balazs 1970). Its most interesting and unique properties are a high capacity to retain water and viscoelasticity. These properties are closely linked. It is the high water content which confers to this polysaccharide its remarkable viscoelasticity. This quality determines also its physiological roles in tissues. Young skin is rich in hyaluronan and confers to skin elasticity and hydration, component together with resistance to pressure. With age, the hyaluronan content of the skin decreases, with it decreases also the hydration of the skin. This contributes to the loose, wrinkly aspect the skin takes on old people. The long hyaluronan polysaccharide chains are susceptible to degradation by enzymes, called hyaluronidases, and also by free radicals (or better reactive oxygen species, abbreviated as ROSs, comprising also hydrogen peroxide (H_2O_2)). A simple experiment to demonstrate this physiologically important property of hyaluronan is to add to its solution a small amount of vitamin C (ascorbic acid) with some ferrous iron (Fe^{++}) to see the viscosity of the polysaccharide to decrease rapidly – measured with a viscosimeter – as a result of the rapid degradation of the polysaccharide by free radicals generated by this reagent. A testicular extract, rich in hyaluronidase, will exhibit the same effect. Both processes, degradation by ROSs and by hyaluronidases, are of great biological

importance. Because of its exceptional physicochemical properties, hyaluronan is industrially produced for medical purposes as, for instance, injection in arthritic articulations (as, for instance, the knee joint) for lubrication. A cross-linked hyaluronan preparation is used to fill wrinkles on the face. High molecular weight hyaluronan is used also in eye surgery. Injected before opening the eyeball, it will prevent the dislocation of intraocular structures during the surgical intervention. The inventor of this method, E.A. Balazs in the USA, called this type of surgery under the protection of hyaluronan "viscosurgery."

3 Polysaccharides of Proteoglycans

Proteoglycans (PGs) are also important macromolecular components of connective tissues. They are composed of a protein backbone carrying from one to hundreds of polysaccharide chains, called, according to their composition, chondroitin sulfates or dermatan sulfates. They are composed, as hyaluronan, of alternating units of a hexosamine and uronic acid, with one exception, keratan sulfate to be described later. There are several types of chondroitin sulfates: chondroitin A sulfate or better chondroitin 4-sulfate is composed of a succession of alternating hexosamines and uronic acids, different from those in hyaluronan. Chondroitin 4-sulfate is composed of an acetylgalactosamine-4-sulfate linked to 2-sulfated glucuronic acid. Chondroitin 6-sulfate is similar, but its *N*-acetylgalactosamine components are sulfated on position 6 as the only difference. Dermatan sulfate, another component of proteoglycans, is a polysaccharide chain composed of 4-sulfated *N*-acetylglucosamine linked to iduronic acid which can be also sulfated on position 2 of its ring, but not all iduronic acids in the polysaccharide chains are sulfated. Keratan sulfate, mentioned above, is a different polysaccharide, differing from the chondroitin and dermatan sulfates by the absence of uronic acid. In its chains, *N*-acetylglucosamine is 6-sulfated and linked to a unit of galactose (an isomer of glucose), being therefore different from chondroitin or dermatan sulfates, all containing uronic acids.

4 Heparin and Heparan Sulfates

These polysaccharides differ both in composition and localization from chondroitin or dermatan sulfates. Their hexosamine component is glucosamine which can be acetylated and/or *N*-sulfated, linked to an iduronic acid which also can be 2-sulfated. These polysaccharide chains are located on cell membranes where they play important roles in "helping" the fixation of growth factors enhancing cell proliferation. Heparin is well known for its anticoagulant capacity, used in medicine.

In the proteoglycans, these polysaccharide chains are mostly linked by an O-glycosidic linkage to the OH – group of the amino acids serine and threonine. Some polysaccharides are however linked to asparagine residues by an N-glycosidic linkage of the hexosamine component of the polysaccharide.

When bound to the central protein of proteoglycans, these polysaccharide chains are sticking out laterally and interact with collagen fibers, oriented parallel to the protein part of the proteoglycans. These interactions consolidate the orientation of collagen fibers as well as the construction of fiber bundles, important for the solidity of tissues.

5 Matrix or Structural Glycoproteins (SGPs)

Glycoproteins were first isolated from blood plasma or serum. Most plasma proteins are glycated, with the exception of serum albumin which is not, at least in bovine and human blood. The glycan content and composition are variable in quantity – from a few % to 20 % or more of the molecular weight – as well as in quality. For most, but not all, glycoproteins, the glycan chains are linked to the protein by an N-glycosidic linkage. The usual monosaccharide constituents are glucosamine, mannose, galactose, fucose, and sialic acid, at least in vertebrates and in human plasma. The detailed structure of these glycan chains was elucidated and described in great detail, among others by Jean Montreuil in Lille. The interest in blood glycoproteins increased considerably when it was demonstrated that some of them, as orosomucoid or better α_1-acid glycoprotein as well as haptoglobin, increase in blood during inflammatory processes. For this reason, determinations were described and widely used in hospital laboratories to follow the course of such diseases. One of the precursors of this medical research, M.F. Jayle at the Paris Medical School, who discovered haptoglobin – a glycoprotein forming a 1 to 1 complex with hemoglobin – proposed that connective tissues, actively participating in the inflammatory process, are the source of the glycans attached to inflammatory glycoproteins. Although this hypothesis could not be confirmed – most circulating glycoproteins are elaborated in the liver – we started to look for similar glycoproteins in connective tissues. Using an avascular tissue, cornea, we could show that it contains and synthetizes glycoproteins, similar in composition to circulating glycoproteins (Labat-Robert et al. 1986). Their glycan portion was of a comparable importance (of ~12 %) compared to circulating glycoproteins. The composition of the glycan chain was also similar; for the cornea preparation, it contained mannose, galactose, glucosamine, fucose, and sialic acid, and the only difference with plasma glycoproteins is that it was sulfated. To distinguish circulating glycoproteins from tissue glycoproteins, we called them structural glycoproteins (SGPs). We also demonstrated, using radioisotope-labeled precursors, that SGPs, present in all tissues investigated, were synthesized locally by connective tissue cells, fibroblasts, and others. A large number of such tissue-originated glycoproteins were described, forming a large part of the matrisome, the molecular component of ECM. The most studied component of these tissues – glycoproteins – is fibronectin (FN), which acts as a molecular linkage fastening cells to the surrounding ECM. Only adherent cells survive and detached cells die by apoptosis, a sort of cellular suicide. FN links ECM components to cells by interacting with cell receptors called integrins (Hynes and Yamada 2012). This adhesion process enables

cells to exchange "informations" with ECM components and is also "informed" of the behavior and fate of ECM components. This exchange of information, called "inside-out" and "outside-in" by R.O. Hynes, who discovered integrins, is of crucial importance for the homeostasis (normal physiology) of tissues.

6 Collagens

Collagens are quantitatively the most important components of ECM. They appeared with the sponges during the "Cambrian explosion"; the original, ancestral gene coding for the typical collagen sequences X–Y–glycine, where X and Y are often proline or hydroxyproline, was demonstrated in fungi (mushrooms) and even in some large viruses. Collagen molecules are composed of three peptide chains of the above composition, forming a triple helix. These peptide chains contain lysine and hydroxylysine residues. Some of the hydroxylysine residues are glycosylated, containing O-linked glucose or galactosyl-glucose residues. Therefore, collagen molecules are also part of the glycoprotein family. There are a number of different collagen types coded by different genes and differing also as far as their glycan content is concerned. Among the collagen types in vertebrates, only type VI is rich in glycans; an important part of this molecule has the typical composition of a glycoprotein, quite different from collagen composition. Therefore, it can be considered as a structural glycoprotein. Some tissues, as the cornea, are rich in type VI collagen (about 20 %), suggesting an important structural role for this molecule. As a matter of fact, the perfectly regular arrangement of collagen fibers is the condition of corneal transparency. This regular arrangement is created by the interaction of collagen type VI and proteoglycans of the cornea during its development in the embryo.

7 Elastin

As stated above, elastin is the only nonglycated macromolecule of the ECM. Its subunit, tropoelastin (TE), is not glycated and remains unglycated after its cross-linking by the formation of specific cross-link – amino acids, desmosine and isodesmosine, catalyzed by an enzyme called lysyl oxidase (LOX), as elucidated by Miles Partridge in GB. In order to form elastic fibers in tissues as the large, "elastic" blood vessels, elastin must interact with "microfibrils." These are composed of a number of SGPs, among them the fibrillins, which all are glycated. Such microfibrils (MFs) were shown to be present also in tissues, except elastin, and were present at earlier stages of phylogenesis, before the appearance of elastin with the vertebrates. Microfibrils, rich in fibrillins, replace elastin in invertebrate tissues. With aging, and even more during the development of the atherosclerotic process, the elastic fibers are degraded by elastolytic enzymes, elastases, liberating elastin peptides in the blood circulation reaching an average concentration in human blood serum of about 10 μg/ml. This is not a neutral process. The liberated elastin peptides

interact with an elastin receptor on cell membranes, triggering a series of reactions, some of which are harmful, as the release of more elastases and free radicals. This is a vicious circle, playing an important role in tissue aging.

Finally, let us say a few words on the biological importance of glycoconjugates, in particular of their glycan portion. As they exhibit specific carbohydrate sequences with their stereospecific conformations, they can specifically interact with complementary surfaces on other macromolecules and especially with lectins. These are proteins possessing stereospecific conformations enabling them to interact specifically with some carbohydrates. One example is the class of galectins specific for galactose end groups on glycan chains. A component of the elastin receptor acts as a galectin. Lectins are widespread in plants; also, the best known is concanavalin which found some practical applications in biochemistry. Glycan chains on most if not all glycoconjugates interact with stereo-compatible conformations on other molecules to fulfill their biological roles.

8 Conclusions

Oligo- and polysaccharides attached to proteins (glycoproteins) formed an important family of biological macromolecules. Most, but no all, proteins of the body are glycoproteins. The glycan chains, of specific composition, impart characteristic properties to glycoproteins and define their biological roles. Glycoproteins are present in tissues as well as in the blood circulation. Another family of polysaccharides, hyaluronan, and protein–polysaccharide complexes, proteoglycans, are important tissue components especially in connective tissues, designated as the Matrisome. They fulfill specific functions of vital importance for the body.

Polysaccharides from Bioagro-Waste for New Biomolecules

20

Paola Di Donato, Annarita Poli, Valentina Taurisano, and Barbara Nicolaus

Contents

Abstract

Polysaccharides are the main chemical components of several kinds of agro-wastes including food processing residues and agricultural wastes. These types of biomass are produced in huge amounts every year and therefore represent a global environmental issue. The exploitation of agro-wastes as rich sources of valuable polysaccharides, according to the biorefinery approach, could afford both a strategy for waste minimizing and a more sustainable production of energy and chemicals. As a matter of fact, indeed polysaccharides are traditionally used in a wide range of production chains, for example, in food, pharmaceutical, material, or packaging industries.

1 Polysaccharides from Bioagro-Wastes: A Sustainable Source of Chemicals and Energy

Polysaccharides' market is continuously increasing because of the wide range of potential applications of this class of natural polymers that indeed, as such or by means of chemical and/or biological transformations, can constitute the main feedstock in many industrial activities such as food, materials, chemicals, and energy production.

Polysaccharides are produced by animals, microorganisms, and plants, but the latter are the main source of these biomolecules: indeed about 90 % of total natural

polysaccharides produced on Earth can be found in the vegetables. Polysaccharides are the main constituents of vegetable biomass that, in turn, is currently exploited for the production of chemicals, materials, and energy: many examples of biorefinery facilities (a new production system resembling the petroleum refinery for the production of chemicals and fuels, but that is based on renewable feedstock like vegetables) can be found such as corn or sugarcane refineries that produce food and biofuel.

Notably polysaccharides are massively processed for different production chains; they are indeed the sources of the sugars that in turn are the starting materials for the production of those chemical compounds that have been included in the list of the so-called "building block" molecules, according to the National Renewable Energy Laboratory (NREL) of the United States. These "building block" substances (i.e., succinic, fumaric, and malic acids; 2,5-furandicarboxylic acid, 3-hydroxypropionic acid, aspartic acid, glucaric acid, glutamic acid, itaconic acid, levulinic acid, 3-hydroxybutyrolactone, glycerol, sorbitol, and xylitol/arabinitol) are fundamental feedstock for the production of secondary and intermediate chemicals that are then used in several industrial sectors such as cosmetic, pharmaceutical, material, food, transportation, industry, etc. (Pacific Northwest National Laboratory 2004).

For these reasons in the last years, an increasing demand of plant polysaccharide-derived goods (energy and foods) has caused an increase in the intensity of acreage, agricultural production, and agro-industrial activities that in turn generate million tons of wastes. Such wastes, i.e., bioagro-wastes, comprise all the residues produced from horticulture and/or agricultural activities during cultivation, postharvest, and processing of plants. Indeed all the different phases of manufacturing of vegetable materials (e.g., selection of fruits and vegetables for the whole market or food industries, industrial processing of crops for the production of chemicals, energy, food, and so on) produce every year huge amounts of highly heterogeneous residues. Depending on the feedstock and on the production chain considered, such waste biomass is constituted by unemployed parts of plants, like roots, straw, leaves, cobs, etc., or by vegetable transformation residues like exhausted pulps, peels, and seeds, etc.

The proper disposal of such residual biomass represents a critical environmental concern and an economical problem that all agro-industries have to face with. Nonetheless, since bioagro-wastes still contain a variety of value-added chemicals, they could be considered as starting material for other production chains rather than residual matter. Indeed significant amounts of proteins, polysaccharides and fibers, polyphenols, carotenoids, fatty acids, etc., that are lost in the discarded materials could be used for the production of a variety of goods like biomaterials, food additives, nutraceuticals, antioxidant and antimicrobial agents, bioenergy, etc. The reuse and then the valorization of bioagro-wastes could be implemented in the frame of an integrated biorefinery approach to biomass exploitation, in which the exploitation of full plant feedstock could be a solution to the issues of sustainability and of waste disposal.

Therefore, on these bases, vegetable biomass like bioagro-wastes is under investigation as sources of biologically and biotechnologically useful polysaccharides (Sanchez-Vazquez et al. 2013).

In the next sections, after a brief overview of main plants' polysaccharide structures, some of the principal agro-waste sources of polysaccharides and the most diffused and promising biotechnological applications of such biomolecules are discussed.

2 Polysaccharides of Vegetable Origin: Chemical Structure and Classification

Polysaccharides are carbohydrate polymers made up of different monosaccharide units and are mainly located in plants that indeed produce more than 90 % of the total polysaccharides on Earth.

Generally referred to also as "glycans," polysaccharides are very complex polymers: indeed they can be defined as "polydisperse" molecules (due to the wide range of molecular weights they can have) and as "polymolecular" since they exhibit different fine structures, depending on their natural source.

Their classification can be made on the basis of chemical and structural features or depending on their biological role.

On the basis of structural criteria, the following groups can be distinguished:

- Homoglycans (made up of one type of monomer unit) and heteroglycans (made up of two or more types of monomer units)
- Linear and branched (with different degrees of branching, i.e., with few and very long branches regularly or irregularly spaced, with short branches grouped to form clusters, or with branch-on-branch structures, i.e., with bush-like structures)
- Neutral or charged (cationic or anionic)

Finally, on the basis of their biological role, they can also be distinguished in:

- Structural elements
- Energy-reserve polysaccharides

Following the latter classification, in this section the main polysaccharides that can be found in higher plants and therefore in the different kinds of bioagro-wastes are described.

2.1 Structural Polysaccharides in Higher Plants

The main and most abundant structural polysaccharide that is found in plant kingdom is cellulose, a homoglycan constituted by β-(1→4)-linked

D-glucopyranose (Glc*p*) units. Cellulose is a high-molecular-weight polysaccharide made up of repeating cellobiose units (n) forming a linear structure in which both intra-chain and interchain molecular hydrogen bonds occur to link the chains.

The intermolecular hydrogen bonds give a sheetlike nature to the native polymer that possesses a crystalline structure whose organization varies from source to source (Klemm et al. 2005).

The cellulose chains are organized to give supramolecular structures, namely, elementary fibrils (with a length between 1.5 and 3.5 nm), microfibrils (between 10 and 30 nm), and microfibrillar bands whose length can be on the order of several hundred nm (Klemm et al. 2005). Nevertheless, the physical organization of cellulose polymers into such fibrillar structures varies depending on the plant source (Reddy and Yang 2005).

Cellulose is found both in primary and secondary plant cell wall in tight association with other polysaccharides, namely, the group of hemicelluloses. Historically identified as those polysaccharides extractable from higher plant tissues by means of hot aqueous alkaline solutions, hemicelluloses are a group of structurally different polysaccharides that can be distinguished in xylans, mannans, β-glucans, and xyloglucans (Ebringerova et al. 2005).

Xylans are the most abundant polysaccharides that can be found in the secondary cell walls of both mono- and dicotyledon (hardwood, grasses, cereals), and they include both homopolymers (the less frequent ones) and heteroglycans containing glucuronic acid and arabinose units. Xylans can be distinguished in: glucuronoxylans (GXs), arabinoglucuronoxylans (AGXs) and glucuronoarabinoxylans (GAXs), and arabinoxylans (AXs).

GXs possess a linear backbone of β-(1→4)-linked D-xylanopyranose (Xyl*p*) units decorated by single 4-*O*-methyl-α-D-glucopyranosyl uronic acid (MeGlcA) residues linked at C-2 of Xyl*p* monomers (Figs. 1 and 2).

AGXs (Fig. 3) and GAXs are made up of a linear β-(1→4)-D-Xyl*p* unit chain branched with MeGlcA at position 2 and α-L-arabinofuranose (L-Ara*f*) at position 3 of the backbone units.

Finally AXs are polysaccharides consisting of a linear chain of β-(1→4)-D-Xyl*p*-linked units bearing branches of α-L-Ara*f* at position 2 or 3 of xylan residues (Fig. 4).

The second group of xylans, namely, mannans, are the main components of the secondary cell walls of softwoods, although some of them can be found also as reserve polysaccharides. Mannoglycans can in turn be divided in: galactomannans (GaMs), glucomannans (GMs), and galactoglucomannans (GGMs).

GaMs (Fig. 5) are composed of linear chains of β-(1→4)-linked D-mannopyranose (Man*p*) units substituted at position 6 with galactopyranose (Gal*p*) residues with the Man:Gal ratio ranging from 1:1 to 5.7:1.

GMs (Fig. 6) possess a backbone consisting of β-(1→4)-D-Man*p* and β-(1→4)-D-Glc*p* units that, like in the case of Konjac's mannans, can be acetylated at two or three position of some Man*p* residues.

GGMs are characterized by a backbone made up of alternating segments of β-(1→4)-linked D-Man*p* and segments made up of both β-(1→4)-linked D-Man*p*

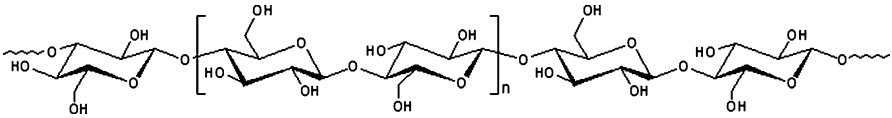

Fig. 1 Structure of cellulose backbone with the cellobiose repeating unit in brackets

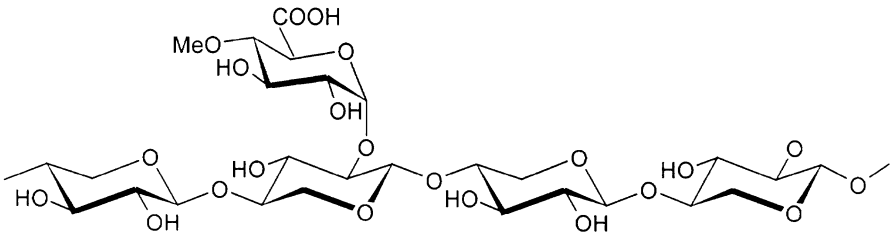

Fig. 2 Structure of glucuronoxylans (*GXs*) (Ebringerova et al. 2005)

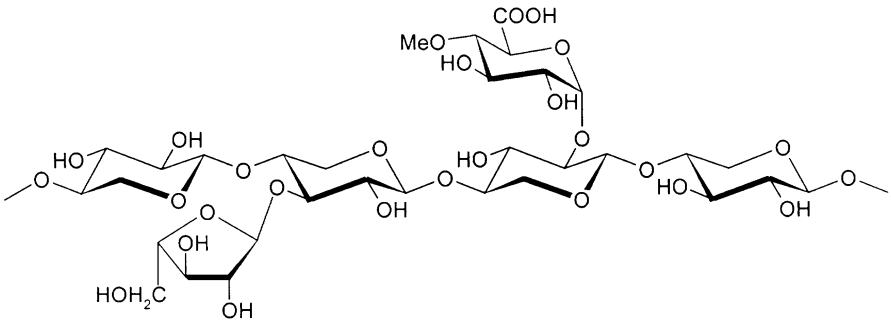

Fig. 3 Structure of arabinoglucuronoxylans (*AGXs*) (Ebringerova et al. 2005)

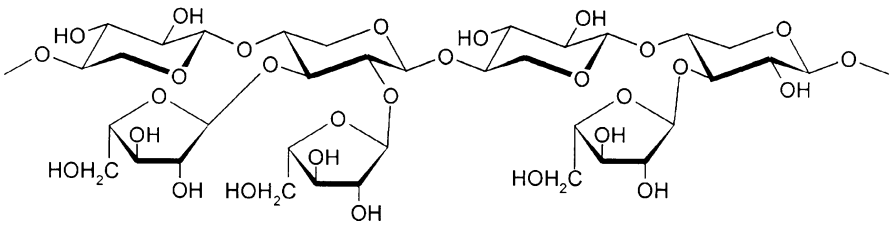

Fig. 4 Structure of arabinoxylans (*AXs*) (Ebringerova et al. 2005)

and (1→4)-D-Glc*p* units, with branches of Gal*p* units linked at two, three, or six position of Man*p* and at three or six position of Glc*p* units. Either GMs or GGMs are also present as storage carbohydrates in the seeds or roots of some plants such as Konjac.

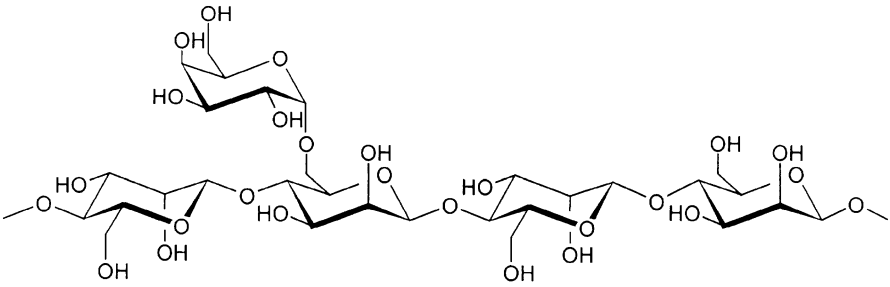

Fig. 5 Structure of galactomannans (*GaMs*) (Ebringerova et al. 2005)

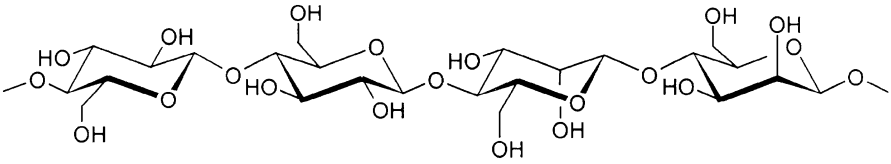

Fig. 6 Structure of glucomannan (*GM*) (Ebringerova et al. 2005)

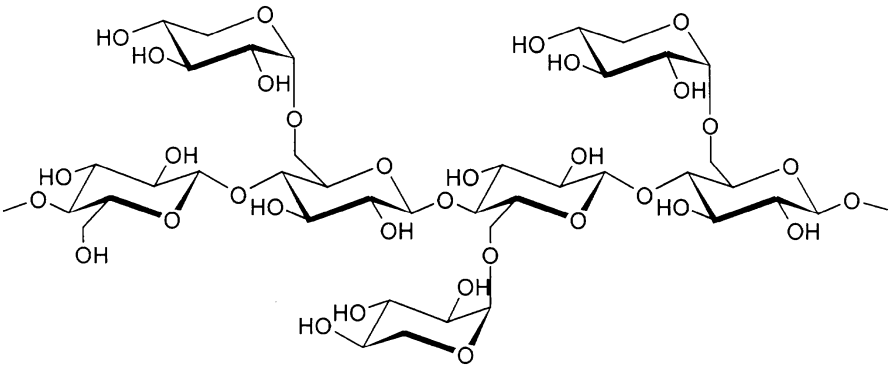

Fig. 7 Structure of xyloglucan (*XG*) (Ebringerova et al. 2005)

β-Glucans, also named (1→3, 1→4)-β-D-glucans, are the hemicellulose components of cereal grains. They are unbranched homopolymers in which about 70 % Glc units are (1 →4) linked and the remaining 30 % are (1→3) linked, mainly assembled as repeating units of cellotriosyl, cellotetraosyl, or less frequently of chains of 9–14 Glc residues, separated by single (1→3) links.

Xyloglucans (XGs) are the most abundant polysaccharides that can be found in the primary cell walls of dicotyledon. They present a cellulose-like backbone made up of (1→4) β-D-Glc*p* units decorated with α-D-Xyl*p* residues linked at 6 position of Glc monomers (Fig. 7), with a degree of xylosylation ranging from 30–40 % in grasses to 60–75 % in some dicotyledons.

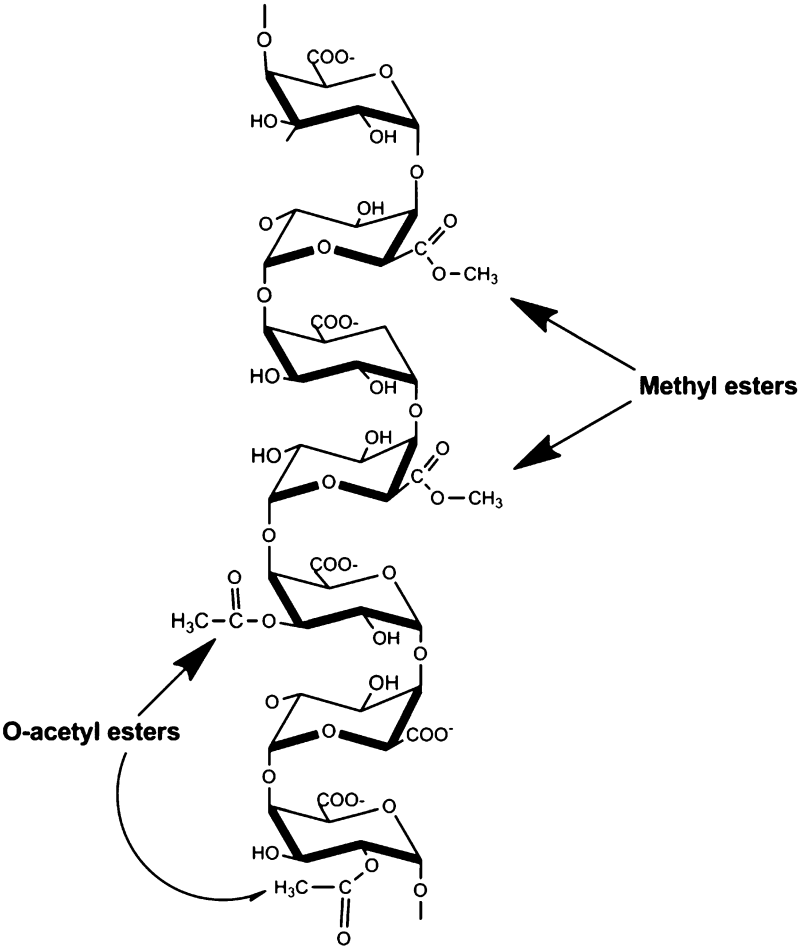

Fig. 8 Structure of homogalacturonans (*HGs*) (Ochoa-Villarreal et al. 2012)

XGs can be distinguished in two types: XXXG, in which three xylosylated Glc units are separated by one free Glc unit, and XXGG, in which there are alternating sequences of two xylosylated and two non-xylosylated Glc units.

The other main group of structural polysaccharides that can be found in plants is represented by the complex of pectic polysaccharides that are constituted by both neutral and acidic sugars. They comprise the homogalacturonans (HGs) also called the "smooth region" of pectins, and the heteropolymeric rhamnogalacturonans (RGs) and arabinogalactans (AGs), the "hairy regions" of pectins.

Homogalacturonans (HGs), the most abundant members of pectins, are homopolymers of α-(1→4)-D-GalA*p* units partially methyl esterified at C-6 and *O*-acetyl esterified at C-2 or C-3 (Fig. 8), depending on the source. Depending on the degree

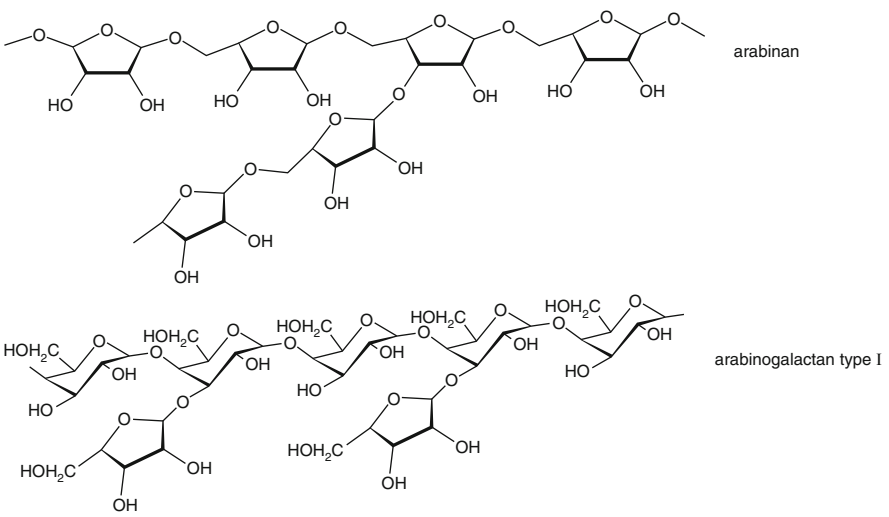

Fig. 9 Structure of arabinogalactans I (*AG-I*) (Wong 2008)

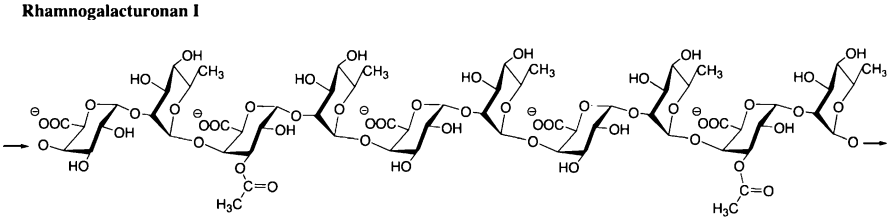

Fig. 10 Structure of rhamnogalacturonans I (*RG-I*) (Wong 2008)

of methyl esterification (DM), HGs can be distinguished in "high methyl-esterified HGs" (DM >50 %) or "low methyl-esterified Hgs" (DM <50 %) (Yapo 2011).

The "hairy region" of pectins is composed of arabinogalactans (AGs) linked to rhamnogalacturonans (RG) chains. AGs can be distinguished in two groups: type I arabinogalactan (AG-I) (Fig. 9) and type II arabinogalactan (AG-II) (Fig. 10). AG-I, also defined as arabino-4-galactans, are constituted by a β-(1→4)-Gal*p* backbone (Fig. 9) with side chains, linked at C-3 of Gal, made by arabinans. Arabinans are linear or branched chains of 1→5-linked L-Ara*f* units (Fig. 9): linear ones are substituted by single L-Ara*f* residues at C-2 or C-3 of the chain.

Type II arabinogalactans (AG-II), also defined as arabino-3,6-galactans, present a linear backbone of 1 →3- and 1→6-linked Gal*p* units, branched at 1, 3, or 6 position with arabinan chains. Both AG-I and AG-II are the constituents of RG-I pectins.

Rhamnogalacturonans (RGs), also defined as the real pectins, are heteropolymers of galactopyruronic acid (GalA*p*) and rhamnopyranose (Rha*p*) branched with AGs chains. They also are divided in two groups:

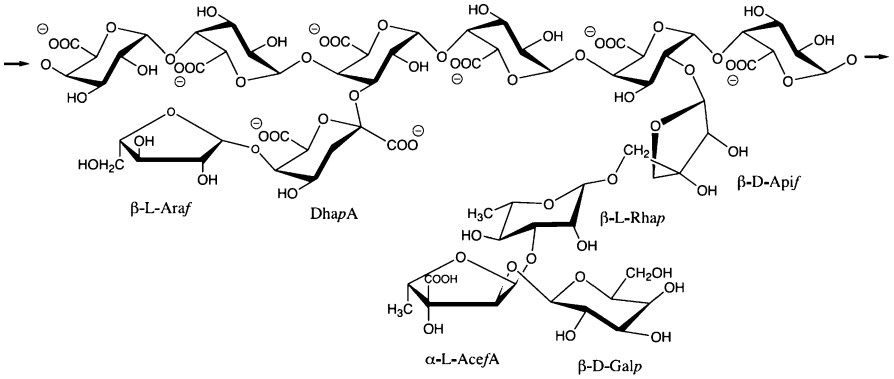

Fig. 11 Structure of rhamnogalacturonans II (*RG-II*) (Wong 2008)

rhamnogalacturonans I and II (RG-I and RG-II). RG-I possess a linear backbone of alternating α-1,4-linked GalA*p* units and α-1,2-Rha*p* units, the latter being the branching point to which (on position 4) arabinans or AGs chains are linked (Fig. 10).

Rhamnogalacturonans II (RG-II) are constituted by a homogalacturonan (HG) backbone of about 9–10 GalA*p* monomers, partially methyl esterified, and branched at position 3 or 4 by four different types of oligosaccharide (Fig. 11).

The side chains of RG-II present some glycosyl residues rarely found in other polysaccharides such as apiose (3-C-hydroxymethyl-β-D-erytrose), AceA (3-C-carboxyl-5-deoxy-L-xylofuranose), 3-deoxy-D-manno-octulosonic acid (KDO), 2-*O*-methylfucose, 2-*O*-methylxylose, 3-deoxy-D-lyxo-2-heptulosaric acid (DHA), aceric acid, and L-Gal (Paulsen and Barsett 2005).

2.2 Energy-Reserve Polysaccharides in Higher Plants

Starch is the main energy-storage polysaccharide that can be found in higher plants: it is composed of two glucose homopolymers, namely, the linear amylose and the branched amylopectin. Amylose is a linear chain of α-(1→4)-linked Glc*p* units, while amylopectin has a linear backbone of α-(1→4)-linked Glc*p* units with branches at C-6 made up of linear chains similar to amylose chains (Fig. 12). The degree of branching of amylopectin can vary, depending on the source of starch, from 4.2 in maize to 5.2 in oats. Similarly, the ratio of amylose vs. amylopectin component is different in the diverse natural sources: in general the branched component is the prevailing one since it can range from 75 % in maize or 77 % in wheat or 78 % in potatoes or 80 % in rice till up to 100 % in the mutant waxy maize (Robyt 2008).

Although starch is the main energy-reserve carbohydrate, other glycans such as fructans can be found as reserve in about 15 % of flowering plants. Fructans include both linear and branched polymers made up mainly of fructofuranose (Fru*f*) units

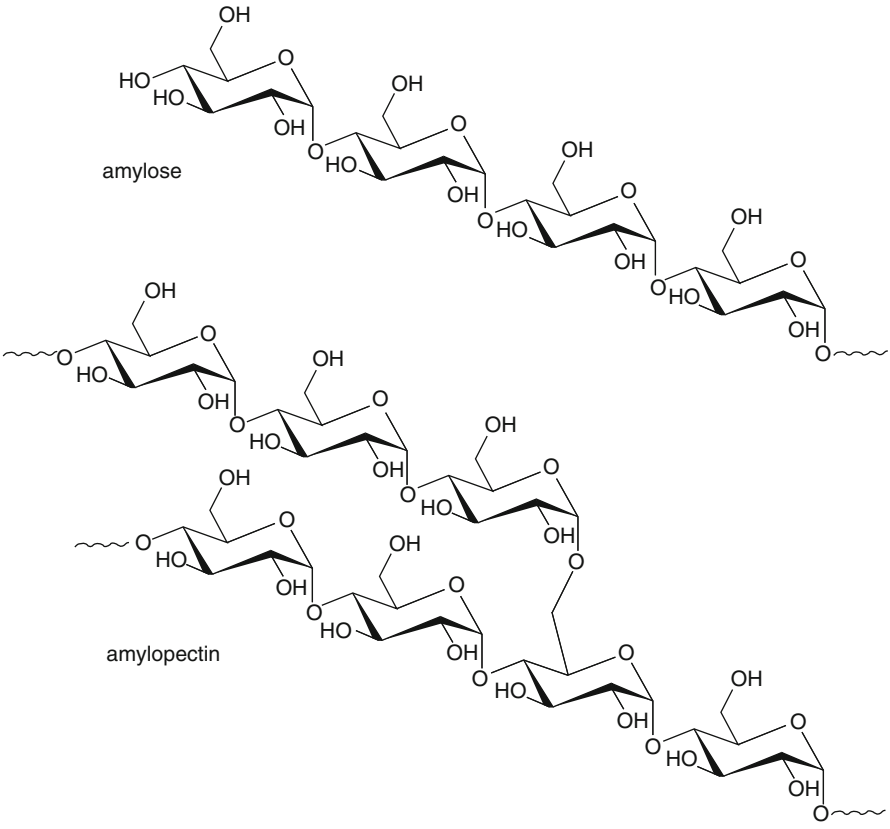

Fig. 12 Structure of amylose and amylopectin

that can be linked by β-(2→1) or β-(2→6) or both glycosidic bonds. The most studied fructans are the inulin-type fructans that possess a linear backbone of β-(2→1)-linked Fru*f* units attached to an initial sucrose (Suc) unit (Fig. 13).

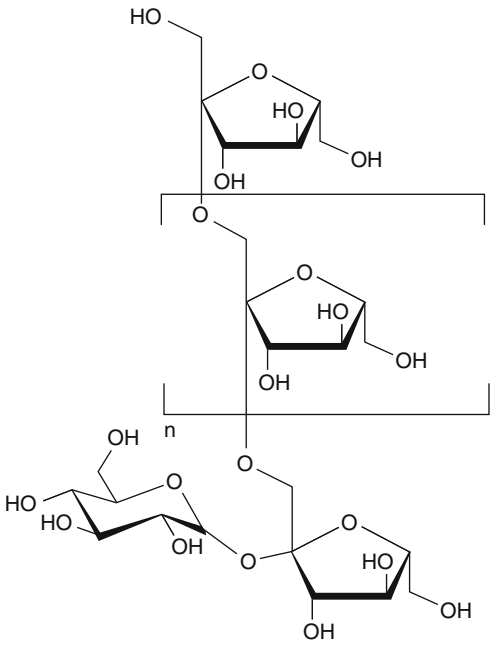
Notably, as mentioned in the previous section, some structural glycans can also serve as energy-reserve polysaccharides in higher plants, such as galactomannans in some legumes, mannans and glucomannans, and β-glucans in cereal grains.

3 Main Bioagro-Waste Sources of Polysaccharides

Agro-industrial wastes' chemical composition includes a complex of diverse polysaccharides that, in the frame of the biorefinery approach, could be converted in chemicals and/or energy by means of chemical and/or biochemical treatments.

Agro-wastes that potentially could afford sources of polysaccharides can be divided in two groups, namely, food wastes, i.e., residues of processing (canning, squeezing, peeling, milling, etc.) of fruits, cereals, and vegetables for

Fig. 13 Structure of inulin



food production, and agricultural residues, i.e., residues of harvesting and postharvesting phases.

3.1 Food Wastes

Food wastes that are currently used or that could potentially be exploited for polysaccharide production include mainly vegetable processing residues like seeds, peels and skins, husks, exhausted pulps, unripe or damaged fruits, etc. (Fig. 14).

Such residues are rich in structural carbohydrates (cellulose, hemicellulose, or pectins) or in other kinds of glycans and/or dietary fibers (i.e., a mixture of nondigestible carbohydrates comprising cellulose, hemicelluloses, pectins, and inulin in association with other nonsugar molecules like lignin, waxes, and polyphenols).

Several examples are available in literature concerning the chemical investigation of polysaccharide fraction of different vegetable wastes: in Table 1 some of them that are already exploited for industrial purposes and others that could be promising sources of valuable polysaccharides are listed.

Apple pomace annual production can rise up to 3.42 Mtons since nearly 50 % of the fruit is discarded after industrial processing for fruit juice production (Min et al. 2011; Walia et al. 2013). Depending on the extraction method employed, such wastes can be an interesting source of pectins and arabinans that can account from

Fig. 14 Some main food wastes: **a** apple pomace, **b** lemon residues, **c** tomato peels, **d** potato peels

4.6 % to 11.7 % or of hemicellulose and cellulose (Nawirska and Kwasniewska 2005) that in turn can be employed as soluble dietary fibers.

Banana is among the main agricultural resources in tropical and subtropical countries, and its cultivation and consumption generate about 10.9 Mtons of wastes per year (Sanchez-Vazquez et al. 2013). Banana wastes, i.e., peels, account for about 40 % of the fresh fruit weight and are composed of 50 % of dietary fibers of which 21.7 % are pectin polysaccharides, 3.8 % are hemicellulose, and 1.3 % are cellulose (Das and Singh 2004).

Pomace is also the main kind of residue remaining after the industrial processing of other fruits: some examples are constituted by black currants, cherries, chokeberries, and pears that are used in several European countries for the production of juices and beverages. These wastes are almost composed of dietary fibers (comprising besides polysaccharides like pectins, hemicellulose, and cellulose also lignin as main noncarbohydrate fraction) whose amount for the above-listed fruits is equal to 90.8 %, 91.37 %, 90.3 %, and 94 % of dry matter weight, respectively. The pomaces of the listed fruits present variable amounts of pectins, hemicellulose, and cellulose (Nawirska and Kwasniewska 2005), as reported in Table 1.

World citrus fruit production reaches more than 80 Mtons every year [Pourbafrani et al. 2010], and about 50–60 % of this biomass is discarded after squeezing for juices or peeling for liquor or jams production. Such wastes

Table 1 Main food waste sources of polysaccharides (Partially adapted from Poli et al. 2011)

Waste		Polysaccharides		
Source	Amount (Mtons y^{-1})	Chemical composition	Content (% dry weight)	Reference
Apple pomace	3.42	Pectins (arabinans)	4.6–7.7	Min et al. 2011; Walia et al. 2013
		Pectins/ hemicellulose/ cellulose	11.7/24.4/43.6	Nawirska and Kwasniewska 2005
Banana peels	10.9	Pectins/ hemicellulose/ cellulose	21.7/3.8/1.3	Sanchez-Vazquez et al. 2013; Happi Emaga et al. 2008; Das and Singh 2004
Black currant	≈ 0.5	Pectins/ hemicellulose/ cellulose	2.73/25.3/12.0	Nawirska and Kwasniewska 2005
Cherry		Pectins/ hemicellulose/ cellulose	1.51/10.7/18.4	
Chokeberry		Pectins/ hemicellulose/ cellulose	7.85/33.5/34.6	
Pear		Pectins/ hemicellulose/ cellulose	13.4/18.6/34.5	
Orange peels	7.4	Pectins	18/25	Kratchanova et al. 2004; Pourbafrani et al. 2010
		Pectins/ hemicellulose/ cellulose	23.0/11.0/37.1	Sanchez-Vazquez et al. 2013
Mandarin peels	3.1	Pectins/ hemicellulose/ cellulose	16.0/6.0/22.6	Sanchez-Vazquez et al. 2013
Lemon residues	≈ 2.5	Pectic polysaccharides	14.3	Poli et al. 2011; Sanchez-Vazquez et al. 2013
Carrot residues	≈11	Pectins/ hemicellulose/ cellulose	3.88/12.3/51.6	Vazquez et al. 2013; Nawirska and Kwasniewska 2005
Coffee husk	5	Pectins	12.4	Sanchez-Vazquez et al. 2013; Passos et al. 2014
Corn bran	7.8	Starch/ hemicellulose/ cellulose	4–11.2/28/70	Rose et al. 2010; Sanchez-Vazquez et al. 2013
Corn fiber	11.4	Starch	15–20	
Peanut husk	10	Arabinans/ galactans/ mannans	0.7/0.2/0.1	Sanchez-Vazquez et al. 2013

(*continued*)

Table 1 (continued)

Waste		Polysaccharides		
Source	Amount (Mtons y^{-1})	Chemical composition	Content (% dry weight)	Reference
Potato	>80	Starch/ hemicellulose/ cellulose	67.5/9.2/1.2	Sanchez-Vazquez et al. 2013; Das and Singh 2004
Tomato	11	Xyloglucan	7.5	Tommonaro et al. 2008
		Hemicellulose/ cellulose	11/9.1	Das and Singh 2004

(mainly coming from oranges, mandarins, grapefruit, lemons, and limes transformation) include peels, seeds, and pulps that contain different polysaccharides among which pectins are the most abundant. The total pectins' amount that can be recovered from citrus fruit residues depends upon both the extraction method employed and the citrus species: as shown in Table 1, the extraction yields can vary from 18 % to 25 % of dry matter for orange fruits (Kratchanova et al. 2004; Pourbafrani et al. 2010) to 23.0 % of mandarin peels (Sanchez-Vazquez et al. 2013) or finally to 14.3 % in the case of lemon residues (Poli at al. 2011). With regard to lemon residues, they account for about 50 % of starting material; therefore, since the total world production of lemons is ≈5 Mtons y^{-1}, a potential quantity of ≈2.5 Mtons of such residues could be exploited as source of pectins. In addition also other structural glycans could be recovered from citrus fruits, for example, hemicellulose and cellulose that share a significant portion of the polysaccharides extracted from orange and mandarin wastes (Table 1).

Exhausted pulps are produced also in the conversion of vegetables like carrots whose world production reaches about 33.6 Mtons per year (Sanchez-Vazquez et al. 2013): about 30–40 % of such amount is lost as by-products. Notably, 54.2 % of carrot pulp, on weight basis, is constituted by dietary fibers in which the main polysaccharides are represented by pectins, hemicellulose, and cellulose (see Table 1).

Corn is one of the main cereal crop productions indeed; according to data from the Food and Agriculture Organization of the United Nations (FAO, http://faostat3.fao.org/faostat-gateway/go/to/home/E), its world production is more than 800 Mtons per year. Corn bran and fibers are the main residues from processing of grains for food production: bran is the residue of dry milling for meals and floor production, while fibers are left after wet milling of grains for starch and oil recovery. Since corn grains account for about 15 % of total harvested maize, and considering that bran represents 6.5 %, while fiber is 9.5 % of total corn grain, a total production per year of about 7.8 Mtons and 11.4 Mtons of bran and fibers can be hypothesized, respectively. Corn fibers still contain interesting quantities of starch, while bran can afford besides starch also significant yields of cellulose and hemicellulose.

Among the most abundant vegetable food wastes, also potato and tomato residues have to be mentioned. Potato wastes, mainly peels, are about 80 Mtons y^{-1} and contain besides starch, as main polysaccharide, also appreciable quantities of cellulose and hemicellulose polymers. Tomato residues from canning industry (more than 11 Mtons of peels, seeds, and exhausted pulps, according to FAO data), besides the structural glycans of cell wall (cellulose and hemicellulose), are also an interesting source of new polysaccharides like the xyloglucan fraction isolated from peels and seeds by means of alkaline extraction (Tommonaro et al. 2008).

Husks from coffee and peanuts are also food waste sources of polysaccharides. About 55 % of coffee wastes are produced in Latin America, and husks contain pectins as main polysaccharide, accounting for more than 10 % of waste dry weight. Peanut is also cultivated and used in several countries; indeed its world production is about 34 Mtons: the by-products, mainly husks, are a rich source of arabinans, galactans, and mannans accounting in total for about 1 % of residues.

3.2 Agricultural Residues

Agro-wastes that are potential sources of polysaccharides encompass all the residues that are produced during the cultivation, harvesting, and postharvesting steps of several crops such as sugarcane or cereal crops like corn, barley, rice, wheat, etc. (Fig. 15). Such wastes are also classified as "lignocellulosic residues": lignocellulose is the complex of cellulose, hemicellulose, and lignin that are characteristic of plant cell wall.

Among the most abundant agricultural and lignocellulosic residues, sugarcane bagasse and cereal straw are particularly interesting polysaccharide sources because of their total annual production and significant lignocellulose content.

According to FAOSTAT data, the world total sugarcane production in 2012 has been more than 1,000 Mtons. Sugarcane bagasse, i.e., the residue of crushing of canes for sugar juice extraction, represents about 30 % of the plant, and it is composed of cellulose (40–45 %) and hemicelluloses (30–35 %), besides lignin (Cardona et al. 2010).

Cassava is a tuber crop that represents the basic food for more than 700 million people in Asia (where it is known as tapioca), Latin America, and Africa. According to FAO data, its world total production in 2012 has been about 263 Mtons y^{-1}. Cassava processing for flour production and starch extraction from tubers results in the production of peels and of a solid residue, the bagasse, that still retains high levels of starch that indeed (on a weight basis) constitute about 50 % of the biomass (Pandey and Nigam 2009).

With regard to cereal crops, the main residues left after harvesting are represented by straws that comprise more than 50 % of the crops: since in late years the world production of cereals on average has been about 2600 Mtons (FAO data), it can be estimated that potentially 1,300 Mtons of these lignocellulosic residues are produced and can be exploited as valuable carbohydrate polymer sources.

Fig. 15 Some main agricultural residues: **a** corn stover, **b** rice straw, **c** wheat straw, **d** sugarcane bagasse

Corn world production, as mentioned in the previous section, equals about 800 Mtons per year: only the grains are harvested and used for food applications, while the other components (leaves, shell, stalks) are left on the ground. Corn residues from harvesting, i.e., corn stover, account for about 85 % of the plant; therefore, the total amount of such wastes is nearly 700 Mtons per year. These wastes are particularly rich in cellulose and hemicellulose thus representing the main renewable source of world lignocellulose (Sanchez-Vazquez et al. 2013).

Barley, oat, rice, sorghum, and wheat world production in 2012, according to FAOSTAT data, were ≈13, 21, 719, 57, and 670 Mtons, respectively.

Barley grain is used as animal feed, as malt, and for human food: after harvesting, the main residue is constituted by straw whose chemical composition reveals that more than 60 % of this biomass is made of valuable polysaccharides, namely, cellulose and hemicellulose. Since cereal postharvest residues account on average for 50–75 % of crop, therefore in the case of barley potentially, 5.6–9.8 Mtons could be available for polysaccharide recovery.

Table 2 Main agro-industrial waste sources of polysaccharides (PS)

Waste source	Waste amount (Mton y^{-1})	Chemical composition	PS content (% dry weight)	Reference
Sugarcane bagasse	300	Hemicellulose/ cellulose	30–35/40–45	Cardona et al. 2010
Cassava bagasse	≈200[a]	Starch	50	Das and Singh 2004
Corn stover	696	Hemicellulose/ cellulose	32.0/27.8	Sanchez-Vazquez et al. 2013; Li et al. 2012
Barley straw	≈5.6–9.8	Hemicellulose/ cellulose	27/44	Das and Singh 2004
Oat straw	≈10.5–15.7	Hemicellulose/ cellulose	16/41	Das and Singh 2004
Rice straw	731	Hemicellulose/ cellulose	26/33	Das and Singh 2004; Binod et al. 2010
Sorghum straw	≈28–43	Hemicellulose/ cellulose	30/31	Das and Singh 2004
Wheat straw	550	Hemicellulose/ cellulose	36/39	Kuan and Liong 2008; Das and Singh 2004

[a]85 % moisture, not on dry weight basis

Oat is diffused in temperate regions, and it is mainly used as breakfast cereal as flakes or for porridge; indeed it is not suitable for baking since it lacks gluten. Its by-products still retain significant quantities of both cellulose and hemicellulose, as reported in Table 2. The potential waste from oat that is yearly produced should be about 42 Mtons.

Together with corn and wheat, rice is one of the main cereal crops in the world with China as the main producer; notably it also represents the principal staple food for more than 50 % of the world's population. After harvesting, the rice is dehusked, and the resulting straw is usually left onto the soil or burned: nevertheless it is an interesting lignocellulose biomass since it still retains appreciable amounts of cellulose and hemicellulose (Table 2).

Sorghum is native to Africa, but nowadays it is cultivated in Africa, the United States, and Asia where Nigeria, Mexico, the United States, and India are the main producers, respectively. Sorghum is mainly exploited as animal feed or for alcohol production, but in poorest areas it also serves for human nutrition. Sorghum straw is among the lignocellulosic biomass under investigation due to its polysaccharide fraction that is mainly constituted by cellulose and hemicellulose, as shown in Table 1. On the basis of sorghum total world production, its straw yield is estimated to be between about 28 and 43 Mtons per year.

Wheat is mainly cultivated in Asia (43 %) and Europe (32 %) followed by North America as the third producer with 15 % of total global production. The main part of wheat is used for food production, with a minor fraction for animal feeding. The remainder part is estimated to be about 550 Mton y^{-1} and is also a biomass rich in cellulose and hemicellulose that could be further exploited for other purposes.

4 Brief Phytochemistry

In the assessment of polysaccharide structure, two stages can be distinguished: firstly, the determination of primary structure, which means the polysaccharide composition, the configuration, and position of glycosidic linkages and the ring configuration, and, secondly, the determination of spatial structure that can be obtained through the knowledge of bond lengths, bond angles, and torsional angles overall regarding the glycosidic torsional angles and the exocyclic torsional angle. Besides the primary structure, a detailed knowledge of the spatial structure is essential in order to assess structure-function or structure-property relations. The clarification of polysaccharide structures is very important to explain the physicochemical and biological properties of these biopolymers and to attribute and in some cases to predict the biotechnological applications of these biomolecules. The rheological properties of these polymers are surely influenced by the primary conformation. Furthermore, the ordered secondary configuration frequently takes the form of aggregated helices. Moreover, the presence or also the absence of specific acyl groups, for example, O-acetyl or O-succinyl esters or pyruvate ketals, can influence the formation of ordered helical aggregates (Poli et al. 2011). Several chemical and physical techniques are used to determine the primary structure of polysaccharides: chemical degradation and derivatization, in association with chromatographic methods and mass spectrometry analysis, are used to determine the sugar composition, their absolute configuration, and the presence and the position of possible substituents. In details, molecular size analyses are carried out by Sepharose CL-6B column using a mixture of dextrans for calibration curves (Pazur 1994). Fourier transform infrared (FT-IR) spectroscopy spectra of EPS are obtained with FT-IR spectrometer between 400 and 4,000 wave numbers (cm^{-1}). Thermogravimetric analysis (TGA) of EPS is obtained with TGA apparatus where a known amount of polysaccharide sample in H_2O is heated from 30 to 400 °C at a rate of 20 °C min^{-1} under a constant flow of nitrogen. For carbohydrate analysis, the purified polysaccharide fractions are hydrolyzed with 2 M trifluoroacetic acid (TFA) at 120 °C for 2 h. Sugar components are firstly detected by thin-layer chromatography (TLC), using a mix of acetone/butanol/H2O (8:1:1, v/v/v) as mobile phase and standard monosaccharides for qualitative determination. Afterward monosaccharide composition is defined by high-pressure anion exchange-pulsed amperometric detector (HPAE-PAD). Sugars are eluted isocratically with 16 mM NaOH and identified by comparison with reference standards (Poli et al. 2011). The linkage positions of the monosaccharides are determined by methylation analysis: the samples are methylated with CH_3I in dimethyl sulfoxide and NaOH, and the products are hydrolyzed using TFA 1 M at 70 °C for 45 min. After reduction with $NaBD_4$, the samples are acetylated, and then the sugar derivatives are analyzed by GC-MS. The absolute configuration of the sugars is determined by gas chromatography of the acetylated (S)-2-octylglycosides (Manzi and van Halbeek 2009).

The scrutiny of unknown structures still lies in the crucial point of polysaccharide research, and the nuclear magnetic resonance (NMR) technique persistently

continues leading this procedure. Even today, when important technological advances occur, the unambiguous identification remains a challenging task (Halabalaki et al. 2014). Toward this direction, computational tools might hold a key role in the future. Expert systems equipped with versatile algorithms enabling structure or spectra prediction are able to give recourses for the structure elucidation of natural molecules in complicated mixtures. Comprehensive and qualified open access natural products databases support considerably the identification of unknown molecules (Halabalaki et al. 2014). NMR contribute to the determination of the repeating unit of polysaccharides by using in particular two-dimensional ^{1}H- and ^{13}C-NMR. For conformational analysis it is important that the primary structure of polysaccharide being studied is known and that as many signals as possible have been assigned unambiguously. In order to make possible NMR or mass spectrometry analysis, it is necessary to carry out a chemical or enzymatic digestion of polysaccharides to obtain smaller fragments that are more easily analyzed. Two types of homonuclear 2D NMR spectroscopy could be used for structural analysis of oligosaccharides: the first is characterized by magnetization transfer through scalar coupling (COSY type); in experiments of the second type, the magnetization is transferred through space (NOESY type) at short interproton distances. The most useful method of the COSY type is the 2D homonuclear Hartmann-Hahn (2D HOHAHA) spectroscopy. Advantages of 2D HOHAHA over other COSY-type techniques are higher sensitivity; pure in-phase magnetization, which avoids signal canceling by antiphase magnetization in conjunction with large line widths, as in 2D double-quantum filtered COSY (DQF-COSY); and the possibility to obtain complete subspectra by multistep magnetization transfer. In some cases also NOESY-type experiments are useful for assignment purposes often in combination with COSY-type experiments (Halabalaki et al. 2014).

Other assignment techniques exploit the large spread in chemical shift in ^{13}C NMR spectra. Since the proton-detected heteronuclear multiple-quantum coherence (HMQC) experiment renders information about direct (one bond) ^{1}H-^{13}C connectivities, it is used for the assignment of either the ^{1}H or the ^{13}C spectrum. Long-range heteronuclear correlation experiments such as the proton-detected heteronuclear multiple-bond correlation (HMBC) spectroscopy afford linkage information and therefore useful for the determination of carbohydrate sequences. In addition, the HMBC experiment makes it possible to assign carbon atoms that are not accessible by HMQC spectroscopy, namely, quaternary carbon atoms (Halabalaki et al. 2014).

In addition, a solid-state NMR has been adopted as uniquely suited for the examination of insoluble and complex macromolecule, or, for example, to study whole-cell systems and also to check the integrity of the polysaccharide structures (Finore et al. 2014). Solid-state NMR spectroscopy allows investigation of molecules in the solid state and reveals information about crystal packing using a noninvasive and nondestructive analysis. This method can provide not only chemical information but also chemical environment and ultrastructural details that are not easily accessible by other nondestructive high-resolution spectral techniques

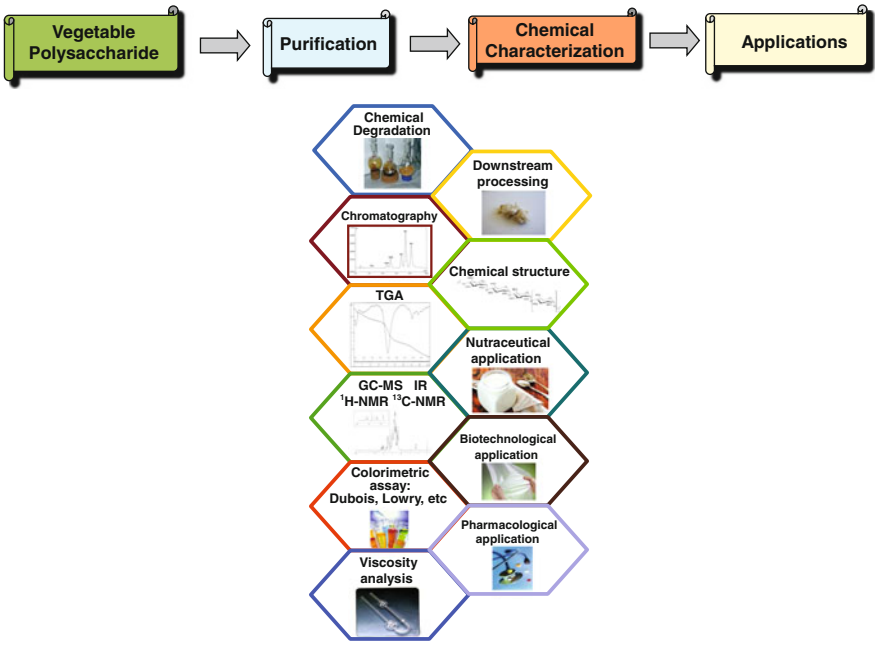


Fig. 16 Main steps and methods for purification and structural characterization of polysaccharides

(Foston 2014; Serra et al. 2012). The solid-state NMR methodologies result is particularly useful when studying structural problems in complex biological systems, for example, in the study of the mechanisms of biosynthesis and deconstruction for lignocellulosic biomass or individual plant cell wall components. The most frequently used solid-state NMR techniques are ^{13}C CPMAS, a double-bearing cross-polarization magic-angle spinning NMR spectroscopy that is the combination of three techniques: firstly, cross polarization; secondly, magic-angle spinning; and, thirdly, high-power decoupling (Foston 2014).

Recently, a bioanalytically probing technique has been developed to study biomaterials at cellular and molecular level within intact tissue (Yu 2011). This technique named synchrotron radiation Fourier transform infrared microspectroscopy (SR-IMS) takes advantage of bright synchrotron light which is a million times brighter than sunlight (Marinkovic and Chance 2006). It is able to have simultaneous information about tissue chemistry, tissue composition, tissue environment, and tissue structure by a noninvasive and nondestructive tool. An appropriate example of this technique comes from the study of microstructural features of the embryo (germ) in sorghum (*Sorghum bicolor* L.) seeds in which the intensity and distribution of the various chemical functional groups (including cellulosic compounds) could be chemically mapped (Yu 2011) (Fig. 16).

5 Biotechnological Approaches to Waste Polysaccharide Exploitation

Polysaccharides from renewable and sustainable sources, like food and agricultural wastes, can play a central role in the emerging biobased economy, i.e., the new economy system shifting from fossil resources of energy and chemicals to renewable resources such as biomass. Indeed the wide variety of structures and biological functions of polysaccharides that can be recovered from agro-wastes make them biotechnologically useful biopolymers that either are already exploited for several purposes or are under investigation for new applications (Fig. 17).

Since a great share of industrial production of chemicals and energy is based on the exploitation of plant polysaccharides, like starch, the search for new biotechnologies and strategies for exploiting and employing waste materials in several industrial fields is therefore the object of growing interest. Such an approach to polysaccharide waste biomass exploitation comes under the frame of the so-called biorefinery, i.e., a new production system in which a variety of goods (fuels, chemicals, and biomaterials) can be recovered from renewable feedstock by using a single or a combination of chemical, physical, and biological treatments.

Biorefinery of biomass is a multistep process that can be divided in: choice of starting material and of suitable pretreatment method, in order to render it more prone to the following processes, and conversion of the pretreated biomass by means of one or combined biological, chemical, and physical techniques to obtain

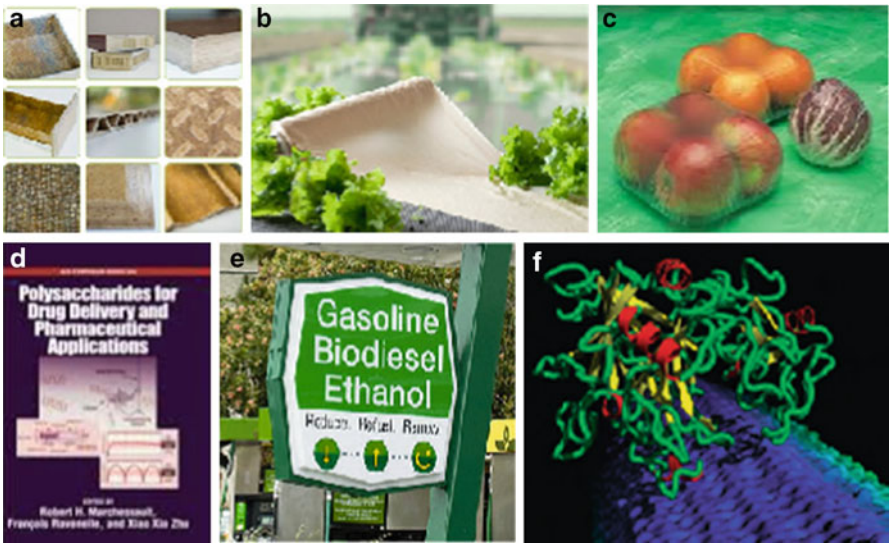

Fig. 17 Main industrial applications of polysaccharides for biomaterials and biodegradable plastics (**a**, **b**), for food packaging (**c**), for pharmaceutical industry (**d**), for fuel ethanol (**e**) and enzyme (**f**) production (Photos' web sources: (**a**) www.jetsongreen.com; (**b**, **c**) www.novamont.com; (**d**) www.bookdepository.com (**e**) http://www.indianaenvironmentallaw.com/agriculture/)

energy or value-added chemicals and/or building blocks for further production processes.

Polysaccharide rich waste biomass is the ideal feedstock for biorefinery since they are renewable, not in competition with the food chain and not impacting on land use and biodiversity.

In addition, such materials are available in significant amounts every year (see Tables 1 and 2) and therefore are under investigation for several industrial applications, for example, production of green chemicals, biomaterials, second-generation biofuel, etc.

In the following section some remarkable examples of useful products that can be obtained from polysaccharides recovered from agro-industry waste biomass by means of physical, chemical, and biological transformation are described.

5.1 Building Blocks for Composites and Biomaterials

Waste polysaccharides like cellulose and starch are valuable building blocks for the material's preparation like composites or bioplastics.

Cellulose is the main glycan found in the lignocellulosic agro-wastes that in turn are emerging as potential renewable sources of fibers for paper, material, and textile industry. Cellulose can be recovered by waste biomass fractionation by means of different pretreatment techniques such as steam explosion, ionic liquid-based fractionation, and acidic treatment followed by shear mechanical treatment. The cellulose polymers that in such ways can be recovered, for example, from wheat (Dufresne et al. 1997), rice straw (Ping and Hsieh 2012), and from sugarcane bagasse (Mandal and Chakrabarty 2011), are essentially nanocrystalline cellulose, i.e., a cellulose polymer that is formed by rigid rodlike particles whose widths and lengths are from 5–70 nm to 100 nm up to micrometers in range. Cellulose nanofibers, extracted from wheat straw by these methods, have been used for the reinforcing of polypropylene composites, for the preparation of biocomposites and of thermoplastic starch-based nanocomposites, and for the production of composition panels that have shown to be particularly resistant to earthquake (Kalia et al. 2011). Also other several applications have been identified for nanocrystalline cellulose from wastes such as in nanocomposites as filler, improving mechanical and barrier properties, as building block for selectively permeable membranes, as foams or aerogels, as adhesive or to prepare adhesive materials, and as a reinforcing agent for polymer electrolytes in lithium batteries (Brinchi et al. 2013), but further and maybe still unknown applications in these fields are possible.

Other examples of application of waste cellulose for composites are represented by: wheat straw cellulose that has been used as a natural filler to reinforce composites of a polyolefin and of a biodegradable polyester (Le Digabel et al. 2004); by rice straw cellulose that has been used to prepare composite boards for construction that afforded good acoustical and electrical insulation, besides possessing anti-caustic and anti-rot properties (Yang et al. 2004a); by banana

peels fibers that have been employed to prepare composites with polyester matrix (Pothan et al. 2007); by rice residual cellulose that has been investigated as reinforcing filler for polypropylene-based thermoplastic composites (Yang et al. 2004b); and finally by bagasse wastes that, like the previously mentioned waste sources of cellulose, were employed to produce composite materials by mixing with low-density polyethylene, acid stearic, or maleated low-density polyethylene (Habibi et al. 2008).

Starch is also very promising for new biodegradable polymers that can find several applications in materials science; after blending with other natural polymers like gutta-percha or natural rubber, they can afford more suitable composite materials (Yu et al. 2006). With particular regard to cassava bagasse starch, it has been used with different approaches to produce biocomposites: it has been mixed with Kraft paper to obtain a composite similar to cardboard that showed mechanical properties resembling the recycled paper (Matsui et al. 2004); it has also been used to produce thermoplastic starches using glycerol as plasticizer (de Morais Teixeira et al. 2005).

Also food wastes like tomato wastes showed to be potential sources of polysaccharides for bioplastics: indeed a glucan isolated from tomato canning wastes, after addition with glycerol as plasticizer agent, showed to possess promising properties as bioplastic for mulching or solarization applications (Tommonaro et al. 2008).

5.2 Biomaterials for Food Packaging

Several examples of polysaccharide-based edible films and coatings are available in literature, but most of them are based on the exploitation of polysaccharides from non-waste sources. Recently several examples of the reuse of agro-industrial residues for the preparation of edible and biodegradable films appeared: in this section a survey of very recent examples of applications of waste polysaccharides to this issue will be presented.

Hemicellulose polymers from both food wastes and agricultural residues can find applications in packaging; indeed, for example, arabinoxylans (AXs) isolated by alkali extraction from barley residues were used to prepare edible films by water casting and showed to have interesting mechanical properties (Mikkonen and Tenkanen 2012). On the other hand also AXs recovered from corn residues and blended with glycerol, propylene glycol, or sorbitol were used to produce stable films that showed to be able to afford moisture barrier in a preservation experiment with grapes samples (Zhang and Whistler 2004); AXs from corn bran were emulsified with fats (palmitic acid, oleic acid, triolein, a hydrogenated palm oil) and then used to prepare water vapor-permeable films (Peroval et al. 2002).

Cellulose from sugarcane bagasse has been exploited to prepare a cellulosic film fully biodegradable, with very high tensile strength and good water vapor permeability that potentially could be used for food packaging (Ghaden et al. 2014); cellulose nanocrystals obtained from the same agro-waste were used to reinforce

starch-based films that showed in this way higher water resistance and water barrier properties (Slavutsky and Bertuzzi 2014).

Residual starch from cassava bagasse proved to have potential application in bioactive food packaging since it was used to prepare biodegradable films impregnated with antimicrobial agents and possessing favorable water sorption and permeability properties (de Souza et al. 2014); cassava bagasse polysaccharides (cellulose and starch mixture, see Table 2 for chemical composition) have also been mixed with cassava starch to prepare a thermoplastic starch matrix (de Morais Teixeira et al. 2009).

Also pectins from food wastes have been studied for their potential exploitation in food packaging: pectins indeed have been used to produce bioactive films and coatings that are useful for prolonging food's shelf life. Such materials, besides providing a semipermeable barrier to oxidizing agents, can also be added with antimicrobial, antioxidant, and anti-softening agents, thus preventing food deterioration (Raybaudi-Massilia and Mosqueda-Melgar 2012).

5.3 Human Nutrition, Food Additives, and Prebiotics

Pectins, cellulose, and hemicellulose are part of human nutrition since they constitute the so-called dietary fibers: thanks to their chemical properties, during human digestion, they reach the small intestine where they have beneficial effects on the microflora.

High dietary fiber powders can be obtained from both food and agricultural residues. Dietary fibers can be recovered from orange peels, in peach residues, orange and lemon peels, or apple pomace. Agricultural residues like corn, wheat, and rice bran are also a good source of such valuable compounds. Thanks to their physicochemical features, dietary fibers can find application in food industry for improving the texture, viscosity, and shelf life of foods: several reports are found in literature concerning their beneficial effects when added to jams, bread, pasta, frozen foods, dairy products, etc. (Elleuch et al. 2011).

Pectins are the most popular polysaccharide from food wastes that, for generations, have been used as food ingredients or additives in all countries of the world. Their chemical structure, characterized from the coexistence of polar and nonpolar regions, makes them suitable for incorporation in different kinds of foods. Commercially employed pectins are mainly derived from apple pomace and citrus peels, and their principal application is in food industry as gelling agents, thickeners, water binders, and stabilizers. Pectins are indeed exploited for the industrial preparation of jam and jellies, to which they are added as a powder during the cooking step; fruit juices, where they act as clouding agents; soft drinks, where they counterbalance the deprivation of sugar; yogurts, where they prevent floatation of fruit pieces; frozen foods, where they exert a great firming effect and retard ice crystal growth thus improving food texture (Thakur et al. 1997).

Polysaccharides from food wastes have also a great biotechnological potential as sustainable sources of prebiotics. The latter are a group of food ingredients that

resist digestion in the intestine and stimulate the growth and activities of indigenous bacteria (commonly *Bifidobacteria* and *Lactobacilli*) that constitute the beneficial gut microflora. Oligosaccharides are among the most known molecules that are able to exert a prebiotic effect, and some of them can be produced starting from food wastes by means of enzymatic modifications. Pectic oligosaccharide with prebiotic properties has been prepared from commercial pectins by using an enzyme membrane reactor and proved to be effective against toxins produced by *Escherichia coli* and to be able to induce apoptosis in human adenocarcinoma cells. Moreover, pectic oligosaccharides recovered from orange peel were able to favor *Bifidobacteria* sp. and *Escherichia rectale* growth (Pandey and Nigam 2009). Cellulose oligosaccharides also showed prebiotic properties: indeed the cellulosic fraction of apple pomace was used to produce prebiotic oligosaccharides like glucooligosaccharides, xylooligosaccharides, and arabinooligosaccharides by digestion using an enzyme cocktail (cellulose and cellobiase from *Trichoderma reesei* and *Aspergillus niger*) (Pandey and Nigam 2009).

5.4 Feedstock for the Production of Chemicals, Enzymes, and Biopolymers by Microbial Fermentation

The polysaccharide components of residual agricultural raw materials can be used, by means of bioconversion, for the production of chemicals like organic acids (citric acid and lactic acid) or building block molecules, enzymes, and biopolymers that in turn are employed in a wide range of industrial fields.

With regard to organic acids, citric acid has a great commercial importance since it has many applications in food industry (as antimicrobial, preservative, or pH adjuster for soft drinks, confectionery, dairy, marmalades, fats, and oil production), in pharmaceutical industry (as anticoagulant, acidulant, or effervescent), in cosmetic industry (as antioxidant, metal chelator, or pH adjuster), and finally for other miscellaneous sectors (textile, paper industry, tobacco production, waste treatment, etc.) (Pandey and Nigam 2009). Thanks to their high polysaccharide content, citrus wastes and apple pomace have been evaluated as carbon sources for the production of citric acid employing *A. niger* strains in both submerged fermentation (SmF) and solid-state fermentation (SSF) conditions (Pandey and Nigam 2009). Citric acid can be produced by means of SmF with different *A. niger* species using several agro-residues including apple pomace, orange and carrot wastes, coffee husks, and sugarcane and cassava bagasse. Lactic acid is another organic acid that can be produced using waste polysaccharides. It is also used for several purposes in food industry (as preservative, for production of fermented foods and dairy products), in pharmaceutical industry (as blood coagulant or for preparation of anti-inflammatories), and for the synthesis of biodegradable and biocompatible plastics (by polymerization to polylactic acid, PLA). Lactic acid is produced in SSF conditions by means of fungi (*Rhizopus* species) or bacteria using cassava bagasse, wheat straw, or carrot wastes (Pandey and Nigam 2009).

With regard to the building block molecules production (Pacific Northwest National Laboratory 2004), some hemicellulosic wastes have been investigated for the production of xylitol, a natural sweetener substitute of sucrose that is widely used in food industry because it is anticariogenic and also suitable for diabetes patients (Canilha et al. 2005). Xylitol can be produced by fermentation of xylose recovered from hemicellulose hydrolysates from several food and agricultural wastes such as: barley and corn wastes, by *Debaryomyces hansenii* fermentation (Cruz et al. 2000); corn cobs, by a xylitol-producing yeast (Domínguez et al. 1997), *Candida* sp. 11–2; and peanut husks by *A. niger* fermentation (Mudaliyar et al. 2011).

With regard to enzyme production, agro-wastes are also valuable feedstock for their industrial production by means of microbial fermentation. A remarkable example is represented by residual cellulose polysaccharides that can be employed as sole carbon sources for the fermentation of biotechnological strains that in turn are usually exploited for the production of industrially useful enzymes. This is the case, for example, of cellulose and hemicellulose from sugarcane bagasse that have been exploited to produce: cellulase enzymes by fermentation of *Streptomyces*, *Trichoderma*, and *Aspergillus* species, xylanase that can be generated in SSF conditions by cocultured *T. reesei* and *A. niger* or *A. phoenicis* or by *Penicillium janthinellum* and *Trichoderma viride*, and inulinase, by fermentation of *Kluyveromyces marxianus* (Pandey and Nigam 2009). Also pectins in food wastes like citrus and apple pomace can be exploited as fermentation medium for the production of useful enzymes. Such wastes have been investigated, both in SmF and SSF conditions, as growth substrate for the production of bacteria, yeasts, or fungi producing pectinase activities. Such enzymes are the object of interest since they are used in different fields like in food and alcoholic drinks production, in textile and paper industry, for wastewater treatment, etc. (Jayani et al. 2005). Moreover polysaccharide fraction in apple pomace has been exploited also to produce by fermentation other useful enzymes like β-fructofuranosidase, xylanase, β-glucosidase, peroxidase, and cellulose activities. Similarly it has been reported for citrus waste polysaccharides that they can be used to produce α-amylase, protease, xylanase, and cellulose enzymes (Pandey and Nigam 2009).

Finally, with regard to microbial biopolymers' production, an interesting example is given by residual starch from cassava that has been employed also for xanthan gum's production by means of *Xanthomonas campestris* SmF on cassava acid hydrolysate as fermentation medium. Other studies showed the benefit in using residual pectin, cellulose, and hemicellulose recovered from citrus wastes to produce xanthan, by means of *X. campestris* fermentation (Pandey and Nigam 2009). Commercial uses of xanthan gum are mainly as food additives in salad dressing and sauces or for the preparation of low-fat and gluten-free foods. Acid hydrolysates from sugarcane bagasse have been used for the synthesis of microbial biopolymers like polyhydroxyalkanoates (PHAs), a biopolyester that is the object of interest as biodegradable plastic.

Bagasse polysaccharides have been used to produce PHA by aerobic bacterium *Ralstonia eutropha*.

5.5 Pharmaceutical Applications

Several kinds of polysaccharides already find numerous applications in the pharmaceutical industry, for example, cellulose that since many years is usually used for drug delivery, or starch that is the starting material for cyclodextrins' production. Notably, also polysaccharides from food and agricultural residues recently have received attention for their biological properties that make them potentially useful for different pharmaceutical applications.

Pectins can be exploited for pharmaceutical purposes, for example, for the preparation of mucoadhesive polymers for gastrointestinal adhesion, in combination with other polymers such as Carbopol and chitosan; against poisoning by lead and mercury; as antihemorrhagic and coagulating agent; for overeating control; and for drug delivery, for controlled release of active principles in the treatment of diseases like ulcerative colitis, Crohn's disease, or colon carcinomas (Srivastava and Malviya 2011). Pectic polysaccharides from citrus wastes are able to bind and thus inhibit galectin-3 (GAL3), a prometastatic protein that is overexpressed in many cancer types.

By means of enzymatic and/or alkali treatment, it is possible to produce chemically modified pectins that have also been claimed to be potential anticancer agents. Some modified citrus pectins, patented as PectaSol (commercially available as supplement) and as GCS-100 (Maxwell et al. 2012), showed indeed to be active against human prostate cancer and to be effective in the treatment of patients showing solid tumors, respectively. The encouraging results obtained in human studies have been confirmed also in animals and tumor cell lines. Oral intake of modified citrus pectins in mice caused a decrease in colon cancer; on the other hand modified apple pectins showed to be able to lower inflammation and to prevent tumor formation in a mouse model of colitis-associated colon cancer. Several studies performed with cancer cell lines showed that modified pectins from citrus fruits are able to inhibit GAL3 and thus to induce apoptosis in murine endothelial cells (Maxwell et al. 2012); moreover, modified citrus pectins have been shown to be active against cultured leukemic cells (Ramachandran et al. 2011).

Hemicellulose and in particular xylans from agricultural wastes can be useful for biomedical applications: xylans recovered from corn stover and wheat straw have indeed been reported to inhibit the growth rate of sarcoma-180 and other tumors, and on the other hand water-soluble AGXs isolated from corn residues showed to possess in vitro mitogenic and co-mitogenic activities (Ebringerova et al. 1999).

Finally a glucan isolated from tomato wastes showed interesting biological properties as a potential anti-inflammatory agent. Indeed in an in vitro experiment of J774 macrophages stimulation with bacterial lipopolysaccharide, the tomato waste polysaccharide proved to be able to inhibit NF-κB activation and iNOS

expression by preventing the production of reactive oxygen species. Therefore it could be a promising molecule for controlling oxidative stress and/or inflammation processes (De Stefano et al. 2007).

5.6 Feedstock for the Production of Second-Generation Bioethanol

Polysaccharides from wastes and more specifically from cellulosic agricultural residues represent the main and most important feedstock for the production of second-generation bioethanol, since they are not in competition with food chain. Lignocellulosic wastes could afford a less environmentally impacting production of ethanol because their production do not require further exploitation of land (they are the residues of "primary crops") and also because they are available at zero cost in significant amounts (see also Tables 1 and 2).

The most studied waste biomass for second-generation bioethanol are some lignocellulosic residues, like cereal straw or sugarcane bagasse: the biotechnological potential of cellulosic and hemicellulosic residues for renewable energy production has been indeed the object of various researches carried out in the last 40 years. Due to the complex chemical composition and to the recalcitrance of lignocellulosic biomass, such studies have been focused on the problems connected to the different stages of the industrial process for conversion of biomass to fermentable sugars and finally to ethanol, i.e., the initial delignification treatment step, necessary to remove the nonsugar lignin fraction from the carbohydrate complex matrix, the fractionation of the complex polysaccharide matrix made of cellulose embedded in the hemicellulose envelope, the production of highly concentrated monomer sugar mixtures by means of enzymatic hydrolysis of polysaccharides (the so-called saccharification), the fermentation of sugar syrups, and the final distillation phase to gain pure ethanol.

The pretreatment step that is necessary to enable enzymes to degrade the glycosidic bonds in the polymer, by enhancing the surface area, can be accomplished by steam explosion, ammonia fiber explosion (AFEX), SO_2/H_2SO_4 or CO_2 explosion, hot liquid water, dilute acid or alkaline treatment, or finally ionic liquid or ligninolytic enzyme treatment. After the first step, hydrolysis of polysaccharides (saccharification) is carried out by using cellulose enzymes: the most studied include cellulose and β-glucosidase enzymes produced by fungi such as *Trichoderma reesei*, *Trichoderma viride*, and *Aspergillus niger*. The mixture of sugar resulting from cellulose and hemicellulose depolymerization is therefore fermented by ethanologenic microorganisms like *Saccharomyces cerevisiae* and *Zymomonas mobilis*. The main challenge associated to the fermentation in bioethanol production based on cellulosic feedstock is represented by the conversion of pentoses (deriving from hemicellulose fraction degradation) that are not fermented by the conventional yeast species. For this reason many recent researches have been devoted to identify a microorganism able to ferment both C6 and C5

sugars generated from hydrolysis of lignocellulosic biomass. Among the most interesting species is also *Z. mobilis* that has shown to be able to ferment both glucose and xylose derived from corn stover.

The biotechnological process by which biomass after pretreatment is converted in ethanol can be accomplished in different configurations, and it is the object of study too. The basic process is represented by separate hydrolysis and fermentation (SHF) that allows the optimal temperature conditions either for cellulose enzymes or for fermenting microorganisms, but that can be less efficient due to the glucose inhibition of cellulose enzymes; therefore, a simultaneous saccharification and fermentation process is under investigation to afford higher saccharification yields. Although the latter could be a more sustainable and efficient process, some problems are still to be solved, such as the different temperature operation's conditions required from enzymes and yeasts. For these reasons recently the so-called consolidated bioprocessing (CBP) has received increasing attention: in such a biotechnological process, biomass would be converted in ethanol by using a single engineered strain able to carry out the cellulase enzyme production, the saccharification of cellulose, and the fermentation of monomer sugars to ethanol (Cheng and Wang 2013). It is noteworthy to underline that a commercially available microorganism able to perform a CBP process has not yet been reported, but research in this field is still going on (Pandey and Nigam 2009).

6 Conclusion

Vegetable biomass is one of the most promising renewable sources of energy and chemicals. Its exploitation for biofuel and commodity chemicals is indeed the focus of continuous researches since many years. In the last decades the gradual shift toward the so-called biobased economy (an economy system based on exploitation of renewable resources such as biomass) has determined a global increasing demand for goods derived mainly from polysaccharide components of vegetable biomass. However this phenomenon is causing many environmental, social, and economical problems such as the intensive exploitation of land (e.g., for energy crops), the competition with food chain, and the consequent increase of foods prices, especially dramatic for developing countries. In order to ensure a more sustainable productivity and the global food security, wastes coming from biomass cultivation, harvesting, and processing of vegetables are more currently considered as an alternative source for polysaccharides that are used for energy and chemical production.

Indeed different kinds of agro-wastes such as food residues (coming from industrial processing of cereals, fruits, and vegetables) or such as agricultural wastes (resulting from harvest and postharvest operations of sugar or cereal crops) are massively produced every year. Therefore several million tons of such residual biomass are available as valuable sources of polysaccharides that in turn

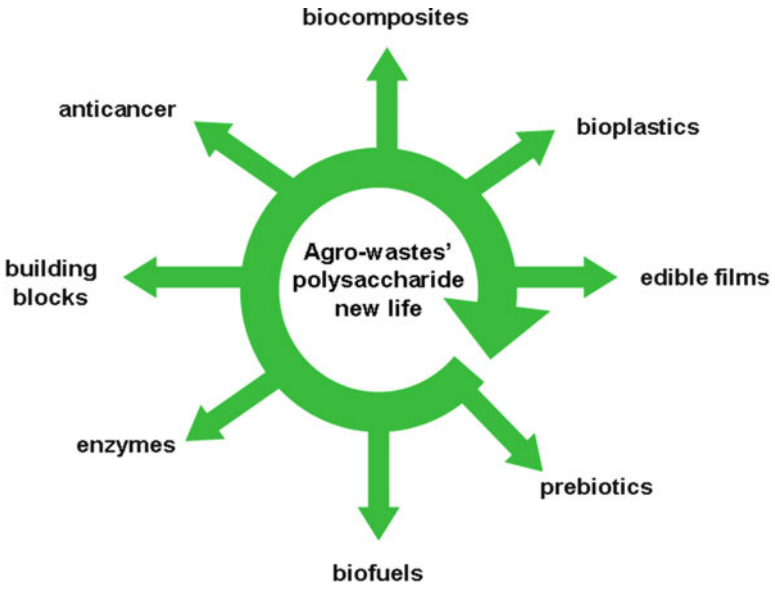

Fig. 18 Schematic representation of potential biotechnological uses of agro-wastes

could be exploited as feedstock for the production of a wide range of value-added chemicals and for renewable energy generation.

Several biotechnological strategies for the conversion of agro-waste polysaccharides are available for the production of food additives (dietary fibers, stabilizers, preservatives, sweeteners, etc.), of biomaterials (biocomposites, edible films for food packaging, or biodegradable plastics), of bioactive compounds (prebiotic or anticancer agents), of enzymes and value-added compounds (organic acids or building block chemicals), and of renewable energy (second-generation bioethanol) (Fig. 18).

Some of these production systems are already an industrial reality, while others are under investigation for the scaling up of laboratory scale processes. A remarkable example of the biotechnological potential of agro-wastes is represented by polysaccharides from tomato canning residues. Indeed in a recent study, it showed promising features (Fig. 19) since it was able to inhibit inflammatory processes, but also it could be used as a building block for biodegradable plastic suitable for agricultural uses.

The future biobased economy development will be limited only by the availability of biomass; therefore, in such a scenario polysaccharides from agro-wastes can represent not only a more environmentally friendly and sustainable source of goods but also the economical solution to supplementing feedstock for a wide range of industrial activities.

Food

Gum of *Prosopis*/*Acacia* Species

21

Yolanda L. López-Franco, Francisco M. Gooycolea, and Jaime Lizardi-Mendoza

Contents

Abstract

This chapter presents the structural and physicochemical characteristics, functional properties, and main applications of two exudate gums: gum arabic (*Acacia senegal*) and mesquite gum (*Prosopis velutina*). Gum arabic is the oldest and best known of all natural gums. It possesses physicochemical characteristics and functional properties that make it unique in the international trade of food, pharmaceutical, textile, and other industries. Mesquite gum is other exudate less known in the international market, but it has potential applications in food and other industries. The chemical structure and functional properties of mesquite gum are comparable with gum arabic. It is a good emulsifier and stabilizer of oil–water emulsions, and it may be compared with gum arabic for such application. The information contained in this chapter considers that mesquite gum can be a suitable replacement of gum arabic in arid regions of the world where *Prosopis* trees have widespread occurrence.

Polysaccharide • Exudates • Gum arabic • Mesquite gum • Chemical structure • Functional properties • Industrial applications

1 Introduction

Gums represent one of the most abundant raw materials due to their sustainable and bio-safe characteristics. The term gum is used to describe a group of natural polysaccharides that have widespread industrial applications due to their ability either to make the viscous solutions or stabilize the emulsion systems. The plant gum exudates are complex polysaccharides produced by species of trees of the genus *Acacia* and *Prosopis*. Exudation is produced under conditions of heat and drought stress, as part of the normal metabolism of plants or result of the protection mechanisms against mechanical or microbial injury.

Plant gum exudates are highly heterogeneous complex polysaccharides with variable quantities of protein and other minor components (i.e., lipids, polyphenols). The chemical composition, physicochemical characteristics, and quality of these gums differ from botanical species and from cultivar to cultivar. Also, there is a considerable variation in gums from the same species collected from trees grown under different climatic conditions or even from the same tree in different seasons (Boothby 1983; Nussinovitch 2010). These variations can also be attributed to factors such as size and age of tree, soil type, rainfall, drought, temperature, storage conditions, and processing method (Nussinovitch 2010; Al-Assaf et al. 2012).

Chemically, gum arabic and mesquite gum are known as macromolecular complexes of type II AG and proteoglycans (arabinogalactan protein, AGP) comprising ca. 2.0–2.5 % of protein to gum arabic (Randall et al. 1989; Osman et al. 1993a, b) and 3–7 % to mesquite gum (López-Franco et al. 2004, 2008). The gums are soluble in water but not in organic liquids such as benzene, chloroform, ether, turpentine, and fixed oils (Howes 1949). These polysaccharides are capable to produce highly concentrated solutions without large viscosity increase. The considerably growing interest in plant gum exudates is due to their diverse structural characteristics and functional properties in food, pharmaceutical, cosmetic, textile, and biomedical products and colloid science. Gums can be used as a dietary fiber, texture modifiers, thickeners, emulsifiers, stabilizers, coating agents, and packaging films.

2 Gum Arabic (*Acacia senegal*)

2.1 Source and Production

There are approximately 1,373 *Acacia* species distributed throughout tropical and warm areas of the world. It is possible to find 955 species in Australia, 185 species in America, 144 species in Africa, and 89 species in Asia (Al-Assaf et al. 2007).

Many of these species produce and exude gum. This gum is a polysaccharide hydrocolloid with many practical uses. Sudan is currently the largest gum producer in the world with a gum arabic belt zone of approx 520,000 km^2 (Nussinovitch 2010). *Acacia senegal* and *Acacia seyal* are the most commercially exploited species and referred to as gum arabic.

The gum formation occurs in the cambial region of the stems or branches by a process named gummosis. The tree must be 5 years and older for gum production to happen. The exudation can be caused either by natural causes such as heat, drought, and attack by insects or pathogens or by injuries caused intentionally (tapping). Distinctively, in Sudan gum arabic tapping process is well established, and it is carried out by farmers during the dry season (November/December). The gum yield is influenced by environmental circumstances as rainfall or maximum temperature and also by harvesting conditions like the time of tapping or its intensity.

Superficial incisions are commonly made on the branches by using axes, but a more sophisticated tool, called a sonki (sharp spear), is available (Elrayah et al. 2012). The gum is exudated as sticky fluid and grown up to 1.5–7.5 cm in diameter and gradually dried and hardened in the sun and collected in the wound within 4–6 weeks depending on the weather condition. The tapping is done once a year, although in some areas there are two tapping seasons. However, it has been suggested that a second tapping has a significant damaging to the health of the trees (Elrahay et al. 2012: Al-Assaf et al. 2012); therefore one tapping season with more than one picking is recommended.

The production of gum arabic suffers large seasonal fluctuations depending primarily on the weather and also on its price. The production and trade of gum arabic is dominated by Sudan, accounting for 80–90 % of the world market (Chikamai et al. 1996). Nigeria is the second largest producer and exporter of this hydrocolloid. The production of gum arabic in these regions faces a number of problems, such as weather conditions, plagues (e.g., locusts), scarce funding for smallholders, and political instability. However, the production in Sudan has been estimated between 25,000 and 95,000 ton, averaging 50,000 ton per year (Williams and Phillips 2000). Other African countries as Ethiopia, Tanzania, Cameroon, and Senegal produced and exported volumes below 1,000 ton a year.

The gum is frequently exported raw, and only manual cleaning, sifting, and sorting operations are carried out to remove large impurities that could occur. Clean, large, and light color nodules make the handpicked selected (HPS) grade. This grade is the most expensive and tends to be of highest quality compared to the rest of the gum (Al-Assaf et al. 2012). Also, gum arabic is processed at industrial scale by companies such as Dansa Food Processing Co. Ltd in Nigeria, or Sanimex in Chad, or Khartoum Gum Arabic Processing Co (GAPC) in Sudan. These companies produce spray-dried gum arabic powder of various grades for direct use without further processing, and it is exported to global market. The international market for gum arabic has been usually unstable, due to an increasing demand, social and political volatility in the producing regions, and large variability in price, quality, and supply. Europe (France, the United Kingdom, Germany, Italy, Belgium, and Ireland) is the biggest importer of gum arabic, and the United States is its

second largest market. France and the United States are the mayor countries for both importing and reexporting gum arabic products (Verbeken et al. 2003).

2.2 Collection

Partially dried nodules of gum arabic are collected manually on multiple harvests every 2 weeks. A yield of 0.5–2 kg is obtained per tree annually, although production may range from few grams up to 10 kg (Elrahay et al. 2012). The collected gum is cleaned manually, usually by women who remove foreign matter and sort the gum according to the size of the pieces.

2.3 Regulatory Status

Gum arabic originating from the *Acacia senegal* and the *Acacia seyal* is recognized by the Codex Alimentarius (food additive E414). The gum is safe for human consumption based on a long history of usage as well as toxicological studies. The exudate is also used in nonfood applications, such as: pharmaceuticals, cosmetics, textiles and lithography, and minor forest products (Wang and Anderson 1994).

Gum arabic contains no pathogens and no more than 10^3 microorganisms per gram (Blake et al. 1988). Because of the high temperatures involved, spray-dried preparations contain no more than ~40 % of the usual microorganism count (~4×10^2 microorganisms per gram). The number of viable bacteria contained in the gum can also be reduced by treatment with ethylene oxide (no longer permitted for food use), or propylene oxide (less efficacious). Heating carried out during manufacture to reduce the microflora can lead to precipitation of the arabinogalactan protein complex (Anderson and McDougall 1987a), which promotes stabilization and emulsification in a range of food products (Randall et al. 1989).

Recent European Community legislation has approved gum arabic as an ingredient which can be labelled as a food dietary fiber. This recent change has created an opportunity and demanded for *A. seyal* due to its lower viscosity, which can be used at higher concentration compared to *A. senegal*. The low viscosity is due to its highly branched structure and therefore can be dissolved up to 50 % (wt %) to produce a solution of moderate viscosity.

2.4 Structure

The physicochemical characteristics of gum arabic are listed in Table 1. These characteristics may vary depending on the geographical origin and age of trees, weather conditions, soil environment, and the place of exudation on the tree (Islam 1997).

The chemical structure of gum arabic consists of (1→3)-linked β-D-galactopyranose backbone with branches of (1→6)-linked galactopyranose units.

Table 1 Physicochemical characteristics of gum arabic from *Acacia senegal*

Characteristics	Gum arabic
Appearance	Amber transparent nodules

Both the main and the side chains contain residues of α-L-arabinofuranosyl, α-L-rhamnopyranosyl, β-D-glucuronopyranosyl, and 4-*O*-methyl-β-D-glucuronopyranosyl. It also contains 2–3 % of protein as an integral part of the structure (Randall et al. 1988).

The gum has been studied extensively by different techniques such as: sequential Smith degradation (Anderson and McDougall 1987a, b, c), enzymatic degradation (Connolly et al. 1988), hydrophobic interaction chromatography (Randall et al. 1989; Osman et al. 1993a; Ray et al. 1995; Fauconnier et al. 2000), anion exchange chromatography (Osman et al. 1995), gel permeation chromatography (Osman et al. 1993b; Idris et al. 1998; Picton et al. 2000; Al-Assaf et al. 2005a, b), and asymmetrical flow field-flow fractionation (Alftrén et al. 2012).

Using hydrophobic interaction chromatography, it has demonstrated the heterogeneous complex nature of this polysaccharide by the presence of three main fractions: arabinogalactan (AG), arabinogalactan protein complex (AGP), and glycoprotein (GP). Each fraction contains a range of different molecular weight components with different protein contents (Randall et al. 1989; Williams et al. 1990b).

These components represent 88 %, 10 %, and 1 % of the molecule. The protein is covalently attached to the carbohydrate and demonstrated the presence of hydroxyproline-oligoarabinose and serine-carbohydrate linkages (Akiyama et al. 1984).

The molecular structure of AG fraction of gum arabic was unknown until Sanchez et al. (2008) proposed a thin disk model based on small-angle neutron scattering and microscopy. The model consisted of an inner branched structure and a ring both mainly composed by sugar residues (98 %). Polysaccharide domains were linked to a central short polypeptide backbone, forming a spheroidal random coil (Sanchez et al. 2008).

The AGP fraction conformation is described by the "wattle blossom" model in which approx. five AG blocks, ~200,000 Da each, are arranged along the GI polypeptide chain which may contain up to 1,600 amino-acid residues (Connolly et al. 1987). Other alternative model proposed for the structure of AGP of gum arabic is the twisted hairy rope (Qi et al. 1991). Using preparative gel permeation chromatography and transmission electron microscopy, it was possible to find that the molecule consisted of ~400 amino acids containing ~130 hydrohyproline residues with a 10–12 residue repetitive motif. The polypeptide backbone of the gum arabic GP is composed of repeating sequences of 19 amino acids (Goodrum et al. 2000).

2.5 Physicochemical Properties

Gum arabic functional properties are closely related to its structure, which determines, for example, solubility, viscosity, degree of interaction with water and oil in an emulsion, and microencapsulation ability, among others. Table 1 gives some physicochemical characteristics of the gum arabic from *Acacia Senegal*.

Solubility: Gum arabic is highly soluble in hot and cold water in concentration up to 50 %. The gum has the ability to produce concentrated solutions without causing an excessive increase in viscosity, because principally to the branched and compact structure and a small hydrodynamic volume (Williams et al. 1990a; Goycoolea et al. 1995; Verbeken et al. 2003).

Viscosity: Gum arabic solutions are distinguished by their low viscosity (0.19 dL g^{-1}) at high concentrations (50 % w/w) (Goycoolea et al. 1995), enabling the use of high gum concentrations in various applications (Dziezak 1991; Imeson 1992). Solutions display Newtonian behavior at concentrations of up to 40 % and become pseudoplastic at higher concentrations. Above ~30 %, the hydrated molecules effectively overlap and steric interactions result in much higher solution viscosities generating the pseudoplastic behavior (Nussinovitch 1997). The pH of the solution is usually around 4.5–5.5, but maximal viscosity is found at pH 6.0. At still higher pH, ionic strength of the solution increases until the repulsive electrostatic charges are masked, yielding a compact conformation with lower viscosity (Anderson et al. 1990; Williams et al. 1990a, b; Imeson 1992). The use of prolonged heating causes the denaturation and precipitation of the proteins from AGP and GP fractions, and these cause a reduction in the emulsification capacity and solution viscosity.

Molecular Association: The physicochemical characteristics of gum arabic (i.e., molecular weight, shape, size, etc.) determine the way how the molecules interact with each other in aqueous media. The resulting molecular associations can affect its function in specific applications. There are several factors such as hydrogen bonding, associations mediated by ions, and electrostatic or hydrophobic interactions, which depend on the gum concentration, and the presence of protein components that affect the ability to form supramolecular complexes.

Acacia gum (gum arabic) can be modified in the dry state in a range of physical forms. The treatment involves maturation under strictly controlled conditions of temperature and humidity of the dry gum (Al-Assaf et al. 2007). The process does not involve change in the basic structural components, and while the maturation takes place, the level of association increases giving way to AGP with higher molecular weight and protein content. Subsequently, the role of protein components in gum arabic to promote molecular association when the gum is subjected to different processing treatments such as maturation, spray drying, and irradiation was analyzed (Al-Assaf et al. 2009). Results demonstrate the ability of protein components to promote hydrophobic associations that influence the size and proportion of the high-molecular-weight component AGP. When gum arabic undergoes maturation, there is an increase in the hydrophobic nature of the gum and therefore an increase of its emulsifying properties. Spray drying involves not only the aggregation through hydrophobic associations but also changes in the surface properties of protein increasing gum arabic hydrophilicity compared with the association promoted by the maturation treatment in solid state. Ionizing radiation in both aqueous solutions and solid state induces cross-linking between polysaccharide blocks by the formation of C−C bonds (Aoki et al. 2007).

Emulsification Capacity: It is now widely accepted that gum arabic is an excellent emulsifier, thanks to its amphiphilic character due to the presence of protein and polysaccharide moieties. It works by reducing the oil–water interfacial tension, thereby facilitating the disruption of emulsion droplets during homogenization. The protein is strongly adsorbed onto the oil droplet surface, while the polysaccharide chains extend out into aqueous phase, preventing droplet flocculation and coalescence through electrostatic and steric repulsion forces. The interfacial membrane formed around the oil droplets prevents them from aggregating (flocculating and/or coalescing). However, only 1–2 % of the gum is absorbed into the oil–water interface and participates in the emulsification; thus, over 12 % of GA content is required to stabilize emulsions with 20 % orange oil (Randall et al. 1988). Randall et al. (1988) reported that the AGP complex is the main component responsible for gum arabic ability to stabilize emulsions, and after treatment with protease, the gum significantly reduces its emulsifying properties.

Encapsulation Capacity: In the food industry, encapsulation is an important process to improve the chemical stability of sensitive compounds that need to be protected, isolated, or slowly released over time. The encapsulating material must preserve and protect the encapsulated compounds during manufacture, storage,

and handling to release them into the final product during manufacture or consumption. Gum arabic is an effective encapsulant agent because it produces stable emulsions with most oils in a wide pH range, and it has the ability to form films (Kenyon 1995).

Nutraceutical Properties: Gum arabic can be categorized as a nondigestible carbohydrate or dietary fiber. It is fermented by intestinal bacteria to short-chain fatty acids, particularly propionic acid in the large intestine, leading to a wide range of potential health benefits (Phillips and Phillips 2011).

Compatibility: The gum arabic is compatible with most gum, starches, and proteins, but it is incompatible with sodium alginate and gelatin. However, gum arabic in combination with gelatin at low pH gives coacervates that can be used for oil encapsulation (Imeson 1992).

2.6 Food Applications

Gum arabic has been used in a wide range of food products for many years. It is a multifunctional food additive being emulsifier, flavoring agent, humectant, stabilizer, thickener, and retards sugar crystallization. In the food industry, gum arabic is primarily used in confectionery, bakery, dairy, beverage, and as a flavor microencapsulating agent (Imeson 1992).

Confectionery: Gum arabic has a major role in the confectionery industry for many centuries, especially in products in which sugar content is high and moisture content comparatively low, from soft lozenges to hard gums (Whistler and BeMiller 1973). The gum may influence crystallization in three different ways: the hydrocolloid can attach itself to a growing crystal surface and thus alter its normal growth pattern; the hydrocolloid and the crystal may compete for the same building blocks; the gum may combine with impurities that affect crystal growth (Shuman 1960; Glicksman 1969). Low levels of gum arabic (up to 2.0 %) are included in chewy sweets based on gelatin to improve product adhesion, reduce elasticity, and produce extra-fine sugar crystallization with a smooth texture. Chewy gels with desirable texture can be produced by creating special conditions of pH, protein concentration, and heating, among others (Anson and Pader 1958). Concentrated gum acacia solution (up to 25 % w/w) is applied over snacks as an adhesive coating to retain seasoning, e.g., dry-roasted peanuts (Idris and Haddad 2012). It is also used in toffees as an emulsifier to maintain a uniform distribution of the components throughout the product (Verbeken et al. 2003).

Bakery Products: Gum arabic is extensively used in baking due to its moisture adsorption properties. Baking properties of wheat and rye flours can be improved by adding a small amount of gum arabic since its capacity for retaining moisture reduces the hardening of bread. It also has favorable adhesive properties to be used in glazes, toppings, and meringues. Another useful property is that gum arabic provides softness when used as emulsion stabilizer (Glicksman 1983).

Beverages and Flavors: Gum arabic has a unique combination of excellent emulsifying properties and low solution viscosity, making it very useful as a stabilizer of citrus oil emulsion concentrates in soft drinks and as a flavor encapsulator. Gum arabic ability to stabilize foams is used in the manufacture of beer. In addition, it can be used to clarify wines (Idris and Haddad 2012) or as a source of soluble fiber in low-calorie and dietetic beverages (Phillips 1998).

2.7 Nonfood Applications

Gum arabic is being widely used for industrial purposes such as a suspending agent, stabilizer, thickener, adhesive and binder, emulsifier, and encapsulator in textiles, ceramics, lithography, cosmetic, and pharmaceutical industry (Verbeken et al. 2003).

In ancient Egypt, gum arabic was used as a binder in cosmetics and inks and as an agent in the mummification process. In cosmetics, gum arabic functions as a stabilizer in lotions and protective creams, where it increases viscosity, imparts spreading properties, and provides a protective coating and a smooth feel. It is used as an adhesive agent in blusher and as a foam stabilizer in liquid soaps (Whistler 1993).

Gum arabic is also used as a suspending agent or protective colloids in soluble inks, watercolors, and quick-drying and typographic inks. In these types of ink, the gum helps to reduce the sedimentation rate of particles in suspension. In lithographic processes, the gum is used to protect images during etching. During printing, water adheres to the gum arabic surfaces and avoids the oily parts, while the oily ink used for printing does the opposite (Whistler and BeMiller 1973).

Sizing is the application of various materials to a fabric to produce stiffness or firmness. Gum arabic is applied as a sizing agent for cloth, particularly in silk or rayon, where the gum imparts body to the fabric without interfering with its transparency (Whistler and BeMiller 1973).

It is used as a dispersant in paints and insecticidal/acaricidal emulsions, respectively, keeping the pigments and active components uniformly distributed throughout the product (Fuyama and Tsuji 1981). Other applications are corrosion inhibitor (Umoren et al. 2006), pigment manufacture, ceramics, and polishes (Nussinovith 2010).

Also, gum arabic is recognized by its ability to sustain colloidal stability for systems of carbon nanotubes in aqueous solutions due to nonspecific physical adsorption (Bandyopadhyaya et al. 2002). It is also used as a steric stabilizer in the preparation of colloidal silver particles (Velikov et al. 2003), and it has probed for the coating and increased biocompatibility of iron oxide magnetic nanoparticles (Williams et al. 2006; Banerjee and Chen 2007a, b, 2008; Roque and Wilson 2008; Wilson et al. 2008) and gold nanoparticles (Kannan et al. 2006; Kattumuri et al. 2007).

3 Mesquite Gum

3.1 Source and Production

Mesquite trees are leguminous plant trees that are widespread in arid and semiarid regions of the world. The genus *Prosopis* comprises about 44 species that grow mostly in North America (9 species) and South America (31 species) and also in northern Africa (1 species) and eastern Asia (3 species). Around ten species of *Prosopis* are found in Mexico being *P. juliflora* the most abundant (Vernon-Carter et al. 2000), which has been suggested to correspond with *P. laevigata*. In northwestern state of Sonora, *P. velutina* and *P. pubescens* are found, although it is possible to find hybrid species. The case of *P. chilensis* is notorious, that is, a mesquite species that was introduced and promoted as garden ornamentals or as shade trees in schools and private gardens. Now it could be found in the Sonora desert among other native species.

The bark of *Prosopis* produces an exudate known as mesquite gum as response to insect attack, wounding or weather conditions (temperature), drought, age, and health of the tree that can affect the exudation. The production of mesquite gum is not known around the world. However in Mexico, there are two main regions where mesquite gum is produced, in the desert plains of northwestern state of Sonora and in the lowlands of northeastern state of San Luis Potosi.

Mexico can be considered as the main producer of mesquite gum, and in the absence of national statistics, the information available on the production of mesquite gum from wild plantations comes only from few field studies that have estimated the availability of the gum in the two regions in Mexico since time ago. In central region of Sonora with mean tree density of 80 trees per ha, only 10 % of the trees produced gum. The amount of gum exudates was calculated in per tree equivalent to 240 g gum ha. The gum production spans over 5 weeks in hot–dry weather time (May–June) (Goycoolea et al. 2000). In San Luis Potosi, there is a higher tree density (200 trees ha), and 70 % of them produce gum in a production time of 24 weeks. With these data the estimated potential of production reach over 2,000 ton per year (Vernon-Carter et al. 2000). This production is sufficient to fulfill the demand of gum arabic that during the last 3 years was 1,500 ton·per year with an importation total price of six million of USD (Table 2) (INEGI 2012). However, mesquite gum is collected and traded at very low level, just to cover the demand of local commodities of markets. There are neither commercial plantations nor established processing facilities.

There is the possibility that the production of mesquite gum oscillates by the different factors mentioned above. Therefore, alternative production methods have been investigated. In vitro studies of the culturing of *P. laevigata* have demonstrated that the application of combined environmental conditions (temperature increase) and biotic elicitors can be utilized for increasing mesquite gum production with similar characteristics to those produced in situ by wild trees (Orozco-Villafuerte et al. 2003, 2005).

Table 2 Gum arabic imported by Mexico

Year	Imported quantity (kg)	Imported value (USD)
2010	1,500.130	5,951.875
2011	1,560.598	6,177.042
2012	1,572.775	6,106.625

Source: Statistical data from the Instituto Nacional de Estadística y Geografía (INEGI)

3.2 Collection

The production season of mesquite gum in Sonora begins during the late spring and early summer months May–July, ending with start of the rain season at late July or August. The collection of mesquite gum is done by hand in hard environmental conditions as low humidity, high temperature, and thorny vegetation and is not properly organized or established as the gum arabic. There is no standard quality grading system available to sort the mesquite gum nodules. However, they can be classified by size, color, and the contents of bark and foreign matter. This classification procedure is a method for the selection of mesquite gum that meets the quality requirements of the Joint FAO/WHO Expert Committee on Food Additives for gum arabic intended for foods (López-Franco et al. 2012).

3.3 Regulatory Status

Mesquite gum is not permitted as food additive neither by the FDA nor by the Codex Committee on Food Additives. However, in Mexico the gum can be used as processing aids in food and beverages (Secretaría de Salud 2006, 2012). The authorization was given after a multigeneration study to three generations in Wistar rats. The study evaluated and compared the toxicity and mutagenicity of mesquite gum (*P. laevigata*), commercial gum arabic and cellulose included in the diet. In general, the tests proved that the rats' growth, development, and survival rate were not affected by the inclusion of mesquite gum in the diet and that mesquite gum did not induce any kind of mutagenicity; thus it did not present any carcinogenic activity (Flores-Dominguez et al. 2000).

Mesquite gum is not an established hydrocolloid in the world market. However, the gum was widely used by the native cultures of the northwest of Mexico and southwest of the United States since pre-Columbian times (Felger 1977). It is used mainly as hard candy and as medicinal aid, i.e., to prepare eye drops or to treat sore throat (Felger and Moser 1974). Similar uses prevail in regions where mesquite tree grows, and this gives account of its safety for human consumption.

3.4 Structure

Mesquite gum is a neutral salt of a complex acidic branched polysaccharide formed by a core of β-D-Gal residues comprising a (1→3)-linked backbone with

(1→6)-linked branches and bearing L-Ara (pyranose and furanose rings form), D-glucuronic acid, and 4-*O*-methyl-β-D-glucuronic acid (White 1946, 1947a, b, 1948; Cuneen and Smith 1948a, b; Akher et al. 1952; Aspinall and Whitehead 1970a, b). Mesquite gum from *P. velutina* yields L–Ara and D–Gal as main carbohydrate residues, and traces of D-Glc, D-Man, and D-Xyl after acid hydrolysis were detected (López-Franco et al. 2008). Small amount of uronic acids (4 %), mainly glucuronic acid, was also detected. A notable composition difference with gum arabic is that *P. velutina* mesquite gum does not contain L-rhamnose (Rinaudo et al. 2008; López-Franco et al. 2013).

Mesquite gum contains protein (3–7 %) that is formed mainly by hydroxyproline, serine, glycine, and valine (Fincher et al. 1983; Goycoolea et al. 1998; Orozco-Villafuerte et al. 2003; López-Franco et al. 2008, 2012, 2013). Several studies have established that protein plays an important role on the emulsification properties of the gum (Goycoolea et al. 1995; Vernon-Carter et al. 1996, 1998).

In addition to the polysaccharide and protein components, mesquite gum has a lipid fraction mainly formed by palmitic (C16: 0), stearic (C18: 0), and behenic (C22: 0) fatty acids. Also, traces of phosphorous (P) were detected in the gum. These components could be related to the presence of glycosylphosphatidylinositol anchor (GPI) (López-Franco et al. 2013).

It has been documented that mesquite gum consists of three main fractions obtained by hydrophobic interaction chromatography and referred to as arabinogalactan (AG), arabinogalactan protein (AGP), and glycoprotein (GP). These fractions differ in molecular weight, protein content, and surface activity (López-Franco et al. 2004). The AGP represents about 2.49 % of the total gum, and it has 11 % of protein and a molar mass of 484,000 g mol^{-1} (López-Franco et al. 2004, 2008) and can be classified into classical AGPs due to its composition of carbohydrate (Ara and Gal) and amino acids (abundant quantities of Hyp, Ser, Gly) and because it reacts to the β-glucosyl Yariv reagent (López-Franco et al. 2013).

Unlike gum arabic, there are no models that explain the tertiary structure of AGP of mesquite gum. However, by structural parameters (R_g, R_h, $P_{(\theta)}$) obtained by light scattering, measurements have allowed to conclude that mesquite gum is more extended than gum arabic and that it can be considered as a polydisperse macrocoil (López-Franco et al. 2004) in agreement with the "twisted hairy rope" proposal AGP for gum arabic (Qi et al. 1991).

3.5 Physicochemical Properties

Physicochemical characteristics derived from various studies on the gums from *P. velutina* are compiled in Table 3.

Solubility: Mesquite gum has high solubility in aqueous medium, which can yield solutions above 50 % (w/w) concentration (Goycoolea et al. 1995). It is soluble in aqueous ethanol, with up to 70 % ethanol. In organic solvents mesquite gum has either limited solubility, e.g., in glycerol or ethylene glycol, or it is insoluble, e.g., in alkanes or oils (Vernon-Carter et al. 2000). The solutions of

this type of gum display a range of colors that vary from slight yellow or amber to dark brown depending on concentration and botanical origin.

Viscosity: The viscosity of aqueous gum solutions decreased as the gum concentration increased (1.0–15 %). The solutions show shear thickening as the shear rate was increased up 637.12 s^{-1} (Vernon−Carter and Sherman 1980). Gum solutions at 20% (w/w) in 0.1 M NaCl, measured at 20 °C, display an average viscosity of 8.7 mL g^{-1} and Newtonian behaviour (Goycoolea et al. 1995). At higher concentrations, from 25% (w/v) and over, the mesquite gum solution exhibited a pseudo-plastic behaviour.

The intrinsic viscosity of 5 % (w/w) mesquite gum solutions in 0.1 M NaCl at 30 °C is 10.9 mL g^{-1}. This result was lower than that obtained with gum arabic at the same experimental conditions (21.18 mL g^{-1}) (López-Franco et al. 2013). This is related to the occurrence of larger-size macromolecular species in gum arabic than in mesquite gum.

Molecular Conformation: Static and dynamic light scattering techniques were used to determine structural parameters of native gum and fractions. It was possible

determine the ratio $R_g/R_h > 2$, indicating the possibility of an elongated structure for all samples of mesquite gum. The dependence of form factor with theoretical model allows to observe that mesquite gum and fractions were best fit by a model for a polydispersed coil structure (López-Franco et al. 2004).

Surface Activity: Mesquite gum showed the highest water and oil absorption at temperatures of 23, 35, and 45 °C in comparison with gum arabic. The activation energy for water and oil absorption for gum arabic was 21.98 and 39.57 kJ mol^{-1}, compared to that of mesquite gum having values of 15.79 and 46.16 kJ mol^{-1}, respectively (Beristain et al. 1996).

Mesquite gum and its fractions have been studied by Langmuir monolayers spread at an air–water interface and compared with gum arabic and its corresponding fractions. The most active species at the interface were those containing greater amounts of protein. However, the observed mechanical properties of the monolayer of mesquite gum and its fractions can also be explained by differences in macromolecular dimensions, conformation, and topology of the molecule and the hydrophobic/hydrophilic sites adsorbed at the interface (López-Franco et al. 2004).

The interfacial tension is affected by the gum concentration and the pH of the solution. It decreases when the gum concentration increases. At high concentrations (i.e., over 25 %, w/v) of mesquite gum, the interfacial tension decreases faster. The influence of pH solution has been also observed, and it has been related to molecular configuration changes of the gum (Vernon-Carter et al. 2000).

Emulsification Capacity: Mesquite gum is a surface-active biopolymer, because of its amphiphilic character. Mesquite gum forms and stabilizes oil-in-water emulsions and has the ability to encapsulate orange citrus oil during spray drying (Vernon-Carter et al. 1996; Beristain et al. 1996; Goycoolea et al. 1997). Mesquite gum solutions of 15 % (w/w) concentration are able to form emulsions with *n*-alkanes of varying chain length, D-limonene, and orange oil. The mean diameter of droplets of *n*-decane, *n*-dodecane, *n*-tetradecane, and *n*-hexadecane was of 4–4.5 μm, and with orange oil the average droplet diameter was found to vary in the range 2.5–3.0 μm. The behavior of particle size (R_h) for D-limonene emulsions showed a higher rate of change with time, at difference, than those orange oil droplets that remained almost without change after more than 100 h (Acedo-Carrillo et al. 2006). This behavior of mesquite gum on the orange oil emulsions to stop or control Ostwald ripening is attributed, among other causes, to the fact that orange oil is less water soluble than D-limonene (Rinaudo et al. 2008).

Encapsulation Capacity: The most widely used encapsulation agents are gum arabic and modified or hydrolysed starches. Mesquite gum has been reported as having the ability to encapsulate orange peel oil (Goycoolea et al. 1997) (80.5 % of the starting oil) (Beristain and Vernon-Carter 1994). A blend of gum arabic and mesquite gum (60:40) was able to encapsulate the same amount of orange peel oil compared to pure gum arabic (Beristain and Vernon-Carter 1995). Another blend of maltodextrin 10 DE and mesquite gum (3:2) retained 84.6 % of the starting orange peel oil, providing better encapsulating capacity. In other studies, the orange peel oil encapsulating capacity of native and low-tannin mesquite gums was slightly lower than gum arabic (Goycoolea et al. 1997, 1998).

Film Forming: Mesquite gum-based films have become an important research topic mainly due to their capability to regulate moisture, lipid migration, and gas transport and can be used to improve the quality and extend the shelf life of foodstuffs. Emulsion films based on mesquite gum as structural agent and a blend of candelilla wax with white mineral oil as the lipid phase prolong the shelf life of treated guava fruit (*Psidium guajava* L.) by retarding ethylene emission and enhancing the texture of the fruits (Tomás et al. 2005a). On the other hand, combinations of mesquite gum (*Prosopis* spp.) with whey protein concentrate form films less effective as moisture barriers (Tomás et al. 2005b). Mesquite gum–chitosan complex has also been used to form edible films against water vapor permeability (Ruiz-Ramos et al. 2006).

Compatibility: Mesquite gum has been used in combination with gum arabic, maltodextrins, lipids, vegetal and animal proteins, chitosan, sodium alginate, and κ-carrageenan. In all cases synergistic effects using the mesquite gum have been observed (Vernon-Carter et al. 1996, 1998; Perez-Alonso et al. 2003; Tomás et al. 2004; Pérez-Orozco et al. 2011).

3.6 Food Applications

Mesquite gum has been used in Mexico for centuries mostly in folk medicine and more recently as a substitute for gum arabic in food and drinks. However, the fact that it does not have approval from the FDA has limited its more widespread use in the world. Many studies account for the novel and beneficial uses of mesquite gum in food and other systems, and the main applications have been reviewed (Vernon-Carter et al. 2000).

As mentioned in the previous section, mesquite gum solutions are effective in the preparation and stabilization of oil-in-water emulsions. This has been exploited mostly for the stabilization of orange peel essential oil and oleoresins. Independent studies have demonstrated that mesquite gum exhibits smaller average oil droplet size and better stability than identical emulsions made with gum arabic (Beristain 1996; Acedo-Carrillo et al. 2006). Mesquite gum has been used in trials by the food industry. Soft drinks made from concentrated orange essential oil-in-water emulsions were found to require 70 % less mesquite gum than gum arabic for achieving similar initial particle size and stability, while no significant differences in flavor were detected among both formulations (Vernon-Carter et al. 2000). In other studies, Aztec marigold (*Tagetes erecta*) oleoresin-in-water emulsions have been stabilized against drop coalescence and loss of color. Also, in chilli oleoresin-in-water emulsions, mesquite gum has been found to confer smaller and more uniform initial particle size and greater stability against droplet coalescence and color degradation than gum arabic (Vernon-Carter et al. 1998).

Flavor and color encapsulation by spray drying are industrial applications of mesquite gum. To this end, mesquite gum has been used as the sole encapsulation agent or mixed with maltodextrin (Beristain and Vernon-Carter 1994;

Goycoolea et al. 1997, 1998) to encapsulate orange essential oil during spray drying. In both series of studies, it was found that mesquite gum has the ability to retain more than 80 % of the oil load, though to a slightly lesser extent than gum arabic. In low-tannin ultrafiltrated mesquite gum, it was found that when only species of 10 kDa are removed, the oil encapsulation capacity is not significantly affected when compared with that of gum arabic (Goycoolea et al. 1997, 1998). More recently, mesquite gum has been evaluated as color protection agent of blueberry extracts microencapsulated by spray drying. The sample showed minimal changes in color after 4 weeks, demonstrating that the gum provides an advantage in the conservation of colorants (Jiménez-Aguilar et al. 2011).

3.7 Nonfood Applications

Among the earliest documented uses of mesquite gum in the chemical industry was as a source of L-arabinose (Anderson and Otis 1930; Loeza-Corte et al. 2007), which is an important ingredient in culture media. The use of mesquite gum mixed with other polysaccharides for the microencapsulation of artificial diet for larvae shrimp (*Litopenaeus vannamei*) was found to improve the survival rates and overall quality of the microcapsules (Pedroza-Islas et al. 2000, 2004). Mesquite gum has also been used as a binder in tablet dosage forms and as a suspending agent, where it compared well with gum arabic and was superior to tragacanth gum (Khanna et al. 1997). In Sonora, household applications of mesquite gum include hardening of hats and as paper glue (Balderrama 1998).

The properties of mesquite gum are very similar to that of gum arabic; this suggests that the applications of mesquite gum can be expanded to pharmaceutical industry in the fields of biomedicine, especially in nanomaterials. For instance, mesquite gum has been studied as stabilizer of iron oxide nanoparticles with potential application in biomedicine (Ortega-Ruiz 2013).

4 Conclusions

Gum arabic is, by far, the most important plant exudates in the international market. Although there is the availability of several new alternative industrial hydrocolloids, gum arabic still is the first option in diverse applications in food, pharmaceutical, and chemical industries. However, the instability of the international market and an increasing demand along with social and political volatility in the producing regions are factors that impulse a continuous search for suitable alternative gums. Among other related gums, there are several that have considerable potential to compete with gum arabic. One of them is the mesquite gum produced by trees of the *Prosopis* genus. This gum has diverse traditional uses in food and other applications by the native cultures of America. Many studies account for the chemical structure and functional properties that are comparable with acacia gums.

Resistant Starch in Food Industry

22

Leyla Khalili and Amir Amini

Contents

Abstract

Dietary starches can make quite specific contributions to health and are important sources of energy for most people. For both its potential health benefits and functional properties, resistant starch has received much attention. It can positively influence the functioning of the digestive tract, the microbial flora, the blood cholesterol level, glycemic index and assist in the control of diabetes. Apart from the potential health benefits of resistant starch, another positive advantage is its lower impact on the sensory properties of food compared with traditional sources of fiber, as whole grains, bran, or other prebiotics. The low water-holding capacity, increased viscosity and gel formation and high water-binding capacity make it useful in a variety of foods. In this chapter, it was intended to discuss about different resistant starch types, food sources, potential health benefits and food applications of resistant starch.

Cheese • Dietary fiber • Microencapsulation • Pasta • Resistant starch

1 Introduction

The functional features of resistant starch (RS), along with its potential physiological benefits, provide a means to increase total dietary fiber (DF) in the diet through common foods. DFs are carbohydrate polymers with 10 or more glucose units that are not hydrolyzed by the endogenous enzymes (McCleary et al. 2012). Being metabolized by advantageous colonic microorganisms which are called probiotics is the important property of DF, and this may lead to an enhanced bacterial growth and increased fecal bulk (Homayouni et al. 2014). The health benefits of DF for consumers such as reducing glycemic responses to carbohydrate ingestion, decreasing the risk of colorectal cancer, and enhancing mineral absorption make it a valuable prebiotic (Kumar et al. 2012).

Prebiotics have attracted the attention of producers more than ever due to the importance of them in prevention of certain disease. Prebiotics are nondigestible oligosaccharides that offer many helpful effects on the gastrointestinal system which are shown by selectively stimulating the growth or activity of certain indigenous bacteria (Sarkar 2007). Typical prebiotics are DFs that usually consist of inulin, oligosaccharides, and RS (Buttriss and Stokes 2008).

The growth in the use of new technologies and ingredients is because of the increase in consumer request for high-quality food products. Several factors influence changes in consumer requests, including health concerns (cholesterol, cancer, obesity, etc.), changes in demographic characteristics (ethnics, population aging, etc.), the need for convenience, and changes in distribution systems and price. As a result of these changes, attention in new products, mainly convenience-oriented products prepared using novel technologies, high pressures, etc., has intensely increased in recent years (Fuentes-Zaragoza et al. 2010). The food industry offers quality and convenience to a wide variety of consumers including single households, working couples, the aging population, and others (Fagan and Gormley 2005). To develop these types of products, one must evaluate consumer awareness, the most important quality aspects being that they taste good, appear healthy, and have nutritional value (Garcia-Segovia et al. 2007). Any functional food must be safe, healthy, and tasty as well. Actually, considerable importance is given to functional foods, which, in addition to their basic nutritional functions, provide physiological benefits and/or reduce the risk of chronic diseases, as they either contain (or add) a component with a positive health effect or eliminate a component with a negative one. One of the added components could be RS, which is commonly used as a functional ingredient, especially in foods containing high dietary fiber levels (Mikulíková et al. 2008).

There is general agreement among public health authorities and nutritionists that the inclusion of fiber in the human diet provides health benefits (Férnandez-López et al. 2009). That benefit message has reached consumers, and many meat product

companies, for example, have responded by launching products fortified with fiber. Many studies have found that people on diets high in fiber have reduced risks of certain diseases such as cancer, coronary heart disease, obesity, and possibly diabetes (Canovas and Pérez-Alvarez 2006). Some health benefits linked to fiber consumption are well established (e.g., promoting a regular bowel habit), and others are slowly becoming more firmly established (Buttriss and Stokes 2008; Viuda-Martos et al. 2010).

Resistant starch can influence the functioning of the digestive tract, the microbial flora, the blood cholesterol level, and the glycemic index and assist in the control of diabetes (Fuentes-Zaragoza et al. 2010). So it has received much attention for both its potential health benefits and functional properties.

1.1 Resistant Starch

Starch is the storage form carbohydrate of plants; many different types of starch exist depending on the plant source. A proportion of the starch, however, known as RS, is indigestible even after prolonged incubation with amylase. RS is a component of dietary starch that is not absorbed in the small intestine of healthy individuals and thus reaches the colon undigested, similar to other DFs. It has drawn considerable attention over the last two decades due to its demonstrated and putative positive impacts on health (Perera et al. 2010). Several diseases, especially digestive ones, are caused by inadequate or inappropriate diets. It is reasonable to accept an increase consumption of RS (Topping et al. 2008) which is among the important indigestible carbohydrates and has approximately half calorific value (8 kJ/g) compared with digestible starch (15 kJ/g) (Rochfort and Panozzo 2007). Most health effects of RS can be ascribed to its fermentation by the colonic microbiota (Robertson et al. 2000). Therefore, producing short-chain fatty acids (SCFA) by probiotics makes an environment less liable to the development of cancerous tumors (Yao et al. 2009). Other effects of RS consumption are preventing constipation, increasing excretion frequency and fecal bulk, decreasing production of mutagenic compounds, and lowering the colonic pH and ammonia levels (Fuentes-Zaragoza et al. 2011; Toden et al. 2005). RS can prevent diabetes by lowering postprandial insulin response, increasing insulin sensitivity, lowering postprandial glucose response, and delaying onset of insulin resistance (Torres-Zapata et al. 2012). It can reduce total liver cholesterol by causing higher excretion rates of cholesterol and bile acids (Fuentes-Zaragoza et al. 2011; Yao et al. 2009; Topping et al. 2008; Toden et al. 2005; Hashimoto et al. 2006; Wong et al. 2006). Increased absorption of calcium and magnesium by producing SCFA in large bowel is another effect of RS (Younes et al. 2001; Scholz-Ahrens et al. 2007). It can reduce energy intake due to its low caloric value, resulting in less appetite, so it can prevent obesity (Brown 2004; Bodinham et al. 2010). RS prevents diarrhea by shortening of the duration of rotavirus diarrhea by probiotics (Ramakrishna et al. 2000; Raghupathy et al. 2006). Prevention of colorectal cancer is another important benefit of RS. The Production of SCFA by fermentation of RS caused by

anaerobic bacteria and acetic, propionic, and butyric acid can lower the lumen pH, creating an environment less prone to the formation of cancerous tumors (Homayouni et al. 2014).

Apart from the potential health benefits of RS, another positive advantage is its lower impact on the sensory properties of food compared with traditional sources of fiber, as whole grains, fruits, or bran. Among its desirable physicochemical properties are its swelling capacity, viscosity, gel formation, and high water-binding capacity, which make it useful in a variety of foods (Fuentes-Zaragoza et al. 2010).

1.2 Resistant Starch Types

RS has been classified into four categories in almost all studies; however, RS type five was considered lately (Homayouni et al. 2014). RS1 is a physically inaccessible starch that is protected in cell walls and can be found in whole or partly milled seeds, grains, legumes, and pasta. RS2 is a granular native starch, with highly crystalline structure, that is found in raw potato, unripe bananas, and high amylose starches. RS3 is a retrograded nongranular starch that is found in cooked and retrograded starchy crops and foods. RS4 is a chemically modified starch and resistant dextrin that is found in functional foods with modified fiber. Also RS5 is found in crops or foods that contain starch–lipid complex (Noronha et al. 2007).

2 Application in Food Industry

As an insoluble product, resistant starch is especially suitable for grain-based low- and moderate-moisture foods (Yue and Waring 1998). Its physical properties, such as its low water-holding capacity, allow it to be a functional component that provides good handling in processing and crispness, expansion, and improved texture in the final product. Considering the technological features of RS, numerous food products have been enriched with RS including cheese, ice cream, yogurt, milk dessert, Iranian fermented drink (doogh), bread, corn flakes, cakes, muffins, pasta, and battered fried products (Charalampopoulos et al. 2002; Espírito-Santo et al. 2013; Vernaza et al. 2011; Mahadevamma and Tharanathan 2007; Mangala and Tharanathan 1999; Aravind et al. 2013; Mirzaei et al. 2012; Laguna et al. 2012; Yeo and Seib 2009; Tas 2000). Each type of RS has a distinct profile of physiological and technological functionality. For example, firmness and adhesiveness are textural properties which are the most important parameters for cooking quality of baked cereal products. In addition, due to the different stability and sources of RS, the appropriate selection should be considered. According to Faraj et al. in most cases in which high temperature and moisture are included (e.g., frying and high-temperature drying), RS1 and RS2 may be destroyed, but RS3 is able to resist or can be formed after process (Faraj et al. 2004; Ozturk and Koksel 2009). RS has more efficacies in food technology as mentioned in the following. The most studied products among cereals are pasta and bread.

2.1 Pasta Products

Pasta, a basic foodstuff with several nutritional values and important role in diets, can be easily produced, stored for a long time, and prepared for eating. In addition it has a lower glycemic index (GI) in comparison with starchy foods like white bread (Bustos et al. 2011). The compact structure created by extrusion process causes a compressed protein network that reduces the availability of starch granules to be hydrolyzed by a-amylase (Fardet et al. 1999).

According to the consumers' criteria for choosing high cooking quality pasta, manufacturing a good product which includes the optimum cooking time, low water absorption, and proper texture, with additional nutritional value, becomes a state of art. RS2 in pasta formulation enhanced the quality of the final product.

Pasta enriched with RS4 improved textural characteristics; however, pasta enriched with 5 % bran substituted changed cooking properties positively, whereas substitution with RS2 had no negative effect up to 10 % (Bustos et al. 2011). Increasing the amounts of RS2 in pasta resulted in a significant decrease in yellowness, no change in brightness, and minimal change in redness. Pasta enriched with 50 % of RS2 was brighter than all the other pastas. The substitution of RS up to 20 % did not change the sensory properties such as slippery, firmness, chewy, rubbery, and floury mouthfeel compared to the control pasta. Also in vitro digestibility reduced in 20 % RS2 substitution (Aravind et al. 2013). The properties of pasta dough with RS2 and RS3 in two levels (10 % and 20 % substitution with semolina) were investigated by Aravind et al. As more RS was added, the dough would be weakened. This may be explained by low WHC of RS and its competition with the semolina for hydration (Aravind et al. 2013). According to the results of the studies, the appearance of functional pasta may be of the most important parameter for good marketing.

2.2 Bread

The bread fortification with conventional DFs such as wheat bran and barley flour has some disadvantages like reduced volume, dark color, and disguising of flavor that caused a decrease in customers' acceptance (Sajilata et al. 2006). Ozturk et al. investigated the addition of RS2 (Hylon VII) and RS3 (Novelose 330) in bread formulation, each one at 10 %, 20 %, and 30 % w/w, and evaluated their effects on both properties and RS contents of the bread. Results were shown that doughs supplemented with RS absorbed more water (due to the low WHC) and were weaker than those of the base flour. Loaf volume decreased significantly above the 10 % RS3 and above the 20 % RS2. However crust color values decreased at 30 % addition of RS3 and RS2 supplemented breads.

Firmness of breads increased above 10 and 20 % for the addition of RS3 and RS2, respectively, after 7 days of storage, and RS content increased significantly as the addition level of both RS types increased (Ozturk and Koksel 2009). The results showed that up to 4 days of storage in three different conditions (ambient,

refrigeration, and freezing temperature) the RS content in crumb and whole bread increased and then dwindled (Niba 2003). The decrease might be the result of a converse in retrogradation of amylopectin, instability of amylopectin crystals, or unavailability of starch. This was the result of the formation of starch–protein or starch–lipid complexes, which could be caused by formation of RS5 (Rabe and Sievert 1992). The enrichment of bread with RS may result in the preparation of functional bread with healthy effects on consumers.

The most studied foods among dairies were cheese products.

2.3 Cheese

Mozzarella cheese normally contains about 20–27 % fat and is popular for its use in pizzas, so it is a great candidate for fat substitution with RS (Noronha et al. 2007). A study showed that it was possible to reduce up to 50 % of fat content with Novelose 240 (RS2) or Novelose 330 (RS3) in mozzarella cheese. Hardness linearly increased with increasing fiber content which the effect of RS3 was more than RS2. Cohesiveness was increased linearly with increasing RS2, but RS3 did not influence it (Montesinos-Herrero et al. 2006). It was possible to substitute up to 43.2 % of dry matter with RS in cheeses with 52–60 % moisture content while reserving desirable functional properties. The presence of RS showed a smooth and homogeneous texture without noticeable loss of moisture (Noronha et al. 2007). A kind of RS2 which its commercial name is Hi-maize 240 was also used as a crisping agent in imitation heat-expanded cheese. Arimi et al. produced a functional cheese which its fat content was successfully replaced with 15.3 % Hi-maize 240 (Arimi et al. 2008).

It was stated that RS organizes water molecules to be physically entrapped within the cheese matrix. The effects of RS2 content on aw, moisture sorption isotherms, and functional properties of imitation cheese were studied by Duggan et al. Cheese moisture remained constant (58 %), while the RS2 content was increased from 8.9 % to 18.2 %. With increasing RS2 content, hardness and cohesiveness showed no significant increase except at 12.9 %. Increasing starch concentration from 8.9 % to 12.9 % caused the reduction of aw from 0.986 to 0.978; nevertheless, higher concentration had no significant effect on aw. Finally the sorption behavior of the cheese was not affected by increasing the RS2 content (Duggan et al. 2008). It can be concluded that 18 % RS2 not only had no effect on the cheese texture and overall acceptability but also has healthy effects on consumers.

2.4 Microencapsulation of Probiotics

Microencapsulation is a new method which helps to isolate the bacterial cells from the effects of the hostile environment and gastrointestinal tract, thus potentially preventing cell loss and increasing probiotic survival (Homayouni et al. 2008). To some extent, Kebary et al. have shown that *Bifidobacterium* spp. survive in high

Table 1 Functionality of resistant starch types in food technology

Food products	Type	Result	Reference
Pasta	RS2	↑ Lightness, ↓ adhesiveness, ↓ water absorption	Aravind et al. 2013
	RS3	↓ Cooking loss, ↑ firmness, ↓ in vitro digestibility	Sozer et al. 2007
	RS4	↓ Glycemic index, without negative sensory effects	Bustos et al. 2011b

	RS1	↓ Elasticity and ↓ deformability in muffin	Baixauli et al. 2008
Cheese	RS2	Fat replacer in mozzarella, ↓ water activity	Montesinos-Herrero et al. 2006
	RS3	↑ Homogenous and smooth texture	Noronha et al. 2007
Fermented drinks	RS2	↑ Viability of *L. acidophilus*	Nobakhti et al. 2009
		↑ Viscosity and consumer acceptance	Allgeyer et al. 2010
Yogurt	RS2	↑ Hardness and adhesiveness	Gustaw et al. 2011
		↓ Syneresis	Ramirez-Santiago et al. 2010
Ice cream	RS2	↑ Survival rates of *L. acidophilus*	Haynes and Playne 2002
		↑ Number of *L. casei* and *B. lactis*	Homayouni et al. 2008
Microencapsulation	RS2	↑ Delivery of *B. animalis*	Ziar et al. 2012
		↑ The number of *L. casei*	Sultana et al. 2000
	RS4	↓ Protection against oxidation of fish oil	Chung et al. 2010

numbers in frozen ice milk in beads made from alginate than those made from k-carrageenan. Shah and Ravula reported that the survival of probiotic bacteria in fermented frozen desserts improved with encapsulation. Encapsulation thus may enhance the shelf life of probiotic cultures in frozen dairy products. RS2-Calcium Alginate is a type of microencapsulation material that is used in several food products (Zanjani et al. 2014).

In 2000 Sultana et al. investigated the survival of probiotics encapsulated by alginate–starch gel in yogurt over a period of 8 weeks during storage at 4 °C. They stated the addition of RS2 (Hi-maize 260) at 2 % concentration to alginate mix resulted in an increase in number of *Lactobacillus casei* from 4×10^8 to 3.1×10^{11} CFU/g, although adding 4 % RS2 did not improve the encapsulation efficiency. Over 8 weeks of storage, one log decline was observed in both strains of *Lactobacillus acidophilus* and *Bifidobacterium infantis* when presented as free cultures, whereas encapsulated cells showed a 0.5 log decrease which meant the

positive role of using RS2 (Sultana et al. 2000). The same results were achieved in a study by Ziar et al. for evaluating the viability of *Bifidobacterium animalis* and *Lactobacillus rhamnosus*. After 4 weeks of yogurt refrigeration, no significant differences in bacterial counts were detected. Also under simulated gastrointestinal conditions, the number of viable encapsulated cells was significantly higher than those attended with free cells. Moreover, pH values did not change significantly from day 1 to 28 in *Bifidobacterium animalis* microencapsulated sample; conversely, in yogurt with encapsulated *Lactobacillus rhamnosus*, a significant decrease in pH values was obtained from day 7 cells (Ziar et al. 2012).

In 2008, Homayouni et al. studied the survival of *Lactobacillus casei* and *Bifidobacterium lactis* which was monitored during the storage of ice cream for 180 days at −20 °C. They found that microencapsulation of the specified probiotics with a 2 % starch–calcium alginate mixture was significantly increased at a rate of 30 % in comparison with control sample. Moreover, the points that were given out for color, taste, and texture showed that the addition of encapsulated probiotics had no effect on sensory properties of non-fermented synbiotic ice cream (Homayouni et al. 2008). So the best symbiosis model of prebiotic–probiotic is microencapsulation. Encapsulation is often mentioned as a way to protect bacteria against severe environmental factors (Mirzaei et al. 2012). Application of RS in food industry is summarized in Table 1.

3 Conclusion

Many fiber-enriched foods have been developed with the aim of increasing fiber intake in the diet. RS is a recently recognized source of fiber and is classified as a fiber component with partial or complete fermentation in the colon, producing various beneficial effects on health, and is a perfect DF with many nutritional values. As a functional fiber, its fine particles and bland taste make the formulation of a number of food products possible with better consumer acceptability and greater desirability than those made with traditional fibers. RS shows improved crispness and expansion in certain products, which have better mouthfeel, color, and flavor than products produced with traditional insoluble fibers.

Inulin and Health Benefits

Abstract

Inulin-type fructans are prebiotic dietary fibers, naturally occurring in numerous plants. The chicory root with its high content of inulin-type fructans is the most common basis for gaining inulin from the plant. The process applied is a hot water extraction. This means, contrary to a number of commercially available dietary fibers, inulin is not synthesized but occurs naturally and was eaten by mankind 100,000 years ago. The colon, the main place of action of inulin-type fructans, is a highly active metabolic organ, containing an excessively complex collection of microbes. Inulin-type fructans are nondigestible in the small intestine and fermented in the large intestine, resulting in modifications in the colonic microbiota composition, towards a healthier pattern, and in the production of several metabolites. Thereby, they are among the very few scientifically proven prebiotics. Several health effects are related to this activity in the colon.

They may range from local effects, starting with improvement of bowel movement, effects related to local immunity, to more systemic benefits for the body, as a result of the metabolic events, like weight and blood sugar management and bone health. This book chapter aims at providing a comprehensive review of the physiology related to inulin-type fructans and the health benefits related to this. Current developments in understanding the role of the microbiota in health and disease will probably also further contribute to understanding these complex influences originating from the gut and the role "colonic nutrients" such as prebiotic dietary fibers may play therein.

1 Introduction

The role of the large intestine for health and well-being has been underestimated for a long time. Nutrients that reach the large intestine are characterized by their indigestibility in the small intestine. Dietary fibers were regarded as an unnecessary burden rather than a necessary nutrient in the history of nutrition research. Today, scientists are even discussing whether dietary fibers should be classified as essential in human nutrition, a discussion that took place at the 10th Vahouny Dietary Fiber Symposium 2014 and will continue (Theis 2014). Physiological effects that support health and well-being are the attenuation of the postprandial glycemic/insulinemic response, reduced blood total and/or LDL cholesterol levels, reduced blood pressure, increased fecal bulk/laxation, decreased transit time, increased colonic fermentation/short-chain fatty acid production, positive modulation of the colonic microflora, weight loss/reduction in adiposity, and increased satiety as discussed at the 9th Vahouny Fiber Symposium (Howlett et al. 2010).

Prebiotic fermentation by the colonic microbiota plays a key role in a number of these health benefits. Inulin-type fructans are naturally derived plant extracts; they are completely fermented in the large intestine and therefore are the ideal source for short-chain fatty acid production (SCFA), contrary to a number of other nondigestible carbohydrates. They are proven prebiotics, i.e., the microbiota is stimulated selectively with numerous positive effects. Intensive research on the role of prebiotics and the selective changes to the microflora and their metabolites is ongoing. This is reflected in the fact that over the last 5 years, more than 1,000 research articles on the prebiotic topic have been published (Theis 2014).

Recent developments in the direction of research go beyond the large intestine as the place of action. Research is related to the gut-brain axis that is influenced by fermentation processes associated with, e.g., prebiotic inulin. A decrease in caloric uptake on a long term leads to a role of inulin-type fructans in healthy nutrition that can prevent the development of overweight and support weight management (Parnell and Reimer 2009; Kellow et al. 2014). A further direction of research is the significance of a lower blood glucose response and the related insulin response

which is discussed to support healthy metabolism in various ways (EFSA NDA Panel (EFSA Panel on Dietetic Products, Nutrition and Allergies) 2014; De Vadder et al. 2014).

2 Sources, Preparation, and Usage

Inulin-type fructans are naturally occurring dietary fibers. A number of plants build their energy storage by inulin production, i.e., chicory, Jerusalem artichoke, onions, leeks, garlic, bananas, wheat, rye, and barley (Van Loo et al. 1995). All over the world, the chicory root and, to a less extent, the Jerusalem artichoke (tuber) and the Agave (leaf) are used for the commercial production of inulin.

Scientists investigating ancient cooking and eating habits discovered that in the diet of hunters and gatherers 10,000 years ago, the plant-based diet delivered about 135 g of prebiotic inulin-type fructans per man and day (Leach and Sobolik 2010). Today, intake of inulin-type fructans from fruits and vegetables is estimated to be around 5 g per day in Western-style diets in the United States and 3.2–11.3 g in Europe (Mishfegh et al. 1999; Van Loo et al. 1995).

The chicory root contains about 15–20 % of inulin on a fresh weight basis, which allows for large-scale extraction. In Europe, the farming of chicory as a crop has a long tradition as it was used in former times as a substitute for coffee when chicory roots were chopped-up and roasted. The process can be divided into two major phases. Firstly, the chicory roots are washed to remove stones, weeds, sand, and dirt. In the second phase, the roots are sliced and inulin is gained as raw juice by hot water extraction, which is then purified and dried. Inulin extraction is done by hot water (Moser et al. 2014).

Inulin-type fructans are linear polydisperse carbohydrates, mainly composed of fructose units joined by a series of β 2-1 fructosyl-fructose linkages. The chemical formula of inulin is $C_6H_{11}O_6(C_6H_{10}O_5)_nOH$ and the systemic name for all fructans is α-D-glucopyranoside-(1-2)-β-D-fructofuranosyl-[(1-2)-β-D-fructofuranosyl]n (notably, the α-D-glucopyranoside-(1-2) is not always present). The "n," which represents the number of fructose units, ranges mainly from 2 to more than 60. All fructan products contain molecules with a variety of chain lengths. Inulin-type fructans are referred to by various terms, including inulin, oligofructose, fructooligosaccharide (FOS), and short-chain (sc) or long-chain (lc) fructooligosaccharide, sc or lc inulin, or, more consumer-friendly, chicory fiber or chicory root extract. The structure of inulin and oligofructose is visualized in Fig. 1.

In addition to the naturally derived inulin-type fructans from chicory, short-chain fructooligosaccharides are on the market as well. These are fructans that are synthesized from sucrose.

Inulin-type fructans from chicory are soluble dietary fibers that have been used in food applications since the late 1980s. The uniqueness of these dietary fibers is the combination of an impressive scientific basis of nutrition and physiology, excellent organoleptic properties, and parameters relevant for technical applications providing all options for a top quality, tasty, and healthy food product.

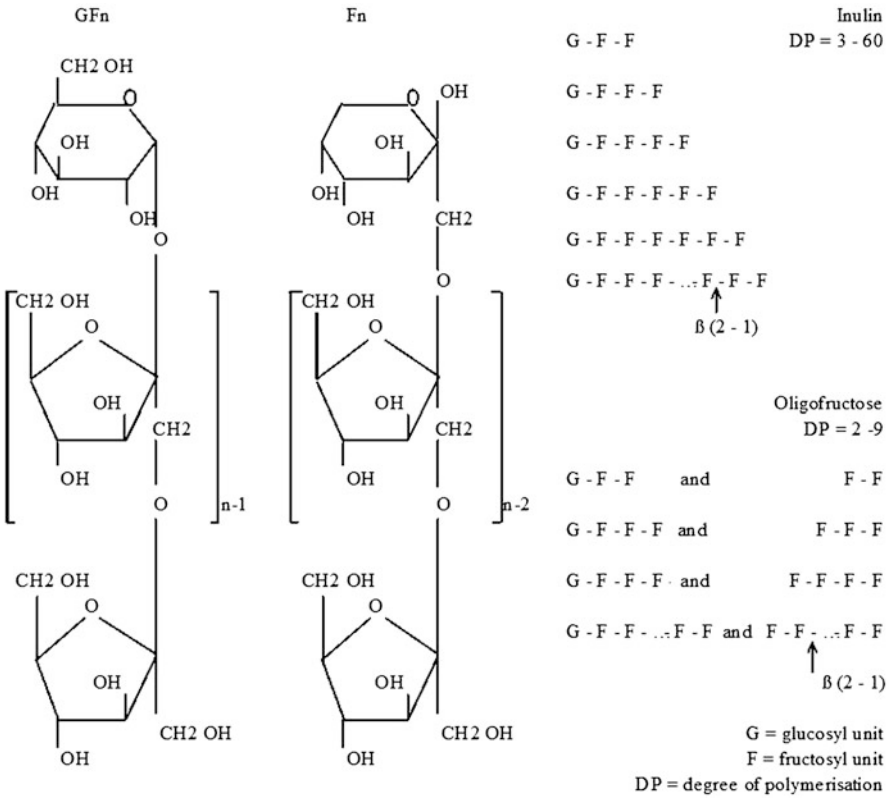

Fig. 1 Chemical structure of inulin and oligofructose from chicory

The contributions of inulin-type fibers to product development are manifold and all product categories are possible. These are, e.g.,

- Fiber enrichment (e.g., for a "high fiber" or "source of fiber" claim).
- Sugar reduction by replacement (also combined application "sugar out, fiber in").
- Fat out – fiber in: inulin has a unique property as a fat replacer. Inulin simulates the mouth-feeling and mouth-coating properties of fat. This enables also lower caloric, light versions of, e.g., dairy products.

  Calorie reduction (fibers often replace available carbohydrates or fat in a recipe; dietary fibers provide 2 kcal/g which is half of an available carbohydrate and less than one fourth of fat) (Moser and Wouters 2014).

Taste is always the key to consumer acceptance. Physiological benefits and support of a health-oriented diet are a cornerstone to success. Awareness of the need to change from a public health perspective having the burden of noncommunicable diseases (NCDs) in mind and the "Silver tsunami" approaching is also increasing.

3 Biological and Physiochemical Properties

3.1 Physiological Properties

3.1.1 Nondigestibility and Fermentability: Inulin-Type Fructans Are Dietary Fibers

Inulin-type fructans from the chicory root consist of a linear fructose polymer in a β-(2→1) fructosyl-fructose configuration, with a possible end-standing glucose unit.

The human enzymes that digest carbohydrates cannot hydrolyze the β-linkages of inulin-type fructans. As a result, inulin including its short-chain fraction, also called oligofructose or fructooligosaccharides (FOS), passes through the mouth, the stomach, and the small intestine without undergoing any significant change and without being metabolized. The nondigestibility of inulin and oligofructose has been confirmed in human studies with ileostomized volunteers. Eighty-eight percent and eighty-nine percent, respectively, of an ingested amount of inulin or oligofructose were recovered in ileostomy effluents, which clearly indicates indigestibility in the small intestine (Ellegård et al. 1997). The small loss of about 10 % can be explained by the difficulties in recovering and analyzing ileal effluents and by the fermentation of fructans by bacteria that colonize the distal part of the small intestine in these patients.

Inulin and oligofructose thus enter the large intestine almost intact where they are totally fermented by the microbiota. Thanks to these properties, inulin and oligofructose are dietary fibers, this is the case not only from the physiological angle but also from the food legislatives perspective. They are recognized as such in most countries worldwide.

In the colon, inulin and oligofructose are completely and selectively fermented by saccharolytic bacteria (mainly *Bifidobacterium* and *Lactobacilli*). This complete fermentation is substantiated by the complete disappearance of inulin-type fructans in vitro (Wang and Gibson 1993) as well as in human studies (Castiglia-Delavaud et al. 1998).

Inulin-type fructans are consequently converted into bacterial biomass, short-chain fatty acids (SCFA), lactic acid, and gases (mainly CO_2 and H_2). Gases are utilized by bacteria, or excreted in stools or after absorption excreted in breath. The principal SCFA resulting from their fermentation are acetate, propionate, and butyrate. Lactic acid is an intermediate that accumulates or that is further metabolized to SCFA by a cross-feeding process. Acetate and propionate are absorbed and systematically metabolized. Butyrate is largely metabolized by the colonic epithelium, where it serves as the preferred energy substrate as well as a regulator of cell growth and differentiation. Butyrate plays an important role in the maintenance of a normal epithelium as well as a reduction in symptoms of inflammatory bowel disease (Roberfroid et al. 2010). SCFA and their effects in the colon and beyond are the subject of intensive research that will be addressed further. As described above, inulin-type fructans can be produced with different chain-length distributions. Fructans with shorter-chains have been shown to be fermented faster than longer

chains (Stewart et al. 2008). Long-chain inulin reaches more distal parts of the colon. Specific chain-length compositions (e.g., Orafti®Synergy1) are produced to take physiological advantage of these properties.

Inulin-type fructans belong to the nutrient category of dietary fibers. Dietary fibers are well known for providing several positive physiological effects, and epidemiological evidence shows that a high consumption of dietary fibers has clearly been associated with a lower risk of cardiovascular disease, type 2 diabetes, hypertension, obesity, and certain large intestine disorders (Anderson et al. 2009).

These epidemiological data serve as a basis for the recommendations in dietary fiber intake made by various government agencies worldwide. Different endpoints might be at the basis for these recommendations.

The US Food and Nutrition Board has, for instance, used data from cohort studies related to coronary heart disease (CHD) for setting its adequate intake recommendation for total dietary fiber intake (Institute of Medicine (IoM) 2005). In Europe, EFSA considered the effect on bowel function as the basis for the adequate intake of dietary fiber and set a level of 25 g per day for adults (adequate for normal laxation) (EFSA 2010). Most public health advisory groups thus provide guidance for achieving the recommended levels of fiber consumption. This is mostly done through traditional food-based dietary advice, recommending the increased intake of whole grains, fruits, and vegetables. However, when comparing actual fiber intake assessments (derived from national nutrition surveys) to the recommended levels in the respective countries, it appears that the dietary fiber intake does not meet the recommendations in most countries around the world. This observation is striking, despite the cultural diversity in eating habits by the various populations (Fig. 2). The fiber gap is thus impressive, despite the widespread knowledge that fibers are "good for you" and the willingness of consumers to follow a healthy diet. This indicates a need for the consumption of more fiber-containing foods and foods enriched with fibers, such as inulin or oligofructose.

The colonic fermentation of inulin-type fructans will result in subsequent benefits. Those will be described in detail in Sect. 3.2.

3.2 Health Benefits

3.2.1 Gut Health

Modulation of the Microbiota Composition: The Prebiotic Effect

The Human Microbiome

Humans are composed, to a large extent, of microbes. This complex ensemble of microorganisms is referred to as the human microbiome. It plays an essential role in our development, immunity, and nutrition and has a profound effect on human health (Greenblum et al. 2012). The gut microbiome plays an essential role in many processes, including vitamin and amino acid biosynthesis, immune development,

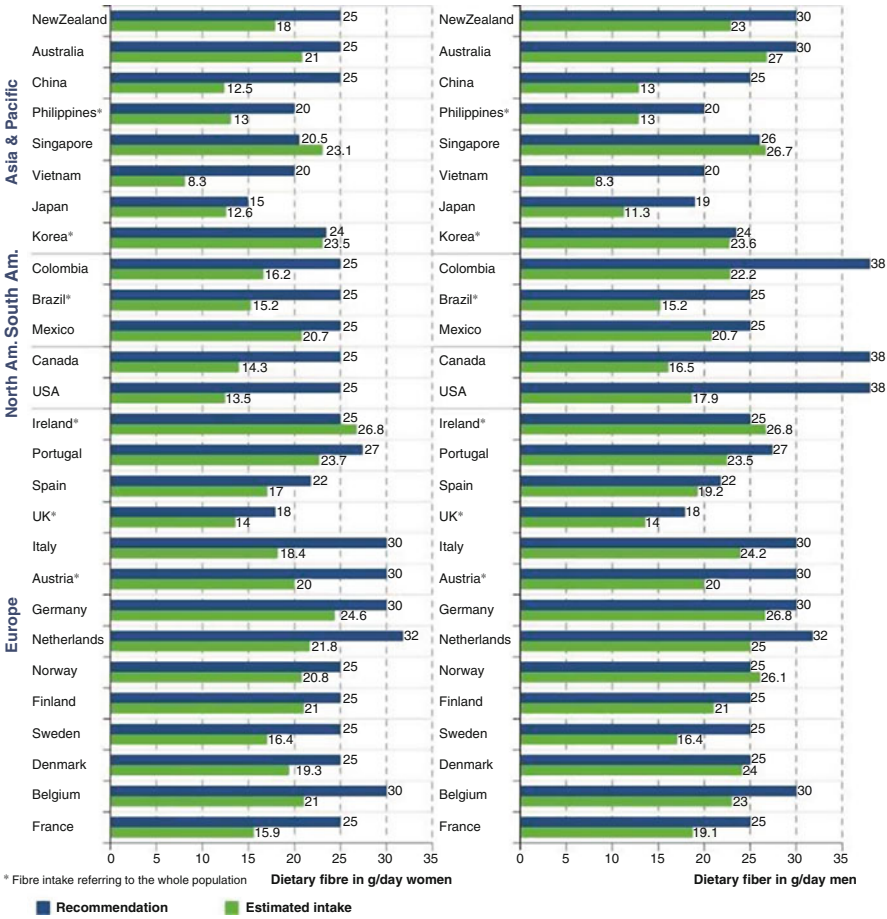

Fig. 2 Dietary fiber "gap" in several countries around the world (Window to Science 1/2011)

and enhanced resistance to colonization by pathogenic microorganisms. Humans harbor over 100 trillion microbial cells (Ley et al. 2006a).

Among the various organ habitats of microbes, the colon is by far the most densely colonized part of the gastrointestinal tract. The colon has been considered for a long time to be the place where digestion ends. Nowadays, with the intestinal microbiota it harbors, it has been elevated almost to the status of an active organ, playing a role in a wide range of host physiological processes (Latulippe et al. 2013).

The colon is indeed a very favorable organ for bacterial growth, reaching a high microbial density of 10^{11} to 10^{12} cells/g content because of its slow transit time, readily available nutrients, as well as favorable pH (Cummings and Macfarlane 1991). The physiology of the colon is controlled to a large extent by the gut microbiota, through the fermentation of indigestible compounds, the production

of secondary metabolites, and their interaction with the host epithelium or with the GALT (gut-associated lymphoid tissue). The immense collection of microbes composing the gut microbiota interacts with the host in a very intricate manner and is involved in the regulation of several metabolic pathways, with immune-inflammatory physiologically connecting the gut, the liver, muscles, and the brain (Nicholson et al. 2013).

Recently, intense research initiatives have been conducted to improve understanding of the complexity of the gut microbiota. Projects, such as the Human Microbiome Consortium, the European Commission's Metagenomics of the Human Intestinal Tract Project, among others, are conducted with the aim of generating resources to enable comprehensive characterization of the human microbiota and allow for an analysis of its role in human health and disease. They are focused on the identity, genetic potential, and metabolic activities of microbes (Bäckhed et al. 2012).

Despite significant progress in understanding the human microbiome, the composition and functional characteristics of a "healthy microbiome" remain to be precisely defined. Although several patterns of microbial colonization associated with various disease states have been documented, a health-associated pattern is more challenging to establish and therefore is less clear at the moment (Bäckhed et al. 2012). A healthy microbiome could be described in terms of stability of a microbial community, or its ability to resist structural changes under stress, or to return to its initial composition after a stress-related change (Bäckhed et al. 2012). Other parameters could be an idealized (presumably health-associated) composition or a desirable functional (metabolic) profile, although this remains to be defined. The concept of a "healthy microbiome" is based on the probability that stabilization of a balanced microbiota and the maintenance of "normobiosis" keep the organisms healthy for longer or in other words provide less harmful loads to the body. A shift in the composition of the microbiota or a loss in its balance such that it may become deleterious to host health is termed "dysbiosis." Certain microbial distributions, for instance, may favor the susceptibility to infections or diseases.

Several disease states have been associated with changes in the composition of fecal and intestinal mucosal communities, including inflammatory bowel diseases, obesity, the metabolic syndrome, type 1 diabetes, allergy, celiac disease, and even autism (Honda and Littman 2012; Million et al. 2013; Manichanh et al. 2012). However, a causal relationship is difficult to establish.

Certain species and/or their metabolic activities are acknowledged as being beneficial to the host when they are present in increased amounts, and bacterial groups such as bifidobacteria and lactobacilli are among the most cited bacterial groups of this category and are part of the potentially health beneficial microbiota. It has been hypothesized that *Bifidobacterium* spp. might improve health status and reduce disease risk (Roberfroid et al. 2010).

Bifidobacterium was first acknowledged as a beneficial bacterial group because it is predominantly present in the feces of breastfed infants, where it is thought to play an important role in the improved health and the development of these infants compared to formula-fed babies. It is recognized that formula-fed infants

are more susceptible to gastrointestinal infections such as diarrhea and other disturbances such as acute respiratory infections (Benno et al. 1984; Heavey and Rowland 1999).

Several other situations of dysbiosis (less stable or unstable gut microbiota) point a decrease in bifidobacteria.

An aging ailing population, subject to infections or antibiotic treatment, is, for instance, more prone to developing microbiota dysbiosis, which also provides an indication of the difference between a balanced and an unbalanced microbiota. Observations have notably shown a reduction in species diversity in anaerobic bacterial groups such as bifidobacteria and prevotella in elderly versus younger people (Woodmansey et al. 2004). These authors also noted lower bifidobacteria compared to healthy elderly, when the elderly were hospitalized and received antibiotics. Bartosch et al. (2004) reported reductions in bacteroides, prevotella, bifidobacterium, and *Faecalibacterium prausnitzii* in hospitalized versus healthy elderly. Under antibiotic treatment, a marked increase in enterobacteria was noted.

In subjects with inflammatory bowel disease (IBD), compositional changes have been evidenced compared to a healthy population. In adults, despite study heterogeneity, lower numbers of lactobacilli, bifidobacteria, and more recently *Faecalibacterium prausnitzii* counts in feces or biopsies have been frequently reported (Favier et al. 1997; Frank et al. 2007; Sokol et al. 2008). Increases in numbers of bacteria that are considered less desirable in the gut have been reported as well, such as higher numbers of Escherichia and enterobacteriaceae in subjects with IBD (Kotlowski et al. 2007; Martinez -Medina et al. 2006; Seksik et al. 2003). Schwiertz et al. (2010a) found a lower number of *Faecalibacterium prausnitzii* and bifidobacteria in children with active and inactive Crohn's disease compared to healthy children. These data, as well as others, demonstrate that there is a difference in the microbial composition of subjects with IBD compared to healthy individuals.

Regarding desirable functional (metabolic activity) of a healthy microbiota, one can look at the end products that result from the microbial activity. Microbes considered beneficial display a carbohydrate or saccharolytic fermentation as the preferred mode of energy generation, resulting in the production of short-chain fatty acids. The fermentation process by a healthy microbiota should not give rise to the formation of toxic metabolites. Microbes considered to be beneficial do not display pathogenic or toxigenic traits and are not associated with diseases. They further may have a range of potential benefits for the host, involving interactions with the immune system and competitive inhibition of pathogens (Binns 2013).

Based on current knowledge, bifidobacteria (and lactobacilli) clearly fulfill all the characteristics that can currently be defined of a "healthy microbiota" and low levels are reported in impaired gut state such as in several cases of dysbiosis.

It is important to realize however that "healthy microbiota concept" does not mean that an individual with a "less beneficial" microbiota signature would show obligatory impairments in body function. A more beneficial microbial pattern cannot be seen in a medical sense, as is the case, for instance, for the link between cholesterol levels and cardiovascular disease.

Inulin-Type Fructans: Prebiotics

In view of the above, the microbiota composition and maintenance and ways that modulate it has become a new target to study for potential impact on health. The diet is one factor which can modulate the composition of the microbiota once established; other factors include the intake of antibiotics, the environment, and disease.

Bifidobacteria and lactobacilli are among the best-known bacteria recognized as having a metabolic activity that is beneficial for the host. Their selective stimulation by specific nutrients (proven for inulin-type fructans and only a few other nondigestible carbohydrates) within the large intestine is referred to as the "prebiotic effect."

The concept of supporting the "good" bacteria selectively within the natural microbiota of an individual by a specific choice of food was developed in Japan within the FOSHU framework legislation in the 1980s. The observations of stimulating bifidobacteria were expanded by Gibson and Roberfroid who already realized the importance of a healthy gut flora for the well-being of the host in 1995 and developed the scientific concept for human gut microbiota modulation or the "prebiotic" concept (Gibson and Roberfroid 1995). Since then, the prebiotic concept has been the topic of intensive research. It is now defined as a "selectively fermented ingredient that results in specific changes in the composition and/or activity of the gastrointestinal microbiota, thus conferring benefit(s) upon host health" (Gibson et al. 2010).

Although a number of ingredients that are fermented in the colon claim to be prebiotics, scientists from ISAPP (International Scientific Association for Probiotics and Prebiotics) concluded that only a few ingredients satisfy the criteria for classification of a given food ingredient as prebiotic (criteria defined in Gibson et al. 2004). Inulin and oligofructose are part of this category. Main proof that is lacking for most ingredients is the human evidence.

Individuals' responses to dietary interventions aimed to test effects on the microbiota are highly variable and poorly predictable by in vitro assays. In addition, in vitro models alone cannot take into account the complexity of the ecosystem of the colon and of the numerous bacterial interactions that take place therein. Human intervention trials are thus required. Appropriate techniques for the quantification of bacteria are also an important consideration, and today's molecular techniques are considered to be more reliable as they encompass a much wider diversity of the gut microflora than the plate count techniques. To ascertain consistency and exclude incidental findings, more than one human intervention trial should be performed.

Much of the early research has focused on increasing the relative populations of bifidobacteria and lactobacilli. In that regard, inulin-type fructans have demonstrated their prebiotic effect in a vast amount of human intervention studies. More than 20 studies have shown a consistent and significant increase in bifidobacteria (and sometimes lactobacilli) counts, while having no measurable or significant effect on most other bacterial groups (Gibson and Roberfoid 2009; Roberfroid et al. 2010). The effect on *Bifidobacterium* is selective. The prebiotic effect was

demonstrated with a wide range of daily dosages, starting at 5 g/day (Rao 2001; Bouhnik et al. 2007). Significant compositional changes have been demonstrated after only 1 week of intake (Tuohy et al. 2001; Kleessen et al. 2007). Logically, several studies report that when the prebiotic intake was stopped, the levels of bifidobacteria decreased to their original level. Fructans of all chain lengths have been shown to have this unique effect on the composition of the microbiota in common.

As feces constitute the most readily accessible material to study the effects of prebiotics on the microbiota in a noninvasive manner, most microbiological assessments have been done on stools and have thus assessed the effects of bacteria that are living free in the gut lumen. Bacteria inhabiting the colon might also be attached to the mucosa, and they are thus called "mucosa associated flora" (MAF). Because of their location, it is thought that these bacteria could play a critical role in protecting the mucosal epithelium, notably due to their ability to exclude adherence of pathogens (Langlands et al. 2004). In volunteers who underwent a colonoscopy, Langlands et al. (2004) collected biopsy samples from the mucosa and were able to show that a combination of oligofructose and long-chain inulin (similar to Orafti®Synergy1) increased (mucosal) bifidobacteria and lactobacilli. This increase occurred both in the proximal and distal part of the colon, indicating that the prebiotic fermentation (and the resulting beneficial environment) took place over the full length of the colon.

This selective stimulation most probably originates from the capacity of bifidobacteria to utilize them specifically. Several bifidobacteria strains possess cellular uptake systems and express various β-fructofuranosidase genes, allowing them to hydrolyze the β (2–1) link between fructose moieties and thus to efficiently use inulin and oligofructose as growth substrates in a competitive environment, such as the colon (De Vuyst and Leroy 2011).

In general, most other genera are not affected in a consistent way by inulin or oligofructose intake. Recent data, however, have shown that some other bacteria that could also be considered as members of a healthy gut microbiota may be affected by inulin and oligofructose intake. Studies notably show that *Faecalibacterium prausnitzii* counts are increased upon inulin intake (Ramirez-Farias et al. 2009; Dewulf et al. 2013). Further research is needed to confirm these data and may unravel further interesting findings.

Direct Physiological Outcomes of Fermentation

Benefits from prebiotic fermentation can be examined from the metabolites produced by the colonic microbiota and the impact of these metabolites on health, which is currently a topic of research.

Main substrates available for the colonic microbes are constituted by nondigestible carbohydrates and proteins, which result in saccharolytic and proteolytic fermentation, respectively. Dietary carbohydrates reaching the human large intestine mainly constitute of structural polysaccharides and oligosaccharides of plant origin, as well as resistant starch, synthesized by chemical denaturation of available starch.

As outlined above, the fermentation of inulin and oligofructose by the saccharolytic microbiota results in the production of SCFA. Butyrate, in particular, represents the major intestinal energy substrate of human colonocytes and can be regarded as a supportive marker for physiological gut function in this context. A small proportion of SCFA reaches the general circulation, which could contribute to some of the systematic effects of inulin-type fructans. The process of reabsorption of SCFA explains the low amount that is found back in the feces. SCFA seem also to be involved in many other metabolic processes with systemic effects, such as glucose and energy homeostasis (effects described further on in the chapter). SCFA are indeed also signaling molecules, acting as endogenous ligands for the G protein-coupled receptors FFAR3 and FFAR2 (Brown et al. 2003).

Results from in vitro as well as in vivo studies show that the intake of inulin-type fructans increases the production of SCFA and/or notably the amount of molar ratio of butyrate. A concomitant decrease in cecal pH is also shown. Since bifidobacteria mainly produce acetate and lactate, the question of the origin of the "butyrogenic effect" of inulin and oligofructose has long remained unclear. In vitro studies have revealed that cross-feeding mechanisms between bifidobacteria and butyrate-producing bacteria most probably explain the butyrate production following inulin and oligofructose intake. Certain bacterial strains such as *Eubacterium hallii*, *Retortamonas intestinalis,* or *Anaerostipes caccae* were shown to use lactate or acetate produced by bifidobacteria to convert them into butyrate. In this way, cross-feeding between these microorganisms and inulin degraders (bifidobacteria) may contribute to the butyrogenic effect of inulin and oligofructose (Falony et al. 2006; Belenguer et al. 2006). Butyrate could also directly come from butyrate-producing bacteria, such as *Faecalibacterium prausnitzii*, also shown to be stimulated upon inulin intake (Ramirez-Farias et al. 2009; Dewulf et al. 2013).

As the major part of produced SCFA is absorbed and only a small proportion is recovered in stools, the measure of residual SCFA in feces thus does not accurately reflect their rate of production by the colonic microbiota, and no pertinent conclusion can be drawn from measurement of fecal SCFA. SCFA arising from fructans' fermentation are thought to contribute to the integrity and functioning of the epithelial cell lining. The results of a recent randomized, double-blind, crossover study conducted in healthy young volunteers showed that the administration of inulin decreased small intestine permeability as evidenced by lower levels of circulating zonulin and a significantly higher basal glucagon-like peptide 2 (GLP-2) level compared to the control group (Russo et al. 2012). The protein zonulin is involved in mucosal barrier function and the disassembling of the tight intercellular junctions characterizing the early inflammatory states. GLP-2, a peptide secreted from enteroendocrine L-cells present in the distal intestine, enhances mucosal barrier function among other properties. This study indicates a potential effect in regulating intestinal barrier function by inulin. In studies performed in obese rodents as well, the intake of oligofructose was shown to improve gut barrier function by decreasing intestinal permeability and improving tight-junction integrity. These effects were related to higher levels of GLP-2 (Cani et al. 2009a; Everard et al. 2011).

This might have implications that are not limited to the direct environment of the gut, as, for instance, obesity is associated with an increase in gut barrier permeability, thus allowing an atypical translocation of gut bacteria or gut bacteria components into the circulation and tissues (see section on weight management for further information on the topic).

In contrast to the benefits associated with saccharolytic fermentation, proteolytic fermentation that takes place in more distal parts of the colon results in the formation of more toxic metabolites, such as primary and secondary amines, ammonia, aromatic compounds (phenols and indoles), mercaptans, as well as linear and branched short-chain fatty acids (Macfarlane and Macfarlane 1995). Amines may be absorbed by the host and systemically metabolized or further converted by the colonic bacteria. Secondary amines may be precursors of N-nitroso compounds (Calmels et al. 1985). Non-protonated ammonia may be absorbed and may lead to intoxication in subjects with liver impairment. Phenols and indoles are also associated with various adverse effects in the host.

An important amount of proteins in the colon has been linked with chronic colonic diseases, and extended saccharolytic fermentation is thought to contribute to the reduction of the production and impact of products of amino acid metabolism.

Some studies have investigated the effects of inulin-type fructans on some potentially toxic metabolites characteristic of a proteolytic fermentation.

De Preter et al. (2007) studied the influence of Orafti®Synergy1 on the outcome of two biomarkers of proteolytic fermentation, lactose[^{15}N, ^{15}N]ureide and *p*-cresol. Lactose[^{15}N, ^{15}N]ureide is a biomarker allowing the investigation of the metabolic fate of ammonia. It is expected that higher amounts of ammonia are incorporated into colonic bacteria during fermentation, thus reducing its excretion in urine. *p*-cresol is a bacterial metabolite produced in the colon and excreted in urine. Its reduced presence in urine thus reflects a lower proteolytic activity in the colon. In healthy volunteers receiving Orafti®Synergy1 during 4 weeks, the urinary excretion of ^{15}N and *p*-cresol was significantly reduced, thus showing positive effects on colonic ammonia and proteolytic activity. These results correlated as well with an increased bifidobacteria level in the feces. The same research team conducted an in vitro study (anaerobic fermentation with fecal slurries), in which they assessed the impact of Orafti®Synergy1 on the production of a total of 107 different volatile organic compounds. Orafti®Synergy1 promoted a pattern of saccharolytic fermentation and in parallel inhibited the generation of S-compounds, as well as the production of metabolites of proteolytic fermentation, such as phenolic compounds (De Preter et al. 2010).

The effect of fructans on various metabolic activities in the large intestine with toxic potential was also investigated. The activity of fecal β-glucosidase and β-glucuronidase was studied in humans, with most studies showing reduced activity of these enzymes (De Preter et al. 2008; Bouhnik et al. 2007; van Dokkum et al. 1999). These glycosidases are known for their carcinogenic potential. Results do not, however, all point in the same direction, with other investigations reporting no effect on the level of β-glucosidase and β-glucuronidase activities (Kleessen et al. 1997; Gråsten et al. 2003).

In conclusion, the prebiotic concept is now well confirmed by scientists worldwide, as recently reviewed by an expert panel under the umbrella of the International Life Science Institute (Roberfroid et al. 2010). Among its conclusions, the expert panel confirmed that "*the prebiotic effect is now a well established scientific fact. The more data are accumulating, the more it will be recognized that such changes in the microbiota's composition, especially increase in bifidobacteria, can be regarded as a marker of intestinal health.*"

Bowel Regularity

A normal defecation pattern is considered to be an important indicator of gut health and well-being. As dietary fibers, inulin and oligofructose improve bowel function.

The fermentation of inulin-type fructans by the colonic microbiota results in an increased bacterial cell mass and SCFA. Due to the high water content of intestinal bacteria, the moisture content of feces is increased after inulin-type fructan supplementation. As a consequence, stools become softer and excretion is facilitated (Cherbut 2002).

The SCFA that are produced are also susceptible to affect intestinal motility and to lead to faster intestinal transit (Grider and Piland 2007). This results in facilitated fecal excretion as well as enhanced propulsion of colonic contents via chemical and mechanical stimulation of peristaltic reflex. The end result is an increase in frequency of bowel movements.

The intake of inulin and oligofructose has been demonstrated to result in an increase in stool frequency and/or in stool weight in humans in several human intervention studies starting with an intake of 8 g/day (Gibson et al. 1995; Van Dokkum et al. 1999; Menne et al. 2000; Cummings et al. 2001; Kleessen et al. 2007).

A positive impact on stool frequency was not only demonstrated in healthy subjects but also in slightly constipated subjects where 15–20 g/day of inulin was shown to relieve constipation (Kleessen et al. 1997; Den Hond et al. 2000). Oligofructose has also been shown to increase stool frequency and to reduce constipation in adults with irritable bowel syndrome (Isakov et al. 2013).

Data are also supportive of more regular and/or softer stools in infants and young children. In infants aged 4–12 months, the intake of oligofructose included in a cereal resulted in a more regular and softer stools, as well as a lower reported frequency of symptoms associated with constipation (Moore et al. 2003). Positive effects on higher stool frequency and softening of the stools are also reported in neonates receiving Orafti®Synergy1 in an infant formula (Veereman-Wauters et al. 2011; Closa-Monasterolo et al. 2013; for more details, see section on infant nutrition).

3.2.2 Prebiotic Effect and Immune Influence

The intestinal microbiota is a source of antigens and potentially harmful compounds. Most of the time, a good balance exists between the large number of bacteria we cohabit with and our immune cells. With respect to their gut and the interactions with the immune system, humans can be considered to exist in a state of

natural balance with their microbial inhabitants. The immune structure of the gut (the largest of the human body in fact) allows the protection of the body against pathogens and prevents non-virulent microbes and opportunistic pathogens from translocation into the internal milieu (Trebichavsky et al. 2009). Gut bacteria play an important role in immunity, and the intestinal ecosystem is established to avoid colonization by pathogenic bacteria and potentially harmful indigenous microorganisms, known as the "barrier effect."

Several mechanisms play a role in this protective effect, including a direct competition for limited nutrients and the modulation of the host immune response (Kamada et al. 2013).

The prebiotic effect may influence the immune system directly or indirectly as a consequence of intestinal fermentation and the resulting changes in bacterial composition and metabolites present in the colon. The presence of increased numbers of certain bacterial species (including mainly bifidobacteria) may induce an effective competition for nutrients and ecological niches. Bifidobacteria synthesize antimicrobial peptides that inhibit the growth of several pathogens (Collado et al. 2005). In addition, changes in the composition of the colonic microbiota (including increase of certain microbial genus or species and decrease of others) may change the collective immunoreactive profile of the microbiota (Roberfroid et al. 2010).

In addition, the changes in metabolites, i.e., increase in SCFA production, are accompanied by a decrease in the luminal pH, and the totality of acids and in particular the intermediate lactic acid is considered important to discourage obligate and facultative pathogens in the lower gut. These SCFA may further interact with immune cells and enterocytes and modify their activity. G protein-coupled receptors (GPR)41 and GPR43 have been shown to be receptors for SCFA and are expressed on leukocytes as well as enterocytes and enteroendocrine cells in the human colon (Roberfroid et al. 2010).

Few human studies have investigated potential positive influences of inulin-type fructans on indirect parameters related to immunity or, in general, to better resistance or outcome towards infectious diseases. In patients who developed *C. difficile* infection due to an antibiotic therapy, oligofructose supplementation (12 g/day) significantly decreased relapses of diarrhea at the end of the treatment period. This was correlated with significantly higher numbers of total anaerobes and bifidobacteria in the oligofructose group compared with the placebo. Patients who relapsed stayed in the hospital longer than those who did not (Lewis et al. 2005). A trend towards less episodes of diarrhea was also noted by Cummings et al. (2001) in a study involving 244 healthy people receiving oligofructose (10 g/day) traveling to destinations at risk of traveler's diarrhea. In a randomized, double-blind, placebo-controlled trial involving 123 young children attending day-care centers, the addition of oligofructose to a weaning cereal (0.55 g per 15 g of cereal) resulted in significantly fewer episodes of fever and missed days of day care because of diarrhea, as well as a lower use of antibiotics for respiratory illnesses (Saavedra and Tschernia 2002). These data constitute preliminary, yet promising findings that support potential beneficial effects of prebiotics with respect to immune-related status. Additional data from clinical studies are needed to support these effects.

3.2.3 Inulin-Type Fructans in Infant Nutrition

The gastrointestinal tract of the newborn is (almost) sterile at birth, and microorganisms quickly colonize it during and after birth. Essential factors that influence bacterial colonization are the mode of delivery, prematurity, the excessive use of antibiotics during the perinatal period, the mother's microbiota, the infant's genetic signature, and the type of feeding. Breastfeeding is of primordial importance in the initial colonization process that takes place at the beginning of an infant's life. The microbial contact in utero and during the neonatal period (which is influenced by the mode of delivery and breastfeeding) has a long-term impact on the intestinal colonization pattern and plays a crucial role on the immune and metabolic programming of the fetus and infant and consequently on the risk of disease later in life (Rautava et al. 2012). These interactions with colonizing microbes and the consequent establishment of a balanced microbiota are necessary for the development of an appropriate innate and adaptive immune response and of oral tolerance. As a consequence, the disruption of the normal colonization process leads to alterations in the establishment of this immune homeostasis (Rautava et al. 2012; Walker 2013). The state of dysbiosis (e.g., premature delivery, excessive use of antibiotics) consecutive to inadequate colonization is related to aberrant immune activation and to higher risk of immune-related diseases, notably allergic and autoimmune disease (Renz et al. 2011). Several diseases, associated with excessive or aberrant T-helper (T_H)1 or T_H2 immune responsiveness (allergic diseases, type 1 diabetes, celiac disease), have been associated with deviations in the compositional development of the gut microbiota, i.e., a less diverse microbiota lacking, among others, bifidobacterial species, with simultaneous higher levels of specific clostridia (Rautava et al. 2012). Necrotizing enterocolitis (NEC), a condition present in premature infants, is another example of disease characterized by dysbiosis and lower diversity of bacterial species (Torrazza et al. 2013).

At weaning, the microbiota composition changes in numbers and diversity, to begin to resemble that of the future adult. The "adult microbiota" is established around the age of 2 years and stays relatively stable during the adult life (Binns 2013).

Breastfeeding, which is by far the unequivocal preferred mode of feeding infants, results in a more stable microbial stool pattern characterized by higher levels of bifidobacteria in breastfed babies compared to formula-fed babies (Harmsen et al. 2000; Fanaro et al. 2003; Bezirtzoglou et al. 2011). This is notably due to the presence in breast milk of a variety of nondigestible oligosaccharides which are nonabsorbed and stimulate the growth of *Bifidobacteria* and *Lactobacilli*. Human milk oligosaccharides are present in human (but not in other mammalian's milk) at concentrations ranging from 10 to 20 g/L and represent the third most abundant group of milk compounds. They are nondigestible and fermented by the infant's colonic microbiota, therefore being one important factor contributing to the specific microbial composition of breastfed babies. In contrast, formula-fed babies harbor a wider range of bacteria, including bifidobacteria, bacteroidetes, clostridia, enterobacteria, and streptococci. Human milk oligosaccharides comprise a highly complex mixture of oligosaccharides that are attached in various ways through

different linkages. The quantity of these compounds depends on the lactation stage but also on the expression of specific glycosyltransferases in the mammary gland (Rudolff and Kunz 2012). In total, about 200 different molecular species have been detected (Ninonuevo et al. 2006).

Breastfeeding has been shown, among other things, to be protective against infections of the gastrointestinal and respiratory tract and the development of necrotizing enterocolitis in the newborn and decreases the occurrence of allergic and autoimmune diseases or type 1 diabetes later in life (Guaraldi and Salvatori 2012).

Prebiotics in Infants

As infant formulae (as well as breast milk) represent the sole source of nutrients during the first few months of a baby's life, it is crucial that these formulae are of the highest standard possible. Infant formulae must be safe and promote normal growth and development, and their composition, as well as functional and physiological benefits, should come as close as possible to those of human milk.

In the absence of breastfeeding, especially during the first months of life, infant formulae enriched with prebiotics or probiotics may overcome an initial inadequate colonization process and therefore help establish a normal mucosal immune system (Walker 2013). Inulin-type fructans have been evaluated in several studies involving neonates, where they were added to infant formulae.

In 110 healthy neonates, Veereman-Wauters et al. (2011) conducted a randomized, double-blind, placebo-controlled study to assess the effects of Orafti®Synergy1 on the growth, stools, and composition of the microbiota of the babies. Term infants were enrolled within 5 days after birth and were randomly distributed to receive, during 28 days, one of the four infant formulae: standard, enriched with 0.4 or 0.8 g dl^{-1} of Orafti®Synergy1 or 0.8 g dl^{-1} of a commercially used mixture of galacto-oligosaccharides and long-chain inulin in a 90/10 ratio (GOS/FOS). A reference group of breastfed babies was included as well. The bifidogenic effect of Orafti®Synergy1 was confirmed in the babies, as its supplementation in the infant formulae resulted in enhanced *Bifidobacterium* counts after 2 and 4 weeks, reaching levels comparable to the breastfed group. Numbers of lactic acid bacteria, bacteroides, and clostridia were comparable and levels were not modified by the addition of prebiotics. Growth parameters were similar between all groups.

More recently, a study was conducted to confirm the safety and efficacy of Orafti®Synergy1 (Closa-Monasterolo et al. 2013). In a large randomized, double-blind, placebo-controlled study, 252 infants were enrolled within their first 4 weeks of life, for an intervention up to 4 months of age. One hundred thirty-one breastfed babies were also included in the study. The infant formula was supplemented with 0.8 g dl^{-1} of Orafti®Synergy1 (or with maltodextrin as control).

The results of this study showed that Orafti®Synergy1 added to infant formula at a level of 0.8 g dl^{-1} is well tolerated and supports the normal growth of a baby. Water balance as well as blood and urine biochemical parameters were similar in both formula groups and demonstrated safety of the prebiotic formula. Higher

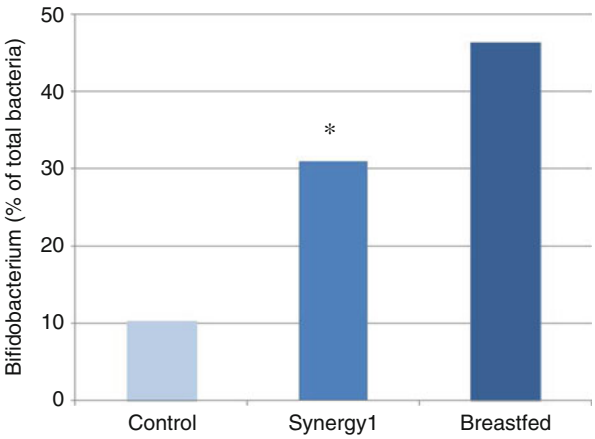

Fig. 3 Percentages of *Bifidobacterium* in the stool samples of infants at 3 months of age. *$p < 0.05$ versus control group (Adapted from Closa-Monasterolo et al. 2013)

bifidobacterial counts were shown following Orafti®Synergy1 intake, resulting in a microbiota composition closer to that of breastfed babies (Fig. 3.).

In addition to the effects on the microbiota, these two studies have shown effects on the stools of the babies. In the study of Closa-Monasterolo et al. (2013), stool frequency increased and stool consistency was softer in the Orafti®Synergy1 supplemented group, compared to the standard formula babies. Similarly, Veereman-Wauters et al. (2011) showed that the infants receiving the prebiotic formula had significantly softer stools, consistency of the stools still being harder than that of the breastfed babies. In a randomized, blinded trial involving 212 term infants assessing and demonstrating the safety of an oligofructose-enriched infant formula (1.5 and 3 g l^{-1}), the babies receiving the formula containing 3 g l^{-1} had less constipation compared to the control group receiving the standard formula (Bettler and Euler 2006).

These effects could be beneficial in preventing the problem of hard stools and of constipation often encountered in formula-fed babies.

Inulin-type fructans have also been evaluated in slightly older infants.

Here also, effects on stools have been shown, by Moore et al. (2003), where 16–46-week-old infants receiving a weaning cereal enriched with oligofructose had slightly more frequent and softer stools and less "hard" stools compared to the group receiving the standard cereal.

Two studies in toddlers between 4 and 24 months of age have shown that the ingestion of oligofructose is associated with a bifidogenic effect, with less events of diarrhea, vomiting, and fever (Waligora-Dupriet et al. 2007) and with a reduced severity of diarrheal or respiratory infectious episodes (decreased antibiotic use and fever) (Saavedra and Tschernia 2002).

Conclusions from studies conducted in infants and young children are that inulin-type fructans are safe, are well tolerated, and support adequate growth when added to infant formulae or to foods for young children. In babies, inulin-type fructans and in particular Orafti®Synergy1 show benefits of modulating the

microbiota of formula-fed babies, by rendering it more similar to that of breastfed babies. As such they have the potential to contribute to both the immediate and long-term health benefits of a balanced microbiota established early in life.

3.2.4 Inulin-Type Fructans and Weight Management

Achieving and sustaining appropriate body weight over a lifespan is vital to maintain good health. Obesity, which is today recognized as a disease, is one of the most important public health problems nowadays, as it affects a large part of the worldwide population. About one billion adults are currently overweight, and a further 475 million are obese (International Association for the Study of Obesity (IASO) 2011).

Overweight and obesity are major risk factors for a number of chronic diseases such as cardiovascular disease, type 2 diabetes, and some types of cancer (World Health Organization (WHO) 2011). Causal factors of overweight and obesity are multiple and their interaction is complex. We can see those as the result of interactions between human biology and environmental factors, being involved in the complex process of regulation of energy balance in order to maintain body weight. Central to the problem however is today's society characterized by excessive energy intake and by minimal energy expenditure, the so-called obesogenic environment.

Strategies to support weight management and to prevent obesity postulate, among others, the development of healthier food choices.

An increase in dietary fiber intake is encouraged, among other things, in an effort to overcome the gap between recommended and actual fiber intake. Apart from their beneficial role in colon health, dietary fibers have received increasing attention with respect to their role in energy intake and weight management.

Epidemiological evidence suggests that a higher dietary fiber intake is associated with lower body weight (Du et al. 2010; Tucker and Thomas 2009).

Foods rich in dietary fiber are usually less energy dense, as dietary fibers have a lower energy value than digestible carbohydrates, fat, and protein. For instance, inulin and oligofructose provide 1–1.5 kcal/g, while fully available carbohydrates provide about 4 kcal/g and fat about 9 kcal/g. Enriching foods with dietary fibers like inulin and oligofructose or replacing ingredients of higher caloric value like sugars and fat can directly reduce the intake of metabolizable energy.

Controlled human intervention studies indicate that individual dietary fibers – apart from their "energy diluting" properties – may specifically influence energy intake and appetite control. Different types of fibers may act differently in this respect.

Recent well-designed human studies, both in healthy, overweight, and obese volunteers, suggest a particular role for Orafti®Synergy1 and oligofructose in promoting a moderate negative energy balance in humans consuming a diet ad libitum.

In experimental animal models, numerous studies have described the effects of inulin-type fructans (5–10 % in feed) and more specifically of Orafti®Synergy1 and oligofructose on lowering energy intake, body weight, and/or fat mass. Several

models were studied, from normal growing rats (Cani et al. 2004), where first evidence of an impact of inulin-type fructans on lower (epididymal) fat mass accumulation and energy intake was shown in several models of obesity.

In Zucker *fa/fa* rats (genetically obese rats), the addition of 10 % Orafti®Synergy1 or oligofructose to the diet of the animals decreased their energy intake and resulted in a lower body weight and lower (epididymal) fat mass development compared to the control group (Daubioul et al. 2000, 2002). These effects were not observed when non-fermentable fibers (e.g., cellulose) were added to the diet, highlighting that it was not a fiber effect per se, but that the effects are linked to the distinct colonic fermentation of prebiotic fibers. These effects on energy intake and lower fat mass and/or body weight were confirmed in several further models, such as diabetic rats (streptozotocin-treated Wistar) (Cani et al. 2005), in a mouse model on a high-fat diet (Cani et al. 2006a, 2007) or a rat model on high-fat diet (Delmée et al. 2006) as well as in a genetically obese mouse model (ob/ob mice) (Cani et al. 2009a; Everard et al. 2011). In a study involving diet-induced obese Sprague-Dawley rats, and receiving either oligofructose (10 %) or a probiotic (*Bifidobacterium animalis* subsp. *lactis* BB12) (BB-12), the prebiotic, but not the probiotic, reduced energy intake, weight gain, and fat mass, which also highlights a probable role for fermentation related to the prebiotic fiber (Bomhof et al. 2014). The observed effects on body weight are persistent over time, as shown by a lifelong intervention study in rats where Orafti®Synergy1 supplementation resulted in a lower body weight evolution during the whole lifespan of healthy animals, and at the same time prolonged their survival rate to 24 months (Rozan et al. 2008).

The specific colonic fermentation is an important aspect to take into account to understand the effects of inulin-type fructans on energy intake and body weight. The observations made in animal studies are accompanied by changes in the levels of gastrointestinal hormones involved in appetite regulation, i.e., mainly of glucagon-like peptide-1 (GLP-1), peptide YY (PYY), and ghrelin.

GLP-1 is a peptide gut hormone released postprandially in response to nutrient intake. GLP-1 is produced in the intestinal endocrine L-cells, mainly present in the ileum and the colon, and higher circulating levels of this hormone are associated with lower subjective hunger feelings and lower food intake. The gut hormone PYY is a peptide synthesized and released like GLP-1 (from L-cells) present in the distal gastrointestinal tract. PYY levels are low in the fasting state and also rapidly increase in response to food intake. Peripheral infusion of PYY3–36, the major circulating form, reduced appetite and caloric intake in normal-weight and overweight human subjects (Karra et al. 2009). Ghrelin is a hormone primarily released by the stomach but also from the small and large intestine. Its blood levels rise during fasting and rapidly fall postprandially. Higher ghrelin levels are associated with higher appetite and hunger sensations.

In several of the animal studies cited above, the effects on energy intake, body weight, or body fat mass were accompanied by increased intestinal and portal levels of GLP-1 in the fasting state as well as postprandial GLP-1 response in the plasma. Orafti®Synergy1 and oligofructose increased proglucagon mRNA level

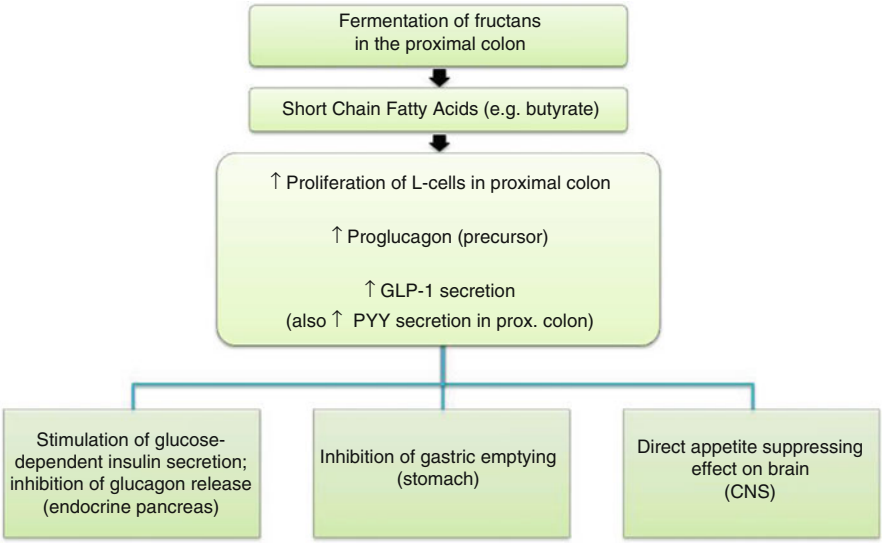

Fig. 4 Proposed mechanism of action of the effects of inulin-type fructans on appetite regulation and food intake (Adapted from Delzenne et al. 2005)

(the precursor of GLP-1) in the proximal colon and cecum in the fasting state and postprandially. Increased postprandial expression of cecal PYY was also shown in lean and obese animals. In mice receiving a GLP-1 receptor antagonist (exendin 9–39) or in GLP-1 receptor knockout mice (i.e., mice lacking a functional GLP-1 receptor), the decrease in energy intake and body weight observed with oligofructose supplementation was abolished, which clearly underlines the role of GLP-1 as mediator of the effects of fructans (Cani et al. 2006a).

The effects of inulin-type fructans on gut peptides and in particular on GLP-1 could be mediated by SCFA, which are also signaling molecules acting as endogenous ligands for the G protein-coupled receptors FFAR3 and FFAR2 (Brown et al. 2003), also named GPR41 and GPR43, respectively. These receptors are expressed in a variety of gastrointestinal cells and signaling through these receptors mediates the synthesis of GLP-1 by L-cells (Tolhurst et al. 2012). Figure 4 outlines the potential mechanism of action of fructans on appetite regulation and food intake.

In humans, several well-designed studies, both in healthy, overweight, and obese volunteers, have confirmed the effects of both Orafti®Synergy1 and oligofructose on reduced ad libitum energy intake in the context of body weight management.

In a randomized, double-blind, placebo-controlled trial, the intake by 36 overweight or obese individuals of 2 × 6 g/day of Orafti®Synergy1 during 3 weeks resulted in a significantly lower energy intake (McCann et al. 2011).

In healthy normal-weight (or normal to slightly overweight) adults as well, two randomized interventions conducted with 2 × 8 g/day of Orafti®Synergy1 or oligofructose (vs. maltodextrin as placebo) have similarly evidenced a reduction

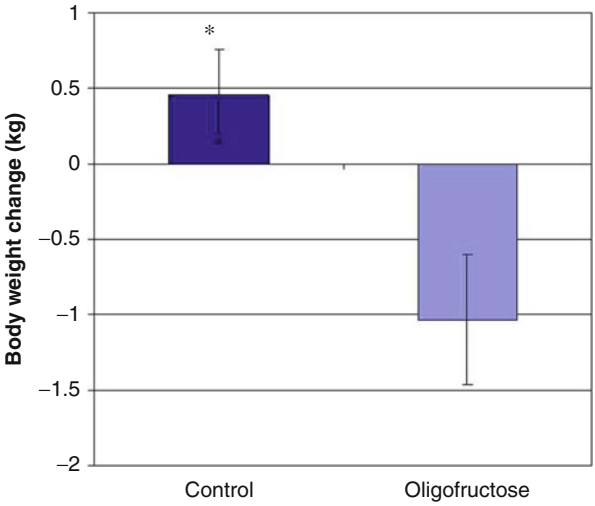

Fig. 5 Effect of 12 weeks supplementation with oligofructose (21 g/day) or placebo on body weight modulation (mean ± SEM) in overweight and obese subjects. *$p < 0.05$ versus placebo (Adapted from Parnell and Reimer 2009)

in energy intake (of 5–6 %) after a 2-week intake period of the fructan. This reduction of energy intake was measured during a test day where participants had ad libitum access to free-choice buffet meals. During the intervention, volunteers were instructed to keep their normal eating habits (Cani et al. 2006b, 2009b). In those studies, the findings on lower energy intake were accompanied by significant effects on appetite sensations (decreased hunger, increased fullness and satiety) as well as significant postprandial higher levels of GLP-1 and PYY (Cani et al. 2009b).

Consequently, benefits on body weight management have further been found in a randomized, double-blind, placebo-controlled trial, involving 48 overweight or obese healthy adults. The subjects receiving oligofructose (21 g/day) experienced a significant reduction in body weight of 1.03 kg, while the control subjects gained 0.45 kg weight, after 12 weeks of intervention (Fig. 5). The weight loss affected mainly body fat mass, in particular trunk fat mass. The weight loss could be explained by the lower energy intake observed in subjects in the oligofructose group. The subjects did not modify their physical activity or dietary habits, thus attributing the observed results concerning body weight, fat mass, and caloric intake to the oligofructose supplementation. An analysis of the blood levels of hormones involved in appetite regulation further revealed lower postprandial ghrelin and higher PYY responses in the subjects consuming oligofructose. GLP-1 levels remained unaffected (Parnell and Reimer 2009). A slight decrease in fat mass was also observed in obese women receiving 16 g/day of Orafti®Synergy1 compared to placebo (Dewulf et al. 2013). An earlier randomized, double-blind intervention trial, initially designed to study the impact of Orafti®Synergy1 on bone metabolism, adds further weight to these more recent observations of favorable effects of Orafti®Synergy1 in the context of body weight management (Abrams et al. 2007a). Ninety-seven healthy adolescents were randomized to receive 8 g/day of Orafti®Synergy1 or maltodextrin during a year. After 1 year, the body mass index (BMI) increase and the total body fat mass were

significantly lower in subjects who received Orafti®Synergy1 compared to maltodextrin. The BMI Z-score (age and sex normalized BMI value) of the adolescents in the maltodextrin group significantly increased, as compared to the Orafti®Synergy1 group where no significant increase was observed during the year. The BMI change in the Orafti®Synergy1 group was consistent with an adequate increase during puberty. The authors concluded that Orafti®Synergy1 supplementation had a significant benefit in the maintenance of an appropriate BMI increase during pubertal growth in primarily non-obese young adolescents which could help avoid undesirable weight increase at this critical stage of life.

On the whole, these well-designed human intervention studies conducted on normal-weight, overweight, and obese subjects have consistently shown a reduction in energy intake with 12 g/day of Orafti®Synergy1 and 16 g/day of oligofructose. Putative mechanisms of action, widely demonstrated in animal models, probably involve the effects of inulin-type fructans on appetite-related hormones, such as GLP-1 and PYY, and subsequent consequences on respective sensations (hunger, satiety...) which are shown in few human studies as well. A recent systematic review of human studies conducted with prebiotics indicates that current evidence supports that prebiotic supplementation increases self-reported feelings of satiety significantly in healthy adults (Kellow et al. 2014).

Weight management is not only a question of losing weight, but also the prevention of unhealthy weight gain. It has been estimated that the increase in obesity rates in the United States (USA) between 1980 and 1994 could be accounted for by an excess of just 4 kcal/day over maintenance energy requirements in women and 13 kcal/day in men (Khan and Bowman 1999). Preventing this small daily calorie gain thus has important repercussions for the prevention of obesity. Inulin-type fructans may help to make such changes.

In addition to the effects described above, another topic of growing interest is the association between obesity and changes in the composition of the gut microbiota. The composition of the gut microbiota has been shown to differ between lean and obese individuals (Ley et al. 2006b). Early studies have reported changes at the phylum level, mainly assessing the Bacteroidetes-to-Firmicutes ratio, with inconsistent associations. Of note, this ratio is a rough measure because such broad classification of bacterial taxa includes pathogens as well as bacteria generally regarded as beneficial to the host (Karlsson et al. 2013). A few human studies examined also possible differences in the gut flora composition below the phyla level, i.e., at the groups or species level and looking at groupings like bifidobacteria, bacteroides, or clostridia. In those studies, in which the bifidobacteria level between normal-weight and overweight or obese individuals was compared, a significantly and/or numerically higher bifidobacteria level related to normal body weight was observed as well (Schwiertz et al. 2010b; Balamurugan et al. 2010).

Determining whether the altered gut microbiota contributes to obesity or the opposite (chicken or egg causality dilemma) requires prospective studies. Kalliomäki et al. (2008) showed that children who had a normal weight at 7 years of age showed a higher Bifidobacterium level during their first year of life than children who became overweight.

The gut microbiota is also suggested to be involved in the development of a low-grade inflammation, that in turn is associated with the metabolic disorders related to obesity (Delzenne et al. 2013). Increased levels of serum lipopolysaccharide (LPS) are shown in obese or high-fat diet-fed individuals. LPS is the main compound of Gram-negative bacteria and is among the most potent inducers of inflammation (Cani et al. 2012). This LPS increase might be the consequence of an increase in chylomicron formation, a decrease in gut barrier integrity and/or a decrease in alkaline phosphatase activity (an enzyme responsible for the cleavage of LPS in the intestine) (Delzenne et al. 2013). Diet-induced obesity in rodents resulted in altered gut microbiota composition (notably with lower levels of Bifidobacterium spp.) and induced a low-grade inflammation state (higher LPS levels) (Cani et al. 2012). In these models inulin-type fructans were able to counteract the increase in LPS levels, notably through an improvement of the expression and activity of proteins involved in gut barrier function (GLP-2) (Delzenne et al. 2013), in addition to the modulations in microbiota composition. Gut microbiota modulations following prebiotic intake (context of obesity and type 2 diabetes animal models) not only abolished gut permeability, endotoxemia, and inflammation but also decreased body weight and fat mass accumulation as consistently observed in several studies (Everard and Cani 2013). In addition, improved glucose homeostasis was also shown.

3.2.5 Inulin-Type Fructans and Blood Sugar Management

Carbohydrates represent the main energy source of the body via the glucose they supply in a direct or an indirect way. Not all carbohydrates or carbohydrate foods are however alike with respect to physiological effects and elevation of postprandial glycemia. Carbohydrates that have a lower glycemic response (GR) may be beneficial for individuals with impaired glucose tolerance. As recently reviewed by leading experts in the field of carbohydrate metabolism, there is convincing evidence from meta-analysis of controlled dietary trials that low glycemic diets improve glycemic control in people with type 2 diabetes and type 1 diabetes (reviewed in ICQC 2013). There is further convincing evidence from meta-analysis of prospective cohort studies that low glycemic diets reduce the risk of type 2 diabetes and of coronary heart disease (reviewed in ICQC 2013). Based on a large body of scientific evidence, these experts concluded that reducing postprandial glycemic response is recognized as a beneficial physiological effect (ICQC 2013; EFSA 2011; Ceriello and Colagiuri 2008; Levitan et al. 2004; Coutinho et al. 1999).

Inulin and Oligofructose Reduce Postprandial Glycemic Responses

Since inulin and oligofructose are nondigestible carbohydrates, they do not contribute to postprandial glycemia. Replacing digestible and glycemic carbohydrates (e.g., sugars or maltodextrin) partially or completely by inulin or oligofructose on a weight-by-weight basis in a food product reduces the amount of available carbohydrates and consequently the postprandial blood glucose response of the food. Depending on the level of refinement, commercially available forms of inulin and

oligofructose may contain varying amounts of accompanying mono- and disaccharides that can contribute to the blood glucose response. A recent systematic review of human studies related to the metabolic benefits of prebiotics concluded that prebiotic supplementation significantly reduces postprandial glucose and insulin concentrations (Kellow et al. 2014).

If fructans (oligofructose) are present in relevant amounts, for instance, in a commercial product with about 15 % sugars, they show only about 20 % of a blood glucose response of glucose, but still provide sweetness to the product (Meyer 2007). Other types of commercial products contain very few or no residual sugars at all. A well-considered choice of oligofructose or inulin with respect to its blood glucose response and other functional properties like pleasant taste makes an optimization of product applications possible.

Further studies (including unpublished data) show significant reductions in the postprandial glycemic response for different foods in which sugars have been replaced by oligofructose at levels of 20 % or more. A linear relationship between the extent of sugar replacement and a reduction in the resulting blood glucose response shows that higher fructan levels will result in greater effects, respectively.

A reduction of postprandial glycemic responses (as long as postprandial insulinemic responses are not disproportionally increased) might be a beneficial physiological effect according to the European Food Safety Authority (EFSA). Based on the data available including a recent unpublished study conducted by BENEO together with other inulin producers, a scientific dossier was compiled by BENEO and submitted to EFSA. It received a positive opinion (EFSA 2014) and is currently subject to the final Regulation that will be adopted by the EU Commission. Food products where sugar has been replaced by inulin-type fructans will be able to bear a claim stating that the "Consumption of a food product containing oligofructose (or inulin) instead of sugars, raises blood glucose concentrations less after consumption, compared to the sugar-containing regular food product" (or similar wording).

Long-Term Blood Glucose Control

Some studies show that a higher intake of inulin or oligofructose with a balanced diet can positively influence markers of blood glucose control and insulin sensitivity.

For instance, in the study by Russo et al. (2010) conducted in a 2-arm double-blind, randomized crossover design, the daily consumption of inulin-enriched pasta with 11 % inulin as part of a controlled diet for 5 weeks was associated with significant beneficial effects on fasting glucose and protein glycation (fructosamine, HbA1c) as well as insulin resistance (Homeostasis Model Assessment of Insulin Resistance, HOMA-IR) in 15 healthy male adults, whereas no significant changes were seen with regular pasta. Significant beneficial effects of inulin-enriched pasta were also seen on HDL cholesterol and triglyceride levels, with no significant changes in the control intervention.

Daubioul et al. (2005) found in their 8-week intervention study conducted in 2-arm double-blind, randomized, placebo-controlled crossover design that the

intake of daily 16 g oligofructose at breakfast and dinner as part of the otherwise normal diet was associated with significantly lower levels of fasting insulin and C-peptide in seven patients with nonalcoholic steatohepatitis (NASH) after 4 weeks in comparison to maltodextrin.

In a randomized intervention study involving women with type 2 diabetes, the effects of inulin supplementation (10 g/day) versus placebo (maltodextrin) were studied with respect to diabetes control and inflammatory status notably. The results of this trial show that inulin significantly reduces fasting plasma glucose, HbA1c levels, fasting insulin, and HOMA-IR in comparison with the control group. In addition, inflammatory markers, such as high-sensitivity C-reactive protein (hs-CRP), tumor necrosis factor-alpha (TNF-α), and LPS, were also significantly reduced upon inulin intake (Dehghan et al. 2013, 2014a, b; Pourghassem Gargari et al. 2013). Subclinical inflammation is linked to the development of insulin resistance, and the results of the above study show positive outcomes with respect to biomarkers of inflammation, in addition to the improvement of the glycemic status of diabetic women.

With respect to mechanisms of action, several data in animals support an effect of inulin-type fructans on enhanced GLP-1 production in the colon (see section on weight management for more details). GLP-1 is secreted in response to the presence of a meal in the gut and stimulates insulin secretion in a glucose-dependent way, thereby contributing to the so-called incretin effect. GLP-1 also inhibits gastric emptying. GLP-1 has become a target for research into antidiabetic therapies: GLP-1 agonists and dipeptidyl peptidase (DPP)-4 inhibitors (the enzyme responsible for the inactivation of GLP-1) are nowadays used for the treatment of type 2 diabetes.

This GLP-1 production might thus be part of the beneficial effects of fructans shown with respect to glycemic control (Roberfroid et al. 2010):

- GLP-1 has been shown to increase β-cell differentiation.
- In streptozotocin rats receiving inulin-type fructans, improvement in glucose tolerance and pancreatic β-cell mass is not reproduced by only pair-feeding restrictions, indicating that the beneficial effects of inulin-type fructans are not due to their effect on appetite alone.
- Improved insulin sensitivity was shown in rodents fed oligofructose, and this effect was mediated by GLP-1 (Cani et al. 2006a).
- Other mechanisms, like the effects on lowering inflammatory tone, could contribute to the positive effects of fructans observed in glucose metabolism.

A recent publication has also suggested a role for SCFA produced by the microbial fermentation of fructans in their metabolic benefits. In an experimental design where rats were fed oligofructose or SCFA (propionate or butyrate), it was shown that oligofructose and SCFA improved glucose tolerance and insulin sensitivity. SCFA were shown to activate intestinal gluconeogenesis (IGN). Intestinal gluconeogenesis has been shown to induce beneficial effects on glucose and energy homeostasis. The metabolic benefits (on glucose control) induced by oligofructose

or SCFA being absent in mice deficient of IGN, this experience pointed to a specific causal role of IGN regulation in the metabolic benefits associated with oligofructose (De Vadder et al. 2014).

We can conclude, from the long-term studies above, that enrichment of the diet with inulin or oligofructose has beneficial effects on biomarkers of long-term blood glucose control such as fasting glucose, HbA1c, and insulin functionality. These data encourage the use of inulin and/or oligofructose as an approach to reduce blood glucose and insulin profiles in the diet of people aiming to improve blood glucose control in the prevention and management of glucose tolerance impairments, beyond their beneficial effects on colon health.

3.2.6 Inulin-Type Fructans and Bone Health

Osteoporosis is a major widespread health-care problem, with around one in three women and one in five men being at risk of an osteoporotic fracture (International Osteoporosis Foundation (IOF) 2013). Osteoporosis is a chronic and progressive disease characterized by low bone mass and micro-architectural impairment of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture. Bone mass increases during childhood and adolescence, reaching its peak value during young adulthood (Prentice et al. 2003). It is estimated that a 10 % increase of peak bone mass in children reduces the risk of osteoporotic fracture during adult life by 50 % (IOF 2013). Therefore, prevention of osteoporosis starts early on by maximizing peak bone mass during adolescence. Calcium, as a structural component of the bone, plays an essential role here, as it represents 40 % by weight of the mineral in the skeleton (Prentice et al. 2003). Adequate calcium intake is thus clearly an important factor in maintaining bone mass throughout life. In addition to dietary intake (often inadequate), intestinal absorption is a key factor that controls the retention of calcium in the body and thus the mineralization of the bones.

The fractional absorption of calcium depends on a number of aspects, including the calcium load and source. The absorption of calcium from cow's milk is around 30 %, but the efficiency of this process declines as we get older. Two main mechanisms are involved in calcium absorption: an active transcellular transport, which takes place mainly in the small intestine, is vitamin D mediated, and becomes saturated with an increased dietary calcium load, and a passive, paracellular, non-saturable process, which takes place throughout the whole intestine and which can be influenced by inulin-type fructans.

Colonic fermentation of inulin-type fructans is thought to be the main mechanism contributing to their effect on the stimulation of intestinal calcium absorption. The SCFA and lactic acid produced as a consequence of fermentation contribute to lower the luminal pH in the colon, which brings some of the insoluble calcium complexes arriving in the colon into solution, thus making it available for absorption (Scholz-Ahrens and Schrezenmeir 2002; Raschka and Daniel 2005). As a consequence, inulin-type fructans influence the passive absorption contribution in the colon. This was confirmed in studies with animal models showing that the solubility of dietary calcium in the large intestine was enhanced during supplementation with different inulin-type fructans (Younes et al. 2001; Coudray et al. 2003).

Other mechanisms may include a direct exchange of these SCFA on transcellular calcium absorption by increasing the exchange of cellular H^+ for luminal Ca^{2+}, increased butyrate production which stimulates colonic mucosal proliferation thus increasing the absorptive surface area of the gut, and/or an increase in mucosal calbindin D_{9K} and vitamin D receptor in the large intestine (Roberfroid et al. 2002; Cashman 2006).
