In more than 20 animal studies, the beneficial effects of inulin-type fructans related to higher intestinal calcium absorption, bone turnover, and bone mineralization have been demonstrated. The positive effects on calcium absorption of inulin-type fructans did not affect the absorption of other nutrients. Several studies further demonstrated favorable effects by showing an increase in bone mineral density and/or content (BMD/BMC) (Roberfroid et al. 2002; Scholz-Ahrens et al. 2002; Kruger et al. 2003; Nzeusseu et al. 2006; Weaver et al. 2010) and could even lead to improved biomechanical properties of the bones (Lobo et al. 2006). Positive outcomes were also confirmed in ovariectomized rats, a model mimicking the estrogen-deficient postmenopausal status of a woman (Scholz-Ahrens et al. 2002; Zafar et al. 2004; Legette et al. 2012). It was shown that inulin-type fructan supplementation could prevent the ovariectomy-induced loss of bone structure, compared to rats in the control group (Scholz-Ahrens et al. 2002).

Studies comparing Orafti®Synergy1 with oligofructose and/or inulin in parallel showed that the positive effects on calcium absorption were more pronounced with Orafti®Synergy1 (Coudray et al. 2003; Legette et al. 2012). This can be explained by the fact that Orafti®Synergy1 may have a more favorable chain-length distribution, which results in a more evenly distributed fermentation pattern, which includes both the proximal and distal part of the colon. Hence the surface of the full length of the colon can be used to increase calcium absorption efficacy.

This observation was confirmed in a randomized, double-blind human study, where 8 g/day of Orafti®Synergy1 significantly increased true calcium absorption (by almost 20 %) in adolescent girls compared to placebo, while oligofructose did not show a similar effect at the same dose (Griffin et al. 2002). In contrast, a previous study had shown a positive outcome on calcium absorption with 15 g/day of oligofructose (van den Heuvel et al. 1999). Both studies recruited young adolescents because of the importance of a high calcium absorption during that life stage. In a multicenter extension of their first study, Griffin et al. (2003) demonstrated that volunteers with a low calcium absorption efficiency under basal conditions seemed to benefit the most from Orafti®Synergy1 intake.

Beneficial effects were also demonstrated in a placebo-controlled, randomized, double-blind crossover study in postmenopausal women (Holloway et al. 2007). A 10 g/day ingestion of Orafti®Synergy1 significantly increased true calcium absorption, while the control group showed a slight decrease in calcium absorption. In addition, certain biomarkers related to bone formation (serum osteocalcin) or to bone resorption (urinary deoxypyridinoline cross-links) were positively modulated.

To demonstrate that the effects of Orafti®Synergy1 on calcium absorption occur mainly in the colon, Abrams et al. (2007b) included kinetic measurements to

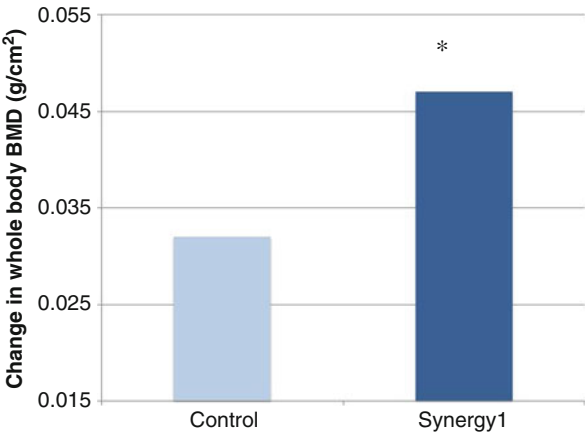

Fig. 6 Changes in whole-body bone mineral density after supplementation with Orafti®Synergy1 in children. *$p = 0.01$ versus control (Adapted from Abrams et al. 2005)

evaluate the time course of calcium absorption. Based upon literature showing that calcium absorption takes place in the colon around 7 h after oral intake, this research team not only confirmed the increased calcium absorption with Orafti®Synergy1 in young adults, but they also showed, by following the kinetic of calcium absorption in the blood, that the relative increase in calcium absorption after Orafti®Synergy1 intake was mainly related to the colonic part of the gastrointestinal tract.

One human intervention study has examined the effects of Orafti®Synergy1 on calcium absorption and on bone mineralization on a long term. A total of 100 adolescents (from 9 to 13 years old) were involved in a 1-year randomized, double-blinded intervention study and were supplemented with 8 g/day of either Orafti®Synergy1 or placebo (maltodextrin). True calcium absorption was significantly enhanced after 8 weeks in the Synergy1 group, and this beneficial effect was maintained during the whole intervention year. At the end of the experimental period, adolescents supplemented with Orafti®Synergy1 had a significantly greater increment in both whole-body bone mineral density (BMD) (Fig. 6) and whole-body bone mineral content (BMC). The authors noted that the net benefit associated with intake of Orafti®Synergy1 was an average increase in calcium accretion to the skeleton of approximately 30 mg per day (Abrams et al. 2005).

In conclusion, the totality of the data shows that the ingestion of inulin-type fructans, in general, and Orafti®Synergy1, more specifically, results in an increased calcium absorption, and the study of Abrams et al. (2005) further shows that this increase in calcium absorption persists over the long term and that the additionally absorbed calcium is reaching the bones and used there (increased bone mineralization).

3.3 Healthy Aging and Noncommunicable Diseases

Human aging is inevitable and has an impact on morbidity, quality of life, as well as health-care costs. Our societies are aging, and both the proportion of older people

and the life expectancy are increasing throughout the world. In Europe, the proportion of people aged 65 years and over is expected to be 24 % of the population in 2030, and in the United States (USA), this group may number 72 million (or 19 % of the population) by 2030 (US Department of Health & Human Services). Similar increases in the elderly population have been reported in Asia and in South America. These demographic changes have implications for health, as well as for pensions, social care, and housing. Healthy aging, i.e., an absence of chronic disease and slower decline in cognitive and physical function, is the goal of everyone. However, disease statistics tell a different story and confirm that a significant proportion of older people experience chronic disease, poor mobility, and frailty in their final years. The demographic figures and concern have prompted the World Health Organization (WHO) to develop and publish a 2012–2020 strategy for healthy aging in Europe focused on prevention of falls and promotion of physical activity among other policy interventions (WHO 2012). Life expectancy continues to rise in Europe, but healthy life expectancy is not improving, measured as the number of years spent free of activity limitation at a particular age. Thus, while a man from France, Spain, or Italy could expect to live to around 78 years, he will spend the last decade of his life with a chronic illness. The gap between actual and healthy life expectancy is greater in countries with a lower gross domestic product (GDP) suggesting that poverty has a detrimental impact on wellness.

Getting older healthier is strongly influenced by the development of noncommunicable diseases (NCD), the leading cause of death in the world (WHO 2011). NCDs include cardiovascular disease, obesity, cancer, type 2 diabetes, osteoporosis, chronic respiratory, and age-related macular degeneration. According to the same WHO report on NCDs, raised blood pressure, tobacco use, raised blood glucose, physical inactivity, and overweight and obesity are the risk factors underlying most NCDs. The development of NCDs is a long-term silent process, caused by the additive effects of genetic susceptibility, age-related physical and metabolic changes, as well as years of lifestyle deviations.

In this global context, it is clear that prevention of risk factors is a much more efficient approach than the treatment of established medical consequences. Prevention is achieved through changes and adaptations in lifestyle, including a balanced energy intake and a balanced food choice. These, for instance, include small changes to modifiable risk factors, such as lowering total and/or LDL cholesterol, aiming for lower blood glucose and insulin profiles, maintaining a healthy body weight, increasing dietary fiber intake, and taking regular physical exercise.

In view of all health-related aspects that have been reviewed in the present book chapter, it appears that inulin-type fructans, through their impact in the large intestine and globally in several aspects of the functioning of our body, may support healthy nutrition, through different windows of opportunity and at different ages.

During the first year(s) of life, nutrition is capital for a normal development of the infant and child and strongly influences health later in life. Early-life programming is notably becoming an accepted scientific concept with nutrition having an impact on sensitive time periods of a fetus and infant development that have long-term consequences. Adaptations during these sensitive periods may predispose

individuals to health problems such as metabolic syndrome or related diseases, including glucose intolerance, insulin resistance, or obesity (Nauta et al. 2013). Large-scale research programs, e.g., in the European Union, are investigating various aspects in infant nutrition. Getting closer to breast milk feeding conditions is the goal, if the "gold standard" breastfeeding is not the option chosen by the mother. In infants and young children, inulin-type fructans from chicory promote the growth of naturally occurring bifidobacteria selectively so that the composition of the intestinal microbiota of a bottle-fed baby gets closer to that of a breastfed baby. Stools are also a target of prebiotics in infants as there is less constipation and less features related to constipation when added to infant formulae.

Childhood and adolescence are critical periods of life for building up adequate bone mass density and reducing therefore the risk of osteoporosis later in life. In this context, a specific inulin-type fructan (Orafti®Synergy1) was shown to increase calcium absorption with resulting effects on bone mineralization. Effects on better calcium absorption have been shown in postmenopausal women as well. The mode of action is linked to fermentation and the resulting environment in the colon that favors the absorption of additional calcium.

During adulthood, the promotion of bacteria considered as representative of a healthy microbiota is regarded as something important for overall digestive health balance. Weight management is a nutrition challenge that an important part of the adult population is facing. Related to overweight and obesity, diabetes mellitus is of key concern as both diet-related challenges lead to health political avalanches. The increase in weight during this period is very often around 1 kg per year or higher leading to significant overweight and metabolic consequences. Obviously, there is a multifactorial logic behind this. Ingredients such as inulin-type fructans that influence energy intake naturally and have an impact on blood glucose response are new approaches in a healthy diet supporting proper weight management and blood glucose management.

In elderly, as cited already, on top of all other health concerns, osteoporosis prevention is highly relevant. In all age groups, digestive health is certainly in the focus. The concerns related to cancer and other gut-related diseases are increasing, constipation affects an important proportion of the population (increasing with age), and digestive health plays an important role in overall well-being. Most people know about fiber and are interested in bridging "the fiber gap" and more and more receptive as well to learning about positive influences of prebiotics of their gut microbiota.

4 Conclusion

The present book chapter highlighted the broad spectrum of effects of inulin-type fructans. As dietary fibers, they easily allow the enrichment of traditional foods and help consumers to meet their fiber needs. As fermentable fibers, inulin-type fructans show their efficacy firstly in the large intestine, where their selective fermentation by the microbiota induces favorable changes in its composition, with most human

studies showing a consistent and selective stimulation of *Bifidobacterium* ssp. Further research focuses on changes in the metabolites produced, resulting from the saccharolytic fermentation. Because of the central role of the large intestine in health, and the intricate relationships that exist between microbes in the colon, their metabolites, and human metabolism, the effects of inulin-type fructans are not restricted to the colon. Metabolic effects radiate towards other parts of the body and are mediated by several metabolites from fermentation. Experimental research shows that these metabolites find receptors to convey their messages and explain the changes observed in terms of metabolism with the actual resulting health benefits. Recent human data support benefits of inulin-type fructans on energy homeostasis, controlling the level of calories ingested. These events probably also arise from the colon, through modulations of gut peptides involved in appetite regulation. The colon is also a center of inner protection, and several plausible mechanisms exist by which inulin-type fructans may influence immune functions starting in the gut. Research is ongoing in this area as well.

Positive effects on bone metabolism, with higher calcium absorption and resulting higher bone mineralization, have been demonstrated. To date, hundreds of studies have been conducted with inulin-type fructans, and all point, in one way or another, to benefits, from babies, where the microbiota development is central, to an aging population.

Knowledge about the microbiota composition and its health effects is probably still only the tip of the iceberg. Understanding the effects of the microbiome further on health and on the pathogenesis of several common diseases will allow further health developments. In that context, colonic nutrients that have an impact on these processes and favor them in a beneficial way may play an important role in supporting health. Further exciting research is likely to contribute to understanding the impact of prebiotic inulin-type fructans on health.

Active Edible and Biodegradable Starch Films

24

Laura Sánchez-González, Elmira Arab-Tehrany, Maite Cháfer, Chelo González-Martínez, and Amparo Chiralt

Contents

Abstract

Starch appears as a good alternative to petro-based plastics. This biopolymer exhibits a greater potential to obtain biodegradable films, thanks to its easy availability and low cost. Starch has been used to develop edible, biodegradable, active films using different strategies: blending with antimicrobial polymers, active nanoparticles, and other antioxidant or antimicrobial compounds, such as essential oils of phenolic extracts. The incorporation of these compounds to starch or starch blend films has an impact on their physical properties which can affect their functionality as a packaging material.

1 Introduction

In the last few years, a great number of studies have focused on the development of environmentally friendly materials to substitute the petro-based plastics as a means of solving the environmental problems that they cause and to reduce the petroleum dependence, whose reserves are limited. Substituting synthetic nonbiodegradable plastics requires the development of low-cost materials with similar properties which can compete in the packaging market (Psomiadou et al. 1996; Mali et al. 2002; Mali et al. 2006; Famá et al. 2007; Jiménez et al. 2012d). Likewise, the biodegradable polymeric films should be obtained from renewable sources (Lu et al. 2005; Tharanathan 2003; Yu and Chen 2009). Of the polymeric materials which are biodegradable or compostable (bioplastics), obtained from renewable sources, starch occupies a significant position. Starch constitutes more than 60 % of cereal kernels and is relatively easy to separate from the other chemical components (Arvanitoyannis and Kassaveti 2009). The film-forming ability of starch and its easy availability and low cost make it one of the raw materials with greater potential to obtain biodegradable films.

Starch granules are not soluble in cold water due to the strong interchain hydrogen bonds which hold the starch chains together. However, when starch is heated in water, the crystalline structure is disrupted and water molecules interact with the hydroxyl groups of amylose and amylopectin, producing the partial solubilization of starch (Hoover 2001). Heating starch suspensions in an excess of water or of another solvent able to form hydrogen bonding (e.g., liquid ammonia, formamide, formic acid, chloroacetic acid, and dimethyl sulfoxide) at high temperatures (between 65 °C and 100 °C approximately depending on the type of starch) provokes an irreversible gelatinization (destructuration) process. This process is greatly affected by the kind of solvent and the starch–solvent ratio. Starch gelatinization or grain destructuration is required for the purposes of obtaining starch films. This process introduces irreversible changes in starch granules, such as the loss of crystallinity, water absorption, and the swelling of the granules (Zhong et al. 2009; Carvalho 2008). Gelatinization involves two steps: the hydration and diffusion of the solvent into the starch granules and the melting of starch crystals (Donovan 1979; Liu et al. 1991; Jenkins and Donald 1998). The gelatinization process and its relevance in the production of starch-based films are reviewed in the next section.

Starch films exhibit some very good properties, since they are tasteless, odorless, transparent, and with very low oxygen permeability, which is highly appropriate for food preservation. However, they also have some drawbacks: highly sensitive to water (hygroscopic character), which provokes changes in mechanical response depending on the relative humidity; high values of water vapor permeability; and retrogradation phenomena, associated to the progressive chain aggregation/crystallization, depending

on the molecular mobility in the system. To mitigate these aspects, different strategies have been considered such as starch blending with other components – lipids (Jiménez et al. 2012a; Ortega-Toro et al. 2014a), organic (Curvelo et al. 2001; Müller et al. 2009; Cano et al. 2014) or inorganic fillers (Carvalho et al. 2001; Avella et al. 2005), and other hydrocolloids (Jiménez et al. 2012b, c; Ortega-Toro et al. 2014b). The use of different polymer compatibilizers (Ortega-Toro et al. 2014b) or starch modifications (Kaur et al. 2012) has also been tested in order to increase the polymer's compatibility and to improve film properties.

The incorporation of bioactive compounds, with antimicrobial or antioxidant properties, in order to obtain active films has also been studied in starch or starch blend films (Pyla et al. 2010; Zhong et al. 2011; Bonilla et al. 2013; Jiménez et al. 2013, 2014; Fabra et al. 2014). Active films represent a great hope for the food industry and consumers. They make it possible to prolong the product shelf life, thus increasing benefits for producers and consumers through waste reduction, while food quality can be better assured. Nevertheless, the incorporation of these compounds to starch or starch blend films has an impact on their physical properties which can affect their functionality as a packaging material. In this chapter, the effect of starch blending with antimicrobials or antioxidant compounds on the film's active and physical properties is analyzed.

2 Starch in the Development of Biodegradable Films

2.1 Starch: Structure, Properties, and Sources

It is well known that starch is composed of two types of polysaccharides, amylose and amylopectin, polymers of α-D-glucose connected by (1→4) linkages with very different properties (Table 1). Amylopectin is the major component of most starches (Table 2) and consists of a number of chains bounded together by a (1→6) linkage, leading to an extensively branched structure of high molecular weight. On the other hand, amylose is considered to have an essentially linear structure with lower molecular weight than amylopectin. Amylose content usually ranges around 20 % in most cases, except for waxy starch, in which the amylose content is almost zero.

Even if the chemical composition of starches is very simple, every starch has its own characteristic shape and size distribution. The different shapes and sizes of most common starches are detailed in Table 2, which range from the typical large spherical granules (up to 100 μm) found in potato to the small polygonal particles (2–10 μm) found in rice. In general, the amylose content of starch is proportional to the granule size and maturity of starch (Pan and Jane 2000).

Starch granules are composed of layers of both amylose and amylopectin around a nucleation center called the hilum. Often, these layers in many starch grains are visible when viewed under the light microscope. The granule grows alternating radial amorphous and semicrystalline rings from the hilum, forming a lamellar structure. The amylopectin, which comprises around 75 % of the granule, is mainly responsible for the granule crystallinity and exhibits birefringence under

Table 1 Characteristics of amylose and amylopectin

Property	Amylose	Amylopectin
Shape	Mainly linear	Branched
Molecular weight	<2,6 million	50–500 million
Linkage	Mainly α-1,4	α-1,4 and α-1,6
Color with iodine	Blue	Reddish brown

Table 2 Amylose and amylopectin contents (wt. percentage) of some starches

Starch type	Source	Shape	Size (μm)	Amylose content	Amylopectin content
Tapioca	Root	Oval	3–28	17	83
Potato	Tuber	Oval, spherical	10–100	20–30	80–70
High-amylose corn	Cereal	Polygonal		55–70	45–30
Dent corn	Cereal	Polygonal	5–30	25	75
Waxy corn	Cereal	Polygonal	5–25	<1	>99
Wheat	Cereal	Round, lenticular	5–35	25	75
Rice	Cereal	Polygonal	2–10	19	81
Pea	Legume	Oval	–	25–40	75–60
Cassava	Root	Round	–	9–22	91–78

cross-polarized light. Thus, the starch grains appear bright against the dark field and each starch grain shows a Maltese cross. The crossing point of the Maltese cross is located at the hilum (Gallant et al. 1997).

The presence of crystalline structure in the starch granules has also been analyzed by X-ray diffraction. Three types of crystalline structure have been identified as A, B, and C types, the latter consisting of a mixture of A and B types. As commented above, the granule crystallinity is mainly due to amylopectin, whose side-chain branches intertwine to form the double helices, whose association gives rise to the crystalline zones, whereas amylose remains mainly amorphous in the granule (Donald 2004). Due to this fact, the larger amylose content of the B-granule starch is likely to result in a lower percentage of the crystallinity in the B-granule starch than the A-granule starch (Zeng et al. 2011). As an example, the degree of crystallinity in the native cassava starch was found to be 38 %. The X-ray diffraction pattern of each starch sample is the "fingerprint" of the crystalline structure within starch grains.

Crystalline structures are also formed in starch products from amylose and amylopectin fractions. According to the characteristic X-ray diffraction lines, the crystalline structure of starch products can be divided into four types: A, B, C, and V. Of these, A, B, and C types are similar to those observed in native starch, while V type is typical of the amylose–lipid complexes in which the helical conformation of amylose chains is involved.

During the gelatinization process, starch granules undergo an irreversible order–disorder transition. If the granules become fully swollen, high temperature and shear cause granule disruptions with an increase in viscosity and translucency. This is due to the dissolution and leakage of the amylose from the granules and to

the loss of initial native crystallinity of starch. Starch gelatinization is an endothermic process which can be analyzed by DSC. The gelatinization temperature depends on the starch–water ratio. With a large excess of water, only one endotherm can be observed by DSC, whereas with no excess of water, the only endotherm appears at higher temperatures. With intermediate water content, two endothermic transitions are observed, corresponding to the hydration of the granule and to the melting of the crystallites, respectively (Carvalho 2008).

Once the starch has been gelatinized, a recrystallization process takes place due to the rearrangement of amylose and amylopectin molecules into an ordered structure during the cooling process. Composed of linear chains, the crystallization rate of amylose is much greater than amylopectin, which remains semicrystalline (Gidley and Bulpin 1989).

Starch, as a semicrystalline structure, also exhibits a glass transition. The glass transition temperature (Tg) of the starch amorphous regions at low moisture content is around 90–180 °C, depending on the variety of starch and the water content (García et al. 2000; Delville et al. 2003; Zeleznak and Hoseney 1987).

2.2 Film Preparation

Starch films can be obtained from the native starch or its components, amylose and amylopectin, by two main techniques: solution casting and subsequent drying (wet method) and thermoplastic processing (dry method). Modified and soluble or pre-gelatinized starches have also been used to obtain starch films (Jiménez et al. 2012d). In the wet method, films are formed from a film-forming dispersion or emulsion, which contains a high percentage of water. A great number of studies have been carried out using this technique to obtain films based on starch from different sources (Jiménez et al. 2012d). Gelatinization of starch in the aqueous dispersion is required prior to film formation. In the thermoplastic processing (dry method) of starch, the water content is much lower and it can only be used with thermoplastic starch (TPS). Thermoplastic materials become soft (melted or rubbery), and so, they can be molded into a determined shape when submitted to a thermal/mechanical process. Starch does not present this characteristic in its native state, but it is capable of becoming a thermoplastic material if it is adequately treated.

2.2.1 Wet Process

The most commonly used laboratory-scale method for obtaining edible films is the drying of the cast film-forming dispersion. The complete process for the starch films could be divided into several steps: starch gelatinization, homogenization of the mixture, casting, and drying.

In the gelatinization step, granules are disrupted in an excess of water. The optimal process conditions depend on the origin of the starch, since the granule structure depends on the starch source. The type of starch and the plasticizer content affect the gelatinization temperatures. A wide range of gelatinization temperatures and times have been reported. The gelatinization step is avoided if pre-gelatinized

starch is used to obtain films. Pre-gelatinized starches have been precooked and drum-dried to yield products which disperse quickly in cool water to form stable suspensions.

Gelatinization conditions (temperature, time) change when other components are present in the starch aqueous dispersion. For instance, the gelatinization temperature increased as the glycerol content rose (Tan et al. 2004), but it did not change when triglycerides (Chiotelli and Le Meste 2003) or fatty acids (Zhou et al. 2007) were added to various types of starch in different conditions. In order not to modify gelatinization conditions, additives of the films may be mixed with starch after gelatinization, as Petersson and Stading (2005) have described in films with native potato starch and commercial monoglyceride.

Alkaline medium can also be used to provoke starch gelatinization. The use of an alkali produces starch hydrolysis, which leads to granule disruption. This method is called cold gelatinization and can be used in combination with a low gelatinization temperature step (Bertuzzi et al. 2007). However, some negative effects of cold gelatinization on the final properties of starch films have been described by different authors. These are mainly due to the partial hydrolysis and reduction of the polymer molecular weight which leads to a decrease in film mechanical resistance and poor barrier properties. SEM observations showed a homogeneous matrix when hot gelatinization was carried out, whereas cold gelatinization led to a cracked structure.

Starch formulations with lipids or other nonmiscible components require a homogenization step in order to obtain a stable emulsion and an adequate dispersion of all the components. In general, this step is carried out by means of different equipments, such as a rotor-stator Ultra-Turrax homogenizer (Jiménez et al. 2012a), a Fischer Scientific high-speed homogenizer (Han et al. 2006), or a Brabender Viscograph (Petersson and Stading 2005).

In formulations containing different hydrocolloids, a mixing step is also required to obtain film-forming dispersions. Different studies prepared dispersions by means of a step mixing starch with other polymers. As a consequence of the homogenization step, bubbles are frequently incorporated into the film-forming dispersions. If this occurs, vacuum devices are used (Famá et al. 2006) to remove these bubbles, which can provoke microholes in the final films.

After the gelatinization and homogenization steps, film-forming dispersions must be poured or cast on dishes and allowed to dry in controlled conditions. Casting has been carried out either immediately after the homogenization step or after cooling to a determined temperature, and afterwards, films are dried in controlled conditions in order to eliminate the excess water and to obtain an easily manageable film. Leveled dishes of different materials have been used for film formation, such as Petri dishes of polystyrene, polyethylene, polytetrafluoroethylene (Teflon®), stainless steel, or glass (Jiménez et al. 2012d).

Different film-drying conditions have been applied, without a standard method. Nevertheless drying conditions seriously affect both the film functionality and its physical properties, which make it enormously difficult to compare the properties of the different films. Table 3 summarizes the different conditions used to obtain

Table 3 Conditions of gelatinization and drying for different types of starch films

Starch source	Gelatinization conditions	Drying conditions	References
Sago	85 °C, 30 min	40 °C, 20 h	Abdorreza et al. (2011)
Cassava	70 °C, 1 min	30 °C, 18, 24 h	Bergo et al. (2008)
Corn	Alkaline medium (10 g/L NaOH)	60 °C, 8 h	García et al. (2000)
Pea	Boiling temp, 15 min	Room temp, at least 40 h	Han et al. (2006)
Potato, maize, banana	98 °C, 30 min	40 °C, 48 h	Hernández et al. (2008)
Quinoa	97 °C, 30 min	34–50 °C, 55 % RH, for different times	Araujo-Farro et al. (2010)

starch films from distinct sources. Most of the studies used glycerol as plasticizer, while some films were obtained with sorbitol and polyethylene glycol (Abdorreza et al. 2011). It is necessary to add plasticizers so as to adequate the film mechanical properties, thus reducing its brittleness. The kind of starch and plasticizer and the process conditions greatly affect the film properties.

2.2.2 Dry Process

The casting method, described above, involves conditions that do not permit large-scale manufacturing. The production of starch films by means of thermoplastic treatment is more appropriate. As native starch is not a thermoplastic material, it must be processed in order to obtain this characteristic. Thermoplastic starch (TPS) is generally produced by processing a starch–plasticizer(s) mixture in an extruder (or other melt-blending equipment) at temperatures between 140 °C and 160 °C, under high-pressure and high-shear conditions. The result of the process is the disruption of starch granules and the mixture with plasticizers, in order to obtain a rubbery material, without brittleness (Forsell et al. 1997). Carvalho (2008) described TPS as an amorphous or semicrystalline material composed of gelatinized or destructurized starch containing one plasticizer or a mixture of them.

According to Liu et al., starch can be thermally processed by means of different techniques (2009), such as sheet/film extrusion, foaming extrusion, injection molding, compression molding, and reactive extrusion (a special type of extrusion in which chemical reaction and typical extrusion take place). These techniques can be used with starch in combination with both natural and petroleum-derived polymers (Frost et al. 2011).

The thermal process of starch usually includes two steps. First, the starch is mixed with plasticizers and extruded in order to disrupt the starch granules, thus obtaining TPS, followed by a final step in which the obtained paste (or pellets) is thermo-molded to form films. Once the starch is in an amorphous state, it can be injection molded, extruded with a film-blowing die, or thermopressed (Jiménez et al. 2012d).

The thermal processing of starch biopolymers also involves several chemical and physical changes (water diffusion, granule expansion, gelatinization,

decomposition, melting, and crystallization) in the starch granules in which gelatinization plays an important role in the conversion of starch to a thermoplastic (Liu et al. 2009). In this case, gelatinization is achieved at low moisture content due to the high-shear and high-pressure conditions used which tear down the starch granules, allowing faster water transfer into the starch molecules. The mechanical disruption caused by the intense shear conditions provokes a loss of crystallinity in the starch samples.

Different studies analyzed the influence of the extruder's temperature on the properties of the final product and found a significant effect (Li et al. 2011).

3 Active Films Based on Starch

3.1 Antimicrobial Activity of Starch Films

The antimicrobial activity of starch films can be achieved by blending this polysaccharide with another polymer exhibiting antimicrobial activity or by adding natural antimicrobial compounds or nanoparticles. Examples of innovative bioactive starch films are shown in Table 4.

Chitosan is a nontoxic, biodegradable, biocompatible, and antimicrobial material and can be used both as a matrix or an additive for packaging materials. Lopez et al. (2014) obtained thermoplastic corn starch films with chitosan by melt-mixing and thermo-compression. These films exhibit antimicrobial properties against Gram-positive and Gram-negative bacteria (*Staphylococcus aureus*, *Escherichia coli*). In addition, the starch–chitosan association improves the mechanical and barrier properties of the starch matrix. Authors reported an increase in both the tensile strength and elastic modulus. Moreover, by adding 10 g of chitosan or chitin to 100 g of starch, water vapor permeability decreases by 35 % and 56 %, respectively. Others studies showed more complex polymer associations. Bie et al. (2013) developed an antimicrobial material based on poly(lactic acid)/starch–chitosan blends, with slow-release properties, in which chitosan acted as an antimicrobial agent while PLA and starch together were used as a slow-releasing device. The release of chitosan was observed to occur in two stages, initially with a very fast release stage and afterwards with a slow, but durable, release stage. These two stages exhibited the effectiveness and long residual action of the antimicrobial property of the blends against two strains (*E. coli*, *S. aureus*).

Natural plant extracts (mainly essential oils or pure substances derived from them) have also been extensively studied as antimicrobial compounds as a result of the increase in consumer demand for a more limited use of chemicals. Several studies reported interesting antimicrobial effectiveness of starch–essential oil composite films (Souza et al. 2013; Ghasemlou et al. 2013; Jiménez et al. 2014). Cinnamon essential oil was successfully incorporated into starch matrix, the films exhibiting significant antimicrobial activity against several fungi (*Penicillium commune* and *Eurotium amstelodami*) (Souza et al. 2013). In this study, the addition of cinnamon essential oil significantly modifies the film mechanical properties.

Tapioca starch/natamycin/nisin	*Listeria innocua* *Saccharomyces cerevisiae*	Olle Resa et al. (2014)

The tensile strength (TS) and elongation at break (E) of films with incorporated cinnamon essential oil varied from 2.3 ± 0.4 to 1.05 ± 0.16 MPa and from 260 ± 35 to 190 ± 20 %, respectively. Therefore, an increase in the content of cinnamon essential oil, glycerol, and emulsifier lowered the TS and the E of the films. Of the natural compounds, enzymes with antimicrobial activity can be added to the starch matrix. A recent study reported that the incorporation of lysozyme (0, 50, 75, and 100 mg lysozyme/g hydrocolloid) to starch films was effective at reducing *Listeria monocytogenes* growth in vitro at 10 °C (Fabra et al. 2014). Antimicrobial peptides can also be incorporated into the starch matrix to obtain active films. In this sense, ε-poly-L-lysine was added to corn starch films (Zhang et al. 2015). This peptide is a homo-poly(amino acid) characterized by a peptide bond between the α-carboxyl and the ε-amino groups, which is industrially produced by *Streptomyces albulus*. ε-Poly-L-lysine molecules are cationic, surface-active agents due to their positively charged amino groups in water, and they have been shown to have a wide antimicrobial spectrum by growth inhibition studies on

yeast, fungi, and Gram-positive or Gram-negative bacteria. In this study, the antimicrobial activity of starch films with ε-poly-L-lysine against bacteria and molds (*E. coli*, *Bacillus subtilis*, *Aspergillus niger*) was tested. Authors concluded that composite films exhibited poor antifungal activity but effective inhibition against *E. coli* and *B. subtilis*. Films containing 2 % (w/w) antimicrobial peptide effectively inhibited the growth of the tested bacteria ($P < 0.05$).

Other common antimicrobial compounds, used in edible films, are nanoparticles. The nanocomposites obtained by the incorporation of the low percentage of clay to starch films exhibit interesting barrier, thermal, and oxidative properties in comparison with the pure film. Barzegar et al. (2014) showed that the addition of potassium sorbate to the starch–nanoclay films leads to an increase in water vapor permeability and elongation at break and a decrease in tensile strength. A minimum concentration of 7.5 % of sorbate inhibits the growth of *A. niger* in vitro. In this study, the authors conclude that these active starch–clay nanocomposite films could be successfully applied to preserve foods, especially bakery products. Yoksan and Chirachanchai (2010) developed silver nanoparticle-loaded chitosan–starch films. The incorporation of silver nanoparticles led to a slight improvement in the tensile and oxygen gas barrier properties of the films, with diminished water vapor/moisture barrier properties. In addition, silver nanoparticle-loaded films exhibited enhanced antimicrobial activity against *E. coli*, *S. aureus*, and *B. cereus*.

The control of the release of antimicrobial compounds is a complex phenomenon. The diffusion of the antimicrobials is dependent on numerous factors, such as the film structure, the food characteristics, and the storage conditions (Cagri et al. 2004). The degree of interactions between the active compound and the polymer matrix could also affect the release of the antimicrobial. Fabra et al. (2014) studied the effect of the incorporation of lysozyme on the microbial properties of starch films against a foodborne pathogen, *L. monocytogenes*. The authors reported that the structure of the film and the possible interactions existing between the polymer and enzyme must be considered to understand the antimicrobial effectiveness of the starch films.

3.2 Antioxidant Activity of Starch Films

Starch films do not exhibit antioxidant activity naturally, but the addition of antioxidant compounds, such as α-tocopherol, was evaluated in recent studies (Table 5). α-Tocopherol is a lipid-soluble antioxidant whose antioxidant activity has been clearly documented (Ruperez et al. 2001; Manzanarez-Lopez et al. 2011). Like other tocols (tocopherols and tocotrienols), α-tocopherol acts as a free radical scavenger specifically within cell membranes, by preventing the oxidation of polyunsaturated lipids by free radicals, especially hydroxyl radical OH (Hejtmánková et al. 2010). Jiménez et al. (2013) reported that the incorporation of α-tocopherol greatly increased the antioxidant capacity of starch–sodium caseinate films (1.37 ± 0.06 instead of 0.249 ± 0.002 mM Trolox equivalent antioxidant capacity). Polyphenol, such as tannic acid, could be equally added to the starch matrix to

Table 5 Examples of starch films with antioxidant properties

Film composition	Method	References
Corn starch/sodium caseinate/oleic acid/α-tocopherol	*Trolox* (*ABTS*)	Jiménez et al. (2013)
Corn starch/buttermilk	*Trolox* (*ABTS*)	Moreno et al. (2014)

Cassava starch/essential oils (cinnamon, fennel)	*DPPH*/*FRAP*	Oriani et al. (2014)

confer antioxidant properties (Pyla et al. 2010). Tannic acid, present in a variety of plants and fruits, is considered as a "generally recognized as safe" (GRAS) food additive. In this study, the antioxidant activity of starch films containing tannic acid on soybean oil, doubling the induction time of oil oxidation, was shown.

4 Physical Properties of Active Starch Films

4.1 Barrier Properties

One of the main functions of food packaging is to avoid or minimize moisture transfer between the food and the surrounding atmosphere. Water vapor permeability (WVP) should, therefore, be as low as possible in order to optimize the food package environment and potentially increase the shelf life of the food product (Hosseini et al. 2013).

The moisture barrier properties of edible films have been studied by many authors. Edible films and coatings made from carbohydrates and proteins generally exhibit lower moisture barriers due to their hydrophilicity (Hiemenz and Rajagopalan 1997). To improve the moisture barrier, hydrophobic compounds, such as lipids, have been added to hydrophilic materials. Surfactants have also been used to reduce the surface tension of the film-forming dispersion, improving the wettability and adhesion of the coating (Ribeiro et al. 2007; Rodríguez et al. 2006). Several authors studied the effect of active molecules on water permeability. As lipids are known to improve water barrier properties, the incorporation of essential oils into edible coatings was an attempt to improve the water vapor barrier. Lipids that are solid form coatings with a better water vapor barrier than liquid lipids (Olivas and Barbosa-Cánovas 2005). Essential oils are liquid, which could justify the slight reduction of the water vapor transmission rate (WVTR) when they are incorporated in the film formulation. No differences in the WVTR of the coatings based on cassava starch (CS) were observed when essential oils were added at low concentrations. Oriani et al. (2014) analyzed the effect of different concentrations of cinnamon bark and fennel essential oils in edible cassava starch (CS) coatings applied to apple samples. Edible coatings prepared with 2 % and 3 % CS and 0.30 % (v/v) essential oils (fennel or cinnamon bark) exhibited similar WVTR values, although they were significantly different to that obtained for uncoated fruit.

Ghasemlou et al. (2013) developed an antimicrobial film based on corn starch and two essential oils from *Zataria multiflora* Boiss (ZEO) or *Mentha pulegium* (MEO) at three concentration levels (1 %, 2 %, and 3 % (v/v)). The obtained results indicate that there was a significant difference ($P < 0.05$) in the WVP values between films containing ZEO or MEO and the control films. The addition of ZEO or MEO improved the barrier properties of starch films, decreasing the WVP by up to 50 % relative to the control sample. The lower WVP of the starch films containing either ZEO or MEO was attributed to the hydrogen and covalent interactions between the starch network and these polyphenolic compounds.

The oxygen and carbon dioxide permeabilities of biodegradable films or coatings are also an important characteristic to take into account when respiration or oxidation reactions could affect product quality. Edible films with antioxidants could provide continuous protection for foods against oxidation during storage or after opening, while also providing a recyclable packaging material (Min and Krochta 2007; Kleen et al. 2002; Herald et al. 1996). Edible films and coatings can prevent the deterioration of many food products because they often possess excellent oxygen barrier properties. Thus, the relationship between antioxidant addition and any oxygen permeability change in the films is of immediate concern. According to Ghasemlou et al. (2013), the presence of essential oils from *Zataria multiflora* Boiss (ZEO) or *Mentha pulegium* (MEO) modifies the oxygen permeability (OP) of composite corn starch films. The OP value of the pure starch film was 12.11 $cm^3 \mu m m^{-2} day^{-1} kPa^{-1}$, indicating that this film is a very good oxygen barrier. The incorporation of 3 % (v/v) ZEO to the starch film increased the permeability value to 16 $cm^3 \mu m m^{-2} day^{-1} kPa^{-1}$.

4.2 Mechanical Properties

The mechanical properties of edible films and coatings depend on the type of film-forming material and especially on its structural cohesion. Cohesion is the result of a polymer's ability to form strong and/or numerous molecular bonds between polymeric chains, thus hindering their separation. This ability depends on the polymer structure and especially molecular strength, geometry, molecular weight distribution, and position of its lateral groups (Guilbert et al. 1996). The mechanical properties of edible coatings are greatly affected by the physical, chemical, and temperature conditions, which influence the film stability and flexibility. Moreover, it is well known that the environmental conditions during the production, storage, and use of these materials affect their mechanical properties (Garcia et al. 2009).

Perazzo et al. (2014) have developed an innovative active food packaging from cassava starch containing green tea and palm oil carotenoid extracts, as active natural compounds to be used as packaging for fatty products, thus adding value to different agro-industrial chains. They showed that the addition of colorant and green tea extract significantly improved the functional properties of the resulting films. These changes were attributed to the interactions between functional groups

of starch, colorant, and polyphenols of green tea extract which give rise to a cohesive molecular reorganization, thus providing greater rigidity to the material compared to the controls.

Moreno et al. (2014) studied the effect of buttermilk (BM) incorporation on the properties of the film-forming dispersions and the mechanical characteristics of corn starch films. The impact that heat treatment has on films containing buttermilk was analyzed. The incorporation of BM to starch films provoked a significant decrease in film stiffness and resistance to break without any notable changes in film stretchability, except for 60 % of non-heated BM, when films become more extensible but very soft.

Bonilla et al. (2013) showed the effect of adding different antioxidants – essential oils (basil and thyme), citric acid, and α- tocopherol – on the mechanical behavior of wheat starch–chitosan films. The incorporation of active compounds had different effects on the mechanical parameters, depending on their specific nature. Citric acid promoted an increase in the elastic modulus but a decrease in the tensile strength and deformation at break, probably due to cross-linking with starch chains.

4.3 Optical Properties

The functionalization of a biodegradable film, such as starch, as an active packaging or coating can either improve the visual presentation of the packaging or the food product or, on the contrary, decrease their attractiveness. This is one of the most important limits to the use of biodegradable films on an industrial scale. The objective of most coating producers is to reach transparency or at least to reach the same color as the product surface so as to make it very discreet. The main case where color is not a problem is chocolate, for which the visible brown color is an attractive part of the food product. This particular attractiveness offers new developments for food coatings, because young consumers are always attracted by a new product with unexpected colors.

Moreno et al. (2014) show the spectral distribution of the internal transmittance (Ti) of the films, as an indicator of the translucency level. The internal transmittance decreased as the buttermilk content rose in the starch films, mainly at low wavelengths, which indicates a rise in the film opacity. This was explained by the formation of a more heterogeneous structure with changes in the refraction index through the film structure, which promotes light dispersion. As the ratio of the dispersed phase (BM components) becomes higher, a loss in transparency occurs.

Ghasemlou et al. (2013) show the color parameters, **L**, **a**, and **b**, and the total color difference (ΔE) values for pure starch-based films and those containing essential oils. There were no differences observed between the **a** values of any film studied. Generally, starch films with *Zataria multiflora* Boiss (ZEO) exhibited higher L values but lower b values than those with *Mentha pulegium* (MEO), although films with MEO were darker in appearance. According to Bonilla et al. (2013), the functionalization of wheat starch–chitosan films with essential

oils (basil and thyme), citric acid, and α- tocopherol modified the visual aspect. All the antioxidants provoked a loss in film gloss but a gain in transparency, while α-tocopherol induced yellowness and a reduction in the whiteness index.

5 Conclusion

Starch has been used to develop edible, biodegradable, active films using different strategies: blending with antimicrobial polymers, active nanoparticles, and other antioxidant or antimicrobial compounds, such as essential oils of phenolic extracts. In most of the cases, films or coatings were obtained by casting the film-forming dispersions containing the active compounds. However, the industrial production of films requires the use of thermo-processing applied to conventional plastics. Starch can be processed in this way, but a great number of the active compounds are thermolabile and cannot be submitted to the high temperatures used in these processes. Likewise, the incorporation of active compounds to the polymer matrix provokes positive or negative changes in their functional properties that must be evaluated, together with the release kinetics of antimicrobials/antioxidants into the food system. The extension of active polymer layers on thermo-processed films can be a good strategy with which to obtain active films, avoiding the thermostability problems of active compounds. The properties of both the bilayer films and the bioactive release kinetics must be studied so as to offer adequate starch active packaging materials for food preservation

Contents

Abstract

An increasing consumer trend towards healthy and additive-free food has made dextran from food grade lactic acid bacteria (LAB) an attractive solution. Dextrans are homopolysaccharides of D-glucose produced by extracellular dextransucrase released from LAB of the genera, viz., *Leuconostoc*, *Lactobacillus*, *Streptococcus*, *Weissella*, and *Pediococcus*. Dextrans have been known for their viscosifying, emulsifying, texturizing, stabilizing attributes in food

applications. Dextran has the potential to be recruited as a novel ingredient replacing the commercial hydrocolloids in bakery and other food industries. Prebiotic oligosaccharide production by hydrolysis of dextran is a rather new field, garnering research and industrial attention. The applications, available sources, preparation, and characterization of dextran and problems associated with its use have been discussed. This chapter also highlights the key developments in recent times and discusses the importance of bio-prospecting novel dextran-producing isolates from biodiversity.

Keywords
Dextran • Dextransucrase • Exopolysaccharide • Food • Lactic acid bacteria

1 Introduction

The progressively increasing demand of natural polymers for various industrial applications has led to the exploration of microbial exopolysaccharide (EPS) in recent years. Among several EPS, dextran has gained worldwide recognition due to its biodegradability and biocompatibility properties (Patel et al. 2010; Aman et al. 2012; Varshosaz 2012). The EPS dextran was first discovered by Louis Pasteur (1861) as a microbial product in wine. Scheilber in 1874 confirmed that this microbial polysaccharide has a positive (dextrorotatory) optical rotation with the empirical formula $(C_6H_{10}O_6)_n$ and therefore named as "dextran." The physiological roles of EPS in the microbial host are not yet completely understood, but they are involved in protection against dehydration, pathogenicity, biofilm formation, and quorum sensing. The presence of a dextran layer around the bacterial cell may have paramount effects on the cellular diffusion properties. Dextran has gained importance owing to its applications in the food, pharmaceutical, biomaterial, photo film manufacturing, and fine chemical industries. A large number of lactic acid bacteria (LAB) are known to produce dextran.

Hehre in 1941 reported the first cell-free synthesis of dextran using sucrose as the substrate from enzyme dextransucrase. Dextransucrase (sucrose: 1,6-α-D-glucan 6-α-glucosyltransferase) is the key enzyme that catalyzes the synthesis of dextran from sucrose. Dextrans generally vary in their molecular weight, spatial arrangement, type and degree of branching, and length of branched chains, depending on the source of strains and also on the cultivation conditions. A survey of dextrans from 96 strains (primarily *Leuconostoc mesenteroides*) demonstrated that the amount of α-(1 → 6) linkages in a specific dextran can vary from 50 % to 97 % of the total glycosidic linkages (Jeanes et al. 1954). Apart from α-(1 → 6) linkages in main chain, dextrans also contain α-(1 → 2)-, α-(1 → 3)-, and α-(1 → 4)-branched linkages. Branched dextrans have also been reported to possess prebiotic (Das et al. 2014) and anticancer potentials (Shukla and Goyal 2013).

Dextrans are extracellular bacterial homopolysaccharides with a linear backbone of α-linked D-glucopyranosyl repeating units. Dextrans belong to α-D-glucans

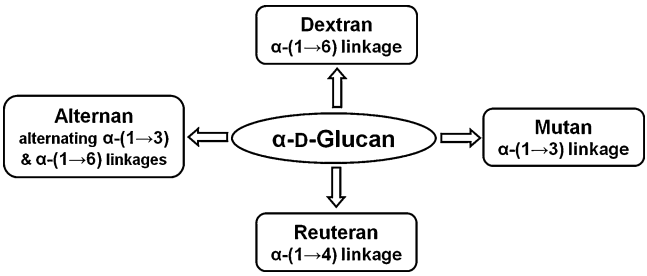

Fig. 1 Classification of α-D-glucan depending upon the type of linkages

containing α-(1 → 6) linkage in the main chain and variable amounts of α-(1 → 2)-, α-(1 → 3)-, or α-(1 → 4)-branched linkages. There are four distinct types of α-D-glucan produced by LAB (Fig. 1): (i) mutan contains a majority of α-(1 → 3) linkages in main chain and is produced by *Streptococcus* species; (ii) alternan containing alternating α-(1 → 3) and α-(1 → 6) linkages, reported only in *L. mesenteroides*; (iii) reuteran containing α-(1 → 4) linkages found only in *Lactobacillus reuteri* (Monchois et al. 1999; van Leeuwen et al. 2008); and (iv) dextran containing α-(1 → 6) linkages in main chain and α-(1 → 2)-, α-(1 → 3)-, or α-(1 → 4)-branched linkages (Jeanes et al. 1954; Naessens et al. 2005; Kothari and Goyal 2013). The production of dextran has been extensively studied in LAB of genera, viz., *Leuconostoc*, *Streptococcus*, *Lactobacillus*, *Weissella*, and *Pediococcus*.

2 Sources of Dextran

Dextran occurs naturally in small amounts in foods, such as refined crystalline sugar, maple syrup, sauerkraut juice, and honey, and also as a component of dental plaque. Dextran is synthesized by the action of bacterial enzyme, dextransucrase, on sucrose. Dextransucrase is the sole industrial enzyme used in the commercial production of dextran and is produced by LAB of genera, viz., *Leuconostoc*, *Streptococcus*, *Lactobacillus*, *Pediococcus*, and *Weissella*. The structure of each type of dextran depends on the microbial strain and hence on the specific dextransucrase. To date, commercial dextran is produced from *Leuconostoc mesenteroides* NRRL B-512F and serves as a model in studying the structure of dextran and the mechanism of its biosynthesis by dextransucrase (Robyt et al. 2008; Siddiqui et al. 2014).

The amount of dextran produced however is practically insufficient to meet the dextran requirements of the various industries; hence, there is the need for the isolation and characterization of hyper dextran-producing LAB. Several examples of dextran with their linkage pattern from LAB isolated from various food sources are mentioned in Table 1.

Table 1 Dextrans with their linkage pattern from different LAB isolated from various food sources

Microorganism	Source	Linkage	References
Leuconostoc mesenteroides CMG713	Grape	α-(1 → 6) linkages only	Sarwat et al. (2008)

Weissella cibaria CMGDEX3	Cabbage	96.6 % α-(1 → 6) and 3.4 % α-(1 → 3)	Ahmed et al. (2012)
Weissella confusa Cab3	Fermented cabbage	97 % α-(1 → 6) and 3 % α-(1 → 3)	Shukla et al. (2014)
Weissella cibaria JAG8	Apple peel	93 % α-(1 → 6) and 7 % α-(1 → 3)	Rao and Goyal (2013)

3 Dextransucrase

Dextransucrases (EC. 2.4.1.5) are the sole industrial enzymes used in the commercial production of dextran (Parlak et al. 2013). Dextransucrase is classified in the family of glucansucrase, and most of the enzymes classified in this family use sucrose as the D-glucopyranosyl donor to synthesize α-D-glucans of high molecular mass with the concomitant release of D-fructose. They are also referred to as glucosyltransferases (GTF) because they synthesize α-glucan polymers using the glucose unit of sucrose (Leemhuis et al. 2013). Glucansucrases have been listed within family 70 glycoside hydrolase (GH70) in carbohydrate-active enzyme database (http://www.cazy.org/Glycoside-Hydrolases.html) based on sequence similarity (Cantarel et al. 2009; Vujicic-Zagar et al. 2010). They are evolutionarily closely related to the enzymes such as amylosucrase, cyclodextrin glucanotransferase, amylomaltase, and α-amylase from families GH13 and GH77 (Cantarel et al. 2009). Together with the families GH13 and GH77 enzymes, they form the clan GH-H (Vujicic-Zagar et al. 2010; Leemhuis et al. 2013). However, glucansucrases are much larger enzymes (~1,600–1,800 amino acid residues) than GH13 and GH77 (~500–600 amino acids), and they contain an N-terminal domain of variable region of unknown function (Vujicic-Zagar et al. 2010). Glucansucrases usually display a $(\beta/\alpha)_8$ barrel-shaped protein folding pattern and the acid–base-assisted substrate catalysis via a double-displacement (retaining) mechanism. GH70 enzymes are transglucosylases produced by LAB of genera, viz., *Streptococcus*, *Leuconostoc*, *Weissella*, and *Lactobacillus* (Monchois et al. 1999;

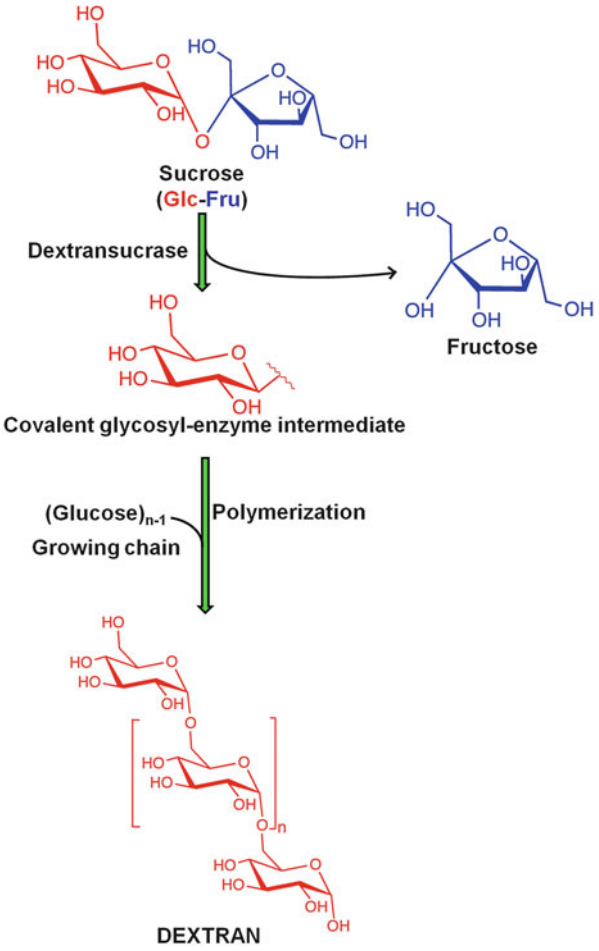

Fig. 2 Double-displacement mechanism of dextransucrase reaction (Adapted from Leemhuis et al. 2013)

Ito et al. 2011; Leemhuis et al. 2013). Four distinct types of GH70 glucansucrases have been identified based on the polysaccharides produced by them (Andre et al. 2010).

- Dextransucrase (E.C. 2.4.1.5): dextran, containing above 50 % α-(1 → 6) linkages
- Mutansucrase (E.C. 2.4.1.5): mutan, containing above 50 % α-(1 → 3) linkages
- Reuteransucrase (E.C. 2.4.1.5): reuteran, containing above 50 % α-(1 → 4) linkages
- Alternansucrase (E.C. 2.4.1.140): alternan, containing alternating α-(1 → 3) and α-(1 → 6) linkages

The enzyme dextransucrase synthesizes dextran from sucrose with concomitant release of fructose by double-displacement mechanism (Fig. 2). In the first stage of

double-displacement reaction, α-(1 → 2) glycosidic linkage of sucrose is cleaved with the release of fructose, and a glucosylenzyme intermediate is formed, in which the glucosyl unit is covalently attached to the catalytic nucleophile via a β-glycosidic linkage. In the second stage of reaction, the covalently bound glucosyl moiety is transferred to the accepting nonreducing end of sugar of a growing glucan chain, with reformation of the α-glycosidic bond (Leemhuis et al. 2013).

4 Preparation of Dextran

Dextran is produced commercially by cultivating *L. mesenteroides* strains in situ in growth medium supplemented with sucrose and in vitro by using purified dextransucrase with sucrose as a substrate (Leemhuis et al. 2013). The dextran of desired molecular weight can be achieved by the direct enzymatic synthesis using purified dextransucrase, which allows more control over the reaction conditions as compared with the fermentative synthesis (Falconer et al. 2011). The production of dextran by dextransucrase from LAB is affected by factors like temperature, aeration, and concentration and type of medium components (Tsuchiya et al. 1952; Lazic et al. 1993; Purama and Goyal 2005; Bejar et al. 2013). Dextran production is also influenced by solubility, viscosity, nitrogen, phosphorus, and ash content of the medium (Jeanes et al. 1954). The molecular weight of dextran is inversely proportional to the concentration of enzyme and directly proportional to the concentration of sucrose. Moreover, the molecular weight of dextran increases as the temperature increases from 20 °C to 30 °C (Falconer et al. 2011). Several physical and chemical techniques such as UV irradiation (Patel and Goyal 2010; Agrawal et al. 2011; Siddiqui et al. 2013), ethyl methanesulfonate (Kim and Robyt 1994) and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (Kitaoka and Robyt 1998), and site-directed mutagenesis (Funane et al. 2005) have been used for the enhancement of dextransucrase and dextran production from various LAB.

A single dextransucrase can catalyze the synthesis of several types of dextran linkages, thereby permitting the formation of a branched polymer (Neely and Nott 1962; Smith et al. 1994). Certain bacterial strains have been shown to produce dextrans of different structures due to the elaboration of different dextransucrases (Cote and Robyt 1982; Zahnley and Smith 1995). Thus, the structure of each dextran is a characteristic of the specific dextransucrase produced by a specific microbial strain (Jeanes et al. 1954; Vettori et al. 2012; Kothari and Goyal 2013).

5 Properties of Dextran

5.1 Physicochemical Properties

Dextran polymers have a remarkable diversity in chain length and in physicochemical properties due to the variation in degree of branching in their glucose backbone. In general, dextran is readily soluble in water, dimethyl sulfoxide, formamide,

ethylene glycol, and glycerol but insoluble in monohydric alcohols, e.g., methanol, ethanol, and isopropanol, and also most ketones, e.g., acetone and 2-propanone. However, the water solubility of dextrans depends upon the branched linkage pattern. Linear dextrans have high water solubility, and the aqueous solutions behave as Newtonian fluids. However, some branched dextrans showed shear rate thinning effect, exhibiting non-Newtonian pseudoplastic behavior (Das and Goyal 2014). Viscosity of dextran solution depends on its concentration, temperature, and molecular weight. As dextran is a neutral polysaccharide, the viscosity is not significantly influenced by changes in pH or salt concentration. Dextrans with >43 % branching through α-(1 → 3) linkages are water insoluble. Dextrans have molecular weight in the range of 3–500,000 kDa. Dextrans with a molecular weight of 2,000–10,000 kDa exhibit the properties of an expandable coil, and at lower molecular weights (<2,000 kDa), dextran is more rodlike. Low molecular weight dextrans (40, 60, and 70 kDa) are generally preferred in clinical applications (Naessens et al. 2005). High molecular weight dextrans with few branched linkages are required for the application in sourdough (Lacaze et al. 2007). The surface morphological studies of dextran revealed a porous structure (Shukla and Goyal 2013; Das and Goyal 2014). The dextran has excellent thermal stability with degradation temperature ~300 °C (Das et al. 2014; Rao et al. 2014).

5.2 Structural Properties

The specificity of the synthesized linkages in the dextran is strain dependent. The most studied dextran is produced by *Leuconostoc mesenteroides* NRRL B-512 F. It contains 95 % α-(1 → 6) linkages and 5 % α-(1 → 3)-branched linkages (Naessens et al. 2005; Vettori et al. 2012). *L. mesenteroides* NRRL B-742 produces a dextran with 87 % α-(1 → 6) linear linkages and 13 % α-(1 → 4)-branched linkage. The strain *L. mesenteroides* NRRL B-1299 produces a rare kind of dextran with 63 % α-(1 → 6), 27 % of α-(1 → 2), and 8 % of α-(1 → 3) linkages (Remaud-Simeon et al. 2000). The molecular structure of dextran is shown in Fig. 3.

6 Characterization of Dextran

The structural characterization of dextran is an important factor for its utilization. A general strategy for dextran characterization is shown in Fig. 4.

6.1 Isolation of Pure Dextran

The structural analysis of dextran starts with its isolation in pure form in such a way that the chemical and physical properties are not affected (Leemhuis et al. 2013). The recovery or purification from culture medium or enzymatic reaction mixture generally involves the following steps: (i) cell removal by centrifugation or filtration

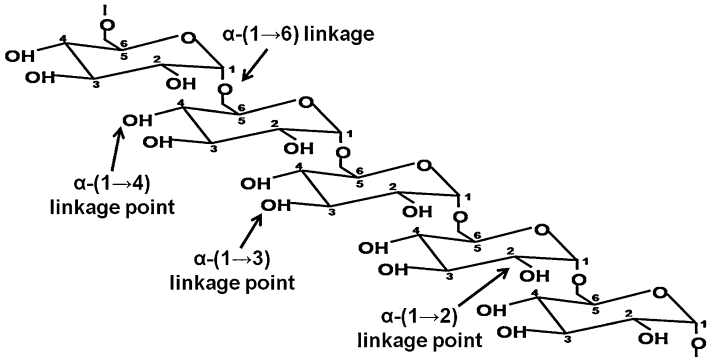

Fig. 3 Structure of dextran showing α-(1 → 6) glycosidic bonds in main chain and possible branches of smaller chains with α-(1 → 2), α-(1 → 3), or α-(1 → 4) linkages

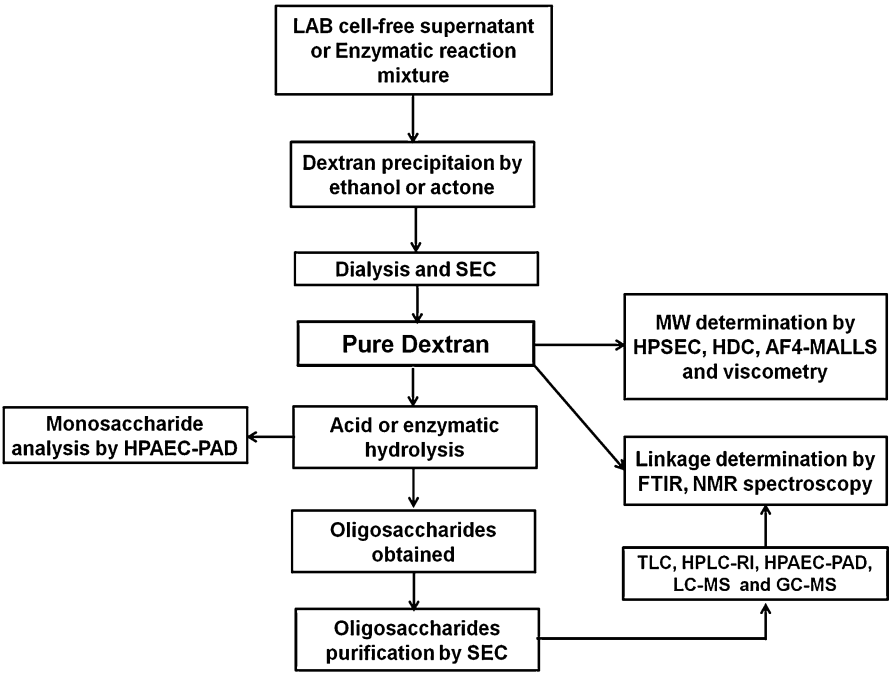

Fig. 4 A general strategy for the characterization of dextran

in case of culture medium, (ii) dextran precipitation from the cell-free supernatant or enzymatic reaction mixture by the addition of water-miscible organic solvents (e.g., ethanol, acetone, etc.), (iii) re-precipitation and dialysis of dextran, and (iv) size-exclusion chromatography (SEC) of dextran (Vettori et al. 2012; Shukla et al. 2014; Das et al. 2014). The high molecular weight dextran can be purified by SEC; however, low molecular weight dextran can be purified by ultrafiltration.

6.2 Molecular Weight Analysis

The molecular weight (MW) of dextran can be determined by colorimetric determination of reducing sugar, viscometry, hydrodynamic chromatography (HDC), high performance size-exclusion chromatography coupled with refractive index detector (HPSEC-RI), or with multi-angle laser light scattering (HPSEC-MALLS) (Leemhuis et al. 2013). However, higher branched polysaccharides are not well fractionated by means of classical SEC due to their shear scission, low exclusion limit (Cave et al. 2009), and limited resolution (Vilaplana and Gilbert 2010). Avoiding these problems, asymmetrical flow field flow fractionation (AF4) has emerged as a powerful technique for determination of the macromolecular structure of high molar mass branched biopolymers up to 10^8 Da (Rolland-Sabate et al. 2011). Recently, AF4 coupled with MALLS have been used to determine the MW of hyperbranched α-glucans (2×10^6 to 4.3×10^7 Da) (Rolland-Sabate et al. 2014).

6.3 Structural Unit and Glycosidic Linkage Analyses

The monosaccharide composition of dextran can be determined by acid hydrolysis followed by high-pH anion-exchange chromatography with pulsed amperometric detection (HPAEC–PAD) (Mopper et al. 1992; Kothari and Goyal 2013; Shukla et al. 2014). The structural characterization of dextran can also be accomplished by well-known techniques such as one-dimensional (^{1}H and ^{13}C) or two-dimensional (TOCSY, NOESY, ROESY, and HMQC) nuclear magnetic resonance (NMR) spectroscopy, Fourier transform infrared (FTIR) spectroscopy, and scanning electron microscopy (SEM) (Maina et al. 2008; Bounaix et al. 2010; Vettori et al. 2012; Shukla et al. 2014). To elucidate the structure of larger dextrans, it is often necessary to prepare oligosaccharides from the native polysaccharide by mild acid or enzymatic hydrolysis (Leemhuis et al. 2013). These oligosaccharides are then identified by thin layer chromatography (TLC), high performance liquid chromatography with refractive index detector (HPLC–RI), HPAEC–PAD, mass spectrometry coupled with liquid or gas chromatography (LC–MS or GC–MS), and FTIR and NMR spectroscopy (Naessens et al. 2005). Finally, by combining the dextran analysis data as well as structural information of the oligosaccharides produced will unveil all the structural features of the dextran (van Leeuwen et al. 2008).

7 Food Applications of Dextran

Dextran has been studied as a food ingredient since the 1950s. The US Food and Drug Administration (US FDA) currently lists dextran as GRAS (generally recognized as safe) additive for food and feed applications. In general, dextran is used as gelling, viscosifying, texturing, and emulsifying agent in various food products (Leemhuis et al. 2013). Commercial applications of dextran from LAB are

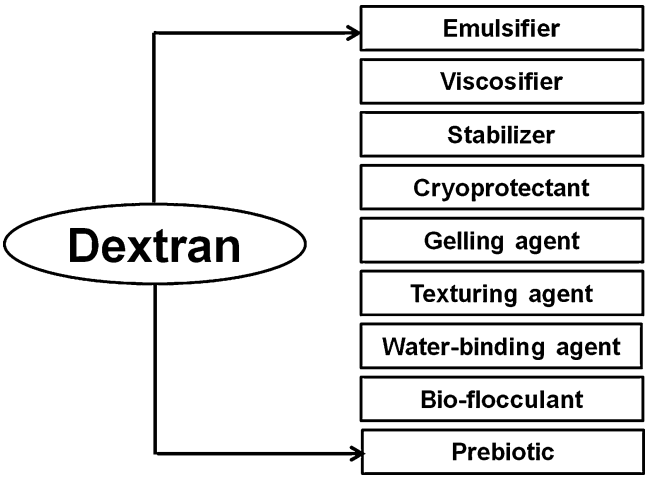

Fig. 5 Properties of dextran used in food industry

generally found in food and pharmaceutical industry; however, dextran also has several potential applications in photo film manufacturing, fine chemical, cosmetic, paper, petroleum, and textile industries (Naessens et al. 2005; Leemhuis et al. 2013). Due to the heterogeneity of dextran produced by various LAB, their application may depend on well-defined chemical and physicochemical properties. The properties of dextran that are applied in food industry are shown in Fig. 5.

Long-chain, high molecular weight polysaccharides that dissolve or disperse in water to give improved rheological (gelling, thickening) or physicochemical (emulsion stabilization, particle suspension, etc.) properties are important for food product formulation. A current consumer trend towards healthy and additive-free food has made the dextran an attractive food ingredient (Table 2). The microorganisms such as *Leuconostoc mesenteroides*, *Saccharomyces cerevisiae*, *Lactobacillus plantarum*, and *Lactobacillus sanfrancisco* are used for the production of dextran for its application in food processing without any restriction.

7.1 Bakery

The incorporation of dextran in bread for the improvement of rheological properties and quality is gaining interest (Galle et al. 2012; Wolter et al. 2014). The increasing knowledge of sourdough fermentation generates new opportunities for its use in the bakery field. In situ dextran production from *Weissella* sp. and *Leuconostoc mesenteroides* improved the freshness, mouthfeel, texture, loaf volume, softness, and shelf life of sourdough wheat bread (Katina et al. 2009; Galle et al. 2012). It came forth that dextran should have a high molecular weight and few branched linkages for the application in sourdough (Lacaze et al. 2007). The European Commission has approved the use of dextran in baked goods, up to the levels of 5 %.

Table 2 Food applications of dextran

Applications	References
Bakery	Katina et al. (2009)
Improves freshness, mouthfeel, softness, crumb texture, loaf volume, and shelf life	
Confectionary	Maina et al. (2011)
Improves moisture retention and viscosity and inhibits sugar crystallization and as gelling agents in gum and jelly candies	
Fermented dairy products	Mende et al. (2013)
Increases viscosity and creaminess and reduces syneresis	
Ice cream	Naessens et al. (2005)
Cryoprotectant	
Frozen and Dried foods	Bhavani and Nisha (2010)
Protection from oxidation and chemical changes and preservation in texture and flavor	
Cheese making: reduced-fat cheese	Awad et al. (2005)
Improves water binding and increases moisture content in the nonfat substances	
Prebiotics	Olano-Martin et al. (2000), Sarbini et al. (2013), Rao et al. (2014), Das et al. (2014)
Functional food	
Protein–dextran conjugates	Zhang et al. (2012), Chen et al. (2014), Spotti et al. (2014)
Improves emulsifying, foaming, gelling, and solubility attributes of protein by Maillard reaction	

The addition of 2 % native dextran increases the water absorption of flour dough by about 12 %. However, in situ formation of dextran in sourdough was reported to be more effective than external addition (Brandt et al. 2003). High molecular weight dextrans of (1–2) $\times$ 10^6 Da have been approved by the European Union as food ingredients in bakery products (Naessens et al. 2005). The required molecular mass has been reported to be from 2 $\times$ 10^6 to about 4 $\times$ 10^6 Da (Katina et al. 2009).

Celiac disease is an autoimmune, nutrient-induced disorder, triggered in genetically susceptible individuals by ingesting gluten from wheat, rye, barley, and other closely related cereal grains (Goggins and Kelleher 1994). It was reported that celiac disease is a major health problem affecting around 1 % of population in the western world (Mustalahti et al. 2010). Currently, the only available treatment is the complete avoidance of gluten-containing cereals (Arendt et al. 2011). Gluten is an important protein-building structure which contributes to appearance and crumb structure in many bakery products. The replacement of gluten in bread presents a significant technological challenge due to the low nutritional quality, poor sensory characteristics such as dry crumb, poor mouth feel, and off flavors of gluten-free products (Galle et al. 2012; Hager and Arendt 2013). Hydrocolloids are currently used to substitute gluten and to obtain gluten-free bread with acceptable sensory properties (Galle et al. 2010; Hager and Arendt 2013). Incorporation of sourdough

to a gluten-free formula gained interest recently in bread making. Dextran from *Weissella* and *Leuconostoc* species improves dough rheology and bread texture and can be used to replace nonbacterial hydrocolloids such as guar gum and hydroxypropyl methylcellulose for the generation of gluten-free soft bread with good texture and shelf life (Tieking and Ganzle 2005; Galle et al. 2012). Hence, dextran holds potential application in baking industry for the generation of gluten-free food products for patients suffering from celiac disease (Schwab et al. 2008; Galle et al. 2010; Rao and Goyal 2013).

7.2 Confectionery

Dextran is used for maintaining flavor, viscosity, moisture, inhibition of sugar crystallization, and as gelling agent in gum and jelly candies in confectioneries (Maina et al. 2011). It is also used in soft drinks, flavor extract, milk beverages, and icing.

7.3 Ice Cream

Dextran is also used as a cryoprotectant in ice cream (Naessens et al. 2005). Dextran is bland, odorless, tasteless, and nontoxic and is considered to have many advantages over other ice cream stabilizers. Ice cream mixes containing 2–4 % dextran conferred beneficial properties on viscosity (Bhavani and Nisha 2010).

7.4 Fermented Dairy Products

The texture of yogurt and yogurt-like products made from milk by fermentation with LAB can be modified by in situ production of EPS (Cerning 1995; Tamime and Robinson 1999). EPS produced by LAB, particularly dextran, positively affected the rheological properties of acidified milk gels with enhanced viscosity, creaminess, and reduced syneresis because of its water-binding ability (Mende et al. 2013) and hence can replace the commercially used texturizers, viz., xanthan, carrageenan, pectin, guar gum, and β-glucan.

7.5 Frozen Foods

The favorable properties of dextran for stabilizing vacuum, air-dried, and freeze-dried or frozen foods enable the use of dextran in fish products, meat, vegetables, and cheese. A film of dextran could protect food from oxidation and other chemical changes and also help to preserve texture and flavor. The increasing demand for fast food in frozen or dried state creates an opportunity for the use of dextran as a preservative, as well as a texture, flavor, and smell enhancer (Bhavani and Nisha 2010).

7.6 Reduced-Fat Cheese

The fat reduction in cheese results in many textural and functional defects. The high casein content in reduced-fat cheese imparts a firm and rubbery body and texture. Dextran is a good candidate for making reduced-fat cheese for several reasons. Dextran has the ability to bind water and increase the moisture in the non-fat mass (Awad et al. 2005).

7.7 Prebiotics

In recent years, there is a considerable interest in the use of prebiotics as functional foods in order to modulate the composition of the colonic microbiota to provide health benefits to the host (Saad et al. 2013). Foods containing prebiotic have also been associated with the protection against risk of several diseases, viz., bowel cancer, inflammatory bowel disease, diarrhea, coronary heart disease, obesity, osteoporosis, cholesterolemia, and type 2 diabetes. The α-(1 → 6) linkages are known to be resistant to hydrolysis by human intestinal enzymes, which results in the slow digestion of dextran in human. Moreover, α-(1 → 2) linkages are also highly resistant to the attack of digestive enzymes (Remaud-Simeon et al. 2000). Dextran and dextran-derived oligosaccharides have also been reported to increase the fraction of *Bifidobacterium* species in an in vitro model of the fermentation process in the human colon exhibiting prebiotic activity (Olano-Martin et al. 2000). A low molecular weight dextran containing α-(1 → 2)-branched linkages was also reported to act as prebiotic with selective effect on the gut microbiota (Sarbini et al. 2013). This dextran induced the growth of beneficial bacteria such as *Bifidobacterium* sp. and *Lactobacillus* sp. Recently, dextrans from *Weissella cibaria* JAG8 (Rao et al. 2014) and *Lactobacillus plantarum* DM5 (Das et al. 2014) showed promising prebiotic potential with very low gut digestibility and selective stimulation of probiotics.

7.8 Protein: Dextran Conjugates

Proteins are widely used in the food products such as beverages, yogurt, mayonnaise, and ice creams due to their functional properties, viz., emulsifying, foaming, gelling, and solubility (Oliver et al. 2006; Zhang et al. 2012). The functional properties of proteins can be improved by the conjugation of proteins and polysaccharides through Maillard reaction (Spotti et al. 2014). The Maillard reaction or nonenzymatic browning refers to any chemical reaction involving the interaction between amines and carbonyl compounds. Maillard reaction adds to the aroma, taste, and color of coffee and cocoa beans, bread, cakes, cereals, and meat (Martins et al. 2001). Dextran-conjugated proteins have displayed significant improvement in physical and chemical properties of proteins, such as thermal stability, emulsification, and antioxidant properties (Zhu et al. 2010).

The improvement of functional properties of different proteins, such as ovalbumin, lysozyme (Chen et al. 2014), peanut protein (Liu et al. 2012), soy protein (Zhuo et al. 2013), and whey protein (Spotti et al. 2014), after conjugation with dextrans has been studied.

8 Side Effects of Dextran

Dextrans have acquired the GRAS status from the US FDA, which was renewed in 2013. However, several side effects are also associated with dextran polymer. Dextran is involved in the process of dental caries. Pathogenic bacteria of the genus *Streptococcus* produce insoluble dextran, which favors the adhesion of bacteria on the teeth and causes the formation of dental plaque. The orally ingested dextran rapidly converts into glucose, and therefore, it is harmful to the diabetic patients. The swelling or osmotic effect of dextran is also associated with acute renal failure in patients. It has also been reported that the high molecular weight dextran induces anti-dextran antibodies, leading to anaphylactoid reactions in some patients.

The production of dextran has been recognized as a nuisance to sugar industry for decades. Dextran formation creates processing problems in raw sugar factory operations and leads to a decline in sugar recovery, translating into economic loss. Dextran also creates processing difficulties by increasing juice viscosity, poor clarification, and crystal elongation. In addition, dextran has a significant impact on the resulting market on the final processed product. In some cases, dextran formation is also responsible for food spoilage in rum industry and cured meat products.

9 Conclusions

The sources, preparation, characterization, and food applications of dextran have been described. The biocompatibility, high water solubility, and water-holding capacity make dextran an important food ingredient. Therefore, the hunt for new, novel sources of dextran seems to be an interesting quest for food applications. Moreover, the production of dextran using cheaper substrates such as food wastes and agricultural by-products is prerequisite for its economical recovery at industrial level. Dextran conjugation has aided the design of new tailor-made polymers with different molecular weights, shapes, structures, and functional activities. It will be useful from an application viewpoint, if the functional properties of dextran, viz., rheology, molecular weight distribution, degree, and length of branching, and the fine structure of the dextran-conjugated products would be explored in greater details. The identification and characterization of novel dextransucrases with random mutagenesis followed by high-throughput screening will provide the best methods to obtain novel types of dextrans.

Contents

Abstract

Galactan is a generic term to design a very large family of polysaccharides identified in terrestrial plants and other organisms but above all in red marine macroalgae. They are mainly represented by agars and carrageenans which have been largely investigated and used in industry for their unique rheological properties. The recent emergence of many studies, which report the wide range of biological activities of various galactans, opens the way to a new field of applications. This chapter focuses on the origins, the structural characteristics associated to extraction procedures, the biological activities, and the techno-functional properties of galactans.

1 Introduction

"One chapter more about 'galactans!'" will be probably the first thought of the future readers. We hope this point of view will change after reading this chapter which aims to provide a synthetic and updated document with the main advances on galactans and its applications to the community of students and academics. Galactans (Gs), sulfated galactans (SGs), and galactan-containing polysaccharides are widely distributed in terrestrial plants and macroalgae. SGs from marine macroalgae have no equivalent in terrestrial plants and may constitute up to the 70 % of the dry matter of some red seaweeds. As other polysaccharides, galactans present shared features such as their high density of hydroxyl functions (-OH) leading to a hydrophilic character and a high capacity to establish hydrogen bond network. So, they extensively modify the rheology of aqueous media into which they are introduced, even at low concentrations. This is the basis of their functional properties as thickening and gelling agents. In the case of SGs such as carrageenans and agars, these properties are reinforced by their sulfate contents which give an anionic character able to interact with other compounds. The structure of SGs from marine red macroalgae, despite a simple backbone composed of a disaccharidic unit, is in fact highly complex depending on its substitution by (i) sulfate groups, (ii) non-galactose monosaccharides, (iii) the nature of galactose stereoisomers, and (iv) the presence of 3,6-anhydrogalactose. This structural variability conducts to the existence of numerous families of SGs with specific rheological properties and leads the manufacturer to develop specific processes often closely guarded as closed secrets. Indeed, SGs from red marine macroalgae form an old family of texturing agents which has known a success story in an economic point of view. Nowadays, SGs are currently used in dairy products, pastry, bakery, meat products, spreads, sauces, pet foods, and beverages as they thicken and stabilize food systems. According to some Food and Agriculture Organization (FAO) statistics, the sole world carrageenan seaweed farming production increased from less than 1 million wet tonnes in 2000 to 5.6 million wet tonnes in 2010, with the corresponding farmgate value increasing from USD 72 million to USD 1.4 billion. Moreover, the recent emergence of glycosciences and the improvements in the knowledges of polysaccharidic structures offer a new area of research and applications for these complex carbohydrates. In this context, the description of wide biological activities obtained with SG from natural occurring has increased for therapeutic applications, e.g., anticoagulant, immunomodulatory, antithrombotic, antiviral, and antitumor effects. Even if this new way of innovation has not yet known an economical takeoff, the increase of patents and academic publications allows optimism. Overall, this chapter focuses on the recent developments in the topic of galactan polysaccharides and their applications.

2 Galactan Sources Associated to Their Structures

Sulfated galactans (SGs) are among the most marine polysaccharides studied since the last two decades, as also sulfated fucans or glycosaminoglycans (GAGs). Composed of α-L- and/or β-D-galactopyranosyl (gal*p*) units, the structures of SGs

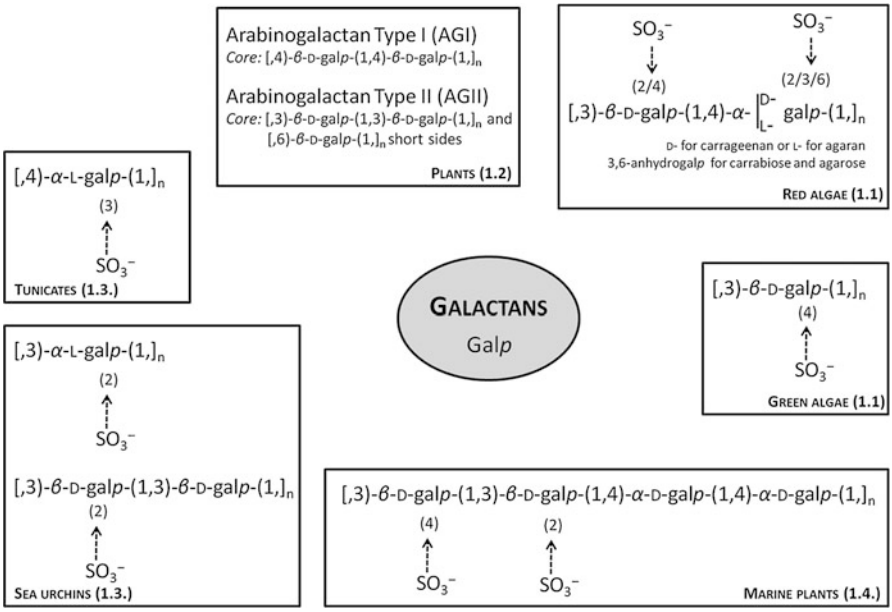

Fig. 1 The occurrence and structural diversity of galactans in nature

are in general complex and heterogeneous (Pomin and Mourão 2008) although their main structural features are conserved among phyla (Pomin 2010). Owing to their sulfate groups, SGs possess a strongly anionic character which increases possible electrostatic interactions with other charged oligo- and/or polysaccharides and/or proteins. In addition to these molecular interactions, SGs usually exhibit high molecular weights (MWs) higher than 100 kDa (Pomin 2010), which contribute to their biological potential and rheological behavior. Depending on the point of view, *stricto* sensu SGs are exclusively synthesized by marine organisms (Pomin and Mourão 2008). However, the occurrence of *largo* sensu SGs is quietly extensive since these GAG mimetics can be extracted from seaweeds, superior plants, marine invertebrates, and also microorganisms and fungi (Fig. 1) (Arifkhodzhaev 2000; Pomin and Mourão 2008; Delattre et al. 2011; Jiao et al. 2011).

2.1 Well-Known Sources of SGs: The Abundant Seaweeds

Marine algae are well known for their content in sulfated polysaccharides (Pereira et al. 1999; Berteau and Mulloy 2003). Marine SGs are widely abundant in red algae (Pomin and Mourão 2008; Delattre et al. 2011) and also found in green algae (Farias et al. 2008). Thus, SGs are currently extracted from *Rhodophyta* (red algae) cell walls (Craigie 1990) and more recently from the genus *Codium* (green algae) (Bilan et al. 2007; Farias et al. 2008). Nowadays, only 70–80 species of *Rhodophyta,* among more than 4,000 species, are used for industrial production

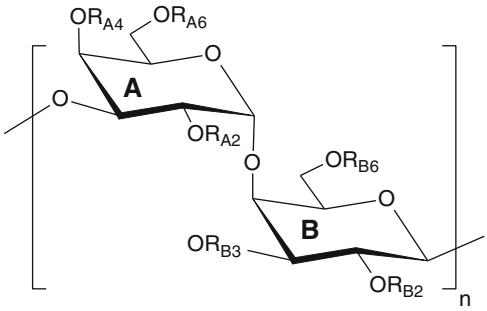

Fig. 2 Schematic representation of SGs from red seaweeds from Delattre et al. (2011). R_{A2}: H or SO_3^-; R_{A4}: H or SO_3^- or $C_3H_4O_3$ (cyclic ketal with O_6), R_{A6}: H or CH_3 or SO_3^- or $C_3H_4O_3$ (cyclic ketal with O_4), R_{B2}: H or CH_3 or SO_3^-, R_{B3}: H, R_{B6}: H, SO_3^-

of galactans (Delattre et al. 2011). As described by Witvrouw and De Clercq (1997), the most important ones belonged to Florideophyceae (2nd subclass of *Rhodophyta* division), orders Gelidiales and Gigartinales, and mainly genera *Ahnfeltia*, *Chondrus*, *Eucheuma*, *Furcellaria*, *Gelidiella*, *Gelidium*, *Gigartina*, *Gracilaria*, and *Pterocladia*. Based on their stereochemistry, the SGs produced by these red algae are classified as agarans, carrageenans, and D/L-hybrids which are also called nonideal SGs or complex SGs (Delattre et al. 2011; Jiao et al. 2011). Note to mention the origin of the name of "agaran" derived from "agar" which means jelly in the Malay language (Knutsen et al. 1994; Lahaye 2001), and "carrageenans" comes from the name of an Irish village (Bixler 1994).

In general, they are constituted of a linear backbone of 3-linked *β*-D-gal*p* residues (A units) and 4-linked *α*-D/L-gal*p* residues (B units) respecting an alternated sequence (AB)*n* (Fig. 2). B units can also be partially or totally replaced by 3,6-anhydro derivatives. Various hydroxyl groups can be substituted by methyl groups, sulfate ester groups, or pyruvic acid (Usov 1998; Delattre et al. 2011). The sulfate pattern is the major structural variation of SGs, and the distribution is quite heterogeneous and specific of red algae species and biotic/abiotic conditions when the samples are collected. Besides, it is noteworthy that *largo* sensu SGs can be ramified by neutral monosaccharides residues such as xylose, glucose, mannose, and/or arabinose.

2.1.1 Agarans

SGs with B units of the L-series are termed agarans (Fig. 3a) (Rees 1969; Knutsen et al. 1994). Agarans can be divided in two groups, i.e., agars and agaroids (Craigie 1990; Delattre et al. 2011), depending on the part of B units in the form of 3-6-anhydro-*α*-L-gal*p* (*α*-L-AnGal*p* units) and the percentage of sulfate groups. Thus, the ratio of *α*-L-AnGal/*α*-L-Gal units is higher in agars than agaroids, on the contrary to the percentage of sulfate groups which is close to 2 % for agars or up to 20 % for agaroids (Lahaye 2001; Delattre et al. 2011). However, this distinction is not always done in the literature, and numerous works just refer to the regular agaran backbone, more or less substituted by various chemical groups (Pomin and Mourão 2008; Jiao et al. 2011).

Agars are essentially extracted from *Gelidium*, *Gracilaria*, *or Pterocladia* species (Table 1) and are made up of a linear polysaccharide named agarose and a mixture of heterogeneous highly charged galactans called agaropectin (Fig. 3b) (Rinaudo 2007; Delattre et al. 2011).

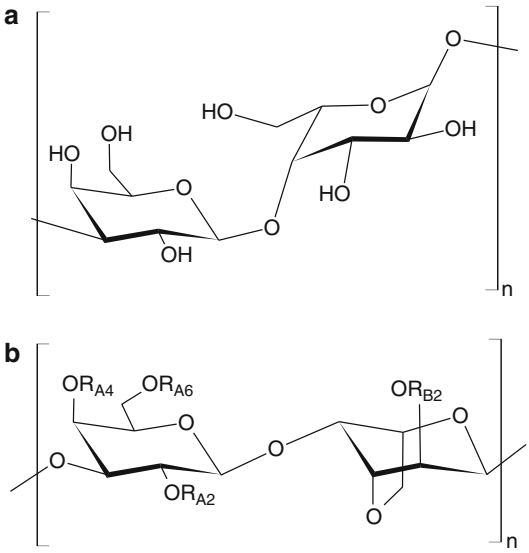

Fig. 3 Schematic representations of **a** generic agarans and **b** the alternating agarobiose sequence constituting agarose and agaropectin. R_{A2}: H or SO_3^-; R_{A4}: H or SO_3^-or $C_3H_4O_3$ (cyclic ketal with O_6), R_{A6}: H or CH_3 or SO_3^-or $C_3H_4O_3$ (cyclic ketal with O_4), R_{B2}: H or CH_3 or SO_3^-

Agarose, with an average molecular weight of 120 kDa, is often highly substituted in R_{A6} position by methyl groups (up to 20 %). On the other hand, agaropectin exhibits a similar backbone to agarose with numerous substituted groups as sulfate, pyruvate, methyl, or glycuronate (Furneaux and Stevenson 1990; Knutsen et al. 1994; Akari et al. 1996; Rinaudo 2007).

The backbone of agaroids is close to agarobiose but the ratio of AnGal units is lower than for agars and the ratio of R_{A6} sulfate groups is greatly higher (until ten times). Agaroids are widely studied (Table 2) and especially porphyrans which are isolated from *Porphyra* species, e.g., *Porphyra capensis* (Zhang et al. 2005), *Porphyra haitanensis* (Zhang et al. 2004, 2009), or *Porphyra umbilicalis* (Delattre et al. 2011). They are constituted of 3-linked 6-*O*-methyl-*β*-D-gal*p* and 4-linked 6-*O*-sulfo-*α*-L-gal*p* (Fig. 4a). Porphyrans-like are also produced by *Polysiphonia* species, such as *Polysiphonia abscissoides* (Miller and Furneaux 1997), *Polysiphonia atterima* (Miller 2003), *Polysiphonia nigrescens* (Prado et al. 2008), or *Polysiphonia strictissima* (Miller and Furneaux 1997). In fact, many species of Ceramiales produce agarans such as *Ceramium*, *Chondria*, *Cladhymenia*, *Delesseria*, *Laurencia*, *Odonthalia*, or *Rhodomela* (Table 2). Note to mention some species belonging to these genera produced polysaccharides containing both agaran- and carrageenan-type backbones, e.g., *Rhodomela larix* (Takano et al. 1999). Besides, the regular agaroid backbone can include *O*-linked methyl, pyruvate, and xylosyl groups as reported for species like *P. nigrescens* or *Acanthophora spicifera* (Gonçalves et al. 2002; Duarte et al. 2004; Prado et al. 2008). These structures are often considered as belonging to the well-known D/L-hybrids or also complex galactans (Delattre et al. 2005). It is the same for funorans, which are extracted from species such as

Gloiopeltis complanata or *Gloiopeltis furcata* (Takano et al. 1995, 1998) and are composed of AB alternative backbone of agars but whose C2 and C6 hydroxyl groups of 3-β-D-gal*p* and 4-α-L-gal*p* (Fig. 4b) are substituted by sulfates or methyl groups.

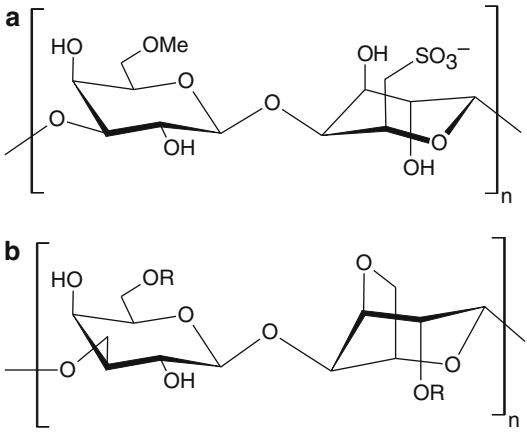

Fig. 4 Schematic representations of **a** porphyran and **b** funoran. R: CH_3 or SO_3^-

2.1.2 Carrageenans

SGs with B units of the D-series are termed carrageenans (Knutsen et al. 1994). D-gal*p* (B residues) of the repeating unit AB, also called carrabiose, can be replaced by 3-6-anhydro-*α*-D-gal*p* (*α*-D-AnGal*p*). Carrageenans can be isolated from various species of red algae, such as *Gigartina*, *Chondrus*, *Eucheuma*, or *Hypnea* (Table 3) (Stanley 1987; Prajapati et al. 2014). Carrageenans are classified by a Greek prefix according to their own structural characteristics such as sulfation and AnGal*p* patterns and their solubility in potassium chloride, which has been largely described in the literature (Smith and Cook 1953; Usov 1998; Lahaye 2001; van de Velde et al. 2004; Delattre et al. 2011; Jiao et al. 2011). Besides, other carbohydrate residues (Xyl, Glc, Uronic acids) or pyruvate or methyl ether groups can also be found (Knutsen et al. 2001). These multiple variations give birth to the well-known large structural heterogeneity of carrageenans (Lahaye 2001). Note to mention carrageenans are also high molecular weight polysaccharides, between 100 and 1,000 kDa (Kloareg and Quatrano 1988; Campo et al. 2009). These polysaccharides are split into various basic groups whose the kappa (κ), iota (ι), or lambda (λ) carrageenans (Campo et al. 2009), but this nomenclature slightly changes depending on authors (Fig. 5). The kappa family includes κ-carrageenans which can be obtained by alkali treatments from the μ precursors. The iota family includes ι-carrageenans which can be obtained by similar treatments from the ν precursors (Anderson et al. 1973). Each member of these families is C4 sulfated (A unit). Yet, ι-carrageenans are C2 sulfated and less composed of 3,6-anhydro-gal*p* (25–30 %) than the subfamily κ-carrageenans (up to 35 %). Thus, κ- and ι-carrabioses have respectively one (20 %) and two (33 %) sulfate ester groups (w/w) (Fig. 5). It is noteworthy that μ and ν precursors are composed of a 6-*O*-sulfated B unit instead of a 3,6-anhydro-gal*p*. The red seaweeds *Kappaphycus alvarezii* (also named *Eucheuma cottonii*) (Anderson et al. 1973; Estevez et al. 2000; Rudolph 2000) and *Hypnea musciformis* (Cosenza et al. 2014) are some examples of κ-carrageenan sources while ι-carrageenans can be extracted from species such as

w/o with or without chemical treatments

Eucheuma denticulatum (also called *Eucheuma spinosum*) (Campo et al. 2009), *Eucheuma spinosum* (Funami et al. 2007), or *Sarconema scinaioides* (Kumar et al. 2012) (Table 3). Note that Pereira et al. (2009) have described numerous sources of carrageenans produced by carrageenophytes. On the other side, the lambda family includes carrageenans which are not C4 sulfated (B unit) and not composed of 3-6-anhydro-gal*p* but which possess three (41 %) sulfate ester groups (w/w) per carrabiose. The sulfate groups are located on C2 of A unit and C2 and C6 of B unit (Fig. 5). It is noteworthy that λ-carrageenans are extracted from species of

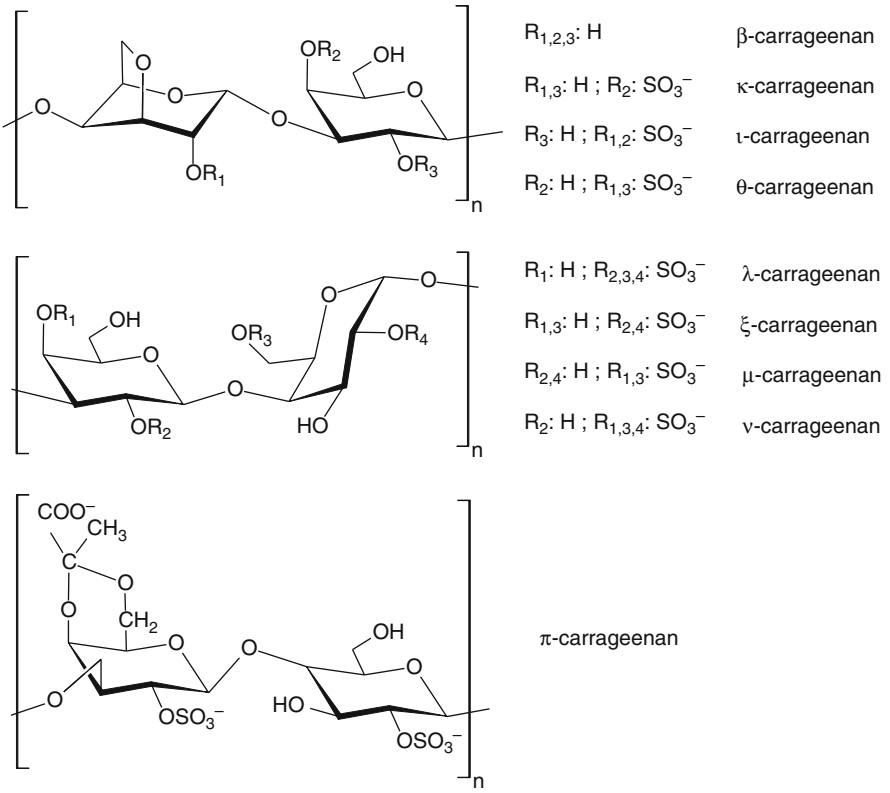

Fig. 5 Schematic representations of main carrageenans

the *Gigartina* and *Chondrus* genera (Zhou et al. 2006). Three subfamilies are categorized in the lambda family, i.e., the theta (θ), xi (ξ), and pi (π) carrageenans, where only the 4-*α*-D-gal*p* unit varies. θ-carrageenans are only one-time C2 sulfated on the B unit and are obtained from chemical treatments (Ciancia et al. 1993) or naturally found in algae, e.g., *Callophyllis hambroniana* (Miller 2003; Falshaw et al. 2005). As reported by Delattre et al. (2011), desulfated carrageenan (Penman and Rees 1973) and pyruvated carrageenan (DiNinno et al. 1979) have already been observed in tetrasporophytes from different species of *Gigartinaceae* (McCandless et al. 1983; Falshaw and Furneaux 1995, 1998).

To date, natural carrageenans often occur as mixtures of different hybrid types (Jiao et al. 2011). Craigie (1990) reported the difficulty to estimate if a carrageenan is constituted of one or two distinct types of carrageenans. Thus, κ/β- (Yang et al. 2011), κ/ι- (Hilliou et al. 2009), κ/μ- (Jouanneau et al. 2010), or ν/ι- (van de Velde 2008) hybrids have already been described in the literature. Otherwise, it has been well established that the nature of carrageenans also depends on the different generations of biological cycle. Sulfate and AnGal patterns can thus be affected.

Falshaw et al. (1995, Falshaw and Furneaux 1998, Falshaw, Bixler and Johndro 2001) clearly highlighted the presence of κ/ι- or ι/κ-hybrids in the gametophytes of *Gigartina* species, such as *Gigartina atropurpurea*, *Gigartina alveata*, *Gigartina pistillata*, or *Sarcothalia crispate*, while tetrasporophytes contained λ-, ξ-, and/or π-types.

2.1.3 Complex Galactans (D/L-hybrids)

Complex galactans, also named D/L-hybrids or nonideal galactans, are SGs from red algae composed of the alternating AB sequence (Fig. 2) which was previously described but ramified by other pentoses and/or hexoses and with other various substitutions such as sulfate groups, pyruvic acid ketals, or methoxyl groups. In this way, xylogalactans can be considered as nonideal SGs and can be extracted as example from *Corallina officinalis*, *Lithothamnion heterocladum*, *Jania rubens*, or *Calliarthron cheilosporioides* (Cases et al. 1994; Navarro and Stortz 2008; Martone et al. 2010; Navarro et al. 2011). Also termed corallinan, they are nonideal agarans with a *β*-D-xyl*p* ramified on *O*-6 position of D-gal*p* units. Other xylogalactan structures were also isolated from red seaweeds such as *Delesseria sanguine* (Grünewald and Alban 2009), *Laurencia obtuse* (Canelón et al. 2014), *Palisada flagellifera* (Ferreira et al. 2012), or *Polysiphonia nigrescens* (Prado et al. 2008). Highly complex structures have also been isolated from *Asparagopsis armata*, *Kappaphycus alvarezii* (*β*-D-xyl and *β*-D-glc substituents), *Pachymenia lusoria* (Xyl substituent), *Cryptonemia crenulata* (*β*-D-xyl and *β*-D-gal substituents), *Grateloupia indica* (Fuc, Glc, Gal substituents), *Gymnogongrus torulosus* (*β*-D-xyl), or *Halymenia durvillei* (Xyl, Ara, Fuc) (Miller et al. 1995; Estevez et al. 2004; Garon-Lardière 2004; Zibetti et al. 2005; Chattopadhyay et al. 2007; Estevez et al. 2008; Fenoradosoa et al. 2009). Note to mention that an in-depth study of literature obviously highlights that numerous complex galactans from red algae are classified by many authors as ideal SGs with minor amounts or other sugar residues. Thus, this complex galactan category is not well documented.

2.1.4 3-β-D-Galp-1 Units from Green Algae

Red algae are often considered as the only source of interesting galactans because of their structures (related to various physicochemical properties) and "the ease" of production/extraction/purification steps. Alternatively, SGs have also been characterized in green seaweed species belonging to the genus *Codium*. It is well described that the cell walls of *Codium* species, such as *Codium isthmocladum* and *Codium yezoense*, are constituted of galactose-composed polysaccharides and other heteropolysaccharides (Matsubara et al. 2001; Bilan et al. 2007; Farias et al. 2008). SGs from green algae exhibit a backbone of 3-linked *β*-D-galp-1 units mainly sulfated in position C4 and also minor amounts of substitutions, e.g., sulfate groups in positions C6 or pyruvic acid groups forming cyclic ketals with Gal units (Fig. 6) (Bilan et al. 2007; Farias et al. 2008). Other sugar residues (Gal, Ara, Glc) can also be found, as it has already been observed for *Codium fragile* or *Codium cylindricum* (Love and Percival 1964; Matsubara et al. 2001;

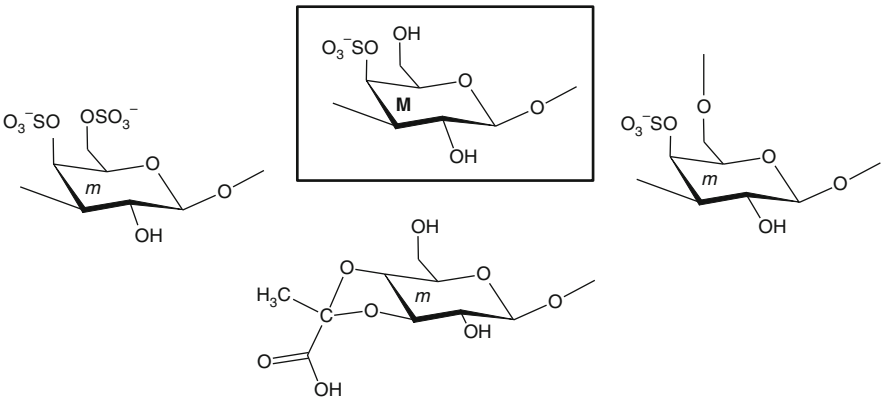

Fig. 6 Schematic representations of green algae SGs from *Codium isthmocladum*. *M* Major residue, *m* minor residue

Estevez et al. 2009; Lee et al. 2010a, b). Overall, the 3-linked β-D-galp-1 units seem to be the dominant of these SG backbones, bearing in mind that the green algal SGs are more complex than those of red algae (Pomin 2010).

2.2 Parallel Sources of SGs: The Superior Plants

Extensive investigations of polysaccharides from higher plants have been performed since the last two decades, and it was well defined that plants can contain a very large number of carbohydrate polymers. Beside starch material and fructans, plants are also composed of cell wall storage polysaccharides (CWSPs), mainly present in seeds (McCann and Roberts 1991; Carpita and Gibeault 1993). CWSPs can be split into three families: mannans, xyloglucans, and galactans. Note to mention that seed cell wall galactans were firstly characterized in 1947 from the seeds of *Lupinus albus* (Hirst et al. 1947). Galactans and galactan-composed polysaccharides are at least distributed in 30 families (Arifkhodzhaev 2000). Arabinogalactans can be categorized depending on their structures into two types, i.e., arabino-4-galactans (arabinogalactans I, AGI) and arabino-3,6-galactans (arabinogalactans II, AGII) (Aspinall 1970).

2.2.1 Arabinogalactan I

AGI are composed of a main backbone of (1-4)-linked β-D-gal*p* with short side chains of (1-5)-linked α-ara*f* attached in *O*-3 position. Other residues such as galactose, arabinose, and ferulic acid could also be found, for example, in some tissues of sugar beet (Ralet et al. 2005). Overall, AGI can be isolated from various primary walls of dicotyledonous plant tissues including numerous fruits (Perez et al. 2000). A non-exhaustive list of AGI plants sources is given in Table 4.

Table 4 Some plants producing galactans, adapted from Arifkhodzhaev (2000)

Species	Monosaccharide composition	MW (u.a.)	Linkages	References

2.2.2 Arabinogalactan II

AGII are highly complex polysaccharides often associated to proteins and described as well-known arabinogalactan proteins (AGPs). These proteoglycans are widely distributed in plants and are one of the most complex natural macromolecules. AGII can be extracted from various plants (Table 4), along with covalently linked pectic polymers (Vincken et al. 2003). Type II arabinogalactans are constituted of (1,3)- and (1,6)-β-D-gal*p* residues. Short side chains of (1,6)-β-D-gal*p* units including one to three residues in length are also present. Terminal α-L-ara*f* residues are often attached on position *O*-3 and *O*-6 of this backbone. Note to mention that few amounts of Glc*p*A can also be found.

2.3 Animal Sources of SG: The Use of Marine Invertebrates

As previously said concerning the large distribution of galactans in the nature, SGs have been described in some species of invertebrates (Fig. 1). Thus, ascidians (also called tunicates or sea squirts), such as *Herdmania momus* or *Styela plicata*, respectively contain a sulfated galactan composed of 3-sulfated, 4-linked α-L-gal*p* residues, i.e., [,4)-α-L-gal*p*-3(OSO_3^-)-(1,]$_n$ (Santos et al. 1992), and a similar backbone structure with non-sulfated L-gal*p* branched in *O*-2 position of the central core, i.e., [4)-α-L-gal*p*-2[1)-α-L-gal*p*-2(OSO_3^-)-3(OSO_3^-)-(1,]$_n$ (Mourão and Perlin 1987). It is interesting to understand that SGs are components of the extracellular matrix of these invertebrates and so play a similar role to glycosaminoglycans in vertebrates (Mourão and Perlin 1987). On the other hand, sulfated galactans are also found in sea urchins. Few examples are fully documented but *Echinometra lucunter* and *Glyptocidaris crenularis* can be cited as galactan

producers. Thus, *Echinometra lucunter* produces a 2-sulfated 3-linked α-L-galactan, i.e., [,3)-α-L-gal*p*-2(SO_3^-)-(1,]$_n$ (Alves et al. 1997) while *Glyptocidaris crenularis* produces a disaccharide repeating structure of alternating 2- and non-sulfated 3-linked β-D-galactan, which is similar to galactan structures from green algae (Pomin and Mourão 2008).

2.4 Alternative and Original Sources

2.4.1 Potential of Marine Plants

SGs have never been described in vascular flowering plants (angiosperm) until the recent work of Aquino et al. (2005) on *Ruppia maritima*. This marine plant, which grow in highly saline marine environments, produced an SG composed of a regular tetrasaccharide unit of [,3)-β-D-gal*p*-2(OSO_3^-)-(1,4)-α-D-gal*p*-(1,4)-α-D-gal*p*-(1,3)-β-D-gal*p*-4(OSO_3^-)-(1]$_n$. It is interesting to note that these units are not distributed in an alternating sequence as in the case of red seaweeds. Aquino et al. (2005) suggested that this structure could contribute for the structural arrangement of the cell wall but also be involved in the osmotic regulation phenomena. As reported by Pomin (2010), the authors speculated about the role of sulfate groups for salt ion sequestration.

2.4.2 Why Not Investigating Microorganisms or Fungi?

The polysaccharide market is continuously blooming in terms of biotechnological operations and value addition. The specific needs of newer structures (and so properties) and the high competitiveness of the market require perpetual innovative changes. These changes can concern the sources of SGs, the extraction procedures, and the physicochemical modifications of the polysaccharides (eco-friendly if possible). The production of SGs by the bacterial fermentation could be a significant alternative to the seaweed exploitation (algaculture and/or harvesting) and to the use of plants or animals (Delattre et al. 2011). Indeed, the production of bacterial polysaccharides is subjected to fewer constraints and clearly presents advantages in terms of: (i) harvesting steps depending on seasons, (ii) production rates and yields, (iii) extraction procedures and yields, (iv) media (at least water) and energy saving, etc. That is the reason why screening of original microorganisms is becoming one of the newest challenge of this decade. As examples, galactan structures could be produced by *Methylobacterium sp.* (Verhoef et al. 2003), *Lactococcus lactis* subsp. *cremoris* H414 (Gruter et al. 1992), and *Lactococcus lactis* subsp. *cremoris* B891 (van Casteren et al. 2000). It is interesting to note that *Mycoplasma mycoides* subsp. *mycoides* can produce capsular galactans-like (Bertin et al. 2013). Besides, the literature is little explicit concerning the potential of fungi as galactan producers. *Pleurotus* is the only clearly reported genus able to produce galactan structures such as a 6-α-D-gal*p* by *Pleurotus eryngii* (Carbonero 2008) or 4-α-D-gal*p* by *Pleurotus ostreatoroseus* (Rosado et al. 2002, 2003). Other fungi such as *Inonotus levis* have been reported for producing similar structures (Vinogradov and Wasser 2005). *Cordyceps dipterigena* BCC2073 can also produce

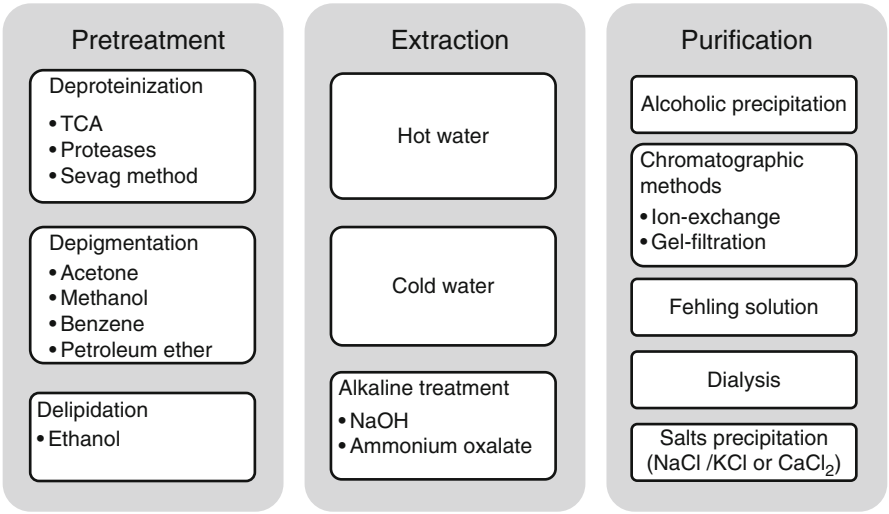

Fig. 7 Main methods used for galactan extraction and purification from seaweeds or superior plants

a (1,3)-galactan as described by Methacanon et al. (2005). Note that a rhamnogalactan was recently produced from *Fusarium solani* SD5 (Mahapatra and Banerjee 2013).

2.5 Extraction of Galactans

Depending on the galactan source (seaweeds, superior plants, or marine invertebrates), methods applied to recover polymers are different. However, all include three main steps: pretreatment, extraction, and purification. Main methods applied for galactan isolation and purification from seaweeds and plants are summarized on Fig. 7.

2.5.1 Pretreatments

Prior to extraction and depending on the polysaccharide source, some pretreatments should be needed. Before extraction of polysaccharides from seaweeds, a depigmentation step is often useful to prevent colorless extracts. The main method used is based on the use of acetone or methanol (Siddhanta et al. 1999). Nevertheless, some authors have used Sohxlet apparatus and benzene (Chattopadhyay et al. 2007) or petroleum ether (Karmakar et al. 2009) prior to acetone extraction. Moreover, it is often needed to remove lipids before extraction of galactans. The defatted fraction is then obtained by boiling sample in ethanol (Yang et al. 2011; Li et al. 2013). As main examples, deproteinization of samples can be achieved using Sevag method (n-butanol:chloroform, 1:4, v/v) (Staub 1965), conjunction of barium hydroxide and zinc sulfate (Pierre et al. 2011), or by acid precipitation with TCA

(Palacios et al. 2012). Moreover, proteases can also be used (Stevens and Selvandran 1984; Palacios et al. 2012). Finally, for plant extracts, processes can include a step consisting of a methanolic extraction in order to remove phenolic compounds (Palacios et al. 2012). In some cases, an increase in the effectiveness of extraction was observed (Park et al. 2009; Palacios et al. 2012).

2.5.2 Extraction of Galactans from Seaweeds

Galactans from seaweeds are generally extracted by two main methods: hot water extraction and sodium hydroxide extraction. In the two cases, dried and milled seaweeds are incubated in the corresponding solution at hot temperature (generally between 80 °C and 100 °C) for 1–4 h (Fenoradosoa et al. 2009). The mixture is then filtrated or centrifugated to remove non-soluble residue. The polysaccharides are then precipitated (generally three times) using alcohol prior to drying. As recently detailed by Prajapati et al. (2014), there are some differences in the processing of carrageenans. Kappa-carrageenans are generally extracted by using NaOH (5–10 %) treatment at 80–90 °C for 1–4 h depending on the texture of the macroalgae. As in the case of *Eucheuma* or *Furcellaria*, kappa-carrageenans are precipitated using cold 1–1.5 % of KCl solution followed by: washing with water, dehydrating (using pressing method), drying, and milling in order to get kappa-carrageenan in powder form. Lambda- and iota-carrageenans are generally extracted in alkali solution (NaOH or KOH) at 80–100 °C during 1–4 h. After filtration, the carrageenan solution is concentrated using evaporator and finally precipitated using alcohol (propyl or ethyl alcohol).

Alkaline extraction often leads to higher extraction yields; nevertheless, these polymers have shown a modified structure, with alteration of monosaccharide composition and substitution (Greer and Yaphe 1984; Fenoradosoa et al. 2009) and then a modification of final properties, as for example, a modification of the gel strength of agar (Lahaye and Yaphe 1988).

2.5.3 Extraction of Galactans from Terrestrial Plants and Mushrooms

Concerning terrestrial plants, different extraction methods exist, but as plants can contain several different polysaccharides (cellulose, hemicelluloses, pectin substances. . .), isolation of galactans generally require several steps to obtain a purified fraction. The first extraction step generally implies cold (Siddiqui and Wood 1972; Srivastava and Pande 1974; Gupta et al. 1979; Antonova and Usov 1984) or hot water (Mandal and Das 1980; Tomoda et al. 1990; Chen et al. 2008; Braz de Oliveira et al. 2013) as the easiest methods. Alternatives are the use of phosphate buffers (Tsumuraya et al. 1987), ammonium oxalate (Das et al. 1977; Stevens and Selvandran 1984; Mikshina et al. 2012), and sodium hydroxide. In some cases, comparative extraction with hot water and ammonium oxalate has shown modified composition of polymer mixture, with a proportion of uronic acids greater in the case of ammonium oxalate (Das et al. 1977). Palacios et al. (2012) have tested cold water, hot water, and hot aqueous NaOH extractions on fruiting bodies of the edible mushroom *Pleurotus ostreatus*. Polysaccharides recovered after alcoholic precipitation were analyzed, showing

that only the cold water fraction was constituted of α-(1,3)(1,6)-linked galactopyranosyl residues on a linear backbone, whereas the others consisted of glucose-linked units.

Because the extracted compounds are a heterogeneous mixture, homogeneous polysaccharides are further purified by various methods: treatment with Fehling solution (Unrau 1964; Braz de Oliveira et al. 2013), dialysis (Lahaye and Yaphe 1988), fractional precipitation with alcohol (Sarkar and Chatterjee 1983; Shimizu et al. 1990), and NaCl (Das et al. 1977) or $CaCl_2$ solutions (Mandal and Das 1980). But most of time, chromatographic separations are achieved, using various resins: ion-exchange resins (Blake et al. 1983; Tsumuraya et al. 1987) such as Sephadex (Sarkar and Chatterjee 1983; Shimizu and Tomoda 1987; Tomoda et al. 1990; Zhang et al. 2014) or DEAE cellulose (Siddiqui and Wood 1972; Das et al. 1977; Ghosh and Das 1984; Shimizu et al. 1990). In some cases, gel filtration separation has been applied, using Sepharose (Das et al. 1977; Blake et al. 1983) or Sephacryl (Blake et al. 1983; Tomoda et al. 1990).

2.5.4 Extraction of Galactans from Marine Invertebrates

Some galactans have been identified in animals, especially from marine organisms such as mollusks. Methods applied generally include a protease digestion step. For extraction of polysaccharides from ascidians (tunicates), Albano and Mourao (1986) incubated tissues with papain at 60 °C during 48 h. After centrifugation, polysaccharide was collected from supernatant by ethanol precipitation and dialyzed extensively against water. Similar protocol has been successfully applied to eggs and ovaries of sea urchins (Cinelli et al. 2010), leading to obtain sulfated L-galactans. To extract galactans from sponges, Esteves et al. (2011) have tested four methods. The most efficient one comprised a papain digestion step, followed by incubation with DNase during 24 h. After centrifugation, 10 % (w/v) cetylpyridinium chloride (CPC) was added to the supernatant to recover a precipitate. The resulting cetylpyridinium-polysaccharide complexes were dissolved in 2 M NaCl-ethanol (100:15, v:v) to obtain the corresponding sodium salt-polysaccharides, before precipitation with ethanol.

3 Biological Properties of Galactans

As described by Delattre et al. (2011), galactans from algae, plant, animal, and microorganisms could be considered as pharmaceutical key in human biological systems. As mentioned by Misurcova et al. (2012), there was increasing interest of functional food ingredients such as galactan for its putative health benefits during the last years. Generally speaking, lots of examples have related the biological activities of polysaccharides and particularly, SGs as antithrombotic (Mourao and Pereira 1999; Berteau and Mulloy 2003), antimetastatic (Coombe et al. 1987), antiviral (Harrop et al. 1992); anti-inflammatory (Berteau and Mulloy 2003), anticoagulant (Pereira et al. 2002), and antiadhesive (Berteau and Mulloy 2003) agents. The biological activities of SGs can be correlated to their chemical

composition and mainly to their sulfation patterns (Delattre et al. 2011; Misurcova et al. 2012). Due to their diverse health advantageous effects, a great agreement of significance has been observed by the people consumers toward natural bioactive molecules as practical food ingredients. Therefore, it can be recommended that bio-processed products from marine origin could be very interesting alternative sources as surrogates of synthetic food ingredients in order to provide health benefits and well-being to consumers. This paragraph gives an overview of our present knowledge about the potential application of galactans as bioactive molecules.

3.1 Antiviral Activities

All over the world, one of the most important causes of human death is the pathogenic virus infections (Kim et al. 2006). Even if lots of antivirus agents have been proposed and developed for treatment of viral diseases, there are needs of new natural ones because of synthetic drug resistance and bad side effect. As Kim et al. (2006) explained, the current searches for antivirus compounds focus more and more on polysaccharides from natural products with an important attention for marine algae. In this context, antiherpes virus galactans extracted from marine algae have been used and considered as potential therapeutical food antiviral ingredients (Kim et al. 2006).

The last years, several structural kinds of marine galactans such as carrageenan have revealed effective antiviral activities against viruses counting more especially: *i*) the human pathogen herpes simplex virus type 1 (HSV-1), (*ii*) the human pathogen herpes simplex virus type 2 (HSV-2), (*iii*) the dengue virus (DENV), (*iv*) human cytomegalovirus (RSV), (*v*) respiratory syncytial virus (RSV), and (*vi*) human immunodeficiency virus type 1 (HIV-1) (Carlucci et al. 1999; Gunay and Linhardt 1999; Talarico et al. 2004, 2005; De SF-Tischer et al. 2006; Carlucci et al. 1997b). It was clearly established by the studies of Chen et al. (1997) that these viruses could interact with glycosaminoglycan-type polysaccharides as heparan sulfate during the initial binding with the host cell. For that reason, some studies propose carrageenans as antiviral agents at the early event viral infection. De SF-Tischer et al. (2006) have shown that carrageenans derived from *Meristiella gelidium* (*Solieriaceae*) were more effective inhibitors of DENV than carrageenans from *Gymnogongrus griffithsiae* (Talarico et al. 2004) and other reference antiviral polysaccharides such as heparin and dextran sulfate 8000 (DS 8000). In the same way, studies have revealed the antiviral properties of lots of SGs as those of the red seaweeds: *Grateloupia indica* (Chattopadhyay et al. 2007), *Schizymenia binderi* (Matsuhiro et al. 2005), *Callophyllis variegata (*Rodríguez et al. 2005), *Stenogramme interrupta* (Cáceres et al. 2000), *Gymnogongrus torulosus (*Pujol et al. 2002), *Bostrychia montagnei* (Duarte et al. 2001), or even *Cryptonemia seminervis* (Mendes et al. 2014).

Nevertheless, according to literature (Damonte et al. 2004), galactans extracted from the red seaweed *Meristiella gelidium* could be considered as among the most effective antiviral sulfated polysaccharides against herpes virus.

Note to mention that another study revealed that galactan derivatives from terrestrial plants have been as well proposed as antivirus agents. In fact, for example, pectic arabinogalactan containing β-(1,6)-linked D-Gal*p* and extracted from leaves of *Stevia rebaudiana* has been described for its antiviral activities against herpes simplex virus type 1 (De oliveira et al. 2013). In addition, Dong et al. (2012) have proposed galactans from the edible plant *Basella rubra L.* as antiviral agents against herpes simplex virus type 2.

Therefore, the prospective of galactans as antiviral agents continues to be of considerable interest for therapeutical applications. Finally, it is also clear that as stated by Lee et al. (2004), in antiviral field using natural polysaccharides, there is a large diversity of structure correlated with antiviral potencies. Comparative researches on biological effect of polysaccharides have largely revealed that the antiviral activities appeared to be strongly associated with glycosidic linkage and monosaccharide composition as well as molecular weight and sulfate contents.

3.2 Antioxidant Activities

When we speak of human oxidative stress, we are talking about an extreme generation of reactive oxygen species called ROS. As a result, oxidative damage of macromolecules among nucleic acids, lipids, and proteins led to cellular tissue injuries (Halliwell and Auroma 1991). Usually, mainly organisms are able to protect themselves against adverse effects of oxidation. Nonetheless, for more serious oxidative stresses of human body, the innate defense mechanisms cannot be sufficient. In fact, as mentioned by Cuzzocrea et al. (2001), oxygen-derived free radicals such as hydroxyl radical and superoxide anion radical are well known to play an important role as mediators in the development of carcinogenesis and aging mechanism. With the aim to protect both food and human body against oxidative damages, antioxidant agents are used. These exogenous antioxidant molecules are necessary to regulate the amount of ROS (Cuzzocrea et al. 2001). Currently, synthetic antioxidants like tert-butylhydroquinone (TBHQ), butylated hydroxyanisole (BHA), propyl gallate (PG), or butylated hydroxytoluene (BHT) are commonly employed in food industry (Qi et al. 2005). However, as related by Elboutachfaiti et al. (2011), BHA, BHT, and TBHQ are more and more restricted by legislation in food because of their possible impact in carcinogenesis. For this reason, the last years, there is a growing attention in using natural antioxidants. Among natural sources, marine algae represent one of the richest sources of bioactive compounds. One particularly interesting feature of marine algae is their richness in polysaccharides such as galactans. These polysaccharides have been largely described to be effective nontoxic compounds and have been confirmed to play a significant role as antioxidants and radical scavengers against oxidative damage in human living organisms (Zhang et al. 2003, 2004; Souza et al. 2007; Jimenez-Escrig et al. 2012). Generally speaking, antioxidant activities of polysaccharides have been evaluated by using diverse methods such as lipid peroxide inhibition, 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) radical

scavenging, 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging, ferric reducing antioxidant power (FRAP), or superoxide and hydroxyl radical scavenging assays (Ngo and Kim 2013).

In this context, lots of SGs from red seaweeds have been described for their antioxidant properties. For example, Costa et al. (2010) have highlighted the antioxidant effect of carrageenans from tropical seaweeds and more especially from the Rhodophyta *G. caudata*. In the same way, Souza et al. (2012) revealed the antioxidant activities of SGs from red seaweed *Gracilaria birdiae* and Zhang et al. (2003) studied the in vivo applicability of SGs from marine red alga *Porphyra haitanensis* in aging mice. In addition, other SGs from red seaweeds were investigated for their antioxidant capacity related to their sulfate amount (Jiao et al. 2011; Jiménez-Escrig et al. 2012). In another study, Souza et al. (2007) have investigated the in vitro antioxidant activities of iota (from *Eucheuma spinosum*), kappa (from *Eucheuma cottonii*), and lambda (from *Gigartina acicularis* and *G. pistillata*) carrageenans. It was shown that lambda-carrageenan was the highest antioxidant agent and free radical scavenger. It should be noted as well that the antioxidant properties of polysaccharide depend not only on degree of sulfation but also on the molecular weight. Indeed, previous works have shown that carrageenans and their oligomers have antioxidant properties (Abad et al. 2013). Moreover, it has been clearly demonstrated that the lower molecular weight (LMW) carrageenans exhibited better antioxidant abilities. Overall, it has to be noted that all these studies clearly show once again that the antioxidant activities of galactans strongly depend on the combination of sulfation as well as molecular weight.

Even now, many scientists still continue to isolate antioxidant polysaccharides since more recently, a sulfated galactan from the red macroalga *Mastocarpus stellatus* has been reported for its antioxidant ability (Gómez-Ordonez et al. 2014).

3.3 Anticoagulant and Antithrombotic Activities

As mentioned by Ngo and Kim (2013), the blood coagulation mechanism is well known as processed by factor of coagulation so as to end the flow of blood though the ill vessel wall during occurrence of an abnormal vascular condition. Therefore, since exogenous or endogenous anticoagulant agents interacted with the coagulation factor, the coagulation of blood can be blocked. Commonly, heparin, which is a glycosaminoglycan currently extracted from porcine tissues, was the most anticoagulant/antithrombotic drug used (Fareed et al. 2000). Nevertheless, heparin has been largely criticized for its limitations caused by collateral effects linked to the contamination of heparin preparation with chondroitin sulfate (Guerrini et al. 2008; Pomin and Mourao 2008). As related by Kishimoto et al. (2008), when heparin was administered by intravenous injection, the contamination by chondroitin sulfate induced a phenomenon of hypotension. Moreover, other side effects have been observed and described after administration of heparin as for examples: hemorrhagic effect, antithrombin deficiencies, or thrombocytopenia (Costa et al. 2010). Consequently, research has been investigated to discover new heparinoid-like

molecules as coagulators, and various galactans from marine algae have been described for their anticoagulant/antithrombotic properties (Farias et al. 2000; Fonseca et al. 2008; Pereira et al. 2002; Pomin and Mourao 2008). In that sense, different types of anticoagulant galactans have been extracted from macroalgae such as *Codium cylindricum* (Matsubara et al. 2001), *Botryocladia occidentalis* (Farias et al. 2000; Pereira et al. 2005), *Gelidium crinale* (Fonseca et al. 2008), *Grateloupia indica* (Sen et al. 1994), *Gigartina skottsbergii* (Carlucci et al. 1997a), *Schizymenia binderi* (Zuniga et al. 2006), *Lomentaria catenata* (Pushpamali et al. 2008), and *Porphyra haitanensis* (Zhang et al. 2010). Note to mention that in addition to SGs from macroalgae, other SGs with anticoagulant properties have been isolated from the egg jelly coat of sea urchin of *Echinometra lucunter* (Alves et al. 1997) or from the tunic of ascidians such as *Herdmania momus* (Santos et al. 1992) and *Styela plicata* (Mourão and Perlin 1987).

In a general way, as mainly revealed by Pomin and Mourao (2008), the activities of galactans were strongly mediated by heparin cofactor II as well as antithrombin. In some cases, a serpin-independent anticoagulant effect was exhibited, probably correlated to the fibrin polymerization inhabitation as supposed by Matsubara et al. (2001). Besides, in their study, Fonseca et al. (2008) have clearly shown that minor differences in sulfation level and sulfation distribution of algal galactans could lead to differences in their anticoagulant and venous antithrombotic activities.

Moreover, as mentioned by Pomin and Mourao (2008), the slight difference in sulfation pattern of galactans was described as critical for interactions between some activators, proteases, and inhibitors during coagulation, which could cause diverse patterns in antithrombotic activity as well as pro- and anticoagulant properties. For this reason, sulfated galactans possess procoagulant as well as anticoagulant effect depending on the sulfation distribution. Finally, from all these studies, new perspectives are opened for the development of galactans as pharmaceutical drugs in thrombosis field.

3.4 Anticancer Activities

Nowadays, cancer is considered as one of the first reason of human death, and globally, in the last decades, its incidence has doubled according to Amaro et al. (2013). Overall, cancer was classified as a disparity in the levels of cellular proliferation and cell apoptosis. The last one is well known as a biological mechanism which implicated several protein families such as caspases taking part in tumor growth at several stages of the carcinogenesis (Guedes et al. 2011). Inhibition of tumor cell mediated by specific protease activities led to the cell tumor suppression mechanism. More, the attenuation of tumor involved angiogenesis, immunostimulation, and cell apoptosis (Amaro et al. 2013). As related by Ehrke (2003), therapeutical methodologies using the chemotherapy technology was habitually used for the cancer treatment. Nevertheless, for the most part, anticancer agents currently employed are particularly cytotoxic. Consequently, lots of natural

compounds have been proposed for their beneficial effects as cancer-preventive agents (Ooi and Liu 2000; Schepetkin and Quinn 2006; Tzianabos 2000; Fedorov et al. 2013).

Then, the anticancer activities of sulfated galactans from red seaweeds have been recognized many times by in vivo and in vitro experimentations. For example, a sulfated galactan from the toxic marine dinoflagellate *Gymnodinium* sp. A3 (called GA3P) has been revealed as a potent inhibitor of specific enzyme such as DNA topoisomerase I and topoisomerase II (Umemura et al. 2003). Moreover, in their study, Umemura et al. (2003) have shown the growth inhibition of human cancer cell line by using this SG from these marine microalgae. For that reason, GA3P could be a good candidate for the development of anticancer chemotherapeutic agent. In recent times, several studies have reported that SGs from red macroalgae have inhibitory activity against tumor growing in mice as well as antiproliferative activity in cancer cell lines (Khotimchenko 2010). Furthermore, Lins et al. (2009) have proved the antitumor activities of SGs extracted from the red seaweed *Champia feldmannii*. A galactan from red algae *Porphyra yezoensis* could induce cancer cell death via apoptosis in a dose-dependent manner in vitro (Kwon and Nam 2007). In this work, it was particularly reported that when HT-29 colon cancer cells and AGS gastric cancer cells were cultured in presence of low concentration of purified galactans, the growth of cancer cells was inhibited by around 50 %. Note that low molecular weight (LMW) sulfated galactans from *Porphyra yezoensis* have been already reported to have immunoregulatory and antitumor activities (Osumi et al. 1998). In this study, LMW SGs were produced by enzymatic digestion of sulfated galactans using enzymes from *Arthrobacter* sp. and tested for their in vitro antitumor activities against WI-38 and VA-13 cells. It was then observed a very important antitumor activity against Meth-A fibrosarcoma and Ehrlich ascites. In addition, numerous works have reported that sulfated galactans such as carrageenans could have inhibitory activity of tumor growth in mice as well as interesting antiproliferative activity in cancer cell lines in vitro (Yuan et al. 2006; Zhou et al. 2006, 2004). In their studies, Zhou et al. (2004, 2006) investigated the positive effect of lambda-carrageenan from *Chondrus ocellatus* on the antitumor H-22 activity. Besides, Yamamoto et al. (1986) have already mentioned a considerable decrease in the impact of carcinogenesis after the oral administration of several red seaweeds. Indeed, they have shown the inhibition of growth of sarcoma-180 cells subcutaneously implanted into mice after dietary but also intraperitoneally injected red seaweed polysaccharides. On the other hand, Hagiwara et al. (2001) investigated the modifying effects of carrageenans on colonic carcinogenesis in male rats. Hu et al. (2006) have shown that low molecular weight carrageenans from the red alga *Kappaphycus striatum* may exert antitumor activities by immune system promoting on mice inoculated with a suspension of S180 tumors cells.

Finally, as already detailed above, galactans were largely described for their important antioxidant and free radical scavengers for the prevention of oxidative injuries which is one of the most important providers in carcinogenesis. Hence, these polysaccharides could be added as functional and active agents in food as cancer-preventive substances.

3.5 Antibacterial Activities

As related by Pierre et al. (2011), lots of microorganisms have adapted resistance against antimicrobial drugs. In fact, these microbial pathogens have developed specific multiple drug resistance during repeating treatment of infectious diseases. For that reason, there are strongly needs to find alternative antimicrobial compounds. Then, researches have been focused on the seaweed field and notably on the utilization of polysaccharides such as galactan from marine algae (Al-Haj et al. 2009; Kim et al. 2007).

According to literature, several seaweeds have antibacterial properties. For example, a galactan from the red algae *Hypnea musciformis* has been described for its antimicrobial activities against *Pseudomonas aeruginosa* and *Staphylococcus aureus* (Selvin and Lipton 2004). In addition, Yamashita et al. (2001) have revealed that commercial iota-carragenans showed significant growth inhibitory effect on *Salmonella enteritidis, Escherichia coli, and Staphylococcus aureus.*

In their study, Pierre et al. (2011) highlighted the antibacterial activities of a sulfated galactan from *Chaetomorpha aerea* which is a green filamentous alga from the French oyster ponds (Marennes-Oléron, France). Authors have investigated antimicrobial properties of galactans against some microorganisms, such as *Candida glabrata* (DSMZ 6425), *Pseudomonas aeruginosa* (ATCC 27853), *Enterococcus faecalis* (CIP 103214), *Staphylococcus aureus* (ATCC 25923), *Salmonella enteritidis* (ATCC 13076), *Micrococcus luteus* (ATCC 4698), and *Bacillus subtilis* (CIP 5262). It was shown that this sulfated galactan from *Chaetomorpha aerea* was efficient only against *S. aureus*, *M. luteus*, and *B. subtilis*. So, these results confirmed the potential use of the green algae *Chaetomorpha aerea* as a source of new antibacterial agent. In the same way, iota-carrageenan extracted from the red algae *Eucheuma denticulatum* has shown interesting antibacterial activity against *Streptococcus pyogenes* and *Staphylococcus aureus* (Al-Haj et al. 2009). Additionally, in recent works, it was revealed that carrageenan was efficient in producing antibacterial defense when it was used as raw material in the edible food (Plotto et al. 2006, 2010; Bico et al. 2009).

Aqueous extract of red seaweed such as *Gracilaria chilensis*, *Porphyra columbina*, and *Gigartina skottsbergii* have been described by Jimenez et al. (2011) for anti-phytopathogenic activities against the fungal plant pathogenic strain *Phytophthora cinnamomi*. In their study, authors described that extracts from *G. chilensis* led to an inhibition of the *P. cinnamomi* growing in a dose- and season-dependent manner. Note to mention that this extract was not efficient against *Botrytis cinerea*. As suggested by the authors, the main effective components in these extracts were polysaccharides such as sulfated galactans. Besides, Amorim et al. (2012) have tested a sulfated galactan from the red seaweed *Gracilaria ornata* against the growth of bacteria including *Staphylococcus aureus, Enterobacter aerogenes*, *Bacillus subtilis*, *Salmonella choleraesuis*, *Escherichia coli*, and *Pseudomonas aeruginosa*. In this study, data have clearly showed that the sulfated galactan from *G. ornata* inhibited only the *E. coli* growing. It should be noted that research continues in this area since very recently, Raposo et al. (2014)

observed that sulfated galactans from the red microalgae *Porphyridium cruentum* had significant ability to inhibit the growth of *Salmonella enteritidis* bacterium.

According to Pierre et al. (2011), several hypotheses have been proposed to explain why sulfated galactans are active against microbial strains: (i) the interaction of polysaccharides with specific target from the cell wall of the bacteria or (ii) the ability of the bacteria to modify the structure of the galactans. However, there are publications which suppose antimicrobial mechanisms may be linked to the binding properties of the sulfated galactans to positive regions of microbial membrane during the interaction step (Pomin and Mourao 2008; Pomin 2010; Amorim et al. 2012). Nevertheless, even if there is evidence that galactans could act as antibacterial agents, no real mechanism proofs have been confirmed up to now (Pomin 2010).

4 Physicochemical Properties

Carrageenans and agars are the generic names for a large family of gel-forming and viscosifying polysaccharides that are obtained commercially from red seaweeds (*Rhodophyceae*). These hydrocolloids are the most important polysaccharides exploited as texturing agents in food and in other industrial areas (Hoffman 2002; Campo et al. 2009). They can bind water, promote gel formation, and thicken, stabilize, and improve tastiness and appearance through interaction with other substances (Piculell 2006). The wide employments of these sulfated polysaccharides are essentially based on their properties to form strong aqueous gels (Rees et al. 1969; Lahaye 2001). It was largely defined that higher levels of 3,6-anhydro-α-L-galactopyranosyl units and lower sulfate contents were the major structural requirements for gelling (Lahaye 2001). Moreover, it is well known that modifications in the backbone of SGs allowed to greatly changes in their physicochemical and biological properties (Lahaye 2001).

4.1 Conformation, Properties in Solution, and Mechanism of Gelation of Agars

Agar, also previously named agar-agar, is extracted from red seaweeds. It is known from the seventeenth century in Japan for its gelling properties, and now farming is developed in Indonesia. Agar gels melt between 60 °C and 97 °C and solidify in the range from 30 °C to 45 °C. As described above, agar is a generic name and several kinds of compounds are recognized depending on sulfate, pyruvate, and 3,6-anhydro-α-L-galactopyranose contents. Gelation of agars is an exothermic phenomenon based on a coil-helix transition followed by aggregation of double helices each other. The gels, thermoreversible, are stabilized by cooperative hydrogen bonds. Agar is known to form a very porous gel. Gelation temperatures are related to sulfate but also methoxyl contents of polymers that adversely influence gelation. The alkali-treated agar showed higher melting and gelling temperatures

but also higher gel strength compared to non-alkali-treated ones (Rinaudo 2007). This phenomenon was explained by the hydrolysis of sulfate groups after conversion of (1,4)-linked galactose-6-sulfate to anhydrogalactose units. However, gel strength of agars decreased with an increase in the duration of alkali treatments as the 3,6-anhydrogalactose content decreased (Higuera 2008). Agars differ from other hydrocolloids by their high gel strength and their wide range of hysteresis (defined as the difference between the transition temperatures measured upon heating and cooling). Among agars, agarose is the better gel-forming polysaccharide and is the component responsible for gelation of agars. Agaropectin with higher sulfate content is a poorer gelling agent compared to it. The stronger gels are obtained with pure agarose, but they exhibit high levels of syneresis (separation of water). Even if agaroses are globally uncharged, they are sensitive to salts such as NaCl for lyotropic effects (increasing of H bonds) (Rinaudo 2007; Delattre et al. 2011).

As other polysaccharides and notably carrageenans, the texturing properties of agars can be modulated by their interaction with other components in complex matrix such as food media. High sugar concentration (glucose or sucrose) can increase gelling and melting temperatures of agars but also gel strength (Meena et al. 2006). Recent experiments clearly indicated a competition of the different carbohydrates for water (Russ et al. 2014). This phenomenon is called "sugar reactivity" by authors (Meena et al. 2006). The gelation of agars is also modified by interactions with other hydrocolloids. With locust bean gum (a galactomannan), a synergistic effect is observed with some agars increasing the gel strength (Lundin and Hermansson 1997) and leading to a more effective and economical use of these two polysaccharides. In contrary, the mechanical performances of films and gels obtained with mix of agar and starch and with agar and arabinoxylan blends are degraded compared to those obtained with agars alone (Phan The et al. 2009). Blends of agar with alginate give films that are more flexible and easy to manage than pure agar, but the strength of gels obtained with these blends decreased as a consequence (Laurienzo 2010). In the same way, the mixed gels composed of κ-carrageenans and agars were much more deformable, had a higher failure strain, and lower strength (Norzia et al. 2006). They can be stabilized by cross-linking with genipin, showing remarkable swelling capacity and solution stability in a wide range of pH (Meena et al. 2009). Agar does not show any protein reactivity and has a good acidic stability compared to other polysaccharides and notably to carrageenans. This property is a significative advantage for its use in dairy products where carrageenan would cause excessive flocculation due to its protein reactivity.

4.2 Conformation, Properties in Solution, and Mechanism of Gelation of Carrageenans

For several hundred years, carrageenans have been used as gellifying, thickening, and stabilizing agents in food (note that carrageenans has no food value) and food

industries in Europe and the Far East (Van de Velde and De Ruiter 2002). The first use of carrageenans started more than 600 years ago in Ireland in the village of Carrageenan where flans where made by cooking red seaweed in milk.

Carrageenans are water soluble, but their solubility depends on the type of carrageenans, temperature, pH, and type and concentrations of counter ions (McHugh 2003). The three most prevalent, and of highest commercial interest, carrageenans are iota, kappa, and lambda species, having different properties due to their high capacity of water retention and mechanical strength of their gels (Van de Velde and De Ruiter 2002). These three biopolymers are biodegradable and biocompatible.

The most soluble carrageenan is λ-carrageenan lacking hydrophobic 3,6 anhydrogalactose in its structure and having a high sulfate ester content. This carrageenan species is present in a random coil conformation and cannot form gel but can be used as a thickener.

In gelling applications, only κ- and ι-carrageenans form thermoreversible gels in aqueous solutions as the other carrageenans lack the essential $^1C_4$-conformation that results from the 3,6-anhydro bridge. κ-carrageenan sodium salt is soluble with difficulty in cold water, whereas κ-carrageenan potassium salt is only soluble in hot water solutions. It can occur in two forms: an unstructured random coil conformation at elevated temperature (above temperature around 60 °C called coil-helix transition temperature) and a structured double helix formed upon cooling. ι-carrageenan has an intermediate solubility, but as κ-carrageenan, it can occur in two forms. The main difference between ι-carrageenan and κ-carrageenan is their behavior upon cooling. At temperature above 60 °C, ι- and κ -carrageenans are always in the random coil conformation. Depending on the chemical characteristics of κ-carrageenan and of nature of its physicochemical environment, its coil-helix transition temperature is around 38 °C. In the presence of potassium ions, the helices of κ-carrageenan cluster together into bigger units where potassium forms electrostatic interactions with the sulfate groups and anhydro oxygen atom (Tako and Nakamura 1986). The properties of the obtained gels depend on the strength of these electrostatic interactions and then on the level of aggregation of double helices. This association explains also the hysteresis observed during rheological measurements of κ-carrageenan. The gelation of κ-carrageenan is also strongly promoted by other monovalent cations such as rubidium and cesium (Takemasa and Chiba 2001). κ-carrageenan gels are strong and brittle.

For ι-carrageenan, the coil-helix transition temperature is around 45 °C. Even if helices are formed below this temperature, they are not dependent of cations, and they do not form aggregates as suggested by the thermal conformational transition of ι-carrageenan showing no hysteresis. However, helices of ι-carrageenan can be bridged by calcium. In this case, the strength of the gel is related to the amount of calcium. Gels obtained from ι-carrageenan are weak and thixotropic (Van de Velde and De Ruiter 2002).

As described for agars, the texturing properties of carrageenans can be modified after interaction with other components in food systems. κ-carrageenan has a stabilizing effect on proteins resulting in mixed-gel large deformation behavior

which depends on physicochemical properties of the system. Protein addition increases gelation temperatures, melting temperatures, and storage moduli of carrageenan gels. Moreover, some proteins are protected by carrageenans which enhance their temperature of denaturation. The mechanism involved in this phenomenon is poorly known, but carrageenans could prevent interactions between hydrophobic regions of proteins and stabilize them after formation of hydrogen bonds. In milk, very low concentrations of carrageenans are required to obtain a gel. The synergistic effect of proteins and polysaccharides is related to the negatively charged polysaccharides and positively charged amino acids of caseins. Synergisms are also observed between κ-carrageenan and other polysaccharides such as galactomannans (locust bean gums). The mechanism at the origin of this synergism is based on the alignment of the non-branched mannan backbone regions of the galactomannan with the aggregates of the double helices of κ-carrageenan (Arda et al. 2009). These interactions lead to elastic gels with low syneresis compared to those of κ-carrageenan alone. Interactions with starch have been also described by authors. Carrageenan, as other polysaccharides, can interact with starches leading to a modulation of their gelatinization and retrogradation and then to their viscosity. The impact of carrageenans on starch is highly dependent to the type of carrageenan. Globally, carrageenans increased the apparent pasting temperature of starch and increase its apparent viscosity. Carrageenan was found to act as a protector for starch granules mostly against shear degradation (Appelqvist and Debet 1997). Funami et al. (2007) investigated the gelatinization and retrogradation of the aqueous starch/ι-carrageenan composite systems and their dependence on salinity. They explained the different behaviors as a combination of two phenomena: a similarity in structure between iota-carrageenan and amylose, leading to both a thermodynamic incompatibility and phase arrangements for the heating behavior, and physical interactions (both molecular complexes and steric hindrance) for the cooling behavior.

5 Conclusion

Often described as well-known macromolecules, galactans and sulfated galactans from various origins appeared as very complex polymers exhibiting a large diversity of biological activities and techno-functional activities. At this time, the rheological properties of sulfated galactans are well known and abundantly employed in industry. The future advances for this family of polysaccharides are probably a better understanding of relationships between their structures and the biological activities observed in various models. For this, progresses are necessary in the field of structural analysis but also in preparation of well-defined galactan sequences with controlled addition of noncarbohydrate groups and other substitution on the galactan backbone. These well-defined oligo- and polysaccharidic structures are not available in nature or only in small quantities after fastidious strategies of extraction, fractionation, and purification leading often to the collection of nonnative compounds. Indeed, their obtaining implies the development of

chemical and/or enzymatic tools to modify and/or synthesize galactans patterns. These galactan libraries could be then used in glycoarrays with a goal of building a systemic and biological approach of glycan structure-function relationships.

Functional Components in *Zizyphus* with Emphasis on Polysaccharides

27

Tsai Hua Kao and Bing Huei Chen

Contents

Abstract

Zizyphus jujuba (Chinese jujube), mainly distributed in the subtropical regions of Asia, has been cultivated for over 4,000 years and used as food, food additive, flavor, as well as traditional Chinese herb, as it possesses analeptic, palliative, and antibechic functions. The fruit of jujube is quite popular due to high nutritional value and presence of many functional components, in which polysaccharide is the most important one. Polysaccharides, being essential constituents of all living organisms, are naturally occurring polymers of aldoses and ketoses linked together through glycosidic linkages. In recent years, polysaccharides of plant origin have emerged as a vital class of bioactive nature products; however, there is a lack of information regarding analysis and biological activity of jujube polysaccharides. Moreover, the composition of polysaccharides in jujube may vary with different species, growth environment, cultivar variety, and extraction and separation methods, which in turn may affect the overall biological activity. The objective of this manuscript is to review the current status associated with jujube polysaccharide, including nutritional and functional components; methods of extraction, purification, separation, identification, and quantitation; as well as biological activity.

1 Introduction to *Zizyphus*

Zizyphus, a kind of spiny shrubs (Fig. 1), belongs to the Rhamnaceae family, with the leaves being alternate and entire. Several species of *Zizyphus* are deciduous, while the others are overgreen. The flowers are small and possess yellow-green appearance (Fig. 2). In general, the florescence is about from April to May, while the fruit maturation period is from July to September. Also, the fruits contain drupe and possess yellow-brown, red, or black appearance, with shape being globose or ovoid, size up to 6 × 4 cm, skin smooth or rough, glossy, thin but tough, and taste crisp and juicy, subacid to sweet (Pareek 2013). *Zizyphus* is mainly grown

Fig. 3 Changes in color with maturity and ripening of Indian jujube fruits (Pareek 2013)

in warm subtropic area, originally distributed in Asia, Africa, Europe, and America, possessing more than 700 species, including the most common *Z. jujuba* (jujube), *Z. spina-christi* from southwestern Asia, *Z. lotus* from the Mediterranean region, and *Z. mauritiana* from western Africa to India. In addition, *Z. joazeiro* is grown in Caatinga of Brazil, while *Z. celata* is listed as an endangered species in the United States (Wikipedia 2014). Botanically, *Zizyphus* is derived from its wild relative sour jujube or wild jujube. In ancient times, people selected and cultivated sour jujubes with big fruit and good flavor, which then gradually became the modern jujube species (*Z. jujuba*). Nevertheless, there are still semicultivated sour jujubes like "Tiger Eye" and "Yanjishan," both of which are popular in Beijing and Shandong Province of China, respectively (Guo and Shan 2010). Fresh jujube fruits are often consumed as fruits and can be processed into dried jujube, candied jujube (honey jujube), spirited jujube (drunk jujube), smoked jujube, roasted jujube, or jujube paste/filling (Yao 2013). Nonetheless, in Asia dried jujube fruits are often used as traditional herbs (Fig. 4).

China is the main production country of *Zizyphus*, with *Z. jujuba* being the major species, also named as Chinese date, red date, or zao, which has been grown over 4,000 years, and the production yield accounts for 90 % of total yield in the world. The cultivation area is widely distributed in mainland China, in which Gansu, Hebei, Henan, Ningxia, Shandong, Shaanxi, Shanxi, and Xinjiang produce the

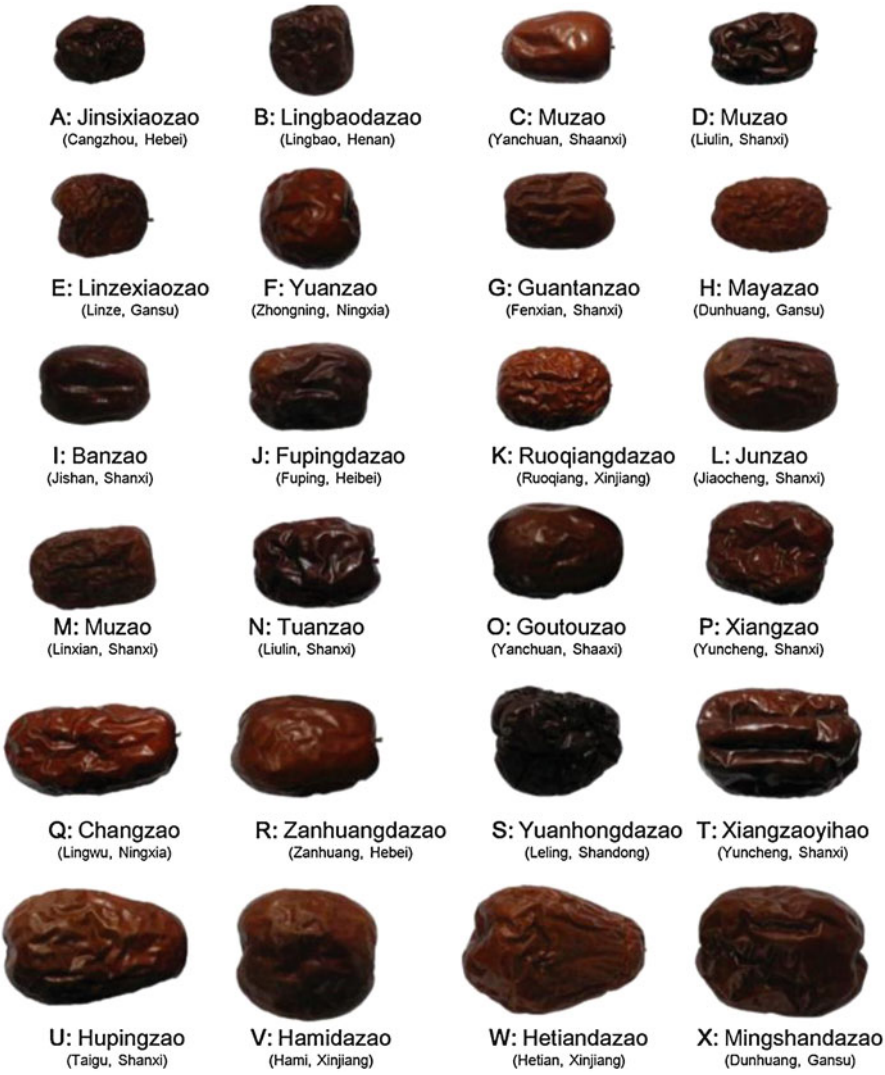

Fig. 4 The geographical locations and photographs of Chinese dates (Chen et al. 2013)

largest yield (Guo and Shan 2010; Yao 2013). Some other countries such as Korea and Japan also cultivate a small amount of jujube, and the main production area of jujube in Taiwan is located in Miaoli County. In addition, there is one more common species of *Zizyphus* named as *Ziziphi spinosi* semen (sour jujube seed), which is made from the dried seed of *Z. jujuba* var. *spinosa*. Although both jujube and sour jujube seeds are from the same species, the consumption mode and therapeutic efficiency can be varied greatly (Lee et al. 2012).

Jujube is often subject to direct sun-drying after maturation, or oven-drying until peel becomes soft followed by sun-drying, or boiling in hot water until pulp becomes soft followed by sun-drying (Wang et al. 2003). Jujube not only tastes sweet but also rich in nutrients, and thus it can be used as a common food and a vital drug source of the Chinese Materia Medica. According to the Divine Husbandman's Herbal Foundation Canon and the Compendium of Materia Medica, jujube possesses many important biological functions such as strengthening of the spleen and stomach, improvement of digestion and blood circulation, treatment of insomnia, and prolongation of life (Tsai 2004; Lee at al. 2012), all of which may be associated with the presence of functional compounds such as anthocyanin and polysaccharides in jujube (Lee et al. 2012). Additionally, in recent years, several studies have shown that jujube is protective against cancer, inflammation, allergy, and diabetes (Goyal et al. 2011; Lee et al. 2012). The traditional therapeutic effect of sour jujube is for treatment of insomnia and anxiety, as well as for pain-relieving and anticonvulsant (Guo et al. 2011; Han et al. 2009; Ma et al. 2008). As for functional components, they include alkaloids (sanjoinine A), flavonoids, saponins (jujubosides), and fatty acids (Cao et al. 2010; Ma et al. 2008; Zhao et al. 2006a).

2 Nutrients in Jujube

2.1 Basic Composition

According to the Chinese Academy of Agricultural Sciences, the basic composition of dried jujube is moisture (25–30 %), carbohydrate (55–80 %), crude protein (2.92 %), crude fiber (2.41 %), crude fat (0.96 %), phosphorus (0.09–1.27 %), potassium (0.61–1.05 %), calcium (0.03–0.06 %), magnesium (0.03–0.05 %), and trace minerals such as iron, manganese, copper, zinc, and selenium (Lei et al. 2006). Li et al. (2007a) determined the main composition of the five species of Chinese jujubes including Jinsixiaozao, Yazao, Jianzao, Junzao, and Sanbianhong, and moisture was found to range from 17.38 % to 22.52 %, carbohydrate from 80.86 % to 85.63 %, protein from 4.75 % to 6.86 %, fat from 0.37 % to 1.02 %, soluble fiber from 0.57 % to 2.79 %, insoluble fiber from 5.24 % to 7.18 %, reducing sugar from 57.61 % to 77.93 %, and ash from 2.26 % to 3.01 % (Table 1). Fructose and glucose are the major soluble sugars in all the five species, while rhamnose, sorbitol, and sucrose are present in a lesser amount. For minerals, potassium is present at 79.2–458 mg/100 g, calcium 45.6–118 mg/100 g, manganese 24.6–51.2 mg/100 g, and trace amounts of iron, sodium, copper, and zinc as mentioned above. Total phenolic contents are from 5.18 % to 8.53 mg/g (Li et al. 2007a).

According to a report by Pareek (2013), the jujube fruits contain 81–83 % moisture, 17.0 % carbohydrate, 0.8 % protein, 0.07 % fat, 0.76–1.8 % iron, 0.03 % each of calcium and phosphorus, 0.02 mg/100 g of carotene and thiamine, 0.020–0.038 mg/100 g of riboflavin, 0.7–0.9 mg/100 g of niacin, 0.2–1.1 mg/100 g of citric acid, 65–76 mg/100 g of ascorbic acid, 22 g/100 g of sugar, 1.3 g/100 g of

fiber, and 0.2 g/100 g of fat, with a caloric value of 104 kcal/100 g. Galactose, fructose, and glucose are the major sugars found in jujube fruit (Muchuweti et al. 2005).

Guil-Guerrero et al. (2004) analyzed several jujube varieties from Spain for fatty acid composition and found that triglycerides having medium-chain fatty acids were the most abundant in all samples. The main fatty acids included lauric acid (12:0), capric acid (10:0), linoleic acid (18:2 n6), palmitoleic acid (16:1 n7), palmitic acid (16:0), and oleic acid (18:1 n9) in total saponifiable oil. On an average, 1.3 g/100 g of saponifiable oil was found in fruit on a dry weight basis. In another study, San and Yildirim (2010) reported that jujube fruit also contained

methyl caproate (6:0), benzoic acid (6:3), methyl caprylate (8:0), ethyl hexanol (8:0), 2-octenoic acid (8:1), nonoic acid (9:0), benzenepropanoic acid (9:3), methyl caprinate (10:0), undecanoic acid (11:0), methyl laurate (12:0), methyl myristate (14:0), palmitic acid (16:0), *cis*-palmitoleic acid (16:1), *trans*-palmitoleic acid (16:1), stearic acid (18:0), 11-octadecenoic acid (18:1 n7), oleic acid (18:1 n9c), linoleic acid (18:2 n6c), linolenic acid (18:3 n3), and methyl heptacosanoate (28:0).

2.2 Functional Components

In addition to the nutrients mentioned above, jujube also contains some other functional components such as organic acid, carotenoid, nucleoside, vitamin, flavonoid, triterpenic acid, and polysaccharide, all of which will be discussed below. The general composition of jujube fruit is given in Table 2.

2.2.1 Organic Acids and Carotenoids

Citric, malonic, and malic acids were identified as the major organic acids in jujube fruit (Muchuweti et al. 2005). Carotenes were also found in jujube fruit; however, the contents were lower when compared to some other fruits. San and Yildirim (2010) analyzed four varieties of four jujube fruits, and β-carotene was present at a level from 7 to 35 μg/100 g based on fresh weight, whereas the amount of carotenes was from 4.12 to 5.98 mg/100 g of dry weight as reported by Guil-Guerrero et al. (2004). It was also shown that a much higher amount of β-carotene (15.6 mg/100 g) could be retained by freeze-drying (Gao et al. 2012).

2.2.2 Nucleosides and Nucleobases

It is well known that nucleosides and their bases (nucleobases) are involved in the regulation and modulation of various physiological processes in the body (Jacobson et al. 2002) and thus exhibit multiple bioactivities such as antiplatelet aggregation (Anfossi et al. 2002), antiarrhythmic (Conti et al. 1995), antioxidant (Virag and Szabo 2001), antiseizure (Schmidt et al. 2000), and antitumor (Kinahan et al. 1981). Jujube fruit is also a rich source of cAMP and cGMP, both of which possess the same physicochemical properties as pure cAMP and cGMP. The cAMP contents of jujube fruits ranged from 100 to 150 nmol/g of fresh fruit and 100 to 600 nmol/g of dried jujube fruit, with the cGMP content being 30–60 nmol/g of dried fruit and rose by 90-fold as the fruit ripened (Cyong and Takahashi 1982; Qu et al. 1987). Liu and Wang (1991) reported that cAMP in jujube cultivar Muzao was present in largest amount (303 nmol/g) based on fresh weight, which is the highest ever found in higher plants. Cyong and Hanabusa (1980) found the jujube cAMP content to be ten times higher than all the other fruits tested. According to a report by Guo et al. (2010a), both nucleosides and nucleobases are abundant in 49 varieties of jujube fruits, which ranged from 287.79 to 1239.23 μg/g. The contents of both cAMP and cGMP can be affected by species, climate, or geography. In a recent study, Chen et al. (2013) determined the chemical composition of 24 jujube fruits in mainland China, with uracil and cytidine being found in Hamidazao; uridine,

Table 2 Nutritional composition of jujube fruit (on fresh weight basis)

Constituents	Amount (per 100 g)	Ref
Moisture (g)	81.6–83.0	Pareek 2013

Pectin (% dry basis)	2.2–3.4	Pareek 2013

xanthine, and guanine in Jinsixiaozao; cAMP and guanosine in Goutouzao; cGMP in Yuanzao; and adenine in Hupingzao.

2.2.3 Vitamins

Jujube fruits also contain many vitamins such as A, B complex, C, E, and P, in which both vitamins C and P are present in the largest amount (Yao and Yin 2006). Bi et al. (1990) analyzed the vitamin C content in 121 jujube cultivars and reported an average of 412 mg/100 g of fresh weight with fresh-eating cultivars containing a lower amount of vitamin C than drying cultivars. However, most vitamin C underwent degradation during sun-drying, and only about 10 % could be retained. Thus, the consumption of fresh jujube fruits should be much better than dried ones. In addition to vitamin C, vitamin P is also present at a high amount

(3,300 mg/100 g) in the pulp of jujube fruit. Conversely, thiamine, riboflavin and vitamin E are present at a lower amount, which equal 0.04–0.08, 0.05–0.09, and 0.04–0.07 mg/100 g, respectively (San and Yildirim 2010). Nevertheless, the consumption of one fresh jujube fruit per day can meet the daily requirement of both vitamins C and B complex for an adult as recommended by WHO (Pareek 2013).

2.2.4 Polyphenols and Flavonoids

According to literature reports, total phenolic contents in jujube fruits ranged from 5.18 to 8.53 mg/g, with *p*-hydroxybenzoic, caffeic, ferulic, and *p*-coumaric acids being the most abundant at a concentration of 366, 31, 20, and 19 mg/kg DW, respectively, whereas vanillic acid was present at a lesser amount of 2.5 mg/kg DW (Pareek 2013). Wang et al. (2010a) determined polyphenol compounds in five varieties of jujube fruits – Hamidazao, Muzao, Goutouzao, Jinsixiaozao, and Tanzao in Xi'An, China – and a total of six compounds including gallic acid, protocatechuic acid, caffeic acid, *p*-coumaric acid, rutin, and quercetin were found, with caffeic acid and rutin being the dominant ones. Likewise, the polyphenol compounds in jujube fruits produced in Turkey were shown to contain catechin, caffeic acid, epicatechin, ferulic acid, rutin, *p*-hydroxybenzoic acid, and chlorogenic acid, with catechin and rutin being the major ones (San and Yildirim 2010). Similar outcome was also reported by Hudina et al. (2008) and Liu (2006). However, in a recent report, some more phenolic compounds such as gallic acid, protocatechuic acid, *p*-hydroxybenzoic acid, chlorogenic acid, vanillic acid, caffeic acid, *p*-coumaric acid, ferulic acid, ellagic acid, cinnamic acid, epicatechin, catechin, quercetin, and rutin were found in jujube fruits (Du et al. 2013). Also, a total of 24 varieties of jujube fruits were found to contain (-)-catechin, procyanidin B2, (-)-epicatechin, quercetin 3-*O*-galactoside, quercetin 3-*O*-rutinoside, quercetin 3-*O*-β-D-glucoside, and kaempferol 3-*O*-rutinoside by Chen et al. (2013). In a later study, Liao et al. (2012) further reported the presence of several flavonoids including isospinosin, spinosin, 6‴-sinapoylspinosin, 6‴-feruloylspinosin, and 6‴-coumaroylspinosin in jujube fruits produced in China. In jujube seeds, the flavonoids such as spinosin, 6″-feruloylspinosin, 6‴-*p*-hydroxybenzoylspinosin, saponarin, swertish, and vitexin were present (Choi et al. 2011).

2.2.5 Triterpenic Acids

Triterpenic acids are widespread in plants in the form of free acids or aglycones for triterpenoid saponins, which have been reported to possess multiple biological effects such as anti-inflammatory, antimicrobial, hepatoprotective, antioxidative, and anticarcinogenic activities (Liu et al. 1998; Fan et al. 2004; Gbaguidi et al. 2005; Martin et al. 2009; Kalogeropoulos et al. 2010). According to a report by Lee et al. (2004), jujube fruits were found to contain 11 terpenoides, including colubrinic acid, zizyberenalic acid, alphitolic acid, 3-*O*-*cis*-*p*-coumaroyl alphitolic acid, 3-*O*-*trans*-*p*-coumaroyl alphitolic acid, betulinic acid, betulonic acid, 3-*O*-*cis*-*p*-coumaroyl maslinic acid, 3-*O*-*trans*-*p*-coumaroyl maslinic acid, oleanolic acid, and oleanonic acid. However, some more triterpenic acids such as ceanothic,

alphitolic, zizyberanal, zizyberanalic, epiceanothic, ceanothenic, betulinic, oleanolic, ursonic, and zizyberenalic acids were shown to be present in dried jujube fruits by Guo et al. (2009a, b). Apparently, the composition and amount of triterpenic acids in jujube fruits can be affected by species, growing season, as well as geographical and environmental conditions (Guo et al. 2010b). In addition, both jujubosides A and B are also present in jujube fruits, which have been demonstrated to possess biological functions such as anti-proliferation of cancer cells (Xu et al. 2014).

3 Polysaccharides in Jujube

3.1 Introduction to Polysaccharides

Polysaccharides contain neutral and acidic polysaccharides, both of which are composed of one specific monosaccharide or two to six different monosaccharides connected with each other through glycosidic bond. The degree of polymerization is about between 100 and 1,000, and the physical and chemical properties of polysaccharides can be varied with monosaccharide variety and bonding mode. In general, polysaccharides possessing biological activity often carry negative charge and contain galacturonic acid (Paulsen 2001). Polysaccharides are widely distributed in plant, animal, and microorganism tissues, with more than 300 polysaccharides being characterized in nature. There are two main functions of polysaccharides: one is the basic structural substance of tissues such as cellulose in the cell wall of plants and chitosan in crustaceans for maintenance of tissue strength; the other one is to provide energy such as starch in plant tissue and glycogen in animal. In addition, several polysaccharides derived from plants or fungi participate in the regulation of cell signal transduction for life maintenance. Among the various polysaccharides, polysaccharides from Chinese herb are of particular importance as they have been shown to be nontoxic in vivo and effective in inhibiting tumor growth, enhancing immunity and antioxidant activity, as well as lowering blood sugar.

3.1.1 Factors Affecting Pharmaceutical Activity

Bonding Mode of Main Chain

Most polysaccharides possessing antitumor activity are found to have 1,3-β-D-glucan linkage. Bohn and BeMiller (1995) pointed out that the inhibition percentage of 1,3-β-D-glucan-containing polysaccharides derived from fungi toward tumor growth could reach 99–100 %, while the inhibition percentage of the other polysaccharides was only 10–40 %. In an early study, Matsuzaki et al. (1986) combined curdlan (1,3-β-D-glucan) and cellulose (1,4-β-D-glucan) for the synthesis of β-D-glucan containing a D-mannosyl and D-arabinofuranosyl branch chain, which was shown to possess high antitumor activity. This outcome implied that the bonding mode of main chain could affect biological activity.

Molecular Weight

The size of polysaccharides is another important factor which can affect biological activity. For instance, polysaccharides with MW 9,000 Da of dextrose were reported to exhibit biological activity, which could decrease sharply when the MW was higher or lower than 9,000 Da (Wang et al. 2004). Likewise, the antitumor activity could lose completely when the MW of fungi polysaccharides decreased to 10,000 Da by sonication mode (Kojima et al. 1986). In a study dealing with the inhibition of sarcoma 180 cell, Maruyama et al. (1989) reported that polysaccharides from *fungal mycelia* with MW $>$ 10,000 Da did not show inhibition effect. Gao et al. (1997) also found that the anticoagulation activity of sulfated polysaccharides increased following a rise in MW. For enhancement of immunity, polysaccharides with MW in the range of 200–1,000 kDa were the most effective (Borchers et al. 1999). As controversial outcomes over the antitumor activity as affected by MW of polysaccharides have been reported in the literature, more researches need to be done in clarifying this issue.

Functional Group

The physiological activity of polysaccharides can also be affected by displacement position and amount of functional groups such as sulfated, acetyl, and alkyl groups. Most sulfuric acid-esterified polysaccharides are effective in antivirus, antitumor, and anticoagulation. When the O-3 position was bonded with acetyl group in a polysaccharide molecule, the highest antitumor activity was shown. However, when the O-5 position was bonded with acetyl group, the antitumor activity could diminish. Under the condition of complete acetylation, the antitumor activity could lose completely as more hydroxyl groups are exposed, resulting in a change of polysaccharide activity (Wang et al. 2004). The antioxidant activity of polysaccharides extracted form longan peel was studied by Yang et al. (2009), reporting that the scavenging effect toward DPPH and superoxide radicals could decrease following a rise in degree of methylation.

Monosaccharide Composition

A study on mushroom indicated that polysaccharides with monosaccharide composition such as glucose, galactose, mannose, xylose, arabinose, fructose, ribose, and glucuronic acid could have antitumor activity (Zhang et al. 2007). In a similar study, Manning and Gibson (2004) found that polysaccharides containing glucose, galactose, xylose, and fructose could promote growth of probiotics. Also, the scavenging effect of carbohydrates did not correlate with the type of intrachain linkages, molecular weight, or degree of polymer branching but did appear to correlate with monosaccharide composition of polymer. A portion of the activity seems to be associated with monosaccharides, as both dextrose and mannose exhibited weak free radical scavenging activity. However, polymers were significantly better free radical scavengers than the polymeric structure confers additional free radical scavenging ability (Tsiapali et al. 2001).

Configuration

In addition to the factors mentioned above, the biological activity of polysaccharides can also be associated with configuration. For instance, a triple helical structure formed for schizophyllan with high MW 90,000 Da could be responsible for biological activity (Kojima et al. 1986). This finding was supported by a study by Maeda et al. (1988), who reported a decline in antitumor activity following breakdown of triple helical structure of mushroom polysaccharide (lentinan). Ohno et al. (2001) further reported that polysaccharides possessing a triple helical structure of 1,3-β-D-glucan could regulate immune function. Conversely, compared to a triple helical structure, a single helical structure was shown to exhibit a higher biological activity (Saito et al. 1991). Thus, more studies need to be conducted in clarifying this issue.

3.2 Extraction of Jujube Polysaccharides

The extraction methods of polysaccharides from plant tissues have been well documented and can be different due to variation in structure, location, and MW. In general, prior to polysaccharide extraction, solvents such as ethanol, acetonitrile, or methanol can be applied to remove interfering substances such as lipids, pigments, or proteins.

In an early study, Hormadova et al. (1999) used hot water or alkaline to extract polysaccharides from *Salvia officinalis* by sonication. Luo et al. (2004) extracted polysaccharides from dried *Lycium barbarum* L., followed by grinding into powder (<710 μm), using chloroform–methanol (2:1, v/v) for defatting, refluxing with 80 % ethanol, extraction with hot water (90 °C), precipitation with 95 % ethanol, 100 % ethanol and acetone separately, centrifugation, and drying to obtain crude polysaccharide. Zhang et al. (2004) compared the effect of two extraction methods (100 °C hot water for 3 h and sonication for 2 h) on MW distribution and antitumor activity of polysaccharides from *Pleurotus tuber-regium* and observed a higher antitumor activity for the former method and a larger MW for the latter method. Obviously, the variety and biological activity of polysaccharides can be affected by extraction method.

By summarizing all the results in the literature reports, it can be concluded that the extraction of jujube polysaccharides is usually conducted by 80–95 % ethanol with refluxing for removal of lipids, proteins, monosaccharides, or pigments (Zhao et al. 2006a; Wang et al. 2012a; Li et al. 2013), followed by hot water (80–100 °C) extraction, precipitation with 75–95 % ethanol, centrifugation or filtration, and freeze-drying (Zhao et al. 2006a; Chang et al. 2010; Wang et al. 2012a; Li et al. 2013). In addition, some more new methods, such as application of enzyme, sonication, and flocculation for polysaccharide extraction, have been developed, which are described below.

3.2.1 Hot Water Extraction and Ethanol Precipitation

As mentioned above, the most common method used for the extraction of polysaccharides from plant tissue is to employ hot water for extraction, followed by

precipitation with ethanol, and centrifugation for collection. Thus, the extraction efficiency of polysaccharides can be affected by variety and volume of solvent as well as extraction time and temperature (Li et al. 2007b). In a study dealing with the extraction of jujube polysaccharides in Taiwan, Chang et al. (2010) used 75 mL of hot water (90 °C) for extraction for 6 h, followed by precipitate removal by centrifugation, collection of supernatant for concentration, addition of 95 % ethanol for polysaccharide precipitation for 5 h at 4 °C, protein hydrolysis by proteinase, dialysis, and column chromatography for fractionation into neutral and acidic polysaccharides. Several similar methods were also used by some other authors (Li et al. 2013). The main advantage of this method is that not only many impurities such as fat, protein, pigment, and monosaccharide can be discarded but also only simple equipment is required. Nonetheless, this method may suffer a partial loss of immunity-enhanced polysaccharides. Also, the yields of both acidic and high MW polysaccharides can be reduced, while solvent consumption can be too high and extraction lengthy (Chang 2008).

3.2.2 Alkaline Extraction

The extraction efficiency of high MW and acidic polysaccharides can be enhanced by alkaline treatment as its solubility in hot water is low. Several alkalis such as sodium hydroxide, potassium hydroxide, and sodium carbonate in a concentration ranged from 0.1 to 1 mol/L are frequently used for polysaccharide extraction followed by ethanol precipitation (Li et al. 2007b). Based on a report by Yang et al. (2004), who compared the extraction efficiency of polysaccharides from jujube waste by several alkalis, the following order was observed: sodium carbonate > calcium oxide > sodium hydroxide. Similarly, a high yield (12.7 %) of polysaccharide could be attained by employing sodium carbonate solution (0.5 mol/L) with extraction temperature at 80 °C, raw material and solvent ratio at 1:20 (g/mL), and extraction time 3 h (Hu and Chen 2011). Most importantly, the solvent concentration has to be carefully controlled for alkaline extraction as several polysaccharides can be degraded through hydrolysis under strong base condition. Additionally, long extraction time and high solvent consumption are the major drawbacks for alkaline extraction. To overcome this, polysaccharides should subject to neutralization or dialysis immediately after alkaline extraction (Li et al. 2007b).

3.2.3 Enzyme Extraction

Enzyme extraction is a new technique widely used for polysaccharide extraction from plant tissues in recent years. Compared to some other extraction methods, the condition of this method is much milder, and the release of polysaccharides can be faster (Li et al. 2007b). Also, the polysaccharide purity can be greatly raised as the major interfering components such as starch, pectin, lipid, and protein can be degraded (Chang 2008). Moreover, the extraction can proceed at lower temperature and energy due to decrease of activation energy (Chang 2008). Thus, the major drawbacks associated with polysaccharide extraction such as high solvent consumption, low purity, and low in polysaccharide extraction recovery can be

remedied (Hou et al. 2013). Nevertheless, enzyme is very sensitive to temperature and pH changes, as well as the presence of inhibitors, such as Cu^{+2}, Hg^{+2}, and Al^{+3}. Also, the extraction cost can be relatively high, making enzyme extraction more difficult for commercialization (Chang 2008).

Due to the presence of thick cell wall and abundant amount of pectic substance and protein in jujube fruits, the polysaccharide release can be more difficult. Thus, during extraction process, several enzymes such as cellulase, pectinase, and protease can be added to facilitate polysaccharide release (Shi 2006). There are several proteases including neutral protease, acidic protease, trypsin, and pepsin that can be selected (Shi 2006). Cellulase can be used to degrade cellulose in the cell wall, pectinase can hydrolyze high MW pectin to reduce viscosity caused by dissolution of mucilaginous materials in hot water, and protease can hydrolyze protein to facilitate release of polysaccharides (Shi 2006; Li et al. 2013).

Accordingly, enzyme extraction can be divided into single enzyme extraction and complex enzyme extraction. The former aims to select only one enzyme for a particular characteristic of plant tissue, while the latter can select more than two enzymes for enlargement of limitation in enzyme extraction (Shi 2006). As described above, a combination of enzymes including cellulase, pectinase, and protease is often applied for jujube polysaccharide extraction. In addition, there are several commercially available proteases containing a small amount of pectinase and amylase, which can decrease capital cost and enhance convenience in application.

There are only a few literature reports dealing with jujube polysaccharide extraction by enzyme. For single enzyme extraction, Yang and Sun (2005) used papain to extract jujube polysaccharide and reported that the highest yield could be reached with papain concentration at 0.3 % (w/v), extraction temperature at 70 °C, and extraction time at 3 h. A similar outcome was shown by Meng et al. (2006), who used papain to extract jujube polysaccharides with papain concentration at 0.5 mg/mL, extraction temperature at 55 °C, pH at 7, and extraction time at 2.5 h. Interestingly, Yang and Yan (2012) employed a different enzyme (pectinase) for jujube polysaccharide extraction and observed a high yield of 7.29 % with pectinase concentration at 0.05 g/L, extraction temperature at 52 °C, and extraction time at 45 min.

For complex enzyme extraction, Yang et al. (2003) compared the effect of five enzyme systems, i.e., pepsin, papain, trypsin, papain plus trypsin, and trypsin plus papain (trypsin first followed by papain), on the yield of jujube polysaccharides and reported that the most efficient extraction could be attained at pH 7, trypsin concentration at 3 % (w/v), and extraction temperature at 65 °C for 1.5 h, followed by addition of 2.5 % (w/v) papain and extraction at 55 °C for 1 h. In a later study, a total of 3 complex enzyme systems, i.e., acidic protease containing a small amount of pectinase and amylase, cellulase containing a small amount of pectinase and semi-cellulase, as well as pectinase containing a small amount of semi-cellulase and amylase, were compared with traditional aqueous extraction for jujube polysaccharide yield (Shi 2006). Results showed that the application of acidic protease

system is the most efficient as the extraction time could be shortened to be within 2 h with extraction temperature at 50 °C, protease concentration at 1 % (w/v), and pH at 3.2, while a polysaccharide yield of 4.9 % with a purity of 47.9 % was obtained. Comparatively, the extraction time can exceed 3 h for traditional aqueous extraction method. Likewise, a combination of acidic protease, cellulase, and pectinase was adopted by Shi et al. (2010) for jujube polysaccharide extraction, which was shown to be superior to hot water extraction under the condition of enzyme concentration 1 % (w/v), temperature 48 °C, pH 5.2, and extraction time 2.2 h, with a polysaccharide yield of 4.61% being attained.

3.2.4 Ultrasonic Extraction

The ultrasonic extraction efficiency is based on its high frequency, short wavelength, and strong penetration. Theoretically, ultrasonic belongs to longitudinal wave, which can produce numerous minute vacuum bubbles through pressure change in liquid during extraction. A phenomenon of cavitation can be produced by the explosion of these vacuum bubbles, which can generate great impact to enhance the extraction efficiency largely. Additionally, ultrasonic extraction can be regarded as a physical disruption process through high-speed vibration during ultrasonic extraction, which in turn results in instant breakdown of the cell wall to allow components to dissolve into solvents (Li et al. 2007b). Also, ultrasonic can produce heat to accelerate extraction efficiency (Sun et al. 2011). Many recent studies have shown that with application of high strength and energy of ultrasonic, many bioactive compounds such as alkaloids, flavonoids, polysaccharides, proteins, chlorophylls, and essential oils can be extracted from *Panax ginseng*, *Salvia officinalis*, *Coptis chinensis* Franch, *Gynostemma pentaphyllum* (Thunb.) Makino, *Lycium chinense* Miller, *Humulus lupulus*, *Cinnamomum camphora*, and peanut (Li et al. 2007b).

The advantages of ultrasonic extraction are to shorten extraction time, lower solvent consumption, increase yield of polysaccharides, prevent heat loss due to operation at low temperature, and avoid vaporization of bioactive compounds with low boiling point (Li et al. 2007b).

Yao et al. (2007) reported that with ultrasonic frequency 28 KHz, extraction time 2.5 h, and temperature 70 °C, the jujube polysaccharide yield was higher than that without ultrasonic treatment by 48.7 %. In another study, Sun et al. (2011) employed ultrasonic extraction initially, followed by enzyme treatment of jujube polysaccharides by papain, trypsin, and neutral protease, and reported a high yield (21.95 %) and purity (13.05 %) to be reached with frequency at 70 W for 25 min at 70 °C, 0.15 % (w/v) papain, pH 6, and extraction temperature 70 °C for 2 h. In a recent report, Qu et al. (2013a) studied the effect of ultrasonic extraction on the yield and antioxidant activity of jujube polysaccharides and found that the experimental data fitted the quadratic response surface model by multiple regression analysis. The largest yield of polysaccharides was obtained by ultrasonic frequency at 120 W, extraction time 15 min, and temperature 55 °C, whereas the highest hydroxyl radical scavenging activity was observed at 80 W, 15 min and 40 °C.

3.2.5 Microwave Extraction

Microwave is an electromagnetic wave, consisting of electric field and magnetic field which oscillate perpendicularly to each other in a frequency ranged from 0.3 to 300 GHz. Microwave energy can not only penetrate into certain materials and interact with polar components to generate heat but also act directly on molecules through ionic conduction and dipole rotation. Thus, only selective and targeted materials can be heated based on their dielectric constants (Chen et al. 2011). Ionic interaction denotes that foods contain water or some other salts which can be dissolved in water to form ions for attraction caused by difference in electric poles in electric fields. Then positive ions can move toward negative pole and negative ions toward positive pole. However, the formation of microwave energy can be dependent upon the production of alternating field. Thus, when there is a fluctuation in electric field, positive and negative poles can exchange each other which lead to migration of positive and negative ions in foods toward to a 180° direction difference, after which heat caused by friction can be generated. On the other hand, the polar water molecules belong to a V-shaped structure with a clip angle at 105°. Both the positive charge (H^+) and negative charge (O^-) in water molecules can be affected by fluctuation in electric field to produce rotation, the so-called dipolar interaction, which lead to heat generation and subsequent temperature elevation during rotation (Buffler 1999).

The major advantages of microwave extraction are reduction of extraction time through temperature elevation as well as moderation of capital cost and improvement of performance under atmospheric condition (Chen et al. 2011). The efficiency of microwave treatment depends upon dielectric loss (ε'') and dielectric constant (ε') of materials. The larger the dielectric loss, the higher the efficiency of microwave conversion into heat. Likewise, a higher dielectric constant of a material implies a better absorption capacity of microwave. However, due to the presence of more than one component in foods, the difference in ε'' and ε' between food components can result in non-homogenicity of microwave energy and thus more difficult to control. From the cellular point of view, the pressure generated through water evaporation during microwave cooking can disrupt cell wall for tiny pore formation. After successive heating, cells can undergo shrinkage and form wrinkle on surface, making the penetration of solvents into cells more readily to leach active substances out (Lu 2003). In a review report, Chen et al. (2011) pointed out that the factors affecting microwave extraction included solvent nature, solvent to feed ratio, microwave power and extraction temperature, extraction time and cycle, plant matrix characteristics, and condition of stirring. Many commercial extraction equipments are now available, and the manufacturers include Milestone, CEM, Sineo, etc.

Microwave extraction is basically a novel extraction technology and now applied to the extraction of bioactive components like polysaccharides. Shi et al. (2008) reported that the best extraction efficiency of jujube polysaccharides could be attained by mixing 20 g of jujube powder with 200 mL of water, followed by microwave extraction at 480 W for 4 min. The optimum pH range was from 6.0 to 7.2, and a polysaccharide purity (83.62 %) and yield (4.07 %) were obtained.

A higher polysaccharide yield (7.99 %) in jujubes could be reached by controlling material to solvent ratio at 1:50 (g/mL) and microwave energy at 420 W for 8 min (Han and Ma 2013).

3.2.6 Flocculation

Flocculation is a process wherein colloids come out of suspension in the form of floc or flake, either spontaneously or due to the addition of a clarifying agent (An 2006). The action differs from precipitation in that, prior to flocculation, colloids are merely suspended in liquid and not actually dissolved in solution. In the flocculated system, there is no formation of cake, since all the flocs are in the suspension. According to the IUPAC definition, flocculation is "a process of contact and adhesion whereby the particles of a dispersion form larger-size clusters" and is synonymous with agglomeration, aggregation, and coagulation/coalescence (IUPAC 2006). During flocculation, gentle mixing accelerates the rate of particle collision, and the destabilized particles are further aggregated and enmeshed into larger precipitates. Flocculation is affected by several parameters, including mixing speed, mixing intensity, and mixing time.

The advantages of flocculation process are low capital cost, high efficiency, simple operation, and management. It has been widely applied to wastewater treatment, mineral substance separation, molasses and protein recovery, as well as drug manufacture (Liu 2005). The most commonly used flocculating agents include chitosan, gelatin, sodium alginate, and some other commercial products such as ZTC1 + 1 and 101. Factors affecting flocculation efficiency include MW, dose, contact time, temperature, and pH. Chang (2008) compared the efficiency of various flocculating agents and found both chitosan and ZTC1 + 1 possessed the best clarification efficiency, while a high polysaccharide recovery was maintained. Nevertheless, more studies need to be done to strengthen its application.

3.2.7 Comparison of Various Extraction Methods

Lin et al. (2005) compared the extraction efficiency of jujube polysaccharides by hot water, sonication, and microwave, with the latter two shown to be fast, safe, convenient, low in capital cost, stable in components, and high in yield, which equaled 0.899 %, 0.982 %, and 1.137 %, respectively. Similarly, in a later study, Qi et al. (2012) compared the extraction efficiency of jujube polysaccharides by the same extraction methods, but a higher yield of 11.33 %, 12.40 %, and 10.98 %, respectively, was obtained. Comparatively, there is a large difference in polysaccharide yield even with the same extraction method, which can be due to the difference in hot water temperature, extraction time, sonication and microwave power, ratio of solvent to raw material, and species of raw material. More specifically, the factors affecting degree in extraction efficiency of jujube polysaccharides by hot water extraction were in the following order: pH > soaking temperature > raw material to solvent ratio > soaking time; by sonication, pH > time > temperature > power; and by microwave, soaking time > microwave time > pH. In addition, the polysaccharides extracted by hot water and microwave showed a similar hydroxyl radical scavenging capacity, while sonication showed the least capacity.

3.3 Purification of Jujube Polysaccharides

As mentioned above, the crude polysaccharides obtained by various extraction methods still contain some other impurities like proteins, mucilaginous materials, and small-molecule substances.

3.3.1 Protein Removal

Organic Solvent

Sevag method is the most common and mildest method to remove protein based on protein denaturation in the presence of organic solvents such as chloroform. A suitable amount of chloroform-*n*-butanol (4:1, v/v) can be added to polysaccharide extract, followed by shaking vigorously, settling, or centrifuging. At this time, denatured protein will form colloidal substance between organic solvent and water layer, after which protein can be removed to obtain polysaccharide extract. Alternatively, protein denaturation can be accelerated by lowering pH of crude extract to 4–5. However, this method suffers a major drawback of low efficiency and repetitive operation. Thus, some other methods can be adopted to remove most protein, followed by residual protein removal with Sevag method to minimize polysaccharide loss (Li and Zhou 2007).

In addition to chloroform, trichlorotrifluoroethane can be used to denature protein. However, this solvent cannot be used in large quantity due to its low boiling point and high volatility. Some other solvents such as trichloroacetic acid can also be used to denature protein; however, this solvent may cause polysaccharide degradation. It is worth pointing out that for the production of polysaccharide as functional food, the toxicity of organic solvents has to be taken into account.

Enzyme Hydrolysis and Solvent Addition

As mentioned above, protease can be used to hydrolyze protein in crude polysaccharide extract and peptide linkage (Peng and Zhang 2003; Liu et al 2006). The protein removal step can be omitted if enzyme hydrolysis is carried out in the beginning. The most commonly used proteases are pepsin, trypsin, and papain. The advantages of enzymes are high specificity, low toxicity, and prevention of polysaccharide degradation. However, the capital cost is high for enzyme treatment but may be compromised by employing immobilized enzyme for repetitive use.

3.3.2 Defatting

The fat content in crude polysaccharide extract is very low; however, some authors used petroleum ether or diethyl ether with Soxhlet extraction apparatus to remove fat and enhance polysaccharide purity (Chen et al. 2006). Usually, the fat removal step has to be conducted before extraction.

3.3.3 Bleaching

Jujubes also contain a large quantity of red pigments. According to a report by Lu (2003), the pigments in jujubes can be applied to food, cosmetics, or medicine as

coloring agent, but the pigment characteristics need further investigation. As aqueous solutions are often adopted for polysaccharide extraction, lipid-soluble pigments should only present in small amount. Most pigments belong to phenolic-type compounds and anthraquinone derivatives. Crude polysaccharide extracts often possess brown or brown red appearance, which make pigment extraction more difficult because of high viscosity of crude extract. The current bleaching methods include ethanol precipitation, active carbon adsorption, resin adsorption, and hydrogen peroxide bleaching. The principle of ethanol precipitation method is based on the repetitive use of ethanol until the precipitate color becomes pale (Li 2004). Active carbon adsorption has been applied to bleaching of many materials like fat or oil through physical adsorption amid its porous and high surface area characteristics; however, the residual powdered active carbon is difficult to remove. Also, active carbon can not only adsorb a portion of polysaccharides, but also a low adsorption efficiency is shown for pigments carrying negative charge (Lu 2003). Thus, in recent years, some other adsorbents such as weak base resin DEAE-cellulose, Duolite A-7 (Wang et al. 2010b), and macroporous resins (LSA-800B or AB-8) are used for pigment adsorption (Qiu et al. 2007; Liu et al. 2007). The bleaching efficiency of resin is good but only suitable for crude extract containing a low amount of pigments and with low viscosity; otherwise, the regeneration of resins will be more difficult (Liu et al. 2007). Some other drawbacks of resins are as follows: the capital cost is high, the use of a chromatographic column is a must, and a large solvent consumption can create a solvent residual problem. Hydrogen peroxide is highly soluble in water, and the bleaching effect is based on the release of ion HO_2^- ($ka = 1.78 \times 10^{-12}$) in water, with the bleaching efficiency even being better under alkaline condition. Nonetheless, the concentration of hydrogen peroxide has to be carefully controlled; otherwise, it can create a residual problem and affect the integrity of polysaccharide structure. Meanwhile, the hydrogen peroxide degradation into water has to be prevented (Lu 2003).

3.3.4 Desalting

After bleaching, dialysis technique is often used to remove salt and other small-molecule substances in crude extract by a semipermeable membrane with designated MW. Based on osmotic pressure principle, large molecules like polysaccharides can be retained inside the membrane, while small molecules like salt can migrate toward outside of the membrane (Feng et al. 2004).

3.4 Separation of Jujube Polysaccharides

The purity of polysaccharides can be enhanced by removal of impurities; however, difference still exists in chemical composition, degree of polymerization, and molecular shape of various polysaccharides in crude extracts. Thus, polysaccharides in jujubes have to be further separated by employing chromatographic techniques such as ion exchange, gel filtration, affinity, etc.

Most water-soluble polysaccharides are weak acidic, present as charge-carrying complex in aqueous solution. The separation principle of ion-exchange chromatography is based on the difference in polarity of solutes, showing different affinity toward ion-exchange resins. Thus, through change in ionic strength and pH of mobile phase, solutes can be separated in column. In practice, initially a suitable buffer solution pours into a column for elution to attain equilibrium, followed by pouring sample solution for adsorption with stationary phase, and the solutes can be separated successively through increase in ionic strength or change in pH of mobile phase. The separation of different solutes can be dependent upon characteristics, density, and surface distribution of charges, resulting in different degree of interaction with ion-exchange resins. Usually the solute with weak interaction can be eluted first. The most commonly used negative ion-exchange resins are DEAE-cellulose, DEAE-Sepharose CL-4B or CL-6B, and Toyopearl DEAE-650 M (Li et al. 2011a). For positive ion-exchange resin, the SP Sepharose can be adopted (Wang et al. 2010b). Mobile phase can be composed of water, sodium chloride, sodium acetate, sodium bicarbonate, or salt of boric acid. After separation, the eluates containing polysaccharides can be dialyzed, concentrated, and freeze-dried (Wang and Fang 2004).

Gel filtration chromatography (GFC) or gel permeation chromatography (GPC), a kind of size-exclusion chromatography, is applicable to high MW compounds. Packing material for GLC/GPC can be small (~10 μm) silica or polymer particles containing a network of uniform pores into which solute and solvent molecules can diffuse (Skoog et al. 2007). The various polysaccharides can be separated based on MW or size by GFC/GPC with quickness, high selectivity, and good repeatability. The polysaccharide with large MW can be eluted first, which is then measured via a calibration curve prepared from a series of standards possessing different MW (Wang and Fang 2004). In general, the stationary phases include Sephadex (G-100, G-75, G-50, or G-25), Sephacryl (S-200 or S-300), TSK (G5000-PW or G3000-PW), Toyopearl HW-65 F, Sepharose CL-6B, and Fractogel HW-65, whereas the mobile phase can be distilled water, 0.1–0.2 M NaCl, phosphate, etc. (Wang and Fang 2004; Li et al. 2011a; Gao et al. 2013).

In addition, affinity chromatography is regarded as an efficient method for purification of protein–polysaccharide complex, with ConA or Sepharose 4B column and water or sodium chloride solution as eluent being frequently used (Huie and Di 2004).

3.5 Qualitative and Quantitative Analyses of Jujube Polysaccharides

Compared to monosaccharides, disaccharides, and oligosaccharides, the analysis of polysaccharides is more difficult due to large molecular weight, complex structure, and inert chemical activation. Colorimetry with different chromogenic systems, such as carbazole–sulfuric acid, anthracenone–sulfuric acid, phenol–sulfuric acid, etc. can be applied to analyze total polysaccharides. However, the quantitative data

can be less accurate. For identification, several chromatographic methods are extensively applied to the compositional and structural analysis of polysaccharides when combined with some other detection methods such as laser induced fluorescence (LIF), electrochemical detection (ED), UV, IR, MS, NMR, etc. Thus, the structure of polysaccharides can only be elucidated by a combination of various techniques, which are described below.

3.5.1 Molecular Distribution of Polysaccharides by GFC/GPC

The MW distribution of polysaccharides can be determined by GPC or GFC based on the standard curve of polydextrin or some other polysaccharides with known MW (Yang et al. 2006). Chang et al. (2010) reported the average MW of polysaccharides in *Zizyphus jujuba* to be 129,518 and 46,740 Da for crude polysaccharide, 131,825 and 40,566 Da for deproteinated polysaccharide, 47,100 Da for neutral polysaccharide, and 55,522, 60,053 and 52,407 Da for three acidic polysaccharides obtained by column chromatography. This outcome is different from that reported by Zhao et al. (2006a), showing the average MW of the acidic polysaccharide fraction in Jinsixiaozao to be 2×10^6 Da, but a lower MW (1.4×10^5 Da) was reported by Li et al. (2007b). Apparently, the difference in MW distribution may be accounted for by variation in *Z. jujuba* species, extraction, purification, as well as separation conditions. In Chang's study (2010), a total of one neutral polysaccharide fraction and three acidic polysaccharide fractions were obtained, which should explain why a wide range of MW was observed.

3.5.2 IR

If the difference of rotational or vibrational energy level in a molecule conforms to infrared frequency, this molecule can absorb infrared light. This phenomenon can be used to analyze polysaccharide structure through absorption, reflection, and emission spectra. Generally purified polysaccharides can be dried, ground into powder, and mixed with KBr for compression into pastille for IR spectrum scanning.

Several researches have shown that the IR absorption spectra of jujube polysaccharides are as follows: 3,600 and 2,500 cm^{-1} refers to O-H stretching absorption due to inter- and intramolecular hydrogen bonds. The O-H stretching vibrations that occur within a broad range of frequencies indicate several features of a compound: free hydroxyl group stretching bands occur in samples in vapor phase and bonded O-H bands of carboxylic acid, the absorbance band at 3,414 cm^{-1} represented the stretching vibration of O-H in the constituent sugar residues, and the small band around 2,935 cm^{-1} refers to C-H absorption, including CH, CH_2, and CH_3 stretching and bending vibrations (Li et al. 2013).

The FT-IR spectra in the wave number between 850 and 1,200 cm^{-1} are regarded as the "fingerprint" region for carbohydrate, which is unique to a compound. These bands are usually difficult to interpret, but this region allows the identification of major chemical groups in polysaccharides as the position and intensity of these bands are specific to each polysaccharide (Cerna et al. 2003). The attributions of the main absorptions are characteristics of glycosidic structures

and related to CO stretching (1,097 cm^{-1} and 1,020 cm^{-1}) as well as anomeric C_1H group vibration (831 cm^{-1}). The small absorption bands at about 831 cm^{-1} in the spectrum can be associated with α-glycosidic linkage between the sugars units. The broader band of 1,149 cm^{-1} represents C-O-C and -OH in pyran structure. The bands representing ester carbonyl (1,760–1,745 cm^{-1}) and free carboxylate groups (1,640–1,620 cm^{-1}) are important in the identification and quantitation of polysaccharides. The bands occurring between 1,751 and 1,629 $cm^{-1}$are derived from the ester carbonyl (-COOR) groups and carboxylate ion stretching band (-COO-), respectively (Li et al. 2013).

According to Wang's study (2011), the absorption band at around 3290.20 cm^{-1} can be assigned to the stretching vibrations of hydrogen-bonded OH groups. The weak absorption bands at about 3,000–2,900 cm^{-1} are related to the C-H stretching vibration of free sugar. The absorption at 1616.20 cm^{-1} is assigned to the stretching vibrations of the CHO and C=O bonds. The broad absorption bands with strong intensities at 1,407.35, 1,342.96, and 1,254.35 cm^{-1} can be assigned to deforming vibrations of C-H bond. Similarly, the absorption bands at about 1,188.65, 1,143.50, and 1,025.43 cm^{-1} can be assignable mainly to the C-O-C stretching vibrations and C-O-H bending vibrations. The weak absorption bands at 917.28 and 865.20 cm^{-1} can be related to the C-H deforming vibrations in β-pyran ring, whereas the absorption at 816.57 cm^{-1} is related to the C-H deforming vibrations in α-pyran ring. Taken together, these outcomes suggest that Chinese jujube polysaccharides possess typical IR absorption peaks of polysaccharides. In a similar study, the IR spectra data for the identification of jujube polysaccharides were found as follows (Chang et al. 2010): all the polysaccharide fractions showed the same absorption bands at 3,600–3,200, 3,000–2,800, and 1,400–1,000 cm^{-1}, which are characteristics of stretching vibration of O-H, C-H, and bending vibration of C-H, respectively. Also, there are three absorption peaks present at 1,100–1,010 cm^{-1}, implying the presence of pyranose ring. A weak absorption peak at 1,250 cm^{-1} may be due to the stretching vibration of nonsymmetrical C-O-C. Likewise, the absorption peaks at 1,018 cm^{-1} and 1,146 cm^{-1} may be caused by stretching vibration of C=O and C-O-C, respectively. The α-glycosidic linkage in glycosyl residue may account for the absorption peak at 860 cm^{-1}. Another absorption peak at 1,250–950 cm^{-1} should be due to stretching vibration of O-H and C-O in pyranose ring.

3.5.3 Methylation

Methylation analysis has been used to determine carbohydrate structure for over a century, and today it is still the most powerful method in determining the sugar linkage of polysaccharides (Cui 2005). The methylated derivatization of a polysaccharide includes conversion of all free hydroxyl groups into methoxyls followed by acid hydrolysis, resulting in cleavage of the inter-glycosidic linkage in poly-methyl-ether while leaving the methyl-ether bonds intact. The hydrolyzed monomers are thus reduced and acetylated to give volatile products, such as partially methylated alditol acetate (PMAA), which can be identified and quantified by GC–MS. The substitution pattern of the *o*-methyl and acetyl groups in PMAA

reflects the linkage pattern and ring size of the corresponding sugar in the original polymer (Li et al. 2013).

In this technique, saccharides are reduced with sodium borodeuteride prior to per-*O*-methylation. Prior to per-*O*-methylation, the polysaccharides containing uranic acid residues are allowed to pass through a cation-exchange resin (H^+ form) in order to convert all the carboxyl groups into protonated form, thus permitting a more complete permethylation of polysaccharides containing uranic acid residues. High recovery of the per-*O*-methylated products can be attained by employing reversed-phase liquid chromatography after cleanup by a Sep-Pak C18 cartridge. Identification of microscale partially *O*-methylated alditol acetates by GC–MS with multiple, selected ion-mode electron-impact MS was found to be about sevenfold as sensitive as standard (Srivastava and Kulshreshtha 1989).

3.5.4 Mass Spectrometry

Following the development of new ion source like desorption ionization, mass spectrometry (MS) can be applied to analysis of nonvolatile, highly polar, and large MW components.

Methane and isobutane chemical ionization (CI) mass spectra of saccharides generally carry a large number of fragment ions; in the ammonia CI mass spectra, ammonia clusters and sample adduct ions are abundantly observed. Some other important features of the ammonia CI mass spectra are the higher stability of molecular ion adduct. Improvements in sensitivity and specificity have been reported by using methane chemical ionization MS and selected ion monitoring (Srivastava and Kulshreshtha 1989).

With field desorption mass spectrometry (FDMS), di- and trisaccharides give rise to $[M+H]^+$ and $[M+H\text{-}H_2O]^+$ ions with little fragmentation at a lower emitter current. A higher emitter current can be used to produce cleavage on either side of the glycosidic oxygens leading to sequence information. While the lower MW oligosaccharides can be analyzed without much difficulty, saccharides in the MW from range of 2,500 can be handled after partial methylation (Srivastava and Kulshreshtha 1989). Fast atom bombardment (FAB) MS and laser desorption (LD) MS are now in extensive use in the analysis of biopolymers such as polysaccharide. This approach utilizes a beam of projectiles or photons to ionize and desorb sample molecules deposited on a solid support (Srivastava and Kulshreshtha 1989).

3.5.5 NMR

The determination of anomeric configuration of the number of different sugars present in a repeating unit, the presence of amino and deoxy sugars, and the identification of *O*-acetyl groups and other nonsugar substituents are now routinely performed by ^1H and ^{13}C NMR spectroscopy, but the former can only provide limited information due to increase in size and complexity of molecules. Moreover, single broadening resulting from the decreased spin–spin relaxation time (T2) further adds to the intractability of the spectra. In the helical form, the C-3 signal of β-glucosyl moiety appeared at δ89, whereas in the random coil structure,

C-3 signal resonated at a higher field (δ86) in the ^{13}C NMR spectrum (Srivastava and Kulshreshtha 1989).

3.6 Sugar Composition in Jujube Polysaccharides

The average MW of neutral polysaccharides in jujube dates is about 23,000, which is mainly composed of arabinose, galactose, and glucose (Lei et al 2006), whereas the average MW of acidic polysaccharide is about 263,000, with the monosaccharide composition being rhamnose, arabinose, galactose, mannose, and galacturonic acid (Lei et al 2006). The monosaccharide composition can be analyzed by HPLC with refractive index (RI) detection, evaporative light scattering detection (ELSD), capillary zone electrophoresis combined with amperometric detection (CZE-AD), and thin-layer chromatography (TLC) (Zhao et al. 2006b).

In a study conducted by Yao et al. (2007), the monosaccharide composition of jujube polysaccharides after extraction by ultrasonic was shown to be L-rhamnose, D-fructose, glucose, D-galactose, and L-arabinose. In a later study, Chang et al. (2010) reported that after identification and quantitation by GC-FID, six monosaccharides including rhamnose, arabinose, xylose, mannose, glucose, and galactose were present in deproteinated polysaccharide at a molar ratio of 1:3.7:0.4:0.2:1:1.8, respectively. The same monosaccharides were also found in both ZJPa1 and ZJPa2 (2 acidic polysaccharides), with a molar ratio of 0.3:9.6:0.1:0.4:1:12.1 for the former and 3:16.8:1.2:0.2:1:12.2 for the latter. However, only 5 monosaccharides of arabinose, xylose, mannose, glucose, and galactose were present in neutral polysaccharide at a molar ratio of 0.3:0.2:0.2:1:0.7, respectively, as were rhamnose, arabinose, xylose, glucose, and galactose at 21:24:2:1:20 in ZJPa3 (one acidic polysaccharide). By comparison, galactose was the most abundant sugar in all the polysaccharide fractions. In several similar studies, Zhao et al. (2006a) reported a molar ratio of 2:1:1 for rhamnose, arabinose, and galactose, respectively, in the acidic polysaccharide fraction isolated from *Z. jujuba* cv. Jinsixiaozao fruits. But for the same fruit variety, Li et al. (2007a) reported the presence of rhamnose, arabinose, mannose, and galactose at a molar ratio of 13.8:4:3:8, respectively. This phenomenon implied that the monosaccharide composition might be different even for the same variety of *Z. jujuba*, which should be caused by the difference in extraction, purification, and separation conditions.

3.7 Physiological Activity of Jujube Polysaccharides

The pharmacological activity of jujubes has been well documented in many traditional Chinese herb books, with most functions focusing on improvement in insomnia, digestion, and blood circulation (Lee et al. 2012). In recent years, the researches on physiological activity of jujube polysaccharides have risen gradually. However, the scientific evidence associated with biological activity of jujube polysaccharides remains inadequate. Most jujube polysaccharide-related studies are

carried out in mainland China. The major challenge associated with biological activity research for jujube is the purity of polysaccharides. As noted before, even after extraction and purification, there are still many impurities present in polysaccharide fractions. Thus, it is possible that in addition to polysaccharides, some other functional components in jujube matrix may also play a vital role in maintaining biological functions. In view of this, more studies need to be done in terms of the relationship between function and structures such as position of activation and functional group, as well as metabolic route and products, so that the underlying mechanism on biological functions of jujube polysaccharides can be well elucidated.

3.7.1 Antioxidation

Compared to other research topics, the antioxidative activity of jujube polysaccharides has been studied more often. For instance, the antioxidative activity of hot water extract of jujubes was studied by Fan (1995), reporting the efficiency in inhibiting precursor formation of reactive oxygen species. Likewise, the activities of superoxide dismutase (SOD) and catalase (CAT) in mice blood could be raised by jujube polysaccharides, while the lipid oxidation product malondialdehyde in the blood, liver, and brain of mice could be lowered (Lee et al. 2005). In a later study, Chang et al. (2010) developed an appropriate analytical method for the isolation of polysaccharides from *Z. jujuba* fruits and evaluated their antioxidant activities *in vitro*. Results showed that all the four polysaccharide fractions including three acidic and one neutral polysaccharides were more effective in scavenging superoxide anions than hydroxyl radicals, while the acidic polysaccharides showed a more pronounced effect in chelating ferrous ion. Similarly, Li et al. (2011b) isolated four water-soluble polysaccharide fractions from *Z. jujuba* cv. Jinsixiaozao by DEAE-Sepharose CL-6B and Sepharose CL-6B columns and determined the free radical scavenging activity of each fraction. Data obtained in this study suggested uronic acid to be a reliable indicator of antioxidant activity. Also, the more the uronic acid in the structure, the higher the free radical scavenging activity. Wang et al. (2012b) measured the antioxidant activity of crude polysaccharide prepared from Z. jujuba cv. Shaanbeitanzao and reported a strong free radical scavenging effect that could prevent or ameliorate oxidative stress. More recently, Qu et al. (2013b) compared the antioxidant activity of jujube polysaccharides extracted by different methods and found that the polysaccharides extracted by ultrasonic showed a higher hydroxyl free radical scavenging activity than that extracted by hot water or microwave.

3.7.2 Immunomodulation

Many studies have pointed out that polysaccharides are effective in enhancing killing action of macrophage cells; inducing formation of TNF-α, IL-1, and NO; promoting stimulation of TNF-α by macrophage cells (Chang et al. 1999); and increasing anticomplementary activity (Yamada et al. 1985; Li et al. 2013).

Zhao et al. (2006b) isolated two pectic polysaccharides (Ju-B-3 and Ju-B-2) from fruits of *Z. jujuba* Mill. cv. Jinsixiaozao, with the latter showing a larger

proliferation effect of spleen cells at a higher dose (>30 μg/mL), whereas the former did not show any proliferation activity compared with control. From the structural point of view, rhamnogalacturonan and side chains (arabinan and galactan at O-4 of rhamnose residues) were proposed as the major contributors in stimulating immune responses. Li et al. (2011c) studied immunological activity of polysaccharide fractions from *Z. jujuba* cv. Jinsixiaozao (ZSP) and reported that the crude ZSP not only dramatically increased thymus and spleen indices in mice but also enhanced proliferation of splenocytes and peritoneal macrophages. Two fractions of ZSP (ZSP3c and ZSP4b) were believed to be responsible for immunological activity.

Zhang et al. (2013) purified four polysaccharides through protein removal and column chromatography, followed by addition of chlorosulfonic acid and pyridine under an optimal condition to obtain four sulfated polysaccharides $sOPS_{80}$, $sOPS_t$, $sJPS_{50}$, and $sJPS_t$, for comparison of immune-enhancing activity, with four unmodified polysaccharides as control. The *in vivo* finding showed that the sulfated polysaccharides could stimulate lymphocyte proliferation more effectively than their corresponding unmodified polysaccharides, with $sOPS_{80}$ possessing the highest efficiency. For in vivo experiment, the sulfated polysaccharides could also increase serum antibody titer. In a recent study, Hsu et al. (2014) studied the immunomodulatory effect of deproteinated polysaccharide isolated from *Z. jujuba* and observed a decline in IL-2 production in phytohemagglutinin-activated Jurkat T cells in a dose-dependent manner after 48 h incubation.

3.7.3 Hepatoprotection

Chang and Wu (2006) studied the effect of jujube polysaccharides on carbon tetrachloride-induced liver damage and exercise-induced fatigue in mice and found that with medium (200 mg/kg) and high (400 mg/kg) doses, the activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) decreased and the pathological change in liver tissue improved. Also, both muscle and liver glycogens rose in mice. With administration of high dose, the activity of lactic acid dehydrogenase (LDH) after exercise was elevated. Obviously, the intake of jujube polysaccharides can be protective against acute liver damage and fatigue. In a similar study, Wang et al. (2012b) showed that administration of the polysaccharides from *Zizyphus jujube* cv. Shaanbeitanzao significantly reduced the activities of CCl_4-elevated ALT, AST, and LDH in serum, as well as the level of hepatic malondialdehyde (MDA) level. Furthermore, mice treated with ZSP showed a better profile of hepatosomatic index (HI) and antioxidant system with normal glutathione peroxidase (GSH-Px) and superoxide dismutase (SOD) activities in the liver. All these findings suggested that jujube polysaccharides could be protective against CCl_4-induced hepatic injury through mediation of antioxidative and free radical scavenging activities.

3.7.4 Others

In addition to the findings shown above, some other studies have shown the neutral polysaccharides isolated from jujubes to be efficient in improving chest thickness,

increasing spleen lymphocytes in mice, and alleviating shrinkage and aging of immune organs in mice, as well as in antiaging (Miao and Shen 2001). Moreover, jujube polysaccharides could promote hemopoietic modulation system, stimulate proliferation and differentiation of hemopoietic stem cell and hematopoietic progenitor cells, and finally enrich blood (Xu et al. 2004). Also, the swimming time of mice could be extended through administration of jujube polysaccharides, and thus the antifatigue activity was enhanced (Wang 2009). Additionally, during exercise, jujube polysaccharides could provide energy source, avoid excessive utilization of protein, raise antioxidant activity, and elevate the amount of sugar stored (Wang 2009).

4 Conclusion and Future Perspective

Owing to modernization of extraction and analytical technique, the development of functional food with therapeutic efficiency has become a vital research area all over the world. Jujube polysaccharides represent an important class of health foods with potential therapy of chronic diseases. However, the studies dealing with biological activity of jujube polysaccharides remain inadequate. More researches need to be done in elucidating the relationship between physiological activity and polysaccharide structure. Also, new methods have to be developed to remove impurities and enhance polysaccharide purity. To overcome this, it is feasible to develop a botanic drug with jujube polysaccharide as raw material in the future.

Chitosan-Based Edible Films

28

Maher Z. Elsabee

Contents

Abstract

What is an edible packaging? An edible film or coating is simply defined as a thin film of edible material formed and sprayed on foods or food components. This package can be eaten as a part of the whole food product; it is also biodegradable, so if dumped it will disintegrate in reasonable short time.

Edible films and coatings offer extra advantages such as edibility, biocompatibility, esthetic appearance, barrier to gas properties, nontoxicity, nonpolluting, and having low cost (No et al. J Food Sci 72(5):87–100, 2007). In addition, biofilms and coatings by themselves are acting as carriers of food additives (i.e., antioxidants, antimicrobials) and have been particularly considered in food preservation due to their ability to extend the shelf life.

This chapter will focus mainly on edible films based on chitosan – a wonderful amazing material which is derived from the naturally occurring polymer chitin.

Keywords
Chitosan • Chitosan blends • Starch • Essential oils • Antibacterial • Shelf life

1 Introduction

According to the US Environmental Protection Agency, 32 million tons of plastic wastes were generated in 2012, representing 12.7 % of the total municipal solid waste (MSW). In 2012, the United States generated almost 14 million tons of plastics as containers and packaging, about 11 million tons as durable goods such as appliances, and almost 7 million tons as nondurable goods, such as plates and cups. Almost every year 1.6 million metric tons of packaging waste is dumped into landfills in the United States. Packaging waste is app. 30 % of municipal waste by weight, and 13 % is due to plastic material which is not biodegradable. This dumped packaging includes mainly plastics which reduce moisture and O_2 transfer rate of soil and deteriorates the quality of land. Plastics are nonbiodegradable and they are the biggest threats to environment in present world. Edible package can be a partial solution to these environmental problems. Recently, considerable research has been conducted to develop and apply bio-based polymers made from a variety of agricultural commodities and/or of food waste products (Vásconez et al. 2009). Numerous review articles have described the nature of these films and their antimicrobial constituents, construction, and general effectiveness (Elsabee and Abdou 2013; No et al. 2007; Joerger 2007; Alvarez 2000; Cutter 2002, 2006; Appendini and Hotchkiss 2002; Quintavalla and Vicini 2002; Suppakul et al. 2003; Ozdemir and Floros 2004; Cha and Chinnan 2004).

This increased interest was intensified due to concerns about limited natural resources of the fossil fuel reserve and the environmental impact caused by the use of nonbiodegradable plastic-based packaging materials (Catarina et al. 2009). Such biopolymers include starches, cellulose derivatives, chitosan/chitin, gums, proteins (animal or plant based), and lipids (Cutter 2006). These materials offer the possibility of obtaining thin films and coatings to cover fresh or processed foods to extend their shelf life.

Chitin, a naturally abundant polymer, consists of 2-acetamido 2-deoxy-b-D-glucose through a β (1–4) linkage. In spite of the presence of nitrogen, it may be regarded as cellulose with hydroxyl at position C-2 replaced by an acetamido group (Abdou et al. 2008). Like cellulose, it functions as structural polysaccharides. Its natural production is inexhaustible; arthropods, by themselves, account for more than 106 species from the 1.2×10^6 of total species compiled for animal kingdom, constituting a permanent and large biomass source. Chitin is a white, hard, inelastic, nitrogenous polysaccharide and the major source of surface pollution in coastal areas. Chitin is usually isolated from the exoskeletons of crustaceans and more particularly from shrimps and crabs where a-chitin is produced (Minke and Blackwell 1978; Austin et al. 1989). Squid is another important source of chitin in which

it exists in the β form which was found to be more amenable for deacetylation. It also shows higher solubility, higher reactivity, and higher affinity toward solvents and swelling than α-chitin due to much weaker intermolecular hydrogen bonding ascribable to the parallel arrangement of the main chains (Pawadee et al. 2003; Gardner and Blakwell 1975; Hunt and Elsherief 1990; Chandumpaia et al. 2004). The production of chitosan from crustacean shells obtained as a food waste is economically feasible, especially if it includes the recovery of carotenoids. The shells contain considerable amount of astaxanthin, a carotenoid that has so far not been synthesized and that is marked as a fish food additive in aquaculture. Chitosan itself was directly extracted from fungi by alkaline and acid treatment (Rane and Hoover 1993; Cai et al. 2006; Suntornsuk et al. 2002; Chatterjee et al. 2005). Some authors (Wang et al. 2006; Gagne and Simpson 1993; Oh et al. 2000; Yang et al. 2000) have developed methods to use microorganisms or proteolytic enzymes for the deproteinization of the crustacean chitin wastes; in this way a more economic production of chitin and chitosan can be achieved. The major procedure for obtaining chitosan is based on the alkaline deacetylation of chitin with strong alkaline solution. Isolation of chitin itself from different sources is affected by the source. Generally the raw material is crushed, washed with water or detergent, and cut into small pieces. The mineral content of the exoskeleton of the different crustaceans is not the same, and consequently different treatments may be used.

The potential of chitosan to act as a food preservative of natural origin has been widely reported on the basis of in vitro trials as well as through direct application on real complex matrix foods (Coma et al. 2002, 2003; Durango et al. 2006; Han et al. 2004; Park et al. 2004; Ribeiro et al. 2007). Chitosan is also an excellent film-forming material (Domard and Domard 2001). Chitosan films have a selective permeability to gases (CO_2 and O_2) and good mechanical properties. However, the fact that chitosan films are highly permeable to water vapor limits their use as being an important drawback since an effective control of moisture transfer is a desirable property for most foods, especially in moist environments. Therefore, several strategies have been used to improve the physical properties of biopolymer-based films.

2 Chitosan

The incorporation of natural antimicrobial substances in the packaging film is an alternative way to reduce the chemical substances used in food preservation (Cissé Mohamed et al. 2013). These antimicrobial-enhanced packaging films can ensure the safety of food surfaces through controlled release of antimicrobial substances from the carrier film structure to food surface. The antimicrobial compounds and their incorporation into packaging materials have been well reviewed (Appendini and Hotchkiss 2002; Han 2000; Park et al. 2004). These films have advantages over the direct application of antibacterial agents onto food, because edible films can be designed to slow antimicrobial diffusion to the surface of food (Dawson et al. 2002; Sebti and Coma 2002). Therefore, smaller amounts of antimicrobial agents would

be needed in edible films to achieve a target shelf life, compared with direct application on the food surface. Cisse et al. have prepared chitosan films using dilute lactic acid as a solvent at pH 5.5 and added a lactoperoxidase system (LPOS) which consists of lactoperoxidase (LPO; 140 U/mg), glucose oxidase (GO; 158.9 U/mg), D-glucose (Glu), and potassium thiocyanate (KSCN), not potassium iodide. This system possesses a broad antimicrobial spectrum and showed a bactericidal effect on gram-negative bacteria and a bacteriostatic effect on gram-positive bacteria also, which has antifungal and antiviral activity. The mechanical properties of the films showed slight enhancement due to the incorporation of the enzyme system; however, the water vapor permeability, which is a key parameter to ensure the organoleptic qualities of food and the film capability to fight against dehydration or rehydration, was not improved with this modification. The chitosan films obtained containing different amounts of the peroxidase system were used for mango packaging and coating to protect them against pathogens. Its use can help preventing the loss of mango due to fungi and bacteria during storage and transport.

A comprehensive review dealing with the application of chitosan in food protection applications has been published by No et al. (2007). The application of chitosan in food industry is mainly due to its film-forming ability and its antimicrobial activity against a wide range of food-borne filamentous fungi, yeast, and bacteria. Three mechanisms were given to explain the antimicrobial mechanism of chitosan albeit being not very exclusive. The first hypothesis attributes the antimicrobial property of chitosan to a change in cell permeability due to interactions between the positively charged chitosan molecules and the negatively charged microbial cell membranes. This interaction leads to the leakage of proteinaceous and other intracellular constituents. Other mechanisms are the interaction of diffused hydrolysis products with microbial DNA, which leads to the inhibition of the mRNA and protein synthesis. Finally a chelation of metals and spore elements with chitosan results in depriving the cells from their essential nutrients, leading to their starvation and death. The review discussed the effect of chitosan on several food items 1- bread; applications of chitosan for extension of shelf life of baguette bread by retarding starch retrogradation and/or by inhibiting microbial growth. Park and others (2002b) coated the surface of dough with 0.5 %, 1.0 %, or 1.5 % chitosan in 1.0 % acetic acid using a brush after molding. The baguette, with 1 % chitosan, showed less weight loss, hardness, and retrogradation than the control during storage for 36 h at 25 °C, and the shelf life of 1 % chitosan coated was extended by 24 h compared to the control. In another experiment by Ahn and others (2003), it has been shown that bread coated with 1 % and 2 % chitosan (120 kDa, DD = 85 %) dissolved in 0.3 % lactic acid showed lower total bacterial counts and thiobarbituric acid-reactive substances (TBARS) and higher water content than those of the control after 8 days of storage at room temperature. Mold growth was detected in the control after 4 days of storage. Also, Lee and Lee (1997) reported that the shelf life of fermented pan bread containing carboxymethyl chitosan was extended by retarding retrogradation and by inhibiting growth of microorganisms. Therefore, the improved shelf life and quality of bread by chitosan coating or addition is attributed to moisture barrier property and ability to retard retrogradation and

microbial growth of chitosan. The review contains a compiled data of scientific publications reporting the antimicrobial activity of chitosan and its applications in food science. The second item in the review was the application of chitosan for the protection and extending the shelf life of eggs. It has been shown by several workers (Lee et al. 1996; Bhale et al. 2003; Caner 2005) that chitosan coating is effective in preserving the internal quality of eggs without affecting consumer acceptance. Using chitosan with different molecular weights in 1 and 2 % concentration in 1 and 2 % acetic acid with or without glycerol and coating eggs with brush or sponge or by immersion lead to reducing weight loss and obtaining more desirable albumen (higher Haugh unit) and yolk (higher yolk index) quality during a 5-week storage period. The Haugh unit and yolk index values indicated that the albumen and yolk quality of chitosan-coated eggs could be preserved up to 5 weeks at 25 °C, which was at least 3 weeks longer than observed for the control noncoated eggs. Caner (2005) observed that the albumen pH of chitosan-coated eggs (3 % in 1 % acetic acid) increased from 7.49 to 8.83, while that of uncoated eggs increased from 7.48 to 9.3 after 4-week storage at 25 °C. These results indicate that chitosan coating decreased carbon dioxide release through the shell by acting as a gas barrier. These results indicate that chitosan coating decreased carbon dioxide release through the shell by acting as a gas barrier. This provides evidence that the improved quality and extended shelf life of eggs by chitosan coating is attributed to the protective barrier properties of chitosan film for moisture and gas transfer through the egg shell.

The review discussed also the role of chitosan as a protective film to extend the shelf life of fruit and vegetable and provided several references dealing with this subject.

Among the interesting points in the review is the use of chitosan for extending the shelf life of milk, and a negative effect of chitosan was found; however, banana-flavored milk showed complete inhibition of microbial growth in contrast to that observed in control milk (without chitosan) during storage for 15 days at 4 °C and 10 °C. The banana-flavored milk containing chitosan also maintained relatively higher pH than that of control milk during storage for 15 days at both temperatures. The review deals also with many other items which should be inspected in more details for each individual subject for the interested researcher. A quick summary is given below: Kimchi is a traditional Korean fermented vegetable food, made mainly from Chinese cabbage with various ingredients such as garlic, red pepper powder, ginger, green onion, and fermented fish sauce. Several workers have reported that chitosan was effective in extending the edible periods of kimchi (No et al. 1995; Hur et al. 1997; Lee and Jo 1998; Yoo et al. 1998; Lee and Lee 2000). The shelf life of kimchi supplemented with chitosan oligosaccharide (0.005 %, 0.02 %, and 0.2 % in water) could be extended by 2–6 times compared to 2 days of the control kimchi at 20°. For mayonnaise, chitosan was found to increase the emulsifying capacity of egg yolk, and the addition of chitosan enhanced the emulsion stability of mayonnaise by 9.4 % compared to the control (Lee 1996). For meat, chitosan possesses antioxidant in addition to its antimicrobial properties (Kamil et al. 2002; No et al. 2002). The addition of chitosan to meat may retard and

inhibit the growth of bacteria and fungi during storage. Noodle and rice cake were found to half longer shelf life after treatment with chitosan solution with different concentrations and molecular weight (Lee and No 2002). Soybean curd (tofu) soybean sprouts were treated with chitosan solution, and it was found that this treatment extends the shelf life of the curd and increased the growth rate and weight of the sprout. The use of chitosan addition to sausage was found to be useful in reducing the amount of sodium nitrite which is usually used as a preservative and curing agent. However, the nitrite has a strong toxicant effect to human health (Park et al. 1999; Youn et al. 1999, 2000, 2001b).

The use of chitosan as an antimicrobial agent to extend the shelf life of starch jelly has been demonstrated by Moon et al. (1997). The shelf life of acorn starch jelly containing 0.5 % chitosan (44 kDa, DD = 75.2 %) dissolved in 1.0 % acetic acid was extended to 6 days at room temperature, twice longer than that of the control. The addition of chitosan to the acorn starch jelly formulation also increased its hardness compared with that of the control.

Since seafoods and seafood products are highly susceptible to quality deterioration due to lipid oxidation of unsaturated fatty acids, catalyzed by the presence of high concentrations of hematin compounds and metal ions in the fish muscle (Decker and Hultin 1992), the review devoted thorough and detailed studies regarding the use of chitosan as a protective coating and antioxidant to salmon and other seafood product. The main conclusion here is that the antioxidant efficacy of chitosan is highly dependent on the molecular weight of chitosan and its concentration (Kim and Thomas 2007; Peng et al. 1998; Kamil et al. 2002). The protective action of chitosan is also effective when it is applied as a protective film, where it retards lipid oxidation and microbial spoilage by acting as a barrier against oxygen (Jeon et al. 2002).

Another review dealing with antibacterial films used in packaging and food protection was also published in 2007 by Rolf D. Joerger. The review catalogues and analyzes the outcome of researches conducted in the last decade to develop and test films with antimicrobial properties to improve food safety and shelf life. It discussed the methodologies for measuring antimicrobial activity of both edible and inedible films. The article contains interesting data and comparison between edible and inedible films used as packaging materials carrying antimicrobial compounds. The data are represented as a pie diagram with figures representing the number of articles dealing with each specific type of polymer, in which chitosan occupied the largest number of articles describing its application as edible films with antimicrobial property. Many diagrams and figures were included in the review describing the use of particular antimicrobial compounds used in packaging films with antimicrobial applications and the organisms that were subjected to antimicrobial film tests which were inoculated into nonfood media or onto food surfaces and those that are indigenous to foods. Also the media described in the literature are reviewed in another pie diagram. Numerous figures were given compiling data regarding the antimicrobial efficacy for the different antibiotics and natural materials used in corporation with packaging films both edible and inedible.

The effect of chitosan coating as a barrier to gases, water vapor, solutes, and microbiological safety has been demonstrated by covering minimally processed

garlic with agar–agar-based (1 %) coatings incorporated with 0.2 % chitosan and 0.2 % acetic acid (Geraldine et al. 2008). Filamentous fungi and aerobic mesophilic were inhibited on the coated garlic cloves. Coated garlic cloves had a respiration rate halved compared to the noncoated garlic cloves. Water vapor transmission was lower for the films added with chitosan. The uncoated garlic samples turned brown rapidly due to the effect of polyphenol oxidase enzyme that oxidizes the phenolic compounds in the garlic in the presence of O_2, causing browning in tissues.

Coating has probably reduced the O_2 concentration around the clove tissues, making it unavailable for the browning reactions (Geraldine et al. 2008). The data obtained by the authors indicated that coating of garlic leads to a reduction of log (UFC g^{-1}) from 10^{-8} to 10^{-5} after 9 days of storage at 25 °C as compared to the uncoated samples. No noticeable effect of coating has been found regarding mesophilic count.

The authors concluded that the active coatings with chitosan and agar–agar can guarantee the quality of minimally processed garlic for an extended period, especially with respect to microbiological aspects; ensured lower color variation, moisture loss, and respiration rate; and prolonged shelf life (Geraldine et al. 2008).

Chitosan (CH) and chitosan lactate (CL) have been used in a powder coating technique to preserve and extend the shelf life of shredded radish (Pushkala et al. 2013). The effects of the two forms of chitosan as a powder coating on the physicochemical parameters, bioactive compounds, microbial quality, consumer acceptance, and marketability of radish shreds stored in macro-perforated LDPE packages have been investigated. Radish shreds were spread as a thin layer in polypropylene trays. Chitosan powder 0.2 % was applied uniformly over the surface of the shreds, followed by thorough mixing to ensure adequate coating.

The physiological loss in weight (%) of radish shreds stored for 10 days at 10 °C for the untreated control was found to be 8–10 %, while that for the coated samples with 0.2 % purified CH and CL was 4–6 % which was attributed to the ability of chitosan to act as water vapor barrier preventing the migration of moisture to the environment. Vitamin C content of 147.5 mg/kg was recorded in all the radish shreds samples immediately after processing. A gradual decrease in ascorbic acid content during storage was observed, which was attributed to the stress induced during shredding operation. The CH- and CL-treated samples exhibited 53 % and 72 % higher vitamin C content, respectively, compared to the control after 10 days of storage. Better retention of vitamin C has been also demonstrated in chitosan-coated fresh-cut mango (Chien et al. 2007), chestnut, and pear (Pen and Jiang 2003; Xiao et al. 2010). Mango pulp is very perishable and so has a short shelf life, which both marketers and consumers would like to be longer. Manually sliced mango was treated with aqueous solutions of 0 %, 0.5 %, 1 %, or 2 % chitosan; placed into plastic trays; and over-wrapped with PVDC film and then stored at 6 °C. Chitosan coating retarded water loss and the drop in sensory quality, increasing the soluble solid content, titratable acidity, and ascorbic acid content. It also inhibited the growth of microorganisms.

This has been related to the reduced respiration rate as a result of coating treatment (Jiang and Li 2001). An association was observed between the bioactive

compounds and antioxidant activity, with the chitosan-coated samples recording higher bioactive compounds and correspondingly higher antioxidant activity especially on the fifth and tenth day of storage.

Chitosan-coated samples, CH and CL, exhibited a lower microbial mesophilic aerobic bacterial count and yeast and mold count in the samples during storage. On the seventh day of storage, the microbial load was found to increase to 6.74 log CFU g − 1 in control samples, whereas in both CH and CL samples, 2 log reductions in microbial counts (4.3 and 4.6 log CFU g − 1) were witnessed, respectively. Application of chitosan coating also led to a significant reduction in the yeast and mold count. An increase in the yeast and mold population was observed in control samples on the 7 days (4.4 log CFU g − 1), whereas treatment with chitosan brought about a 2 log decrease in the yeast and mold numbers.

The authors concluded finally that both CH- and CL-coated samples showed comparable results with regard to physicochemical parameters, bioactive compounds, microbial quality, and sensory acceptability throughout the 10 days storage period, significantly better than the control. Chitosan coatings were also beneficial in maintaining a higher product quality during the storage period. Hence, a powder coating technique using chitosan biopolymer and macroperforation is proposed as a practical method to preserve the quality and to extend the shelf life of fresh-cut radish (Pushkala et al. 2013).

Chitosan was successful in inhibiting the growth of *Pe. chrysogenum*, *Fusarium oxysporum*, and *Aspergillus parasiticus* in in vitro study; chitosan coating also gave good results for table grapes and honey-cut melons against *F. oxysporum* growth. There were no significant differences between 1.5 % and 3.0 % concentrations of the coating, and better hunter color values were obtained from fruits with chitosan coating. It was concluded that 1.5 % of chitosan coating may be considered as an optimum edible coating concentration in the preservation of cut fruits or fruit salads (Irkin and Guldas 2013).

The effects of chitosan edible coating on microbiological and sensory quality of refrigerated broccoli were studied by Moreira et al. 2011. The antimicrobial effects of chitosan on the native microflora (mesophilic, psychrotrophic, yeast and molds, lactic acid bacteria, and coliforms) and on the survival of *E. coli* O157:H7 inoculated in broccoli were evaluated. Chitosan treatments resulted in a significant reduction in total mesophilic and psychrotrophic bacteria counts with respect to the control samples during the entire storage period. Chitosan coating inhibited the growth of total coliform throughout the storage time. Also, chitosan treatments resulted in a bactericidal effect on endogenous *E. coli* and a significant decrease in total *E. coli* counts (endogenous and O157:H7). The application of chitosan coating on fresh-cut broccoli inhibited the yellowing and opening of florets.

Chitosan CH was also used to protect white leg shrimp from microbial spoilage and endogenous enzymatic browning during 0 ± 1 °C storage and could prolong shelf life up to 10 days (Huang et al. 2012). Carboxymethyl chitosan (CMC), a water-soluble derivative of chitosan, can keep working against spoilage bacteria throughout 10 days storage and thus extend shelf life of shrimp. Both CMC and CH can be applied onto the shrimp surface then slowly diffuse into the shrimp

after the treatment. However, CMC can be less efficient on melanosis that maybe because it gradually dissolved under high-humidity storage in fridge. Either CH or CMC and refrigerated storage have a synergistic effect on extending shelf life of white shrimp. The authors of this work recommend more research on soluble, compatible, antimicrobial, and antioxidative CH derivatives and foresee a growing interest in natural potential bio-preservatives in the future.

In another study chitosan-based solutions were applied on frozen salmon as edible coatings and water glazing preservation by Soares et al. (2013). For this purpose, three chitosan solutions (0.25 %, 0.50 %, and 0.75 % w/v) and water were applied in different amounts (6 %, 8 %, and 11 % of coated fillet weight) directly on the surface of frozen salmon. The results obtained showed that chitosan coatings can be a good barrier to protect frozen fish from deterioration. Microbial growth, assessed by total viable counts (TVC), and total volatile basic nitrogen (TVB-N) were maintained below the maximum limits recommended which are 5×10^5 CFU/g and 35 mg nitrogen/100 g fish, respectively. The use of 0.50 % and 0.75 % chitosan solutions generally demonstrated to be more efficient in preventing salmon weight loss (Soares et al. 2013).

Listeria monocytogenes, a gram-positive rod, is a bacterium that can cause illness brought about by a variety of contaminated food products. Eating foods contaminated with *L. monocytogenes* normally causes the disease listeriosis which is more serious for elderly adults and adults with compromised immune systems and can cause meningitis (Roberts and Greenwood 2003). In pregnant women, the disease may cause spontaneous abortions or stillborn babies (Anonymous 2003).

Beverly et al. (2008) evaluated the antimicrobial effect of chitosan (high or low molecular weight), as an edible film, that was dissolved in lactic acid or acetic acid at 0.5 % (w/v) or 1 % (w/v) against *L. monocytogenes* on RTE roast beef. The roast beef samples were dipped into the chitosan solution, and the bacterial counts were determined on days 0, 7, 14, 21, and 28. It was found that on day 14, *L. monocytogenes* counts were significantly different for all the chitosan-coated samples from the control counts by 2–3 log CFU/g and remained significantly different on day 28. Their data have shown that the acetic acid chitosan coating was more effective in reducing *L. monocytogenes* counts than the lactic acid chitosan coating. Hence chitosan coatings could be used to control *L. monocytogenes* on the surface of RTE roast beef (Beverly et al. 2008). The use of the edible coating containing chitosan preserved the overall visual quality and reduced surface whiteness of carrot sticks during storage. Microbial populations were very low and not influenced by coating or modified atmosphere packaging (MAP) (Adriano et al. 2009).

The conclusion of this work was that the combined application of edible coating containing chitosan and moderate O_2 and CO_2 levels could maintain the quality and enhance the phenolic content in carrot sticks (Adriano et al. 2009).

A quite high efficiency of chitosan in food preservation was demonstrated by Mohan et al. (2012) by inhibiting bacterial growth and reducing the formation of volatile bases and oxidation products of Indian oil sardine (*Sardinella longiceps*) in iced condition significantly. Chitosan with high degree of deacetylation (83 %) in

1–2 % concentration was used in this study. The chitosan coating improved the water holding capacity, drip loss, and textural properties significantly compared to untreated sample. The eating quality was maintained up to ~8 and 10 days for 1 and 2 % chitosan-treated sardine, respectively, compared to only 5 days for untreated samples (Mohan et al. 2012).

An interesting study to improve the homogeneity and transport properties of chitosan films by using electric field was performed by Souza et al. 2009. Ohmic heating is based on the passage of electrical current through a sample that has electrical resistance. The electrical energy is directly converted to heat and instant heating occurs, at a rate which depends on the intensity of the current passing through the material. Four different field strengths were tested (50, 100, 150, 200 V cm^{-1}), and for each electric field treatment, the water vapor, oxygen, and carbon dioxide permeabilities of the films formed were determined, together with their color, opacity, and solubility in water. The results showed that ohmic heating had statistically significant effects on film's physical properties and structure. The most pronounced effect of the field strength was observed for treatments made at 100 V cm^{-1} or higher, a positive correlation being found between the water vapor, oxygen, and carbon dioxide permeability coefficients and field strength. The surface of chitosan films is much more uniform when an electric field is applied, which may be related with a more uniform gel structure leading to the differences observed in terms of transport properties (Souza et al. 2009).

In a recent study the effect of chitosan on blue mold caused by *Penicillium expansum* on jujube fruit has been investigated (Wang et al. 2014). The study showed that application of chitosan reduced disease development of blue mold caused by *P. expansum* in wounded and inoculated jujube fruit at 25 °C. Chitosan also provided an inhibitory effect on natural decay of jujube fruit during storage at 0 °C. The results indicated that spore germination, germ tube length, and mycelial growth of *P. expansum* were significantly inhibited by chitosan in a concentration-dependent mode. Electron microscopy observation and fluorescent measurements indicated that plasma membrane of *P. expansum* was gradually disrupted after chitosan application (Wang et al. 2014).

3 Blending of Chitosan

The functional properties of chitosan-based films can be improved by combining them with other hydrocolloids. Chitosan-/pectin-laminated films have been developed by the interaction of the cationic groups of chitosan with the anionic groups of pectin. A decrease in water vapor transmission rates (WVTRs) by combining chitosan with two thermally gelatinized cornstarches (waxy starch and regular starch with 25 % amylose) has been observed. However, composite film made with regular starch showed higher TS and *E* than those with waxy starch. The addition of starch decreased WVTRs of the composite films (Xu et al. 2005). An alternative way to improve the mechanical and physical properties of these biofilms is by combining proteins (e.g., milk proteins, soy protein, collagen, and gelatin)

with polysaccharides (e.g., starches, alginates, cellulose, and chitosan). Chitosan–gelatin blend films have been shown to be homogeneous due to the good miscibility between both biopolymers (Haider et al. 2008; Silva et al. 2007; Pereda et al. 2008) leading to improved material properties of the blend films as compared to those obtained from the pure polymers. This is explained by the formation of electrostatic interactions between the ammonium groups of the chitosan and the carboxylate groups of the gelatin. On the other hand, chitosan-/soy protein-blended membranes (Silva et al. 2007) are not completely miscible. The blended membranes became more brittle with increasing soy protein content and showed a rougher surface morphology; this is probably related to phase separation among blend components. Chitosan/sodium caseinate films have also been studied; in this case no phase separation was observed due to the complexation of the two polymers within the blend film matrix (Pereda et al. 2008). Chitosan/whey protein films have been prepared at pH 6 with different protein concentrations, in the absence or presence of transglutaminase as a cross-linking agent. The chitosan was the main film component, and its amount was kept constant, the protein was from a spray-dried whey product still rich in lactose, and the amount of whey protein did not exceed the proportion of 1:9 (protein: chitosan) in the final films. The films prepared in the presence of the enzyme showed low solubility at a wide range of pH, a lower degree of swelling, and good biodegradability following protease treatments. The presence of transglutaminase induced also an enhancement in film mechanical resistance and a reduction in their deformability. Finally, the barrier efficiency toward oxygen and carbon dioxide was found to be markedly improved in the cross-linked films which showed also a lower permeability to water vapor. Catarina et al. (2009) prepared films of chitosan/whey protein blend with a high amount of protein in order to obtain a blend with new functionality out of the interaction of the cationic polyelectrolyte chitosan with protein. The study was aimed also at preparing an edible film-forming material with antimicrobial properties.

4 Chitosan–Starch Blends

Considering the advantages and unique characteristics of starch and chitosan, it is expected that a blend of chitosan–starch would be able to form a biodegradable film that would show improved mechanical properties (better strength and flexibility), lower water permeability, and antibacterial properties compared to starch-based films without chitosan.

Antimicrobial activity of edible coating solutions based on chitosan and blends of chitosan–tapioca starch with or without potassium sorbate (KS) addition was studied (Vásconez et al. 2009). This study showed an antagonist effect on the efficiency of chitosan against *Lactobacillus* spp. when KS and/or tapioca starch was present. A salmon slice coating assay showed that the chitosan solution was the best coating since aerobic mesophilic and psychrophilic cell counts were reduced and pH and weight loss remained acceptable throughout refrigerated storage,

extending global quality to 6 days. Chitosan–tapioca starch-based films reduced *Zygosaccharomyces bailii* external spoilage in a semisolid product but were not effective against *Lactobacillus* spp.

The results suggest that antibacterial action depended on the application technique, due to the fact that chitosan is more available in a coating solution than in a film matrix. The addition of chitosan reduced water vapor permeability and solubility of starch films. Starch-based films have been particularly considered for the reason that they exhibit physical characteristics similar to synthetic polymers: transparent, odorless, tasteless, semipermeable to CO_2, and resistant to O_2 passage (Nísperos-Carriedo 1994).

The main differences between starch and chitosan are the glucoside linkage – α (1, 4) for starch and β (1, 4) for chitosan – and the hydroxyl group of the second carbon that is replaced by the amine group which appears acetylated in the case of the natural polymer chitin.

Studies about the production and application of edible starch-based films incorporating preservatives have confirmed the availability of the latter to extend the shelf life of fresh and minimally processed vegetables (Durango et al. 2006; Garcia et al. 1998). According to the Food and Agriculture Organization (FAO 2004), one important source of starch in South America is tapioca.

Fernandez et al. (2004) studied the physical stability and moisture sorption of aqueous chitosan–amylase starch films plasticized with polyols. They used high, medium, and low molecular weight chitosan with amylose-rich cornstarch as a co-film former in the presence of glycerol and i-erythritol. In comparison to regular cornstarch which contains approximately 28 % amylose, Hylon VII is a corn hybrid containing approximately 70 % amylose. Since amylose is a linear polymer, it can closely align or associate through hydrogen bonding. This characteristic of amylose is primarily responsible for the gelling and film-forming ability of starches. Since Hylon VII contains more than twice as much amylose as regular cornstarch, it can form more rigid gels and contribute to the formation of stronger and tougher films. Chitosan–Hylon VII solutions plasticized with glycerol or erythritol were prepared in a high-pressure reactor equipped with a blade mixer.

Edible chitosan–starch film has been used for extending the shelf life of Mongolian cheese (Mei et al. 2013). In this work the physicochemical, mechanical, optical, and structural properties of edible films from mung bean/water chestnut starch and chitosan containing glycerol/perilla oil have been investigated. The shelf life of Mongolian cheese coated by the films was monitored by the microbiological and physicochemical changes of Mongolian cheese after 30 days of storage period. The obtained results showed that the incorporation of perilla oil resulted in a decrease in moisture content, solubility, and mechanical properties and an increase in total color difference (ΔE*). High water vapor permeability (WVP), good transparency, and low solubility were observed with the addition of glycerol. Meanwhile, the film based on mung bean chitosan–starch (MSC) exhibited higher moisture content, WVP values, ΔE* and less transparency than that based on water chestnut chitosan–starch (WSC). The morphology of films was also different. The results showed that the cheese coated by WSC film containing perilla oil presented

better treatment performance in terms of microbial growth delay, weight loss, and shelf life length. Mung bean is the seed of *Vigna radiata* and is traditionally used in soup, pancake, and cold noodle in China. Water chestnut (*Eleocharis dulcis*) is a fruit crop grown in China, India, and Southeast Asia, and the cake made from its flour is a traditional dessert in the south of China (Mei et al. 2013).

In order to enhance the antibacterial capacity of chitosan–starch films, irradiation of compression-molded starch-based mixture in physical gel state with electron beam (EB) at room temperature was performed (Zhai et al. 2004). The tensile strength and the flexibility of starch film were improved largely after incorporation of 20 % chitosan into starch film. X-ray diffraction and scanning electron microscope analyses indicated that there was interaction and microphase separation between starch and chitosan molecules. The antibacterial activity of the chitosan–starch blend films against *Escherichia coli* (*E. coli*) was measured via optical density method. After irradiation, there is no obvious change in the structure of chitosan–starch blend films, but antibacterial activity was induced even when the content of chitosan was only 5 % due to the degradation of chitosan in blend films under the action of irradiation.

Biodegradable blend films from rice chitosan–starch were developed by casting film solution (Bourtoom and Chinnan 2008). The film from rice chitosan–starch showed an increase in tensile strength (TS), water vapor permeability (WVP), lighter color and yellowness and a decreasing elongation at the break (*E*), and film solubility (FS) after incorporation of chitosan. The introduction of chitosan increased the crystalline peak structure of starch film; however, too high chitosan concentration yielded phase separation between starch and chitosan. However, the water vapor permeability of rice chitosan–starch biodegradable blend film was characterized by relatively lower water vapor permeability than chitosan films but higher than polyolefin; these films could be a potential candidate for edible packaging.

Edible film with antimicrobial property was developed based on poly(lactic acid)/starch in which chitosan was the active antimicrobial ingredient which is released slowly from the poly(lactic acid)/starch matrix (Bie et al. 2013). An increase in the starch content drastically improved the hydrophilicity of the blends, which was favorable for the diffusion of the embedded chitosan. Moreover, the release of chitosan was observed to occur in two stages, with a very fast release stage initially and a slow but durable release stage as the latter. These two stages exhibited the effectiveness and long residual action of antimicrobial property of the blends, respectively, demonstrating the suitability to be used for foods with high water activity, such as fresh meat. The authors recommend the use of the blend material in packaging (Bie et al. 2013).

Chitosan–starch (high amylose) blend film (1:1), via microfluidization, was prepared by casting with different glycerol concentrations (0 %, 2.5 %, 5 %, and 10 %) (Liu et al. 2013). Microfluidization is a well-documented promising high-energy homogenization method that had been widely applied in the emulsion preparing process in various areas including personal care, cosmetics, health care, pharmaceuticals, and agrochemicals to improve the stability of the emulsion,

attributing to its ability to produce exceptionally fine and stable emulsion (Jafari et al. 2007). During microfluidization, two steams of flow that collide with each other at a pressure of up to 150 MPa and force them through microchannels toward an impingement area create a tremendous shearing action (Salvia-Trujillo et al. 2012).

The films were characterized for their mechanical, thermal, and morphological properties. The addition of glycerol at 5 % (w/w) and higher concentrations resulted in decrease in tensile strength and increase in elongation at break due to plasticization.

An antiplasticization effect was observed in chitosan–starch–glycerol films when the glycerol concentration was 2.5 % (w/w). The antiplasticization was reflected in visible surface cracking in the SEM image and the high Tg value of 2.5 % (w/w) glycerol film. At glycerol concentration of 5 % (w/w) and above the chitosan–starch–glycerol films were typically plasticized by glycerol as evidenced from the significant ($p < 0.05$) decrease in both tensile strength and Tg (Liu et al. 2013).

Chitosan has been previously added to films prepared with starches from different origins, such as potato (Mathew and Abraham 2008; Shen et al. 2010), tapioca (Vásconez et al. 2009), corn (Xu et al. 2005), and kudzu (Zhong et al. 2011). In this work, blends of wheat starch WS and chitosan CH have been used for the preparation of films with antimicrobial activity and tested on minced pork meat (Bonilla et al. 2013).

The incorporation of CH to WS films did not provoke a significant increase in their oxygen permeability OP values at 5 °C. At 25 °C, OP values tend to increase as the CH content is increased in the film, although this was only significant when more than 30 % CH is present in the blend and the differences were very small. This behavior represents an advantage of the blend films, since CH incorporation led to an enhancement of starch films, inhibiting retrogradation and increasing mechanical resistance, but did not improve their barrier properties notably. The lower requirement of glycerol in blend films plays an important role because glycerol contributes to promote mass transfer processes due to the promotion of molecular mobility. With lower ratio of glycerol, chitosan-containing films showed similar barrier properties to wheat starch–glycerol films. The replacement of wheat starch–glycerol with chitosan affected the properties of film-forming dispersions and films. Chitosan addition led to a significant increase of the particle surface charge and apparent viscosity of the film-forming dispersion and yielded glossier and thicker films. The mechanical properties were significantly improved as the chitosan ratio increased in the films. Water vapor permeability (WVP) and OP values tend to slightly increase when chitosan was incorporated to the film, although induced differences are not relevant. A notable antimicrobial effect was detected in the blend films when the proportion of chitosan was 50 %. The obtained results suggest that it would be possible to formulate edible antibacterial films with thermoplastic properties by combining wheat starch and chitosan (Bonilla et al. 2013). In a further improvement of the previous work, Bonilla et al. have added four antioxidant ingredients, namely, basil essential oil, thyme essential oil,

citric acid, and α-tocopherol, to the edible WS/CH blends. The starch–antioxidant mass ratio was 1:0.1. The incorporation of antioxidants led to a heterogeneous film microstructure, mainly in those containing α-tocopherol, which affected the surface roughness. Yellowness was induced in films when α-tocopherol was added, and no notable color changes were observed in the other cases, although all the antioxidants increased the transparency of the films. Despite of the fact that the mechanical properties were barely affected by the incorporation of antioxidants, citric acid promoted an increase in the elastic modulus but a decrease in film stretchability. The water vapor barrier properties of the films were only slightly improved when citric acid and α-tocopherol were added, whereas the oxygen barrier properties were significantly improved in all cases. The greatest antioxidant capacity of the films was reported for films containing α-tocopherol, which exhibited the highest antioxidant power (Bonilla et al. 2013).

Li et al. 2013 investigated the effect of cross-linking using glutaraldehyde on the physical and mechanical properties of CH–starch blend films. They found that the compatibility of the blends deteriorated after cross-linking but showed improved water barrier performance. This was further confirmed by the results of mechanical properties. The use of trace concentrations of glutaraldehyde in chitosan–starch films allows for possible application in the biomedical field (Li et al. 2013).

Zhong et al. 2011 investigated the effect of solvent on the mechanical and antibacterial behavior of chitosan/kudzu starch. The roots of kudzu plant contain starch, and its leaves show antioxidant activity that suggests food uses (Shurtleff and Aoyagi 1977). Acetic acid, lactic acid, and malic acid were used to dissolve chitosan. Fourier transform infrared spectra showed that kudzu starch and chitosan could form miscible films. X-ray diffraction data indicated that the crystalline of each single component was suppressed after film-forming process. The composite film using malic acid as a solvent showed the best antimicrobial activity against *Escherichia coli* and *Staphylococcus aureus*, which may be due to the highest amount of dissolved amino group, the lowest water sorption ability, and the best water barrier property. The film that chose acetic acid as the solvent presented the strongest mechanical property, the smallest solubility, and the lightest yellowness and color. The film made from lactic acid solution displayed the greatest flexible property demonstrated by the maximum elongation (Zhong et al. 2011). These composite films could also find applications in bioactive packaging.

In an easy one step, a valuable thermoplastic material derived from secondary wheat B-starch, which is a low-quality by-product in the starch industry, had been prepared by Kelnar et al. (2013). The combination of a tiny amount of chitosan and montmorillonite represents a promising method to improve the mechanical and barrier properties of thermoplastic starch. The combination of 0.6 % CS and 3 % clay has a synergistic effect on the starch films. These effects were reflected in the reduced permeability for oxygen and enhanced thermal stability. However, the hydrophilicity of both added components resulted in increased water vapor absorption (Kelnar et al. 2013). The effect of CS primarily consists of modifying the matrix and improving the interfacial properties due to the strong potential of the amino groups in the CS for polar interaction/ionic exchange with the nanosilicate (Kelnar et al. 2013).

5 Chitosan with Alginate and Carrageenan

Alginate is linear copolymer extracted from brown seaweeds known as *Phaeophyceae* and composed of (1 → 4)-linked-β-D-mannuronate (M) and (1 → 4)-linked-α-L-guluronate (G) units. These units are arranged in G blocks, M blocks, and alternating sequences of GM blocks forming the polymeric structure, where the sequential arrangement depends on different factors such as the species, age, or parts of the seaweeds from which this material was obtained. It has been well characterized in both the liquid and gel state, making this biopolymer unique compared to other gelling polysaccharides. Alginates possess good film-forming property, producing uniform, transparent, and water-soluble films.

Alginate-based films are impervious to oils and fats but, as other hydrophilic polysaccharides, have high WVP. However, alginate gel coating can act as a sacrificing agent, where moisture is lost from the coating before the food significantly dehydrates. The coating can also improve the adhesion of batter to the surface of fruits and vegetables (Lin and Zhao 2007). Alginate coatings are good oxygen barriers that can retard lipid oxidation in various fruits and vegetables and have been found to reduce weight loss and natural microflora counts in minimally processed carrots (Amanatidou et al. 2000). Calcium alginate coatings were found to improve the quality of fruits and vegetables, such as reducing shrinkage, oxidative rancidity, moisture migration, oil absorption, and sealing in volatile flavors, improving appearance and color and reducing weight loss of fresh mushrooms in comparison with uncoated ones (Hershko and Nussinovitch 1998).

6 Chitosan- and Gelatin-Based Edible Films

Composite edible films and coatings can be formulated to combine the advantages of each component. Whereas biopolymers, such as proteins and polysaccharides, provide the supporting matrix, lipids provide a good barrier to water vapor (Anker et al. 2002). Since gelatin and chitosan are hydrophilic biopolymers with good affinity and compatibility, they are expected to form composite films with good properties (Sionkowska et al. 2004). Gelatin–chitosan blends have been used extensively for the production of scaffold and bilayers for biomedical applications (Pereda et al. 2011; Jiankang et al. 2009).

A bilayer and laminated biodegradable composite film based on gelatin and chitosan has been developed by Rivero et al. (2009). The aims of this work were to develop composite, bilayer, and laminated biodegradable films based on gelatin and chitosan. A distinction was made between them, calling bilayer the system prepared by the coating technique which is a two-step procedure and laminated the one formed by two independent films, placed one on the other. Gelatin and chitosan concentrations used were 7.5 % and 1 % (w/w), respectively. Glycerol (0.75 %) was added as plasticizer. In composite film, it was evident that the presence of chitosan led to stronger films, while glycerol improved film flexibility. Composite and bilayer systems showed a compact structure indicating a good compatibility

between components. Water vapor permeability (WVP) was independent of film thickness up to 120 μm for gelatin films and 60 μm for chitosan ones. Both bilayer and laminated systems resulted effective alternatives to reduce WVP of composite films (at least 42.5 %). Bilayer systems showed better mechanical properties than laminated ones. The resistance at break increased from 54.3 for composite to 77.2 MPa for bilayer films, whereas elongation at break values of both composite and bilayer films was similar (2.2–5.7 %).

A coating made in cold from a blend of a chitosan and a gelatin solution was applied to patties made of chilled cod, and its preservative effect was assessed by color measurements, rheological measurements (hardness, elasticity, cohesiveness, chewiness, gumminess, and adhesiveness), biochemical determinations (total volatile bases and thiobarbituric acid as measures of rancidity), and microbiological assays (total bacterial counts, luminescent bacteria, enterobacteria, *Pseudomonas*, lactic acid bacteria, and *Staphylococcus aureus*). The effect of dry powdered chitosan mixed into the patties was tested as well (López-Caballero et al. 2005). Chitosan was effective in preventing bacteria spoilage only when it was applied in the powder form in the cold. Gelatin made from fish skins offers an alternative to the more commonly used mammalian gelatin that is highly suitable for coating seafood products. Fish gelatins with a variety of attributes can be prepared for this purpose, depending on the raw material, i.e., source species and body parts used, and the manufacturing. Consequently, a mixture of fish gelatin and chitosan, both derived from marine sources, would seem to be especially suitable for use in the preparation of seafood products. The fish patty coating was quite natural looking and translucent, producing a more uniform and smooth surface. In the case of cooking the fish patties, the coating would turn liquid as the gelatin melted from the heat, leaving the mince patty completely uncoated with no remnants that could be seen or tasted (López-Caballero et al. 2005).

Fish gelatin, especially cold-water fish gelatins, is a good alternate to consider when dealing with composite edible films aimed at reducing water vapor transmission, and this is attributed to its higher hydrophobicity than bovine or porcine gelatin, since it has lower proline and hydroxyproline contents, as the hydroxyl group of hydroxyproline is normally available to form hydrogen bonds with water molecules (Avena-Bustillos et al. 2006). Hosseini et al. (2013) have prepared fish gelatin-based composite films with increasing concentrations of chitosan of 0, 20, 30, 40, and 100 % and investigated their physical and functional properties. It was found that fish gelatin and chitosan were totally compatible to form solutions and films. The addition of these positively charged polysaccharides improved the properties of films made from fish gelatin and improved mechanical properties and decreased water vapor permeability. The film prepared with the blend 60 % gelatin and 40% chitosan was found to be the best as it had lower water vapor permeability and film solubility. The addition of CH caused significant increase in the tensile strength (TS) and elastic modulus, leading to stronger films as compared with gelatin film, but significantly decreased the elongation at break. These results suggest a high potential of these films to be used as active packaging materials (Hosseini et al. 2013).

The effects of chitosan molecular weight (MW) and degree of deacetylation (DD) on the physicochemical properties of gelatin-based films were studied (Liu et al. 2012). The determination of the dynamic viscoelastic properties (elastic modulus G′ and viscous modulus G″) of the film-forming solutions revealed that the interactions between gelatin and chitosan were stronger in the blends made with chitosan of higher molecular weights or higher degrees of deacetylation than the blends made with lower molecular weights or degrees of deacetylation.

Films of chitosan and gelatin were prepared by casting their aqueous solutions (pHb4.0) at 60 °C and evaporating at 22 or 60 °C (low- and high-temperature methods). The physical, thermal, and mechanical properties and gas/water permeation of the water- or polyol-plasticized films have been investigated (Arvanitoyannisa et al. 1998). A considerable decrease in elasticity modus and tensile strength occurred with increasing the content of the plasticizer (30 % plasticizer was added), whereas the elongation percent increased up to 150 %. Higher percent crystallinity was obtained with the low-temperature method of preparation than high-temperature method. The higher crystallinity led to a decrease, by one or two orders of magnitude, of CO and O permeability in the chitosan/gelatin composite films, which is an advantage for edible packaging (Arvanitoyannisa et al. 1998).

Kołodziejska and Piotrowska (2007) design biodegradable material with good mechanical and barrier properties using fish gelatin–chitosan films plasticized with glycerol suitable for packages of many kinds of food products with different acidities and contents of moisture.

The physical characteristics of plain gelatin and chitosan films have been improved by using several gelatins of different origins (commercial bovine-hide gelatin and laboratory-made tuna-skin gelatin) (Gómez-Estaca et al. 2011). The dynamic viscoelastic properties of the film-forming solutions upon cooling and subsequent heating revealed that the interactions between gelatin and chitosan were stronger in the blends made with tuna-skin gelatin than in the blends made with bovine-hide gelatin. As a result, the fish gelatin–chitosan films were more water resistant (w18% water solubility for tuna vs. 30 % for bovine) and more deformable (68% breaking deformation for tuna vs. 11 % for bovine) than the bovine gelatin–chitosan films. The antimicrobial activity of the resulting films over *S. aureus* was also evaluated; the good inhibitory effects of the chitosan against *S. aureus* were maintained in spite of the gelatin–chitosan interactions observed (Gómez-Estaca et al. 2011). In a more recent work, Jridia et al. (2014) have demonstrated that mixing cuttlefish skin gelatin and chitosan rendered films of homogeneous structure, due to their high compatibility, as revealed by the thermal and microstructure analysis of composite films. Chitosan addition greatly reduced the extensibility, the thickness, and the solubility of composite films, while it increased their tensile strength. Furthermore, in composite films the presence of chitosan increases the thermal stability of the film and increased the antibacterial activity, while it decreased the antioxidant activities of composite edible films. The gelatin used in this work was obtained from cuttlefish (*Sepia officinalis*) skin gelatins by pretreatment with different pepsin concentrations at pH 2.0

(Jridi et al. 2013). The extraction of gelatin from alkali-pretreated skin of cuttlefish with pepsin affected the molecular weight and biophysical and functional properties of the resulting gelatins. Gelatin extracted without pepsin showed higher gel strength and transition, gelling, and melting temperatures. All of these values decreased with increasing enzyme concentration (Jridi et al. 2013).

7 Chitosan/Essential Oil Films

In spite of the extensive use of chitosan as edible films for coating, it still suffers from high water vapor permeation (WVP) which lowers its protective action. Therefore, the addition of oils may increase its hydrophobicity and improve its water vapor permeation. Vargas et al. (2006) reported data on the effect of unsaturated oils, such as olive oil, on the properties of chitosan-based films and the interactions between chitosan and olive oil or chitosan and olive oil components (Ham-Pichavant et al. 2005; Muzzarelli et al. 2000; Vargas et al. 2006). The study published by Vargas et al. (2006) focused on the improved physicochemical quality of the strawberries coated with the edible coatings. Muzzarelli et al. (2000) reported that the capacity of chitosan to alter the composition of olive oil is due to the percolation of the oil through a bed of chitosan powder. Ham-Pichavant et al. (2005) reported on the potential replacement of fluorocarbon treatment of paper-based materials by chitosan coating to produce oil barrier packaging.

Vargas et al. (2009) have further investigated the formation of edible films based on high molecular weight chitosan (CH) and different concentrations of oleic acid (OA). Film-forming dispersions (FFD) were characterized in terms of rheological properties, surface tension, particle size distribution, and ζ-potential. Their results showed that the increase in OA promoted changes in the size and surface charge of the FFD particles, which had an impact on the rheological properties of the FFD. As regards the film properties, the higher the OA content, the lower the WVP and the moisture sorption capacity.

In general, the addition of OA into the CH matrix leads to a significant increase in gloss and translucency and a decrease in the tensile strength, elongation at break, and elastic modulus of the composite films. The mechanical and optical properties of the films were related with their microstructure, which was observed by SEM.

Chitosan was mixed with olive oils in different concentrations to prepare homogeneous films which were found to have decreasing moisture sorption, lower water vapor permeation, and smaller effective diffusion coefficients of the films as the oil concentration increases (Pereda et al. 2012). All the tensile properties (Young modulus, strength, and maximum elongation) increased with olive oil concentration, which were explained considering the interactions developed between lipid and carbohydrate phases in addition to the lubricant action of the oil (Pereda et al. 2012). Physical characterization confirmed that the lipid globule distribution in the films was homogeneous, which was associated to the emulsion stability.

Contact angle measurements showed that increasing the olive oil concentration causes a slight increase of contact angle values, from approximately 60° for 0 %

olive oil to 65° for 15 % olive oil, which is due to the hydrophobic nature of the added lipid. In general when hydrocolloid and lipid ingredients are combined, they may interact favorably, resulting in edible films with improved structural and functional properties, as the mechanical and barrier properties depend not only on the compounds used in the polymer matrix but also on their compatibility.

Films prepared from quinoa protein extracts (Q) were mixed with chitosan and were obtained by solution casting (Valenzuela et al. 2013). From the optimal Q/CH mixture, the addition of three different concentrations of sunflower oil (SO) (2.9, 3.8, and 4.7 g/100 mL), and the optimal proportion of SO, g/100 mL was selected based on the mechanical and barrier properties of the films. The CH, Q/CH, and Q/CH/SO optimal blend films were characterized by FTIR, X-ray diffraction, and SEM. The 0.1 Q-8/CH blend was found to have high degree of interaction between the quinoa proteins and CH. The optimum concentration of SO used in the Q-8/CH/SO film was 2.9 g/100 mL. The addition of SO to the film improved the water vapor permeability (WVP) as a result of hydrophobic interactions and the presence of clusters of hydrophobic masses on the surfaces of these films but reduced the film's tensile strength and oxygen permeability due to the formation of micropores and microfractures detected by SEM. The elongation at break increased from Q-8/CH and Q-8/CH/2.9SO due to the plasticizing characteristics of the quinoa protein and lipid, in addition to the strong interactions developed between the lipid and hydrocolloid phases. The formation of the composite films in the absence of a plasticizer, producing good mechanical properties and lower WVP values, may lead to new applications in the food industry. The fields of application of Q/CH/SO blend may be on low-pH fresh fruits, to increase shelf life and consumer acceptability (Valenzuela et al. 2013).

Fresh fish is highly perishable due to its biological composition. Spoilage of fish muscle results from changes brought about by biological reactions such as oxidation of lipids, reactions due to activities of the fish's own enzymes, and metabolic activities of microorganisms. These activities lead to a short shelf life in fish and other seafood products (Arashisara et al. 2004). Ojagh et al. (2010) have used chitosan enriched with cinnamon oil (CH + C) to coat rainbow trout (*Oncorhynchus mykiss*) (Ojagh et al. 2010). *Cinnamomum zeylanicum* L., commonly known as cinnamon, is rich in cinnamaldehyde as well as b-caryophyllene, linalool, and other terpenes. Cinnamaldehyde is the major constituent of cinnamon leaf oil and provides the distinctive odor and flavor associated with cinnamon. It is used worldwide as a food additive. Studies have shown that cinnamon has a good antioxidant and antimicrobial potential (Ojagh et al. 2010). The quality of the coated rainbow trout was examined during refrigerated storage (4 ± 1 °C) over a period of 16 days. A solution of CH (2 %, w/v) and CH + C (2 %, w/v CH + 1.5 %, v/v C) was used for the coating. The control and the coated fish samples were analyzed periodically for microbiological (total viable count, psychrotrophic count), chemical (total volatile base nitrogen (TVB-N), peroxide value (PV), thiobarbituric acid (TBA)), and sensory (raw and cooked fish) characteristics. By the day 8 of storage, the total viable counts (TVC) in trout fillet for all of the different treatments were still below 6 log10 CFU/g, while that of controls attained a count of 7.88 at 12 days, which is

higher than the maximal recommended limit of 7 log10 CFU/g for TVC in raw fish (Ibrahim Sallam 2007), indicating a microbiological shelf life of about 9–10 days for the control samples. The results indicated that the effect of the CH + C coating on the fish samples was to enable the good quality characteristics to be retained longer and to extend the shelf life during the refrigerated storage. Adding cinnamon oil to chitosan coating, therefore, had a synergistic effect. In the case of most herbal extracts, their antioxidant activity has been attributed to their ability to break the free radical chain by donating a hydrogen atom (Ojagh et al. 2010).

The application of citrus essential oils to food preservation has received increased attention because of their use in food products and as safe at flavoring concentrations (GRAS). These factors made them into very promising compounds to be used as a natural alternative to chemical-based preservatives.

Bergamot oil, BO, is a citrus oil (from *Citrus bergamia*) whose major chemical compounds are volatile, such as limonene (32–45 %) and linalool (around 10.23 %) (Moufida and Marzouk 2003; Svoboda and Greenaway 2003). The antimicrobial efficiency of BO and its components, linalool and citral, has been found to be effective against *Campylobacter jejuni*, *Escherichia coli* O157, *Listeria monocytogenes*, *Bacillus cereus*, *Staphylococcus aureus*, *Arcobacter butzleri*, and *Penicillium digitatum* (Fischer and Phillips 2006, 2008), among others, both when oil is applied directly and when in contact with the oil vapor. The mechanisms by which essential oils bring about their antimicrobial effect are not clear, but there are a number of proposed mechanisms (Holley and Patel 2005): terpenes have the ability to disrupt and penetrate not only the lipid structure of the cell membrane but also the mitochondrial membrane, leading to the denaturation of proteins and the destruction of cell membrane, cytoplasmatic leakage, cell lysis, and, eventually, cell death.

Sanchez-Gonzalez and coworkers (2011a) have published a review dealing with the use of essential oils in edible/biodegradable films, and they recommend that this strategy will lead to reduced doses of essential oils while maintaining their effectiveness. This review discusses the use of essential oils as natural antimicrobial and antioxidant compounds to obtain bioactive films or coatings. The advantages and limitations are also reviewed Sanchez-Gonzalez and coworkers (2011a).

Sanchez-Gonzalez et al. (2010a) prepared chitosan-based films containing bergamot essential oil (BO) at 0.5 %, 1 %, 2 %, and 3 % w/w to evaluate their physical and antifungal properties.

The incorporation of BO into the chitosan (CH) matrix provoked a decrease in the water vapor permeability, this reduction being around 50 % when using a CH–BO ratio of 3:1. The CH–BO composite films were less resistant to breakage, less deformable, and less glossy. The load parameters (TS and EM) decreased more than 50 %, and the percentage of elongation at break was also dramatically reduced from 22 % to 5 %, as compared with the pure chitosan films. CH–BO composite films showed a significant inhibitory effect on the growth of *P. italicum*, which depended on the BO concentration. Chitosan films with the maximum bergamot oil content (3:1 CH–BO ratio) led to a total inhibition of the fungus growth during the first 5 days at 20 °C. Although the antifungal effectiveness of the films decreased

throughout the storage time, a significant reduction of 2 logarithm units as compared with the control remained possible, after 12 days at 20 °C, using the highest BO content.

In a different report, Sanchez-Gonzalez et al. (2011b) prepared biodegradable coatings based on hydroxypropylmethylcellulose (HPMC) or chitosan (CH) with and without bergamot essential oil and applied them to table grapes, cv. muscatel, in order to find environmentally friendly, healthy treatments with which to better preserve fresh fruit quality and safety during postharvest cold storage The physicochemical properties (weight loss, Brix, total phenols, antioxidant activity, color, and texture), respiration rates, and microbial counts of the samples were determined throughout cold storage when using CS. CS coatings containing bergamot oil produced the most effective antimicrobial activity and showed the greatest inhibition of the respiration rates in terms of both O_2 consumption and CO_2 generation. Although the coatings did not seem to reduce the rate of grape browning during storage, they inhibited color development, thus improving the product appearance. Taking into account the overall results obtained, the most recommended coating for muscatel table grape is the CS-containing bergamot oil (Sanchez-Gonzalez et al. 2011b).

Among the great variety of EOs, lemon, thyme, and cinnamon EOs have gained greater acceptance among food technologists due to their better sensory evaluation and antimicrobial properties (Bagamboula et al. 2004; Fischer and Phillips 2006; Viuda-Martos and Fernández-López 2008).

The addition of lemon, thyme, and cinnamon EOs in chitosan film led to significant changes in the properties of film solutions and films, wherein the addition of a single EO caused the decrease in apparent viscosity of film-forming dispersions. The combined use of two kinds of EOs contributed to emulsion stability by a decrease in particle size and viscosity. Furthermore, the addition of EOs caused a significant decrease in WVP, color, transparency, and elongation at break of the chitosan films. The combined use of two kinds of essential oils balanced the antibacterial properties of the single essential oil. SEM analysis showed that the oil droplets were homogenously distributed across the film. The emulsification was obviously observed in chitosan/lemon/cinnamon essential oil composite films due to the electrostatic interaction of limonene and cinnamaldehyde. This study (Peng and Li 2014) revealed that an active chitosan film could be obtained by the combined use of two kinds of essential oils in the matrix, which might provide a new formulation option for developing antimicrobial film (Peng and Li 2014).

The essential oil of *Melaleuca alternifolia*, also named as tea tree oil (TTO), is a complex mixture of terpene hydrocarbons and tertiary alcohols (Sanchez-Gonzalez et al. 2010b). Tea polyphenols (TP) are extracted from tea and contain catechin, flavones, anthocyan, and phenolic acid, but catechin is the main component with more than 80 % content (Huang et al. 2007). Catechin mainly contains epigallocatechin-3-gallate (EGCG), epigallocatechin (EGC), epicatechin-3-gallate (ECG), and epicatechin (EC) (Yang et al. 2009). Other compounds responsible for the antimicrobial activity are terpinen-4-ol and 1, 8-cineole. TTO has been used

successfully in the management of oral candidosis in AIDS patients (Vazquez and Zawawi 2002) and other oral fungal infections in patients suffering from advanced cancer (Bagg et al. 2006). Research results demonstrated the antibacterial and antioxidant activities of TP, showing good prospects for their use as preservatives and antioxidants (He et al. 2006). It has been showed that using TP as antioxidant or preservative could extend the shelf life of fresh mutton and fresh-cut lettuce (Kumudavally et al. 2008; Martin-Diana et al. 2008). The antioxidant mechanism of polyphenols is principally attributed to their capacity in trapping reactive oxygen species and chelating metal ions, which could generate radicals through Fenton reaction.

Sanchez-Gonzalez et al. (2010b) incorporated TTO into chitosan matrix and investigated the physical and antibacterial behavior of the obtained composite. The CS films were rough and a reduction of its gloss occurred after the incorporation of TTO. Water vapor permeability was also reduced by 40 % when the CS/TTO ratio was 1:2. Likewise, the films' resistance to break was notably reduced by TTO incorporation due to the presence of discontinuities in the film matrix that affect its mechanical response. The poor mechanical properties obtained by the addition of TTO may be related with the structural arrangement of the lipid phase into the chitosan matrix. Thus, the structural discontinuities provoked by the incorporation of the oil could explain the lowest resistance to fracture of the composite films. Some of these results are in line with those reported by other authors when adding oils to a chitosan matrix (Srinivasa et al. 2007) but differ in some aspects due to the great influence of several, widely studied factors related to CS preparation. Only the composite films with CS/TTO ratios higher than 1 showed a limited antifungal effectiveness against *Penicillium*, which was notably reduced after 3 days of storage. Nevertheless, CS films presented a significant antimicrobial activity against *L. monocytogenes*, and the incorporation of TTO in the CS/TTO ratio of 1:2 improved the antibacterial properties of these films, showing a complete inhibition of the microbial growth during the fifth day at 10 °C.

Liyan et al. (2013) developed chitosan-incorporated tea polyphenol active films with different concentrations of TP. The incorporation of TP caused interactions between chitosan and TP and gave rise to the chitosan/TP films' darker appearance with reduced water vapor permeability and significant increase in the antioxidant activity of the chitosan film which makes the chitosan/TP films show great potential to be used for active food packaging (Liyan et al. 2013). Green tea extract was also used with chitosan to enhance the antioxidant efficacy of the composite edible films (Siripatrawan and Harte 2010).

Galangal extract was added to chitosan solution to prepare biodegradable films with improved antibacterial properties (Mayachiew et al. 2010). Galangal similar to ginger and turmeric is a member of the rhizome family. Rhizomes are knobby underground stems that are known for their pungent and flavorful flesh, and it is a traditional spice used extensively for flavoring and medicinal purposes. Galangal extract has also proved to be an effective natural antimicrobial agent against some food poisoning bacteria, e.g., *Staphylococcus aureus* (Mayachiew and Devahastin 2008). The main compounds of galangal extract are the terpenes, which have

potential antimicrobial activity. The aim of this work was to study the effects of drying methods and conditions (i.e., ambient drying, hot air drying at 40 °C, vacuum drying, and low-pressure superheated steam drying (LPSSD) within the temperature range of 70–90 °C at an absolute pressure of 10 kPa). Chitosan films containing galangal extract at 0.6 % and 0.9 % (w/w) were effective in inhibiting the growth of *Staphylococcus aureus* (*S. aureus*). No inhibition zone was observed when the extract concentration of 0.3 % (w/w) was used. This could be ascribed to a limited galangal extract release probably due to interaction between the extract and chitosan. The results showed that ambient dried film had the highest antimicrobial activity; this was followed by LPSSD films and vacuum-dried films. This may be due to the fact that the film temperature increased more rapidly and stayed at higher levels in the case of vacuum drying than in the case of LPSSD, thus inducing more thermal degradation of the antimicrobial compound (Mayachiew et al. 2010). In addition, different intermolecular interactions also contributed to the observed results.

Chitosan film incorporated with 0.9 % (w/w) galangal extract and prepared by ambient drying could reduce the number of *S. aureus* by about 3.6 log cycle within the contact time of 24 h. On the other hand, ambient dried film incorporated with 0.3 % (w/w) galangal extract exhibited lower cell reduction number of around 2.0 log cycle (Mayachiew et al. 2010).

Strawberry is a highly perishable fruit with a short postharvest life which is mainly due to fungal decay. The shelf life of cold-stored (0–4 °C) fresh strawberries is around 5 days (Perdones et al. 2012). Film-forming dispersions (FFD) were prepared with 1 % high molecular weight chitosan and 3 % lemon essential oil and were submitted to two different homogenization treatments. Lemon essential oil, which is extracted from *Citrus limon*, has limonene, valencene, and ocimene as major components. Limonene is used as a food additive or flavoring agent and is known to have fungicidal properties, including activity against *Botrytis* and *Aspergillus niger* (Perdones et al. 2012). The use of microfluidization to prepare chitosan-based FFD led to a significant reduction in the particle size and apparent viscosity of the dispersions, with no significant effect on the decrease in the WVP of the stand-alone coatings. Chitosan coatings did not show a significant effect in terms of the acidity, pH, and soluble solid content of strawberries throughout storage. In contrast, coatings slowed down the respiration rate of samples when lemon essential oil was added to the FFD. Adding lemon essential oil enhanced the chitosan antifungal activity both in in vitro tests and during cold storage in strawberries inoculated with a spore suspension of *Botrytis cinerea* (Perdones et al. 2012). In general the potential of chitosan coatings in maintaining strawberry flavor and aroma during cold storage has been demonstrated by Almenar et al. (2009) as a reduction in acetaldehyde and ethanol formation in chitosan-coated strawberry samples, which may lead to a prolonged shelf life. Another study (Kerch et al. 2011) indicated that coatings of chitosan and chitooligosaccharides applied to strawberries led to an improvement in fruit firmness and to a reduction in vitamin C and anthocyanin content. Campaniello et al. (2008) used chitosan coatings to control spoilage and browning of fresh-cut strawberries in combination with other preservation factors, such as low temperature and modified atmosphere packaging.

An essential oil that is extracted from Zataria multiflora Boiss is an aromatic medicinal plant that grows widely in warm and mountainous parts of Iran, Pakistan, and Afghanistan. This plant is called *Zataria multiflora* Boiss which belongs to the family Lamiaceae. The essential oil (EO) of this plant (ZEO) possesses significant quantities of phenolic oxygenated monoterpenes and exhibits antioxidant, antibacterial, and antifungal activity in vitro. Antioxidant chitosan-based edible films were developed incorporated with *Zataria multiflora* Boiss essential oil (ZEO) (5 and 10 g/L) and grape seed extract (GSE) (10 g/L) alone and in combination (Moradi et al. 2012). All films, with the exception of 10 g/L GSE + 10 g/L ZEO film, exhibited lower strength and elongation values, and only the addition of investigated 10 g/L ZEO to GSE film improved the water vapor transmission rate of chitosan films. Only GSE-containing films had higher swelling index. The incorporation of GSE and ZEO into chitosan film increased the wettability of the surface, total phenol, and antioxidant activity. Neat chitosan and ZEO-incorporated films had a light yellowish color, whereas GSE + ZEO films were gray. The results showed that GSE-formulated chitosan film may be used as active films at medium moisture products such as muscle food because of its excellent swelling index (%) and antioxidant properties.

A study has been conducted by Gómez-Estaca et al. (2010) in which chitosan–gelatin films containing sorbitol and glycerol as plasticizers were incorporated with several different essential oils. Essential oils of clove (*Syzygium aromaticum* L.), fennel (*Foeniculum vulgare* Miller), cypress (*Cupressus sempervirens* L.), lavender (*Lavandula angustifolia*), thyme (*Thymus vulgaris* L.), herb-of-the-cross (*Verbena officinalis* L.), pine (*Pinus sylvestris*), and rosemary (*Rosmarinus officinalis*) were tested for their antimicrobial activities on 18 genera of bacteria, which included some important food pathogen and spoilage bacteria. In an attempt to evaluate the usefulness of these essential oils as food preservatives, they were also tested on an extract made of fish, where clove and thyme essential oils were the most effective and tested for their antibacterial behavior against 18 different bacterial strains which included some important food pathogen and spoilage bacteria. Clove essential oil showed the highest inhibitory effect, followed by rosemary and lavender. Clove and thyme essential oils were the most effective food preservatives, when tested on an extract made of fish. The gelatin–chitosan-based edible films incorporated with clove essential oil were tested against six selected microorganisms: *Pseudomonas fluorescens*, *Shewanella putrefaciens*, *Photobacterium phosphoreum*, *Listeria innocua*, *Escherichia coli*, and *Lactobacillus acidophilus*. The clove-containing films inhibited all these microorganisms irrespectively of the film matrix or type of microorganism. When the complex gelatin–chitosan film incorporated with clove essential oil was applied to fish during chilled storage, the growth of microorganisms was drastically reduced in gram-negative bacteria, especially enterobacteria, while lactic acid bacteria remained practically constant for much of the storage period.

Oregano essential oil (OEO) dip was used in association with N, O-carboxymethyl chitosan (NOCC) to the control of *Listeria monocytogenes* and in extending the shelf life of chicken breast fillets. *L. monocytogenes* was inoculated

in chicken breast meat at 103 and 105 cfu/g and stored at 4 °C for a period up to 14 days. The results showed that total viable count (TVC) exceeded 7 log cfu/g after days 6 and 10 for control samples and samples treated with OEO, respectively. Samples treated with either NOCC or OEO plus NOCC never reached 7 log cfu/g throughout storage. NOCC had a substantially stronger antimicrobial effect as compared to OEO (Khanjari et al. 2013).

Chitosan and *Origanum vulgare* L. essential oil films were used to control *Rhizopus stolonifer* and *Aspergillus niger* in grapes (*Vitis labrusca* L.) (dos Santos et al. 2012). Oregano (*Origanum vulgare*, *Origanum onites*, *Origanum minutiflorum*, *Origanum vulgare*) is one of the most powerful and versatile essential oils. It contains strong immune-enhancing and antioxidant properties and supports the respiratory system. Oregano may also be used to enhance the flavor of food. Oregano is also a key oil used in the raindrop technique, a massage application of essential oils which is designed to bring about electrical alignment in the body. This study evaluated the efficacy of the combined application of chitosan (CH) and *Origanum vulgare* L. (OV) essential oil in the inhibition of *Rhizopus stolonifer* URM 3728 and *Aspergillus niger* URM 5842 on laboratory media and on grapes (*Vitis labrusca* L.) and its influence on the physical, physicochemical, and sensory characteristics of the fruits during storage (25 °C, 12 days and 12 °C, 24 days). The application of mixtures of different CH and OV concentrations inhibited the mycelial growth of the test fungi. The application of CH and OV at subinhibitory concentrations inhibited spore germination and caused morphological changes in fungal spores and mycelia, in addition to inhibiting the growth of the assayed fungi strains in artificially infected grapes as well as the autochthonous mycoflora of grapes stored at both room and cold temperatures. In general, the application of a coating composed of CH and OV at subinhibitory concentrations preserved the quality of grapes as measured by their physical and physicochemical attributes, while some of their sensory attributes improved throughout the assessed storage time. These results demonstrate the potential of the combination of CH and OV at subinhibitory concentrations to control postharvest pathogenic fungi in fruits (dos Santos et al. 2012). The antibacterial and antioxidant properties of chitosan edible films incorporated with *Thymus moroderi* or *Thymus piperella* essential oils have been investigated by Ruiz-Navajas et al. (2013). The essential oil has moderate antibacterial and antioxidant capacity. A similar information was given to edible film of chitosan with basil essential oil (Bonilla et al. 2011).

8 Chitosan and Clay

Natural polymers suffer from lower mechanical strength compared to synthetic polymers and high moisture barrier because of their hydrophilic nature. Many strategies have been explored to improve these problems of chitosan-based biodegradable packaging films. These include the addition of plasticizers such as glycerol which increase flexibility of the final product and addition of other biodegradable aliphatic polyesters (Correlo et al. 2005).

Other methods included the addition of layered silicates nanoparticles (e.g., sodium montmorillonite) to chitosan to improve its end-use properties such as barrier and mechanical properties (Xu et al. 2006). Montmorillonite (MMT) is the most studied nanoscale clay. It is a hydrated alumina–silicate layered clay made up of two silica tetrahedral sheets fused to an edge-shared octahedral sheet of aluminum hydroxide. Its advantages of high surface area and platelet thickness of 10 A make it suitable for reinforcement purposes.

Several reports deal with the preparation characterization of MMT/chitosan composites and films (Abdollahi et al. 2012; Hsu et al. 2012; Günister et al. 2007; Casariego et al. 2009; Lavorgna et al. 2010; Rhim et al. 2006). It has been shown that chitosan interacts with MMT and forms a homogenous film. Chitosan/MMT nanocomposites were prepared by an ion exchange reaction between water-soluble oligomeric chitosan and Na MMT. Chitosan showed high affinity to MMT clay host. Several studies have reported amelioration of mechanical properties (Lavorgna et al. 2010; Xu et al. 2006), thermal stability (Darder et al. 2003; Wang et al. 2005), functional properties (Rhim et al. 2006), barrier properties (Casariego et al. 2009; Rhim et al. 2006), and water solubility (Casariego et al. 2009) of chitosan films via incorporation of nanoclay into chitosan in the range of 1–5 wt%.

Abdollahi et al. (2012) showed that incorporating MMT and REO into chitosan improves water gain, water vapor permeability, and solubility of the chitosan film by more than 50 %. The combined effect of clay and REO improves significantly the tensile strength and elongation of chitosan ($p < 0.05$). Microstructure of chitosan/MMT–REO nanocomposites was characterized through X-ray diffraction (XRD) and Fourier transform infrared spectroscopy (FTIR). The results showed that incorporating MMT leads to improvements of the composite films, and this in turn is due to the MMT exfoliation and good interaction between chitosan and MMT in the presence of REO. Antimicrobial properties of the films also improved by REO incorporation in 1.5 % v/v. The improvement of thermal stability is mainly due to the strong electrostatic interaction of cationic chitosan molecules with anionic silicate layers. It was also found that the nanocomposites showed a synergistic effect in the antimicrobial activity against *Escherichia coli* and *Staphylococcus aureus* (Han et al. 2010). Delaminated MMT was found to be enriched on the surface of the nanocomposites when the amount of MMT was $>10^3$ ppm. This was accompanied by a decrease of the contact angle (Hsu et al. 2012). The proliferation of fibroblasts on MMT/CS 10^3 ppm was significantly greater than on other materials. The antimicrobial activity was enhanced markedly with the increased amount of MMT. These results suggest a potential application of chitosan–clay nanocomposites in the development of natural biopolymer-based biodegradable packaging materials with antimicrobial activity.

9 Antibacterial Activity of Chitosan and Chitosan Blends

In most fresh or processed foods, microbial contamination occurs at a higher intensity on the food surface, thus requiring an effective microbial growth control. Traditionally, antimicrobial agents are added directly to the foods, but their activity

may be inhibited by many substances in the food itself, diminishing their efficiency. In such cases, the use of antimicrobial films or coatings can be more efficient than adding antimicrobial agents directly to the food since these may selectively and gradually migrate from the package onto the surface of the food, thereby high concentrations being maintained when most necessary (Ouattara et al. 2000).

The molecular weight and amino group of chitosan have strong influence on its antibacterial activity (Liu et al. 2001). It has been found that chitosan activity against fungus to be less efficient as compared with its activity against bacteria (Sebti et al. 2005). On the other hand, results from Bautista-Banos et al. (2006) were much different than those of Guo-Jane et al. (2006) who emphasized on the efficiency of chitosan against fungi. Nevertheless, all these studies indicated that the polycationic nature of chitosan is the key to its antifungal properties in addition to the possible effect that chitosan might have on the synthesis of certain fungal enzymes and that the length of the polymer chain enhances that activity. Bautista-Banos et al. (2006) have shown that not only chitosan is effective in stopping the growth of the pathogen, but it also induces marked morphological changes, structural alterations, and molecular disorganization of the fungal cells.

No et al. (2002) studied the antibacterial activities of six chitosan samples and six chitosan oligomers with different molecular weights (Mws) against four gram-negative and seven gram-positive bacteria and found that chitosan markedly inhibited growth of most bacteria tested; however, the inhibitory effects differed with regard to the molecular weight of chitosan and the type of bacterium. Chitosan oligomers also inhibited bacterial growth by 1–5 log cycles at a 1.0 % concentration; however, effects were more limited than those of the chitosan. Chitosan generally showed stronger bactericidal effects for gram-positive bacteria than gram-negative bacteria.

The antibacterial activity of chitosan film or chitosan–starch films could be enhanced by the action of irradiation (Zhai et al. 2004). The chitosan–starch blend films made by irradiation were tested against *E. coli*. The blend films exhibited significant antibacterial activities after irradiation by 30 kGy compared to the pure or un-irradiated blend films and that the antibacterial activity of blend films improved with increasing the dose (Zhai et al. 2004).

Devlieghere et al. (2004) investigated the antimicrobial effect of chitosan, with high deacetylation degree and low molecular weight, against several psychrotrophic food-borne pathogens and spoilage microorganisms and compared it to those known from the literature. They found that gram-negative bacteria were more susceptible, while the sensitivity of the gram-positive bacteria was highly variable: *Brochothrix thermosphacta* and *Bacillus cereus* were very sensitive to the applied chitosan, while *Listeria monocytogenes* and different lactic acid bacteria were less susceptible. Yeasts, represented by *Candida lambica* and *Cryptococcus humicolus*, showed an intermediate sensitivity, and the activity of chitosan was strongly decreased by high amounts (30 %, w/v) of starch, leading to a significantly shorter lag phase and a significantly higher growth rate.

The antibacterial activity of chitosan–starch film using microwave treatment has been carried out using agar plate diffusion method (Tripathi et al. 2008).

The antibacterial activity of the film and their same solution has been evaluated against three different test cultures, viz., gram-negative bacteria *E. coli*, gram-positive bacteria *S. aureus*, and gram-positive bacteria *Bacillus subtilis*. It was found that the solution of chitosan–starch showed inhibitory effect against the abovementioned test cultures, but the film proved to be negative.

Incorporating chitosan and lauric acid into starch-based film showed more effective antimicrobial ability against *B. subtilis* and *E. coli* (Salleh et al. 2007) the film had synergistic antimicrobial effect when chitosan and lauric acid were combined.

The application of electric fields has also been an important instrument among researchers in the area of edible films and coatings, and there are works showing that the application of electric fields promotes a significant improvement of several properties. Garcia et al. (2009) analyzed the effect of an electric field applied during drying on the microstructure and macroscopic properties of films obtained with different mixtures of chitosan (CS) and methylcellulose (MC). The analysis indicated that CS electrically treated film exhibited a more ordered structure lower WVP and higher Young's modulus values leading to stronger films. The authors concluded that electric field treatment would be a good alternative to improve film flexibility and water vapor barrier properties.

Lei et al. (2007) reported that using ohmic heating for the production of protein–lipid films improves the yield of the film formation rate and the rehydration capacity of the films. Souza et al. (2010) determined the effect of field strength on the functional properties of chitosan coatings. Chitosan films formed from solutions subjected to electric fields at 100 V cm^{-1} or higher were found to have lower values of oxygen and CO_2 permeability. Atomic force microscopy (AFM) observation of chitosan film surface treated at 100 V cm^{-1} or above showed smoother surface as opposed to a rougher surface of untreated films.

10 Increasing the Shelf Life of Foods

Edible coatings could reduce moisture transfer, restrict oxygen uptake, lower respiration, retard ethylene production, seal in flavor volatiles, and carry additional functional ingredients (such as antioxidants and antimicrobial agents) that retard microbial growth and potential discoloration. Many trials and investigations have been made to improve the performance of the edible films (Coma 2008; Rabea et al. 2003; Sathivel et al. 2007; Elsabee et al. 2008).

Pen and Jiang (2003) controlled the browning of fresh-cut Chinese water chestnut (CWC) by treating it with aqueous solution of 0.5, 1, or 2 g chitosan/100 mL, placed into trays over-wrapped with plastic films and then stored at 4 °C. The untreated samples develop surface discoloration of after 3 days of storage at 4 °C and became more serious after 6 days, while the eating quality decreased markedly. Treatment with chitosan coating delayed the development of the discoloration. Furthermore, increasing the concentrations (from 0 to 2 g) of chitosan/100 mL coating enhanced the inhibition of the discoloration and resulted in better appearance maintenance. Application of chitosan coating also inhibited effectively

disease development of fresh-cut CWC. The use of an antimicrobial coating consisting of chitosan-added yam starch helped in controlling the microbiota present in minimally processed carrot, inhibiting the growth of lactic acid bacteria, total coliforms, psychrotrophs, yeasts and molds, and mesophilic aerobes, thereby prolonging its shelf life (Peiyin and Barth 1998). In a different work, Durango et al. (2006) used coatings based on 4 % yam starch (w/w) + 2 % glycerol (w/w) and coatings based on 4 % yam starch (w/w) + 2 % glycerol (w/w) + chitosan in 0.5 % and 1.5 % concentrations, and carrot slices were immersed into these coatings. Starch + 1.5 % chitosan-coated samples after 14 days storage at 10°C showed reductions in mesophilic aerobes, mold, and yeast and psychrotrophic counting of 1.34, 2.50, and 1.30 log cycles, respectively, compared to the control. The presence of 1.5 % chitosan in the coatings inhibited the growth of total coliforms and lactic acid bacteria throughout the storage period. The use of edible antimicrobial yam starch and chitosan coating is recommended by the authors for controlling microbiological growth in minimally processed carrot (Durango et al. 2006).

Elsabee et al. (2008) used the modified polypropylene films by chitosan and chitosan/pectin multilayer as a packaging device for storing and increasing the shelf life of tomato, and they fabricated bags 20 × 20 cm using 12 multilayers (composed of chitosan/pectin) over corona-treated polypropylene (PP) films. Fresh tomato fruits of regular size (50 g) were collected, cleaned, and stored in bag (A). Another similar fruit was stored in regular PP bag (B), and a third one was kept in air (C). The three species were kept in a refrigerator at 4 °C. The above experiment was done in triplicate. The samples were investigated at intervals, and after 13 days the samples were compared, and it was found that samples B and C deteriorated completely, while the sample in the treated bag was kept almost intact with no apparent rotting infection.

Chien et al. (2007, 2013) used chitosan coating on mango and papaya slices which helped in increasing their shelf life by retarding water loss and drop in sensory quality, increasing the soluble solid content and the acidity and ascorbic acid content. It also inhibited the growth of microorganisms. Chitosan (CS1, 1 % w/w solution) was used for producing chitosan film and used for glazing skinless pink salmon fillets by Sathivel et al. (2007) which led to a delay in lipid oxidation in skinless pink salmon fillets after eight months of frozen storage. The chitosan film was a very good barrier to oxygen, while having low WVP. Chitosan-coated fillets had a higher thaw yield than that of the non-glazed control. Their study demonstrated the potential of chitosan solution as an edible glazing for pink salmon fillets (Sathivel et al. 2007).

Strawberries (*Fragaria x ananassa cv. Camarosa*) were treated with 1 % or 1.5 % chitosan acetate solution, with or without the addition of calcium gluconate (Hernández-Muñoz et al. 2006, 2008). The treatments consisted in immersing fruits for 5 min in (a) 1 % chitosan acetate, (b) 1.5 % chitosan acetate, (c) 1 % chitosan + 0.5 % calcium gluconate, and (d) 1.5 % chitosan + 0.75 % calcium gluconate solution. Fruits were allowed to dry for 2 h at 20 °C and were subsequently stored at 10 °C and 70 ± 5 % RH. Uncoated strawberries showed signs of fungal decay after the third day of storage at 10 °C. After six days of storage, 33.5 % of uncoated fruit

was infected by molds, while no sign of fungal decay could be detected by visual inspection of fruits coated with 1.5 % chitosan or 1.5 % chitosan + 0.75 % calcium gluconate. Of the fruit coated with 1 % chitosan, 12.5 % was observed to be infected on the sixth day of storage.

To extend the shelf life of strawberries, Vu et al. (2011) have used several essential oils together with chitosan as coating films. Red thyme (RT) and oregano extract (OR) were found as strong bioactive agents against molds and total flora isolated from strawberries, whereas limonene (LIM) and peppermint (PM) had lower antimicrobial properties. These essential oils were sprayed over the strawberries at 4 °C. RT, PM, and LIM were found to be more efficient preservative agents for strawberries during 14 days of storage. A bioactive coating has been formulated by mixing chitosan derivative with palmitoyl chloride which introduced a long hydrophobic group onto the chitosan backbone increasing thus its hydrophobic character. This modification ensured controlled release and improves its stability and adhesion to the fruit product. Formulations based on modified chitosan containing LIM and Tween®80 were shown to perform better than other formulations (Vu et al. 2011).

Duan et al. (2011) investigated different coatings on the postharvest quality of prewashed fresh blueberries. Both acid-soluble and water-soluble chitosan coatings showed potential for reducing rate of decay of blueberry during room temperature storage. The effects of edible coatings, Semperfresh™ (SF), acid-soluble chitosan (ACH), water-soluble chitosan (WCH), calcium caseinate (CC), and sodium alginate (SA) on the fruit quality of fresh blueberries during storage were studied. Semperfresh™ is a commercial coating product of sucrose fatty acid ester and was reported to effectively decrease weight loss of hardy kiwifruit, cherry, and summer squash and extend shelf life of pineapple (*Ananas comosus*) for up to 5 weeks by preventing moisture loss (Duan et al. 2011). Sodium alginate is a natural linear polysaccharide and has many attractive physical and biological properties, such as moisture retention, gel-forming capability, and good biocompatibility. The ACH, WCH, and WCH + SA coatings helped reduce the decay rate of "Duke" or "Elliott" fruit during room temperature storage. Their data (Duan et al. 2011) suggest that edible coatings have potential for retaining quality of prewashed, ready-to-eat fresh blueberries under commercial storage conditions, when appropriate coating material, container, and method of applying the coatings are used.

Edible coating with chitosan was effective in inhibiting bacterial growth and reduced the formation of volatile bases and oxidation products significantly of Indian oil sardine (Sardinella longiceps) in iced condition. Mohan et al. (2011) used edible chitosan coating (1 and 2 %) with degree of deacetylation of 83 %, and it was found that the coating was effective in inhibiting the bacterial growth and reduced the formation of volatile bases and oxidation products significantly. The chitosan coating improved the water holding capacity, drip loss, and textural properties significantly compared to untreated sample. The eating quality was maintained up to 8 and 10 days for 1 and 2 % chitosan-treated sardine, respectively, compared to only 5 days for untreated samples. Similar investigations were carried out by Fan et al. (2009) for the preservation of silver carp during frozen storage. Fish samples were treated with aqueous solution of 2 % chitosan and then stored

at −3 °C for 30 days. The control and the treated fish samples were analyzed periodically for microbiological (total viable count), chemical, and sensory characteristics. The results indicated that the fish samples retain their good quality characteristics with longer shelf life during frozen storage, which was supported by the results of microbiological, chemical, and sensory evaluation analyses.

Chitosan/whey protein film as active coating of ricotta cheese was studied by Di Pierro et al. (2010). The film had 35 % and 21 % lower oxygen and carbon dioxide permeability, respectively, and about three times higher WVP than film prepared with chitosan alone; they found that edible film reduced the growth of microbial contaminants and extended the shelf life of the product packed under modified atmosphere at 4 °C. Xing et al. (2010) investigated the effect of chitosan coating containing anti-browning agents and modified atmosphere packaging (MAP) on the browning and shelf life of fresh-cut lotus root stored at 4 °C for 10 days and showed that the proposed coating and modified atmosphere packaging could improve and extend the shelf life of fresh fruits. This information could be useful for the development of novel application to edible coating and MAP design for lightly processed lotus root. Maqbool et al. (2010) used a combination of 10 % Arabic gum with potato dextrose agar medium amended with 1.0 % chitosan to suppress the mycelial growth and conidial germination inhibition of the fungus *Colletotrichum musae* that results in major economic losses of banana during transportation and storage. This fungus causes the disease anthracnose, and the proposed treatment with chitosan and Arabic gum could be used as a biofungicide for controlling postharvest anthracnose in banana.

Enzymatic browning is the second largest cause of quality loss in fruits and vegetables. Methods to prevent browning are the subject of a great deal of research in the field of the food industry (Ioannou and Ghoul 2013).

The effect of coatings in combination with anti-browning agents (1 % chitosan, 2 % ascorbic acid + 0.5 % $CaCl_2$, and 2 % ascorbic acid + 0.5 % $CaCl_2$ + 1 % chitosan) on minimally processed apple slices was studied during storage by Haiping Qi et al. (2011). Their results show that chitosan coating treatments effectively retarded enzymatic browning on minimally processed apples during storage and they effectively retarded or avoided tissue softening and apple slices underwent a little loss of firmness. Chitosan coating did not perform very well as water vapor barriers in apple slices. The use of $CaCl_2$ as a firming agent helped apple slices maintain firmness. Apples treated with chitosan at 1 % content also showed constant firmness throughout 8 days of storage due to low level of Ca^{2+} contained in aqueous chitosan solution. In contrast with chitosan coatings, noncoated apples showed reduced firmness. After 2 days of storage, control apples lost around 19 % of their weight, while coated apples lost 15 % of their weight ($p > 0.05$). Chitosan coatings on apple slices did not prove to work effectively as water vapor barriers during the entire storage period.

The effects of edible coatings and mild heat shocks on quality aspects of refrigerated broccoli were studied (Ansorena et al. 2011). Minimally processed broccoli was coated with either chitosan or carboxymethyl cellulose with or without a previous application of a mild heat shock for 1.5 min at 50 °C. Product was

packaged in multilayered polyolefin bags and stored at 5 °C for 18 days. Edible coatings exhibited a beneficial impact on broccoli quality. The weight loss in uncoated broccoli was found to be between two and five times higher compared to coated samples. Chitosan coating always presented the lower ascorbic acid degradation rates (twofold lower compared with control samples). Broccoli texture for uncoated samples increased significantly during storage. However, for carboxymethyl cellulose-coated broccoli, a slight increase in texture was observed, while for chitosan-coated broccoli no significant changes in texture were observed throughout the storage period. After the edible coating application, the microbial broccoli load dropped by around 1.5 and 0.9 logarithmic units in chitosan and carboxymethyl cellulose films, respectively. During storage, the application of chitosan coating significantly reduced the total microbial counts in the thermally and nonthermally treated uncoated samples. Among the assayed edible coatings, chitosan effectively maintained quality attributes and extended shelf life of minimally processed broccoli (Ansorena et al. 2011). Another use of chitosan coating for reducing browning in pears was conducted by Xiao et al. (2011) in which a combined effect of sodium chlorite SC dip treatment and chitosan coatings on the quality of fresh-cut d'Anjou pears was investigated. Pear wedges were immersed in SC solution, followed by coating with CH or the water-soluble derivative carboxymethyl chitosan (CMCH) solutions. The effects of the SC and coating treatments on polyphenol oxidase (PPO) inhibition and microbial inactivation were also evaluated. Results indicated that SC exhibited significant ($p < 0.05$) inhibition of browning and PPO activity. The SC treatment was also strongly effective in inactivating *Escherichia coli* O157:H7 on pear slices. Coating SC-treated pear slices with CH adversely affected the quality of pear slices by accelerating the discoloration of cut surfaces and increasing the PPO activity. On the contrary, coating SC-treated samples with CMCH significantly prevented the browning reaction and inhibited PPO activity. In addition, SC and CH/CMCH coatings maintained tissue firmness and did not affect weight loss.

11 Conclusion

Chitosan, a natural polymer which can be derived from many renewable resources, is a biodegradable eco-friendly polymer with many fantastic properties, to name but few antibacterial and antifungal efficiency, and is also a film-forming material which can be used in making edible biodegradable films. The demand for biodegradable films for the packaging industry became so intense and presently has attracted the attention of a vast spectrum of researchers. The renewable biodegradability is becoming now a great salvation for humanity against the accumulation of garbage pollution from nondegradable plastics coming from fossil origin. Chitosan is proven to be a versatile material in protecting food product whether fresh fruits, vegetables, or meat and fish products. Chitosan alone or its blends with many other degradable polymers can also be used for food protection and extending the shelf life of fresh products. The combination of chitosan with essential oils and

antioxidants was also very successful in prolonging the lifetime of many fresh and other food products. The antimicrobial efficacy of chitosan and its combination with many other bioactive materials is now the focus of an intensive research conducted all over the world. The easy chemical modifications of chitosan impart into it additional properties, for example, increase hydrophobic capacity, making it a better coating for fresh food to reduce water vapor permeability and weight loss.

Characterization of Psyllium (*Plantago ovata*) Polysaccharide and Its Uses

29

Ashwini R. Madgulkar, Monica R. P. Rao, and Deepa Warrier

Contents

Abstract

The *Plantago* is one of the genera in family Plantaginaceae, a large genus of herbs or sub-herbs distributed mostly in the temperate region and a few in the tropics. Psyllium has been in use as a medicinal agent since ancient times throughout the world. It is used for treatment of constipation, diarrhea, hemorrhoids, and high blood pressure. In olden days it was also used topically to treat skin irritations, such as poison ivy reactions and insect bites and stings. The husk of the seeds of various species of psyllium is used for its medicinal properties. The primary ingredient of the seeds and husk is a mucilaginous polysaccharide. Psyllium has been reported for the treatment of constipation, diarrhea, and irritable bowel syndrome, inflammatory bowel disease (ulcerative colitis), colon cancer, diabetes, and hypercholesterolemia. When mixed with water, the therapeutic efficacy of the drug is due to the swelling of the mucilaginous seed coat which gives bulk and lubrication. Psyllium increases the volume of the feces by absorbing water in the gastrointestinal tract, which stimulates peristalsis.

DOI 10.1007/978-3-319-16298-0_49

Modification of the polysaccharide by cross-linking or derivatization has been done to investigate its use as pharmaceutical excipient with multifarious roles. Various cross-linkers that have been studied include methacrylamide, *N*,*N*-methylenebisacrylamide, and polymethacrylamide.

Keywords
Psyllium • Ispaghula • Dietary fibers • Constipation • Irritable bowel syndrome • Cancer • Hyperlipidemia • Acrylamides • Excipients

Abbreviations

AAm	Acrylamide
APS	Ammonium persulfate
DNA	Deoxyribonucleic acid
GLUT-4	Glucose transporter protein
HEMA	Hydroxylethylmethacrylate
HLA-B2712	Human leukocyte antigen
IBS	Irritable bowel syndrome
IP	Indian Pharmacopoeia
LDL	Low-density lipoprotein
MAAm	Methacrylamide
N,NMBAAm	*N*,*N*-methylenebisacrylamide
NVP	*N*-vinylpyrrolidone
PAM	Polyacrylamide
PMA	Polymethacrylic acid
PVA	Polyvinyl alcohol
RAPD	Random amplified polymorphic DNA
SCFA	Short-chain fatty acids
SHP	Seed husk of psyllium

1 Introduction

Natural carbohydrates are the world's most abundant, renewable, and biodegradable polymers. They are the most basic source of fuel for all life forms on earth. The simplest carbohydrates are the monosaccharides such as glucose, fructose, galactose, xylose, and mannose. Polysaccharides are complex carbohydrate polymers consisting of two or more monosaccharides linked together covalently by glycosidic linkages in a condensation reaction. They are usually insoluble in water because of their large molecular size. Polysaccharides can be classified as homopolysaccharides and heteropolysaccharides. A homopolysaccharide is one with repeat units of a single type of monosaccharide, whereas a heteropolysaccharide is composed of two or more types of monosaccharides. In both types of polysaccharide, the monosaccharides are linked in a linear or branched fashion. Polysaccharides are extremely important in organisms for the purposes of energy storage and structural integrity (Berg 2007).

Starch is used as a storage polysaccharide in plants in the form of both amylose and the branched amylopectin. Cellulose and chitin are examples of structural polysaccharides. Cellulose is used in the cell walls of plants and other organisms and is said to be the most abundant organic molecule on earth. Chitin has a similar structure but has nitrogen-containing side branches, increasing its strength. Polysaccharides also include callose or laminarin, chrysolaminarin, xylan, arabinoxylan, mannan, fucoidan, and galactomannan (Campbell 1996).

Complex carbohydrates are important dietary elements for humans and are commonly called as dietary fibers. Dietary fibers are classified as soluble and insoluble fibers. Soluble fibers cause an increase in intestinal transit time of food and are readily fermented in the colon into gases. Insoluble fibers may be metabolically inert and provide bulk to intestinal contents or may undergo fermentation in the large intestine. Insoluble fibers tend to hasten movement of food through the intestine (Dietary Reference Intakes for Energy et al. 2005; Eastwood and Kritchevsky 2005). Soluble fibers reportedly bind to bile acids in the small intestine, thereby reducing their absorption. This consequently leads to lower cholesterol levels in the blood (Anderson et al. 2009). Soluble fibers also interfere with the absorption of sugar, regularize blood lipid levels, and produce short-chain fatty acids as by-products of fermentation in the colon with wide-ranging physiological activities. Although insoluble fibers are associated with reduced diabetes risk, the mechanism by which this occurs is unknown (Weickert and Pfeiffer 2008).

Modern lifestyle has given rise to a plethora of diseases including diabetes, cancer, and cardiovascular diseases. The short-term and long-term side effects associated with the therapeutic regimen used for control of these conditions have shifted the focus to alternative methods of prevention, cure, and control which can work complementarily with the treatment. This in turn has spawned a worldwide interest in the benefits of dietary fibers, the so-called wonder food of the new millennium. Dietary fiber is regarded as important for the diet, with regulatory authorities in many developed countries recommending increase in fiber intake (Dietary Reference Intakes for Energy et al. 2005; Eastwood and Kritchevsky 2005; European Food Safety Authority 2014; Jones and Varady 2008).

1.1 Polysaccharides as Pharmaceutical Excipients

Excipients are an integral part of pharmaceutical dosage forms and comprise the greatest proportion in dosage units. Knowledge of the composition, function, and behavior of excipients is a prerequisite for the successful design, development, and manufacture of pharmaceutical dosage forms. Interest in the physical effects and properties of the excipients used in pharmaceutical formulations has increased in recent years due to the awareness of the fundamental effect that excipients can exert on the bioavailability, bioequivalence, and stability of formulations.

Globally, there is a renewed interest in investigating drugs and excipients from natural sources, especially from plant and marine sources that include starches obtained from corn, wheat, rice, and tapioca (Andreev 2004) and different types of

essential and aromatic oils. A number of polysaccharides like chitosan (Park et al. 2002; Sakkinen et al. 2003; Thanou et al. 2000), tamarind seed polysaccharide (Gholardi et al. 2000; Kulkarni et al. 2005; Sumath and Ray 2002; Miyazaki et al. 1998), psyllium husk (Fischer et al. 2004a), guar gum (George and Abraham 2007), xanthum gum (Attama et al. 2006; Khourefieh et al. 2007), and rice bran wax (Dolz et al. 2007) are currently being used or investigated for varied roles as pharmaceutical excipients which include mucoadhesion, gel former, drug release retardant, plasticizer, thickener, and binder. The investigations to explore and investigate newer and newer plant sources continue unabated despite the availability of a large number of synthetic excipients.

2 Psyllium

Psyllium has been in use since ancient times throughout the world. In India the use of *P. ovata* dates back to 1500 BC in the Ayurvedic system of medicine, whereas the Chinese have used it in traditional medicine for thousands of years. The European use of the herb dates back centuries, and in North America, psyllium gained prominence in healing only near the end of the twentieth century (http://savoursomepsyllium.blogspot.in/2010/11/historytraditional-use.html 2014; Truestar Health: http://www.truestarhealth.com/Notes/2150006.html#Traditional-Use 2014). The Indian and the Chinese have used psyllium since 1500 BC for treatment of constipation, diarrhea, hemorrhoids, bladder problems, and high blood pressure. It was also used topically to treat skin irritations, such as poison ivy reactions and insect bites and stings. Europeans and North Americans began using psyllium for cholesterol and blood glucose-lowering effects (http://www.psylliums.com/psyllium.htm 2014). Typically, psyllium was administered in powder, flakes, or granular form. These would then be diluted in liquids and drank or sprinkled over meals. Only recently have they been made available in tablets, capsules, and liquid forms (http://savoursomepsyllium.blogspot.in/2010/11/historytraditional-use.html 2014; Bluementhal et al. 1998).

2.1 Biological Source

The dried, ripe seeds of *Plantago afra* (*Plantago psyllium*), *Plantago indica* (*Plantago arenaria*), and *Plantago ovata* (Plantaginaceae) are used in medicine. The *US National Formulary* includes all three species under the name "Plantago Seed" (Trease and Evans 2008). Psyllium husk is the cleaned, dried seed coat (epidermis) separated by winnowing and thrashing from the seeds of *Plantago ovata* Forskal. It is commercially referred to as blond psyllium or Indian psyllium or ispaghula. The husk may also be obtained from *Plantago psyllium* Linne or from *Plantago indica* Linne (*Plantago arenaria* Waldstein et Kitaibel) commonly known as Spanish or French psyllium (Plantaginaceae), in whole or in powdered form (United States Pharmacopoeia 2006). As per British Pharmacopoeia, psyllium seed

Table 1 Properties of psyllium seeds

Characters	*Plantago ovata*	*Plantago afra*	*Plantago indica*
Origin	India, Pakistan	Cuba, Spain, France	Egypt, Mediterranean, Europe
Color	Dull pinkish gray brown	Glossy deep brown	Dull blackish brown
Shape	Boat shaped; outline ovate	Boat shaped; outline elongated ovate	Boat shaped; outline elliptical
Length	1.8–3.3 mm	2.0–3.0 mm	2.0–2.5 mm
Weight of 100 seeds	0.15–0.19 g	0.09–0.10 g	0.12–0.14 g

consists of the ripe, whole, dry seeds of *Plantago afra* L. (*Plantago psyllium* L.) or *Plantago indica* L. (*Plantago arenaria* L. Waldstein and Kitaibel) (British pharmacopoeia 1968). According to IP, ispaghula husk (isabgol husk, *Plantago*) consists of the epidermis and collapsed adjacent layers removed from the dried ripe seeds of *Plantago ovata* Forsk (Indian Pharmacopoeia 2010).

2.2 Geographical Source

Ispaghula is an annual herb cultivated in India in the states of Gujarat, Maharashtra, Punjab, and in parts of Rajasthan and Sindh Province of Pakistan (Rangari 2008). *Plantago psyllium* is cultivated in France and Spain for the European market. *Plantago ovate* seeds are cultivated in Southern Europe, North Africa, and West Pakistan (Gupta 2005). India exports about 90 % of the gross production of ispaghula and nearly 93 % of the export being husk. Psyllium husks and industrial powders are exported in countries such as USA, UK, France, Germany, Japan, Indonesia, Canada, Mexico, Sweden, Spain, Norway, Italy, Australia, Denmark, Korea, Pakistan, and some Gulf countries. The USA is the largest buyer of ispaghula from India and accounts for about 75 % of the total husks exports from India (http://www.psylliums.com/psyllium.htm 2014) (Table 1).

2.3 Cultivation, Collection, and Treatment

The crop requires marginal, light, well-drained sandy-loam to loamy soils having pH between 7 and 8. The plant does not have any specific nutrient requirement. It requires a cool climate and dry sunny weather during harvesting. Mild dew, cloudy, or light showers cause seed shedding (Trivedi 2004). Seeds are sown by broadcasting method in sandy, loamy soil. Addition of farmyard manure or animal manure (prepared basically using cow dung, cow urine, waste straw, and other dairy wastes) has favorable effect but generally ammonium sulfate is added as a fertilizer. Irrigation is done regularly at an interval of 8–10 days. Ispaghula is not significantly affected by pests or diseases, but the annual harvest greatly suffers due to

Fig. 1 Morphology of psyllium seeds [*Plantago ovata*]

storm and rainfall. *Plantago* wilt "*Fusarium oxyspirum*" and downy mildew are the major diseases of ispaghula. White grubs and aphids are the major insect pests. The crop is harvested when the flower spikes turn reddish brown, lower leaves dry, and upper leaves turn yellow. Harvested seeds are dried below 12 % moisture to enable cleaning, milling, and storage (Rangari 2008). Ispaghula husk is separated from the seed by crushing in flat stone grinding mills by winnowing. It is marketed as a separate commodity. It is more in demand and fetches more price than that of seeds. Raw psyllium seeds are fumigated in their storage area to avoid any contamination. Psyllium products like husk and powder are treated in the fumigation chamber with approved chemical reagents like methyl bromide as per latest international guidelines. Psyllium products can also be sterilized by ethylene oxide or gamma radiation, if required (http://phytosanitorysolution.com/ 2014). Seeds and husks of *Plantago major* Linn, *Plantago lanceolata* Linn, *Plantago psyllium* Linn, as well as seeds of *Lepidium sativum* are used as adulterants in ispaghula (http://www.psylliums.com/psyllium.htm 2014).

2.4 Morphology

Psyllium seeds are ovoid-oblong in shape, about 2–3 mm long and 0.8–1.5 mm wide (Fig. 1). They are pinkish gray to brown in color with a convex dorsal surface and concave ventral surface with a deep groove running lengthwise along the center (http://www.psylliums.com/psyllium.htm 2014) (Figs. 2 and 3a, b).

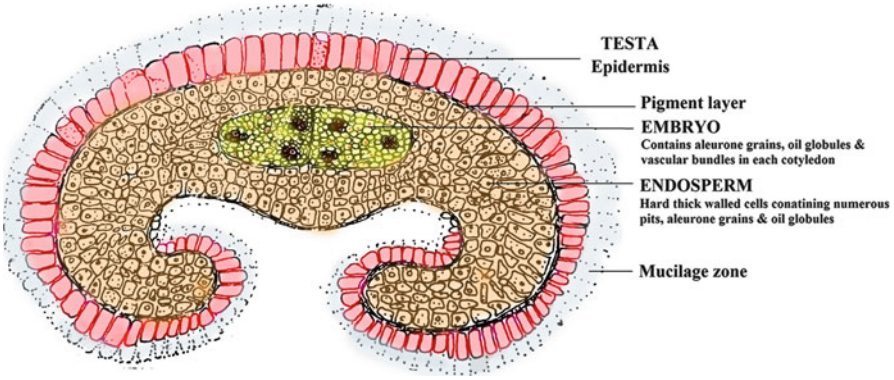

Fig. 2 Transverse section of seeds of *Psyllium ovate*

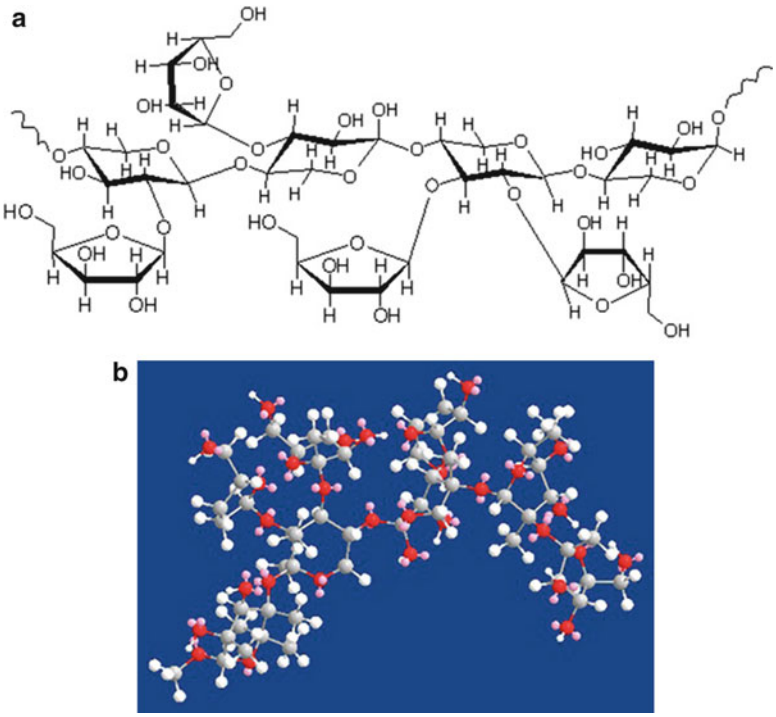

Fig. 3 (**a**) Chemical structure of arabinosyl (galactouronic acid) rhamnosylxylan. (**b**) Ball-and-stick model of arabinosyl (galactouronic acid) rhamnosylxylan

2.5 Microscopy

The transverse sections of the seed that cut through the central region possess a reniform outline and exhibit a spermoderm, endosperm, and embryo.

The spermoderm shows an outer epidermis of mucilaginous epidermal cells with obliterated walls in glycerine mounts; the radial and inner walls swell and disintegrate to form a clear mucilage upon irrigation of the mount with water, and a pigment layer with brown amorphous content. The endosperm is composed of irregular-shaped, thick-walled cells with walls of reserve cellulose. The outer layer of this region consists of palisade cells 15–40 μm in height. Aleurone grains and fixed oils are found in the endosperm cells (Bruneton 1995).

2.6 Chemical Constituents

Many elements have been identified in the seed which include proteins, lipids, sterols, triterpenes, and aucubin glycoside. The mucilage level is about 30 %. The principal constituent of the mucilage is 85 % of a soluble polysaccharide fraction dominated by D-xylose. The polymer backbone is a xylan with 1→3 and 1→4 linkages with no apparent regularity in their distribution. The monosaccharides in this primary chain are substituted on C-2 or C-3 by L-arabinose, D-xylose, and α-D-galactouronyl-(1→2)-L-rhamnose (Bruneton 1999). Psyllium seed mucilage contains 22.6 % arabinose, 74.65 % xylose and traces of other sugars, and 35 % nonreducing terminal residues (Fischer et al. 2004b).

2.7 Structure

The polysaccharide structure constitutes a densely substituted main chain of (1→4)-linked D-xylopyranosyl residues, some carrying single xylopyranosyl side chains at position 2, others bearing, at position 3, trisaccharide branches having the sequence 1-Araf- (1→3)-1-Araf. Chemically the polysaccharide is arabinosyl (galacturonic acid) rhamnosylxylan.

3 Clinical Indications

Psyllium has been reported for the treatment of constipation, diarrhea, and irritable bowel syndrome, inflammatory bowel disease (ulcerative colitis), colon cancer, diabetes, and hypercholesterolemia (Majmudar et al. 2008; Reynolds 1993).

3.1 Constipation

Psyllium husk is widely used for treatment of constipation due to its mucilaginous components.

When mixed with water, the therapeutic efficacy of the drug is due to the swelling of the mucilaginous seed coat which gives bulk and lubrication (Tyler et al. 1988). Psyllium increases the volume of the feces by absorbing water in the

gastrointestinal tract, which stimulates peristalsis (Read 1986). The intraluminal pressure is decreased, colon transit is increased, and the frequency of defecation is increased (Marteau et al. 1994; Sölter and Lorenz 1983). The effectiveness of fiber, and psyllium in particular, on constipation depends on the main cause of the constipation. In a study of 149 patients with chronic constipation, the consumption of 15–30 g daily of a psyllium seed preparation provided bowel relief in 85 % of participants who had no known pathological cause for their constipation. Only 20 % of individuals with slow transit responded to psyllium. A slightly greater percentage (37 %) of those with disorders of defecation – including rectocele, internal prolapse, anismus, and rectal hyposensitivity – found improvement (Alternative Medicine Review 2002; Voderholzer et al. 1997; Kumar et al. 1987; Qvitzau et al. 1988).

3.2 Fecal Incontinence

Psyllium has been shown to have the paradoxical property of both improving constipation by increasing stool weight and ameliorating chronic diarrhea. Because of its ability to retain water, psyllium has also been shown to benefit individuals with fecal incontinence from liquid stools or diarrhea. A placebo-controlled trial of persons with liquid stool fecal incontinence was performed in which supplementation with both gum arabic and psyllium showed approximately a 50 % decrease in the occurrence of incontinent stools. The psyllium group had the highest water-holding capacity of water-insoluble solids and total water-holding capacity of the stool (Alternative Medicine Review 2002; Bliss et al. 2001).

3.3 Hemorrhoids

With the known benefit of psyllium for both constipation and loose stools, psyllium was also reported to be beneficial for the treatment of hemorrhoids. It was found to have a significant improvement in reduction of bleeding and a dramatic reduction of congested hemorrhoidal cushions (Perez et al. 1996; Broader et al. 1974; Webster et al. 1978).

3.4 Irritable Bowel Syndrome (IBS)

Constipation is characterized by unsatisfactory defecation and infrequent stools, difficult stool passage, or both. On the other hand, the presence of clinically important abdominal discomfort or pain associated with constipation defines IBS with constipation. Intake of psyllium may be effective in alleviating chronic constipation in patients without slow colonic transit or disordered constipation. On the other hand, fiber with lactulose may improve stool consistency in patients with IBS with constipation. The easing of bowel dissatisfaction appears to be a major reason for the therapeutic success of psyllium in IBS (Degan and Phillips 1996; Bouchoucha et al. 2004; Koch et al. 1997).

3.5 Ulcerative Colitis (Crohn's Disease)

The two primary sites for Crohn's disease are the ileum, which is the last portion of the small bowel (ileitis, regional enteritis), and the colon (Crohn's colitis). A small number of studies have examined the ability of psyllium to maintain remission in ulcerative colitis. Dietary fiber has been proven to be beneficial in maintaining remission in human ulcerative colitis, an effect related with an increased luminal production of short-chain fatty acids (SCFA), i.e., acetate, propionate, and butyrate in the intestines. Dietary fiber supplementation ameliorated colonic damage in HLA-B2712. In an open label, randomized, multicenter trial of persons with ulcerative colitis, psyllium seed supplementation (10 g twice daily) was as effective as mesalamine in maintaining emission. It was inferred that this effect may possibly be due to increased levels of butyric acid with psyllium supplementation (Alternative Medicine Review 2002; Fernandez et al. 1999).

3.6 Appetite

Psyllium may also have an effect on appetite. A triple-blind study on 17 women looked at the effect of 20 g of psyllium seed 3 h pre-meal and again immediately post-meal during three 3-day study periods. The subjects reported significantly increased feelings of fullness 1 h after meals with the psyllium and exhibited a significantly lower fat intake with those meals (Turnbull and Thomas 1995).

3.7 Hyperlipidemia

Psyllium has been shown to reduce total cholesterol and low-density lipoprotein (LDL) cholesterol in animals and in humans (Fernandez 1995; Fernandez et al. 1995; Terpstra et al. 2000). Sprecher et al. demonstrated a 3.5 % reduction in total cholesterol and a 5.1 % reduction in LDL levels after consuming 5 g of psyllium husk twice daily for 8 weeks (Sprecher et al. 1993). Another study began with individuals on the American Heart Association Step 1 diet, followed by 8 weeks of psyllium, resulting in decreased total cholesterol (4.8 %) and LDL (8.8 %) (Bell et al. 1989). A meta-analysis was performed on eight trials of psyllium husk in conjunction with a low-fat diet in the treatment of hypercholesterolemia. After an initial 8-week, low-fat diet run-in, 10.2 g psyllium was given per day, resulting in a 4-percent reduction in serum total cholesterol and a 7-percent reduction in LDL cholesterol, compared to diet and placebo. A 6 % reduction in the ratio of apolipoprotein (apo) B to apo A-I was also noted (Anderson et al. 2000a; Levin et al. 1990; Anderson et al. 2000b; Olson et al. 1997). A meta-analysis of 12 studies of psyllium-enhanced cereal product consumption on total and LDL cholesterol in 404 adults with mild to moderate hypercholesterolemia demonstrated a reduction of 5 % of total cholesterol and 9 % of LDL cholesterol (Romero et al. 1998). Researchers studied the effect of fiber-enhanced cookies on blood

lipids in hypercholesterolemic men, using wheat bran-, psyllium-, or oat bran-containing cookies (wheat bran was used as the placebo since it has no demonstrated cholesterol-lowering effect). At the end of the 8-week study, plasma LDL cholesterol had decreased to 22.6 % in the psyllium group and 26 % in the oat bran group (Burton and Manninen 1982). A 4-month study of 12 elderly patients showed psyllium husk reduced total serum cholesterol by 20 %, a figure much higher than the abovementioned studies [(Stewart et al. 1991)]. In another study, a significant reduction in total serum cholesterol was noted in 176 elderly persons who used psyllium for 1 year (Vega-Lopez et al. 2001). The authors found that for every 1 g increase in daily psyllium dose, there was a 0.022-mmol/l (0.84 mg/dl) decrease in serum total cholesterol concentration. In a study to examine age and gender differences in the effect of psyllium on blood lipids, men and pre- and postmenopausal women were given psyllium (15 g daily) or placebo. Psyllium lowered plasma LDL cholesterol by 7–9 % in all groups. Triglyceride levels were lowered by 17 % in men, but were increased by 16 % in postmenopausal women. Premenopausal women displayed no significant shift in triglycerides (Agrawal and Pariddhavi 2012).

The mechanism of action of psyllium's hypocholesterolemic effects has not been fully expounded. Psyllium was shown to stimulate bile acid synthesis (7 α-hydroxylase activity) in animal models (Horton et al. 1994; Matheson et al. 1995) and in humans (Everson et al. 1992). The diversion of hepatic cholesterol for bile acid production is an established mechanism for reducing serum cholesterol. Psyllium's effect on the absorption of cholesterol (Everson et al. 1992; Turley et al. 1994) and fat (Ganji and Kies 1994) is negligible but may appear to contribute to cholesterol lowering. Additional mechanisms, such as inhibition of hepatic cholesterol synthesis by propionate (Anderson 1995) and secondary effects of slowing glucose absorption (Jenkins et al. 1990), may also play a role.

3.8 Diabetes Mellitus

Dietary fibers from psyllium have been used extensively in processed food to aid weight reduction, for glucose control in diabetic patients (Anderson et al. 1999). It has been shown to improve postprandial glycemic index and insulin sensitivity. In rats it was found to suppress sucrose and glucose absorption in the gastrointestinal tract. Studies also showed enhanced blood glucose disposal by regulating skeletal muscle plasma membrane GLUT-4 protein (glucose transporter) expression without phosphatidylinositol 3-kinase activation (Yu et al. 2009). The effect of psyllium husk was studied in 34 men with type 2 diabetes and hypercholesterolemia, given either placebo or 5 g psyllium twice daily for 8 weeks. Total cholesterol was lower by 8.9 % and LDL by 1 %. In addition, the postprandial rise of glucose was significantly reduced (Duke 1985). The mechanism for hypoglycemic effect in humans may be due to suppression of diffusion of glucose to small intestinal epithelium for absorption, delayed gastric emptying time, and reduced carbohydrate digestibility by retarding their access to digestive enzymes (Liangli and Wei Liu 2012).

3.9 Cancer

Seeds of *Plantago coronopus*, *P. lanceolata*, *P. ovata*, and *P. psyllium* were used by humans against cancer (Liangli and Wei Liu 2012; Hartwell 1982). Besides, the presence of luteolin-7-*O*-*b*-glucoside, a major flavonoid present in the leaves of *P. serraria*, *P. psyllium*, *P. coronopus*, and *P. lanceolata*, was able to strongly inhibit the proliferation of human cancer cell lines (Galvez et al. 2003). Butyric acid which is reported to exhibit antineoplastic activity against colorectal cancer is the preferred oxidative substrate for colonocytes and may be helpful in the treatment of ulcerative colitis (Whitkus et al. 1994). Butyrate may also dose-dependently suppress cancer cell proliferation, promote differentiation marker expression, and lead to reversion of cells from a neoplastic to nonneoplastic phenotype (Yu et al. 2009). In a study of patients with resected colorectal cancer, those given 20 g of psyllium seeds daily for 3 months exhibited an average increase of butyric acid production of 42 %, which decreased to pretreatment levels within 2 months of cessation of supplementation (Nordgaard et al. 1996).

Psyllium might also alter colonic sphingomyelin metabolism and apoptosis which may have an impact on colon tumorigenesis and inflammation in mice (Cheng et al. 2004).

4 Safety Data

4.1 Precautions

The recommended dose for psyllium varies as per the age and clinical indication. Nonetheless the precautions are common regarding safe use of psyllium. Psyllium should not be taken in case of suspected intestinal obstruction (ileus), diseases of the esophagus, and patients with difficulty in swallowing. It is also not recommended for patients with intestinal atresia and stenosis and for children below 6 years. It should be consumed with sufficient quantity of water, failing which may cause choking due to blockage of the throat or esophagus (New HMPC Commission 2014).

4.2 Drug Interactions

Bulking agents have been reported to reduce the absorption of some minerals (calcium, magnesium, copper, and zinc), vitamin B_{12}, cardiac glycosides, and coumarin derivatives (Gattuso and Kamm 1994; Hänsel et al. 1994a; Drews et al. 1981). The co-administration of psyllium with lithium salts has been reported to reduce the plasma concentrations of the lithium salts due to inhibition of their absorption from the gastrointestinal tract (Pearlman 1990). It has also been reported to decrease both the rate and extent of carbamazepine absorption, inducing subclinical levels of the drug. Therefore, ingestion of lithium salts or

carbamazepine and psyllium should not be concomitant (Etman 1995). Insulin-dependent diabetic people may require less insulin if they are concurrently taking psyllium (Bradley 1983).

4.3 Preclinical Safety Data

The material hydrates and swells to form mucilage in vivo as it is only partially solubilized. Less than 10 % of the mucilage gets hydrolyzed in the stomach. Preclinical studies in various animal species revealed pigmentation of various organs. Albino rats showed a dark pigmentation of the suprarenal gland, kidney, marrow, and liver after 125 days on a diet of 25 % of psyllium seeds. Dogs showed gray color of kidneys after a diet containing 25 % psyllium seeds for 30 days. Similar effects were not observed in humans. The pigmentation could be attributed to the dark pigment in the pericarp of the seeds (Hänsel et al. 1994b).

5 Preserving Genetic Integrity

Proper conservation and successful breeding of commercially viable crops is facilitated by appropriate identification of the plant. Conventionally, identification and classification of plant groups are solely based on differences in morphological features, especially the floral character which was considered to be consistent. It is well established that morphological characteristics are a result of the interaction between the environment and the genotype and can also be influenced by climatic and edaphic factors. Molecular techniques using DNA markers are therefore useful not only to identify the genotypes for authentication, but also in assessing and exploiting the genetic variability (Whitkus et al. 1994b). These techniques are suitable means for estimating genetic diversity because of their abundant polymorphism and the fact that they are independent of environment (Gepts 1993). DNA fingerprinting is a remarkable tool to create the genetic blueprint of all medicinal plants. Genetic diversity in five cultivars of *P. ovate* was estimated using molecular markers by Pal (Pal and Raychoudhuri 2004) and Raychoudhuri (Raychoudhuri and Pramanik 1997). Similarly, Vahabi et al. used molecular and morphological markers for the evaluation of genetic diversity between *P. ovate* (Vahabi et al. 2008). Wolff and Morgan-Richards used random amplified polymorphic DNA (RAPD) markers for differentiating subspecies of *Plantago major* (Wolff et al. 2000). Samantaray et al. used RAPD markers to assess genetic relationships and variance in seven species of Plantago, i.e., *P. ovata* (Forsk.), *P. indica* (L.), *P. arenaria* (Waldst.), *P. psyllium* (Linn.), *P. lanceolata* (Linn.), *P. serraria* (Linn.), and *P. coronopus* (Linn.) (Samantaray et al. 2010). In India, facilities have been developed for long-term storage of germplasm in the National Gene Bank in New Delhi, India, to avoid frequent regeneration and to check genetic drift (Trivedi 2004).

6 Chemical Modifications

A lot of work involving derivatization/cross-linking of polysaccharide obtained from psyllium seeds and husk is underway. The objective of these studies is to modify the properties of the polysaccharide in order to exploit it as a pharmaceutical excipient. Some of the pioneering works done in this field are enlisted below:

1. Singh and Sharma have developed psyllium–PVA–acrylic acid-based novel hydrogels for use in antibiotic drug delivery through graft copolymerization. The use of a very small amount of these petroleum products has developed low energy, cost-effective, biodegradable, and biocompatible material for potential biomedical applications. In this experiment, polyvinyl alcohol and acrylic acid were used as monomers; *N*,*N*-methylenebisacrylamide was used as the cross-linking agent, and ammonium persulfate was used as the thermal initiator (Singh and Sharma 2010).
2. Patil et al. have developed and evaluated psyllium seed husk polysaccharide-based wound-dressing films. In this study, wound-dressing films were fabricated using seed husk of psyllium (SHP) complexed with povidone iodine and were evaluated for various physicochemical properties as well as wound healing activity in albino rats (Basavaraj et al. 2011).
3. Singh and Chauhan have prepared psyllium- and acrylamide-/methacrylamide-based hydrogels, and the effects of pH on the release dynamics of insulin from drug-loaded hydrogels were studied to evaluate the drug release mechanism. Two types of hydrogels were prepared by using acrylamide and a mixture of acrylamide/methacrylamide. The hydrogels were named as psy-cl-poly (AAm) and psy-cl-poly (AAm-*co*-MAAm) hydrogels, respectively. *N*,*N*-methylenebisacrylamide was used as the cross-linking agent and ammonium persulfate was used as the thermal initiator (Singh and Chauhan 2010).
4. Sen et al. conducted research on a novel microwave-initiated method for synthesis of polyacrylamide-grafted psyllium (Psy-*g*-PAM). Psyllium was modified through grafting of polyacrylamide (PAM) chains on it using microwave radiations only, in the absence of any other free radical initiator. The synthesized grades of the graft copolymer were characterized through various physicochemical techniques. The flocculation efficacy of the synthesized graft copolymers was studied in kaolin and coal fine suspension through standard "Jar test" procedure. It was found that the high flocculation efficacy of Psy-*g*-PAM makes it a good candidate to be used as a flocculant for waste water treatment and treatment of effluents discharged from coal washeries (Sen et al. 2010).
5. Singh and Kumar prepared psyllium-*N*-vinylpyrrolidone (NVP)-based hydrogels by radiation-induced cross-linking. The reaction mixture was irradiated with gamma rays of a dose rate of 2.43 kGy/h, in 60 Co gamma chamber for a specific time. The cross-linking polymers thus formed were named as psy-cl-poly (NVP) hydrogels. These hydrogels were then studied for their release dynamics of anticancer model drug (5-fluorouracil). It was found that the release of the drug from the hydrogels occurred through non-Fickian diffusion mechanism (Singh and Kumar 2008).

6. Kumar and Sharma synthesized a new material (Psy-*g*-PMA) by grafting polymethacrylic acid onto the backbone of psyllium using a microwave-assisted method. Acetylsalicylic acid was incorporated in the various Psy-*g*-PMA samples and tablets were prepared to study the in vitro drug release. This biodegradable material is good for the fast release of medicine in acidic environments such as the human stomach. The material also demonstrated superabsorbent capacity for water and may be useful in diapers and feminine sanitary pads (Kumar and Sharma 2013).
7. Singh and Chauhan prepared psyllium 2-hydroxylethylmethacrylate (HEMA) and acrylamide (AAm)-based polymeric networks by using *N*,*N*-methylenebisacrylamide (*N*,*N*-MBAAm) as cross-linker and ammonium persulfate (APS) as initiator. It was concluded that the swelling of the modified psyllium-based hydrogels is affected by the composition of the hydrogels and pH of the swelling medium (Singh et al. 2008).

7 Conclusion

The surge in the development of newer drug molecules for the treatment of a plethora of diseases has definitely led to improved therapy, but it has also resulted in a concomitant rise in side effects and adverse reactions. This has led to a resurgence of plant-based traditional systems of medicine and nutraceuticals which either supplement or complement these therapeutic regimens. The impact of the role of dietary fibers, the "wonder food" of the new millennium, in the control and cure of many lifestyle diseases cannot be underestimated. Psyllium has been in use since ages for its various medicinal effects and continues to rule the roost for the treatment of constipation, diarrhea, irritable bowel syndrome, inflammatory bowel diseases, ulcerative colitis, colon cancer, diabetes, and hypercholesterolemia. The high mucilaginous content of psyllium seeds and husk has also spawned an interest in its use as pharmaceutical excipient. Chemical modifications have been done to improve its profile as multifunctional pharmaceutical excipient. Future studies could be aimed at exploring and discovering more uses of this remarkable but unassuming plant.

Dietary Fiber and Prebiotics

30

Werner Praznik, Renate Loeppert, Helmut Viernstein, Alexander G. Haslberger, and Frank M. Unger

Contents

Abstract

Dietary fiber and prebiotics exert a great impact on health-promoting food for mankind. Under this aspect a general overview is given about the bioavailability of carbohydrates and their influence on dietary fiber intake and about the developing of the prebiotic concept and specific functional foods. Moreover, the occurrence and chemical composition of native dietary fiber such as resistant

starch, pectin, hemicelluloses, ß-glucan, and fructan in context to their properties – in particular the prebiotic potential for human health – will be discussed. Important industrially produced bioactive carbohydrates from plant and seaweed sources with high prebiotic efficacy and increasing economic interest such as fructan – particularly inulin and fructooligosaccharides (FOS), heteropolysaccharides, xylooligosaccharides (XOS), and isomaltooligosaccharides (IMO) – will be presented. Additionally enzymatic processing of prebiotic-active oligosaccharides such as FOS, galactooligosaccharides (GOS), or nondigestible disaccharides such as isomaltulose and trehalulose derived from sucrose and lactose will be demonstrated and discussed.

1 Introduction

1.1 Evolutionary and Historical Background of Human Nutrition

Two million years ago, at the evolutionary development of the *Homo sapiens* from ancient times, the herbivorous *Australopithecus* had a herbal diet that was the main basis of man's daily nutrition. Shortly after, animal diet, obtained by hunting or by consumption of carcasses (Cordain et al. 2000), delivered particular, long-chained polyunsaturated fatty acids enabling advancement of the human brain within evolutionary periods (Eaton and Cordain 2002). In the history of human development, this age is called the period of hunters and gatherers. Descendents of this era may still be found in semitropical regions of today's world, living on nutrition consisting of 60–80 % vegetable matter and about 20–40 % animal food (Eaton and Konner 1985).

Subsequently, starting about 10,000 years ago, cultivation of edible plants was performed intensely, and the era of farming was established (Gordon 1987). Based on agriculture and the production of fodder, it was possible to domesticate farm animals (Grupe 1992), a development followed by increasing consumption of animal food. At the same time, the utilization of milk from domesticated ruminants became an important food source, especially in the European region. The usage of milk, however, requires the genetic adaption of enzyme patterns for digestion of lactose, which took place with a large part of the European people. Yet in Asia and Africa, where milk is hardly used, lactose intolerance is highly pronounced and leads to serious symptoms of incompatibility. This fact proves convincingly the genetic adaption of distinct groups of humans to the intake of foods specific for certain regions in the course of evolution.

Reviewing the different stages of food development, humans can be classified as omnivores with the focus on plant nutrition. Today, a purely vegetarian diet is not a consequence of evolution but reflects certain social and cultural choices of the population. Based on the outstanding adaptability of humans to the availability of food, they possess sufficient genetic variability in order to enable their survival in different regions of the world. To this day, primitive populations with mainly plant and animal nutriment continue to exist their organism shows a fine adaption to the environment. Thus, the human organism, especially the intestinal tract and metabolism, is determined by the disposability of nourishment in many ways.

Only about 200 years ago, the personal living conditions of humans in the industrial regions changed because of a new working world (industrial democracy). Owing to the flight from land and the resulting increased accumulation of people in the cities, the profile of food consumption was totally changed and adapted to the new situation.

Dramatic changes of eating habits occurred: in Germany, for instance, the annual consumption of meat per capita rose from 34 lbs (pound) in the beginning of the eighteenth century to 200 lbs in 1990. Thus, the energy supply of food from animal fare increased to about one third of the total energy consumption. Likewise, the

consumption of animal proteins was raised from primarily 20 % to about two thirds of the total supply of proteins (Lemnitzer 1977). At the same time, drastic innovations happened in the food industry such as the production of foodstuffs with superfine flours, and refined sugars on one side and semifinished goods free from fiber at the other side. Particularly the portion of finely ground flours (superfine flour, refined grains, etc.) with a content of less than 4 % fiber was drastically enhanced and represents more than 80 % of the cereal consumption at present (Wiebke 2004). These changes of eating habits, happening generally in the highly developed industrial countries of the world, reflect the status of nutrition for the population of these countries.

1.2 Living Standard and Diseases of Civilization

Particularly after the Second World War which had caused a short-term undersupply of nutrition for certain groups of the population in many European countries, a targeted rehabilitation of the social system was undertaken in the following decades. Unfortunately, the policies implemented failed to propagate nutrition appropriate to the human species with a high proportion of plant food. On the contrary, the returning prosperity and the resulting living standard were provided with indices in no way compatible with the requirements of healthy nutrition. The consumption apiece of refined sugar and meat became indicators of improved living standards at the yearly statistical reports.

Only in the late 1980s it was recognized that the so-called civilization food with its huge portion of refined sugar, superfine flour, polished rice, animal fat, and protein does not represent a nutrition adequate for the prosperous, akinetic citizen. The problem is that the human body with its excellent adaptability copes for a long time with food extremely denatured and/or poor in fibers. Hitherto unknown disease patterns appeared, summarized under the term lifestyle diseases. Thus, because of inadequate eating habits combined with a deficit of exercise, diseases such as obesity, diabetes mellitus type 2, hypertension, hypercholesteremia, cardiovascular diseases, apoplexy, cancer, musculoskeletal disorders, tooth decay, and weakening of the immune system became commonplace, especially during the last decades (Chadwick et al. 2003; Schaafsma 2004).

1.3 Fast Food: Slow Food

The convenience-oriented marketing of fast-food chains has developed successful strategies that are at variance with the requirements of healthy eating. The fast-food industry is based on foods with long shelf-lives while preserving the valuable food ingredients. However, these foods usually contain significantly more calories than unprocessed, natural foods. Processed foods can be chewed and swallowed faster, and therefore, their saturation efficacy is lower although the consumption of calories is the same. This is one of the essential causes of hypercaloric nutrition.

Fast food only partly fulfills the requirements of the processing food industry. For enterprises marketing fast food, the preparation should preferably require little time and the consumption of the products should be as fast as possible; thus, the components of fast food are industrially prefabricated, minimizing the time of preparation. Finished and half-finished food products for domestic use, the so-called convenience food, also need little time of preparation. Typical examples of fast and convenience foods are precut French fries, deep frozen hamburgers and pizzas, and industrially produced sauces and dressings. These products stimulate substantial fat consumption, large portions of insulin-activating carbohydrates, and disproportionate protein consumption. Especially the rapid degradation of denatured starch products to glucose leads to a short-time elevation of blood sugar and to the cancelation of hungry feeling. This effect, however, vanishes quickly, resulting in new feelings of hunger and additional food consumption without real need. Exceeding consumption of such products is overly stressful to the human organism and frequently followed by uncontrolled obesity.

In 1986, the Slow Food organization was founded in Italy as a counterculture to the fast-food chains, espousing a cuisine based on pleasurable, regional, whole foods. This group counts presently more than 100,000 members in 150 countries around the world. In the light of a species-appropriate nutrition with a high proportion of plant food, the movement tries to give a positive input concerning healthy, tasteful, and satiable fare. Both animal and plant foods are represented in a well-balanced form. The dishes contain little or no fat; proteins are derived from animal as well as from plant sources. For the uptake of carbohydrates, the availability of vegetable raw materials is essential. Thus, whole-meal noodles, natural rice, whole-grain bread, vegetables (mainly in raw, uncooked form), and fruits are emphasized. Because of the constituent substances such as resistant starch and fiber, the level of blood sugar is kept constant and addephagia stay away.

As indicated above, human nutrition was and still is adapted to the regional conditions and may consist of different items of plant and animal food. Plant nutrition, scarcely processed, can be considered species appropriate and optimal for individual health. Additionally, the energy input of food should be controlled and attuned to the physical activity. With increased supply of animal food with high fat content on one side and little exercise on the other side, the risk to contract diabetes type 2 is clearly augmented (Van Dam et al. 2002; Aune et al. 2009).

2 Bioavailability of Carbohydrates

In principle, the nutrition of humans is formed by a mixed diet of about 55–60 % carbohydrates, 10–15 % proteins, and 30 % fat (Elmadfa and Leitzmann 2004). The proportion of digestible carbohydrates however is essentially determined by the ingested food and its processing. As already shown above, highly processed carbohydrates particularly plant starch, industrially produced sucrose, lactose from dairy products, or monosaccharides such as glucose and/or fructose occurring mainly in honey, vegetables, and fruits are converted to glucose by digestive

enzymes and delivered to the human body. Glucose is an essential energy provider for human cells besides fat and protein, the main energy provider, however, for blood and brain cells.

2.1 The Human Alimentary Tract

The digestion of glucose containing α-(1,4)-linked and α-(1,6)-linked polysaccharides, the so-called starches, is partly performed already in the mouth by α-amylase, contained in the saliva – a kind of predigestion into smaller fragments. After passing the stomach, these fragments are basically degraded to glucose by pancreatic and intestinal amylases and maltase in the upper small intestine and transported to the liver by cells of the intestinal mucosa using the portal circuit.

Likewise dietary fibers contained in food are channeled through this way and thus provided for fermentation by the microbiota of the colon. Such fibers are carbohydrates being not degraded by digestive enzymes of the human body. Depending on the kind and amount of plant food, the proportion of insoluble fiber, being very important for the peristalsis of the colon, is rather fluctuant and very different because of digestion of differing plant raw materials like grain. Generally high and sustainable saturation values have to be achieved at the uptake of carbohydrates consisting mainly of starch and fiber. The proportion of resistant starch should be held relatively high by appropriate food processing. A high portion of fibers and starch enhances the volume of nutrition (high water absorption) and makes the effect of saturation immediate. With plant food such as vegetables, potatoes, and whole-grain products, a decelerated transfer of glucose into the blood is achieved and the hungry feeling is delayed. High portions of fiber with high water-binding capacity cause expansion of the emptying time from the stomach to the small intestine, and thus, the feeling of satiety is ongoing for a longer time.

2.2 Glycemic Index and Glycemic Load

The use of finely ground flours and refined sugar produces dishes with high availability of glucose. At consumption of such dishes, the blood sugar load reaches peak values followed by an exceeding insulin secretion in order to lower the concentration of blood glucose back to the normal level. Nutrition rich in fiber causes an improved glucose tolerance which has a positive effect especially on the adjustment of the metabolism of persons suffering from diabetes type 2 (Meyer et al. 2002). For a better control of nutrients, the parameter “glycemic index” (GI) was established in the 1980s of the last century.

The glycemic index refers to the increase in blood glucose following the consumption of food containing 50 g of carbohydrate. The percentage compared to the increase following uptake of the same amount of glucose is calculated. The area corresponding to the glucose uptake is set equal to 100 (Jenkins and Jenkins 1987; Ludwig and Eckel 2002). The glycemic index of whole-grain products is

Table 1 Glycemic index and glycemic load of selected food items (Foster-Powell et al. 2002)

Food item	Glycemic index (glucose = 100)	Serving size (g)	Glycemic load per serving
With high starch content			
Long-grain rice	56	150	24
Jasmine rice	109	150	46
Basmati rice	58	150	22
Instant rice	87	150	36
Spaghetti, durum wheat	47	180	23
Baked potato	60	150	18
Boiled potato	70	150	19
French fries	75	150	22
Vegetable, fruit			
Raw carrot	16	80	1
Banana	42	120	11
Grapes	43	120	8
Apple	28	120	4
Mango	51	120	8
Orange	40	120	5

smaller than that of products from white flour. Pulse rich in dietary fiber need not be considered at the calculation of carbohydrates for diabetics; they hardly have any effect on blood sugar levels (Foster-Powell et al. 2002).

The glycemic index is standardized for carbohydrates and subject to strong fluctuations depending on the way and treatment of carbohydrates and on the composition of the respective food. For better comparison, the parameter of "glycemic load" was introduced. The dimension of the glycemic load is determined by the product of glycemic index and grams carbohydrate per serving of food (Table 1). Thus, a higher proportion of fat in a nutrient (e.g., chocolate) has a rather restraining effect on the rise of glucose levels due to retardation of glucose absorption. Also starch-containing foods (e.g., potatoes) may influence the availability of glucose very differently depending on its treatment.

2.3 The Influence of Dietary Fiber on the Enterohepatic Circulation of Bile Acids - Salts

Bile salts, synthesized from cholesterol only in the liver, are pooled in the gallbladder for their application. Due to the physiology of the gastrointestinal tract, bile salts and acids emulsify no polar compounds (cholesterol, lipids, fat) in order to be absorbed passively in the small intestine and in the jejunum, however actively in the terminal ileum. Bile salts return to the liver via the portal vein to be actively taken up and secreted once again. The rate of synthesis is determined by the availability of cholesterol and, more importantly, by the returning bile salt pool, regulating hepatic

synthesis of bile salts in a negative feedback manner. Only a small portion of bile acids/salts, regularly about 5 %, are lost from the intestine to the exit in the feces with each circuit (Hofmann 2011).

Due to its absorptive properties, dietary fiber manipulates the enterohepatic circulation. Depending on the structural composition of the dietary fiber, different amounts of free bile acids can be fixed and released into the feces. Lignin, arabinoxylan, and pectin show high, ß-glucan (oat bran), guar and alginate still distinct, native celluloses and hemicelluloses only low absorptive properties. Bile acids/salts, being absorbed more intensely in an acid environment than in a neutral one, are thus deprived of recirculation to the liver. To hold the bile acid pool at the same level, now synthesis from cholesterol is necessary anew. By the transformation of cholesterol to bile acids, the total cholesterol level in blood is lowered. At this process the level of undesirable LDL cholesterol is more reduced than the level of the requested HDL cholesterol. By enhanced uptake of dietary fiber from beans, oat bran, guar, and pectin, the cholesterol concentration in the serum could be reduced at about 5–18 % (Kasper 2000) because of absorption and excretion of bile acids and phospholipids.

3 Functional Foods

To ameliorate public health and to enhance personal well-being, great efforts were made worldwide in the last decenniums, developing different projects and programs. Thus, for interaction of healthy food, movement, and fun, the term "wellness" was created, causing an essential revaluation of the idea of health in the population. With the aid of the food industry, regional organizations, and the public health system, new marketing strategies were developed, granting access to a mature citizen responsible for a healthy nutrition, rich in dietary fiber. Thus, the concept of "functional food" had won recognition on the market enriching the fare of the individual more and more.

3.1 Classification of Intrinsic and Extrinsic Functional Food

Starting in Japan food having a certain healthy impact and exceeding its diet-related effect is marked as functional food (FF). The definition of FF is different depending on the producing country. Thus, the Japanese definition is relatively strict claiming natural origin for FF and an own licensing procedure for the name "food for specified health use." In Europe and the USA, the regulations for FF are not totally clear: Besides natural materials, also synthetically produced substances can be used in FF. According to Functional Food Science in Europe (FUFOSE), functional foods are basically foods consisting essentially of bioactive ingredients and their impact should be achieved by normal consumption habits; FF should be part of the daily food and not applied in capsules, in tablets, or in form of powder (Schaafsma 2004; Stehle 2000). There is demand of regulation especially relating to the statements about health, relating to the detectability, and relating to the patent

protection of FF. As one of the continuative expressions for FF, the term "designer food" got attention underlining particularly the effect of foods for tailor-made needs, e.g., nutrition for special groups of persons such as sportsmen, elderly people, or babies. The term "nutraceuticals" meaning bioactive molecules of plant origin is a synonym for FF as well.

Presently the specific value of bioactive molecules and element groups is only partly known. Also the synergistic interaction of these substances both isolated and in connection with nutrients is given only rudimentarily. Basically the knowledge about the biologic activity of single substances delivers additional parameters for a better design and for potential improvement at the processing of preventative food.

Two groups of FF can be distinguished: One group includes enough natural health-promoting components without any addition of bioactive substances marked as "*intrinsic* FF" containing, e.g., bioactive carbohydrates such as dietary fiber and resistant starch or secondary plant components such as phytochemicals and vitamins or health-promoting microorganisms such as probiotics. The second group of FF contains additions of health-promoting substances isolated from natural plant raw materials in order to receive *"extrinsic* FF" in terms of nutritional physiology mostly valuable products with tailor-made demand (Kiefer et al. 2002).

3.2 Human Health and Economic Interests

As already mentioned food should help to avoid or relieve diseases. The connections between diseases of civilization such as adiposities, coronary diseases, and cancer on one side and the daily nutrition on the other side are documented more and more; these diseases might be enhanced by genetic disposition, unlimited consumption of cigarettes, or aging structure. Thus, the target of health policy moves away from the relief of deficiency diseases toward a preventive nutrition strategy optimizing the health condition of the individual and coming along with prolongation of life and improvement of life quality. On behalf of the food industry and trade, this approach is supported vigorously and communicated with different strategies and campaigns to the consumer. The large developing potential of production and trade of FF in the USA, Europe, and Asia verifies the growing economical interest. Supported by research initiative, a considerable increase of sales and profit can still be expected in this market segment.

4 Dietary Fibers: Prebiotic Concept

4.1 Dietary Fiber

4.1.1 Definition and Determination

Dietary fibers are effective bioactive substances in terms of nutritional physiology. Because of its positive impact on the human organism, they gain more and more importance both in the daily nutrition and in the production of intrinsic and extrinsic FF.

The positive effects of dietary fiber in food were already taught by Hippocrates in the school of nutrition in Greece 400 years B.C. These findings were known as well in Asian cultures such as China and India and are the pillars of their traditional medicine till today. Recently the application of practice of Traditional Chinese Medicine (TCM) and of the Indian Ayurvedic attitude toward life gain more and more acceptance in highly industrialized countries and are protagonists for a healthy way of life.

In 1940 the term "dietary fiber" was defined for the first time in literature relevant for food and nutrition, and the responding methods of determination were published. First studies about the composition of dietary fiber concerning the attenuation of risks of lifestyle diseases were published in 1953 (Hipsley 1953). Cleave demonstrated in 1970 the positive impact of plant cell carbohydrates on human health and developed the first scheme of dietary fiber (Cleave 1974). This definition was revised in 1972 and in 1986 (Trowel 1972; Trowel and Burkitt 1986). Trowell established a hypothesis about dietary fiber, indicating that a too small proportion of dietary fiber in food might be a possible reason for diseases of civilization. Further modified definitions were used in 2001 and 2002 by the American Association of Cereal Chemist (AACC) and by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences (FNB). AACC defined dietary fiber as "the edible parts of plants or analogous carbohydrates that are resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine; dietary fiber including polysaccharides, oligosaccharides, lignin and associated plant substances promotes beneficial physiological effects causing laxation, and/or blood cholesterol attenuation, and/or blood glucose attenuation" (Jones 2000). This description includes non-starch polysaccharides, resistant poly- and oligosaccharides, and analogous carbohydrates. In highly developed countries, the definition and the analysis of dietary fiber are often different, leading to mistakes at comparison of proportions of dietary fiber in food. Therefore, indication of the analytical methods is important in tables of and at further information about nutrients.

The detection of the crude fiber is the oldest method for the determination of dietary fiber; the results represent only 20–50 % of the real physiologically effective amount of dietary fiber because of neglect of soluble dietary fiber. Nowadays the recommended official AOAC method 985.29 for a total dietary fiber determination in foods (Prosky et al. 1985) is a gravimetric analysis after enzymatic digestion imitating the human digestion. Low-molecular soluble substances such as oligosaccharides are not caught in this process. Because of upgrading of the definition for dietary fiber – the differentiation into indigestible insoluble and soluble carbohydrates – an adaption of analysis methods was made for determination and distinction of these components including oligosaccharides starting with a degree of polymerization (dp) of 3 (Prosky 1999).

4.1.2 Classification: Soluble and Insoluble Fibers

Dietary fiber can be classified either according to its chemical structure and constituents or according to its solubility or dispersibility in aqueous systems.

Usually dietary fibers are non-starch polysaccharides, resistant oligosaccharides, analogous carbohydrates (e.g., indigestible dextrins, synthesized carbohydrate compounds), lignin and substances associated with the non-starch polysaccharide, and lignin complex in plants (e.g., waxes, phytates, tannins, saponins).

Polysaccharides, such as cellulose, high polymer hemicelluloses, and ß-glucans, and the polyphenylpropan lignin are insoluble fibers. These fibers, however, possess a high water-binding capacity and thus deliver a greater fecal bulk and increase the rate of transit of material through the large intestine called a "decrease in the transit time." Vegetables, wheat, rye, and most grain products contain a relatively high part of insoluble fibers.

Pectins, gums, mucilages, and low polymer hemicelluloses possess a high dispersibility and viscosity and are partially soluble in aqueous systems. Together with water-soluble hemicelluloses and fructans, these carbohydrates can be classified as soluble fibers. Soluble fibers tend to have little effect on the fecal bulk. But as an available fodder for the microflora, they deliver indirectly additional fecal bulk for growing up of bacterial organisms. They decrease the rate of transit of material through the upper gastrointestinal tract and tend to delay the rate of absorption of nutrients, probably because of their ability to form viscous solutions. They may decrease the rate of absorption of glucose by the small intestine as well and may reduce the rate of increase of plasma glucose following the intake of food, and they also may reduce plasma cholesterol levels. Fruits, fructan-containing vegetables, oat, barley, and legumes have a relatively high content of soluble fibers (Kasper 2000; Table 2).

4.1.3 Daily Consumption: Recommended Intake and Their Application

Dietary fiber is collectively acknowledged to be one of the key factors in a health-promoting diet. Today the intake of dietary fibers is not adequate in many developed countries. The intake of fibers per head in Europe amounts to 18–22 g day^{-1} and in the USA even only 13–15 g day^{-1}. This intake does neither meet the recommendations of the World Health Organization (WHO) nor those of the country itself. The WHO recommends more than 25 g day^{-1} (WHO 2003) for dietary fiber intake. Comparatively in rural areas of developing countries, the intake of dietary fiber amounts still to 50–120 g day^{-1}. This proves that generally the supply of dietary fiber decreases with higher material prosperity. At a targeted diet (e.g., vegetarians), however, the intake may rise up to about 40 g day^{-1} (Elmadfa and Leitzmann 2004).

Nutrition high in dietary fiber does not only have a lower energy content but also is able to absorb harmful substances from the food such as saturated fat, a fact that partly may explain the effect of dietary fiber on health. It is unlikely that a diet for adults could have too high fiber content; however it may cause flatulencies being rather inconvenient. Foods containing traditionally no dietary fiber, but being consumed more and more in the current diet of many countries could be enriched by addition of fiber – a new way for the production of healthy food. Consumer's interest in ready-to-eat foods and functional beverages is increasing, and thus, their dietary fiber content could possibly be modified (Elleuch et al. 2011).

Table 2 Dry matter and content of total and soluble dietary fiber in selected vegetable, fruit, and cereals

		Content in fresh matter	
Food item	Dry matter%	Total dietary fiber g.100 g^{-1}	Soluble dietary fiber g.100 g^{-1}
Vegetable			
Bean[a]	9.8	3.0	0.2
Cabbage[a]	9.8	2.3	0.3
Carrot[a]	11.0	3.7	1.2
Potato[a]	20.0	1.8	0.2
Spinach[a]	10.0	2.6	0.4
Tomato	5.9	1.0	0.15
Fruit			
Banana	18.9	1.8	0.7
Mango	20.1	2.0	1.0
Watermelon	5.6	0.6	0.3
Apple	13.4	3.2	0.9
Cereals[b]			
Wheat	88.5	14.9	2.2
Rye	88.0	20.5	4.8
Oat	87.5	11.5	2.9
Barley	88.5	17.6	4.1

[a]Cooked
[b]Grain

4.1.4 Energy Efficiency

The uncertainty about the energy availability of the indigestible part of foods has centered on dietary carbohydrates, in particular non-starch polysaccharides (NSP) and oligosaccharides, resistant starch, and sugar alcohols (Livesey 1992).

From the side of legislative, energy calculations of foods will be extensively unified in different countries or regions of the world. The European Council Directives for current energy values are 10 kJ (2.4 kcal) g^{-1} for all sugar alcohols; for dietary fiber no values have been assigned yet.

Basically the variation in the availability of dietary energy has been related formally to the occurrence, utilization, and effects of those dietary carbohydrates escaping small intestinal digestion. For unavailable carbohydrates found in conventional foods as energy provider, the term unavailable complex carbohydrates (UCC) has been applied. Both NSP and nondigestible resistant starch (RS) contain UCC. There are few published studies about the energy value of NSP alone and few about the starch fraction that escapes digestion in the small intestine. Where studies are undertaken with NSP, carbohydrate is often defined more precisely, for example, as guar gum, crystalline cellulose, inulin, or FOS. Studies about RS deliver results with different energy values depending on quality characteristics.

Generally the combustion heat of UCC equals the energy content of digestible carbohydrates with 17 kJ (4.3 kcal) g^{-1}. Assuming a possible digestibility with a factor of 0.7 for UCC in mixed diets, and a conversion energy for the fecal bacteria of 0.3 kJ per kJ fermented carbohydrate, a value of 8.4 kJ g^{-1} or 2 kcal g^{-1} can be calculated valid for every intake of the UCC. Energy values of UCC related to its apparently small digestibility allow to assign specific energy values to individual carbohydrates and to consider energy losses due to fermentation, thus giving net energy values.

Specific energy values for digestible NSP – e.g., of wheat bran with 4.2 kJ (1.0 kcal) or of apple with 8.2 kJ (2.0 kcal) g^{-1} – prove the different availability of dietary fiber by the microbiota in the large intestine. Similar effects can be shown for water-soluble carbohydrates such as fructan. Inulin, a high polymer fructan, possesses an energy value of approx. 8.4–9.2 $kJ.g^{-1}$. FOS (dp 3–10) with a good accessibility for fermentation deliver values between 12 and 13 kJ g^{-1}. But the effective net energy values of these dietary fibers are about 30–40 % lower than the calculated values in the diet of the human (Roberfroid et al. 1993; FAO/WHO 2003).

4.2 Prebiotic Concept: Influence of Gut Flora and Health Benefits

Generally dietary fiber promotes bioavailability of nutrients, participates in regulation of transit time and intestinal motility of nutrition in the gastrointestinal tract, and supports the formation of a healthy colonic microflora. The specific health-promoting effect of nondigestible food ingredients in particular soluble carbohydrates takes place in the large intestine. Carbohydrates being not digested in the small intestine reach the colon, where they can be partly or totally fermented by the microflora. The efficiency of fermentation is influenced by the monomer composition, the type of glycosidic linkages, the dp, and the structural arrangement of the molecule. Thus carbohydrates of different sources with different structure and properties stimulate the growth and colonization of various bacteria with properties healthy for the human well-being.

Based on this knowledge, the prebiotic term and definition was published (Roberfroid 1993; Gibson and Roberfroid 1995): A prebiotic is "a non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, thereby improving host's health." This prebiotic concept supports the assumption of the efficacy of selected carbohydrates as growth substrate for beneficial bacteria already resident in the colon.

Thus, fructan, for instance, such as both inulin and FOS in the diet or as supplement in foods stimulates the growth of bifidobacteria selectively, maintaining populations of potential pathogens at relatively low level. These findings were successively confirmed in diet-controlled human studies (Roberfroid 1998). Further studies about NSO and RS oligomers as substrate for the microflora confirm this positive effect of the soluble carbohydrates for different beneficial bacteria such as lactobacilli in the colon.

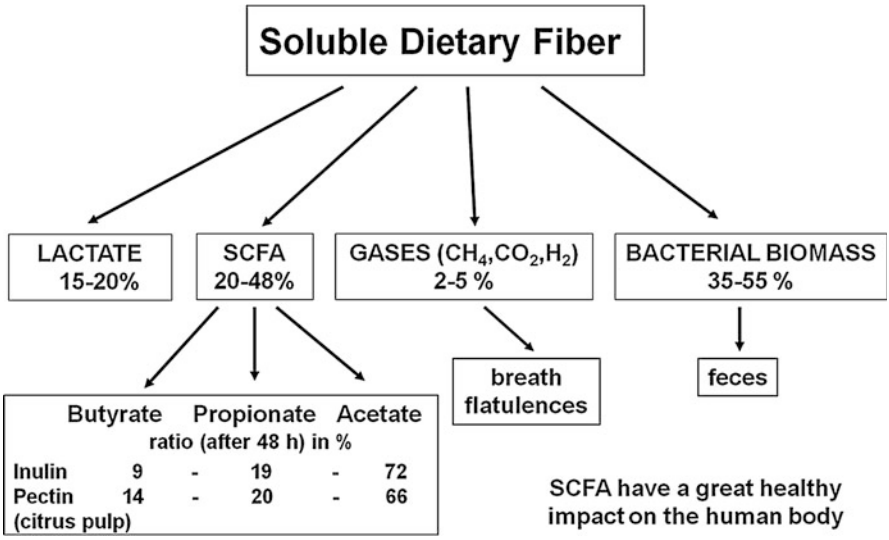

Fig. 1 Fermentation of soluble dietary fiber in the colon by the gut microflora

The major products of prebiotic metabolism are short-chain fatty acids (SCFA), the gases hydrogen, carbon dioxide and methane (in ca. 50 % of persons) and bacterial cell mass. The proportions of SCFA between acetate, propionate, butyrate and lactate are related to the carbohydrate sources in the colon (Fig. 1). In vivo animal studies showed that supplementing a diet with nondigestible oligosaccharides (NDO) decreases the fecal pH and increases the size of the fecal pool of SCFA, with acetate the primary acid followed by butyrate and propionate (Roberfroid and Slavin 2000). When incubated in vitro with a human fecal flora, inulin and FOS produce SCFA. In both cases the butyrate concentration compared to acetate, propionate and lactate was positively stimulated.

Acetate is the energy source; it is transported to the muscle tissues in the body and is a potential precursor for cholesterol synthesis. Contrariwise propionate transported into the liver inhibits the cholesterol synthetase, thus reducing the cholesterol, triglyceride, and LDL level in the blood. Butyrate plays an essential role in the maintenance of colonic mucosa integrity, by acting on metabolism, proliferation, and differentiation of epithelial cell types. It prevents distal ulcerative colitis and reduces the risk of intestinal diseases such as inflammation or certain forms of colon cancer.

Additionally SCFA liberated during the fermentation of prebiotics increase the mineral absorption of calcium in the intestine. Low pH promotes solubility of minerals, and fatty acid absorption is directly accompanied by mineral absorption. The growth of the epithelial cells in the colon stimulated by butyrate might increase their capacity of absorbing minerals. The higher absorption of calcium reduces the risk of osteoporosis and promotes better bone structure and density (Cieślik et al. 2009).

Some studies report about the positive stimulation of the associated immune system of colon by prebiotics. Especially the production of a number of proinflammatory cytokines (e.g., tumor necrosis factor alpha) and the expression of a number of receptors on T and B lymphocytes and macrophages were reported (Sotnikova et al. 2002).

4.3 Probiotics and Their Combination with Prebiotics: Synergistic Effects

The term probiotics for living bacteria was created in the 1960s of the last century for the first time in the case of animal feed supplements in order to reduce antibiotics in the animal husbandry. Living bacteria in pharmaceutical products have been on the market for a long time for different medical applications without being named probiotics.

Probiotic microorganisms affecting the intestinal flora do not act exclusively in the large intestine. They also affect other organs of the human modulating immunological parameters, intestinal permeability, and bacterial location or provide bioactive or regulatory metabolites. Under this aspect the definition of probiotics is "a preparation of or a product containing viable, defined microorganisms in sufficient number, which alter the micro flora (by implantation or colonization) in a compartment of the host and by that exert beneficial health effects in the host" (Schrezenmeir and De Vrese 2001).

The older definition of probiotics refers to cultures of defined viable microorganisms which when applied to man or animal reaching the large intestine in an active state may beneficially improve the properties of indigenous flora.

Both pro- and prebiotics are based on the concept of multiplying those bacteria in the large intestine, which are health promoting or at least not pathogenic or toxic. The combination of pro- and prebiotics is called symbiotic meaning that a synergistic interaction is happening between a specific probiotic and a particular prebiotic (Topping et al. 2003).

For application in the daily diet, probiotic (and prebiotic) foods contain living probiotic microorganisms in an adequate matrix and in sufficient concentration. Today, most of probiotic foods are fermented milk products. Yogurt products with probiotic cultures have a market share of over 15 % with increasing tendency. There are shortcomings with using probiotics for gut health: Only a small proportion of ingested organisms reach the colon unbrokenly; probiotic organisms are washed out of the gastrointestinal tract if probiotic consumption decreases. Prebiotics may safeguard against these losses by providing physical protection and by slowing the rate at which bacteria are lost after cessation of probiotic consumption. In such symbiotic foods, the concentration of prebiotics is often below 10 %. However, the term "symbiotic" should only be used in case of a true synergistic mutual reinforcement (Roberfroid 1998).

5 Occurrence, Chemical Composition, Classification, Properties, and Prebiotic Efficacy of Essential Dietary Fibers

5.1 Bioavailability of Starch: Resistant Starch

Starch is the reserve polysaccharide of a lot of plants being applied as starchy foods. In the vegetal reproduction of annual and biennial plants, starch is transferred into granules being stored in roots, tubers, and bulb organelles such as in potatoes or cassava roots (manioc). During the generative propagation of plants, a continuous storage of starch takes place while simultaneously granules are developed in the amyloplasts of endosperm cells in the seeds. At the same time, the cell body is dehydrated and the water content of seeds reduced. Finally, starch granules in the endosperm of cereals such as wheat, rye, rice, and corn contain about 10–13 % of water. Generally starch granules are insoluble and tightly packed. Size and shape of these granules vary among plant species and even among cultivars of the same species.

Chemically, starch is a glucan being composed of α-(1,4)-linked and/or α-(1,6)-linked D-glucopyranosyl residues. There exist two main structural types of starch: highly branched amylopectin being represented 70–80 % in the granules and the low/non-branched amylose with helical structure. X-ray diffraction pattern confirms crystalline structure of starches being identified as A and B types. Starch granules of cereals with water content between 10 % and 13 % deliver the A-type spectrum. Granules of potatoes and amylose-rich starches with water content between 15 % and 16 % deliver the B-type spectrum. C-type starches, being a mixture of A and B types, are found in legumes. At cooking or hot-water treatment, starch granules swell and disintegrate, resulting in viscous starch solutions being ready for digestion: Thus, starch can be successfully hydrolyzed by enzymes in the small intestine to yield free glucose being then absorbed.

In 1992 while the development of an in vitro assay of non-starch polysaccharides it was found that some part of starch could not be removed by human amylases – it was resistant against these enzymatic attacks. Following in vivo studies with ileostomy subjects, the presence of starch components being resistant against digestion in the stomach and small intestine could be confirmed. These starch components, however, could be fermented in the colon. The term resistant starch (RS) was formed and used to describe starches with such properties (Englyst et al. 1992).

The term RS is not defined by any government agency. The definition was done in a concerted action by the European Union (EU) in the EURESTA (1994) program. RS is defined as the total amount of starch (and the parts of degraded starch) resisting digestion in the small intestine of healthy people (Asp 1992). In the large intestine, RS can act as a substrate for microbial fermentation, the end products being hydrogen, carbon dioxide, methane, and SCFA. This definition described RS only concerning its physiological functionality.

As to the aspect of resistance against enzymatic attack in the small intestine, the knowledge of physical and chemical characteristics of RS as healthy properties is essential (Nugent 2005). Starches being amorphous or crystalline with B- and C-type patterns, high-amylose level, and high disposition for retrogradation appear to be more resistant to digestion. Retrograded starches are referred to certain structural forms of RS. Retrogradation occurs when starch with preferably high content of amylose is cooked in water beyond its gelatinization temperature followed by cooling. Amylose retrogrades and adopts amorphous structure, whereas amylopectin rather shows crystalline structure – both delivering a more complex insoluble structure – retrograded starch with high stability against enzymatic attack.

Resistant starch has been classified into four general subtype groups called RS1–RS4:

The term RS1 is given to RS with physical inaccessibility to digestion, e.g., due to the presence of intact cell walls in grains, seeds, or tubers. In this case the factor of milling and chewing influences the amount of RS content. Whole or partly milled grains, legumes, and pasta products deliver mainly RS of subtype RS1.

RS2 describes ungelatinized native starch granules with crystallinity of B type as potato starch being only slowly hydrolyzed by α-amylases. Digestion is prohibited by conformation or structure of the starch granules as in partly raw potatoes, green bananas, and some legumes. One particular RS2 type is unique – it retains its structure and resistance even during processing and preparation of many foods – these RS2 starches are called high-amylose starches being found in corn, pea, or cassava.

RS3 refers to nongranular starch-derived materials resisting digestion. These RS3 types are generally formed during the retrogradation of starches. Examples for this type are cooked and cooled potatoes, processed cornflakes, different kinds of bread especially after longer storage, and food products produced under specific process conditions at prolonged and/or repeated moist heat treatment.

RS4 describes a group of starches having been chemically modified, e.g., etherized, esterified, or cross-linked with chemicals in such a manner as to decrease their digestibility. At present it is not known if and how the various modifications of RS4 are affected by digestion in vivo.

Thirty to seventy percent of RS under consideration with these different profiles can only be absorbed in the large intestine and deliver high prebiotic efficacy similar to non-starch polysaccharides.

5.2 Pectin

Pectin is found in the primary cell wall of plants such as fruits and vegetables, particularly citrus and apple fruits and in unripe plants. The structure of pectin shows variation with botanical origin, cell wall type and cell wall development. Extracted pectin can be used in the cuisine or in the food industry as gelling, thickening, and film-forming agent. The sources of commercial pectin are apple

pulp or citrus peels. In daily food apples, pears, kiwis, plums, grapefruits, lemons, and oranges are some common sources of pectin.

From the point of chemical composition, pectin is a polysaccharide consisting basically of D-galacturonic residues (main chain) with different kinds of sugar such as L-rhamnose, L-arabinose, D-galactose, and marginally D-xylose in the side chains of the molecules. It is partly esterified with methanol and possesses non-branched and highly branched regions. Pectin forms network structures such as gels, where the chains are interconnected to form a three-dimensional network. This network can be solved at higher temperature; the gel however reforms after cooling (MacDougall and Ring 2004).

The free carboxyl groups of the galacturonic residues enable absorption of calcium and magnesium ions influencing the mineral balance in the intestinal tract. However, the application of pectin amid produced from citrus pectin, being nontoxic and approved as food additive, may avoid this problem.

Pectin is a soluble fiber and effective as prebiotic carbohydrate. Recent studies have shown that pectin promotes beneficial bacteria, lowers blood cholesterol levels, and speeds up recovery from infection due to its ability to promote anti-inflammatory healing cells (Brouns et al. 2012).

5.3 Cellulose, Lignin, and Hemicelluloses

Structure-giving substances of plants are cellulose, lignin, and hemicelluloses located in the cell wall. Normally cellulose microfibrils are linked via hemicellulose links to build up the cellulose-hemicellulose network, being enclosed in the pectin matrix. During ripening or because of stress in plant organs, a lignification process to woody material can take place. In vegetables the content of cellulose and lignin accounts for around 30 % and 3 %, in fruits 20 % and 17 %, and in cereals 17 % and 7 %, respectively, relating to the total polysaccharide fiber content in plant organs.

Cellulose, the most abundant organic molecule in the nature, is a non-branched polymer of several thousand glucose units connected by β(1,4) linkages. Cellulose, an insoluble fiber, occurs in plants in tightly packed aggregates and tends to resist microbial hydrolysis.

Lignin, a three-dimensional network built of units of phenylpropane, is the component of the tough or wood-like portions of plants and seeds. Bran and other cereal products are the main sources of dietary lignin. This fiber is insoluble and differs from others by the fact that it is degraded neither by human enzymes nor by the gut microflora.

Hemicelluloses are heterogeneous polymers occurring in various chemical structures. Different plant sources deliver heteropolysaccharides such as arabinoxylan, glucomannan, glucuronoxylan, or xyloglucan. Most of these polysaccharides contain pentose sugars such as D-xylose and L-arabinose linked with hexose sugars such as D-mannose, D-galactose, D-glucose, and D-rhamnose, and sometimes include acid sugars such as glucuronic or galacturonic acid (Elleuch et al. 2011). At the investigation of plant material, water-insoluble and

water-soluble fractions have been found. Soluble fractions in particular xylan and arabinoxylan deliver high prebiotic efficiency.

5.4 ß-Glucan

High amount of β-glucan is found in cereal grains, in particular in the bran of wheat, rye, oat, and barley. Furthermore, fungi from different provenience possess a high content of β-glucan. The β-glucan content of oat and barley varies between 3 % and 11 % making these grains useful natural sources of β-glucan in nutrition. Isolated β-glucan can also be added to cereal based or other foods, thus expanding the selection of possible sources of fiber in the diet. Commercial food products containing β-glucan are, e.g., pasta, oat flakes, cereals, and bakery products.

β-Glucan is a non-branched polysaccharide consisting only of β-D-glucopyranosyl units. These units are linked by either (1,3)- or (1,4)-β-D-linkages; hence, its exact name is mixed-linked (1,3),-(1,4)-β-D-glucan. Building blocks of 1,3-linked cellotriosyl and cellotetraosyl units constitute over 90 % of the molecule. The (1,3)-linkage prevents close packing of the molecule and makes it partly soluble in water unlike cellulose; 20 % of oat and 40 % of barley β-glucan are insoluble (Åman and Graham 1987).

Soluble β-glucans deliver viscous and shear-thickening solutions even at quite low concentrations. Therefore, they are suitable alternatives for thickening agents in foods, e.g., beverages, sauces, salad dressings, and ice creams. Barley β-glucan, for instance, was found to produce a higher viscosity than pectin at a concentration of about 0.5 %.

In principle the efficacy of β-glucan in the human intestinal tract is dependent on its dose, viscosity, molecular weight, and solubility. The potential physiological mechanisms causing the efficacy of β-glucan are suggested to be its ability to retard the absorption rate of food in the intestine due to increased viscosity, in this way balancing the postprandial glucose and insulin response (Wood 2001). Additionally, high viscosity in the small intestine interferes with cholesterol absorption or reabsorption, in this way affecting the cholesterol balance and synthesis in the body (Sayar et al. 2005; Drzikova et al. 2005). β-Glucan has been shown to reduce elevated blood cholesterol levels and balance blood glucose and insulin response after meals; thus, it possesses a high prebiotic efficacy.

5.5 Fructan

About 15 % of plants, monocotyledons as well as dicotyledons, contain fructan as reserve polysaccharide instead of (sometimes besides) starch. In contrast to starch fructan possesses excellent water solubility and is stored in cells of plant-specific organs as roots, tubers, bulbs, blades, stems, or in the bottom of flower buds. In all cases the biosynthesis and storage of fructan takes place only in particular compartments of cells – in the vacuoles.

Table 3 Dry matter and content of total fructan and fructooligosaccharides (FOS) from plant organs

		Content in fresh matter		
Plant organ	Dry matter %	Total fructan g.100 g^{-1}	FOS dp 3–10 g.100 g^{-1}	Linkages type
Composites				
Chicory, root harvest autumn	25	16.2	6.5	Inulin β-2,1
Jerusalem artichoke, tubers harvest fall	24	15.1	7.5	
Harvest spring	18	9.7	7.2	
Globe artichoke	18.2	9.0	1.3	
Liliaceae				
Onion, bulb	13.5	5.3	4.6	β-2,1 and β-2,6 linked
Leek	12.0	6.6	3.0	
Chives	11.5	6.5	n.d.	
Garlic, bulb	32.5	19.1	0.2	
Asparagus	6.5	1.8	1.0	
Agave, stem	31.5	14.3	9.9	
Banana	25.7	1.4	n.d.	
Poaceae (cereals)				
Wheat, grain	88.5	2.2	n.d.	Levan β-2,6
Rye, grain	88.0	4.8	n.d.	
Oat, grain	87.5	0.4	n.d.	
Barley, grain	88.5	2.7	n.d.	

A lot of fructan plants have been applied in the daily diet of humans preferring more plant food with high level of dietary fiber and prebiotic efficiency. Table 3 shows the fructan content of plants being applied in the cuisine and/or consumed as vegetable or fruit, raw or cooked (Praznik et al. 2004).

Fructan-containing vegetables from roots such as salsify, murnong (yam daisy) and chicory; from tubers such as yacón and Jerusalem artichoke; from bulbs such as onion, garlic and leek; from shoots of asparagus or chicory; or from the stem of agave are delivered by the organs of annual, biennial, or perennial plants cultivated by vegetal propagation. The flower buds of globe artichoke, banana, and the grains of cereals, also applied as vegetable and fruits, are components of the generative propagation of plant. Further fructan sources are flour and products of cereals containing between 1 % and 7 % fructan depending on the degree of milling and food processing.

As to the chemical composition of fructan, three types were found in plants: the inulin-type with β(2,1)-linked fructofuranosyl residues starting from the trisaccharide 1-kestose, the levan type with β(2,6) linked fructan starting from 6-kestose, and the mixed-type fructan containing both β(2,1)-linked and β(2,6)-linked fructofuranosyl residues. Fructans are nonreducing carbohydrates due to their

origin from the sucrose pool of plants. The high variability in elongation, polymerization, and degradation of fructan molecules during their vegetation period delivers polymers with different dp depending on harvest time. Under this aspect the amount of fructooligosaccharides (FOS) in plants – per chemical definition fructans from dp 3 up to 10 – can differ more or less. Mixed-type fructan from garlic or agave with a significant branching structure delivers molecules with random coil characteristic and therefore offers an extremely better solubility in water compared to inulin with mainly helical structure (French and Waterhouse 1993; Praznik et al. 2007).

From the aspect of the physiological functionality in the human body, all three fructan structures deliver the same effect in the intestinal tract: The β-configuration in the linkages of fructan cannot be attacked by the digestion enzymes of the small intestine, which are more specific for α-glucosidic linkages of the starch polymers. In vivo studies with volunteers have demonstrated that fructans such as inulin and FOS are practically indigestible in the small intestine of the human (Andersson et al. 1999). Thus, fructans pass through the small intestine without degradation and without influencing the absorption of nutrients or minerals, only increasing the bulk, directly to the colon where they will be fermented by the microflora to healthy components such as SCFA, thus helping to establish the proper balance of a beneficial intestinal flora. No parts of fructan were ever recovered in the feces. Because of these healthy properties of fructan, its prebiotic effect is excellent and it may easily support the well-being of the human.

At the intake of fructan-containing food in both intrinsic and extrinsic way, the bowel peristalsis is mobilized because of the high water-binding capacity of fructan; the mineral absorption particularly of calcium is enhanced and the energy input is low.

5.5.1 Fructan Plants for Daily Use and Industrial Application

Composites

Chicory (*Cichorium intybus* L.*)* roots contain 18–20 % soluble carbohydrates with a content of inulin-type fructan between 14 % and 18 % (Praznik et al. 2004, Table 3). In several regions, in particular in Belgium, France, and the Netherlands besides the roots even the sprouts of chicory (chicoree) are used as salad and vegetable of light bitter taste due to the taste-dominating bitter compound intybine (lactucopicrin) being contained in the roots as well as in the sprouts of chicory.

The first use of chicory roots was the production of a "healthy" and compliant coffee surrogate: Sliced chicory roots containing fructan in combination with the bitter compounds were roasted together with additional ingredients such as malt from barley and figs.

After the finding that inulin was nondigestible in the human intestinal tract, it became a perfect tool to test renal clearance.

For the last two decades, the interest for inulin as source of soluble dietary fibers has been ongoing. Consumer request for healthy food and consequently "tailored" FOS and inulin matches perfectly the demand of application profiles of prebiotic

foods in various market segments. Of course the predominance of large-scale inulin production from chicory is supported by the relatively simple possibility of cultivating this crop, easy harvesting of the roots, and the utilization of the already existing sugar beet processing technology. The most crucial point in isolation and purification of inulin is the quantitative elimination of salts and bitter compounds.

Jerusalem artichoke (*Helianthus tuberosus* L.) tubers are another source of inulin-type fructan and FOS. In some US areas (California, Washington, Minnesota), Canada, and Europe (Belgium, France, Germany, Ukraine), Jerusalem artichoke tubers are popular vegetables known as sunchoke or topinambur. Recently the interest for Jerusalem artichoke as a vegetable and for industrial application is increasing also in Asia particularly China. Different varieties and different time of harvesting – both autumn and spring in one vegetation period deliver different carbohydrate profiles in the tubers with more or less FOS concentrations. Tubers are consumed crude as well as boiled, baked, or fried. In particular goods made from autumn tubers are a perfect basic food for diabetics because of very low sucrose content.

The tubers of Jerusalem artichoke contain no bitter compounds and can be processed without pretreatment. Moreover, the FOS of Jerusalem artichoke tubers are nonreducing; due to this fact, they form no Maillard products and do not become brownish in low-temperature processing.

However, enzymatically catalyzed oxidation may be observed in juice production if phenoloxidases are not deactivated. Powders of dried and milled slices of Jerusalem artichoke tubers can be utilized at the manufacture of bread and bakery products (Praznik et al. 2002). Utilizable total carbohydrates typically range between 18 % and 20 % containing approx. 90 % fructan with dp >3.

The vegetable **globe artichoke** (*Cynara scolymus* L.) contains about 10–12 % inulin-type fructan in the bottom of the flower bud. The origin of this plant traces back to Ethiopia and it entered South European countries via Egypt. Currently globe artichoke is cultivated in France, Italy, Romania, Bulgaria, and California/USA. The crop grows to a height between 60 and 200 cm and forms pronounced sprouts (flower buds) being utilized as vegetables. For use in many different ways, the sprouts typically are boiled. For therapeutic purposes, extracts of globe artichoke roots and leaves are known for more than 400 years. The effect of such extracts is caused by phenol carbon acids (cynarin, caffeic acid, chlorogenic acid), leteolines (luteolin, cynarosid, scolymosid), and the bitter compound sesquiterpene lactone (cynaropicrin). The composition of inulin and FOS strongly depends on the status of the shoots. Globe artichoke before flowering contains inulin in its flower bottoms with a dp between 60 and 120 being nearly five- to tenfold compared to inulin of other composites.

Liliaceae

Allium L. species, such as **onion**, **leek**, **garlic,** and **chives**, are worldwide applied in the cuisine of any cultures as vegetables, spices, and tasty components. Much of the well-known health preserving and even therapeutic effects of onion and garlic most probably are due to their sulfur-containing compounds. However, even the aqueous

soluble low and high molecular mixed-type fructans, being present in onion and garlic in high percentages, are jointly responsible for the positive image of stimulating the intestinal tract and supporting consumer's well-being. Onion, leek, and chives contain only 3–7 % FOS and fructan, however, predominantly FOS with dp between 3 and 10. Garlic differs significantly with about 19–24 % of fructan with a mean dp of 26.

Sprouts of **asparagus** (*Asparagus officinalis* L.) are a worldwide popular vegetable containing 2–4 % fructan, similar to onion, with mixed-type structure, typical for Liliaceae.

Agave (*Agave tequila* Weber L. var. Azul) from the family of *Agavaceae* has been applied traditionally for the tequila production in Mexico. The content of fructan is 20–23 % being a mixed-type fructan with low content of FOS. Due to the negligible content of monosaccharides (glucose, fructose <0.2 %) and sucrose (0.5–1.5 %), this agave is a perfect raw material to obtain highly pure fructan with branching structure and high solubility in water.

From the Amaryllidaceae family, the most important species are **bananas**, in particular plantain (*Musa sapientum* L.) and banana fruit (*Musa paradisiaca* L.) used as vegetable and as fruit. Besides starch, glucose, fructose, and sucrose, banana fruits contain more than 5 % fructan, corresponding to approx. 1.4 % in fresh weight and approx. 26 % in dry matter, respectively.

Poaceae

Cereals (grasses) such as **wheat**, **rye**, **oat, barley,** and **rice** play an important role in the human nutrition. In the growth period of roots, leaves, and stems, grasses utilize fructan as storage metabolites which finally will be found as co-storage polysaccharides besides starch in the grains (caryopses). In early development states, the caryopses contain a dry matter fructan content of 2–4 %; in adult grains this content is reduced to approx. 1.3–2.5 % (e.g., wheat grains). The content in flour is reduced to 1.0–1.3 % and in the bran at approx. 3 %. Adult rye grains contain 4–6 % fructan with 2.5–4 % in the flour and 7 % in the bran after milling. Barley grains contain 0.5–1.5 % and oat grains approx. 0.5 % fructan.

6 Polysaccharides and Derived Oligosaccharides from Natural Sources for Prebiotic Application

6.1 Fructans from Chicory, Jerusalem Artichoke, and Agave

6.1.1 Inulin from chicory and Jerusalem artichoke; FOS produced by endoinulinase action

For the worldwide production of inulin and FOS, predominantly chicory and partly Jerusalem artichoke are applied. Chicory roots or tubers of Jerusalem artichoke are washed, sliced, milled, and subjected to hot-water extraction. The extracts are decolorized, demineralized, filtered, and concentrated. The concentrated extracts (40 %) are converted to inulin powder by means of spray drying (Orafti 1999).

Native inulin products from chicory mainly include molecules with a dp between 3 and 60. Companies in Belgium and the Netherlands produce inulin in different grade of purity and dps with the trade names Raftiline®, Frutafit®, and Fibruline®.

For the large-scale production of mixtures of FOS from native inulin, *endo*inulinase-catalyzed hydrolysis is applied. This enzymatic inulin hydrolysis yields two types of FOS – FOS with α-(1,2)-linked glucose at one end of the molecules, designated $G_{py}F_n$ (glucopyranosyl-(fructofuranosyl)$_n$), and FOS with a reducing fructopyranosyl residue, designated inulooligosaccharides (IOS) or oligofructose (OF), and having the general formula $F_{py}F_n$ (fructopyranosyl-(fructofuranosyl)$_n$ (Roberfroid 2005). In this manner, IOS of dp ranging from 2 to 7 are produced. A commercial inulinase preparation is the purified endoinulinase from *Aspergillus ficuum*, Novozyme 230, offered by NOVO AS of Denmark. Commercial products of FOS with high amount of IOS are, e.g., Raftilose®, Frutalose®, and Fibrulose®.

Roberfroid demonstrated the important health-promoting effects of inulin and FOS being a selective substrate for the fermentation of bifidobacteria, which are considered, together with lactobacilli, the principal health-promoting bacteria of the human colon (Roberfroid 2003). It was shown that with 15 g of FOS or inulin per day for 15 days bifidobacteria became the preponderant genus in the human feces (Gibson et al. 1995). Inulin and FOS enhance the mineral absorption, especially calcium and magnesium (Coudray et al. 1997), reduce triglyceridemia and cholesterol level (Beylot 2005), and improve stool consistency and microbial balance. This suggests the option of beneficial application of inulin-type fructans in conditions related to hypercaloric nutrition and the metabolic syndrome.

6.1.2 Fructan from Agave

For the production of fructan from agave (*A. tequilana* Weber), pines (5–8 years old) are harvested before flowering and the tough peel is removed by peeling and scraping. The pines are sliced and the slices subjected to water extraction in a counter flow extractor at ca. 75 °C. The crude water extract is decolorized over charcoal/diatomaceous earth, filtered with the aid of filter panels, and further purified by ion-exchange chromatography. The resulting solution is evaporated under vacuum to form a syrup (containing 70 % dry matter). Spray drying of the syrup affords a white, amorphous powder of agave fructan (Loeppert et al. 2009). Agave fructan and Agave FOS from a Mexican company can be obtained with the trade names Metlin® and Metlos®.

The structure of native agave fructan belonging to the mixed-type fructan combines three well-known structural features of fructans, namely, (2,1)- and (2,6)-linkages of fructofuranosyl residues and a chain-internal α-linked glucose residue substituted with a fructofuranosyl residue at C-6. Derivatives containing the chain-internal glucose residue are referred to as neoinuloglycans (Praznik et al. 2013).

Application of fructan and fructan-derived oligosaccharides isolated from agave delivers similar successful health-promoting effects in the human as inulin products from chicory or Jerusalem artichoke (Allsopp et al. 2013).

6.2 Heteropolysaccharides from Plants (Seeds, Exudates, Tubers) and from Seaweeds

The application of exopolysaccharides isolated from seeds, exudates, and tubers of plants and from seaweed constituents as healthy components in food and therapeutic drugs has high reputation and acceptance in the indigenous population of Asia, America, Australia, and partly Europe. "Traditional medicines" deliver hints for application particularly for bowel diseases and the well-being of humans. For a long time the main interest for these polysaccharides was only in the field of hydrocolloid texture modifiers and viscosity enhancers in the food production. Nowadays the interest is changing more and more toward functional food and pharmaceutical products containing partly soluble dietary fiber with prebiotic effect. And additionally the high water-binding capacity, viscosity, and swelling characteristic support the peristalsis of the bowel and the fecal bulk production.

The properties of these polysaccharides depend on monosaccharide composition, organization of moieties, kind of linkages, and molecular weight distribution.

One group of important gums are galactomannans derived from legume seeds. These heteropolysaccharides consist of β(1,4)-linked D-mannopyranosyl residues in the main chain with varying degrees of substitution with α(1,6)-linked D-galactopyranosyl residues in the side chain. Ratios of galactose/mannose determine the physical properties of the galactomannans and are listed, together with an overview of diverse structural studies, in a comprehensive review by Srivastava and Kapoor (2005). Guar gum (also called guaran) comes from the seeds of *Cyamopsis tetragonoloba*, locust bean gum from seeds of *Ceratonia siliqua* (carob tree), and cassia gum from seeds of *Caesalpinia spinosa* (Ramsden 2004).

Galactomannans are used extensively in the food industry for water retention, gelling, binding, suspending, emulsifying, and thickening applications. However, the polysaccharides pass the human digestive tract essentially unchanged, with very little fermentation in the colon (EFSA 2005), and may therefore be considered dietary fiber but not prebiotic. Galactomannans have been reported to have interesting biological effects. For example, galactomannan from *Caesalpinia spinosa* (Tara gum) induces phenotypic and functional maturation of human dendritic cells (Santander et al. 2011).

Structural features of Plantago-mucilage, a representative mucous polysaccharide from the seeds of *Plantago asiatica* L. (psyllium), were reported by Tomoda et al. (1984). The main polysaccharide chain is a highly branched polymer of β-1,4-linked D-xylopyranose units. Present as branches in position 3 of xylopyranose units are β-D-xylopyranose residues and two acidic disaccharide branches, *O*-α-(D-glucopyranosyluronic acid)-(1,3)-α-L-arabinofuranose and *O*-α-(D-galactopyranosyluronic acid)-(1,3)-α-L-arabinofuranose.

Anderson et al. (1988) reported on the cholesterol-lowering effects of psyllium mucous polysaccharide in hypercholesterolemic men. Serum total cholesterol levels were reduced by 14.8 %, LDL cholesterol by 20.2 %, and the ratio of LDL cholesterol to HDL cholesterol by 14.8 %. The results were taken to indicate that psyllium is an effective and well-tolerated therapy for mild to moderate hypercholesterolemia.

Flaxseed or linseed mucilage is a mixture of rhamnogalacturonan I and arabinoxylan with unusual branches (Naran et al. 2008). The backbone of rhamnogalacturonan I is a polymer of the disaccharide repeating unit (1,4)-α-D-galacturonic acid-(1,2)-α-L-rhamnose (Lau et al. 1985) with the rare L-galactopyranosyl units linked to *O*-3 of many of the L-rhamnosyl residues. The arabinoxylan has a backbone of β-(1,4)-linked xylopyranose units, with the unusual feature of nonreducing arabinofuranosyl residues attached simultaneously to *O*-2 and *O*-3 of xylopyranose to form doubly branched units. Flaxseeds are traditionally used whole for a variety of health benefits, with the mucilage considered beneficial for gut health.

Chia seeds from *Salvia* species have been traditionally used as food by Native Americans and rural Mexicans. Besides oil and protein, they contain a polysaccharide that is exuded in water and forms a mucilaginous gel. Lin et al. (1994) have reported on a structure study of this polysaccharide, concluding that is likely a glucoxylan with the repeat unit -4)-β-D-xylopyranose-(1,4)-α-D-glucopyranose-(1,4)-β-D-xylopyranose-(1, with an α-4-*O*-methyl-D-glucuronic acid residue linked to *O*-2 of one of the xylose residues. The composition of D-xylopyranosyl-, D-glucopyranosyl-, and 4-*O*-methyl-glucopyranosyluronic acid residues is in the ratio of 2:1:1 (Lin et al. 1994; Popa and Spiridon 1998).

The seeds of *Sinapis alba* (yellow mustard) release mucilage when they are swelling in water. This mucilage contains two water-soluble polysaccharides: an acidic heteropolymer containing galacturonic acid and rhamnose and a neutral fraction with a ß-glucan characteristic (Ramsden 2004).

Glucomannans originated from tubers of orchid species applied in India in the Ayurveda treatment are gums with non-branched chains of D-mannopyranosyl and D-glucopyranosyl residues linked β(1,4) with some side groups of D-glucopyranosyl and D-mannopyranosyl residues linked β(1,3) (Ramsden 2004).

Soybean oligosaccharides extracted from defatted soybean whey and treated by de-salting, decolorization, and drying (Hayakawa et al. 1990) deliver products with high content of stachyose (α-D-galactopyranosyl-(1,6)-α-D-galactopyranosyl-(1,6)-α-D-glucopyranosyl-(1,2)-β-fructofuranose) and raffinose (α-D-galactopyranosyl-(1,6)-α-D-glucopyranosyl-(1,2)-β-fructofuranose).

The refined oligosaccharides were subjected to in vitro growth studies and were shown to be fermented by most species of bifidobacteria more effectively than FOS. Saito et al. (1992) demonstrated that the administration of the refined oligosaccharide extract decreases the activity of azoreductase, β-glucuronidase and β-glucosidase, enzymes of potential toxicological importance.

The seaweeds or marine algae are excellent sources for polysaccharides being applied as thickeners, stabilizers, and as functional food products as well.

Agar is produced mainly in Asia by hot-water extraction of red seaweeds (Rhodophyta) such as *Gelidium amansii*, *Porphyra yezoensis*, and *Gracilaria verrucosa* (Higashimura et al. 2014). Agarose is the main component of polysaccharides in agar, containing linear chains of alternating 3-*O*-linked β-D-galactopyranose and 4-*O*-linked α-L-3,6-*O*-anhydro-galactopyranose residues (Araki and Arai 1967). Of the two types of glycosidic linkage in the polysaccharide,

the α-L-anhydrogalactose linkage is hydrolyzed more easily, so that agarooligosaccharides (AGO) can be produced by mild-acid treatment (Enoki et al. 2010).

AGO were shown to have antioxidant, hepatoprotective, and antitumor activities (Chen and Yan 2005; Chen et al. 2006; Enoki et al. 2012). An interesting application was reported by Higashimura et al. (2014) who reported on the prevention of anti-inflammatory drug that induced small intestinal injury in mice. According to their interpretation, cytoprotection against NSAIDs (nonsteroidal anti-inflammatory drugs) is achieved via phosphorylation of the JNK pathway, upregulation of heme-oxidase 1, and acceleration of the phenotypic shift to M2 macrophages.

Alginate present in brown seaweeds (*Phaeophyta*) is an acidic polysaccharide, non-branched with regions of preferably alternating (1,4)-linked β-D-mannuronic and α-L-guluronic acid and regions with blocks of only D-mannuronic or L-guluronic acid residues (Ramsden 2004).

Carrageenans are a family of sulfated polymers with non-branched chains of D-galactosyl residues linked alternately α(1,3) and β(1,4). The sulfate groups are present at 2-, 4-, or 6-positions of the hexose units. Also furcellarans are sulfated non-branched polysaccharides with D-galactosyl and D-3,6-anhydrogalactosyl residues linked in α(1,3) and β(1,4) positions and partly sulfated in position 4. Both heteropolysaccharides are isolated from different varieties of red seaweed (*Rhodophyta*) (Ramsden 2004).

6.3 Xylooligosaccharides from Wood and Other Lignocellulosic Materials

Xylooligosaccharides (XOS) are β-1,4-linked oligomers of xylopyranosyl units and have found applications in functional foods, in feed formulations, for agricultural purposes, and as pharmaceuticals. Production and applications of XOS have been comprehensively reviewed by Vazquez et al. (2000). The authors list three strategies for the production of XOS from lignocellulosic materials, namely, direct enzymatic treatment of feedstocks, chemical fractionation mostly with alkali hydroxides or aqueous ammonia to remove lignin and solubilize xylan, followed by enzyme-catalyzed degradation (Kim and Lee 2007), and hydrolytic degradation of xylan by water, steam, or dilute mineral acids (Vazquez et al. 2000). Hydrothermal processing generates relatively high concentrations of undesirable by-products, the removal of which poses complex technical challenges (Vazquez et al. 2005).

The biological activities of XOS were investigated in a semicontinuous, anaerobic colon simulator with four vessels mimicking the conditions of the human colon. Three XOS compounds and a xylan preparation were fermented for 48 h by human colonic microbes (Mäkeläinen et al. 2010). The numbers of bifidobacteria increased in all XOS and xylan fermentations. Similarly increased were concentrations of SCFA, especially butyrate and acetate. The authors concluded that the combination of XOS and *Bifidobacterium lactis* would be a suitable candidate for an effective synbiotic product.

XOS and FOS markedly reduced the number of aberrant crypt foci in the colon of 1,2-dimethylhydrazine treated rats. Aberrant crypt foci are clusters of aberrant

cells in the lining of the colon or rectum. They may develop into colorectal polyps and thus may constitute an early stage of cancer (Takayama et al. 2005). Other parameters beneficially influenced by XOS were decreased cecal pH and serum triglycerides and increased cecal weight and bifidobacteria population. The results were taken to suggest beneficial effects of XOS and FOS on gastrointestinal health, with XOS more effective than FOS.

6.4 Isomaltooligosaccharides from Starch

Commercially isomaltooligosaccharides (IMO) are produced from starches of different sources. In the first stage, starch is converted into high-maltose syrup under catalysis by amylases. By the action of transglucosidase (α-D-glucoside glucohydrolase, E. C. 3.2.1.20), the nonreducing α-(1,4)-linked glucose unit of maltose is released and attached to the 6-position of glucose, maltose, or other saccharides present in the reaction mixture. In this manner, maltose is converted into a complex mixture of IMO and related oligosaccharides. At the turn of the last century, a commercially produced IMO preparation was the market leader in the prebiotic oligosaccharide sector in Japan with annual sales of 10,000 tons (Japanscan 1998). The typical composition of an IMO preparation is described as isomaltose 23 %, isomaltotriose (α-glucose-(1,6)-α-glucose-(1,6)-glucose) 17 %, non-isomaltooligosaccharides as panose (α-glucose-(1,6)-α-glucose-(1,4)-glucose), maltose (α-glucose-(1,4)-glucose), maltotriose (α-glucose-(1,4)-α-glucose-(1,4)-glucose), nigerose (α-glucose-(1,3)-glucose) and kojibiose (α-glucose-(1,2)-glucose), together 30 % and higher oligosaccharides of dp 4 and 6, 26 %.

In a comparative study of fermentation properties of oligosaccharides (Rycroft et al. 2001), IMO and GOS were found to qualify as effective prebiotics as they increased numbers of bifidobacteria with little effect on the other bacterial groups. Furthermore, they increased the production of lactate and produced the lowest gas volumes.

In an interesting application, the enzyme transglucosidase has been administered to humans and has been shown to decrease blood glucose levels and prevent body weight gain in patients with type 2 diabetes mellitus, apparently through the production of oligosaccharides in the alimentary tract and modulation of the gut flora composition (Sasaki et al. 2013).

7 Prebiotics and Dietary Fiber Derived from Disaccharides

7.1 Fructooligosaccharides Derived from Sucrose

Three alternative approaches for FOS production from sucrose have been described by Yun and Song (1999). Crude fructosyltransferase is prepared by lysozyme treatment of *Aureobasidium pullulans* cells grown in submerged culture. The enzyme may be used directly for batch production of FOS from sucrose.

Alternatively, the enzyme may be immobilized on a highly porous ion-exchange resin and used for continuous production in a column reactor. The industrial use of immobilized enzymes has been reviewed by DiCosimo et al. (2013). Immobilization of whole *A. pullulans* cells is another alternative for catalysis in continuous production of FOS (Yun et al. 1992). These authors found the physiological functionalities of FOS as well and confirmed their prebiotic qualities as mentioned above. Commercial products with the application of fructosyltransferase from *Aspergillus niger* are Neosugar® and Actilight®.

7.2 Isomaltulose and Trehalulose from Sucrose

Several bacterial strains have been reported to produce the enzyme sucrose isomerase (sucrose mutase or α-glucosyl transferase, E. C. 5.4.99.11). This enzyme converts the nonreducing disaccharide sucrose (α-glucose-(1,2)-β-fructose) into the reducing disaccharides isomaltulose or palatinose (α-glucopyranosyl-(1,6)-fructose) and trehalulose (α-glucopyranosyl-(1,1)-fructose.

Cheetham et al. (1982) describe the production of isomaltulose using column reactors containing *Erwinia rhapontici* cells immobilized in alginate beads (for a recent discussion of immobilized enzymes see DiCosimo et al. 2013).

Isomaltulose (palatinose) has found extensive use as a sugar substitute. It is only half as sweet as sucrose. With a glycemic index of 32, isomaltulose is metabolically degraded much more slowly than sucrose (Yamada et al. 1985), so that rapid postprandial increases of blood glucose and insulin levels are avoided. Trehalulose has similar properties and is essentially noncarious (Ooshima et al. 1991).

7.3 Galactooligosaccharides Derived from Lactose

Galactooligosaccharides (GOS), also referred to as *trans*-GOS, are produced from lactose (β-D-galactopyranosyl-(1,4)-D-glucose) by the reversed (synthetic) action of certain β-galactosidase enzymes. A β-D-galactopyranosyl residue is cleaved from a lactose molecule and transferred to the 3′, 4′, or 6′-position of the nonreducing galactose unit of another lactose molecule or of the growing oligosaccharide chain. To assure preference of oligosaccharide synthesis over hydrolysis, high concentrations of lactose are required. In this manner, GOS mixtures of dp between 2 and 8 are produced. Transgalactosidase enzymes from different sources will catalyze the preferential formation of different interglycosidic linkages: Thus, the enzymes from *Aspergillus oryzae* (Vera et al. 2012) catalyze the formation of mainly β-(1,6)-linkages, enzymes from *Bacillus circulans* or *Cryptococcus laurentii* favor β-(1,4)-linkages, whereas β-(1,3)-linkages are preferentially formed when enzymes from *Bifidobacterium bifidum* (Rabiu et al. 2001; Tzortzis et al. 2005) are used. The use of microbial β-galactosidases including enzymes from thermophilic and hyperthermophilic organisms in the production of GOS from lactose has been reviewed (Park and Oh 2010).

GOS have been amply demonstrated to have many beneficial effects. In a study in healthy humans, GOS have been shown to have a strong bifidogenic effect, together with FOS, soybean oligosaccharides, and RS3 (Bouhnik et al. 2004). Most of the use of GOS has been in infant formulas. For example, in a study with preterm infants, an oligosaccharide mixture containing 90 % GOS and 10 % FOS was used to supplement a standard preterm formula at a concentration of 10 g/l (Boehm et al. 2002). The supplemented formula was found to stimulate the growth of bifidobacteria and to improve stool characteristics to the level found with preterm infants fed human milk. Mineral absorption was also found improved by GOS in young girls (Whisner et al. 2013) and in postmenopausal women (van den Heuvel et al. 2000).

8 Conclusion

Dietary fiber is collectively acknowledged to be one of the key factors in a health-promoting diet. Foods containing traditionally not enough dietary fiber such as meat are consumed more and more in the current diet of many developed countries. Hence, nowadays the intake does meet the recommendations of neither the WHO (25 g day^{-1} $person^{-1}$) nor those of the country itself and is around 30–50 % under this level. However, consumer's interest in fiber-rich ready-to-eat foods and functional beverages is increasing, and thus, their dietary fiber intake could possibly be modified toward higher doses in the future.

To enhance public health and the personal well-being, great efforts were made worldwide in the last decenniums, developing different projects and programs. For the interaction of healthy food, movement, and fun, the term "wellness" was created, causing an essential revaluation of the idea of health in the population. Predominantly plant nutrition, scarcely processed, can be considered species appropriate and therefore optimal for individual health. Additionally, the energy input of food should be controlled and attuned to the physical activity.

The interest for functional food is increasing more and more. The target for FF is the global population in general – in particular, however, the elderly, pregnant women, diabetics, sportsmen, or obese people. FF products, raw materials for FF, and process technology to produce FF are of enormous economical interest.

In the field of *intrinsic* FF containing enough bioactive carbohydrates with prebiotic efficacy, fructan plants play an important role, especially in the traditional Chinese and Indian health systems. Additionally the overwhelming interest for healthy food in the USA and in Europe paves the way for a bright future of food products with nondigestible carbohydrates such as fructan.

For *extrinsic* FF with tailor-made profiles containing additions of health-promoting substances, a lot of industrially proceeded carbohydrates mostly isolated from natural raw plant materials will be used. Besides fructan such as inulin and FOS, different bioactive carbohydrates are applied for *extrinsic* FF such as heteropolysaccharides isolated from mucilages of different plant seeds and their hydrolyzed oligosaccharides, gums from plant exudates, or specific

polysaccharides collected from seaweeds. These carbohydrates possess a traditional utilization for foods in the countries of origin and gain worldwide acceptance due to excellent prebiotic functionality. Additional prebiotic active oligosaccharides such as FOS and GOS or nondigestible disaccharides such as isomaltulose and trehalulose can be obtained by modification of sucrose and lactose in enzymatic reactors. Prebiotically effective XOS processed from sawdust or pulp of cellulose production and isomaltooligosaccharides from starch are excellent examples for innovative waste utilization. The developments of new patents for tailor-made products, especially the combinations of different bioactive carbohydrates for particular groups of persons (elderly, infants, sportsmen, etc.), are in progress and have high potential for the future.

Furthermore, the health policy of developed countries moves away from relief of deficiency diseases toward a preventive nutrition strategy with the idea of life prolongation and improvement of life quality. The large developing potential of production and trade of FF in the USA, Europe, and Asia verifies the growing economical interest. Supported by research initiative, a considerable increase of sales and profit can still be expected in this market segment.

Polysaccharide-Protein Complexes from Edible Fungi and Applications

31

Jian-Yong Wu

Contents

Abstract

Edible and medicinal fungi (mushrooms) have found wide and increasing applications in functional foods and nutraceutical products because of their proven nutritive and medicinal properties. Polysaccharides (PS) and PS-protein (PSP) complexes represent a major class of constituents of the edible fungi with notable bioactivities such as immunomodulation, antitumor, antioxidant, antiviral, and prebiotic. Commercial mushroom materials including PS and PS-rich hot-water extracts are mainly (>80 %) derived from cultivated mushrooms (in fruit form) and a smaller amount (~15 %) from mycelial fermentation. Although the most common immunobioactive PS structures have a β-D-glucan main chain such as (1→3)-β-D-glucans and (1→6)-β-D-glucans with side chains, various other bioactive PS structures have also been documented such as α-D-glucans, glucomannans, and glycoproteins. In addition to functional food and therapeutic uses, mushroom PS and PSPs have also been applied as cosmeceutical ingredients.

1 Introduction

Edible fungi or mushrooms provide a rich and favorable source of natural and bioactive polysaccharides (PS) for health food and nutraceutical applications. Over the last few decades, considerable research effort has been devoted to investigating the molecular structures and biological activities of PS and PSPs extracted from edible and medicinal fungi as summarized in several reviews (Borchers et al. 1999; Misuno 1999; Wasser 2002; Zhang et al. 2007; Stachowiak and Reguła 2012). In addition to their well-known immunomodulation and antitumor functions, fungal PS/PSP have shown many other health benefits such as antioxidation, anticoagulation, antimicrobial, anti-inflammation, antidiabetic, hypolipidemic, hypoglycemic, prebiotic, and wound healing.

Mushrooms have been used as favorable food and tonic for thousands of years since the early human civilization, and their health benefits and medicinal values have been widely recognized for a long time. Recent years have seen a notable interest in research effort and commercial application of mushroom extracts and PS. This chapter describes the sources, preparation methods, and functional food applications of mushroom PS.

2 Sources, Preparation Methods, and Product Properties

2.1 Sources

Commercial mushroom polysaccharides are mainly extracted from two sources, fruit bodies and fungal mycelia. Currently, 80–85 % of mushroom products has been derived from the fruiting bodies, which are either cultivated or wild, and 15 % from cultivated mycelia from solid or liquid fermentation, such as PSK and PSP

from *Trametes versicolor* and tremellastin from *Tremella mesenterica* (golden jelly fungus). A much smaller percentage of mushroom PS or PSP has been obtained from mycelial culture liquid (as EPS), such as schizophyllan (β-glucan) from *Schizophyllum commune* and scleroglucans from *Sclerotium glucanicum*, *S. rolfsii*, and *Sclerotinia sclerotiorum* (Lindequist et al. 2005; Schmid et al. 2011; Zhang et al. 2013).

2.1.1 Cultivated Mushrooms as a Major Source of PS

Mushroom is a general name referring to the fruiting body of a macrofungus, which is large enough to be picked with hand (Chang and Miles 2004). Mushrooms belong to two major subdivisions of fungi, basidiomycetes for most mushrooms and ascomycetes for relatively few. According to their relationship with the substrate/host, fungi are classified into saprophytic (decomposing nonliving organic matters), parasitic (to other living organisms, e.g., fungi, plants and animals, harmful, or pathogenic), and mutualistic or symbiotic (on an interdependent and beneficial relationship with other living organisms such as plants. The known mushroom species in the world are over 14,000, of which about 2,000 are edible and 700 showing significant medicinal properties (Wassor 2002; Chang and Miles 2004; Stachowiak and Reguła 2012).

Because of the limited supply and high price of wild mushrooms, artificial cultivation has become the major source of most edible mushrooms on the market (Borchers et al. 1999; Smith et al. 2002). World production of edible mushrooms has been increasing constantly at an exponential rate over the last 40 years at a much faster rate than world population (Aida et al. 2009). The most significant growth has been recorded in China and India, due partially to the rapid growth of their economy and wealth. For example, the global mushroom production in 2012 was 7.96 million tons and the production in China was 5.16 million tons, accounting for 65 % of the world production (Factfish http://www.factfish.com). *Agaricus bisporus* (button mushroom) is the most widely cultivated edible mushrooms worldwide, followed by *Lentinus edodes* (shiitake), *Pleurotus spp.* (oyster mushrooms), *Auricularia auricula* (wood ear mushroom), *Flammulina velutipes* (winter mushroom), and *Volvariella volvacea* (straw mushroom).

2.1.2 Submerged Fermentation of Fungal Mycelia

Compared with solid-state fermentation (SSF) systems, liquid or submerged fermentation systems allow for more effective control and operation but also require higher equipment and operating costs and produce a large amount of wastewater (Smith et al. 2002; Kim et al. 2007; Wu et al. 2014). Mechanically agitated fermenters are commonly used for submerged fermentation. The growth of mycelium biomass and the productivity of EPS in the fermentation process are strongly influenced by the liquid medium composition and several operating conditions, such as pH, temperature, oxygen transfer, and agitation power. In most cases, optimum values of temperature and pH for biomass formation and EPS production differ considerably. Moreover, considerable changes in the rheological properties of fermentation liquid occur during the course of fermentation due to biomass and

1. **Fungal species and stock culture.** The fungus Cs-HK1 strain was isolated from a natural Cordyceps fruiting body. The stock culture of Cs-HK1 mycelia was maintained on potato dextrose agar (PDA) medium at 4°C.

2. **Inoculum preparation and liquid fermentation.** For initiation of liquid culture, the stock culture on a Petri dish was incubated at 20°C for about 3 weeks until sporulation. The fungal mycelia/spores were then inoculated into a 250 mL Erlenmeyer flask containing 50 mL of liquid medium and incubated at 25°C on a rotary shaker at 150 rpm for 7 days. The liquid medium was composed of 40 g/L glucose, 15 g/L yeast extract, 5 g/L peptone plus three inorganic salts (K, P, Mg).

3. **Liquid fermentation in a 15-L fermenter.** The mycelial suspension from the shake-flasks was transferred into a 15 L stirred and aerated fermenter filled with ~8 L of liquid medium, and operated for 6 days at 20-25°C, an air flow rate of 1 vvm and dissolved oxygen above 20% air saturation.

4. **Large-scale fermentation.** Inoculum for industrial fermenters was prepared in a 300-L seed fermenter and the inoculum size was about 1% (v/v). The fermentation were operated at an pH 7.0, 20-25 °C, agitation speed 150 rpm, and aeration rate 0.5-1 vvm for an overall period of 6 days. The nutrient chemicals and antifoams were all of food grade for large-scale fermentation.

5. **Separation of mycelium biomass and liquid medium.** The mycelial suspension from the shake-flasks or fermenters was centrifuged at 6000-8000 rpm for 20 min, the biomass pellet was washed thoroughly with distilled water, and dried at 60-80 °C for ~12 h to constant weight, and the supernatant liquid medium was collected for isolation of EPS.

Scheme 1 Liquid fermentation of Cs-HK1 fungal mycelia (Yan et al. 2014; Wu et al. 2014)

EPS production. This results in a highly viscous and non-Newtonian broth which in turn may cause serious problems for mixing, heat transfer, and oxygen supply. Scheme 1 illustrates the procedure for liquid fermentation and EPS production with the Cs-HK1 fungus originated from the Chinese caterpillar fungus *Ophiocordyceps sinensis* (=*Cordyceps sinensis* Berks Sacc.)

2.2 Preparation

2.2.1 Extraction of PS

In both research studies and commercial processes, the first and an essential step in the isolation of bioactive natural products and PS from the source plant and microbial materials is extraction (liquid–solid). The extraction method can strongly affect the quantity (yield) and also the quality (composition and bioactivities) of the isolated products. Since most of the bioactive mushroom polysaccharides are present in the fungal cell wall, the selection of extraction solvents and conditions should be able to effectively dissolve and decompose the cell wall to release the PS into the extracting solvent. Many of the bioactive PS are water soluble and isolated from mushroom fruiting bodies or fungal mycelium through hot-water extraction

(HWE), which is also a common method for the preparation of herbal decoctions in Chinese and other folk medicines and for the isolation of water-soluble bioactive compounds from natural products. Aqueous alkaline has been applied to extract PS that are less soluble in water. In addition to the conventional HWE method, various means have been applied to enhance extraction rate, such as the application of ultrasound, microwave and enzymes, and high pressure.

2.2.2 Purification of PS

PS in the liquid extract solution is usually isolated by ethanol precipitation. In general, 4–5 volumes of ethanol to the extract solution (70–80 % v/v) are required for complete precipitation of PS (Yan et al. 2014). Many high- and low MW impurities such as proteins, fats, and pigments are precipitated together with PS and cause difficulty to the subsequent purification process. Some of the low MW fats and pigments can be removed from the mushroom or mycelium powder prior to water extraction by extraction with an organic solvent such as acetone and ethanol. Crude PS can be further fractionated and purified through column chromatography. Figure 1 shows the common process for extraction of PS from various sources including extracts of mushroom or mycelium biomass and EPS from liquid fermentation medium, and for further isolation and purification of the PS. Scheme 2 illustrates the procedure with conditions for extraction and purification of PS from mycelial fermentation of a medicinal fungus Cs-HK1.

3 Commercial Applications

3.1 Functional Foods and Pharmaceuticals

Functional food refers to natural or formulated food that enhances a physiological performance or prevents or treats a particular disease; nutraceutical is a term referring to a medicinal or nutritional component of food, plant, or naturally occurring material that is used for the improvement of health, by preventing or treating a disease (Doyon and Labrecque 2008). Edible and medicinal fungi have found wide applications in functional foods and nutraceutical products because of their well-known nutritive and medicinal properties (Chang and Buswell 1996; Lindequist et al. 2005; Stachowiak and Reguła 2012; De Silva et al. 2012). Fresh mushrooms have about 90 % water and the remaining 10 % dry matter is composed of 10–40 % protein, 3–28 % carbohydrate, 3–32 % fiber, 2–8 % fat, and 8–10 % ash, varying with the mushroom species and other factors. Mushrooms contain a large array of mineral elements (K, Ca, P, Mg, Fe, Zn, and Cu) and vitamins (niacin, thiamin, riboflavin, biotin, and vitamin C and provitamins A and D), which are beneficial to nutrition and health. Several groups of bioactive low molecular weight (MW) organic molecules have been found in certain mushroom species, including terpenoids, steroids, phenols, nucleotides, and amino acids (Mattila et al. 2001; Smith et al. 2002; Wasser 2002). Among the most popular mushroom dietary

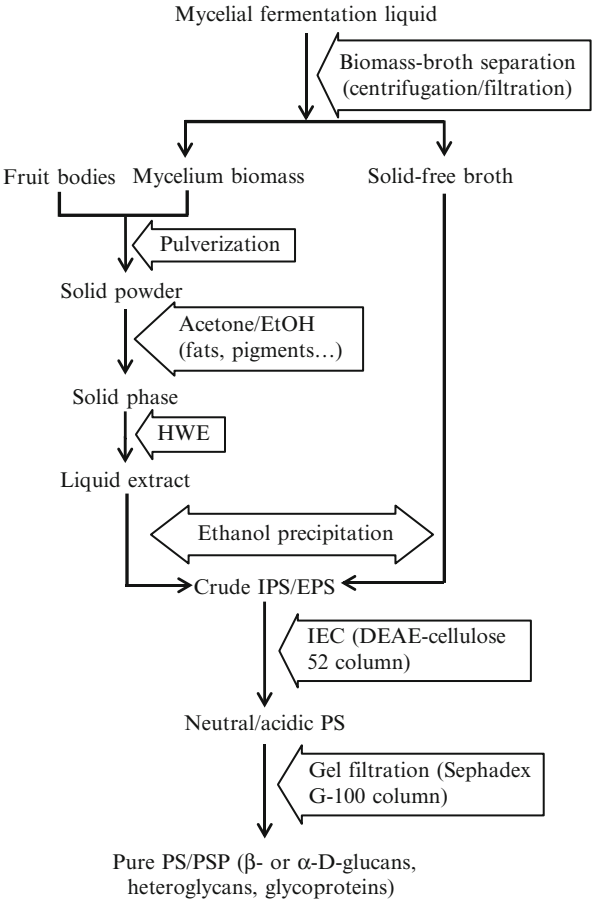

Fig. 1 A general procedure for isolation and purification of fungal polysaccharides from various sources, IPS from extracts of fungal mycelium and fruit bodies, and exopolysaccharides (EPS) from the mycelial fermentation broth

supplements are lyophilized whole and extracts of a few common and specialty mushrooms, *Lentinus edodes*, *Grifola frondosa*, and *Ganoderma lucidum*.

PS represent a major class of high-MW bioactive constituents of edible and medicinal fungi with several health benefits including immunomodulatory, anticancer, anti-inflammatory, antioxidant, hypoglycemic, hypolipidemic, antiviral, and hepatoprotective (Lindequiset al. 2005; Stachowiak and Reguła 2012). Mushroom PS also have a therapeutic function including anticancer and immunotherapy. Some purified PS fractions such as β-glucans and PS-protein (PSP) complexes from edible and medicinal fungi have found clinical applications for immunotherapy and cancer treatment and as the adjuvant for chemotherapy/radiotherapy (Mizuno 1999; Borchers et al. 1999; Ramberg et al. 2010; De Silva et al. 2012). In addition to structure, the bioactivity of PS can be affected by solubility and molecular weight. Table 1 shows the sources and bioactivities of

1. **Separation of mycelium biomass and liquid medium.** The mycelial fermentation broth was centrifuged at 6000 rpm for 20-30 min. The mycelium pellet was washed with distilled water and dried at 60 °C till constant weight.

2. **Extraction of water soluble PS from mycelium biomass.** Mycelium biomass was extracted in hot water at 90 °C under reflux (e.g. 40 g dry mycelium in 600 mL distilled water), followed by centrifugation (6000 rpm, 30 min). The extraction was repeated once and the liquid extract was collected and concentrated by evaporation under vacuum.

3. **Ethanol precipitation of PS from aqueous solution.** The concentrated liquid extract was mixed well with 4-5 volumes of ethanol (~80% v/v), and then left overnight in a refrigerator at 4 °C for PS precipitation. The liquid mixture was centrifuged (6000 rpm, 30 min), and the precipitate was collected and redissolved in distilled water, and then lyophilized to give the crude PS.

4. **Extraction of alkaline-soluble PS.** The mycelium powder was extracted with aqueous solution of 1.25M NaOH and 0.04% NaBH4 for three times (each at 10:1 v/w). The liquid extract was collected after centrifugation and precipitated with 36% acetic acid (final concentration). After centrifugation, the supernatant was collected and concentrated by evaporation, and then precipitated with 3 volumes of cold acetone, followed by centrifugation (8000 rpm, 30 min). The precipitate was collected, redissolved in distilled water and lyophilized, yielding the crude alkaline-soluble PS.

5. **Purification of PS from mycelium biomass**. The crude PS isolated from water or alkaline extract was deproteinized by Sevag reagent and decolorized with 30% H_2O_2. The PS solution was then dialyzed against DI water for 3 days with 12–14 kDa MWCO membrane, and then concentrated, and lyophilized.

6. **Fractionation of PS.** The purified PS was redissovled in water, and loaded into a DEAE-52 cellulose (anion) ion-exchange (IEC) column and eluted with de-ionized water containing 0–0.5M NaCl at a flow rate of 1.0 mL/min. The eluate was monitored by the phenol–sulfuric acid method and the major PS fractions detected were collected and concentrated by evaporation under reduced pressure, followed by dialysis against DI water for 3 days with 12–14 kDa MWCO membrane. The PS was concentrated and lyophilized.

Scheme 2 Extraction and purification of polysaccharides from Cs-HK1 fungal mycelia (Huang et al. 2013; Yan et al. 2014)

several well-known mushroom PS. Beta-1, 3-D-glucans are most well-known antitumor and immunobioactive PS from medicinal fungi. Table 2 presents example commercial products of functional foods and cosmetics made or supplemented with mushroom extracts or PS products.

Mushrooms have also been recognized as a potential and promising source of prebiotics (Aida et al. 2009; Stachowiak and Reguła 2012). The term "prebiotics" refers to a nondigestible food component that stimulates the activity or the growth of gastrointestinal microbiota or the bifidobacteria and lactic acid bacteria in the digestive system (Gibson et al. 2004). The beneficial effects of prebiotics for human health may include the enhancement of the immune

Table 1 Sources, structures, and bioactivities of well-known PS and PSPs from edible and medicinal fungi (Zhang et al. 2007; Yan and Zhang 2009; Mizuno and Nishitani 2013; Yan et al. 2014)

Fungal species (general name)	Raw material/ extraction	PS structure[a]	Main activities
Agaricus blazei Murill. (Almond Portobello, Himematsutake)	Fruit body, alkaline extract	(1→3)-β-D-glucan	Antitumor
	Fruit body, HWE	FA-1b, branched (1→2)-β-D-glucomannan, PSP	Antitumor
	Mycelium, HWE/ alkaline	β-(1→2)- and β-(1→3)-glucomannan	Antitumor
Cordyceps sinensis (Chinese caterpillar fungus, Dong-chong-xia-cao)	Mycelium, HWE	CS-81002, Man:Gal: Glc=10.3:3.6:1	Immunomodulating
	Culture broth (EPS)	Poly-N-hexNAc, $ManNH_2$: $GalNH_2$:Gal=1.0:1.1:0.2	Antioxidant activity
Ganoderma lucidum (Reishi, Lingzhi)	Fruit body, HWE	GL-1, hot-water extract	Antitumor
	Culture broth (EPS)	GLP-2, branched (1→4)-α-D-glucan	Immunomodulating
Grifola frondosa (Maitake, Hui-shu-hua)	Fruit body, HWE	D-Fraction, branched (1→3)-β-D-glucan	Antitumor
Lentinus edodes (Shiitake, Xiang-gu)	Fruit body, HWE	Lentinan, branched (1→3)-β-D-glucan	Anticancer
	Mycelium, HWE	Mannan with protein	Antitumor
Sclerotinia sclerotiorum (White mold)	Mycelial culture broth (EPS)	Scleroglucan (SSG), branched (1→3)-β-D-glucan	Antitumor, antiviral, antimicrobial
Trametes (*Coriolus*) *versicolor* (Turkey tail, Yun-zhi)	Mycelium, HWE	Krestin (PSK), a PSP with 25–38 % protein, branched (1→4)-α-D-glucan	Anticancer

[a]The pure PS/PSPs are usually isolated from the crude and purified with procedure shown in Fig. 1

function, improvement of colonic integrity, reduction of intestinal infections, and suppression of allergic responses. Oligosaccharides such as inulin, fructo-, and galacto-oligosaccharides have been recognized as the most promising candidates for prebiotics (Aida et al. 2009). Therefore, the high-MW PS from mushrooms including chitin, glucans, mannans, and galactans can be digested within the human gut or degraded externally into low MW PS and oligosaccharides to act as prebiotics.

Table 2 Commercial health-care and cosmetic products with extracts and PS of medicinal fungi

Component	Products

3.2 Cosmeceuticals

PS from mushrooms with various bioactivities can be used not only in functional food and pharmaceutical products but also in supportive human health-care products, especially functional cosmetics or cosmeceuticals. PS with a high capacity of hydration and water retention are required for skin repair and skin renewal. PS have become the important ingredients of cosmetic products for revitalizing the skin and anti-skin aging (Hyde et al. 2010). In recent years, we have seen an increasing number of cosmetic and skin care products that are incorporated with mushroom extracts or PS, with a few examples shown in Table 2. Mushroom PS and extracts may be attributable to their antioxidant and cytoprotective activities against skin damage, skin aging, and cancer caused by reactive oxygen species and ultraviolet (UV) radiation. In a reported study (Kim et al. 2007), for example, the EPS as well as the mycelial extract of *G. frondosa* produced by submerged fermentation exhibited significant activities for radical scavenging, stimulation of collagen biosynthesis, and cell proliferation and inhibition of melanogenesis without significant cytotoxicity, which are beneficial and useful for skin care.

4 Conclusions

Edible and medicinal mushrooms are valuable and promising sources of bioactive PS and PSPs with diverse structures and properties. Mushroom PS have remarkable antitumor, immunomodulatory, and other useful functions and activities. The bioactive properties of PS are associated with the structures, molecular weight, water solubility, and other molecular and solution properties. In addition to the bioactive functions, fungal PS can be used as thickening and gelling agents in foods and cosmetic products because of their high-MW and hydration properties. Mushroom PS have been applied to a wide range of health-promoting products including foods, pharmaceutical, and cosmetic on the market for public use. Many new products and applications can be developed to improve human health and life quality.

Contents

Abstract

An extract from *Botrytis cinerea* culture filtrate was sprayed on grapevine plants (*Vitis vinifera*) to investigate its potential to stimulate defense reactions. The extract triggered the induction of genes encoding pathogenesis-related (PR) proteins as chitinases (*CHIT*), polygalacturonase-inhibiting protein (*PGIP*), serine proteinase inhibitor (*PIN*), and enzymes involved in phytoalexin synthesis as phenylalanine ammonia-lyase (*PAL*) and stilbene synthase (*STS*). Correlated to the up-regulation of these latter genes, stilbene content increased in treated leaves. Consequently, treatment of grapevine leaves with the fungal extract triggered protection toward *Plasmopara viticola* and *Erysiphe necator*,

the causal agents of grapevine downy and powdery mildews, respectively. Disease severity was significantly reduced in elicited plants, approximately 61 % for downy mildew and 83 % for powdery mildew. This approach could represent a valuable strategy to protect grapevine from diseases as an alternative or complementary method to the use of pesticides.

1 Introduction

Grapevine (*Vitis vinifera* L.) is susceptible to many diseases, especially fungal ones such as gray mold (*Botrytis cinerea*), downy mildew (*Plasmopara viticola*), powdery mildew (*Erysiphe necator*), and dieback (*Eutypa lata*). To defend themselves against pathogens, plants have evolved several mechanisms. Passive defenses as structural barriers and preformed antifungal compounds help to delay the infection process but are insufficient. So plants have also developed active defense mechanisms leading to the accumulation of antimicrobial compounds such as phytoalexins (stilbenes in *V. vinifera*) and PR proteins (Jeandet et al. 1995; Adrian et al. 1996; Dufour et al. 2013; Rivière et al. 2012).

These active mechanisms are induced only if the plant has recognized the attack by the perception of signal molecules also called elicitors. Elicitors can be abiotic or biotic (Sticher et al. 1997; Mauch-Mani and Métraux 1998; Pieterse et al. 1998; Zimmerli et al. 2000; Ton et al. 2005; Delaunois et al. 2014). "Abiotic elicitors" can be physical stimuli like wounding or UV light exposure (Gus-Mayer et al. 1998; Douillet-Breuil et al. 1999; Colas et al. 2012) or chemicals like aluminum chloride or phosphite (Saindrenan et al. 1988; Borie et al. 2004; Bock et al. 2012). "Biotic elicitor" usually refers to molecules secreted by microorganisms, derived from the cell walls of fungi, bacteria, and host plants (Côté and Hahn 1994; Ebel and Cosio 1994; Guo et al. 2011) or from seaweed (Bouarab et al. 1999; Klarzynski et al. 2000; Cluzet et al. 2004; Trouvelot et al. 2008; Jaulneau et al. 2011). Oligosaccharides were among the earliest elicitors that have been characterized (Ebel 1998), and many cell wall poly- or oligosaccharides, such as microbial β-glucans and chitin-derived oligomers or plant pectin-derived oligogalacturonides (Ebel 1998; Côté et al. 1998; Aziz et al. 2007), exhibit elicitor activities on defense responses across different plant species (Cardinale et al. 2000; Mithofer et al. 2000; Inui et al. 1997; De León and Montesano 2013). Moreover, β-glucans from fungal origin have been reported to enhance phytoalexin production in soybean (Sharp et al. 1984) and protection against viruses in tobacco (Rouhier et al. 1995; Fu et al. 2011). As the intensive use of phytochemicals to protect plants triggers the emergence of pesticide-resistant strains (Leroux et al. 1999; Gressel 2011; Corio-Costet 2012) and as a current attention was paid to the environment, alternative treatments have to be developed. Application of elicitors could be an attractive approach to control plant diseases (Lyon et al. 1992; Benhamou and Nicole 1999; Mishra et al. 2012; Dufour and Corio-Costet 2013).

In a search of new elicitor compounds of grapevine defenses, a preparation of *Botrytis cinerea* extract was performed. *B. cinerea* is one of the most prevalent fungi that damage plants, and in reaction, plants have developed an ability to recognize its elicitors and to react to them strongly by inducing defense responses, as in *Vitis* spp. (Langcake and Pryce 1976). Eliciting properties could be attributed to saccharidic and/or proteic compounds secreted by the fungus. An endopolygalacturonase (BcPG1), purified from culture filtrates of *B. cinerea* and known as a virulence factor participating in this fungus pathogenicity, exhibited elicitor activity on defense responses in grapevine (*V. vinifera* cv. Gamay) (Ten Have et al. 1998; Poinssot et al. 2003). The authors demonstrated that the protein itself, rather than its enzyme activity, was responsible for defense response activation. Another hypothesis of this elicitor activity could be the presence in the filtrate of extracellular polysaccharides such as glucans and rhamno-galacto-mannans (Fanizza et al. 1995). Oligosaccharide fragments have previously been shown to elicit resistance reactions in several plants (Guo et al. 2011; Aziz et al. 2007), like chitooligosaccharides in wheat and grapevine leaves (Vander et al. 1998; Aziz et al. 2006).

The aim of this study was to determine whether exogenous application of a crude preparation of *B. cinerea* (*Bc*) culture filtrate on susceptible grapevine plants (*V. vinifera* L. cv. Cabernet Sauvignon) was able to induce protection toward

major pathogens. After treatment of plants by *Bc* extract, the expression of defense-related genes encoding enzymes involved in the phenylpropanoid pathway (*PAL* and *STS*) and PR proteins (*CHIT1a*, *CHIT3*, *CHIT4c*, *PIN*, and *PGIP*) was monitored by real-time quantitative RT-PCR. Stilbene content in leaves was evaluated by high-performance liquid chromatography (HPLC) analysis. Protection experiments toward downy (*P. viticola*) and powdery (*E. necator*) mildew infections were undertaken on detached leaves of *Bc* extract-treated plants.

2 Sources, Preparation, Usage

2.1 *Botrytis cinerea* Extract Preparation

The ascomycete pathogen *B. cinerea* (strain 163, virulence factor 6.19) was friendly provided by Dr. M. Fermaud (INRA, Villenave d'Ornon, France). The fungus was grown on malt agar medium at 20 ± 2 °C with a 12 h photoperiod to obtain conidia. For elicitor preparation, the fungus was grown in liquid medium as previously described (Fanizza et al. 1995). Conidia from 10-day-old fungal cultures on solid medium were scrapped from the surface of cultures and suspended in water containing 0.05 % Tween 20®. Aliquots of the conidial suspension were added to 2 L Erlenmeyer flasks containing 800 mL of Czapek-Dox medium to give a final concentration of $2.5.10^4$ conidia.mL^{-1} medium. The fungus was grown at 20 ± 2 °C in still cultures in darkness for 4 weeks. Culture filtrate was collected after mycelium removal by filtration and autoclaved for 1 h at 120 °C. This autoclaved filtrate contained 8.5 g of β-glucan.L^{-1} including DP6 (50 %), DP5 (32 %), and DP2–3 (18 %).

Concentration of the extract was expressed in g of glucose equivalents.L^{-1} according to the phenol-sulfuric method (Dubois et al. 1951). Before plant treatment, the solution was diluted in sterile water and the wetting agent Triton X-100® was added at 0.1 % (v/v). The extract was sprayed on plants at a final concentration of 2 g of glucose equivalents.L^{-1}.

3 Biological Properties

3.1 Plant Material, Treatment, and Infection Procedures

Plants of cultivated grapevine (*V. vinifera* L. cv. Cabernet Sauvignon), kindly supplied by Dr. M. F. Corio-Costet (INRA, UMR Santé Végétale, Villenave d'Ornon, France), were propagated from woodcuttings in a greenhouse. Plants were grown under controlled conditions at 25/20 °C day/night temperature, with 75 % relative humidity and a 16 h photoperiod (350 µmol.m^{-2}.s^{-1}). Two-month-old plants with 10–12 leaves were used, and a solution containing either water or the *B. cinerea* extract preparation, both supplied with the wetting agent Triton X-100® at 0.1 % (v/v), was sprayed on all the leaves. In the case of further inoculation tests, a negative control (water) and a positive one (commercial product Aliette® (Bayer)

containing fosetyl-Al) were introduced in the experiment. Twelve plants were used per treatment and each experiment has been repeated three times. At several times after treatment, leaves were collected for analysis. Fungal inoculation tests were performed on 48 h treated detached leaves from the upper part of the shoots. *P. viticola* and *E. necator* fungal strains were kindly provided by the UMR Santé Végétale of the INRA, Villenave d'Ornon, France. *P. viticola* was maintained on grapevine leaf-disk and subcultured two times before the assay. Sporangia were collected and suspended in demineralized water. Thoroughly rinsed, cleaned and dried leaves were placed upside down on moist paper filter in Petri dishes. Lower surfaces of the leaves were inoculated with the fresh prepared sporangia suspension and incubated for seven more days at 22 °C under a 16 h photoperiod. For infection with *E. necator*, detached leaves were cleaned, decontaminated with NaOCl, rinsed, and dried. Leaf disks were deposited lower side down on sterile agar plates and placed at the bottom of a Plexiglas settling tower (Délye and Corio-Costet 1998). Conidia were blown in at the top from leaves displaying spores. Inoculated leaves were incubated for 14 days at 22 °C under a 16 h photoperiod.

3.2 Defense-Related Gene Expression in Grapevine Plants

Most elicitor- and/or pathogen-induced genes that have been characterized in grapevine correspond to genes encoding PR proteins (Dufour et al. 2013; Busam et al. 1997; Davies and Robinson 2000; Jacobs et al. 1999; Robert et al. 2001; 2002; Belhadj et al. 2006, 2008a, 2008b; Bavaresco et al. 2012; Lambert et al. 2013) or enzymes involved in the synthesis of stilbene phytoalexins (Dufour et al. 2013; Belhadj et al. 2006, 2008a, 2008b; Bavaresco et al. 2012; Lambert et al. 2013; Melchior and Kindl 1990, 1991; Sparvoli et al. 1994; Wiese et al. 1994).

In this study, grapevine foliar cuttings of a susceptible cultivar (Cabernet Sauvignon) were sprayed with a fungal preparation derived from *B. cinerea* at the previously determined optimal concentration of 2 g of glucose eq L^{-1}. During the 48 h following plant treatment, expression of several defense-related genes encoding enzymes implicated in the synthesis of stilbenes (*PAL*, *STS*) and genes encoding PR proteins (*CHIT1a*, *CHIT3*, *CHIT4c*, *PGIP*, *PIN*) was analyzed in leaves. This expression was monitored by RT-qPCR using specific primers (Table 1) with an actin gene as internal standard. The quantification of mRNA expression levels was carried out as follows: total RNA was extracted from frozen leaves as described by Chang et al. (1993). Contaminating DNA in the RNA preparation was removed by DNase I (Promega Corp.) and a phenol/chloroform/isoamylic alcohol mixture was done to remove the DNase. Total RNA was checked for its integrity by electrophoresis and 2 µg was reverse-transcribed with oligo (dT) (ImProm-II™ reverse transcription System, Promega Corp.). For the determination of the mRNA copy number of the genes of interest, real-time quantitative RT-PCR (RT-qPCR) was performed using the detection system MyiQ (Bio-Rad) and iQ SYBR Green Supermix (Bio-Rad). PCR reactions were carried out in triplicates in 96-well plates by using SYBR Green I dye and the appropriate primers

couple. To check the specificity of the PCR reaction, melting curves were analyzed for each data point. Transcripts level was calculated as described by Arrieta-Montiel et al. (2001) with the use of a standard curve of known copy number for target sequence. The copy number of the sample was estimated by plotting the threshold cycle (Ct values) against the logarithm of the starting copy number. The absolute copy number for each sample was calculated from standard curves using the Ct value and normalized against grapevine actin gene as an internal control (Bézier et al. 2002) and control leaves as reference sample. The gene-specific primers are indicated in Table 1. Relative gene expression was obtained with the formula: fold induction $= 2^{-[\Delta\Delta Ct]}$, where ΔΔCt = [CtGI where ΔΔCt = [CtGI(unknown sample) – Ct VACT(unknown sample)] – [Ct GI (reference sample) – Ct VATC (reference sample)]. GI is the gene of interest and VACT is the grapevine actin gene used as internal control. The calibrator sample is the sample chosen to represent 1 × expression of the gene of interest (e.g., control leaves) (Winer et al. 1999).

In control leaves, no significant transcript accumulation of the different genes was detected during the 48 h incubation period.

Phenylalanine ammonia-lyase (PAL), the first enzyme of the phenylpropanoid pathway, is involved in the biosynthesis of various defense-related compounds (phenolics, lignin, salicylic acid). In this pathway, downstream of PAL, stilbene synthase (STS) catalyzes the synthesis of resveratrol, the main phytoalexin produced by grapevine in response to biotic or abiotic stresses (Adrian et al. 1997; Coutos-Thévenot et al. 2001; Langcake and Pryce 1977a; Langcake and Pryce 1977b; Shen et al. 2012). Expression of *PAL* and *STS* was highly induced in response to *Bc* extract treatment. In elicited grapevine leaves, *PAL* and *STS* mRNA accumulation was transient and followed the same expression profile. Transcripts were detected at least 3 h after treatment, reaching a maximum around 12 h (300-fold increase for *PAL*, -600 for *STS*), and then rapidly returned to a basal level 24 h after treatment (Fig. 1a).

Bc extract treatment also led to the accumulation of mRNA transcripts of genes encoding PR proteins. The chitinase genes *CHIT1a*, *CHIT3*, and *CHIT4c* showed different expression patterns after treatment (Fig. 1b). Chitinases play a direct role in plant defense by degrading chitin, a major component of fungal cell walls, and thus inhibit hyphal growth (Collinge et al. 1993). An increased pathogen resistance was observed in transgenic plants overexpressing chitinases (Grison et al. 1996; Prasad et al. 2013; Chen et al. 2014). Moreover, chitinolytic breakdown products induce the production of phytoalexins and systemic acquired resistance (Brunner et al. 1998; Van Loon and Van Strien 1999). *CHIT1a* transcripts accumulated during the 48 h incubation with a sixfold maximum increase. *CHIT4c* mRNA transcripts accumulated the first. Induction of this gene started immediately after treatment, with two maxima (40-fold increase each) at 3 and 18 h, then decreased slowly until 48 h. *CHIT3* transcripts accumulation started later, with a peak around 18 h and a 60-fold increased level (Fig. 1b). *CHIT3* is inducible by pathogens such as *P. viticola* and *E. necator* or by chemicals such as salicylic acid (SA), 2,6-dichloroisonicotinic acid (INA), or benzothiadiazole (BTH) (Busam et al. 1997; Jacobs et al. 1999; Robert et al. 2001, 2002).

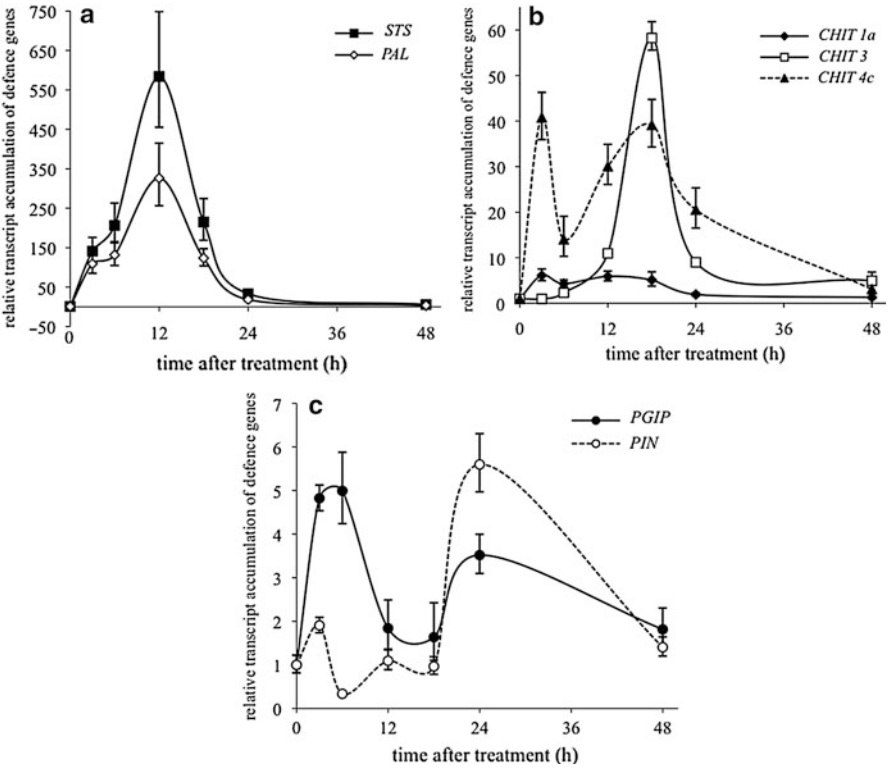

Fig. 1 Transcript accumulation of defense genes in grapevine leaves after treatment by *B. cinerea* extract. Expression profiles of genes encoding (**a**) a phenylalanine ammonia-lyase (*PAL*) and a stilbene synthase (*STS*), (**b**) chitinases (CHIT1a, CHIT3, CHIT4c), (**c**) a serine proteinase inhibitor (*PIN*), and a polygalacturonase-inhibiting protein (*PGIP*). Analyses were performed by RT-qPCR. Levels of transcripts were calculated using the standard curve method from triplicate data, with grapevine actin gene as internal control and no treated leaves (at time zero) as reference sample. Results represent the mean fold increase of mRNA level over no treated leaves, referred as the 1× expression level. In control leaves, the transcript level of defense genes was very low. Results represented are means of triplicate data ± SD of one representative experiment out of three

Bc extract treatment also induced a slight accumulation of polygalacturonase-inhibiting protein (*PGIP*) gene. PGIPs are plant defense proteins which reduce the hydrolytic activity of fungal endopolygalacturonases (PGs), preventing thus plant cell wall degradation and favoring the accumulation of oligogalacturonides (OGs) known to be elicitors of a variety of defense responses (Caprari et al. 1996; Rasul et al. 2012). In *Bc* extract-treated leaves, *PGIP* transcript accumulation increased from 3 h after the treatment with a first maximum (5-fold increase) as soon as 6 h followed by a second peak of lower intensity around 24 h (Fig. 1c).

Inhibitors of serine proteinases (*PIN*) have potent activity against plant and animal pathogens (Van Loon and Van Strien 1999; Revina et al. 2008). The RT-qPCR analysis revealed that the *PIN* gene was up-regulated in grapevine leaves

in response to fungal extract treatment. Accumulation began 5 h after treatment, peaked within 24 h (6-fold increase), and then decreased slowly (Fig. 1c).

3.3 Induction of Phytoalexin Biosynthesis

During the 2 days following *Bc* extract treatment, phytoalexin production in the upper leaves of the plant was monitored. In *V. vinifera*, the best characterized phytoalexins are stilbenes. These phenolic compounds are synthesized by stilbene synthase (STS), which catalyzes the synthesis of resveratrol (3,5,4′-trihydroxystilbene) (Wiese et al. 1994; Schöppner and Kindl 1984; Schröder et al. 1988; Richter et al. 2005). Resveratrol could be metabolized in piceid (glucosylation), viniferins (dimerization), or pterostilbene (methylation) (Bavaresco et al. 2012; Coutos-Thévenot et al. 2001; Pezet et al. 2004a). Identification and quantification of stilbenes were obtained by HPLC with fluorimetric detection, according to calibration curves of pure standards.

The *trans*-form content, which is the main form found in leaves, of five major stilbenic phytoalexins – resveratrol, piceid, ε-viniferin, δ-viniferin, and pterostilbene – was analyzed. Concerning standards, *trans*-resveratrol and *trans*-pterostilbene were purchased, whereas *trans*-piceid (*trans*-resveratrol 3-*O*-β glucoside) was purified from *V. vinifera* L. cell cultures as previously described (Waffo Teguo et al. 1996). *trans*-δ-Viniferin was synthesized by horseradish peroxidase from *trans*-resveratrol (Langcake and Pryce 1977b). *trans*-ε-Viniferin was purified from woody material and characterized by NMR and MS, as previously described (Pezet et al. 2003; Pawlus et al. 2012).

Except piceid, phytoalexins were undetectable in control leaves (Fig. 2a). *B. cinerea* extract treatment of grapevine leaves induced phytoalexin production with different time courses and levels of accumulation (Fig. 2).

Resveratrol was chronologically the first stilbene detected in leaves, 6 h after elicitor treatment. Accumulation of this compound during the 48 h analysis was quantitatively the most important among stilbenes produced. It accumulated transiently, peaked around 14 h after treatment (500 nmol g^{-1} dry weight (DW)), decreased until 24 h, and then remained stable to the end of the analysis (250 nmol g^{-1} DW) (Fig. 2a).

When resveratrol levels began to rise in elicited leaves, the other stilbenes were produced quite at the same time and peaked around 24 h. The level of piceid slowly increased to reach a maximum of approximately 200 nmol g^{-1} DW (fivefold level compared to control leaves) 24 h after treatment and then stabilized at a plateau. Both ε- and δ-viniferin syntheses were induced in elicited leaves. ε-Viniferin appeared earlier (around 6 h) and accumulated quantitatively to higher levels, a maximum around 350 nmol g^{-1} DW for ε-viniferin and 40 nmol g^{-1}DW for δ-viniferin. The levels of δ-viniferin rapidly decreased until 48 h (10 nmol g^{-1}DW), whereas ε-viniferin decreased slower (180 nmol g^{-1}DW at 48 h). Pterostilbene was also detected in treated leaves, but at relatively low levels (10 nmol g^{-1}DW). After reaching a maximum around

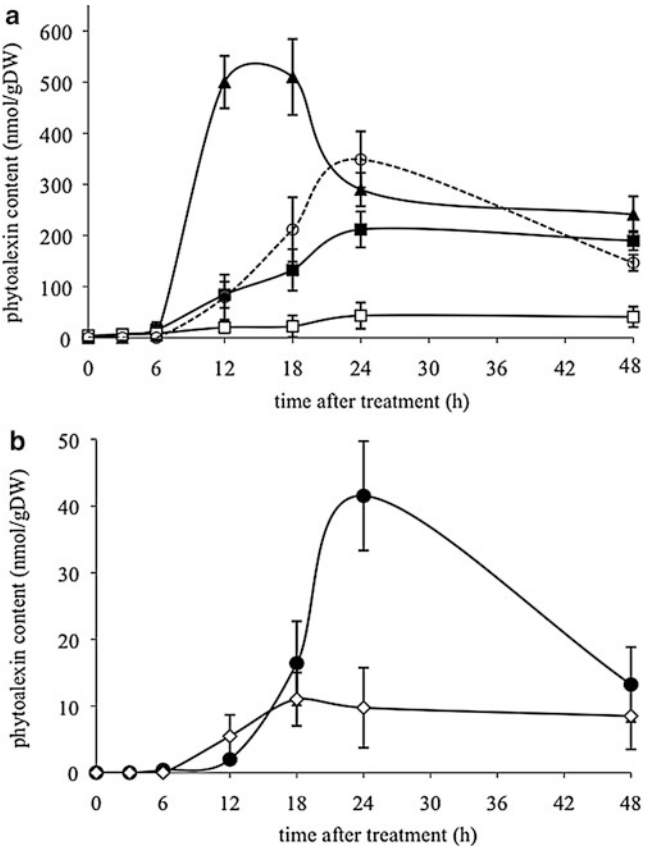

Fig. 2 Time course of several *trans*-stilbenes accumulation in *V. vinifera* (L.) cv. Cabernet Sauvignon leaves in response to *B. cinerea* extract treatment: (**a**) resveratrol (▲), piceid (■), and ε-viniferin (○). (**b**) δ-viniferin (●) and pterostilbene (◊). No stilbene except piceid was detected in untreated leaves (□). Values represent the mean ± SD of triplicate assays of one representative experiment out of three. Stilbenes from leaves were extracted by methanol, then pre-purified on a Sep-Pak® C18 cartridge to remove chlorophylls. Analysis of stilbenes was performed by HPLC on a C18 (5 µm) reverse-phase column (4 mm i.d. × 250 mm). Solvents used for the separation were (**a**) water with 2.5 % TFA and (**b**) 20 % A with 80 % acetonitrile. The elution program at 1 ml/min was as follows: 0–13 min, from 14 % B to 18 % B; 13–15 min, 18 % B; 15–34 min, from 18 % B to 32 % B; 34–36 min, 32 % B; 36–40 min, from 32 % B to 40 % B; 40–49 min, from 40 % B to 80 % B; 49–50 min, from 80 % B to 100 % B; 50–56 min, 100 % B. Fluorimetric detection was recorded at $\lambda_{ex} = 390$ nm and $\lambda_{em} = 300$ nm

20 h, the level of pterostilbene remained constant until the end of the analysis (Fig. 2b).

Forty-eight hours after treatment, the amount of stilbenes in leaves has decreased for resveratrol and ε- and δ-viniferins, compared to the maximal levels they reached during the incubation period, whereas piceid and pterostilbene levels stabilized into a plateau from 24 h to the end of the analysis.

3.4 Protection Against *Plasmopara viticola* and *Erysiphe necator* by Bc Extract

To determine whether our extract induces disease protection in grapevine, *V. vinifera* cv. Cabernet Sauvignon leaves were treated with *Bc* extract.

An aqueous solution of the extract added with a wetting agent to improve penetration into the plant was sprayed on all parts of plants. Two days later, treated leaves were detached from plants and inoculated by *P. viticola* (downy mildew) and *E. necato*r (powdery mildew). As previous authors observed that older leaves from the bottom of the shoots are more resistant (Reuveni 1998), inoculation experiments were performed on young leaves from the upper part of the plant. Disease intensity was estimated 7 and 15 days post-inoculation for downy and powdery mildew, respectively, by measuring the infection rate.

As shown on Fig. 3, the validity of the test was checked according to the results obtained in Aliette® (fosetyl-Al)-treated leaves (3 g L^{-1}). Pretreatment with the fungal elicitor 2 days before inoculation induced a significantly strong reduction of the infection by both fungi, *P. viticola* and *E. necator*. The development of the pathogens was respectively reduced for about 61 and 83 % in leaves of plants pretreated by fungal elicitor extract compared to untreated plants. Aliette® protection rates were almost 100 % against *P. viticola* and about 86 % for *E. necator*.

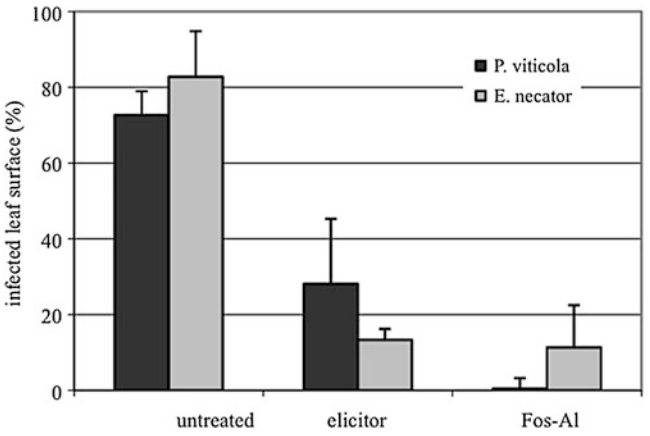

Fig. 3 Protection of grapevine detached leaves pretreated by *B. cinerea* extract against *P. viticola* (*black bars*) or *E. necator* (*gray bars*). Plants were sprayed with Bc extract or the known active Aliette® (fosetyl-Al) 2 days before inoculation, and disease assessment was done 7 days postinoculation for *P. viticola* and 14 days for *E. necator* and expressed as a percent infected leaf surface. Twelve plants were used per treatment. The experience was repeated twice with similar results. Values represent the mean ± SD of triplicate assays of one representative experiment out of two. Disease intensity was estimated by measuring the level of growth and intensity of fungal mycelium and sporulation on leaves. The contamination level was visually evaluated and expressed as percentage of total leaf area according to a 0–100 % scale with steps from 0 to 5 (the note zero corresponding to the absence of pathogen development). The intensity and aspect of spores formation was observed with microscope

4 Discussion and Conclusion

4.1 *Botrytis cinerea* Extract Induces Defense Responses in Grapevine

In *Bc*-treated plants, the expression of two of the three analyzed chitinase genes – *CHIT3* and *CHIT4c* – was rapidly detected after treatment and increased significantly, whereas *CHIT1a* expression remained relatively low during the 48 h incubation period. Indeed, grapevine chitinases are known to be inducible by various biotic stresses but differentially, according to the applied stress, the studied organ, and the grapevine cultivar (Busam et al. 1997; Jacobs et al. 1999; Robert et al. 2002; Aziz et al. 2003). *PGIP* and *PIN* mRNA transcripts accumulated in treated leaves. Levels of *PGIP* have been shown to correlate in several cases with an increased resistance of plants to fungi (De Lorenzo and Ferrari 2002; D'Ovidio et al. 2004; Wang et al. 2013). Increased expression of *PIN* gene was also observed. The prevailing role of serine proteinase inhibitors seems to be the control of endogenous proteinases during seed dormancy and protection against pathogens (Pautot et al. 1991). *PIN* mRNA and protein synthesis accumulation has been shown to occur in tomato leaves after treatment by plant-derived oligogalacturonides and fungal-derived chitosan oligosaccharides (Doares et al. 1995; Akagi et al. 2010).

PAL and *STS* genes were the two most rapidly and intensively up-regulated genes upon *Bc* extract treatment. Indeed, activation of phenylpropanoid metabolism is one of the most important resistance reactions in many plants (Dixon and Paiva 1995; Dixon 2011). In grapevine, previous studies showed that both *PAL* and *STS* genes were induced in leaves infected by *B. cinerea* (Belhadj et al. 2008a; Lambert et al. 2013; Bézier et al. 2002). Moreover, *PAL* and *STS* showed coordinated gene expression.

Consistent with the up-regulation of *PAL* and *STS* genes, we noticed an increased production of resveratrol and its derivatives – piceid, viniferins, and pterostilbene – in leaves of elicited plants. Resveratrol and its dimer ε-viniferin were quantitatively the major stilbenes produced in grapevine leaves in response to the fungal elicitor treatment. This result is in accordance with previous observations made in grapevine treated by biotic elicitors such as laminarin (Lambert et al. 2013; Aziz et al. 2003).

Resveratrol is the primary phytoalexin produced by a stilbene synthase after a stress (Jeandet et al. 2002, 2013). Once resveratrol synthesis began in leaves, consistently with the up-regulation of *STS* gene, its metabolization into the other compounds started. In our experiment, compared kinetics of accumulation of all compounds support the idea that resveratrol is the precursor of the phytoalexin grapevine phytoalexins. Furthermore, the highest resveratrol levels are reached around 12 h, whereas derivatives peaked later, at around 24 h.

The accumulation of ε- and δ-viniferins rapidly occurred in elicited leaves. Both compounds are highly fungitoxic and the presence of both viniferins in stressed

grapevine leaves has been correlated with enhanced protection against downy mildew (Pezet et al. 2004a, 2003, 2004b). The fungitoxic activity of δ-viniferin against zoospores of *P. viticola* is quite similar to the one of pterostilbene, the most toxic known stilbene. Our data showed that this latter compound was also detected in leaves of pretreated plants, even if the amounts seemed low compared to the other analyzed stilbenes. In the majority of grapevine cultivars, pterostilbene levels remain very low or undetectable and few studies reported its presence in response to elicitation. Resveratrol could be also glycosylated as piceid, which is protected from enzymatic oxidation (Regev-Shoshani et al. 2003). In our experiment, the accumulation of piceid was lower to the ones of resveratrol and ε viniferin. This could be explained by the fact that the plant does not need its presence because of its lower fungitoxicity. This stilbene could also represent a form of reserve or transport of resveratrol in the plant (Douillet-Breuil et al. 1999; Belhadj et al. 2008a). If the plant is stressed, the presence of basal piceid levels could constitute a pool of immediately usable resveratrol, which can rapidly be mobilized as a primary defense response.

4.2 *B. cinerea* Extract Treatment Led to an Increased Protection of Grapevine Against Downy and Powdery Mildews

Correlated to the induction of defense-related genes, *Bc* extract treatment of grapevine plants triggered enhanced protection toward two of the most deleterious grapevine fungal diseases. Indeed, pretreatment of plants reduced the development of *P. viticola* and *E. necator* by approximately 61 % and 83 %, respectively, compared to control leaves. In the case of *E. necator*, the protection obtained with *Bc* extract treatment was comparable to the one induced by Aliette®. We observed less difference in the efficiency against both pathogens in Aliette-treated plants than in *Bc* extract-treated ones. This probably could be explained by the fact that fosetyl-Al exhibits at the same time a direct antifungal activity (Dercks and Creasy 1989) and an indirect potentiation of phytoalexin biosynthesis (Adrian et al. 1996).

Bc extract triggers induction of PR genes. Activities of chitinases have been correlated in many grapevine cultivars with their observed field resistance to powdery mildew (Busam et al. 1997; Renault et al. 1996; Giannakis et al. 1998; Nirala et al. 2010), and constitutive accumulation of PR proteins in grape berries after veraison confers increased resistance to fungi such as downy and powdery mildews (Jacobs et al. 1999; Giannakis et al. 1998; Robinson et al. 1997; Tattersall et al. 1997; Salzman et al. 1998; Derckel et al. 1998; Kambiranda et al. 2014).

The protection acquired by grapevine leaves treated by the extract could be due to the up-regulation of *PAL* and *STS* gene expression and the consequent accumulation of the two quantitatively most produced stilbenes, resveratrol and its dimer ε-viniferin. Indeed, a higher tolerance to both powdery and downy mildews was observed in grapevine producing high levels of resveratrol (Dai et al. 1995; Malacarne et al. 2009). ε- and δ-viniferins have been shown to be the major

stilbenes produced in grapevine leaves infected by *P. viticola* (Pezet et al. 2003; Kortekamp and Zyprian 2003) and their synthesis has previously been shown to correlate to grapevine resistance to *B. cinerea* or *P. viticola* (Douillet-Breuil et al. 1999; Pezet et al. 2004a). Moreover, some studies suggest that both *P. viticola* and *E. necator* cannot detoxify resveratrol or suppress phytoalexin production in *Vitis* spp. (Romero-Pérez et al. 2001). In a recent work, Dufour et al. (2013) showed that the treatment of grapevine leaves with benzothiadiazole (BTH) led to a significant reduction in the development of these latter two fungi correlated with a significant increase only in pterostilbene contents (Dufour et al. 2013).

The enhanced tolerance of the treated grapevine leaves could thus be due to both the accumulation of PR proteins and phytoalexins (Belhadj et al. 2006, 2008a; Corio-Costet et al. 2012).

We noticed that the major stilbenes biologically active against pathogens were not present at sufficient levels in our experiments at the moment of the inoculation to counteract pathogen penetration. However, two of the most grapevine-destructive fungi, *P. viticola* and *E. necator*, exhibited a reduced development in treated plants. We can hypothesize that pretreatment of plants with the *Bc* extract certainly triggered a faster and stronger activation of defense responses to subsequent fungal attack as a potentiation.

We have shown the efficiency of an extract derived from *B. cinerea* culture filtrate. This fungal extract certainly contains elicitor compounds: *Bc* extract treatment showed a direct stimulating effect on the expression of defense-related genes which was correlated with the enhanced production of antimicrobial compounds. Consequently, induced plants exhibited a more efficient response to pathogen attack, with highly reduced infection rates. Experiments are in progress with purified fractions of *B. cinerea* filtrate in order to determine which molecules are responsible for the eliciting properties. Exploiting this strategy to control diseases and pests clearly meets with the current need toward sustainable agriculture at a lower environmental cost.

A few oligosaccharide products have been approved in many European countries, in the USA, and in several other countries for their application in agriculture. To our knowledge Iodus^{R} (a laminarin-based product acting as elicitor) approved as plant protection agent against several diseases and Elexa^{R} (a chitosan-based product) available as biological elicitors are the two main used products.

Acknowledgments The authors thank the "Conseil Interprofessionnel des Vins de la Région de Bergerac" for financial support, Mr. Jérôme Jolivet and Mr. Sébastien Gambier for plant care and technical assistance, and Dr. Marc Fermaud and Dr. Pascal Lecomte for scientific advice.

Contents

Abstract

This chapter deals about a carbohydrate polymer highly used as an ingredient in food products and commonly consumed by humans, but very often unnoticed: inulin. The chapter provides an overall view about the inulin, its benefits in human's health, introducing the physical properties, providing a deeper understanding about the relation between its structure and properties, and discussing some technological applications. The chapter is divided into three parts. Section 1 provides an overall view about the inulin and its benefits in human's health and overview some applications. Section 2 introduces the physical properties of inulin,

providing a deeper understanding about the relation between its structure and properties. The importance of the amorphous state in inulin is explained, some undesired characteristics presented during the processing of inulin are revealed, state diagrams are introduced, including a complex state diagram for inulin, and the effect of the polymerization degree on the properties is disused as well. Section 3 presents the technological application of inulin, that is, the performance of inulin in food products; a complex state diagram is presented and discussed for the system inulin-orange juice. In general, the chapter is based on the reviewed literature, which is a very recent research topic, and the presentation of some new experimental results. The aim of the work is to present the inulin in such a way that the reader interested in this topic may recognize this material as a very important ingredient in the formulation of food products. Likewise, the reader who is beginning to learn about this material may realize about the importance of the structure of inulin on the final properties of the food product. Ultimately, the expectation of the authors is that the reader after finishing the chapter be motivated to take a food product from his/her refrigerator and look for the presence of inulin in the nutritional information of the product.

1 Introduction

Inulin is the name given to a heterogeneous blend of fructose polymers found widely distributed in nature as plant storage carbohydrates in more than 30,000 vegetable species. Due to their wide distribution in nature and technological

applications, the extraction, isolation and characterization of this polysaccharide have gained attention in recent years. Inulin is a storage carbohydrate naturally found in plants, vegetables, fruits, and cereals. The chemical and physical properties impart several advantages such as a wide technological adaptability and health benefits in humans. For this reason, inulin is mainly used as ingredient in food products like dairy, bakery, and candies. When inulin is added to the food product, this is converted into a functional product (Glibowski and Pikus 2011), that is, presenting a beneficial selective activity, providing an additional physiological effect to the nutritional value of food components or nutrients. The benefits of inulin are largely related to its chemical structure because the chemical bonds are not hydrolyzed by human digestive enzymes, remaining intact in their journey through the gastrointestinal tract until the colon, where it is totally hydrolyzed and fermented by the bifidobacterium and lactobacillus (Warchol et al. 2002). For this reason, inulin is considered as a prebiotic in addition to contributing in the dietary fiber. The beneficial effect in human's health is related with the improvement of body functions and the decreased risk of disease (Kawai et al. 2011; Silveira et al. 2003).

Among the main plant species from which inulin is produced are chicory root (*Cichorium intybus*), artichoke (*Helianthus tuberosus*), asparagus (*Asparagus officinalis*), American agave (*Agave* spp.), root of dahlia (*Dahlia* spp.), onion (*Allium cepa L*), yacon (*Smallanthus sonchifolius*), and rye (*Secale cereale*). Industrially inulin is mainly extracted from the chicory root because this root contains 79 g of inulin per 100 g of dried material, unlike other species as the root of dahlia and onion containing only 59/100 g and 48/100 g, respectively.

There are no accurate data for the total area harvested with chicory root for the industrial use, however, is possible to estimate the existence of about 120,000,000 m^2 of cultivated land with this specie. Globally, the exportation of inulin is basically dominated by three countries, Belgium, Netherlands, and Chile, with a contribution per country of 50.4 %, 24.1 %, and 18.7 %, respectively. In 2013, these countries together produced 93 % of the total production of inulin in the world.

The main uses of inulin in food industry are as fat substitutes, stabilizer in ice cream, sauces, desserts, and more. It is presented as an odorless withe powder with neutral flavor. The majority of its physical properties are established from a system in the solid state, where molecules have a restricted mobility (Liu et al. 2006). In nature, solids may exist in the crystalline state or in the amorphous (glassy) state. In the former, the molecules or atoms have a long-range order, while in the latter the molecules are accommodated in a disordered fashion or with short-range order. The physical state of inulin, stability, and molecular mobility are closely related to first-order and second-order phase transitions, which in turn depends on the initial arrangement of molecules in the food product. In polysaccharides as inulin, phase transitions play an important role in the physical properties of the employed food product (Kasapis 2006). These phase transitions determine some properties such as the melting of crystals (melting temperature) and the change from the glassy into the rubbery state (glass transition temperature) (Miquel and Hall 2002). Other authors have noted that the most important properties of inulin are its high

thermal stability, resistance to sticking, agglomeration, and crystallization (André et al. 1996; Dan et al. 2009; Glibowski and Pikus 2011; Kawai et al. 2011; Pitarresi et al. 2012; Ronkart et al. 2009; Zimeri and Kokini 2003). These properties are directly influenced by the structure of the polysaccharide, i.e., thermal stability is related to the structure of the molecule, and stickiness, agglomeration, and crystallization are related to the collapse of the structure, defined according to Slade and Levine (1988) as the phenomenon where several time-dependent phase transformations are included. All these properties will be discussed more in detail in the following sections.

2 Physical Properties

2.1 Structure

Fructans are extracted from dicotyledonous and monocotyledonous plants; from the former linear chain, inulin is synthesized, while the latter produces more complex fructans (Barclay et al. 2010). Fructans are natural polymers composed of fructose and derived from sucrose. The length of the polymer chain varies from three to a few hundreds of fructose units. In nature, according to the type of bonding, fructans are classified in five distinct groups: inulin, levans (with bonds β(2-6)), the levan type neoseries, inulin type neoseries, and mixture of branched fructans (Carvalho and Figueredo 2001; Vijn and Smeekens 1999).

Inulin is a mixture of polysaccharides composed of fructose chains linked by β(2-1) bonds with a terminal unit of glucose and fructose chains linked by β(2-1) without a terminal unit of glucose (Fig. 1; Barclay et al. 2010; Franck and De Leenheer 2002). The general formula is represented by

$$GF_n \text{ or } F_n$$

where

G is the terminal glucose unit.
F represents the residue of fructose.
n characterizes the number of fructose units (2–60).

From the chemical point of view, inulin is described as a polyose resulting from the polymeric condensation of fructofuranose (cyclically fructose) monomers linked through a glycosidic bond. In a simpler way, inulin may be defined as a polymer of fructans consisting of chains of fructosyl groups joined by terminal glycosidic bonds. When the reducing end presents a glucose molecule, the structure is named D-glucopyranosyl; when the end molecule is a terminal fructan, the structure is named β-D-fructopyranosyl. Frequently, the linear chains in inulin have a length in the range of 3–60 units of fructose, with a molecular

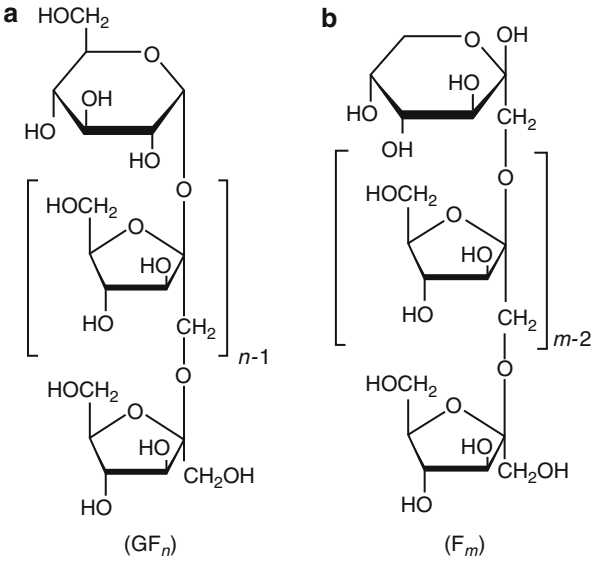

Fig. 1 Structure of inulin

weight in the range of 3,500–5,500 Da (Derycke and Vandamme 1984; Kay and Nottingham 2008).

Inulin is presented in the form of an odorless white powder with neutral flavor. Most of its physical properties are established in the amorphous solid state. This state is reached as the result of several processes such as melting, denaturation, gelatinization, mechanical treatment, solvent removal, and depolymerization of complex structures. Figure 2 depicts a diagram relating the different processes industrially employed to reach the final structure of inulin. The most common processes for reaching the amorphous state are drying, spray drying, freezing, and hot extrusion. In general, a melted material may be converted into an amorphous matrix if the cooling rate is fast enough for avoiding the undesired crystallization (Bhandari and Hartel 2005; Roos 2002). In this sense, Ronkart et al. (2006, 2009) and Zimeri and Kokini (2003) demonstrated that some physical properties such as glass transition temperature, crystallization temperature, and melting temperature are not accurately determined from semicrystalline systems. Table 1 summarizes some physicochemical properties and characteristics observed in inulin.

2.2 Effect of the Degree of Polymerization in Inulin

Microscopically, polymers are comprised of a large number of entangled chains which are conformed of many monomer units chemically bonded by the polymerization process. The length of these chains is not constant through the polymer, which is observed macroscopically as a molecular weight distribution (MWD). MWD may be expressed in different ways depending on the fashion it was determined. The number average molar mass (M_n) and mass average

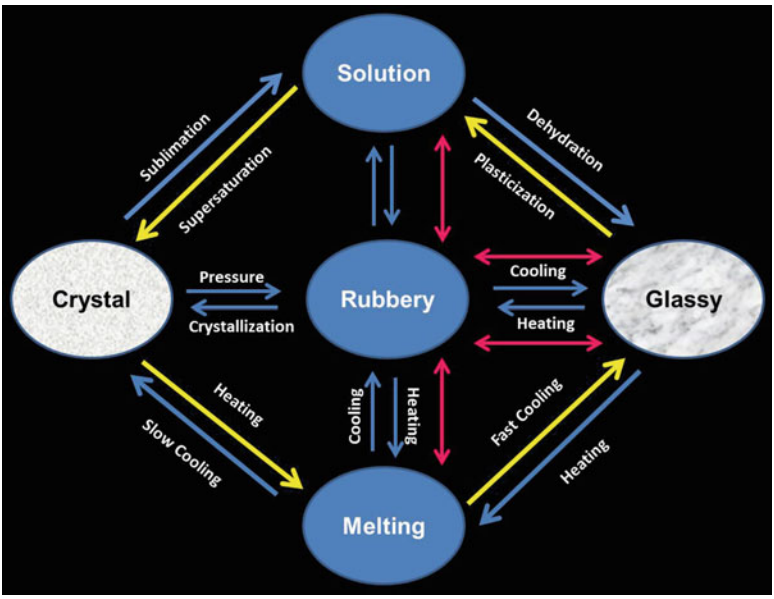

Fig. 2 Mechanism to obtain an amorphous material (Roos and Karel 1991)

Table 1 Physicochemical properties and characteristics of inulin

Properties/characteristic	Value
Appearance	Granular white powder
Flavor	Neutral
Hygroscopicity	High
Range of polymerization degree	2–60 units
Average polymerization degree	12 units
Average molecular weight	5,000 Da
Solubility in water (25 °C)	120 g/L
Viscosity in aqueous solution (5 % w/w and 10 °C)	1.6 mPa.s
Melting temperature (Tm)	165–180 °C
Glass transition temperature (Tg)	125–140°

molar mass (M_w) are the two common average values for describing the molecular mass of a polymer. The former is employed for calculating the degree of polymerization (DP) which is defined as the average number of base units (monomeric units) forming a molecule or chains. Inulin can be characterized according to the molecular size of the chains, i.e., by expressing the DP in terms of the total number of fructose units forming the molecule. The DP strongly influences the final properties of inulin, and it varies according to the type of plant from which the inulin is extracted, the environmental conditions exerted during the farming, and the physiological age of the plant.

In the vegetable origin inulin has been found a maximum DP value of 200 monomers units. Although, inulin from plants was considered only with a linear molecular structure, recently it was found to have a very low percentage of branches (1–2 %) (Franck and De Leenheer 2002; Conceiçáo et al. 2014). Native inulin (NI) is considered as all the powder extracted with an average long chain associated to a DP from 3 to 60 monomer units. Short chain inulin molecules presenting a DP from 1 to 10 monomer units are known as oligofructans (OS). OS are more soluble and sweet than NI and long chain inulin (LCI) and may contribute to increase the mouthfeel because some properties are very similar to those from other sugars. In this sense, OS can be used for replacing sucrose because they possess a similar sweetness profile, but with lower caloric content (1–2 kcal/g) and sweeting powder (30–25 %). In the other hand, LCI is less soluble and more viscous and thermostable than NI. These properties may be used in a beneficial way to improve the sensory properties of dairy products when LCI is used as fat substitute. LCI acts as filler, breaking the structure in the same way with that of fat globules. When mixed and sheared with water or milk, crystals are formed, providing a smooth texture and the creamy sensation of fat in the mouth. Other properties influenced by DP include melting, glass transition temperature, gel formation, and strength (Sobral et al. 2001).

Because inulin is a mixture of polysaccharides, the potential application depends on the distribution size of the fructose units; for example, inulin with a high DP presents a lower solubility in water and higher resistance in the gel form (Mancilla and López 2006). In this regard, only few works have been reported in the literature: Vereyken et al. (2003) found that the presence of fructooligosaccharides (FOS) in plants favors the decrease in the transition temperature from liquid to gel phase. Meyer et al. (2011) evaluated the effect of inulin in nonfat yogurt, finding that after 4 weeks the yogurt with inulin and higher DP FOS presented less syneresis, more water retention, and greater firmness than the control. Nguyen et al. (2005) observed that skim milk supplemented with 1 % of fructan can generate a product with similar sensory attributes with that of a yogurt made of whole milk. Castellanos et al. (2012) indicated that the physical properties of inulin make it unique for a high water retention capacity, synergism in rubbers, and the ability to stabilize foams and emulsions. In addition, the use of inulin as fiber in foods improves the properties of the final product without modifying the production process.

2.3 The Amorphous State of Inulin

Overall, the term amorphous or glassy state is employed for describing those materials showing low molecular mobility, brittleness, high resistance, and transparency. In the fields of polymers physics, the term is referred to a metastable state where molecules have a disordered arrangement, occupying a larger volume than the crystalline state (Roos 1995; Slade and Levine 1988). The structure of the glassy or amorphous solid is described taking as a reference the crystalline structure,

where molecules are well arranged (Liu et al. 2006; Rhaman 2010; Schenz 1995; Yu 2001). Although the general structural arrangement of an amorphous solid is disordered, it may present some short-range ordered regions similar to those found in the crystalline state. Certainly, this mixture of structures may develop different properties from those of the single structures. Because of its high viscosity, amorphous solids show a reduced molecular mobility with limited diffusion phenomena (Rhaman 2010; Ribeiro Santivarangkna et al. 2011; Zimeri and Kokini 2003), where the molecular movements are restricted only to vibrational and short-range rotational displacements (Labuza and Hyman 1998). Then, the alterations occurring in the amorphous state are extremely slow and commonly are observed as the physical aging and changes in the properties as: (i) mechanical and flow properties as elastic modulus and viscosity, both of interest in the texture of food products, and (ii) diffusional properties as diffusivity, on which depend the adsorbed moisture and the crystallization temperature (Roos 1995).

The most important parameter for characterizing an amorphous material is the glass transition temperature (Tg), which is a time-dependent second-order transition. This parameter is the temperature at which the system undergoes in either direction, the transition from the glassy state into the rubbery state. However, glass transition temperature is understood as a state transition rather than a phase transition, and this is because in the metastable nature of the amorphous system, the vitrification process can occur in a wide range of temperatures (Kasapis 2006; Liu et al. 2006; Rhaman 2010). The Tg contributes for the identification, prediction, and control of the stability of food products during the processing and storage. The value has been employed in lipids with different polymorphic forms to differentiate the type of lipid; in proteins it is related to the thermal stability (Bell and Hageman 1996), while in sugars it is the technological base for the processing of amorphous sugars in dairy products (Haque and Roos 2006). In the field of food products, glass transition temperature may be employed for predicting the stability of the products during the processing and storage. In carbohydrate polymers as inulin, glass transition temperature also depends on the concentration of the adsorbed water (Rhaman 2010; Sablani et al. 2010; Sablani et al. 2007; Santivarangkna et al. 2011). In the literature the reported Tg values for amorphous inulin are in the range of 125–140 °C (Kawai et al. 2011; Ronkart et al. 2006, 2009; Saavedra-Leos et al. 2014; Zimeri and Kokini 2003). In these investigations, the first reported results showed X-ray analysis to determine the overall state of inulin at different moisture conditions. Kawai et al. (2011) reported the effect of water content, molecular weight, and crystallinity on the Tg of inulin, emphasizing the importance of knowing the initial state of inulin. In this sense, Saavedra-Leos et al. (2014) reported Tg values for inulin stored at different water contents, finding that for the proper determination of Tg it is necessary to start from the fully amorphous state. The procedure for achieving the desired final state is shown schematically in Fig. 3 and is described as follows: (i) determine the initial state of inulin. If inulin is in the semicrystalline or crystalline state, then the amorphous state must be induced. (ii) Determine the thermal degradation temperature in order to find the maximum temperature supported by the material. (iii) Finally, determine the melting

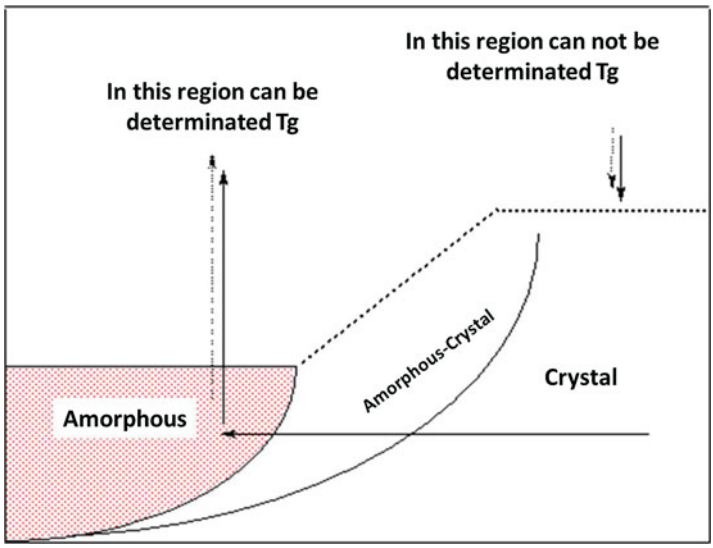

Fig. 3 Diagram of procedure for determining Tg

temperature and glass transition temperature. Following this procedure allows obtaining amorphous inulin powder. Jiang et al. (2008) proposed a method based on calorimetric experiments for determining the Tg of amorphous structures from the melting of crystalline sugars. The method was improved by Saavedra et al. (2011) who employed sugar-rich systems with an initial crystalline structure. As mentioned earlier, inulin is a white powder which apparently looks amorphous. However, X-ray diffraction (XRD) results obtained from Saavedra-Leos et al. (2014) showed that the structure of inulin powder depends on the adsorbed water content and can be either semicrystalline or crystalline. Therefore, for determination of the Tg, the amorphous state in inulin powder must be first induced.

Differential scanning calorimetry (DSC) is a technique widely used for determining phase transitions in organic compounds and food products. The bases of the technique are reported elsewhere. However, if the structure is semicrystalline, Tg may not be determined correctly by this technique. Thus, for the proper determination of Tg, it is necessary to induce the amorphous state according to the procedure shown in Fig. 3. In some reports, DSC has been employed together with a standardized thermal treatment for reaching the amorphous state (Badrinarayanan et al. 2007; Plazek and Bero 2003). Even with the efforts made in this direction, different Tg values have been reported for the same carbohydrate, i.e., for sucrose, a Tg in the range of 60–79 °C is reported. These results are explained in terms of physical or chemical changes exerted on the carbohydrate, which may occur during the thermal treatments (Kalichevsky et al. 1993; Roos 1995). Vanhal and Blond (1999) found that for sucrose, the melting is followed by a decomposition process that starts with the breaking of the glycosidic bond and the further production of glucose and fructose. Unfortunately, the degradation process

is carried out simultaneously during the melting; therefore, the chemical composition of the carbohydrate is varying along the thermal treatment. In this regard, Saavedra et al. (2012) developed a methodology for accurately determining the Tg from mixtures of sugars such as glucose, fructose, and sucrose in the crystalline state. The method consists in preparing an amorphous sugar powder without modifying the chemical composition: (i) the crystalline sugar is heated to the melting temperature (T_1) and kept at this temperature for 2 min. (ii) The sample is rapidly quenched until a temperature of −15 °C (T_2) and held there for 2 min. (iii) The sample is heated again to the temperature (T_3) and the Tg is determined from this heating curve.

For the accurate determination of the Tg, besides the induction of the amorphous state in the sample, it is recommendable to employ the modulated differential scanning calorimetry (MDSC). This technique is similar to DSC but differs in the way the sample is heated. In MDSC the heating is controlled by modulating the temperature amplitude and the period. The advantage from MDSC is the possibility to separate the signals forming the heat flow curve into reversible and nonreversible transitions. This allows to accurately differentiate the events taking place during the heating. For example, in the reversible heat flow curve, the glass transition temperature is observed as the slope of the curve changes, while melting is presented as an inflection point. In the nonreversible heat flow curve, the nonreversible events such as thermal degradation are observed. Recently, Saavedra et al. (2014) employed MDSC and reported accurate values of Tg for inulin and inulin-complex systems stored at different water activities. Among their findings is the observation in the evolution of Tg as water by the systems was adsorbed.

2.4 Undesired Characteristic: Stickiness, Agglomeration, and Crystallization

Stickiness, agglomeration, and caking are three undesired characteristics presented during the processing, handling, and storing of sugar-rich food products. These characteristics are related to the collapsing of the microstructure carried out when the matrix cannot support its own weight, producing radical changes in the macroscopic structure as the decrease of the volume, the stuck of the powder particles, color change, etc. During the collapse, water is released, and as a consequence, the viscosity of the system decreases up to values of 10^{12} (Pa s). Stickiness is defined as the capacity of a material for adhering on a solid surface under the effect of a slight pressure. Again, at the microscopic level there is a competition between the cohesive and attractive forces acting on the sticky material and the solid surface. Cohesion is defined as the attractive forces acting between adjacent particles or molecules in the same matrix; adhesion is the interaction among the surfaces of different bodies. Cohesion is the force responsible for caking and agglomeration of foodstuff powders, while adhesion is responsible for the stickiness presented on the walls of a dryer during the drying process of the powder. Foster et al. (2006) studied the effect of storing time on the cohesion of sucrose, maltose, glucose, galactose,

and fructose powders under environmental controlled conditions of humidity and temperature. They reported that the cohesion of the powders is directly related to the amount of adsorbed water and the glass transition temperature. Likewise, at temperatures above the Tg of the system, agglomeration is promoted because of the formation of liquid bonds inside the powder matrix. Moreover, adhesion which takes place among the drops of liquid and the walls of the drier during the spray drying process was studied by Truong et al. (2005). They reported that some sugar-rich systems behave as hygroscopic thermoplastics which lead to problems of sticking of powder particles on the walls of the dryer. In the case of inulin, Saavedra et al. (2014) showed that the problems of agglomeration and stickiness are presented only when powders were stored at temperature above 60 °C and water activity (a_w) of 0.5. Similarly, they reported the storage conditions for the inulin-orange juice system. The complex system presented agglomeration when stored at temperatures above 45 °C and a_w of 0.2.

The interaction mechanisms between the two surfaces are divided into four groups: intermolecular forces, electrostatic forces, liquid bridges, and solid bridges; all of them are closely dependent on the particle size. If the particle size is smaller than 1 μm, the overall surface area is increased. Then, the attractive forces between the particles are much bigger, observing larger effects of agglomeration and caking in the powder product. The interaction mechanism in stickiness, which is presented during the drying process, corresponds to the liquid bridge. The liquid bridges may be pendulum, funicular, or capillary type. Pendulum type is presented when the liquid is distributed on the solid in a discrete way, forming a mixture of liquid drops and air bubbles. Funicular bonding is similar to pendulum interactions but with air bubbles trapped inside the liquid. In capillary type the liquid is homogeneously distributed on the surface of the solid, creating a continuous liquid phase. Andhikari et al. (2003) studied the stickiness for solutions of fructose and maltodextrin during the drying process. They related the molecular weight with the force required to separate the solution of fructose/maltodextrin from the contact surface. The required force was larger for the fructose than for maltodextrin, because in the former the adhesive interacting forces are larger than the cohesive forces; the opposite was for the maltodextrin. In this sense, inulin is a carbohydrate similar to fructose and maltodextrin with long chain molecules and molecular weight higher than 52 kD. Obón et al. (2009) prepared a powder of red-purple colorant employed as functional food from the juice of *Opuntia stricta*. This powder presented stickiness problems associated to the phenomena of cohesion and adhesion. The solution proposed for this problem was to employ mixtures of inulin or maltodextrin for encapsulating the powder particles while keeping the amorphous state in the fruit juice.

2.5 Phase Stability

Phase stability is related with the structural changes carried out during the processing and storage of food products. For inulin, the study of phase stability is

a very interesting topic because of the potential improving properties on the food product during storage. In this sense, the performance of inulin has been studied as a functional agent in the pharmaceutical and food industries. As functional agent, inulin has been employed as excipient, additive, thickener, emulsifier, gelling agent, sugar and fat substitute, etc. From the point of view of phase stability, the most common problems presented during the handling of amorphous powders are stickiness, agglomeration, crystallization, loss of volatile compounds, and crush (Andhikari et al. 2001; Kay and Nottingham 2008; Khalloufi et al. 2000). Recently, the stability of inulin during the storage has been evaluated and related to the concepts of a_w and Tg, where a_w is expressed as the amount of water adsorbed per 100 g of dried sample. In other works, inulin was analyzed as a model system: Blecker et al. (2003) discussed about the structure, stability, and texture of inulin as a fiber, highlighting the importance of this ingredient in the dietary fiber, fat substitute, and in other applications in the food industry; Kawai et al. (2011) investigated the effect of water content, molecular weight, and crystallinity on the Tg; Zimeri and Kokini (2002) determined the Tg for inulin and inulin-water mixtures at different water contents, finding that Tg increases at low water contents, when inulin is semicrystalline and at high molecular weights; Ronkart et al., (2006, 2009) studied the Tg for inulin with different polymerization degrees, finding that Tg increases with the degree of polymerization. Saavedra et al. (2014) found that, up to a water content of 10 % and water activity of 0.6, the structure of inulin remains stable and without agglomeration; however, at levels higher than 15 % and 0.8, agglomerations were observed. They concluded that inulin was more stable when stored at temperatures lower than its Tg and water content below the monolayer level. Therefore, undesired characteristics such as stickiness, agglomeration, and crystallization, which largely depend on the processing and storage conditions, may be overcome if inulin is kept under those conditions of temperature and humidity.

2.6 State Diagram for Stability of Inulin

In food products, the amount of water adsorbed depends on different characteristics from sample and environmental conditions such as chemical composition, structure, temperature, and relative humidity (Jaya and Das 2009; Roos 1995; Sablani et al. 2010). All of these characteristics and others can be displayed together in a single plot known as state diagram. A state diagram is a graphical representation of the different states observed in a material or mixture of materials at different conditions of temperature, pressure, composition, etc. Thus, in this type of diagram, the final state, i.e., if the structure of the material is amorphous or crystalline, may be predicted for given conditions of temperature and composition. Several authors have reported state diagrams based on Tg and a_w measurements, for systems rich in sugars such as dehydrated fruits and fruit powders (raspberry, blueberry, strawberry, kiwi, grape, tomato, mango, pineapple, apple, etc.): Sá and Sereno 1994; Welti-Chanes et al. 1999; Khalloufi et al. 2000; Bai et al. 2001; Sobral et al. 2001;

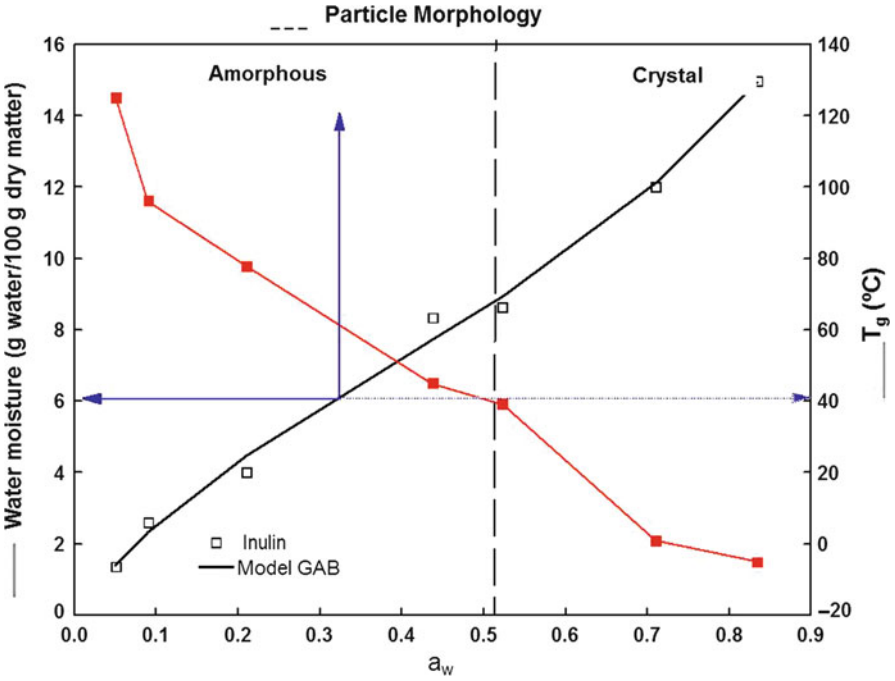

Fig. 4 Diagram for predicting the stability of inulin during storage at different a_w

Telis and Sobral 2001, 2002; Moraga et al. 2004; 2006; Silva et al. 2006; Goula et al. 2008; Wang et al. 2008; Jaya and Das 2009; Fabra et al. 2009; and Tonon et al. 2009. However, for inulin Saavedra-Leos et al. (2014) reported a state diagram including other aspects such as water content, microstructure, and morphology. The data plotted in that diagram provides information for predicting the stability of inulin during storage. Figure 4 presents a state diagram for inulin including the aspects aforementioned. For example, at a (a_w) of 0.31, inulin adsorbed a water content of 6 g of water/100 g of dried material; Tg at these conditions is about 60 °C. This means that inulin will remain in the amorphous state when stored at these conditions of humidity and temperature. On the other hand, if inulin contains an amount of water higher than 8 g of water/100 g of dried material (a_w of 0.523), the powder must be stored below 40 °C in order to avoid crystallization and agglomeration. These results were confirmed by scanning electron microscopy (SEM) and optical microscopy (OM) observations. In Fig. 5 SEM and OM images for inulin at three levels of water activity (a_w = 0.05, 0.523, and 0.71) are presented. In the images the microstructure developed by inulin at the given a_w at room temperature is observed. At a_w of 0.05 and 0.523, the amorphous state is observed in the form of spherical particles of inulin with sizes of about 20 μm in diameter. At a_w of 0.71, the spherical morphology disappeared and inulin is observed agglomerated. In OM images the characteristics of inulin in bulk are observed: powder is observed in white color and the color remains unchanged as

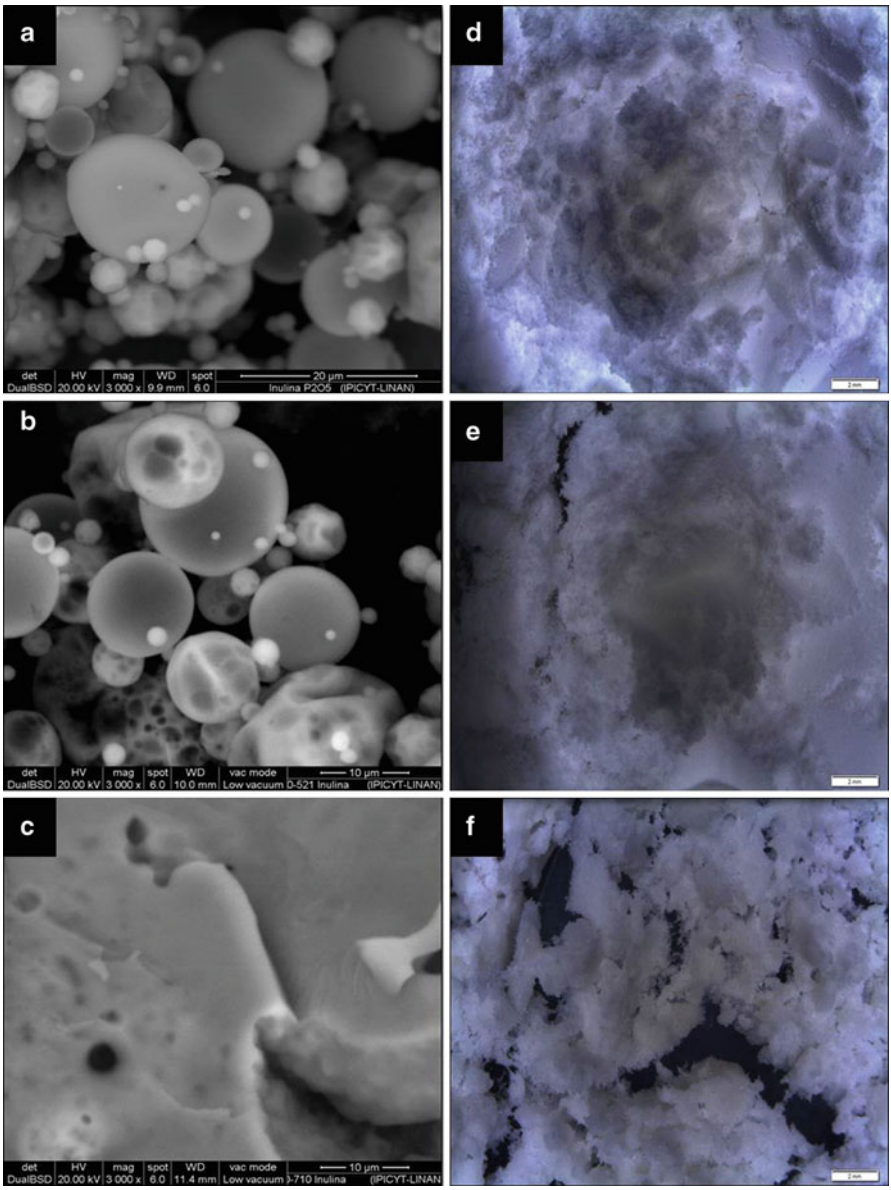

Fig. 5 SEM and OM images from powdered samples of inulin at three water activities corresponding to aw = 0.050, aw = 0.523, and aw = 0.710 and arranged in the figure from *top* to *bottom*, respectively. Images on the *left* column correspond to SEM images (**a**, **c**, and **d**), while those on the *right* side correspond to OM images (**b**, **d**, and **f**)

water adsorbed was increased. However, at this magnification, the only noticeable feature is the morphology of the particles. At low and medium water activities, the particles are randomly accommodated, while at high water activity, particles developed a needlelike morphology. Clearly, state diagrams can be very complex containing much more information measured in the laboratory and are not restricted only to temperature and compositional relationships. As more information is included in the diagram, this will be more useful and thus the physical properties of the material will be easier to predict.

3 Technological Applications of Inulin

From the nutritional and technological points of view, inulin may be considered as an outstanding biopolymer because of its wide range of applications in the pharmaceutical, chemical, and food industries (Franck and De Leenheer 2002). In the pharmaceutical industry, inulin offers a great potential as an excipient material in pills, adjuvant in vaccines, and encapsulating material for a wide variety of bioactive compounds (Rodriguéz et al. 2012). In food industry, inulin is largely employed as an ingredient in healthy food development; this application has been growing because of the benefits offered as natural prebiotic and dietary fiber. However, the interest in this polysaccharide is associated with food technology functions, where it has been employed as stabilizer, fat substitute, and improvement on the texture of food and other applications. In Table 2 some applications where inulin is employed and its functionality in the final food product are summarized.

Inulin represents a renewable resource that can be modified to form novel products, many of which have superior attributes to similar products derived from glucose polysaccharides. Modifications of inulin may expand the amount and type of technological applications because most of these compounds are readily biodegradable. For example, in the chemical industry, modified inulin by different chemistry processes is used as chelating agent and antifouling in pipes, containers, reaction chambers, and separation equipment, among others, or converted into plastic films as a proposed alternative for the substitution of petroleum polymers (Grandther et al. 2005; Kasapis 2006; Verraest et al. 1996).

3.1 Pharmaceutical Applications

The aim of a drug delivery system is to maximize the exposure of a drug into an organ, tissue, or cells requiring treatment. Also it may be used to stabilize labile drugs such as proteins and peptides. This helps to minimize dosage, reducing side effects and cost, while maximizing efficacy and allowing the patients to choose the preferred route of administration, such as oral rather than injected routes. Inulin is generally biochemically inert and nontoxic and can form hydrogels.

Inulin is an ideal vehicle for drug delivery into the colon since the β(2-1) glycosidic linkages are stable to the range of pH and ionic strength observed in

the human gastrointestinal tract, thus avoiding the endogenous enzymatic action of the human digestive system and reaching the colon without reacting. Once there, the glycosidic linkages are broken by the colonic bacteria, releasing the loaded drug directly in the organ. Therefore, while inulin hydrogels might be ideal for drug transport into the colon, the gel swelling characteristics must remain unchanged during the journey inside the digestive system. Hydrogel stability can be increased by modifying the crosslinking conditions, and for inulin polymers this has been achieved through different chemical modifications (Barclay et al. 2010; Kasapis 2006). For example, inulin, inulin acetate, and modified inulin acetate microspheres have been used for the transport of water-soluble model drugs with the modified inulin acetate microspheres being supramolecularly associated with 1,2-dodecanedicarboxylic acid. Encapsulation was similar for all three species, being maximized at 65 %. Drug release was initially quick as the outside of the microspheres. For inulin and inulin acetate, 58–62 % of the drug was released within the first 5 min, whereas for modified inulin acetate, only 32 % was released within the first 15 min. After this time the drug was released slowly by diffusion for approximately 1 day, after which the erosion of the microspheres led to quicker release until complete after 3.5–4 days.

Another application of the inulin in the pharmaceutical area is as a cryoprotectant . In this aspect inulin can be employed in the lyophilization of proteins with for

protecting it from conformational changes and avoiding the loss in its biological activity. In this regard, previous studies have demonstrated that inulin exerts two protective effects: (i) replaces the water that hydrates the proteins and (ii), once the protein is encapsulated within a vitreous structure, prevents its deployment while preserving its morphology and crystallization, inhibiting the kinetics of degradation reactions during storage (Barclay et al. 2010).

3.2 Food Applications

Inulin was first studied as stabilizer by Staffolo et al. (2004), using 1.3 % of inulin fibers for the stabilize bamboo, wheat, and apple in diary medium. They reported a larger stability for the yogurt with inulin fibers than for the control test. The success of this property was observed as the high level of acceptation of yogurts with fiber. The sensory responses were carried out according to a hedonic response, where the texture property was widely accepted in more than 50 % of the individuals surveyed. As fat substitute, inulin has been largely employed in the development of dietary products in the food industry of countries with developed economies, because of the similar features as in fat but without the caloric contribution. The use of inulin as a fat substitute is related with its solubility and degree of polymerization. The solubility is a property utilized in the formation of gels of inulin in dairy products, spreads, dressings, sauces, and meat products, in which functional properties provided by fats are essential to achieve the desired sensory effects by consumers. Inulin gels can be formed by mechanical or thermal effect; those obtained by heat treatments present better texture and firmness. The characteristics of the gel are dependent on the temperature, stirring speed, degree of polymerization, and concentration of inulin. The gel is a three-dimensional network of insoluble particles with sub-micrometric size. Liquid water is immobilized within these particles, which ensures physical stability. When the concentration of inulin in the solution exceeds 15 %, a gel may be formed providing a creamy effect to the product; below this concentration, inulin solutions behave as low viscosity liquids. Since the firmness of the gel is increased with the concentration of inulin, a maximum level of firmness can be achieved by the combination of shear treatments and the addition of seed crystals during the cooling (Kim et al. 2001). Results showed that only the inulin molecules with DP larger than 10 may contribute to the gel, while shorter molecules remain dissolved in the liquid (Staffolo et al. 2004). Chiavaro et al. (2007) studied the ability of commercial LCI for forming gels at 25 °C and 50 °C. They found that inulin composed of oligosaccharides (ICO) gelatinized at concentrations of 30–60 % (w/w), while that with long chains gelatinized at a lower concentration range of 20–40 %. Textural and thermal properties were evaluated during storage at 4 °C. LCI gels showed better behavior, presenting more firmness, adhesion, and less cohesion, than those gels prepared with inulin of heterogeneous composition at a concentration of 40 %. Glibowski and Pikus (2011) evaluated the effect of filtration and the addition of seed crystals on the formation of gels of inulin. They found a larger gel stability for solutions of

inulin passed through large pore filter (>1 mm). Heating the inulin solution at 100 °C by 5 min produces the collapsing of the gel structure or the formation of inulin sediments. However, the addition of seed crystals after the heating treatment promotes the formation of stable gels again. Tseng et al. (2008) studied the influence of LCI and ICO solutions on the thermal and mechanical properties of soy protein gels. The gels containing 8 % (v/v) of LCI showed an improvement larger than 40 % in both the elastic and loss moduli (G′ and G″) with respect to the control test. According to the reviewed literature, the optimal conditions for the formation of stable inulin gels are a concentration of 20–30 % (w/w), a heating temperature of 80–90 °C during 3–5 min, and pH levels between 6 and 8. When inulin is subjected to temperatures higher than 90 °C or to pH levels below 3, inulin chains are hydrolyzed in shorter length chains, avoiding the formation of the gel. At inulin concentrations below 10 %, there is no gel formation either, because the inulin-water system lacks enough inulin particles for forming the three-dimensional network characteristic of the gel.

Regarding the texture of food products, it is important to note that inulin gels present a texture similar to that from fat while giving a desired taste without the caloric intake. Unlike other insoluble fibers that have been used as fat substitute, inulin may be considered as a better option in this application. Besides its neutral flavor, the outstanding property of inulin in this field depends on the immobilization of water molecules during the formation of the gel. The sensory effect produced by the inulin gel during the tasting of the food product causes the sensation of consuming a fatty product. These characteristics allow inulin to be employed in many meat, dairy, and bakery products. In this field, one of the pioneers was Meyer et al. (2011) who employed inulin for modifying the texture of dairy products. They found that the texture of the dairy products tested (fermented milk, kefir, milk drinks, yogurts, desserts, cheese, and ice cream) depends on both the concentration of inulin and the degree of polymerization. Likewise, the addition of LCI in dairy products may affect not only the texture of the product but the rheology. This depends on the interaction of inulin with the other ingredients and solvents presented in the product, especially other carbohydrates and water. The chemical structure of the product and the presence of ingredients such as hydrocolloids may largely affect the rate and degree of crystallization of inulin, which influence its performance as fat substitute. At concentrations higher than 20 % of LCI, in the solution there is a competition between the starch and inulin molecules for the available water: starch can completely gelatinize or inulin can be either fully dissolved or form a gel. The capability of inulin as fat substitute is not only related to the modification on the rheological behavior of the food product but also on other characteristics such as creaminess and smoothness. In general, in products where these two features are desired, it is necessary to employ high concentrations of inulin to achieve the rheological and textural properties showed by the product elaborated with fat. Zahn et al. (2010) evaluated the effect of the full and partial substitutions of fat in the formulation of bakery products (muffins). The results showed that it is possible to replace up to 50 % of the fat required to bake these products.

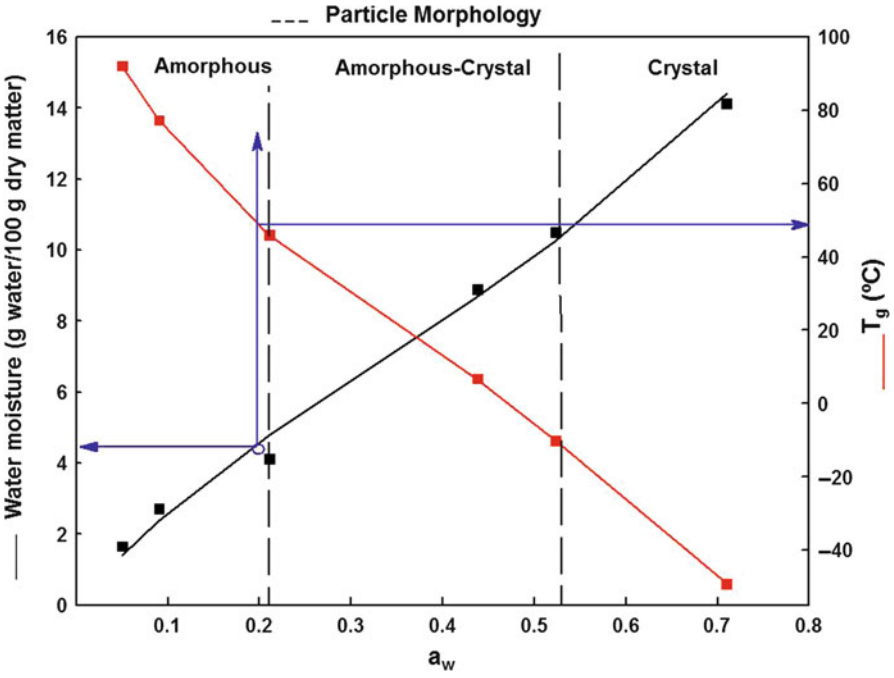

Fig. 6 Diagram for predicting the stability of thr system inulin-orange juice

This fat substitution is equivalent to 45 % of the total fat of the product and reduces the caloric contribution from 13 % to 16 %.

Another application based on the concepts of science and technology was recently reported in literature by Saavedra et al. (2014) who employed inulin for developing a functional food product. The product is a mixture of inulin and orange juice, obtained in the form of a dried powder with an amorphous structure and without sticking problems. The evolution of the properties with the content of water was used as the indicator to set the conservation of the system. They reported a state diagram for the system inulin-orange juice, as that shown in Fig. 6. From the state diagram the optimal storage conditions for the conservation of the amorphous structure were possible to establish: maximum storage temperature of 47 °C, water activity (a_w) below 0.21, and water content below 4.2 g of water per 100 g of dried material. The very first feature observed in this state diagram is the presence of three structures developed by the system: amorphous, semicrystalline, and crystalline. The intermediate structure is a region where both amorphous and crystalline moieties coexist; in the intermediate region, phase transitions have begun producing a physical change in the food product. These zones were established by XRD analysis, SEM, and OM observations at room temperature. The second noticeable feature is the relative position of the curves when compared to the inulin state diagram (shown in Fig. 4). The vertical line separating the

amorphous state from the semicrystalline state has shifted towards the left, thus to lower water activities. Physically, this shift means that the inulin-orange juice powder must be stored under a temperature of 47 °C and with a maximum water content of 4.2 g of water per 100 g of dried material in order to avoid undesired phase transition. The main difference is the amount of water withheld by the systems. While inulin may support approximately 8.8 g of water per 100 g of dried material, inulin-orange juice may withhold only 4.2 g of water. The orange juice is a chemical composition complex system characterized by a high content of low molecular weight sugars (fructose, glucose, and citric acid) which have a wide range of glass transition temperature, from 12 °C to 62 °C (Slade and Levine 1994). The chemical composition of these sugars produces a greater availability of active sites generating more chemical interaction types: van der Waals and hydrogen bonding. Then, water is preferentially adsorbed by the inulin-orange juice system. At the microscopic level, water molecules act as a plasticizer into the polymeric chains of the system intensifying the intermolecular distance and the molecular mobility, which is observed as structural disorder. Macroscopically, this disorder is observed as a decrease in the viscosity of the system and the phase transformation from an amorphous into a crystalline structure.

Another characteristic observed in the state diagram is a small difference in the Tg of both systems, 40 °C and 47 °C for inulin and inulin-orange juice, respectively. Although this small difference in temperatures may be considered as a positive feature for the complex system, it is actually a disadvantage. This is because the slope of the curves is much pronounced for the orange juice complex system than for the inulin. This indicates that small changes in the adsorption of water will require lower storage temperatures. In example, while the inulin system can be stored at a temperature of 40 °C and absorbs water from the environment up to a value of 8.8 g per 100 g of dried material, if the inulin-orange juice powder is stored at 47 °C and water is adsorbed from environment reaching a maximum value of 10.5 g of water per 100 g of dried material, the temperature of the room must be lowered to −9.9 °C in order to avoid crystallization of the powder and product deterioration. Clearly, from the economic point of view, this is a disadvantage for the complex system since it requires more care during handling and storage of the food product. Moreover, higher Tg values means that powders must be stored in warehouses properly conditioned for supporting and maintaining those temperatures. Sugar-rich systems require keeping high room temperatures in order to maintain the product in good conditions. Obviously, this is a dangerous situation for any person handling the powder in a room set at temperatures higher than 35 °C.

As mentioned before, the results were confirmed from SEM and OM observations; these two characterization techniques have the advantages of availability and relative low cost, in industries such as food product companies. Furthermore, the results obtained from these techniques are easy to understand without further interpretation. Figure 7 shows SEM and OM micrographs from the inulin-orange

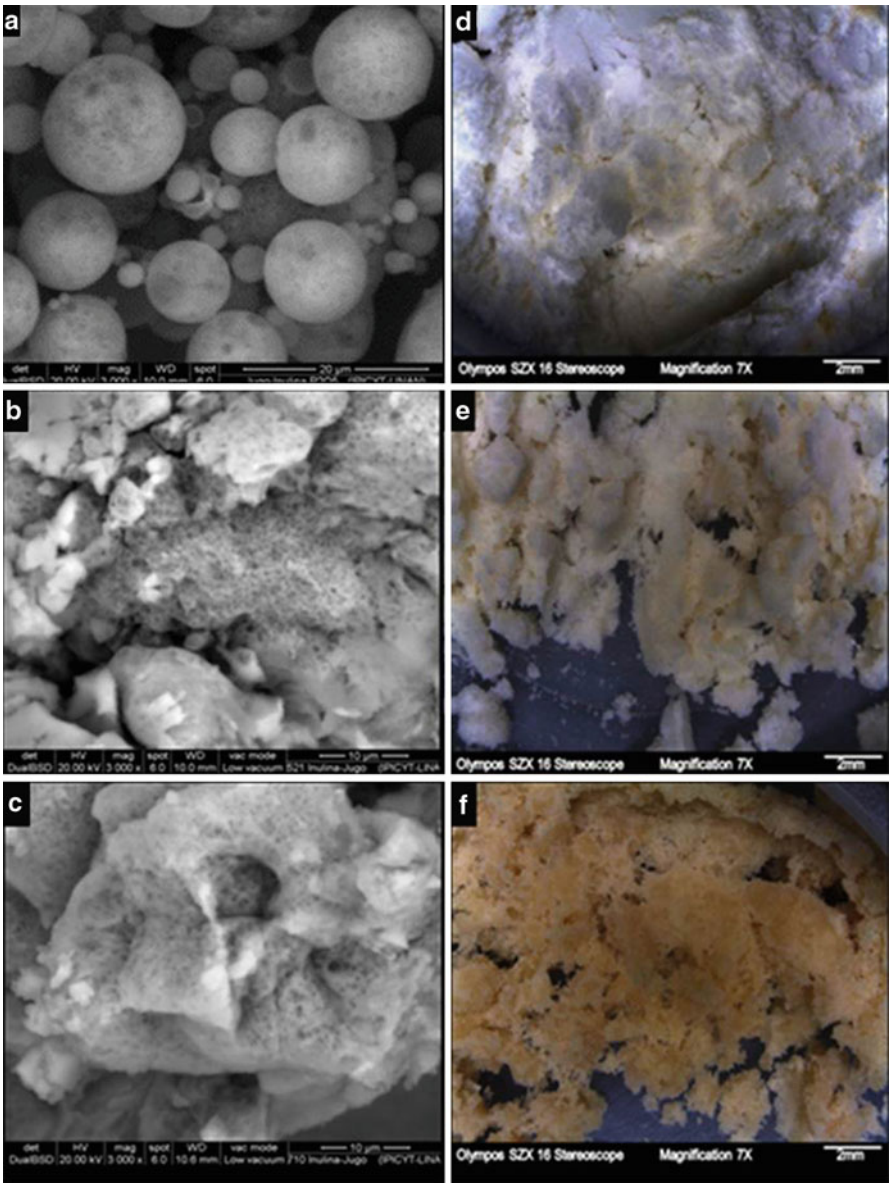

Fig. 7 SEM and OM images from powdered samples of the system inulin-orange juice at three water activities corresponding to aw = 0.050, aw = 0.523, and aw = 0.710 and arranged in the figure from *top* to *bottom*, respectively. Images on the *left* column correspond to SEM images (**a**, **c**, and **d**), while those on the *right* side correspond to OM images (**b**, **d**, and **f**)

juice system. From the SEM images, it is observed that the microstructure of inulin rapidly changes even at low water activities. The well-defined spherical morphology is lost and the material is observed as agglomerated. This effect is magnified at higher water activity. In the OM images another feature is observed: the color of the powder. The inulin-orange juice powder is observed in white color at low water activity. As water adsorption was increased, the color changed to yellowish and later to orange at the major water content. Evidently, these changes are produced by the crystallization of the low molecular weight species content in the orange juice. The overall morphology of the powder also presented a change at these water activities. Morphology was first observed as particles randomly accommodate, i.e., without any specific shape. As orange juice components crystallized in inulin, the morphology changed to needle-shaped particles. These modifications in the microstructure produce an overall appearance that can be easily related to the effect of the orange juice in the system and may help to visually distinguish a crystallized system from an amorphous one.

All the above provides an overview on the applications of inulin; depending on the desired final properties of the food product, inulin may positively affect the performance and in consequence influence the acceptance of the product in the market. Finally, from any point of view, scientific or industrial, this type of information can be very helpful in decision making.

4 Conclusions

Through these pages, inulin a very important natural carbohydrate polymer was reviewed. This polysaccharide is naturally found in a wide variety of plants and is industrially extracted mainly from the chicory root in the form of white, neutral flavor, odorless powder. In the recent decades, scientists and technologists from food, pharmaceutical, and chemical industries have shown great interest in studying the physicochemical properties of inulin to find alternatives in the development of new products. Inulin has a chemical structure mainly made of linear chains of fructose, which imparts very important physical properties. The degree of polymerization largely influences the final properties of the inulin. The application field of this carbohydrate polymer is wide since it can satisfy the requirements from industry related with the development of new products and the needs from consumers related with healthy products. Products formulated with inulin have been well accepted by consumers because the textural, rheological, and sensorial effects are maintained while lowering the caloric ingest in diary, meat, bakery, and candy products. The aim of the work was to provide an overview of the main physical properties of inulin to demonstrate the applicability of this carbohydrate polymer in many products consumed in daily life.

Acknowledgment The technical support provided by Alberto Toxqui-Terán and Miguel Esneider-Alcalá, in the MDSC and OM experiments performed during the development of the state diagrams, is gratefully acknowledged.

Microwave-Assisted Extraction of Polysaccharides

34

Ana Cristina Soria, Laura Ruiz-Aceituno, Lourdes Ramos, and Luz Maria Sanz

Contents

Abstract

In this chapter, the use of microwave irradiation has been reviewed and discussed for the extraction of polysaccharides as well as for combined processes involving extraction and hydrolysis of these compounds. Special attention has been paid to polysaccharides with bioactive properties. Fundamentals and instrumentation, together with a detailed discussion on the effect of the most important parameters affecting the microwave-assisted extraction (MAE) process, are presented. Some of the most recent and outstanding applications of MAE for the extraction of polysaccharides, mainly from food matrices or food by-products, are described and classified according to the type of polysaccharide extracted. The comparison in terms of speed, yield, etc. of MAE with other conventional (solid–liquid extraction) or emerging techniques

(pressurized liquid extraction, ultrasound-assisted extraction) is also shown. The scale-up of MAE technique and the development of hybrid systems (e.g., ultrasonic–microwave-assisted extraction, UMAE) are shown as future trends. To conclude, MAE is shown as a promising emerging technique for extraction of polysaccharides from natural sources.

Microwave-assisted extraction (MAE) • Pectins • Galactomannans • Arabinogalactans • Xylans • Sulfated polysaccharides • Optimization

1 Introduction

Different bioactivities (immunostimulatory, prebiotic, antioxidant...) and technological functionalities (emulsifying, gelling...) have been attributed to polysaccharides (Simões et al. 2009; Zeng et al. 2012; Holck et al. 2014), as mentioned in previous chapters.

Extraction of these compounds from plant and food sources has attracted a great deal of interest with a view to provide natural extracts rich in bioactive ingredients of potential application, among others, in the food industry. It is also known that the composition of extracts and their bioactivity are widely dependent on the extraction technique and experimental conditions used. Conventional treatments based on sequential acid or basic extraction processes have been commonly used for polysaccharide extraction. However, these methods are time-consuming, and yields and purity of the final extract are relatively low. Therefore, there is a wide interest in the search for faster and more efficient alternative methods for the extraction of these compounds. In this sense, different emerging techniques such as microwave-assisted extraction (MAE), pressurized liquid extraction (PLE), and ultrasound-assisted extraction (UAE) have been described (Meireles 2009).

In this chapter, MAE will be evaluated as it generally provides mild extraction conditions, extracts of high purity with high yields of extraction, short processing times, low production cost and waste generation, etc. (Wang and Weller 2006). In addition to an overview of fundamentals and mechanisms of MAE, the characteristics of the most common instrumentation used for polysaccharide extraction and the effect of the main variables affecting the MAE process will be discussed in detail. Some of the most recent applications regarding the extraction of polysaccharides, mostly from foods and food by-products, will be described. Extractions from other biological matrices will also be mentioned in specific cases. For concluding, advantages and disadvantages of this technique and future perspectives will be discussed.

2 Fundamentals

2.1 Operation Mechanism

Microwave (MW) energy is a nonionizing type of electromagnetic radiation with wavelengths typically in the 1 mm to 1 m range, corresponding to 0.3–300 GHz. Nevertheless, most of the commercialized instruments, both for domestic and industrial application, operate at fixed frequencies (typically, 2.45 GHz).

The application of microwaves to a medium promotes the electrophoretic migration of ions following the electric field produced by the microwave (Nadagouda et al. 2011). The direction of the ions changes as many times as the field changes its sign. The resistance of the medium to the ionic migration generates heat as a result of collision between molecules. At the same time, dipolar molecules attempt to align with the electric field. The promoted phenomenon of alignment, randomization, and realignment of the dipoles leads to collisions between them and the surrounding molecules, which generates energy and increases the medium temperature. In general, ionic conduction and dipole rotation occur simultaneously and change microwave energy into thermal one (Zhang et al. 2011), resulting in an almost immediate heating up of the sample.

The mechanism through which the microwave energy is absorbed is consequently not unique and depends on the nature of the considered substance. Thus, molecules that do not have a dipole moment (or in which a dipole moment cannot be induced) cannot be directly heated by microwaves. Gases cannot be heated by this energy either due to the large distances existing in between molecules. However, when applied to solid or dissolved samples, microwave energy is directly absorbed by the medium in which the molecules are imbibed. This is the reason why this form of energy results in a more efficient source of heating than any other conventional thermal heating procedure, in which the walls of the container are primarily heated and heat is then transferred to the sample. The fact that the microwaves penetrate uniformly throughout the volume of the product (liquid, suspension, or semisolid) being heated is usually referred to as microwave volumetric heating (MVH).

Materials can be classified on the basis of their ability to absorb microwave energy as: conductors, whose surfaces reflect microwaves (e.g., metals); insulators, which are transparent to this energy and can be used to support the materials to be heated (e.g., plastic); and dielectrics, which absorb the microwaves and are easily heated (e.g., polar liquids).

In general, the capability of molecules to absorb microwave energy increases as their dielectric constant (ε') does, which in turn results in a faster solvent heating and extraction at higher temperatures. Nevertheless, solvents with low dielectric constants can also be used for MAE. In this type of approach, microwaves are absorbed by the matrix promoting internal heating, which results in cell structure disruption by expansion. The target compound is then liberated to the cool medium.

This procedure has been proved to be useful, for example, for the extraction of thermolabile nonpolar compounds into transparent solvents (Eskilsson and Björklund 2000; Romanik et al. 2007). However, in most applications, polar or mixtures of nonpolar−polar solvents are used as extractants. Table 1 summarizes relevant physical constants for selected solvents commonly used in MW extraction.

The dielectric constant of a solvent can be considered as an indication of its capacity to be polarized in an electric field. However, the so-called dielectric loss (ε''), a measure of the efficiency of the solvent to dissipate the absorbed microwave energy into heat, should also be considered. The ratio between these two values is the dissipation factor ($\ln \delta = \varepsilon''/\varepsilon'$) and determines the efficiency of the extraction process. As previously indicated, polar solvents and ionic solutions absorb microwave energy strongly due to the presence of permanent dipoles, whereas nonpolar solvents, such as hexane, are not really indicated for use in MAE, unless they are mixed with a polar solvent (Table 1). On the basis of their dielectric constant, water has higher ability to obstruct the microwaves as they pass through than, for instance, methanol and, thereby, it will improve microwave penetration. However, methanol has higher ability than water to dissipate the microwave energy as heat (Eskilsson and Björklund 2000). According to these considerations, heterogeneous samples or mixtures containing species with different dielectric properties dispersed into a homogeneous medium will have different capability to absorb microwaves at different points of the mixture. This can result in selective heating of specific components or sample areas. This phenomenon is called superheating (Baghurst and Mingos 1992) and has been exploited, for instance, in the extraction of nonpolar analytes into transparent solvents (Vetter et al. 1999; Hummert et al. 1996).

Table 1 Physical constants and dissipation factors for some solvents commonly used in MAE

Solvent	Dielectric constant[a], ε'	Dipole moment[b]	Dissipation factor, tan δ ($\times 10^{-4}$)	Boiling point[c] (°C)	Closed-vessel temperature[d] (°C)
Acetone	20.7			56	164
Acetonitrile	37.5			82	194
Ethanol	24.3	1.96	2,500	78	164
Hexane	1.89			69	–[e]
Methanol	32.6	2.87	6,400	65	151
2-Propanol	19.9	1.66	6,700	82	145
Water	78.3	2.3	1,570	100	
Acetone–hexane (1:1, v/v)				52	156

2.2 Instrumentation

At present, two types of microwave heating systems are commercially available at laboratory scale: open- and closed-vessel systems (Fig. 1). The former, also named as focused microwave-assisted solvent extraction (FMASE) system, uses open extraction vessels under atmospheric conditions. Consequently, their maximum operation temperature is the solvent boiling point at atmospheric pressure and is frequently refluxed to prevent solvent evaporation. In this type of systems, irradiation is continuous, power can be regulated, and up to eight samples can be simultaneously processed in glass or quart vessels (Milestone 2007). These instruments have been mainly used for the extraction of organometallic compounds (Takeuchi et al. 2008).

Closed MAE systems operate with closed extraction vessels, which allow the use of temperatures above the boiling point of the solvent [up to three folds higher under superheating conditions (Takeuchi et al. 2008)] without a significant solvent evaporation. This high operation temperature frequently results in high extraction efficiencies in short times and with minimum solvent consumption. In these instruments, the temperature and the pressure inside the vessel are typically controlled in only one out of the 4–48 cells that can be simultaneously processed. This makes mandatory that all samples are identical in terms of solvent nature and solid–liquid ratio (SLR). Alternatively, systems provided with infrared sensors are also commercially available for monitoring of the temperature in every extraction vessel. All these MAE systems allow setting different powers and modification of irradiation cycles in a multimode cavity equipped with a turntable that rotates for improved irradiation homogeneity. Due to their advantageous features, these systems are the most profusely used in all application fields.

The basic setup for closed-vessel MAE consists of a magnetron tube (although systems with sequential magnetrons to help fine-tune and maximize MW power are also available), an oven where the extraction vessels are placed upon a rotating

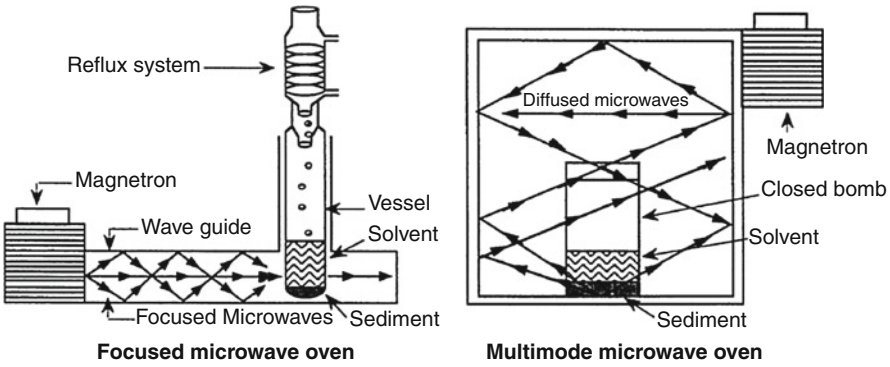

Fig. 1 Schematic view of focused microwave oven and multimode microwave oven (Reprinted from Letellier and Budzinski (1999), with permission of EDP Sciences)

carrousel, and different temperature and pressure sensors. In addition, a number of electronics and safety features can be included, such as a solvent vapor sensor which constantly monitors the cavity to detect solvent leakages, a chamber located in the center of the carrousel and connected to each vessel for vapor collection in the event of solvent leakage, an exhaust fan in the oven, extra oven isolators, and a movable door to release the pressure inside the instrument cavity. Other safety accessories are rupture membranes for the extraction vessels that burst at pressures above 200 psi or resealable vessels that open and close rapidly to prevent over-pressure inside the extraction cells. Vessels are typically made of microwave transparent materials, such as glass and a variety of plastics (polyether imide, tetrafluoromethoxyl, Teflon®, etc.); their selection is usually conditioned by the extractants and the pressure and temperature used during the MAE process. In most models, magnetic stirring is feasible for improved and rapid homogenization of the extraction medium temperature.

A typical MAE experiment consists of loading of the homogenized and, when required, pretreated sample into the extraction vessel, followed by solvent addition and closing of the vessel. Once the vessels are installed in the carrousel, microwave irradiation starts with a short pre-extraction step that allows heating of the solvent at a selected temperature. The duration of this step (typically a few minutes) depends on the set value, the power applied, as well as the type and number of samples. Then, the sample is irradiated for a preselected time under some specific power conditions. Once the MAE step is completed, vessels are allowed to cool down to room temperature before proceeding with solvent and sample separation and, when required, further cleanup and/or concentration of the extracts.

2.3 Parameters Affecting MAE Efficiency

The solvent nature and volume, the extraction temperature and time, and the raw material humidity and polarity have commonly been identified as the most relevant parameters affecting the MAE process. Due to the mutual dependence among some of these parameters, in general, the optimization of the experimental extraction conditions is addressed by using experimental design approaches (Prakash Maran et al. 2013; Rodriguez-Jasso et al. 2011).

This section provides a brief discussion on the effect of some of the most important variables influencing the MAE process in closed-vessel systems, as these setups are the most frequently used for the extraction of polysaccharides.

Solvent nature. The solvent composition has a profound effect on the efficiency of the MAE process. When selecting the extraction solvent for a given application, not only the dielectric properties of the solvent (or mixture of solvents) selected but also the interaction of the extraction solvent with the investigated matrix and the analyte solubility on the solvent should be considered (Eskilsson and Björklund 2000).

Three types of solvents can be used in MAE (Jassie et al. 1997): (i) a solvent (or mixture of solvents) that absorbs microwaves strongly, (ii) a mixture containing

solvents with high and low dielectric losses, and (iii) microwave transparent solvent(s). The former case includes the use of polar organic solvents, water and acidic water mixtures, as well as novel green solvents, such as ionic solvents (Guolin et al. 2012). In all instances, it is the solvent which absorbs the microwave energy so its capability to wet (i.e., penetrate) and/or dissolve the matrix should be taken into consideration to improve the selectivity of the MAE step and to avoid any possible readsorption of the extracted analytes in (previously dissolved) matrix components during the cooling step. The second category of solvents corresponds to mixtures containing variable percentages of polar and nonpolar organic solvents such as acetone–hexane (1:1, v/v) mixture. Alternatively, the use of microwave transparent solvents modified with a relatively small amount of water (typically 10 %) has also been proposed in the literature. As mentioned above, this third possibility takes advance of the so-called superheating phenomenon and performs well with matrices having a high dielectric loss (and with, for instance, a high water content) but results in the destruction of the plant structures. The efficiency of this approach for the MAE of natural products such as essential oils has been illustrated in a number of application studies (Jocelyn Paré et al. 1994).

Finally, in the solvent-free microwave extraction (SFME), the internal heating of the water within the sample, as no additional solvent or water is required, distends the cells and leads to rupture of the glands and oleiferous receptacles of the plant. This process gives rise to the rapid extraction of essential oils from aromatic herbs, spices, and dry seeds (Mircioaga and Calinescu 2011).

Solvent volume. The solvent volume must be sufficient to ensure complete sample immersion. In this sense, special caution should be taken with matrices that swell during the extraction process. Typical solvent volumes used for the extraction are in the 10–30 mL range per gram of analyzed sample (Table 2). Unlike conventional extraction techniques where the higher the volume the higher the recoveries, in MAE, increasing the solvent volume may result in lower recoveries (Prakash Maran et al. 2013). The higher difficulty for homogeneous heat dissipation in the extraction medium as the solvent volume increases has been suggested as a possible explanation for this type of observation (Eskilsson et al. 1999). In such a case, stirring could be considered an appropriate solution to the problem. In this way, according to previous considerations, it looks evident that in MAE the SLR could be a more adequate variable to be considered during method optimization than the solvent volume itself.

Extraction temperature. As in any other extraction technique, the temperature is a key factor affecting the MAE efficiency. In general, an increase of the operation temperature reduces the surface tension and viscosity of the extraction solvent thus increasing its diffusivity into the sample matrix and improving its capacity to dissolve analytes. All together leads to improve the extraction efficiencies and, consequently, to shorten the analytical times. When MAE is performed in closed vessels, temperatures above the atmospheric boiling point of the solvent are frequently applied. Although this can be advantageous from the extraction yield point of view, it can also cause the degradation of thermolabile compounds. In practice, the optimal extraction temperature will depend on the nature of the extraction

Table 2 Some of the most recent applications of MAE of polysaccharides

Polysaccharide	Source	Solvent	Optimal MAE conditions	Yields (%, w/w)	Reference
Pectin	Grapefruit peel	Acidulated water	900 W; SLR[a]: 1:50; pH 1.5; 6 min	26.27	Bagherian et al. 2011
	Lemon peel	Ionic liquids in water	88.4 °C; SLR: 1:15; 9.63 min	25.10	Guolin et al. 2012
	Orange peel	Acidulated water	422 W; SLR: 1:16.9; pH 1.4; 2.81 min	19.24	Prakash Maran et al. 2013
	Sugar beet pulp	Acidulated water	152.63 W; SLR: 1:18.92; pH 1.57; 3.53 min	32.4	Li et al. 2012
	Berries	Water	50–700 W; SLR: 1:10; pH 3.2–4.5; 30 min	59.4–83.7	Bélafi-Bakó et al. 2012
	Citrullus lanatus	Acidulated water	477 W; SLR: 1:20.3; pH 1.52; 2.13 min	25.79	Prakash Maran et al. 2014
	Lime flavedo, albedo, and pulp	Acidulated water	630 W; SLR: 1:25; pH 2; 3 min	14.6	Fishman et al. 2006
	Apple pomace	Acidulated water	499.4 W; SLR: 1:14.49; pH 1.01; 20.8 min	15.75	Wang et al. 2007
	Pumpkin flesh	Acidulated water	60/80 °C; 20/10 min; pH 1.0	11.3	Yoo et al. 2012
	Pericarpium granati	30 % polyethylene glycol with MW 400 Da	Ultrasonic–microwave-assisted extraction (UMAE): US (240 W); MW (365 W); 90 °C; 10 min; SLR: 1:20	7.94	Zhou et al. 2014
Galactomannans and arabinogalactans	Spent coffee grounds	Water	900 W; 200 °C; 5 min; 16 bar; SLR: 1:10; 2 MAE cycles	42 (mannose: 66 %)	Passos and Coimbra 2013
	Spent coffee grounds	Water	900 W; 200 °C; 5 min; 16 bar; SLR: 1:30; 5 MAE cycles	82 (mannose: 69 %)	Passos et al. 2014

Arabinoxylans	Brewers' spent grains (barley husks)	Water/ water/ 0.1 M KOH	3 MAE cycles; 140 °C; 2 min; 180 °C; 2 min; 180 °C; 2 min; SLR: 1:6	62	Coelho et al. 2014
	Wheat bran	4 % (wt) NaOH	110 W; 10 min; SLR: 1:10	60	Panthapulakkal et al. 2013
Arabinoglucuronoxylans	Corn fiber	Water	180 °C; 7 min; SLR: 1:20	20	Benkő et al. 2007
Inulin	*Cynara scolymus* bracts	Water	120 °C; 3 min; SLR: 1:33	11.4	Ruiz-Aceituno et al. (2014)
Fucoidan	*Fucus vesiculosus*	Water	120 psi; 1 min; SLR: 1:25	18.22	Rodriguez-Jasso et al. 2011
Carrageenan	*Hypnea musciformis*	Water	85 °C; 10 min; SLR: 1:50	22.7	Vázquez-Delfín et al. 2014

[a]*SLR* solid–liquid ratio (g mL^{-1})

solvent, the raw sample properties (e.g., polarity, water content, and swelling capability), and the thermal stability of the target compounds.

Extraction pressure. Pressure is a relevant parameter to be considered when MAE is performed in closed vessels. In these systems, elevated pressures are typically applied to ensure that the extraction solvent is kept as a liquid at the high extraction temperatures reached during the extraction step. High pressures also improve solvent penetration into the sample, which facilitates the desorption of the analyte from the active sites of the matrix. Due to the direct relationship existing between these two parameters in MAE, temperature is the variable most commonly considered during method optimization. However, in instruments without temperature control, pressure in the vessel can be optimized instead (Eskilsson and Björklund 2000).

Extraction time. As compared to conventional heating extraction techniques, MAE involves much shorter extraction times (typically in the 3–30 min range for food matrices). In instruments operating at a fixed irradiation power, the time required for quantitative analyte extraction depends on the nature of both the extraction solvent and the sample nature, as well as on the type of targeted compounds. In MAE systems with separate irradiation power control, the influence of this parameter on the extraction yield and its relationship with the extraction time should be considered during method optimization. In any case, for thermolabile compounds, one should consider that long extraction times (as well as high irradiation powers) can result in analyte degradation.

Irradiation power. The selection of the irradiation power is governed by the number of extraction vessels simultaneously processed. Power should be chosen to minimize the extraction time while avoiding solvent projections and degradation of thermolabile analytes. The possibility of system leaks at relatively high irradiation powers (Eskilsson and Björklund 2000) should also be considered when optimizing this experimental parameter.

3 Applications to Polysaccharide Extraction

Extraction temperature and time and SLR are the most common parameters considered for the optimization of MAE of polysaccharides (Prakash Maran et al. 2013). Depending on the nature of the considered polysaccharide, solvent pH is also occasionally selected as a variable in experimental designs aimed to the optimization of experimental conditions. In addition to the effect that the operating conditions play on extraction yield, they also affect the possibility and extent of other phenomena such as depolymerization of polysaccharides that can also take place along the extraction process (Holck et al. 2014). Because bioactivity of polysaccharides usually depends on their molecular weight and their monomeric composition, a trade-off between the extracted amount and the structural composition is usually aimed during the extraction processes.

Before MAE of polysaccharides, samples are usually dried either in convection ovens (45–60 °C; (Bagherian et al. 2011; Li et al. 2012; Prakash Maran et al. 2013;

Panthapulakkal et al. 2013) until constant weight or freeze-dried, ground, and sieved to obtain powdered samples. In some cases, samples are subjected to different pretreatments to enhance extraction efficiency. For instance, sugar beet pulp was bleached at 95 °C for 5 min (Li et al. 2012), pumpkin flesh powder was treated with 0.1 N HCl (pH 1.0) at 25 °C for 1 h (Yoo et al. 2012), birchwood powder was treated with 0.05 M HCl at 70 °C for 2 h followed by a treatment with 14 M NH_4OH (Panthapulakkal et al. 2013), etc.

Although MAE has been applied for the extraction of polysaccharides with a variety of structures, most works have focused on the extraction of pectins and xylans from fruits and cereals, respectively. Table 2 summarizes some of the most recent applications of this technique for extraction of polysaccharides from different matrices. The approaches followed will be discussed in the subsequent subsections according to the type of polysaccharide extracted.

3.1 Pectins

Polysaccharides from fruits and vegetables are mainly pectins consisting of homogalacturonan and rhamnogalacturonan I (RGI) that forms the backbone with arabinan, galactan, and arabinogalactan neutral sugar side chains attached to rhamnose in RGI regions (Holck et al. 2014). Although commercial pectins are extracted from apple pomace and citrus peel, new potential sources such as sugar beet pulp, berries, etc. have been recently investigated for extraction of these polysaccharides (Li et al. 2012; Bélafi-Bakó et al. 2012).

MAE can be applied for fast and low exposure to harsh extraction conditions of pectins (Holck et al. 2014). In general, pectin extraction efficiency is improved by raising microwave power. Microwave radiation loosens the cell wall of plant material and the skin tissues are opened (Kratchanova et al. 2004; Prakash Maran et al. 2014). Therefore, the extracting agent can easily interact with the matrix to extract the pectins.

Irradiation time should be also carefully selected, as an increase of this parameter can help the extraction but an excessive time exposure can give rise to the degradation of pectins (Prakash Maran et al. 2014). These effects are shown in Fig. 2a where maximum yield of pectins from orange peel was achieved at the highest microwave power assayed (480 W) for 125 s; above this time yield decreased (Prakash Maran et al. 2013).

As previously mentioned, both the SLR and the nature of the solvent are important variables to achieve an efficient extraction. Pectin yield increases with solvent volume up to the solution gets saturated, which negatively affects the mass transfer rate into the solution (Prakash Maran et al. 2013).

Some experiments have demonstrated that pectin could not be extracted by MAE under pressure using pure water as solvent (Fishman et al. 2006), and consequently, pectin extraction is usually carried out using acidulated water (pH adjusted to 1.4–1.5 with 0.1 N HCl or H_2SO_4) (Bagherian et al. 2011; Li et al. 2012). Acidic conditions can promote the hydrolysis of insoluble pectin constituents into soluble

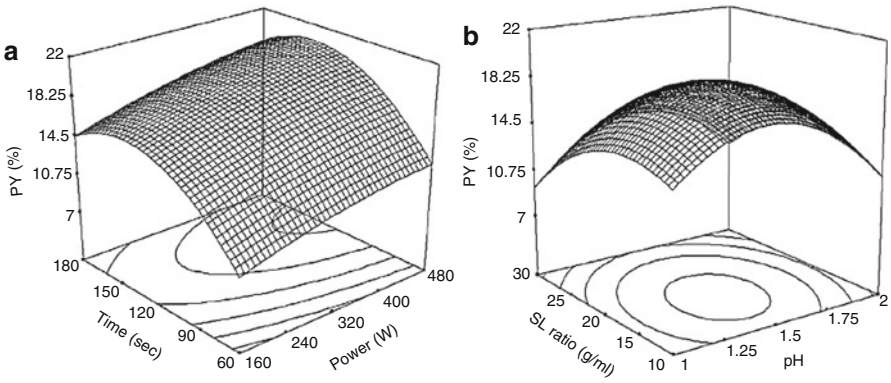

Fig. 2 Effect of irradiation time and microwave power (**a**) and solvent pH and solid–liquid ratio (**b**) on the extraction yields of pectins (PY) from orange peel (Reprinted from Prakash Maran et al. (2013). Copyright (2013), with permission from Elsevier)

pectin, increasing its recovery (El-Nawawi and Shehata 1988; Prakash Maran et al. 2013). However, as shown by Prakash Maran et al. (2013), above pH 1.5 pectin aggregation can take place, delaying its release and decreasing yields (see Fig. 2b as an example). Acidic conditions have been also proposed to obtain good galacturonic acid yields (Buchholt et al. 2004), whereas alkaline conditions have been used in order to achieve high yields of arabinan side chains. These extraction conditions have been combined with chelating agents for preservation of ferulic acid units of pectins (Holck et al. 2014).

The use of ionic liquids (ILs) as extracting agents in MW processes has recently been suggested (Guolin et al. 2012). ILs are low-melting-point salts that exist in liquid phase at relatively low temperatures (generally speaking, below 150 °C) and possess unique and attractive properties such as low volatility, variable viscosity, chemical and thermal stability, and tunable solubility properties, among others (Ruiz-Aceituno et al. 2013). Guolin et al. (2012) assayed different concentrations of IL solutions ([BMIM][Br], [BMIM][Cl], [EMIM][Br], [BMIM][BF_4], and [AMIM][Cl] in distilled water) for pectin extraction. The highest yield (25.1 %) was achieved using 1.0 mol L^{-1} [BMIM][Cl] under optimal conditions (88.36 °C, 9.63 min, SLR: 1:15 w/v). Recently, the use of aqueous polyethylene glycol solutions has also been proposed for the extraction of polysaccharides from *Pericarpium granati* (Zhou et al. 2014). Although yields were not notably high, this solvent could be a good alternative to other more aggressive solvents considering its biodegradability, low flammability, nonvolatility, and stability at high temperature (Bulgariu and Bulgariu 2008).

The effect of microwave irradiation on the pectin structure (Bélafi-Bakó et al. 2012) is also discussed in different manuscripts. As commented before, microwave irradiation could cause a deeper rupture in the cell wall which could result in a more compact pectin structure as compared to conventional extraction.

Heating time and temperature also affect the pectin structure (Holck et al. 2014). As an example, molecules of pectin from lime albedo, flavedo, and pulp became less compact and with lower molar mass and intrinsic viscosity with increasing MAE heating time and temperature (Fishman et al. 2006).

MAE has also been proposed for the sequential isolation of different polysaccharides. As an example, pectin, alkaline-soluble polysaccharides, and cellulose have been successfully isolated from sugar beet pulp by different sequential MW treatments under basic (pH 11.5) and acid (pH 4.0–4.5) conditions (Fishman et al. 2011).

After extraction, samples are usually filtrated. The filtrate (containing pectin) is cooled down and centrifuged. The supernatant is precipitated with absolute alcohol or isopropyl alcohol and left to rest in order to float pectin which is finally dried to constant weight (Li et al. 2012; Bélafi-Bakó et al. 2012).

3.2 Galactomannans and Arabinogalactans

Coffee beans are a rich source of polysaccharides, specifically cellulose, galactomannans (low-branched polysaccharides composed of a backbone of β-(1 → 4)-linked mannose residues, branched at *O*-6 by single α-(1 → 6)-linked galactose and single (1 → 5)-linked arabinose residues) and type II arabinogalactans (high-molecular-weight highly branched polysaccharides composed of a backbone of β-(1 → 3)-linked galactose residues, branched at *O*-6 by β-(1 → 6)-linked galactose and/or α-(1 → 5)-linked arabinose residues) (Passos and Coimbra 2013).

Most of these polysaccharides are not extracted during the beverage preparation and remain present in the spent coffee ground matrix. MAE has been proposed as an efficient technique for the recovery of these polysaccharides. As an example, Passos and Coimbra (2013) evaluated the effect of SLR on the extraction yield of polysaccharides from spent coffee grounds. These authors proposed two consecutive extraction processes using water as solvent, 900 W and 200 °C for 5 min under stirring as extraction conditions. Even at this high temperature, no degradation of polysaccharides was observed. The highest yields (55 %) of galactomannans and arabinogalactans were achieved at intermediate conditions (SLR 1:10) (Fig. 3). These authors also improved this method using five sequential MAE cycles to achieve an extraction yield of 82 % (69 % mannose) (Passos et al. 2014). Fractionation of mannans from cellulose, which remained in the insoluble material (84 %), was also successfully achieved.

3.3 Xylans

Xylans possess a backbone made up of xylose units linked by β-(1 → 4) bonds with different substituents as side chains, namely, acetyl, arabinosyl, glucuronic acid, etc., and frequent esterification by phenolic acids. Heteroxylans occur in

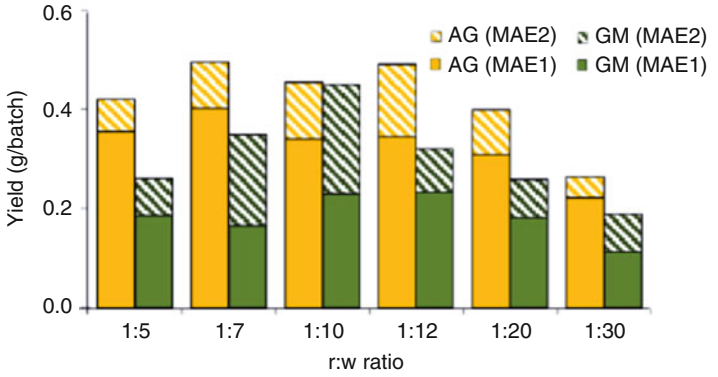

Fig. 3 Amount of arabinogalactans (*AG*) and galactomannans (*GM*) recovered during two cycles of MAE extraction (Reprinted from Passos and Coimbra (2013). Copyright (2013), with permission from Elsevier)

hardwoods, agricultural products of lignocellulosic nature (straw, herbs, and the like), and cereals (Gullón et al. 2014).

In general, low power levels are used for the extraction of xylans, considering that a degradation of these polysaccharides can occur as a result of an increase of the temperature in a short time (Panthapulakkal et al. 2013). Coelho et al. (2014) found that temperatures higher than 180 °C, similar to those proposed by Passos and Coimbra (2013) for the extraction of galactomannans, produced depolymerization, debranching, and de-esterification of arabinoxylans, with the formation of brown products. Similarly, Benkő et al. (2007) observed a decrease in the molecular weight of arabinoglucuronoxylans isolated from corn fiber when temperature was increased from 160 °C to 210 °C. However, recovery of this polysaccharide increased at higher temperatures. These results confirm the relevance of optimizing each extraction method depending on the nature of the polysaccharide and the purpose of the extraction.

The effect of solvent pH and extraction time in the recovery and molecular weight distribution of xylans during MAE is also crucial. In general, lower extraction yields and shorter polymer chains are obtained when low pHs are used (Benkő et al. 2007; Roos et al. 2009). Xylan extraction yields increased with time of extraction, whereas changes in the molecular structure were observed (high-molecular-weight fraction decreased (from 36 % to 25 %) and low-molecular-weight fraction increased (from 21 % to 30 %)) (Panthapulakkal et al. 2013).

Sequential MAE treatments using different solvents and/or conditions have been proposed to improve the recovery of xylans. As an example, Coelho et al. (2014) obtained high yields of arabinoxylans (62 % of poly- and oligosaccharides) from brewers' spent grains (mainly composed of arabinoxylans (22–23 %), followed by cellulose, starch and β-glucans) using firstly water at 140 °C to remove starch and β-glucans and two consecutive treatments at 180 °C with water and 0.1 M KOH to recover the target carbohydrates.

3.4 Inulins

Inulin is composed of a series of oligomers and polymers of several fructosyl moieties and a terminal glucose unit which are linked by β-(2 → 1) bonds. It is naturally occurring in land plants and in some bacteria and it is a well-known prebiotic carbohydrate. Studies on inulin extraction by MAE are very scarce. Recently, a Box-Behnken experimental design has been applied to optimize the extraction of inulin and inositols (cyclic polyalcohols with recognized bioactive properties) from *Cynara scolymus* bracts (Ruiz-Aceituno et al. 2014). The highest yield of inulin was obtained at high temperature (120 °C) and at a short time (3 min). However, 60 °C, 3 min, and SLR 1:33 were selected as optimal conditions when a multiple response analysis was carried out to simultaneously maximize the extraction yield of both bioactive carbohydrates.

3.5 Sulfated Polysaccharides

Sulfated polysaccharides include a wide range of anionic polysaccharides with different bioactive properties (anticoagulant, antioxidant, anti-inflammatory, anti-adhesive, etc.). Among them, fucoidan is a sulfated polysaccharide mainly consisting of fucose units esterified with sulfate groups and found in various species of brown seaweeds. Before extraction of fucoidan from seaweeds, a pretreatment, usually carried out with methanol/chloroform/water (4/2/1, v/v/v), to avoid coextraction of other algal compounds, is required. Rodriguez-Jasso et al. (2011) extracted high yields of fucoidan (18.22 %) from *Fucus vesiculosus*, a brown seaweed specie from North Portugal, by MAE at 120 psi, 1 min, using 1 g algae/25 mL water.

Carrageenans are sulfated polysaccharides of alternating 3-linked β-galactose and 4-linked α-galactose units or 3,6-anhydrogalactose present in edible red seaweeds. These polysaccharides are of great interest for the food industry mainly due to their gelling, thickening, and stabilizing properties. MAE has been reported for the extraction of carrageenan from *Hypnea musciformis* (Vázquez-Delfín et al. 2014). Both aqueous and alkaline (3 % KOH) treatments have been assayed; however, carrageenan yields were higher under aqueous conditions (85 °C, 10 min), as a consequence of the degradation experimented by this polysaccharide under basic conditions.

4 Comparison with Other Extraction Techniques

As previously mentioned, the MVH phenomenon makes of MAE a promising extraction technique. In contrast to conventional thermal methods, which rely on conduction and convection from hot surfaces to deliver energy, MAE provides shorter extraction times and higher extraction yields, due to the effect of microwaves on both the solvent (volumetric heating) and the sample (increased release of target compounds from the matrix into the solvent) (Wang and Weller 2006; Ying et al. 2011).

As for polysaccharides, in a study by Zhang et al. (2012) on the extraction of these compounds from *Artemisia sphaerocephala* seed de-oiling dregs, MAE showed a two times higher extraction yield and a 20–30 times lower extraction time (depending on experimental conditions) over conventional hot-water extraction. Similar advantages in terms of speed and yield have also been reported in the MAE of pectins from pumpkin flesh [10–20 min vs. 2 h; 11.3 vs. 4.2 % (w/w) yield (Yoo et al. 2012)], in the extraction of xylan from birchwood [10 min vs. 1.5 h; 60 vs. 56 % (w/w) yield (Panthapulakkal et al. 2013)], etc.

MVH also minimizes damage to thermolabile compounds, as samples do not come into contact with hot surfaces. This justifies the current acceptance of the MAE technique in many applications related to the extraction of bioactive compounds of interest for the food and pharmaceutical industries (Proestos and Komaitis 2008; Routray and Orsat 2012; Karabegović et al. 2013). Additional advantages of MAE include lower solvent consumption and high versatility, as selectivity and efficiency of extraction can be finely modulated as a function of experimental conditions selected. Moreover, as in the case of polysaccharides subjected to selected operating conditions, combined processes such as extraction and degradation can also simultaneously take place (Prakash Maran et al. 2013).

When compared to conventional heating techniques, MAE at industrial scale usually requires a higher initial investment. However, the low maintenance costs, the energy savings, the reduced equipment size, and the ease of operation are increasingly promoting the use of MAE for extractions at larger scale of different bioactives from plant and other natural sources (Terigar et al. 2011; Ibañez et al. 2012; Li et al. 2013). Despite the above-referred advantages, as far as we know, no reference has yet addressed the extraction of polysaccharides either at pilot or industrial scale.

In MAE methods, it can be difficult to predict the effect of the interaction of the electromagnetic field with the sample to be extracted, as variations in the sample volume, shape, moisture content, and chemical structure, as well as in the microwave system (extractor geometry, vessels, etc.) and operating conditions, might greatly affect the results. This unpredictability is easily overcome by experimentation and, therefore, the optimization of methods for every new application is always mandatory to achieve optimal extractions. In this regard, and despite the large number of applications already available in the literature for extraction of polysaccharides from different sources (see Table 2), extrapolation of methods and immediate implementation is not usually possible.

Regarding the comparison of MAE with other emerging techniques such as UAE, PLE, etc., several papers have compared their performance in its application to the extraction of polysaccharides from different sources (Du et al. 2014). In a paper by Buranov and Mazza (2010) on the extraction of high-molecular-weight hemicelluloses (HMH) from flax (*Linum usitatissimum* L.) shives, authors concluded that pressurized aqueous ethanol provided the maximum yield of HMH (15 % of dry flax shives), whereas microwave-assisted ethanol extraction was as efficient as pressurized low-polarity water and much more than microwave-water extraction (Table 3). However, it is worth noting that the maximum yield

Table 3 Experimental conditions and high-molecular-weight hemicelluloses (HMH) yield from 13 g flax shives using different extraction methods at 180 °C, 5.2 MPa, and SLR ratio of 1 g: 27 mL

achieved by pressurized aqueous ethanol was obtained at a much longer extraction time as compared to the remaining procedures. Bagherian et al. (2011) also evaluated the performance of MAE and UAE for the extraction of pectin from grapefruit. Both the yield and extraction time were better for MAE (28 % vs. 18 %, 6 min vs. 25 min). Finally, Du et al. (2014) compared the extraction of β-glucans from bran of hull-less barley (*Hordeum vulgare* L. var. nudum Hook), a commodity waste rich in this source of carbohydrates, by using PLE, UAE, and MAE. Although yield of crude β-glucan was similar for both UAE and MAE (0.3 %), extraction times were significantly higher for UAE (1 h vs. 2 min). Results achieved by PLE were the best as yields as high as 8.8 % were obtained in only 18 min (3 cycles of 6 min). However, it is worth noting that results obtained in the application of each of these techniques are dependent on a number of factors such as the operating conditions, the characteristics of the sample, or the composition of the extract and, therefore, no general conclusion can be a priori be drawn.

5 Future Trends

As previously mentioned, the application of microwave technologies has been scaled up in the food and cosmetic industries, among others, because of its economic and environmental advantages (Li et al. 2013). In this regard, the large number of successful laboratory-scale applications previously developed has greatly contributed to identify the factors required for scale-up and has helped to promote the implementation of this technique at industrial scale. Thus, and based on the number of advantages above described for MAE of polysaccharides and the ongoing progress regarding microwave technology, it is expected that research in a near future is aimed to the scale-up of this sort of applications and others involving integrated processes (e.g., extraction and enzymatic hydrolysis) from laboratory to pilot/industrial scale.

On the other hand, and following the trend initiated with the development of microwave-assisted Soxhlet extraction (García-Ayuso et al. 1998), new combined techniques have been recently developed. The simultaneous use of microwaves and ultrasound (ultrasonic–microwave-assisted extraction, UMAE) in single reactors (Fig. 4) has been proposed to merge the advantages in terms of improved matter transportation (breakdown of cell walls, improved solvent penetration, etc.) and enhanced energy provided by each of these techniques (Leonelli and Mason 2010). Although application of this hybrid technology results in better and sometimes more targeted extraction yields of flavorings and nutraceuticals from plants, herbs, and seeds (Cravotto and Cintas 2006; Cravotto et al. 2008), its application to polysaccharide extraction is still limited (Bagherian et al. 2011; Zhou et al. 2014). Furthermore, these combined reactors have only been developed at laboratory scale. Taking into account the advances achieved in the last decade regarding microwave instrumentation for applications other than extraction (Leonelli and Mason 2010), further research would be worth doing to explore the

Fig. 4 Apparatus for simultaneous US/MAE irradiation (Reprinted from Cravotto et al. (2008). Copyright (2008), with permission from Elsevier)

potential of UMAE as a large-scale technique for green and efficient extraction of polysaccharides.

Finally, and despite a great progress on safety issues related to MAE systems (pressure and solvent sensors, pressure-relieving doors, high-capacity exhaust devices, multilayered coated cavities, etc.) has been achieved during the last years, conventional quality control methods have been shown to be insufficient to evaluate and control potential hazards for product safety and risks for operators. Hazard analysis and critical control points (HACCP) and hazard and operability (HAZOP) studies have, however, been described as effective for these objectives and must be considered in the design of large-scale MAE applications (Li et al. 2013).

6 Conclusions

MAE has greatly evolved in the last decade and nowadays it can be considered as a mature and efficient technique for extraction of polysaccharides. Selectivity and yield of extraction depend on both dielectric characteristics of the sample and operating conditions which can be easily optimized by using response surface approaches. Despite their undeniable advantages (short extraction times, high extraction yields, reduced solvent consumption, etc.) over conventional extraction methods traditionally used in industry and their ease of operation and reduced costs as compared to other emerging technologies such as SFE and PLE, the full implementation of this technique for polysaccharide extraction at industrial scale still requires further research. Similarly, there is also a need to evaluate the potential of hybrid technologies such as UMAE in its application to the industrial extraction of these compounds.

Preparation and Characterization of Polysaccharides from Mushrooms

35

Fengmei Zhu, Bin Du, and Baojun Xu

Contents

Abstract

Polysaccharides are cellular structural components found in the three domains of life. Polysaccharides possess immune enhancement, anticancer, antioxidant, and antiviral activities. Mushrooms are the fungi that have been used as food and medicines for long time in the Oriental countries. One of main categories of active components from mushrooms is recently identified as polysaccharides. The present work summarizes the preparation, extraction, purification, and characterization along with quantitative analysis of polysaccharides from mushrooms. It reflects on current status of this research area with a view for future direction. This will certainly promote the nutritional, medicinal, and nutraceutical use for mushroom polysaccharides.

1 Introduction

Mushrooms have been cultivated and used for hundreds of years and are being evaluated as edible and medicinal resources in Asian countries. Moreover, numerous species of wild growing mushrooms are widely consumed as a delicacy in Central and Eastern European countries (Kalac 2009). Mushrooms are macro fungi with distinctive basidiomata or ascomata which can be either hypogeous or epigeous, large enough to be seen with the naked eye and to be picked up by hand (Soares et al. 2013). Mushrooms have been traditionally appreciated due to their excellent sensory characteristics, including the pleasant flavor and texture. They are poor in calories and rich in proteins, fibers, carbohydrates, and important vitamins such as thiamin, riboflavin, and ascorbic acid and minerals (Manzi et al. 1999; Kues and Liu 2000; Mattila et al. 2002; Firenzuoli et al. 2008; Mishra and Singh 2010). As a matter of fact, the particular characteristics of growth and development of mushrooms in nature result in the accumulation of essential cell wall components such as polysaccharides (includes β-glucans) and a variety of secondary metabolites such as phenolic compounds, terpenes, and steroids. Polysaccharides from mushrooms have provoked the increasing interest due to the healthy benefits, such as immunomodulation (Wasser 2002), anticancer activities (Ren et al. 2012), prevention and treatment of cardiovascular diseases (Wasser and Weis 1999), and antiviral and antimicrobial effects (Beattie et al. 2010).

In order to reveal the polysaccharides in mushrooms, most researchers employed a routine procedure to fractionate Basidiomycete mushroom: from crude extraction by boiling water to fraction identification, then to further purification of

polysaccharides using a combination of such techniques as ethanol precipitation, fractional concentration, acidic precipitation, ion-exchange chromatography, and gel filtration chromatography (Zhu et al. 2008; Kim et al. 2003; Park et al. 2003a). The aim of this work is to review the main methods for extraction, purification, characterization, as well as the most important quantitative analysis of the polysaccharides from mushrooms.

2 Sample Preparation of Polysaccharides from Mushroom

Generally, the extract solution of mushroom polysaccharide is precipitated by alcohol, methanol, or acetone to obtain the crude polysaccharides. It can be demonstrated with the preparation of crude polysaccharides from *Ganoderma lucidum* and *Ganoderma sinense* as an example. The process was as follows: the fruit bodies of two species of *Ganoderma* were carefully cleaned and cut into slices and then dried at 40 °C for 12 h. The dried mushroom slices were pulverized and then passed through a 0.8 mm mesh. Sample materials were immersed in water and refluxed in a Syncore parallel reactor for 1 h at 100 °C with stirring at 200 rpm. Then the extract solution was centrifuged at 4,500 × *g* for 10 min. An aliquot of supernatant was evaporated to dryness under vacuum. The residue was dissolved in water; ethanol was added to a final concentration of 80 % (v/v) for precipitation of crude polysaccharides (Xie et al. 2012). Another example, the ground stipe powder of mushroom *Coprinus comatus*, was extracted three times with ethanol under reflux to remove lipid, and the residue was further extracted with hot water (Li et al. 2013a). Moreover, the *Hericium erinaceus* polysaccharides were prepared with deionized water by refluxing. The extract was concentrated to a small volume and then mixed with ethanol to yield a 70 % ethanolic solution. The precipitate thus obtained was lyophilized and ground to obtain the coarse powder of polysaccharides (Han et al. 2013).

3 Extraction of Polysaccharide from Mushroom

Extraction always involves a chemical mass transfer from one phase to another phase. Mushroom polysaccharides exist as a structural component of fungal cell wall (Zhang 2007). Selection of an extraction method depends not only on the cell wall structure but also on different physiochemical parameters, for instance, temperature, pressure, pH and ionic strength of the solvent, and fineness of solid particle ground (Villares et al. 2012). Generally speaking, the extraction of polysaccharides can be classified into three main types: One is a conventional solvent extraction method, using hot water, alkali solution, and polyethylene glycol; second uses microwave, ultrasonic or ultrahigh pressure, etc. to extract the polysaccharides; and third is enzyme-assisted extraction method. The extraction methods with detailed procedure are described below and summarized in Table 1.

Table 1 Extraction, purification, and structural features of polysaccharides from different mushroom sources

Source	Part of mushroom	Extraction process	Purification	Structural features	References
Coprinus comatus	Fruit bodies	Water extraction (80 °C)	DEAE-Sepharose CL-6B column (3.5 cm × 30 cm); Sepharose CL-6B column (1.6 cm × 100 cm); Bio-Gel P-2 column (1.1 cm × 48 cm); Sepharose CL-4B column (2.8 cm × 50 cm)	The disaccharide α, α-trehalose [α-*d*-Glc*p*-(1↔1)-α-*d*-Glc*p*]; high-molecular-mass α-*d*-glucans; lower-molecular-mass linear β-*d*-glucans	Li et al. (2013a)
Ganoderma capense	Mycelia	Boiling water	DEAE-Sepharose CL-6B column (2.6 × 40 cm); Sephadex G-75 column (1.6 × 150 cm)	An α-*d*-glucan with the main backbone chain of (1 → 4)- α-*d*-glucopyranosyl residue interspersed with (1 → 4, 6)-α-*d*-glucopyranosyl residue and the side chain attached to the *o*-6 position with (1→)-α-*d*-glucopyranosyl residue	Li et al. (2013b)
Agaricus brasiliensis	Fruiting bodies	Water extraction (100 °C)	DEAE-cellulose column chromatography; Toyopearl HW-65F column; Con A-Sepharose 4B column	A greater proportion of (1 → 6)-β-side branches on the (1 → 3)-β-backbone	Camelini et al. (2005)
Ganoderma lucidum	Spores	Water extraction (100 °C) and graded ethanol precipitation	DEAE-cellulose column and Sephacryl S-300 column	A 1,6-linked β-*d*-glucopyranosyl backbone with different length of branches consisting of terminal and 1,4-linked glucopyranosyl residues, attached to *o*-4 of alternative glucose residues in the backbone	Dong et al. (2012)

Grifola frondosa	Fruit bodies	Alkaline (5 % NaOH) extraction	DEAE-cellulose column	A *β*-*d*-(1–3)-linked glucan backbone with a single *β*-*d*-(1–6)-linked glucopyranosyl residue branched at C-6 on every third residue	Fang et al. (2012)
Coriolus versicolor	Fruit bodies	Hot water extraction	DEAE-cellulose anion-exchange chromatography with 0.7 M NaCl	–	Kang et al. (2013)
Flammulina velutipes	Fruit bodies	Aqueous and alkaline extraction	–	A main chain of (1 → 3)-linked glucopyranosyl residues, substituted at *o*-6 by single-unit *β*- glucopyranosyl side chains	Smiderle et al. (2006)
Auricularia auricula	Fruit bodies	0.15 M Aqueous NaCl extraction (80–100 °C)	–	A *β*-(1 → 3)-*d*-glucan with two *β*-(1 → 6)-*d*-glucosyl residues for every three main chain glucose residues	Xu et al. (2012)
Dictyophora indusiata	Fruit bodies	Water extraction (90 °C)	Sephadex G-200 gel chromatography	A backbone of *β*-conformation, mainly consist of glucose (98.58 %)	Deng et al. (2012)
Geastrum saccatum	Fruit bodies	Water extraction (100 °C)	–	High amount of glucose and traces of galactose. The signal appearing at 103.5 ppm was assigned to C1 of *β*-glucose	Guerra Dore et al. (2007)
Hybrid mushroom of *Pleurotus florida* and *Lentinula edodes*	Fruit bodies	Hot aqueous extraction	Sepharose 6B gel permeation column	→6)-*α*-*d*-Galp-(1 → 6) -*α*-*d*-Galp-(1→	Maity et al. (2013)
Coprinus comatus	Fruit bodies	Distilled water extraction at 100 °C	DEAE-Sepharose anion chromatography	Was composed of L-Fuc and *d*-Gal in the ratio of 1:3.84 (molecular weight: 1.03×10^4 g mol^{-1})	Zhou et al. (2013)

(*continued*)

Table 1 (continued)

Source	Part of mushroom	Extraction process	Purification	Structural features	References
Coprinus comatus	Fruit bodies	Distilled water extraction at 100 °C	High performance size exclusion chromatography (HPSEC)	Was *α*-*d*-(1 → 4)-glucan with branches at C-6 consisting of non-reducing terminal approximately every fourteen residues (molecular weight: 2.44×10^7 g mol^{-1})	Liu et al. (2013)
Ramaria botrytis	Fruit bodies	Hot water extraction followed by treating NaOH	Dialyzed through cellulose tubing membrane	→3)-*α*-*d*-Glcp-(1→	Bhanja et al. (2014)
Phellinus linteus	Submerged culture	–	Sepharose CL-4B column (2.4 cm × 100 cm)	Spherical form; a random coil in an aqueous solution	Hwang et al. (2003)
Phellinus linteus	Fruit bodies	Hot water extraction	Sepharose CL-6B column (150 × 1.5 cm)	A core *β* (1–3) linked glucan heavily substituted via (1–6) links with *β* (1–3) linked mannose chains	Baker et al. (2008)

3.1 Conventional Solvent Extraction

Hot water extraction has been a popular approach for polysaccharide extraction from mushroom because of its safety and environment-friendly compatibility (Nie et al. 2013). In order to obtain high yields, long soaking time, high water temperature, high liquid-to-solid ratio, and multiple extraction steps are usually necessary (Xing et al. 2013). It was reported that the fruit bodies of *C. comatus* were extracted three times with 2 L distilled water for 2 h at 80 °C, followed by intermediate centrifugation (2,000 × *g*, 15 min). After concentrating the collected aqueous supernatants to 400 mL under vacuum (reduced pressure at 40 °C), a precipitation was performed with three volumes of 95 % ethanol. The precipitate was washed with ethanol and acetone and then dried at 40 °C, and the crude polysaccharide material was finally yielded (Li et al. 2013a). Furthermore, a polysaccharide from *Ganoderma capense* was extracted using boiling water (Li et al. 2013b). Before polysaccharide extraction, the lipids were removed from dried *G. capense* mycelia powder using petroleum ether. Kumari et al. (2008) determined optimal operating conditions using one factor at a time method and response surface method to maximize production of schizophyllan by *Schizophyllum commune* from an initial value of 1.06–8.06 g L^{-1}. Moreover, Kim et al. (2005) used distilled water (100 °C) at a ratio of 1:10 (w/v) to extract β-glucan from *Agaricus blazei* with extraction time of 3 h. Similar extraction procedures were conducted for polysaccharide extraction from *Phellinus linteus*, which was extracted three times with boiling water for 2 h, concentrated and precipitated with three volumes of ethanol (Li et al. 2011).

3.2 Microwave-Assisted Extraction

Microwave-assisted extraction (MAE) is widely used in the extraction of bioactive compounds. MAE provides a rapid sample preparation with reduced amounts of solvent. For instance, Ookushi et al. (2006) applied microwave irradiation to extract polysaccharides from the fruiting body of mushroom *Hericium erinaceus*. The results showed that microwave irradiation had an advantage for extraction of polysaccharides in terms of saving extraction time. Moreover, MAE technique was employed for the extraction of himematsutake (*Agaricus blazei* Murill) polysaccharide and optimized by Box-Behnken design. The optimum conditions were extraction time 29.37 min, microwave power 400 W, extraction temperature 74.64 °C, and ratio of water to material 32.7:1 with an enhanced yield of 12.35 % (Zhang et al. 2011b). Huang et al. (2007) studied the MAE of polysaccharides from spores of *Ganoderma atrum* with response surface analysis. The experimental results confirmed that MAE had great efficiency compared with traditional hot water extraction.

3.3 Ultrasound-Assisted Extraction

Ultrasound is primarily associated with cell disruption or disintegration. When sonicating liquids at high intensities, the sound waves that propagate into the liquid

medium result in alternating high pressure and low pressure cycles, with rates depending on the frequency. Ultrasonic-assisted extraction (UAE) is an expeditious, inexpensive, and efficient alternative to traditional solvent extraction techniques. In one study, Pan et al. (2010) determined the optimum UAE conditions for polysaccharides from mushroom *Trametes versicolor*. The ultrasonic power and the ratio of material to solvent were the most significant parameters on polysaccharide extraction. In addition, UAE of polysaccharides from white button mushroom (*Agaricus bisporus*) was studied; the optimal extraction conditions were ultrasonic power 230 W, extraction temperature 70 °C, extraction time 62 min, and water/material ratio 30 mL g^{-1} (Tian et al. 2012). On the other hand, the optimization of polysaccharide extraction from *Pleurotus eryngii* using UAE was investigated and the optimal conditions were obtained using single parameter and orthogonal tests when fruit bodies of *P. eryngii* were suspended in water at a ratio of 1:40 and exposed to 70 W of ultrasonic power for 40 min (Zhang et al. 2010).

3.4 High Pressure Extraction

High pressure extraction (HPE) as a novel technique is used for extraction of active ingredients from plant materials (Prasad et al. 2009). High pressure ranging from 100 to 800 MPa or even more up to 1,000 MPa is considered as an alternative extraction method, which is proven to be fast and more effective (Zhang et al. 2004). For example, Tang et al. (2012) extracted polysaccharide from shiitake mushroom particular ly in a HPE method. Being a cold extraction technique, the super high pressure extraction method generates no high temperature during the whole extraction process, shortens the extraction time to a few minutes, conserves the effective ingredients, and has significant economic benefits and broad prospect of market development. Additionally, Xi et al. (2010a) used ultra HPE to extract lentinan from mushroom. The extraction conditions were optimized with the orthogonal test as follows: extraction time 4 min, pressure 350 MPa, solid to liquid ratio 1:35, and temperature 55 °C. The ultra HPE method showed high extraction efficiency, low energy consumption, and short extraction time and provided a new route for the extraction of lentinan.

3.5 Pulsed Electric Fields Extraction

Pulsed electric fields extraction keeps original properties of nutrients unchanged plus can simultaneously sterilize it. When a plant is treated with high pulsed electric field, the cell membranes are ruptured leading to an increase in permeability of the cell walls (Eshtiaghi and Knorr 2002). In our latest study, three extraction techniques, namely, high intensity pulsed electric fields (HIPEF), MAE method, as well as UAE method, were applied to optimize the extraction conditions of polysaccharide from Jew's ear (*Auricularia auricula*). The results suggested that the HIPEF technique will be an effective method in the manufacture of bioactive natural

polysaccharide (Li et al. 2013c). In another study, Yin et al. (2008) demonstrated the extraction of polysaccharide from mushroom *Inonotus obliquus* using HIPEF. The results showed that HIPEF technique is an effective method to extract polysaccharide from mushroom, with higher extraction yield, shorter time, and fewer impurities.

3.6 Enzyme-Assisted Extraction

Enzyme-assisted extraction (EAE) methods are gaining more attention because of the need for eco-friendly extraction (Puri et al. 2012). EAE methods have been shown to achieve high extraction yields for compounds including polysaccharides, oils, natural pigments, and medicinal compounds (Barzana et al. 2002; Wu et al. 2005; Passos et al. 2009; Yang et al. 2010). For instance, EAE technology was performed for the polysaccharide extraction from *Ganoderma lucidum* in order to increase the amount of extract and polysaccharide extraction yield (Xu et al. 2014). Complex enzyme amount also presents a positive effect on the polysaccharide yield and amount of extract. Chen et al. (2013) conducted three extraction methods (as hot water, microwave assisted, and enzyme hydrolysis assist) to extract polysaccharides from *Clitocybe maxima* stipe. Results indicated that the complex-enzyme-hydrolysis-assist extraction was the optimal approach used for extracting polysaccharide from *C. maxima* stipe. It showed with the advantages in high efficiency, energy, and running time saving.

3.7 Subcritical Water Extraction

Subcritical water extraction (SWE) is a new and powerful technique at temperatures between 100 °C and 374 °C and pressure high enough to maintain the liquid state. The extraction parameter conditions of SWE of polysaccharides from *Grifola frondosa* were optimized using response surface methodology. The results showed that the SWE technology could be a time-saving, high-yield, and bioactive technique for production of polysaccharides (Yang et al. 2013). Furthermore, Lou et al. (2010) reported the extraction of lentinan from mushroom using SWE. The experimental results indicated that the SWE could shorten the extraction time and improve the yield of lentinan compared with the water extraction method.

Recently, complex extraction method has received much attention in natural product research field. For example, Parniakov et al. (2014) compared the efficiency of extraction and stability of extracts from mushroom *Agaricus bisporus* for different extraction methods: pressure extraction, pressure extraction assisted by pulsed electric field, hot water extraction, and ethanol extraction. Pressure extraction was done at room temperature and 5 bar pressure. Pulsed electric field treatment was done using bipolar near-rectangular pulse protocol. The results showed that pressure extraction assisted by pulsed electric field allowed production of mushroom extracts with high contents of fresh-like proteins and polysaccharides.

4 Purification of Polysaccharide from Mushroom

In the recent years, although polysaccharide has been known for its potent anticancer and antiviral activities, the difficulties in its separation and purification have remained an obstacle for its development. Isolation and purification of polysaccharides commonly involve several steps, and different techniques are actually available in order to increase extraction yield and purity (Villares et al. 2012). Polysaccharides extracted from the source material are generally dissolved in water or aqueous solutions. Other macromolecules (such as proteins) and small molecular substances (such as phenolic compounds, monosaccharides, and amino acids) may be also present in the matrix. Firstly, the samples may be subjected to a previous step consisting of a methanol extraction in order to remove small molecular substances. Secondly, proteins can be removed by precipitation with Sevag method (Whistler 1965) using a mixture of chloroform and *n*-butanol, trifluoroacetic acid (20 %, w/v) or by treating with the enzyme protease at 40 °C for 1 h (pH 7.5). Thirdly, polysaccharides are precipitated from the supernatants by the addition of ethanol in different ratios, for instance, 4:1 (v/v) or 3:1 (v/v). Fourthly, pure carbohydrate fractions obtained from ethanol precipitation can be performed by precipitation with ammonium sulfate. The detailed purification procedures were summarized in the following parts and listed in Table 1.

4.1 Chemical Method

The chemical methods for purification of polysaccharide from mushroom were as follows: distribution precipitation method, quaternary ammonium salt precipitation, salting out method, and metal complexes method (Liu and Xu 2007). Distribution precipitation method, which is the addition of miscible solvents such as ethanol or methanol to a solution, may cause proteins in the solution to precipitate. The common quaternary ammonium salt included hexadecyltrimethylammonium bromide and cetylpyridinium chloride. Salting out is the most common method used to precipitate a target protein. Addition of a neutral salt, such as ammonium sulfate, compresses the solvation layer and increases protein-protein interactions. As the salt concentration of a solution is increased, the charges on the surface of the protein interact with the salt, not the water, thereby exposing hydrophobic patches on the protein surface and causing the protein to fall out of solution.

4.2 Chromatographic Method

Column chromatography is a method used to purify individual chemical compounds from the mixtures of compounds. Different column chromatography methods (ion-exchange chromatography and gel filtration chromatography) can be used in polysaccharide purification. Camelini et al. (2005) extracted β-glucan from mushroom *Agaricus brasiliensis* with boiling water, and then the crude polysaccharide was

passed through a DEAE-cellulose column chromatography for further purification. A similar research was conducted to purify water-soluble polysaccharide from the dried powder of submerged fermentation mycelia of *G. capens*e by successive purification through DEAE-Sepharose CL-6B and Sephadex G-75 column chromatography (Li et al. 2013b). Moreover, crude polysaccharide extracts were further purified through a Sephadex column and eluted with water. A water-soluble polysaccharide was purified from the fruit bodies of *C. comatus* using DEAE-Sepharose CL-6B column, Sepharose CL-6B column, Bio-Gel P-2 column, and Sepharose CL-4B column (Li et al. 2013a). In another study, *β*-glucan from mushroom *Sparassis crispa* was prepared using cold alkali (10 % NaOH/5 % urea), and subsequently the extract was applied to a DEAE Sephadex A25 column for further purification (Shibata et al. 2012). The purification techniques used for extraction of polysaccharides from different sources are summarized in Table 1.

4.3 Membrane Filtration

Because membrane processes are increasingly used for separations of mixtures with high complexity, the focus of fouling studies in ultrafiltration has also been in more complicated and less-defined substances such as polysaccharides (Susanto et al. 2008). Interactions of ultrafiltration membranes with polysaccharides have been investigated during processing of bioproduct (Nataraj et al. 2008). Zhao et al. (2010) chose ultrafiltration methods to purify polysaccharide from mushroom *Tricholoma matsutake* Sing. with two membranes of different molecular weight cut-off, namely, 30 and 10 kD. A low-molecular-weight polysaccharide from mushroom *Ganoderma lucidum* fruit bodies was successfully isolated and purified using membrane ultra filtration, anion exchange, and gel filtration chromatography (Zhu et al. 2013).

5 Chemical Characterization of Polysaccharide from Mushroom

Polysaccharides are polymeric carbohydrate structures, formed of repeating units joined together by glycosidic bonds. These structures are often linear, but may contain various degrees of branching. Polysaccharides consist of polymeric structures composed of at least ten monosaccharides sequentially connected by glycosidic bonds (Bertozzi and Rabuka 2009; Mulloy et al. 2009; Stanley and Cummings 2009). The chemical characterization of polysaccharide is an absolute request for a multitude of scientific and industrial applications that go beyond the simple use of polysaccharides where the physical characterization and the knowledge of usage-dependent behavior by specific tests are sufficient. The structural analyses of *C. comatus* polysaccharides were investigated using (*d*/*l*) monosaccharide/methylation analysis and 1D/2D nuclear magnetic resonance (NMR) spectroscopy. The disaccharide *α*, *α*-trehalose [*α*-*d*-Glc*p*-(1↔1)-*α*-*d*-Glc*p*], high-molecular-mass *α*-*d*-glucans, and lower-molecular-mass linear *β*-*d*-glucans were

found to be present (Li et al. 2013a). The structural feature of *G. capense* polysaccharide was investigated by monosaccharide analysis, partial acid hydrolysis, methylation analysis, periodic acid oxidation, gas chromatography-mass spectrometry (GC-MS), Fourier transform infrared spectroscopy (FT-IR), and NMR spectroscopy. The results obtained from the analyses indicated that *G. capense* polysaccharide was an *α-d*-glucan with the main backbone chain of (1 → 4)-*α-d*-glucopyranosyl residue interspersed with (1 → 4, 6)-*α-d*-glucopyranosyl residue and the side chain attached to the *o*-6 position with (1→)-*α-d*-glucopyranosyl residue (Li et al. 2013b). Moreover, Camelini et al. (2005) characterized the *β*-glucans of *Agaricus brasiliensis* fruiting bodies by FT-IR and NMR. The results showed that *β*-glucan had a greater proportion of (1 → 6)-*β*-side branches on the (1 → 3)-*β*-backbone. The structure of β-glucan from a hybrid mushroom, *pfls1h* of *Pleurotus florida and Lentinus squarrosulus* (Mont.) Singer, was characterized using total hydrolysis, methylation analysis, peroxide oxidation, and NMR techniques by Sen et al. (2013). Methylation analysis revealed that purified polysaccharide fraction was composed of (1 → 3, 6), (1 → 3), (1 → 6)-linked and terminal *β-d*-glucopyranosyl residues in a relative proportion of approximately 1:1:1:1. The repeating unit of the glucan consists of a backbone chain of two (1 → 6)-*β-d*-glucopyranosyl residues, one of which is branched at *o*-3 position with (1 → 3)-*β-d*-glucopyranosyl and terminated with a *β-d*-glucopyranosyl residue. In another study, Dong et al. (2012) characterized the chemical structure of *β*-glucan (GLSA50-1B) from mushroom *Ganoderma lucidum* using sugar compositional analysis, methylation analysis, partial acid hydrolysis, acetolysis, and NMR and electrospray ionization mass spectrometry. The results indicated that GLSA50-1B was elucidated to be a novel *β-d*-glucan featured by a 1, 6-linked *β-d*-glucopyranosyl backbone with different length of branches consisting of terminal and 1, 4-linked glucopyranosyl residues, attached to *o*-4 of alternative glucose residues in the backbone. Structural study of a polysaccharide isolated from an edible hybrid mushroom of *Pleurotus florida* and *Lentinula edodes* was investigated based on the results of acid hydrolysis, methylation analysis, peroxidation, and NMR experiments (Maity et al. 2013). Furthermore, the structure of a water-soluble polysaccharide from mushroom *C. comatus* was elucidated by methylation analysis, GC-MS, ^{1}H NMR, and ^{13}C NMR spectroscopy. The polysaccharide moiety was composed of *l*-Fuc and *d*-Gal in the ratio of 1:3.84 (Zhou et al. 2013). Structural characterizations of two water-insoluble glucans from mushroom *Ramaria botrytis* were investigated on the basis of total hydrolysis, methylation analyses, periodate oxidation, Smith degradation, and NMR experiments. The structural features of polysaccharides from different sources are shown in Table 1.

6 Quantitative Analysis of Polysaccharide from Mushroom

An easy quantification method for polysaccharides (like chitin and glucans) from mushrooms, with high precision, is a matter of particular importance (Nitschke et al. 2011). The phenol-sulfuric acid method (Du Bois et al. 1956), which is rapid,

simple, and economic, is a classical colorimetric method for determining total polysaccharides (Xi et al. 2010b). Maity et al. (2013) determined the content of polysaccharides from *C. comatus* based on a phenol-sulfuric acid assay at 490 nm. Kozarski et al. (2011) measured the total polysaccharide content of the extracted polysaccharides from medicinal mushrooms *Agaricus bisporus*, *Agaricus brasiliensis*, *Ganoderma lucidum*, and *Phellinus linteus* using the phenol-sulfuric acid method with *d*-glucose as a reference. A number of existing methods that determine the total amount of β-1,3-glucans (Manzi and Pizzoferrato 2000; Mizuno et al. 2001; Park et al. 2003b; Synytsya 2008; Rhee et al. 2008) were reported previously. Nitschke et al. (2011) described a colorimetric method for β-1,3-1,6-glucan quantification based on the dye Congo red and determined the β-1,3-1,6-glucan content in mycelia and fruiting bodies from various mushrooms, such as button mushroom, enokitake, maitake, shiitake, and shimeji mushroom, among others. Congo red was used for characterization of glucan tertiary structures because of its interactions with the triple helix of β-1,3-1,6-glucan (Mao et al. 2007). It is the first mean of analyzing β-1,3-1,6-glucan with high precision, without extensive clean-up. The methods are useful tools to determine β-glucans in selected samples.

The β-glucan contents of three different fractions extracted from the fruiting bodies of *Pleurotus nebrodensis* were quantitatively determined using a β-glucan assay kit (Cha et al. 2012). Moreover, the content of β-glucans in mushroom *Coriolus versicolor* was determined enzymatically using a Megazyme kit (Kang et al. 2013). Minato et al. (1999) and Mizono et al. (1996) reported the development of an enzyme-linked immunosorbent assay to detect levels of lentinan in mushrooms. However, the use of enzymes is expensive and time-consuming and hydrolysis by acids is very unspecific.

At present, Brauer et al. (2002) reported a method to quantitate a fraction that included lentinan, which is labeled as a high-molecular-weight polysaccharide. In this method, aqueous extracts of shiitake mushrooms were fractionated by ethanol precipitation and size exclusion chromatography. Lentinan recovery during these two steps was quantitative. Moreover, Ko and Lin (2004) developed a fluorescence microassay based on aniline blue dye to measure β-glucan content in foods, including cereals, tubers, vegetables, fruits, and mushrooms. This microassay displayed selectivities among various 1,3-β-glucan species. The results indicated that biologically active ones such as pachyman from mushroom *Poria cocos* and yeast glucan possessed much stronger fluorescent signals than others such as barley glucan and laminarin from *Laminaria japonica*.

In addition, matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) provides rapid and sensitive analyses of larger biomolecules. Hung et al. (2012) demonstrated an efficient method to give glycanbenzimidazole derivatives for polysaccharide determination in MALDI-TOF MS. Polysaccharides isolated from nutritional supplements of *Ganoderma lucidum* and *Saccharomyces pastorianus* were measured using MALDI-TOF MS with 2,5-dihydroxybenzoic acid as the matrix. These glycans were also derivatized to methylated and benzimidazole-tagged glycans by chemical transformation for

molecular weight analysis. The derivatized polysaccharides showed excellent MALDI-TOF MS signal enhancement in the molecular weight range from 1 to 5 kDa. Further research should be undertaken to improve the sensitivity.

7 Potential Applications of Mushroom Polysaccharide

Mushroom polysaccharides have aroused great interest among biotechnologists because of their wide range of potential applications in such fields as pharmacy, foodstuffs, cosmetics, and the petroleum industry (Llamas et al. 2012). Many edible mushrooms, such as reishi, maitake, shiitake, yamabushitake, etc., can be used as highly functional food materials in dishes, concentrates, extracts, liquor, and powdered mushrooms or mycelia. Polysaccharides from mushrooms have been widely applied in the food and medicine fields as immuno-stimulant and antitumor drugs with no toxicity (Zhang et al. 2011a). In medicines, three kinds of carcinostatic polysaccharide drugs, such as immunopotentiators (BRM, biological response modifiers), have been developed in Japan: (a) "lentinan" from the fruiting bodies of Shiitake, (b) "Krestin" from the cultured mycelia of Kawaratake, and (c) "Schizophyllan" (Sonifilan) from the cultured broth products of Suehirotake (Mizuno et al. 1995). The biological activities of polysaccharides have proven to be invaluable and could be employed in the potential industrial applications as natural functional ingredients to obtain possible health benefits.

8 Conclusions and Future Prospectives

Over the years, polysaccharides with potential pharmacological, nutraceutical, functional food, and cosmeceutical properties have been isolated from mushrooms. These polysaccharides attract a great deal of attention of not only researchers but consumers. In the present review, attempts have been made to discuss the preparation, extraction, purification, and characterization along with quantitative analysis of polysaccharides from mushrooms. It is reasonable to evaluate the medicinal quality of mushroom using the bioactive polysaccharide content as a marker, rather than the total polysaccharide level in the future. A number of polysaccharides from mushrooms are recommended for increasing energy, reducing levels of blood glucose, losing weight, and boosting the immune system. However, reliable data from actual animal experiments and human clinical trials are still relatively lacking. In addition, it is essential to develop effective industrialization-oriented methods for the extraction of mushroom bioactive polysaccharides and exploit nutraceutical products based on the bioactive polysaccharides.

Acknowledgments This research was jointly supported by the Natural Science Foundation of Guangdong Province, China (Project code: S2012010008961), and a research grant (UICRG 201402) from Beijing Normal University-Hong Kong Baptist University United International College, China.

Contents

Abstract

The advent of nanotechnology has given a new momentum to enhance the inherent characteristics of naturally occurring polysaccharides when these are subjected to nanofabrication. At the nanoscale, the functionality of the polysaccharides is changed drastically. Many properties are concealed in the polysaccharides that are perhaps not yet discovered. The exploration of nanotechnology to engineer polysaccharides may open up a new horizon that can noticeably change every aspect of human life. In this context, chitosan, as one of the important polysaccharides, will only be studied thoroughly not only because of its abundant availability in nature but its versatility in various biomedical and industrial applications as well. Usually, chitosan is found in the exoskeleton of crab, shrimp, prawn, lobster, squid pen, etc. There is a great impact on the properties of chitosan depending on the nature of methods of extraction. That is why the selection of gentle methods for isolation and purification of chitosan

PEI-PEG	Polyethylenimine-poly(ethylene glycol)
SBP	Systolic blood pressure

1 Introduction

Among other polysaccharides, chitosan is only polycationic in nature, and this important characteristic has made it as a suitable candidate for a wide range of biomedical applications. The properties of chitosan get drastically changed with extraction and purification methods adopted. Chitin, a homopolymer of β(1 → 4)-linked *N*-acetyl-D-glucosamine, is found widely in the cell walls of some microorganisms such as fungi, molds, and yeasts and in the cuticular and exoskeletons of invertebrates such as crabs, shrimps, prawn, lobsters, squid pens, and insects (Zheng et al. 2001; Knaul et al. 1999; Dutta et al. 2002; Dutta et al. 2004a, b). Chitosan occurs rarely in nature, and it is usually obtained by extensive deacetylation of chitin with a hot alkali solution. Chitosan is composed essentially of β(1 → 4)-linked glucosamine units together with some proportion of *N*-acetylglucosamine units (Fig. 1; Dutta et al. 2004a, b, 2008; Jiu et al. 2004; Dong et al. 2004). Despite the abundant availability of chitin in nature, it is still recognized as underprivileged resources. Nevertheless, a vast amount of research has already been carried out on chitin and chitosan. In recent studies, especially, chitosan has been a very good biomedical candidate for its potential applications

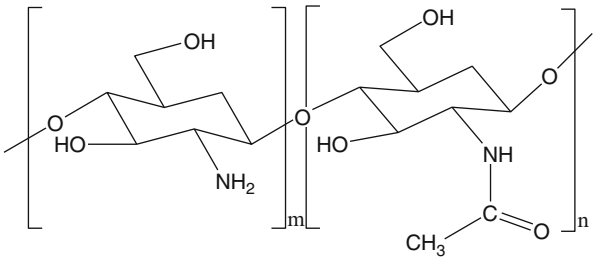

Fig. 1 Chemical structure of chitosan

ranging from drug delivery to cell delivery to gene delivery to wound healing (Khor and Lim 2003; Malafaya et al. 2007; Alves and Mano 2008; Riva et al. 2011; Liu et al. 2011). But the solubility of chitosan has been a major constraint for its versatile applications. Chitosan is not soluble in conventional organic solvents; it is only soluble in acetic acid and a few inorganic acids such as hydrochloric acid (Guibal 2005; Pillai et al. 2009). Therefore, it has been a major challenge to improve the solubility of chitosan. On the other hand, the unmodified forms of chitosan too have confined the practical or commercial uses of it. So it is believed that application of nanotechnology to engineer chitosan may not only boost its solubility properties but also may change its material characteristics that would be beneficial for further processing for its commercialization in various products. This belief has led the chitin and chitosan researchers not only to escalate fundamental research on chitosan but also to work aggressively on applied research to develop chitosan-based nanoproducts by exclusively utilizing its chemical, physical, and biological properties. On the other hand, the variations on the properties of chitosan obtained from various sources are also not yet well documented. This chapter will discuss the different sources of chitosan and its versatile characteristics, isolation and purification method to obtain chitosan, and nanotechnological applications of selective chitosan-based derivatives.

2 History and Origin of Chitin and Chitosan

The word chitin comes from the Greek etymology meaning “envelop.” Prof. Henri Braconnot of France was the first inventor of chitin and he found it in mushrooms in 1811. This was first used by Odier in 1823. Further, in the 1830s, it was isolated from insects and was named chitin. In 1859, Prof. C. Rouget discovered chitosan. Although, in the 1930s and 1940s, the polymers attracted significant attention that is evidenced by about 50 patents but due to the lack of adequate manufacturing facilities and aggressive competition, commercial development of synthetic polymers was restricted. Revived interest in the 1970s encouraged the researchers to better utilize shellfish shells. There are plentiful sources of chitin in the total universe, and chitosan exists naturally only in a few species of fungi (Pochanavanich and Suntornsuk 2002; Bank et al. 2005). Chitin has been found in a wide array of natural sources, namely, crustaceans, fungi, yeasts, insects,

annelids, nematodes, mollusks, coelenterate, marine diatoms, squid pens, etc. (Muzzarelli 1990; Synowiecki and Al-Khateeb 2003; Franco et al. 2005; George et al. 2011). However, chitosan is primarily manufactured from the exoskeleton of crustaceans like crab, shrimp, prawn, lobster, krill, and crayfish, to name a few, because of its abundant availability as a by-product of food processing (Shepherd et al. 1997; Rasmussen and Morrissey 2007).

3 Isolation of Chitin from Plants and Animals

As the principal source of chitin is animal based, this is the reason why it is better to start discussing isolation of chitin from various animals. Over a decade, a small quantity of shell waste was particularly utilized for animal feed or chitin isolation (Synowiecki and Al-Khateeb 2003). Thus, the processing of shellfish was a major concern for environmental pollution. Nowadays, this problem has been overcome to a certain extent because of an increased awareness among the researchers to explore the underprivileged resources (mainly shell wastes) for the isolation of chitin and make it suitable for a variety of biomedical applications. The basic pattern is more or less same for the isolation of chitin from various sources because typically the exoskeleton of crustacean shell consists of minerals (especially calcium carbonate), protein, chitin, pigments, etc. It is quite significant to mention that there are some solvent systems available for direct dissolution of chitin, but no economical and appropriate solvent is, however, known for the dissolution of chitin after isolation of chitin from these exoskeletons (Hudson and Smith 1998; Sannan et al. 2006). The current trend in industry to obtain chitin from their exoskeletons is to make the calcium carbonate and proteins in the exoskeletons soluble in water and then to remove them from the exoskeletons to obtain chitin. Specifically, the exoskeletons of crabs, lobsters, or shrimps are immersed in a dilute aqueous alkaline solution and heated, after which the degraded proteins are washed off with water. Insoluble matter with chitin contained therein is immersed in a dilute aqueous solution of hydrochloric acid to convert calcium carbonate (which is still contained in the insoluble matter) into calcium chloride, which is soluble in water. The insoluble matter is then washed with water to remove the calcium chloride, so that chitin is obtained as insoluble matter. The various sources of chitin differ somewhat in their structure and percent chitin content. Usually, chitin isolation consists of several steps, namely, demineralization, deproteinization, and decoloration. The first two steps can be reversed according to the needs of recovering carotenoids and protein and for further chitin application. Among other crustacean shells, crab and shrimp shells have received a significant attention for the production of chitin and chitosan (Shahidi et al. 1999; Islam et al. 2011). The readers are directed to refer to many reviews, research articles, patents, and books pertaining to traditional isolation of chitin (Okada et al. 1999; Ravi Kumar 2000; Teng et al. 2001; Lertsutthiwong et al. 2002; Wooten and Singer 2003; Sannan et al. 2006; Toan 2009; Das and Ganesh 2010; Kumirska et al. 2011; Limam et al. 2011). Succinctly, demineralization is usually achieved by using diluted

Table 1 Influences on the characteristics of chitin produced by different serial treatments

Treatment 1	Treatment 2
The deproteinization precedes the decalcification	The decalcification precedes the deproteinization
Chitin becomes whiter with increasing concentration of NaOH (1–4 %)	Higher concentration of NaOH (4 %) gave more efficient removal of protein and colored matter
Decalcification with 4 % HCl for only 2 h was sufficient to remove minerals	Decalcification first with 4 % HCl for either 2 or 12 h gave colored matter and the protein still remained bound to the solid matrix
The yield of chitin was 15–20 %. In this case, protein layer gets unprotected as the deproteinization precedes the decalcification. That is why during demineralization more hydrolyses and loss of materials in the solid chitin fraction occur	The yield of chitin was 20–27 % that is attributed to the strong adherence of chitin with protein leading to less hydrolysis of the backbone because the decalcification precedes the deproteinization
Ash content was less than 1 %	Ash content was 1–2 %

hydrochloric acid (1–8 %) at room temperature (Hackman and Goldberg 1965; No et al. 1989). To prevent chitin depolymerization, ethylenediaminetetraacetic acid (EDTA) can be used for the removal of mineral salts (Austin et al. 1981; Roberts 1997). On the other hand, deproteinization involves the usage of aqueous sodium or potassium hydroxide solution, and decoloration is usually carried out by a bleaching treatment with NaOCl or H_2O_2 solutions (Roberts 1992).

The most exploited sources of chitin are shrimp and crab shells. Lertsutthiwong et al. (2002) has studied the effect of chemical treatment on the characteristics of chitosan obtained from fresh local black tiger shrimp shells. In this study, they separately treated the shrimp shells by reversing the conventional order of extraction of chitin from crustacean shells. The differences of the characteristics of chitin produced by different serial treatments are shown in Table 1. Further, they have shown the effect on quality of chitosan obtained from chitin after deacetylation from these different serial treatments. If process 2 is followed by subsequent deacetylation, then there is a possibility of getting chitosan with high viscosity because the protein layer gets protected from more hydrolysis and vice versa in the case of process 1 (See Table 2). Further, to get chitosan with a high viscosity and a high degree of deacetylation at low temperature, the process should be initiated with decalcification and requires multi-deacetylation.

There are many standard operating procedures (SOPs) available for extraction of chitin and chitosan because of their wide range of sources in the earth (Percot et al. 2003; Kim and Rajapakse 2005; Kjartansson et al. 2006; Waldeck et al. 2006; Mahmoud et al. 2007; Rødde et al. 2008; Hayes et al. 2008). Although, lots of works have already been done on extraction of chitin and chitosan from various sources, but a significant research is still required to improve the production process as well as the quality of chitosan, especially from stored material sources. In a study, Toan (2009) has investigated the effect of partial autolysis during storage of shrimp biowaste on the quality of extracted chitin and chitosan. In this study,

Table 2 Influence on various parameter of chitosan during its different serial treatments (Adapted from Lertsutthiwong et al. 2002)

Treatments	Parameter			
	Moisture content (%)	Ash content (%)	DD (%)	Viscosity (cps)
1 % NaOH, 21 h, and 4 % HCl, 2 h	6.71 ± 0.10	0.51 ± 0.04	75.9 ± 0.35	830 ± 30
4 % HCl, 2 h, and 1 % NaOH, 21 h	9.52 ± 0.16	0.89 ± 0.27	74.3 ± 0.07	5,268 ± 146
2 % NaOH, 21 h, and 4 % HCl, 2 h	6.96 ± 0.04	0.52 ± 0.04	75.7 ± 0.71	486 ± 14
4 % HCl, 2 h, and 2 % NaOH, 21 h	8.13 ± 0.09	1.04 ± 0.08	75.5 ± 0.21	6,370 ± 254
4 % NaOH, 21 h, and 4 % HCl, 2 h	8.36 ± 0.06	0.50 ± 0.08	75.7 ± 0.28	435 ± 13

a modified method had been used in which the shrimp shell was allowed to undergo partial autolysis before it was used to produce chitin and chitosan. This revised process for the production of chitin and chitosan is shown in Fig. 2.

In terms of improving the quality of chitosan, partial autolysis plays a crucial role because it facilitates $CaCO_3$ to get exposed directly to the chemicals used during demineralization process. For the industrial practice of chitin extraction, this indicates that a shorter time and lower concentration of HCl may be adequate to demineralize so as to avoid damage due to hydrolytic action of HCl on the polymeric backbone structure of chitin. On the other hand, it was found that the protein content after treatment of autolyzed biomaterial with 2 % NaOH is similar to the protein content after standard 4 % NaOH treatment. Obviously, this study could help reduce the cost of deproteinization in industry and could help prevent the environment from pollution. The production of chitin from various sources with their different treatment processes is summarized in Table 3.

Keeping in mind the importance of chitosan as well as its economic value as an industrial product, we must pay attention on its key physical parameter,

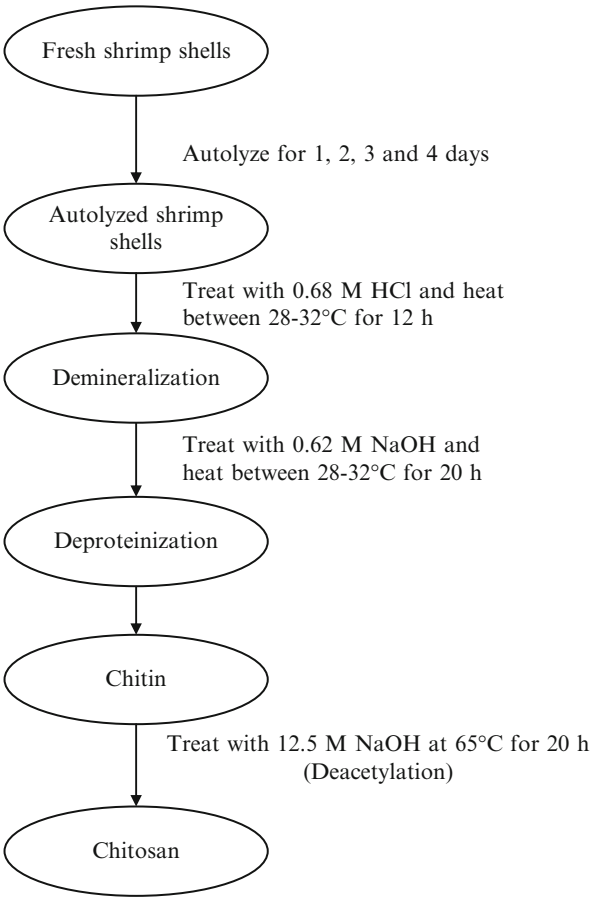

Fig. 2 Flow chart for the processing of chitin and chitosan from fresh shrimp shells

i.e., turbidity. Depending on the source, a marked difference is observed in aqueous solutions of chitosan and its derivatives in terms of their extent of turbidity (Sannan et al. 2006). Consequently, these turbid aqueous solutions of chitosan and chitosan-derived products greatly lose its commercial value. Obviously, such chitosan cannot be used as a commercial product and may have to be discarded in some instances. Therefore, the selection of the source also plays a pivotal role in the production of chitin and chitosan. In a study, Shepherd et al. (1997) reported the production of chitosan from New Zealand's arrow squid (*Nototodarus sloanii*) pens as well as the evaluation of the functional properties of this squid chitosan compared with chitosan extracted from crustacean sources. Squid pen chitin and chitosan were visibly cleaner than chitin and chitosan obtained from crab and crayfish. In addition, due to the presence of lower amount of minerals in squid pen as compared to crustacean shells, demineralization process can be skipped to extract chitin that also makes the production cost cheaper. As shown in Table 4, the squid pen chitosan is similar in composition to commercial chitosan. Further, there

is a substantially lower amount of ash contained in squid chitosan that makes this aqueous solution noticeably cleaner than samples of chitin and chitosan from crab and crayfish. The manufacturing process of chitin and chitosan from squid pen as well as crustacean shell is shown in Fig. 3. The traditional and commercial chitosan production process has a number of unfavorable characteristics as the process requires expensive heat energy and caustic alkali, which is a potential health hazard. The process also produces large amounts of waste, thereby necessitating significant disposal costs. In addition, the supply of shrimp or crab shells is highly dependent upon seasonal and environmental factors, leading to unpredictable limitations on production capacity (Chen et al. 2002). Therefore, low cost and available waste materials may be considered as promising sources of chitin. "Fish scales" are good sources of chitin and chitosan. The fish scales are discarded daily as waste materials from fish markets, canteens, fish processing industries, or kitchens. This abundant waste may pose environmental hazard due to easy deterioration. The use of this waste to produce valuable and biologically sustainable

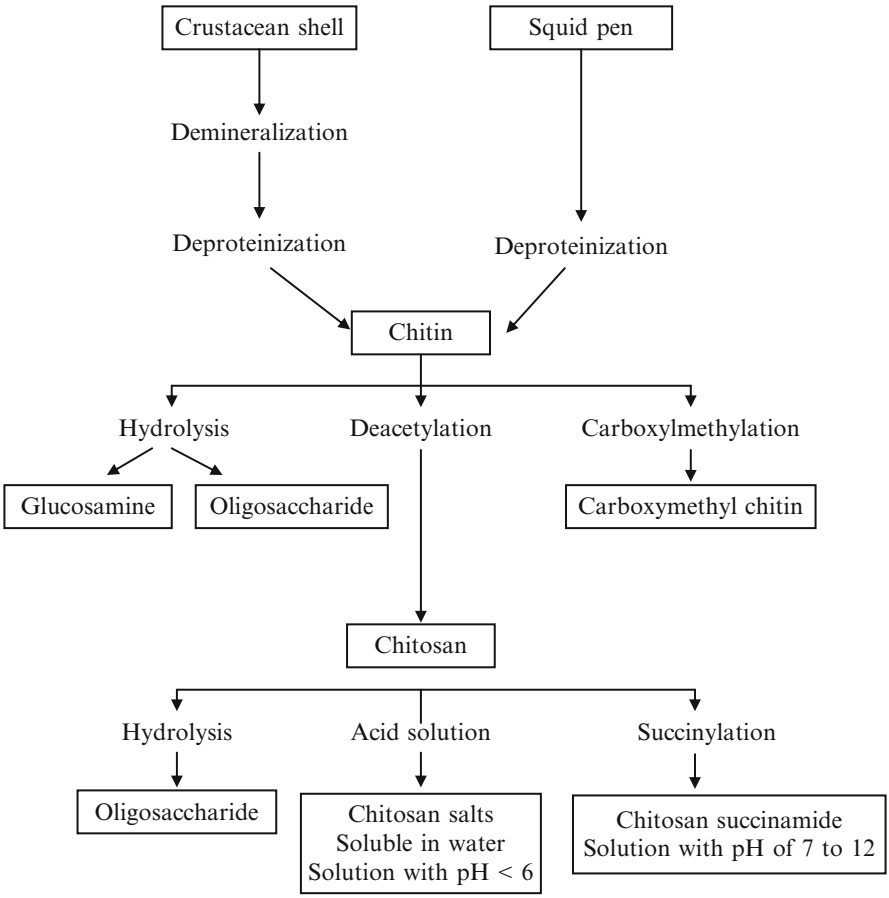

Fig. 3 A schematic diagram for manufacturing chitin and chitosan (Adapted from www.france-chitine.com/fab.e.htm)

materials is a challenge for current research and development (Zaku et al. 2011). Generally, fish scales consist of protein (type I collagen and ichthylepidin) and apatite (calcium phosphate, magnesium carbonate, and calcium carbonate) (Ikoma et al. 2003). A very few information is available on extraction of chitin and chitosan from fish scales. A study on dye-binding interaction of chitosan obtained from the fish scale of Tilapia (*Tilapia nilotica*) was reported by Uawonggul et al. (2002). Recently, a report on extraction and characterization of chitin from scales of common carp fish (*Cyprinus carpio* l) has been published (Zaku et al. 2011). In another study, Tanvir Muslim et al. (2013) demonstrated the extraction of chitin from the fish scales of *Labeo rohita* and subsequent preparation of chitosan from it by deacetylation reaction. The extraction process from the fish scales of *Labeo rohita* is shown in Fig. 4.

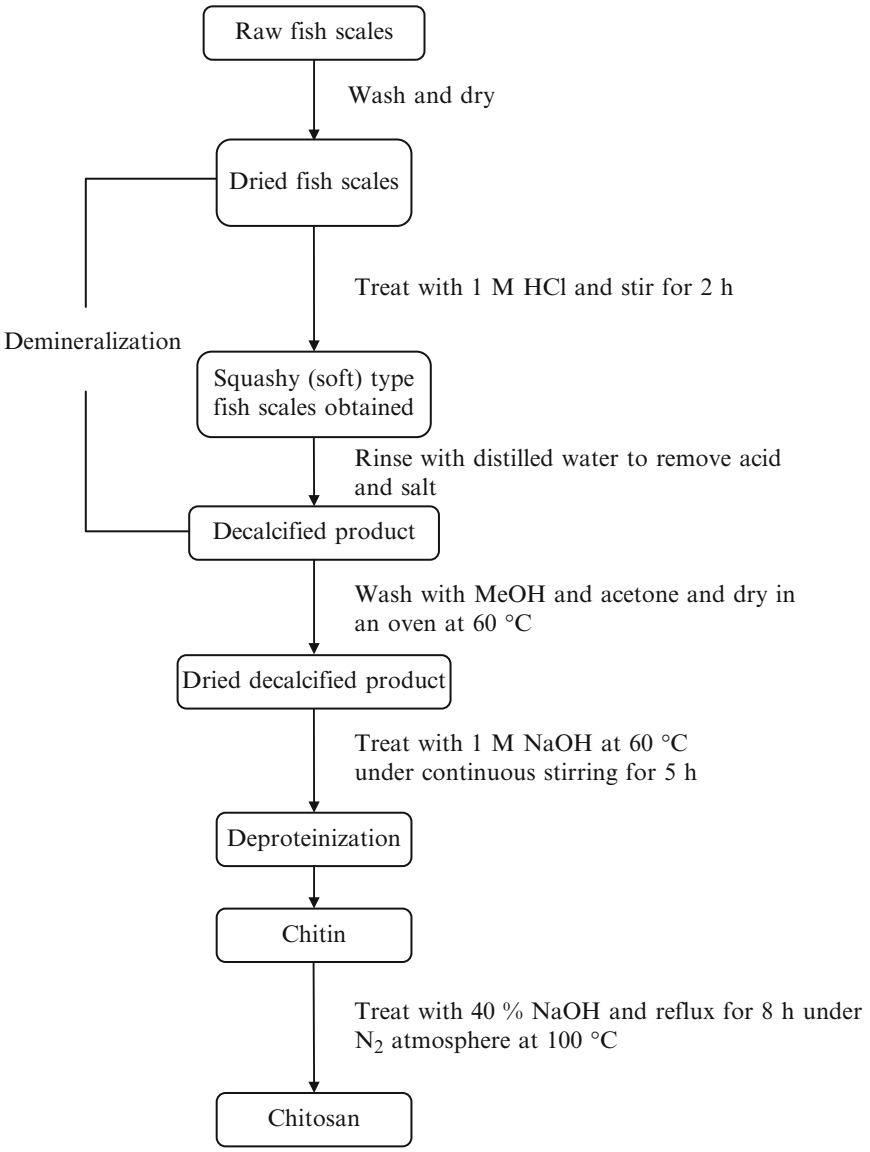

Fig. 4 Flow chart for the extraction of chitin and chitosan from "fish scales" of *Labeo rohita*

On the other hand, fungal mycelia wastes from biotechnological plants can become free and rich alternative sources of chitin and chitosan, in addition to the conventional sources of shellfish waste materials. Fungal mycelia can be cultivated throughout the year by fermentation that is rapid and synchronized and can be organized in a closed or semi-closed technological circuit to comply with modern ecological requirements. Moreover, fungal mycelia are relatively consistent in

composition and are not associated with inorganic materials. Therefore, no demineralization treatment is required to recover fungal chitin (Feofilova et al. 1996). In a study, Teng et al. (2001) investigated the concurrent production of chitin from shrimp shells and fungi by placing shrimp shells in direct contact with the fermentation of filamentous fungi in a reactor so as to avoid the use of conventional chemicals, which can lead to undue deacetylation of chitin or chain degradation of the isolated chitin. Three proteolytic *Aspergillus niger* (strains 0.576, 0.307, and 0.474) were selected from a screening for protease activity from among 34 zygomycete and deuteromycete strains. The proteolytic enzymes released by the fungi facilitate the deproteinization of shrimp powder and the release of hydrolyzed proteins. The hydrolyzed proteins in turn act as a source of nitrogen for further fungal growth, leading to a lowering of the pH of the fermentation medium, thereby further enhancing the demineralization of the shrimp shell powder. Chitin from non-fermented, fermented, and fungal mycelia were directly extracted with 5 % lithium-chloride-*N*, *N*-dimethylacetamide (5 % LiCl in DMAc), a non-degradative solvent for chitin (Austin et al. 1981). Two different problems are being solved simultaneously even without using any harsh chemicals. Fungal fermentation is a cost-effective method compared to commercial protease enzymes that only deproteinize but not demineralize the shrimp shells. Demineralization is an important step in chitin purification process from crabs also. The chemical method of demineralization includes the use of strong acid (HCl) that harms the physicochemical properties of chitin. In an attempt, Das et al. (2010) reported the usage of organic acids (lactic acid or other organic acids) produced by *Lactobacillus plantarum* as a replacement of hydrochloric acid for demineralization and proteolytic enzymes produced by *Aspergillus niger* to substitute alkaline aqueous solution for deproteinization for the extraction of chitin from trash crabs (*Podophthalmus vigil*). Although, the removal of protein entirely from crustacean shells is not yet achieved by using biological treatment during isolation of chitin, but the quality of chitin obtained by this process surely does not compromise with chitin obtained by conventional chemical treatment. The results of chitin derived from the trash crab are shown in Table 5. The study showed that the effectiveness of lactic acid for the demineralization of crustacean shells was virtually comparable to that of hydrochloric acid. For effective removal of minerals from crab shells using lactic acid, shells to acid ratio of 1:25 and temperature of 40 °C were found to be satisfactory. The use of chemicals causes depolymerization of chitin to a certain extent, and thus, its molecular weight and viscosity are affected after solubilization (Waldeck et al. 2006). But in this case, the combination of lactic acid and *Aspergillus niger* not only produces partially soluble chitin which is anticipated to increase its applications in biomedicine and pharmacy industry but also reduces the production cost of chitin. In another study, it was shown that the effectiveness of organic acids (lactic and acetic) for the demineralization of shrimp shells was also comparable to that of hydrochloric acid (Mahmoud et al. 2007). For effective removal of minerals from shrimp shells using organic acids (lactic and acetic), shells to acid ratio of 1:20, temperature of 24 °C (room temperature), and retention time of 2 h were found satisfactory. Under these conditions, the total minerals and

calcium removal efficiencies were 97.4 % and 99.11 % and 86.36 % and 85.33 % for lactic and acetic acids, respectively. Using acetic acid in the ratio of 1:20 g shells to mL acid for the demineralization of shrimp shells would result in the production of 560.38 g calcium acetate and 2.19 g potassium acetate for each 1 kg shells, provided if all the calcium and potassium present in the shrimp shells are removed. Using lactic acid in the ratio of 1:20 g shells to mL acid for the demineralization of shrimp shells would result in the production of 773.17 g calcium acetate for each 1 kg shells, provided if all the calcium present in the shrimp shells is removed. Using organic acids for the demineralization of shrimp shells would result in (a) effective removal of minerals, (b) reduction in the purification cost, (c) retention of natural chitin characteristics, and (d) production of value-added products (food preservatives and deicing agents) besides the purified chitin.

Chitosan is less commonly found in living organisms than chitin, but it can be found in the cell walls of certain groups of fungi. The traditional process of obtaining chitosan is the deacetylation of chitin using strong caustic alkali, but no significant progress has yet been made in establishing new technologies, which leads to the large-scale controlled production of chitosan. The recognition of chitin deacetylase (CDA) in several fungi and insects has given new momentum for the conversion of chitin into chitosan. In contrast to the currently used chemical procedure, the use of CDA offers the possibility of a controlled non-degradable process, resulting in the production of novel, well-defined chitosan oligomers and polymers. Indeed, the uses of biological treatment over chemical treatment for the isolation of chitin from crustacean shells as well as production of chitosan will substantially reduce environmental pollution. The use of CDA as an enzyme for the

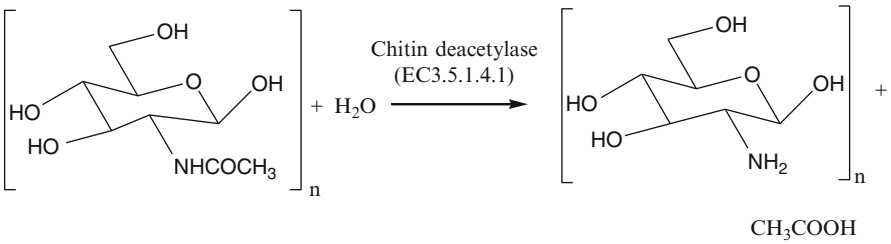

Fig. 5 Bioconversion of chitin to chitosan

preparation of chitosan polymers and oligomers offers the possibility of developing an enzymatic process that could potentially overcome most of the drawbacks as discussed earlier (Tsigos et al. 2000). As shown in Fig. 5, CDA (EC 3.5.1.41) catalyzes the hydrolysis of *N*-acetamido bonds in chitin to produce chitosan. The presence of this enzyme has been reported in several fungi and insect species (Araki and Ito 1975; Kafetzopoulos et al. 1993; Martinou et al. 1993; Tsigos and Bouriotis 1995; Gao et al. 1995; Tokuyasu et al. 1996; Zhao et al. 2010, 2011; Song et al. 2012).

Chen et al. (2002) have patented an alternative method to produce chitin and chitosan without relying on environmentally harmful chemicals or the variable abundance of the crustacean crop. They demonstrated high-yield production of chitosan or chitin from a culture containing a *Rhizopus zygospores* or *Actinomucor taiwanensis* fungus. Further, they have shown that a medium containing corn steep liquor, glucose, yeast extract, and ammonium sulfate is capable of increasing the output of chitin and chitosan from a fungal culture. Although, the isolation of chitin from fungi is environmentally safe, but the enzymes used for the bioconversion of chitin into chitosan are required for further purification that may subsequently increase the purification cost. A selective fungal species for the isolation of chitosan are shown in Table 6. Therefore, an alternative research has been going on to find out corresponding enzymes in bacteria for the biotransformation of chitin to chitosan because bacteria are easier and faster than fungi to grow in a large-scale fermentation system. In addition, bacteria can be utilized without the necessity of purifying the enzyme.

Srinivasan (1998) have patented a method to isolate an unknown bacterium from municipal sewage. This bacterium can deacetylate chitin to the more useful, soluble chitosan. Biotransformation of chitin to chitosan by bacteria can be used in an economical and environmentally friendly process.

In another study, Yong et al. (2005) reported a novel chitinase-producing bacterium strain C4 from the soil samples. The molecular identification confirmed that strain C4 should belong to the genus *Sanguibacter*. The enzyme extracted from bacteria was able to degrade polymeric chitin from crab and shrimp shells and from insect puparium. The enzyme also displayed weak activity to chitosan.

As it is known in the earlier discussion that bacterial growth is faster than fungal growth and CDA-producing capabilities of most fungal strains are low and their

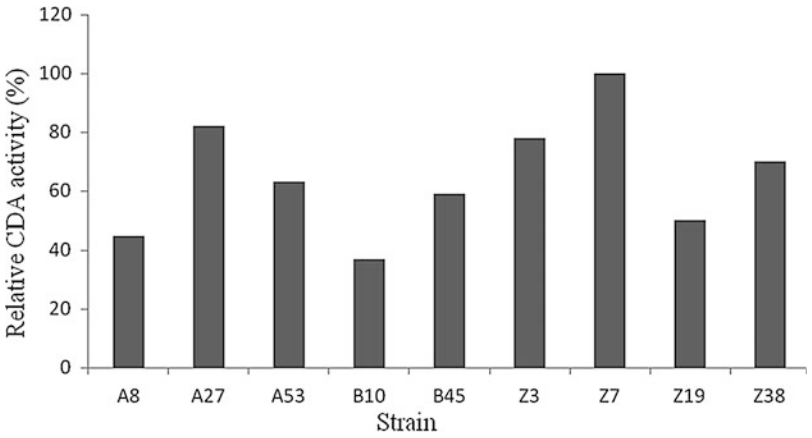

Fig. 6 The relative CDA (chitin deacetylase) activity of nine isolated bacterial strains (Adapted from Zhou et al. 2010)

fermentation requirements are complicated. In a study, Zhou et al. (2010) reported the isolation of CDA-producing bacteria from soil and optimized its fermentation process. Among 208 bacteria isolated from fresh soil samples, 9 were CDA-producing strains of bacteria, namely, A8, A27, A53, B10, B45, Z3, Z7, Z29, and Z38. Percentage of relative CDA activity of them was shown in Fig. 6. As can be seen from this figure, the Z7 strain shows the highest CDA activity, which was determined by enzyme assay screening. To enhance CDA production, various carbon sources (glucose, lactose, sucrose, starch, corn meal, and bran), nitrogen sources (beef extract, yeast extract, casein, proteose peptone, soybean meal, urea, ammonium sulfate, and sodium nitrate), and inorganic salts ($MgSO_4$, $FeSO_4$, $ZnCl_2$, $CuSO_4$, $MnSO_4$, and K_2HPO_4) were separately added to the basal formulated production medium at concentrations of 2 %, 1 %, and 0.04 %, respectively. Based on its cultural, morphological, and physiological characteristics and molecular identification, strain Z7 was recognized as *Bacillus amyloliquefaciens*. It was concluded that yeast extract at a concentration of 1 % was an ideal nitrogen source, starch at a concentration of 2 % functioned best as the major carbon source, and magnesium sulfate at a concentration of 0.04 % was an ideal inorganic salt. Ideal pH and temperature for optimum production of CDA by

Table 7 Proximate analysis of crustacean shell wastes as a percentage of dry weight (Naczk et al. 1981; Shahidi and Synowiecki 1991; Muzzarelli et al. 1997; Synowiecki and Al-Khateeb 2000; Abdulkarim et al. 2013)

[a]It was found in the bank of Gubi Dam in Bauchi, Nigeria

this strain were pH 6 and 37 °C. Further research is going on to find a suitable strain of CDA-producing bacteria for the bioconversion of chitin to chitosan to circumvent environmentally related problems caused during the traditional deacetylation of chitin using a harsh chemical NaOH pyrolysis method.

In another study, Kaur et al. (2012) reported the isolation of 20 strains of bacteria from soil samples collected from different beaches of Chennai, India. Of these 20 bacterial strains, only two strains (S3, S14) are potent degrader of chitin, and they are also good producer of the enzyme CDA that facilitates release of chitosan.

However, crustacean shell wastes are extensively used for the production of chitosan because the percentage availability of chitin is higher as compared to other sources. A proximate analysis of crustacean shell wastes as a percentage of dry weight is given in Table 7.

From the previous discussion, it has been known that chitosan can be produced from the mycelium, but no research has been reported on the use of fungal fruiting bodies as another source of chitin. A lot of research has been done on the extraction of chitin and chitosan from fungal cell wall. A fungus called *Ganoderma tsugae* (*G. tsugae*) was used for this purpose (Chen et al. 2007). The main components of *G. tsugae* fruiting bodies are β-1,3-D-glucan and chitin, which were found to be safe materials in enhancing wound healing in Wistar rats and accelerating proliferation. Further, it also facilitates migration of fibroblasts and keratinocytes with no cytotoxicity. George et al. (2011) carried out a study on chitosan from fungi. He used *Aspergillus flavus*, *Botryodiplodia theobromae*, *Cladosporium cladosporioides*, *Fusarium* sp., and *Phoma* sp., and these were all isolated from stem and leaf segments taken from medicinal plants. Here, the extraction of chitin from Shiitake mushroom (*Lentinus edodes*) will be discussed. Shiitake mushrooms have been known to possess a polysaccharide compound called letinan, a glucan that acts as a potent immune stimulator in the body and also simulates the production of T-lymphocytes in the body, which are important in controlling cancer and infection (Mizuno 1995; Sajoughian 2009). In a study, Senthilmohan et al. (2002)

investigated the feasibility of producing a fungal-derived chitosan by both chemical and enzymatic methods. Using the chemical method (dil. NaOH), 66 % of the proteins was removed, whereas 33 % of the proteins was removed using the enzymatic method. Deproteinization of mushroom fiber was described as follows.

First of all, 2 kg of Shiitake mushrooms was mixed with 4 L of water and refluxed at 100 °C for about 8 h. The solid and liquid fractions were separated by centrifugation at 4,000 rpm for 5 min. Both the liquid and solid fiber fractions were frozen to −20 °C and then freeze-dried until a constant mass was obtained. Fiber was deproteinized either by NaOH (1 N) or actinidin enzyme. Kiwifruit extract was prepared to obtain deproteinizing enzyme actinidin by blending the kiwifruit in a food processor. Then the extract was centrifuged and the supernatant was obtained. The fiber samples were incubated with the kiwifruit extract at room temperature (23 °C) for 48 h in the enzymatic deproteinization. In the chemical method, mixture of the fiber and NaOH was heated for 2 h under reflux at 100 °C. The samples were centrifuged at 4,000 rpm for 5 min and the fiber separated from the liquid. The deproteinized fiber was then stored for deacetylation. In essence, deacetylasing enzyme derived from the fungus *Aspergillus nidulans* was used, but it gave lower conversion compared to that of the chemical method. Despite yielding lower amount of chitosan, the enzymatic method was still encouraging enough to assure further study, because it is an environmentally friendly process alternative to the chemical treatment.

4 Preparation and Purification of Chitosan

By merely substituting secondary hydroxyl group on the alpha carbon atom of the cellulose molecule with the amino group, chitosan cannot be obtained. Chitin is the one and only precursor to prepare chitosan. Up to now, there is an open announcement pertaining to the laboratory synthesis of chitosan. If anybody is able to prepare chitosan synthetically, he or she will be rewarded a huge amount in dollars! Usually, by treating chitin with a hot alkaline concentrated solution, chitosans with various degrees of deacetylation are obtained. The conventional process for producing chitin and chitosan from crustacean shells involves grinding crustacean shells and treating the ground shells with a dilute base (e.g., sodium hydroxide) and then heating to remove protein and lipids (deproteinization). Calcium carbonate is removed by extraction with a dilute acid (e.g., hydrochloric acid) at room temperature (demineralization). Following deproteinization and demineralization, the resulting product is predominantly chitin. An optional decolorization step may be used to bleach the chitin, e.g., extraction with ethanol and ether or bleaching with sodium hypochlorite (Mukherjee 2001). Removal of acetyl groups from the chitin polymer (deacetylation) produces chitosan; deacetylation is usually performed by reacting chitin with concentrated sodium hydroxide or potassium hydroxide and heat. The deacetylation process does not remove any contaminants existing in the chitin starting material. Thus, removal of impurities only occurs during production of the chitin precursor. Chitosan is not a single, definite chemical entity, because its

composition varies depending on the crustacean species used as the starting material and the particular preparation method for extraction used as well (Quian and Glanville 2002). Substantial removal of impurities from chitosan can cause immunological reactions. Because it could be critical for chitosan intended for use as a biocompatible and biodegradable material in medical applications. However, purifying chitosan is very difficult since chitosan in solution is a highly viscous material. Producing highly pure, medical grade chitosan via the conventional techniques is very expensive since such techniques typically require costly instrumentation such as autoclaves, ultrafiltration, and molecular sieves (Jubert et al. 2009). The availability of less expensive medical grade chitosan should expand and accelerate its use in biomedical applications. Apart from this, several methods are available for purification of chitosan. Few of them are discussed here.

Chitosan may be purified from extraneous material which includes inorganic salts, proteinaceous materials, and gums (Doczi 1957). In a method, chitosan is purified by adding an excess of a soluble salicylate, preferably an alkali metal salicylate such as sodium salicylate, to an aqueous solution of a chitosan salt. The resulting mixture can then be immediately chilled in an ice-water bath where upon the chitosan will precipitate as the salicylic acid salt of it. By soluble salicylate, it is meant salicylic acid and salts of salicylic acid that are more soluble in water than chitosan salicylate. The high solubility of the sodium salicylate makes it particularly useful in this invention. The precipitate is separated by centrifugation, redissolved in water and the resulting solution is filtered and adjusted to a pH of about 9, by adding a water-soluble base (such as sodium hydroxide, ammonium hydroxide or diethylamine) to it. Finally, the resulting precipitate is collected, washed with a water miscible organic solvent and dried. Consequently, purified chitosan is obtained as desired.

Chitosan was purified according to the method described by Nasti et al. (2009). Briefly, 5 g of chitosan (batch I, batch II, and batch III) were dissolved in 400 mL of a (2 % v/v) acetic acid solution in deionized water. Complete dissolution was achieved after 16 h of stirring. The solution was then filtered through 0.22 μm pore-size filters in order to remove insoluble acid impurities and boiled for 15 min to denature and precipitate any protein content. The mixture was then centrifuged for 10 min at 4,500 rpm to remove protein; the supernatant was removed and filtered through 0.22 μm pore-size filters. The pH of the solution was then adjusted to 9 with 1 M sodium hydroxide, in order to precipitate chitosan from the aqueous phase and remove any alkali-soluble impurities.

The precipitated chitosan was then recovered by centrifugation and washed with deionized water until the pH and conductivity values reached the values of pure water. The samples were then freeze-dried and stored at 4 °C for further use.

Sometimes, a turbid appearance is found in chitosan solution but that is not favorable for its biomedical applications. Therefore, chitosan can be washed with 30 % isopropyl alcohol before processing it for any biomedical applications (Sannan et al. 2006). A small test was carried out by a group of researchers to ascertain the cause of turbidity in an aqueous solution of chitosan. First of all, chitosan was washed with isopropyl alcohol. Then, the unwashed chitosan and the

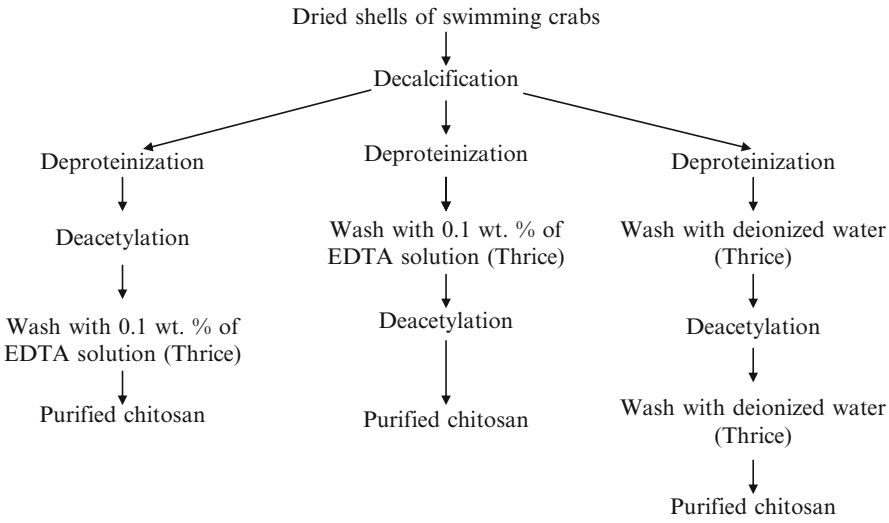

Fig. 7 Various schemes for purification of chitosan

washed chitosan were separately dissolved in aliquots of glacial acetic acid solution, and the resulting solutions were compared in terms of the extent of turbidity. As a result, it was found that the aqueous solution of the washed chitosan had much lesser turbidity. Chitosan was then subjected to extraction with isopropyl alcohol in a Soxhlet extractor, and impurities extracted in the isopropyl alcohol were analyzed by infrared spectroscopy, gas chromatography, and other methods. Those extracted impurities were found to comprise palmitic acid and oleic acid as primary components and also contain a small amount of fatty acids, such as stearic acid and myristic acid, and their corresponding salts.

As can be known from the previous discussion pertaining to the isolation of chitin that chitosan is produced from chitin in three so-called steps, i.e., deproteinization, decalcification, and deacetylation. Purified chitosan can be obtained by serial treatments of the processed crustacean shells (swimming crabs) with either 0.1 % (w/w) of EDTA or deionized water. Various schemes for purification of chitosan are shown in Fig. 7.

On the other hand, purified chitin can also be produced by washing chitin with either ethanol or isopropyl alcohol. This process is considered to be excellent because of its simple operation, it can be widely applied. Further, it has the ability to remove fatty acids and their corresponding salts present in the chitin. Using this process, the total content of fatty acids and their corresponding salts present in the chitin can be reduced to 0.2 % (w/w) or lower in terms of fatty acids. The principal cause of turbidity in an aqueous solution of a chitin is due to the formation of water-insoluble salts such as the calcium salts of fatty acids and the magnesium salts of fatty acids.

5 Pros and Cons of Chitin and Chitosan

It is noteworthy to mention that the structural difference is very important in determining many properties of chitosan, especially solubility. Chitosan obtained by a heterogeneous procedure (deacetylation at various temperatures) is not soluble in water, whereas water-soluble chitosan can be prepared by homogeneous deacetylation (at room temperature) of chitin (Sannan et al. 1976). The acetylation of highly deacetylated chitosan can also produce soluble chitosan (Kurita et al. 1989). Although, the activity of chitosan is limited to acidic conditions due to its poor solubility above pH 6.5 at which chitosan loses its cationic nature. Therefore, researchers have focused on the preparation of water-soluble chitosan derivatives in the entire range of pH. Over several decades, the studies on chitin and chitosan have been intensified as a consequence of their excellent biological properties such as biodegradation in human body, biocompatibility, non-toxicity, immunological activity, antibacterial activity, and wound-healing activity (Zhang et al. 2010). Despite the abundant availability of chitin in nature, it is no longer soluble in diluted aqueous or conventional organic solvents due to the high crystallinity of chitin, supported by strong intra- and inter-hydrogen bonds through the acetamido group. Although, chitin is soluble in hexafluoroisopropanol (HFIP), hexafluoroacetone, chloro alcohols, and chloroacetic acids in conjunction with aqueous solutions of mineral acids, *N*-methyl morpholine-*N*-oxide (NMMNO), DMAc/5 % LiCl, *N*-methyl-2-pyrrolidinone/5 % LiCl, and some other special solvents to a certain extent, but still, these solvents have limited the commercial usage of chitin (Austin 1973; Dutta et al. 1997; Ravikumar et al. 2000; Rinaudo 2006; Mark 2013). Therefore, chitin has yet to find large-scale industrial uses. No economical and suitable solvent is, however, known for the dissolution of chitin upon isolation of chitin from the exoskeletons of crustacean shells. Despite the abundance of chitin in nature and its advantages claimed (for instance, preparation of chitin films and a variety of its derivatives reported so far), satisfactory result has not always been obtained owing to its solubility related issues. Therefore, the weak solubility of chitin has become the main constraint for its usage in biomedicine and biotechnology even after possessing versatile biological activities. The various advantages of chitosan are summarized in Table 8.

6 Preparation of Selective Chitosan Derivatives

Due to the presence of amino groups as well as hydroxyl groups, chitosan can be easily customized to synthesize different derivatives of interest (Tangpasuthadol et al. 2003). Over decades, much emphasis has been given on chemical modifications of chitosan bearing in mind that chitosan is normally insoluble in solutions above pH 6 and requires acid to be protonated (Trapani et al. 2009). Chitin has two hydroxyl groups, while chitosan has three reactive groups, i.e., primary (C-6) and secondary (C-3) hydroxyl groups on each repeat unit and the amino (C-2) group on

Table 8 Various advantages of chitosan

Characteristic(s)	Action(s)
1. Chitosan behaves as a cationic polyelectrolyte in solution	1. As a result of this polycationic character, it can be employed as a flocculating agent in waste water treatment. Further, it can also be used in the food industry for the treatment of fruit juices and wines
2. Chitosan is also known as a multidentate chelating agent	2. Therefore, it is very effective for the removal of transition and posttransition metal ions
3. Chitosan shows antifungal activity	3. As a consequence of this activity, it not only facilitates promoting metabolic changes in plants but also allows influencing favorably on the development of crops and thus inducing increased germination and better yield
4. Chitosan is a biocompatible, biodegradable, nontoxic, and mucoadhesive polymer	4. These characteristics make chitosan an excellent candidate for a wide range of biomedical applications ranging from drug deliver to tissue engineering to gene delivery
5. Chitosan is a good hemostatic agent. But it is worth to mention that its sulfated derivatives exhibit anticoagulant activity	5. Due to this nature, chitosan aids in stopping bleeding
6. Chitosan shows antimicrobial, antiviral, antitumoral, and immunoadjuvant activity	6. All these interesting characteristics have led to the development of numerous applications of chitosan and its derivatives in biomedicine, such as surgical sutures, biodegradable sponges and bandages, and matrices for the delivery of drugs; in orthopedic materials; and in dentistry, among others
7. Chitosan has high specific binding capacity	7. That is why chitosan is used to remove oils, heavy metals, proteins, and fine particulate matter from waste waters. Apart from these, chitosan can also be used in affinity chromatography and for reducing cholesterol absorption
8. Chitosan shows anti-inflammatory activity	8. The ability of chitosan to inhibit an inflammatory response could be exploited in the nutraceutical industry to provide anti-inflammatory foods for the prevention and alleviation of inflammatory diseases
9. Chitosan shows anti-hypersensitive activity	9. Generally, in humans, high-salt diet increases the systolic blood pressure (SBP) and serum-associated angiotensin-converting enzyme (ACE) activity and chloride ion concentration after 1 h. It is experimentally proved that oral administration of chitosan inhibits these increases

(*continued*)

Table 8 (continued)

Characteristic(s)	Action(s)
10. Chitosan shows hypocholesterolemic action	It lowers the level of cholesterol that is also attributed to the interference with bile acid, a mechanism similar to those of dietary fiber constituents
11. Chitosan exhibits antioxidant property	Due to this property, chitosan is safe and nontoxic. Thus, offering protection from free radicals that retard the progress of numerous chronic diseases

each deacetylated unit (Sajomsang et al. 2009). This strong functionality of chitosan gives it an ample opportunity of chemical modifications. Therefore, various chemical modifications have been introduced to increase not only the water solubility of chitosan but also to chemically modify these groups for the regeneration reactions which give rise to various novel biofunctional macromolecular products having the original organization or new types of organization (Prabhakaran and Mano 2005). The chemical modification of chitosan is a powerful tool to control the interaction of the polymer with drugs and to enhance the load capability to tailor the release profile of the particles (Papadimitriou et al. 2012). Chemically modified chitosan improves its bulk properties for the preparation of sustained release systems. Different ways are there to chemically modify chitosan. Among them, chemical modification through graft copolymerization is quite promising as it provides a wide variety of molecular characteristics. In view of increasing the water solubility of chitosan, amphiphilic derivatives of chitosan have received much attention to the researchers. To prepare such type of compounds, hydrophobic moieties are introduced to the chitosan backbone via different methodologies, namely, alkylation, acylation, carboxylation, graft copolymerization, etc. Many works related to chemical modifications of chitosan have been reported in the literature (Van Luyen and Huong 1996; Kurita 2001; Jenkins and Hudson 2001; Kato et al. 2004; Zhang et al. 2004a; Zohuriaan-Mehr 2005; Muzzarelli and Muzzarelli 2005; Dutta 2013). This section will discuss about some of the chemically modified chitosan.

6.1 Chitosan Salts

The simplest form of chitosan derivative is chitosan salt, which is prepared by dissolving chitosan in an appropriate dilute acid. The most familiar chitosan salt is chitosan acetate (Fig. 8); other available salts are chitosan hydrochloride, lactate, and hydroglutamate. These salts have been extensively studied by researchers and exhibit strong antimicrobial activity against a broad spectrum of microorganism.

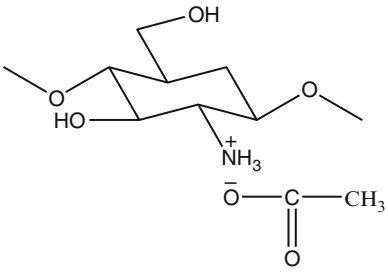

Fig. 8 Chitosan acetate salt

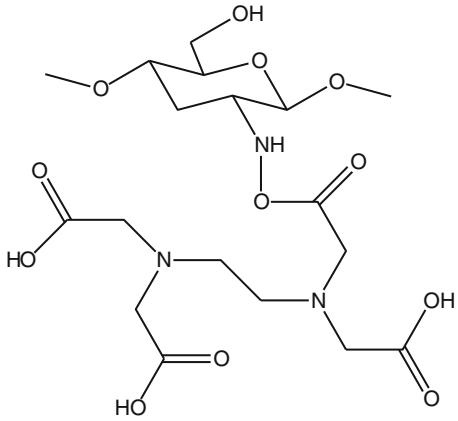

Fig. 9 EDTA-grafted chitosan

6.2 EDTA-Grafted Chitosan

Grafted chitosan presents interesting properties for wound-healing applications, because chitosan derivatives can exhibit enhanced bacteriostatic activity with respect to pure chitosan. EDTA grafted onto chitosan (Fig. 9) increases the antibacterial activity of chitosan by complexing magnesium that under normal circumstances stabilizes the outer membrane of gram-negative bacteria.

6.3 *N*-Carboxymethyl Chitosan/Glycine Glucan

The solubility of chitosan can be improved by carboxylation of chitosan. *N*-carboxymethyl chitosan (NCMC) (Fig. 10) was prepared by dissolving chitosan as a metal-chelating agent in glyoxylic acid solution followed by pH adjustment and reduction with either sodium borohydride or sodium cyanoborohydride. The NCMC was soluble in water at all pH values. The NCMC is also called glycine glucan. The derivative is water soluble and can form insoluble metal chelates after addition to transition metal ion solutions. It has good adsorption capacity for

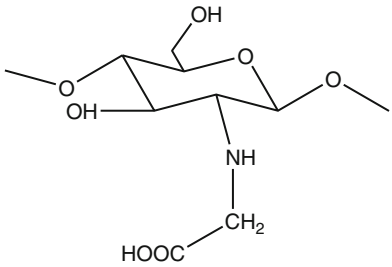

Fig. 10 *N*-Carboxymethyl chitosan/glycine glucan

Cu^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, Pb^{2+}, Co^{2+}, Cd^{2+}, and Uo^{2+} at neutral pH. The incorporation of glycine residues onto chitosan reduces the conformational rigidity of the polymer. Therefore, it shows higher adsorption for metal ions than that of chitosan and fully deacetylated chitosan even though the latter has more free amino groups.

6.4 *N*-Phthaloylated Chitosan

N-phthaloylation of chitosan was expected to be effective for solubilization since it affixes a bulky group to the rigid backbone and breaks hydrogen atoms on the amino groups to prevent hydrogen bonding. Fully deacetylated chitosan was treated with phthalic anhydride in dimethylformamide (DMF) to give *N*-phthaloylchitosan. It was readily soluble in polar organic solvents. The proposed mechanism for the synthesis of phthaloylchitosan is shown in Fig. 11.

6.5 Alkylated Chitosan

The primary amino groups of chitosan undergo a Schiff reaction with aldehydes and ketones to yield aldimines and ketimines, respectively. Further, they are converted to their corresponding *N*-alkyl derivatives by reduction with sodium borohydride ($NaBH_4$) or sodium cyanoborohydride ($NaBH_3CN$). A synthesis scheme for the preparation of *N*-alkyl chitosan is shown in Fig. 12 (Bobu et al. 2011). In brief, chitosan was dissolved in 0.1 M acetic acid solution, and then octanal ($C_8H_{16}O$) and reducing agent ($NaBH_3CN$) were added into it under continuous stirring at room temperature. The reaction was allowed to continue for a period of 20–24 h, and then the pH of the resulting solution was adjusted between 8 and 10 with a NaOH solution so as to form precipitation. The precipitate was separated by centrifugation followed by washing initially with ethanol/water mixtures in the volume ratios either 50/50 or 70/30 and finally only with ethanol. After washing, the precipitate was dried at 50 °C under air circulation. The dried *N*-alkyl chitosan was dissolved in 0.1 M HCl solution to obtain its water-soluble salt. The *N*-alkyl chitosan

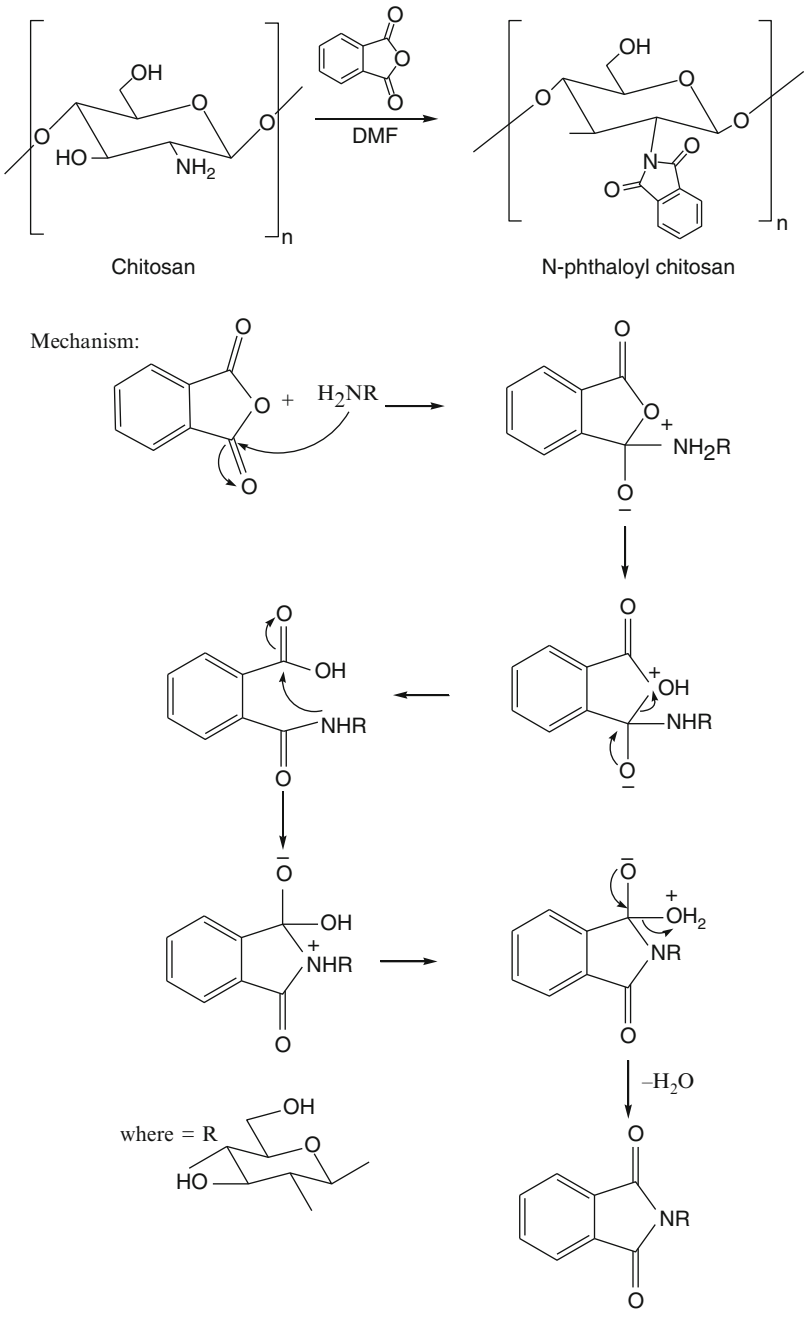

Fig. 11 A plausible mechanism for the synthesis of *N*-phthaloylchitosan

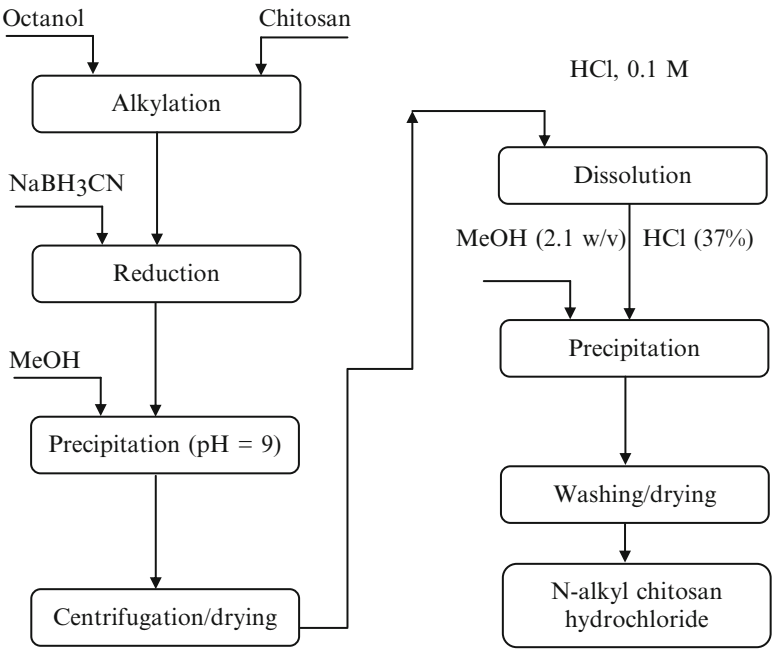

Fig. 12 A synthesis scheme for the preparation of *N*-alkyl chitosan

hydrochloride was precipitated by adding methanol (2:1 v/v) and then HCl (37 %), corresponding to 1.02 mol −L HCl to the final volume. The precipitate was centrifuged and dried afterward so as to obtain the final compound.

6.6 Thiolated Chitosan

According to the method developed by Schnurch et al. (2003) for the chemical modification of chitosan with 2-iminothiolane, Prabhakaran and Mano (2005) reported synthesis of thiolated chitosan. In brief, 500 mg of chitosan was dissolved in 50 mL of 1 % acetic acid. In order to facilitate reaction with thioglycolic acid (TGA), 100 mg of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDAC) was added to the chitosan solution. After the dissolution of EDAC, 30 mL of TGA was added and the pH was adjusted to 5 with 3 N NaOH. The reaction mixture was stirred and was left at room temperature for 3 h. To eliminate the unbound TGA and to isolate the polymer conjugates, the reaction mixture was dialyzed against 5 mM HCl five times (molecular weight cutoff 10 kD) over a period of 3 days in the dark and then two times against 5 mM HCl containing 1 % NaCl to reduce ionic interactions between the cationic polymer and the anionic sulfhydryl compound. The reaction scheme is shown in Fig. 13.

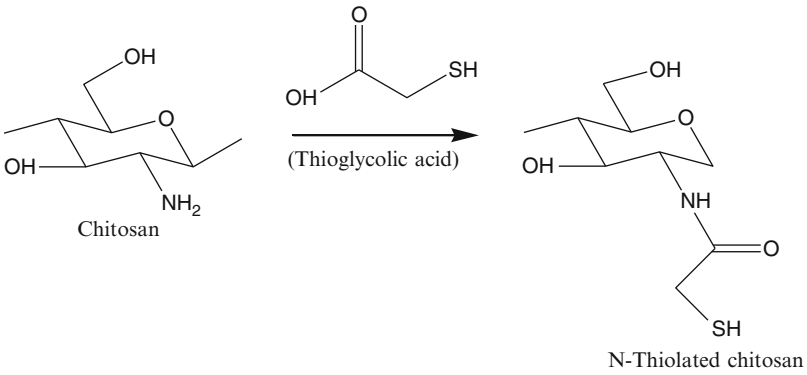

Fig. 13 A synthetic pathway for the formation of *N*-thiolated chitosan

7 Nanotechnological Applications of Chitin and Chitosan

Due to the inherent characteristics of chitin and chitosan such as biodegradability, biocompatibility, non-toxicity, etc., they have found a large variety of biomedical and industrial applications. The development of well-organized carrier systems in the nanoscale range for the biological substances for various biomedical applications has been a major challenge to the worldwide researchers who have been particularly working in the biomedical domain (Arayne et al. 2007; Sahoo et al. 2007; Jong and Borm 2008; Singh et al. 2010; Diebold and Calonge 2010; Wu et al. 2010). In light of developing efficient carrier systems, multifunctional polysaccharide-based nanomaterials combining diagnostic and therapeutic use have recently attracted intensive interests (Meyers et al. 2008). Polysaccharides are a class of biological macromolecules that play important roles in a wide variety of biochemical and biomechanical functions (Andrade et al. 2011). Among the several classes of polymeric materials including polysaccharides that have become the important tools for the biomaterial scientists, chitosan possesses unique properties that have recently been used in a wide variety of biomedical applications. Chitosan also offers possibility of modifying different chemical groups in its structure (Boddohi and Kipper 2010). In order to realize full biochemical and biomechanical potential, biomaterial scientists are exploring ways to engineer chitosan and chitosan-based nanostructures that can be used to tune the response of biological systems, namely, cells, tissues, etc. to these materials (Zhang et al. 2007). Chitosan nanoparticles offer a unique potential not only for clinical and biological applications due to low immunogenicity, low toxicity, and high biocompatibility but also for industrial applications, since due to its polycationic nature, it is capable of binding negatively charged molecules. In this section, chitosan-based nanomaterials and their corresponding applications are summarized in Table 9.

Table 9 Selective chitosan-based nanomaterials and their applications

Chitosan-based nanomaterials	Methods of preparation	Applications	Reference
Chitosan and starch-coated magnetic nanoparticles	Coprecipitation method	To use as a therapeutic modality for treating malignant tumors	Chan et al. (1993), Kim et al. (2009)
Plasmid DNA-loaded chitosan nanoparticles	Complex coacervation method	To use for nasal immunization against hepatitis B	Khateri et al. (2008)
Paclitaxel-loaded chitosan-PEG-cholesterol nanoparticles	–	It is most effective in suppressing tumor growth with a high dose of paclitaxel, while the same at equivalent dose is less effective to suppress tumor growth	Nah et al. (2004)
CS-g-PEG nanoparticles	Ionic gelation method/self-assembly	Protein delivery	Papadimitriou et al. (2012)
Heparinized chitosan/poly(g-glutamic acid) nanoparticles	Self-assembly	To facilitate multifunctional delivery of fibroblast growth factor and heparin	Tang et al. (2010)
Chitosan-dextran sulfate nanoparticles	Self-assembly	To protect protein in an oral insulin delivery application	Sarmento et al. (2007)
Chitosan-cyclodextrin nanoparticles	–	To facilitate nasal drug delivery	Teijeiro-Osorio et al. (2009)
Chitosan-heparin polyelectrolyte complex nanoparticles	–	Protein delivery	Liu et al. (2007)
Chitosan-DNA nanoparticles	–	Liver-targeted gene delivery	Dai et al. (2006)
Monodisperse chitosan nanoparticles	–	Mucosal delivery	Zhang et al. (2004b)
Folate-conjugated pluronic F127/chitosan core-shell nanoparticles	Self-assembly	Breast cancer treatment	Manaspon et al. (2012)
N-succinyl chitosan nanospheres	Self-assembly	Sustained drug delivery system	Aiping et al. (2006)
Magnetic chitosan nanospheres	Coprecipitation followed by ionic gelation	Bioseparation	Hrictu et al. (2009)
PEI-PEG-chitosan copolymer-coated iron-oxide nanoparticles	Chemical coprecipitation	Gene delivery	Kievit et al. (2009)
Folic acid-modified carboxymethyl chitosan nanoparticles	Sonication	Drug carrier for tumor-specific drug delivery	Tan and Liu (2011)

(*continued*)

Table 9 (continued)

Chitosan-based nanomaterials	Methods of preparation	Applications	Reference
Chitosan/chondroitin sulfate/nano-SiO_2 composite scaffold	Lyophilization	Promising for bone tissue engineering	Kavya et al. (2012)
Chitosan-coated ZnS and Zns:Mn^{2+} quantum dots	Radiation technology	Due to low cytotoxicity and high biocompatibility, it could be useful for various biomedical applications	Chang et al. (2011)
Chitosan-coated magnetic nanoparticles for high-efficient cellular imaging	Chemical coprecipitation	These new magneto-fluorescent nanoagents have the potentiality for future medical use	Ge et al. (2009)
Both folic acid (FA)- and methoxypoly(ethylene glycol) (mPEG)-conjugated chitosan nanoparticles	Ionic gelation and chemical cross-linking method	For targeted and prolong anticancer drug delivery system	Hou et al. (2011)
Carboxymethyl chitosan nanoparticles	Ionic gelation method	To inhibit the proliferation of keloid fibroblast	Feng et al. (2011)
Water-soluble chitosan nanoparticles	Ionic gelation	Protein delivery	Chun et al. (2007)
N-hexanoyl chitosan-stabilized magnetic nanoparticles	–	For cellular labeling and magnetic resonance imaging	Bhattarai et al. (2008)
Vitamin C-loaded chitosan nanoparticles	Ionic gelation method	To enhance antioxidant effects because of the continuous release of vitamin C from chitosan nanoparticles in food processing	Jang and Lee (2008)
Chitosan nanorod	Cross-linking method	It is an excellent material as a biosorbent to remove chromium from water	Sivakami et al. (2013)

8 Conclusions

Despite being the second most abundant natural polysaccharide, next to cellulose, chitosan has not yet been completely cherished by the scientific community. Over decades, the deployment of crustacean, mollusk shell waste streams, fungi, etc. for conversion to value-added products has led to significant research and development efforts to investigate innovative uses for chitinous materials via novel modification reactions. In this regard, it is quite noteworthy to mention that depending on the source, various isolation processes (chemical and biological processes), and, obviously, different types of conversion methods, the properties of chitosan are drastically changed that leads to specific applications. In other words, it can be said that one

particular chitosan (depending on its source) used for a particular application may not be suitable for other applications and vice versa. Therefore, it can be suggested that it must be mandatory to mention the source of chitin and chitosan while using chitosan for a particular purpose so as to avoid gross confusion. In view of this, various sources of chitin and chitosan and their extraction processes are explicitly discussed here. Chitosan not only possesses versatile properties but also offers a wealth of biological, biochemical, and biomechanical functionality that can be effectively utilized to develop new biomaterials. In order to understand its full functional potentiality, selective chemical modifications of chitosan as well as various types of chitosan-based nanomaterials along with their possible nanotechnological applications are also discussed. Therefore, it is hoped that this chapter will provide an excellent basis for the researchers that will not only enable them to isolate chitin from various sources but also stimulate them to think in a different way to further conduct research in the new directions by means of nanotechnology for bettering mankind.

Contents

Abstract

Gellan gum is an anionic extracellular bacterial polysaccharide identified in 1978 by CP Kelco (San Diego, USA). It is available in two forms in normal commercial production, native gellan gum and deacylated gellan gum. For deacylated gellan gum, acyl groups present in the native polymer are removed by alkaline hydrolysis resulting deacylated polymer which is known generically as "gellan gum." Gellan gum can form gels at low concentrations when hot solutions are cooled in the presence of gel promoting cations which provides it as a texture modifier to control the viscoelasticity in foods, as delivery vehicle in pharmaceuticals, and

DOI 10.1007/978-3-319-16298-0_46

as cell encapsulation material in tissue engineering etc. Gellan gum has been extensively used as a culture medium in microbiology, as a rheology modifier in foods and cosmetics industries since the early stage of its discovery. Recently, gellan gum as a natural polymer and its hydrogel show a wide range of application perspective in drug delivery and tissue engineering. Gellan gum is nontoxic, biocompatible, biodegradable and the resulting hydrogel is transparent and stable. However, gellan gum-based hydrogels have intrinsic defects such as lack of toughness and tissue tolerance as tissue engineering materials that restrict their use in biomedicine field. In order to solve these problems, quite a large number of studies on chemical modification of gellan gum have been carried out. In this chapter, the gelation behaviors, mechanism as well as various modification methods of gellan gum are summarized. Applications of gellan gum and modified gellan gum in food and biomedicine are highlighted.

Keywords
Enzyme-assisted extraction • Sulfated polysaccharides • Fucoidan • Carrageenan • Bioactivity • Antioxidant • Anticancer

1 Introduction

Living organisms contain a vast variety of biomolecules, some of which are important for the survival of living organisms. For example, carbohydrates, lipids, proteins, and nucleic acids are primary metabolites, and these compounds are important in producing essential cellular building blocks, such as cell walls and membranes, DNA, etc., in living organisms. Some biomolecules, known as secondary metabolites, have a much more limited distribution in nature and are encountered only in specific groups of organisms. Secondary metabolites are synthesized for specific reasons: some provide toxic materials that protect certain animals against predators and allow others to catch prey, some are coloring agents that attract other organisms or warn away predators.

Nearly 70 % of the earth's surface is covered by ocean, a rich ecological system containing a vast diversity of marine organisms, microorganisms, vertebrates and invertebrates, higher plants, and algae (Wijesekara et al. 2011). Algae are widely diverse plant species and are classified according to their size into unicellular algae, microalgae, and macroalgae, the latter of which can grow to 100 or 150 f. in length (Witvrouw and De Clercq 1997). Algae are also divided into three main groups according to the presence of various types of pigments in their cells: green algae (Chlorophyceae), brown algae (Phaeophyceae), and red algae (Rhodophyceae) (Wijesinghe and Jeon 2012). Some types of algae are considered edible; therefore, populations in some nations consume these edible algae in their regular diets.

Algal polysaccharides, especially sulfated polysaccharides, are useful materials with health benefits and are considered as functional foods and nutraceuticals. Various protocols are used to extract sulfated polysaccharides from the algal matrix. These procedures include hot-water, ultrasound-assisted, microwave-assisted,

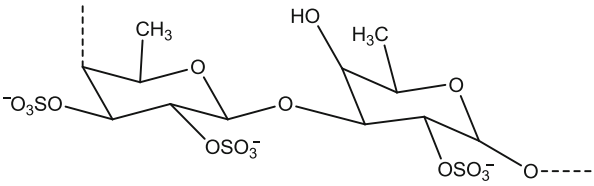

Fig. 1 Repeating unit of fucoidan

and enzyme-assisted extraction (Wijesekara et al. 2011). This chapter primarily discusses enzyme-assisted extraction (EAE) of marine algal sulfated polysaccharides and evaluates their various bioactivities.

2 Sulfated Algal Polysaccharides

Terrestrial plants contain polysaccharides such as celluloses and starches. Marine macroalgae contain quite different types of polysaccharides, which contain a sulfate group in their molecular structure and hence are known as sulfated polysaccharides called carrageenans, xylomannan sulfates, fucoidans, and galactan sulfate. Carrageenans are isolated from red seaweed and contain kappa- (κ-) and lambda- (λ-) carrageenan. *Eucheuma cottonii*, a red alga, is a source for κ-carrageenan isolation (Witvrouw and De Clercq 1997). Kappa-carrageenan consists of sulfated D-galactose and 3,6-anhydro-D-galactose in approximately equimolar amounts (Rosa 1972). Lambda-carrageenan is extracted from *Gigartina aciculaire* and *G. pistillata* and contains sulfated D-galactose. Identification of κ-carrageenan and λ-carrageenan is based on the position of the sulfate group and the presence or absence of anhydrogalactose. A repeating unit of 4-sulfate-β-galactopyranosyl (1 → 4)-linked-3,6-anhydro-α-D-galactose is found in κ-carrageenan. In addition, (1 → 3)-linked disaccharide of 2-sulfate-β-D-galactopyranosyl (1 → 4)-α-D-galactose-2, 6-sulfated is the repeating unit of λ-carrageenan (Witvrouw and De Clercq 1997).

Among these sulfated polysaccharides, fucoidans have been well studied over the past 100 years. Fucoidans are found in brown seaweeds and sea cucumbers. They contain a substantial percentage of the L-fucose and sulfate groups and exist as l-fucose-4-sulfate. Fucoidan polymers show special pharmacological activities due to the presence of the sulfate ester group (Yu et al. 2014; Yang et al. 2014). Fucoidans have been reported for a broad spectrum of bioactivities due to their antioxidant, anti-inflammatory, antitumor, antiproliferative, anticoagulant, and antiviral properties (Zhu et al. 2010). Figure 1 shows the repeating unit of fucoidan.

3 EAE of Algal Polysaccharides

Marine algae synthesize various metabolites, including primary and secondary metabolites, for their survival, and some exist for special reasons, such as defense mechanisms. These algal materials have for the potential for human benefits.

Some compounds extracted from marine algae are used in the pharmaceutical, food, and cosmetic industries. Some compounds have excellent pharmacological properties and provide promising pharmacological efficacy. Hence, most natural product research laboratories and researches tend to find novel natural compounds from plant materials, especially from marine algae. Marine alga is a reliable source that satisfies the increasing demand for natural marine bioactive compounds. However, the amount and availability in plant cells of these useful bioactive compounds is very low (Puri et al. 2012).

To isolate these small quantities of useful compounds from the plant matrix, several types of extraction protocols have been adopted: organic solvent, supercritical, microwave-assisted, ultrasound-assisted, cold press, and EAE (Herrero et al. 2006; Puri et al. 2012). In relation to the isolation of various bioactive compounds from plant matrixes, extraction protocols play the most important role in the process. An ideal extraction protocol should be quantitative, nondestructive, and time efficient (Yang et al. 2011). Some conventional protocols, such as water, hot-water, and organic solvent extraction, have several drawbacks: they are time consuming and laborious, have low selectivity and low extraction yield, and employ toxic solvents that produce environmental pollution (Herrero et al. 2006). Also, organic solvent extraction techniques have limited use in the food industry due to their safety hazards and toxic effects, as traces of organic solvents remain after the extraction process, ultimately decreasing product quality. Furthermore, extraction yields and efficiencies of bioactive compounds are reduced due to plants' cell walls. Therefore, there is great demand for useful, optimized, nontoxic, environmentally friendly extraction protocols to safely recover a higher yield from plant material (Puri et al. 2012).

EAE is an environmental friendly extraction process to which researchers are paying increased attention. During this process, cell walls and membranes are disrupted by particular enzymes, thus releasing bioactive components into the medium (Puri et al. 2012) in higher yields.

Several types of enzymes are used for the extraction of polysaccharides from marine algae. Each enzyme shows the highest efficiency under optimum conditions (Heo et al. 2005) (Table 1). Some of these enzymes are derived from microorganisms for commercial production and are available in markets. According to its commercial producer, Novozymes®, Viscozyme is produced by a select strain of the fungus *Aspergillus aculeatus*. Viscozyme is a mixture of carbohydrases, including cellulase, β-glucanase, hemicellulase, and xylanase. Viscozyme assists in the extraction of cell-wall materials by breaking down pectin-like substances in the algal cells. Celluclast is an enzyme of cellulase produced by a selected fungal strain, *Trichoderma reesei*. It catalyzes the breakdown of cellulose in algal cells into glucose, cellobiose, and longer glucose polymers. Celluclast shows optimum activity at pH 4.5–6.0 and temperatures between 50 °C and 60 °C. The commercial enzyme AMG is a type of amyloglucosidase isolated from *A. niger*. AMG breaks down starches consisting of the 1,4 and 1,6 linkages. The commercial enzyme Termamyl is a type of heat-stable α-amylase isolated from a genetically modified bacterial strain of *Bacillus licheniformis*. Termamyl hydrolyzes starch at

Table 1 Commercially available carbohydrases: origins, enzyme compositions, and optimum digestion conditions

Name of the enzyme	Origin[a]	Optimum condition		Enzyme composition
		pH	Temperature	
Viscozyme	*Aspergillus aculeatus*	4.5	50	Arabinose, cellulase, β-glucanase, hemicellulase, xylanase
Celluclast	*Trichoderma reesei*	4.5	50	Cellulase
AMG	*Aspergillus niger*	4.5	60	Exo-1,4-α-glucosidase
Termamyl	*Bacillus licheniformis* (genetically modified)	4.5	60	Heat-stable α-amylase
Ultraflo	*Humicola insolens*	7	60	Heat-stable, multiactive β-glucanase

[a]Origin of enzymes according to commercial producer, Novozymes (Adapted from Heo et al. 2005)

1,4-α-glycosidic linkages, and its optimum activity is observed at pH 7.0 and 90 °C. Ultraflo is a heat-stable, multiactive β-glucanase isolated from the fungus *Humicola insolens*.

Crude polysaccharide was extracted from the seaweed *Ecklonia cava* by Athykorala et al. using enzymatic hydrolysis and evaluated for antiproliferative and antioxidant activity (Athukorala et al. 2006b). During the study, lyophilized *E. cava* was ground and sifted through a 50-mesh standard testing sieve to obtain small particles. Since surface areas contacted by enzymes increase when the algal particle size is smaller, this method produces higher extraction yields. Water is added to ground algal samples to produce the desired medium, and a desired enzyme is added to digest algal samples at optimum pH and temperature. Some studies report that the desired extraction time is 12 h (Athukorala et al. 2006a; Wijesinghe et al. 2011) whereas others indicate 24 h (Kang et al. 2011; Lee et al. 2011).

In EAE processing, reactants are shaken during the extraction process to increase extraction efficiency under the mixing of enzymes and substrate algae. This increases the collision of enzyme and substrate algae. The enzyme is inactivated by boiling at 100 °C for 10 min to stop further hydrolysis (Athukorala et al. 2006a). The extract is centrifuged at 3,000 rpm for 20 min at 4 °C, and unwanted cell debris and unhydrolyzed residue are deposited as a pellet at the bottom and discarded in the final processing step (Heo et al. 2005). The filtered supernatant is subjected to ultrafiltration and passed through several filters with different membrane pores sizes, such as 5, 15, and 50 kDa, and the extracted water-soluble sulfated polysaccharide is separated according to molecular sizes (Kang et al. 2011; Siriwardhana et al. 2004). Ethanol is added to each filtrate after concentration and the crude polysaccharide is precipitated. Most sulfated polysaccharides have a negative charge due to the sulfate group in their structure. Dielectric constant is reduced when adding ethanol, which is a less polar solvent

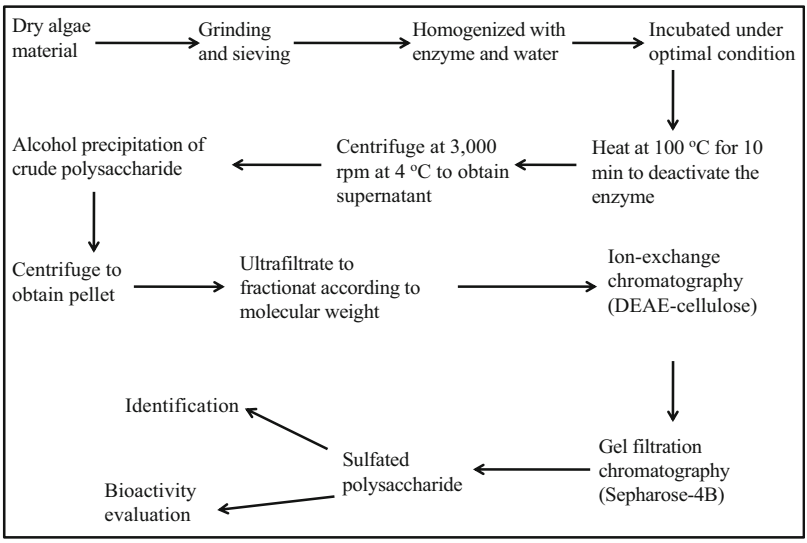

Fig. 2 Preparation, purification, and isolation of sulfated polysaccharides

in contrast to water. Negatively charged sulfated polysaccharide is formed by the ionic bond with cations available in extract, and the sulfated polysaccharide is precipitated. The precipitated extract is centrifuged at 10,000 rpm for 20 min at 4 °C to recover as much as possible of the precipitated sulfated polysaccharide (Kang et al. 2011; Chihara et al. 1970). Figure 2 shows the essential steps involved in all extraction procedures for the isolation and purification of sulfated polysaccharides.

4 Purification and Isolation of Algal Polysaccharides

Sulfated polysaccharides are negatively charged molecules that hence can be separated using ion-exchange chromatography. Diethylaminoethyl cellulose (DEAE-cellulose), a positively charged resin, is used to separate sulfated polysaccharides. Sulfated polysaccharides in crude polysaccharide extract are separated while running through the resin according to the affinity between anionic resin and sulfated polysaccharides. The column is eluted with different types of buffer systems with different pH values, and fractions are collected into small containers such as test tubes. Polysaccharide content is quantified by phenol–sulfuric acid (H_2SO_4) carbazole reaction to identify polysaccharide distribution throughout the column-eluted fractions (Athukoral et al. 2006).

Gel-filtration chromatography is another method for the isolation and purification of polysaccharides depending on their molecular weights. Sepharose is a chromatographic material used for the separation process. Sepharose is a bead consisting of agarose-based crosslinked materials and is available in agarose

contents 2, 4, and 6 % and named 2B, 4B, and 6B, respectively. They have different pore sizes depending on the available agarose amount. The Sepharose column is eluted with water after loading the desire polysaccharide sample and is separated according to sizes. The polysaccharide content is quantified by phenol–H_2SO_4 carbazole reaction to identify the polysaccharide distribution throughout the column-eluted fractions (Kang et al. 2011).

5 Identification of Algal Polysaccharides

Infrared (IR) spectroscopy and nuclear magnetic resonance (NMR) spectroscopy techniques are applied for molecular identification. IR spectroscopy use electromagnetic radiation at the infrared region and IR radiation is associated with the bond vibration of the molecule. The molecular bond is vibrated after absorbing the frequency specific for the particular molecular bond. This allows researchers to identify the functional groups in the molecular structure depending on the absorbed frequency. Melo et al. reported an identified polysaccharide from *Gracilaria cornea* and characterized the sulfated polysaccharide using IR spectroscopy (Melo et al. 2002). NMR spectroscopy is used for characterizing molecules and promises to provide the accurate molecular structure. Melo et al. used NMR spectroscopy to characterize the isolated sulfated polysaccharide from *G. cornea* (Melo et al. 2002). Ruperez et al. studied an edible brown algae *Fucus vesiculosus* to isolate sulfated polysaccharide and used IR and NMR spectroscopic to determine the structure (Ruperez et al. 2002).

6 Bioactivities of Algal Sulfated Polysaccharides

Sulfated polysaccharides possess a broad spectrum of essential bioactivities, such as antioxidant, anti-inflammatory, anticancer, and other bioactivities (Table 2).

7 Antioxidant Activity

Usually, cellular aerobic respiration contributes to the production of reactive oxygen species (ROS) such as superoxide, hydroxyl, peroxyl, alkoxyl, hydrogen peroxide, and singlet oxygen, as well as reactive nitrogen species (RNS), including peroxynitrite, which are formed by reaction between nitric oxide and superoxide in living cells in an oxygen-rich environment. Exogenous factors, such as ultraviolet (UV) radiation, smoking, and metabolites of foreign materials, also contribute to the production of ROS (Yoon et al. 2011). ROS have a greater potential to damage cellular components such as DNA, proteins, and lipids and cause inflammatory lesions and, furthermore, diseases such as cancers, aging, arteriosclerosis, rheumatoid arthritis, and allergies. Recent studies have reported that the sulfated polysaccharide isolated from marine algae show antioxidant properties. Several types of

assays, such as chemical assay, electron spin resonance (ESR) spectroscopy, and cell culture technique are used to evaluate the antioxidant property of the desire sulfated polysaccharide. Different types of ROS species were used to identify antioxidant sulfated polysaccharides, such as 1,1,-diphenyl-2-picrylhyrazyl (DPPH), hydrogen peroxide, hydroxyl, and alkyl. Siriwardana et al. reported antioxidant activity of the enzymatic extract of *Hizikia fusiformis*. The five carbohydrases were used to extract the crude polysaccharides, and antioxidant activity was evaluated by chemical assay, including DPPH and hydrogen peroxide. All enzyme hydrolysates were shown to have $>$ 70 % DPPH radical scavenging ability at 2 ml extract and enzyme hydrolysates of AMG, Termamyl, and Ultraflo exhibited

strong scavenging abilities for hydrogen peroxide (Siriwardhana et al. 2004). Heo et al. screened carbohydrate hydrolyses of seven brown seaweeds (*E. cava*, *Ishige okamurae*, *Sargassum fulvellum*, *S. coreanum*, *S. thunbergii*, *and Scytosiphon lomentaria*) for radical scavenging activity using different ROS, including DPPH, superoxide anion, hydroxyl, and hydrogen peroxide. Hydrogen peroxide scavenging activity was more prominent than for other ROS species, and Ultraflo enzyme hydrolytic extract of *S. horneri* indicated the highest activity in a dose-dependent manner (Heo et al. 2005). Moreover, fucoidan is well studied and well characterized: Kim et al. used fucoidan from extracted *E. cava* by digestion with Celluclast, and in vitro antioxidant activities were evaluated using the ESR technique, as well as on Vero cells (monkey fibroblast kidney cells). Also, in vivo antioxidant activity was evaluated in zebrafish in which oxidative stress was induced using 2,2′-Azobis(2-amidinopropane) dihydrochloride (AAPH). According to the results with ESR, IC_{50} values were 0.73 mg/ml^{-1} for DPPH and 0.48 mg/ml^{-1} for peroxyl radicals. Intracellular ROS scavenging activity was done using 2′,7′-dichlorofluorescein diacetate (DCF-DA) assay on Vero cells; IC_{50} value was 75 μg/ml^{-1}. Furthermore, in vivo antioxidant activity was investigated using a zebrafish model; results showed a higher survival rate in fucoidan-treated zebrafish and a reduction of ROS levels compared with the AAPH-treated group (Kim et al. 2014b). De Souza et al. evaluated the antioxidant capacity of several sulfated polysaccharides, including iota- (ι-), κ-, and λ-carrageenan, as well as fucoidan, and then the IC_{50} values were 0.058, 0.112, 0.332, and 0.046 mg/ml^{-1} of fucoidan, κ-, ι-, and λ-carrageenan, respectively (De Souza et al. 2007).

8 Anticancer Activity

Cancer is caused by abnormal cell growth and has become a major public health problem around the world (Jemel et al. 2008). Chemotherapy is a heavily used treatment for cancer. However, chemotherapeutic drugs are toxic to somatic cells and exhibit serious adverse effects. There is a greater demand for natural nontoxic anticancer therapies (Anastyuk et al. 2012). Fucoidan is a well-studied sulfated polysaccharide, and Athukorala et al. reported that the sulfated polysaccharide isolated from the enzymatic extract of *E. cava*, specially fucoidan, exhibited antiproliferative effects on murine colon carcinoma (CT-26), human leukemia monocyte lymphoma (U-937), human promyelocytic leukemia (HL-60), and mouse melanoma (B16) cell lines in a dose-dependent manner (Athukorala et al. 2006b; Athukorala et al. 2009). Sulfated polysaccharides are the main components of the porphyrins. They showed anticancer activity on human gastric adenocarcinoma cancer cells (AGS) by inhibiting DNA synthesis. They then reduced cancer cell growth and induced apoptosis (Kwon and Nam 2006). Enzyme-digested fucoidan extract from *Cladosiphon novae-caledoniae* Kylin also produced antitumor activity on human fibrosarcoma HT-1080 cells by increasing oxidative stress by ameliorating intracellular ROS levels and suppressing the expression of angiogenesis. It also suppressed the secretion angiogenesis factor for

vascular endothelial growth factor (VEGF), resulting in the inhibition of vascular tube formation of tumor cells (Ye et al. 2005).

Antiangiogenic therapy is another effective treatment for tumor inhibition. Liu et al. reported that fucoidan derived from *Undaria pinnatifida* significantly inhibited cell proliferation and migration and tube and vascular network formation on human umbilical vein endothelial cells (Liu et al. 2012). Zhang et al. reported enhanced anticancer activity of the chemotherapeutic agents cisplatin, tamoxifen, and paclitaxel by fucoidan extracted from *C. novae-caledoniae* Kylin after digestion with glycosidases (Zhang et al. 2013). Furthermore, the study mentioned that the combination of fucoidan and chemotherapeutic agents induced cell growth inhibition, apoptosis, and cell cycle modifications in MDA-MB231 and MCF-7 breast cancer cells.

9 Anti-inflammatory Activity

Inflammation is a bodily response to pathogenic bacteria, viruses, and other pathogens, being a defensive response generated by the host (Kang et al. 2011). Some host-originated inflammatory mechanisms worsen a disease (proinflammatory), but some anti-inflammatory activities help heal the disease processes. Some host-originated anti-inflammatory mechanisms cause harmful effects to the host, such as fever, inflammation, and tissue destruction (Dinarello 2000). Therefore, there is a greater demand for anti-inflammatory drugs. Many studies are ongoing to identify natural compounds with anti-inflammatory activity. Natural marine products play an important role in this field of natural medicinal products. Recent studies show that many researchers have isolated sulfated polysaccharides with anti-inflammatory activity from marine algae. One study reported that the purified polysaccharide, fucoidan, isolated from AMG-assisted extract of *E. cava*, exhibited anti-inflammatory activity on lipopolysaccharide (LPS)-stimulated RAW 264.7 cells by inhibiting nitric oxide (NO) production, and prostaglandin E2 production via inhibition of NO synthase (iNOS) and cyclooxygenase-2, respectively (Kang et al. 2011). Another study reported the isolation of fucoidan by enzymatic extraction and purification using ion-exchange chromatography. The isolated fucoidan exhibited a significant inhibition of NO production on LPS-stimulated RAW 264.7 cells and down-regulated proinflammatory cytokines such as tumor necrosis factor (TNF)-α and interleukin (IL)-6, and IL-1β (Lee et al. 2012). Evaluating bioactivity on zebrafish is the latest technique among in vivo activity assays. It is an advance technique and gives promising results. A recent study in a zebrafish model reported that fucoidan isolated from *E. cava* has anti-inflammatory effects (Lee et al. 2013): according to the study, tail-cutting and LPS treatment significantly increased ROS levels and NO production; fucoidan administration significantly inhibited NO production and reduced ROS levels. In addition, fucoidan showed protective effects in zebrafish embryos in which inflammation was induced by LPS treatment. These results imply that fucoidan is a potential candidate for developing anti-inflammatory drugs.

10 Other Bioactivity

Angiogenesis is the important physiological process that produces new blood vessels from existing blood vessels during some physiological processes, such as reproduction, development, and tissue repair. Kim et al. evaluated the effect of fucoidan isolated from *Laminaria japonica* on human umbilical vein endothelial cells (HUVECs). The observed results suggested that fucoidan was capable of inducing the cell proliferation and migration and tube formation (Kim et al. 2014a). Furthermore other studies reported that sulfated polysaccharide isolated from marine algae has anticoagulant properties: Wijesinghe et al. reported that sulfated polysaccharide isolated from *E. cava* showed anticoagulant properties in both in vitro and in vivo studies (Wijesinghe et al. 2011). In that study, fucoidan isolated using AMG-assisted extraction was evaluated in Wistar rats. Both in vivo and in vitro assays were used to evaluate activated partial thromboplastin time (APTT), thrombin time (TT), and prothrombin time (PT). The results indicated that fucoidan inhibited coagulation in a dose- and time-dependent manner.

11 Conclusion

The EAE technique is an environmentally friendly and effective method for isolating sulfated polysaccharides from algal matrix. Marine algal sulfated polysaccharides have tremendous pharmacological activities, such as anticancer, antioxidant, anti-inflammatory, anticoagulant, and other bioactivities. Research will open new pathways to new natural pharmacological compounds for various medicinal purposes.

Abstract

Known since the end of the nineteenth century, microwave radiation (Zlotorzynski 1995) was used to carry out a chemical reaction for the first time in the 1960s, but in these experiments, irradiation was used for the production of electric arc discharge only in which some organic transformation has been carried out (Streitwieser and Ward 1962). The very first "microwave synthesis," in full sense of the word, was performed in the 1980s of the last century, when Gedye et al. (1986) conducted the microwave-assisted hydrolysis of amides in a substantially shorter time than the corresponding reaction at conventional conditions. A few years later, in 1992, Mingos showed the possibility of heating liquid beyond their boiling points at microwave conditions

1 Introduction

Known since the end of the nineteenth century, microwave radiation (Zlotorzynski 1995) was used to carry out a chemical reaction for the first time in the 1960s, but in these experiments, irradiation was used for the production of electric arc discharge only in which some organic transformation has been carried out (Streitwieser and Ward 1962). The very first "microwave synthesis," in full sense of the word, was performed in the 1980s of the last century, when Gedye et al. (1986) conducted the microwave-assisted hydrolysis of amides in a substantially shorter time than the corresponding reaction at conventional conditions. A few years later, in 1992, Mingos showed the possibility of heating liquid beyond their boiling points at microwave conditions (Mingos and Baghurst 1991). The experiment was a milestone in the development of microwave synthesis. Since then a sharp increase is microwave synthesis in organic synthesis is observed in many parts of chemistry focusing on both low and high molecular compounds.

In contrast to the conventional synthesis (transport of energy into the reaction mixture by means of conduction and convection, i.e., from the source to the reaction mixture), distribution of microwave energy which occurs from within the heated sample has at least several advantages such as:

(a) Direct supply of the energy to the system, while the reaction mixture has no contact with source of heat
(b) Volumetric heating method, leading to a much larger heating rate as compared with conventional methods
(c) Different temperature distribution (reverse temperature gradient)
(d) For heterogenic mixtures, selective heating compounds susceptible to the effects of microwave radiation
(e) Possibility of heating liquids to temperatures much above their boiling temperature (from a few to several degrees)

1.1 The Nature of Microwaves

Microwave radiation is part of electromagnetic radiation from the range of 300 MHz to 30 GHz, which is equal to a wavelength of 1–0.01 m (Kappe et al. 2009). According to definition, it is a kind of energy propagating in space with the speed of light as a

Table 1 Comparison of the radiation energy delivered by the different type of interactions

Interactions	Energy, eV
μν	1.24×10^{-6}–1.24×10^{-3}
C–C dissociation (Morrison and Boyd 1992)	4.0
Hydrogen bonding (Atkins and De Paula 2010)	2.1
van der Waals interactions (Coulson and McWeeny 1979)	2.0
Brownian motion (Morrison and Boyd 1992)	2.70×10^{-3}

form of periodic variation of the electric and magnetic field (Knight 2013). Energy transmitted through this type of radiation is about 1.24×10^{-6}–1.24×10^{-3} eV (calculated using Planck relation: $E = h{\cdot}\nu$) (Berlan 1995). Comparing those values to the power of intra- and intermolecular interactions shown in Table 1, one should note that microwaves cannot be an activating force in organic reactions, because the amount of energy supplied together with the radiation is comparable to Brownian motion only. According to that one can see that interaction of microwave irradiation with matter had to have a complete different character. In fact, it is a result of the reorientation of charged particles of matter (ions, dipoles, etc.) in pulsed electromagnetic field of high frequency; however other mechanisms including so-called nonthermal effects are postulated as well.

Going into details we can say that for dielectrics, if the external static electric field is stopped at the time $t = 0$, the polarization caused by the field is going to diminish exponentially (Davies 1965). The time needed to establish the polarization at the level of 1/e of the initial value describes the relaxation time. Like the constant electric field, the application of alternating fields may cause the phenomenon of polarization in the sample. When acting on the matter, the alternating electromagnetic field with microwave frequencies, dipole reorientation may occur slower than changes in the field. In the extreme case, it may lead to a situation where the dipoles can be oriented contrary to the operating electric field. Such a phenomenon results in energy absorption, and hence, substantial temperature increase of the whole volume of the system is observed. The rate of reorientation of the dipoles is a characteristic of the substances and may be varied with the frequency of irradiation and temperature. As a result different amounts of heat are generated by the system. This energy may be easily estimated using the parameter of dielectric loss factor ε'' – see Eq. 1:

$$\varepsilon'' = \frac{\varepsilon'_0 - \varepsilon'_\infty}{1 + \omega^2 \cdot \tau^2} \omega \cdot \tau \tag{1}$$

where ε'_0 is called static dielectric permittivity, ε'_∞dielectric permittivity in the electromagnetic field with frequencies in visible light range, ω electromagnetic field frequency, and τ relaxation time (Kingston and Haswell 1997).

The mechanism of converting electromagnetic radiation energy into heat for conductors (metals, metal oxides, graphite, other types of carbon, etc.) is substantially different from that described for dielectrics. This is due to the presence of free electrons with conductive material that are nonpermanently linked with specific atomic

structures. Under the influence of an applied electric field, the electrons can move along the guide in the direction of the applied external field. The observed energy dissipation occurs when collisions with other conduction electrons or themetal ions in the atomic network of crystal material takes place (Kingston and Haswell 1997).

Another factor that may be responsible for increasing of the temperature in systems consisting of at least two polarizable components may be interfacial polarization, i.e., the Maxwell–Wagner effect (Baghurst and Mingos 1992). Heating effect in such systems is the result of the differences in dielectric permeabilities and conductivity of the individual components of the system. Observed dielectric properties (dielectric permittivity) of the medium, after the introduction of the second component of described mixture, may increase up to tenfold, which has a substantial effect on the rate of temperature increase in the mixture, when irradiated by microwaves.

1.2 Influence of the Microwaves on Chemical Transformations

Reactions under microwave irradiation allow significant reduction in the total time of synthesis, modification, or distribution of products and also increase in the overall yield of the reaction. Increase in microwave-assisted process efficiency can be explained using the discussed relaxation processes occurring in dielectrics (dielectric dispersity) and conductivity, leading to rapid heating and bulk of reaction mixture, i.e., thermal effects of microwave action. Additionally some specific microwave effects with nonthermal origin have been postulated as well.

1.2.1 Specific Thermal Effects

Microwave thermal effects are directly related to the volumetric heating of the reaction mixtures subjected to microwave irradiation. Considering the effects of this kind, usually one can focus on much faster achieving of appropriate temperature of the irradiated system, as well as efficient mixing of the reactants in the reaction medium and the effect of interfacial diffusion (Kingston and Haswell 1997). In general the heating rate of the mixture irradiated using microwaves may be described as follows (Kingston and Haswell 1997):

$$\frac{\delta T}{\delta t} = \frac{\omega \cdot \varepsilon_0 \cdot \varepsilon'' \cdot E^2}{\rho \cdot C_p}$$

where:

ω – field frequency
ε_0 – dielectric permittivity
ε'' – loss factor
E – electromagnetic field
ρ – density of the mixture
C_p – specific heat

Factors appearing in the equation as dielectric losses and specific heat are temperature dependent. This causes the complete solution to the mathematical problem of the temperature rise of the substance subjected to microwave irradiation to be very complicated.

But the most important factor that is responsible for the acceleration of reactions carried out under microwave conditions seems to be the possibility of achieving temperatures much higher than in conventional conditions. Such a phenomenon can occur in the whole volume of the mixture or solution (due to overheating) (Berlan 1995) or in certain locations only (called hot spots) (Zhang et al. 1999).

Nucleation of gas bubbles, which takes place during the boiling of the liquid, most often occurs on the inner surface of the vessel of heated liquid. During a conventional process when the temperature rises, the bubbles can expand as the process of evaporation will occur at a place where the surface tension is lower and with minimal inner energy. When using microwave radiation, the surface of the reaction vessel does not heat up and is lower than the temperature of the heated liquid. In such a system boiling can occur only if the energy delivered is able to exceed the intermolecular interactions in the liquid. The observed higher boiling point in microwave processes is reached only when the solution is not stirred or in the absence of additional nucleating sources (Baghurst and Mingos 1992). The observed boiling temperature is higher than a few to a few tens of degrees (100 °C vs. 105 °C at μν for water, 82 °C vs. 120 °C for acetonitrile, or 67 °C vs. 103 °C for THF) (Perreux and Loupy 2001; Kingston and Haswell 1997).

The phenomenon of overheating may occur on a local scale also. Subjecting the liquid or solid to microwave irradiation results in local hot spots. Temperature gradients in such mixtures may be up to several dozens of degrees, which enables local reaction rate constants to increase several times. Observation of hot spots, however, is extremely complicated, and their existence has not been conclusively proven.

1.2.2 Nonthermal Effects

The rate of chemical reactions is described using the Arrhenius equation, in which the rate constant of the process depends among others on the activation energy and factors hidden in a pre-exponential coefficient. The electromagnetic field with microwave frequencies can, as it turns out, affect both of these factors, thereby altering the rate of reaction.

Pre-exponential coefficient depends, mainly, on the probability of particles collisions in a chemical reaction. It is postulated that microwave radiation may be influenced on this factor, increasing the possibility of intermolecular collisions of reagents (Langa et al. 1997).

On the other hand, the free enthalpy of activation (defined as $\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}$), in a field at frequencies in the microwave range, can decrease, and this is due to increased ordering in the system, resulting from polarization. The phenomenon leads to an increase in the entropy factor ($T\Delta S^{\neq}$) (Lewis et al. 1992).

It is generally accepted that nonthermal, microwave-specific effects depend on the reaction mechanism, especially since the composition and polarity of the transition state complex (Loupy 2003).

2 Radical Processes Under Microwave Condition

Nowadays, there is growing interest in organic syntheses mediated by free radicals (Tōgō 2004). The methodology has been adapted in thousands of chemical transformation with both low molecular or high molecular (polymer) compounds (Moad et al. 2006). The very first stage of those processes, i.e., initiation of free radicals, may be generated from unstable compounds using different mechanisms including homolytic dissociation after irradiation with electromagnetic field (visible or ultraviolet light) or using chemical processes. In fact, in most cases an introduction of an initiator is needed to start the process. The initiator serves as a source of primary radicals that are generated using several techniques including thermal processes. Because the microwave irradiated may serve as an excellent "heat generator" (especially in the case of polar reaction systems), there are also a growing number of research dealing with employing of microwaves in free radical organic synthesis.

According to that one can state that the general advantage of microwave-assisted radical processes is allowing a reaction mixture to heat rapidly (very often beyond its boiling point). The reduction of total reaction time as well as simple reaction setup and increase in product yield may also be treated as a benefit of the protocol (McBurney et al. 2006). In order to enhance the reaction efficiency or enhance the impact of microwaves on the process, systems containing polar solvents are usually in use. In cases in which low or nonpolar solvents are needed, the heating effect may be obtained using strongly microwave-absorbing additives.

As it was discussed above, the energy linked with microwave irradiation is too low to make any significant changes in chemical bonds. As a result the thermally initiated radical processes are the most common. Next stages of the process include propagation and termination which are also microwave sensitive. In the case of propagation, the high temperature, e.g., overheating that may be observed locally or globally is a key factor for increasing the rate of this process stage. On the other hand, the influence of microwaves on termination is much lower. It is a result of the low activation energy of this step. However in the case of a sterically overcrowded recombination or disproportionations, the microwave effect may be more significant (McBurney et al. 2006).

The microwave grafting techniques allow formation of free radicals on the polysaccharide backbone by means of two different methodologies: microwave-initiated technique that uses microwave irradiation only to initiate grafting reaction or techniques that use a combination of microwaves and chemically initiated free radicals for grafting reaction.

3 Graft Copolymerization

First graft copolymer was synthesized by Alfrey and Bandel in 1950 (Alfrey and Bandel 1951). They polymerized vinyl acetate in the presence of styrene and vinylidene chloride. This idea of graft copolymers was promoted by H.F. Mark; in 1953 he has announced the new graft copolymers (Mark 1953). Generally graft

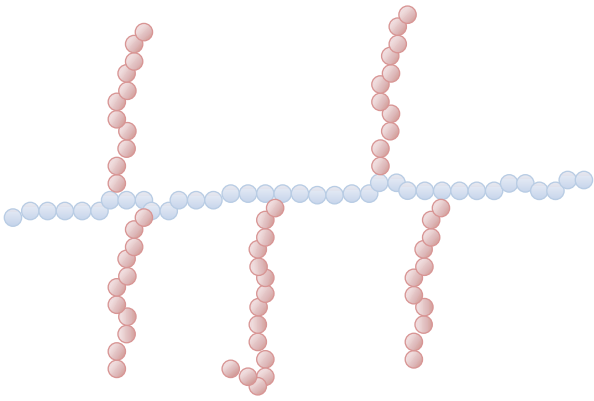

Fig. 1 Structure of typical grafted polymer

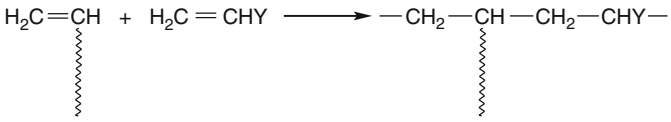
copolymers consist of a preformed polymeric linear backbone of one composition to which other polymeric chains are randomly attached. There is no general rule, but both the backbone and the side chain can be homo- or copolymers. It is believed that in graft copolymer, molecules contained in the polymeric side chain have different molecules or structure from those in the polymeric backbone (Ring et al. 1985). Structure of the common graft copolymer is shown in Fig. 1; monomer X is grafted onto the backbone of the polymer which is built from monomer Y units.

Most methods of synthesizing of graft copolymers base on radical polymerization mechanism. When polycondensation process is involved, non-vinyl graft copolymerization is possible. However this method has not been widely used for preparing polysaccharide grafted copolymers due to low thermal resistance of the polysaccharide backbone as well as harsh conditions which are common for polycondensation reaction. Graft copolymerizations are carried out in heterogeneous as well as homogeneous systems. Polymer chains are grafted through three main strategies:

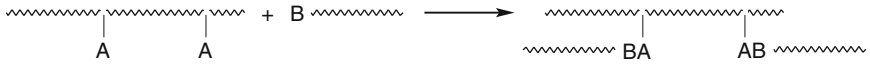
(a) *Grafting through* involves the polymerization (or copolymerization) of a macromonomer, usually a vinyl macromonomer:



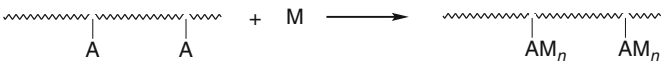
Grafting through method is one of the simplest ways to synthesize graft copolymers with well-defined side chains. In a typical process a low molecular weight monomer is radically copolymerized with a vinyl-functionalized macromonomer (polysaccharide in this case) (Tizzotti et al. 2010).

(b) *Grafting onto* involves the reaction between functional groups on two different polymers. In this technique presynthesized end-functionalized linear polymeric chains are subsequently covalently bonded to the polysaccharides. In most cases copolymers obtained with "grafting onto" strategy are characterized by

low grafting percentage (due to steric hindrance) and complicated polymerization procedures, thus significantly limiting its development.



(c) *Grafting from* technique involves the growth of grafted polymer chains directly from the polysaccharide backbone. The primary requirement for a successful "grafting from" reaction is a macromolecule with distributed initiating functionality. In the case of polysaccharides, radicals can be easily generated along the polysaccharide backbone in the presence of chemical or photochemical initiators or by using irradiation. This technique has been extensively investigated due to the fact that it is possible to obtain densely grafted copolymers. However during radical reaction the homopolymer, which is not chemically bonded to the polysaccharide backbone, can be produced, depending on the experimental conditions.



3.1 Chemical Initiation of Grafting

The grafting is achieved by generating free radicals on the polysaccharide backbone; after that these radicals serve as *macroinitiators* for the vinyl monomer. Free radicals can be generated in a conventional, chemical initiation. The most often, radical/redox initiators are used such as ammonium persulfate (Nishioka and Kosai 1981; Nishioka et al. 1983; Toti et al. 2004), ceric ammonium nitrate (Thimma et al. 2003; Kim and Mun 2009), ceric ammonium sulfate (Wan et al. 2007), ferrous ammonium sulfate/potassium persulfate (Yazdani-Pedram et al. 2000), potassium persulfate (da Silva et al. 2007) or in combination with other coinitiators (Singh et al. 2005b; Singh 2006; Shi and Zhang 2007). Those strategies of initiation of polysaccharide modification have been extensively investigated in recent years. Although this method is not without drawbacks such as inert working conditions, complicated and time-consuming procedures and as mentioned previously, homopolymer formation, which is not chemically bonded with polysaccharide, may occur, thus decreasing the grafting efficiency.

3.2 Radiation-Induced Grafting

Another technique of free radicals generation includes radiation-induced grafting. By careful selection of dose and rate of irradiation, it allows a high degree of

control over the number and length of grafted chains. The radiation techniques advantage is to maintain the purity of the product as it is free from contamination. These features of radiation methods make it a preferred technique of graft copolymerization.

High-energy radiation (γ-rays (Geresh et al. 2004; Liu et al. 2004; Wang et al. 2008) or electron beam (Vahdat et al. 2007)), low-energy radiation (Bertolini et al. 2001; Carlmark and Malmström 2002; Coskun and Temuz 2005; Zhou et al. 2005) (UV radiation and visible light), and microwave irradiation (Kaith et al. 2007; Kumar et al. 2009; Singh et al. 2012; Luo et al. 2012; Işıklan and Küçükbalcı 2012) are used to initiate the grafting process. The irradiation of the polysaccharide backbone with low-energy radiation results in homolytic fission, and free radicals are generated on the polymeric backbone. In the presence of low-energy radiation, grafting may occur with or without using a photoinitiator. High-energy radiation like γ-rays or electron beam has been used for graft copolymerization. The most widely used source of γ-rays is Co-60.

Another important energy source and effective tool for graft copolymerization is microwave radiation that has an advantage in the rapid transfer of energy into the reaction mixture which results in specific interaction of reagents. Moreover using microwave irradiation reduces the use of toxic solvents as well as reaction time. Microwave-synthesized polysaccharide copolymers are characterized with better properties for commercial exploitation in comparison with copolymers synthesized in a conventional way (Singh et al. 2012).

3.3 Other Grafting Methods

In some cases conventional procedures may lead to degradation of the polysaccharide backbone and to formation of a significant amount of homopolymer. Those procedures are characterized by very limited control over graft molecular weight and graft molecular weight distribution. These difficulties can be overcome by controlled/living radical polymerization techniques to obtain graft-functionalized polysaccharide-based macromolecular materials. The most common techniques for controlled/living radical polymerization include nitroxide-mediated polymerization, atom transfer radical polymerization, and reversible addition–fragmentation chain transfer. All mentioned techniques are moisture tolerant and can be performed with a large range of polymers having different functional groups. The properties of polysaccharide-based copolymers can be easily tuned with graft length, the chemical composition, and topology of polymers. All controlled/living radical polymerization techniques base on significant reducing the concentration of propagating radical chain ends. In that way possibility to terminate radical reaction is minimized. Such phenomenon is possible by addition of species with possibilities to reversibly trap the ‘active’ propagating species. This is done on the basis of reversible termination or reversible transfer.

4 Polysaccharides

4.1 Starch

Starch and cellulose belong to the group of the most common and easy to recover biopolymers. According to that both of them are the subject of much research. In fact only a few purposes have been found for raw, so-called "native" starch. Most of the material is modified by various methods, i.e., physical, enzymatic, or chemical processes including grafting. Starch may be found in almost all known plants where it plays a role as a storage material that can be used by the plant in a depolymerized form, i.e., glucose, the only monomer for both starch and cellulose. In fact, starch is not a homogeneous material. It is composed of two different fractions, i.e., linear amylose (AM) and branched amylopectin (AMP). Depending on the botanical origin of starch, the AM/AMP ratio may vary from 1:99 (waxy starches) to about 80:20 for high amylose starches. The most common AM/AMP ratio for nonmodified plants is about 20–30 AM to 80–70 AMP. For both of them glucose is a monomer; however the anhydroglucose is known as a repeated unit in starch. This is the result of starch polymerization in plant. The process may be simplified as the polycondensation of glucose with water as a low molecular side product. In AM anhydroglucose units (AGU) are linked together by α-1-4 glycosidic bond. On the other hand, in AMP, the main backbone is built in a similar manner, but branching points are located at C_6 of AGU which means that α-1-6 glycosidic bond appears at those places. In each case the glycosidic bond is formed between the hemiacetal group of one AGU and the hydroxyl group of another AGU unit (Fig. 2).

As it was mentioned before, starch is one of the most common polysaccharide in the plant kingdom. Due to different concentrations in plants, the occurrence as well as technological capabilities of commercial starch is mainly isolated from: cereals (wheat, corn, rice, etc.), tubers (e.g., potato), or seeds of leguminous plants (e.g., soybean). Alternative sources of starch are also known, but their commercial significance is strongly limited.

Although the native starch is rather uncommon for wider application, the product of its modification finds a lot of attraction. It also includes the chemical modification of AGU by means of etherification, esterification, oxidation, etc. Most of the mentioned processes have also been successfully carried out using microwaves especially when focusing on oxidation in paste, catalytic, and enzymatic esterification. The wide possibility of starch modification is the result of three hydroxyl groups in the AGU molecule that may react with different types of chemicals.

Microwaves were also used for grafting polymers onto the starch backbone. For now several starch grafted copolymers were obtained using microwaves that include: acrylic derivatives or caprolactone (Fig. 3).

In the case of caprolactone, the ring-opening polymerization of the monomer results in the polyester PCL that in the presence of polymers with reactive hydroxyl may be grafted on its backbone (Labet and Thielemans 2009). The ring-opening polymerization of caprolactone in the presence of pea (Yu et al. 2008;

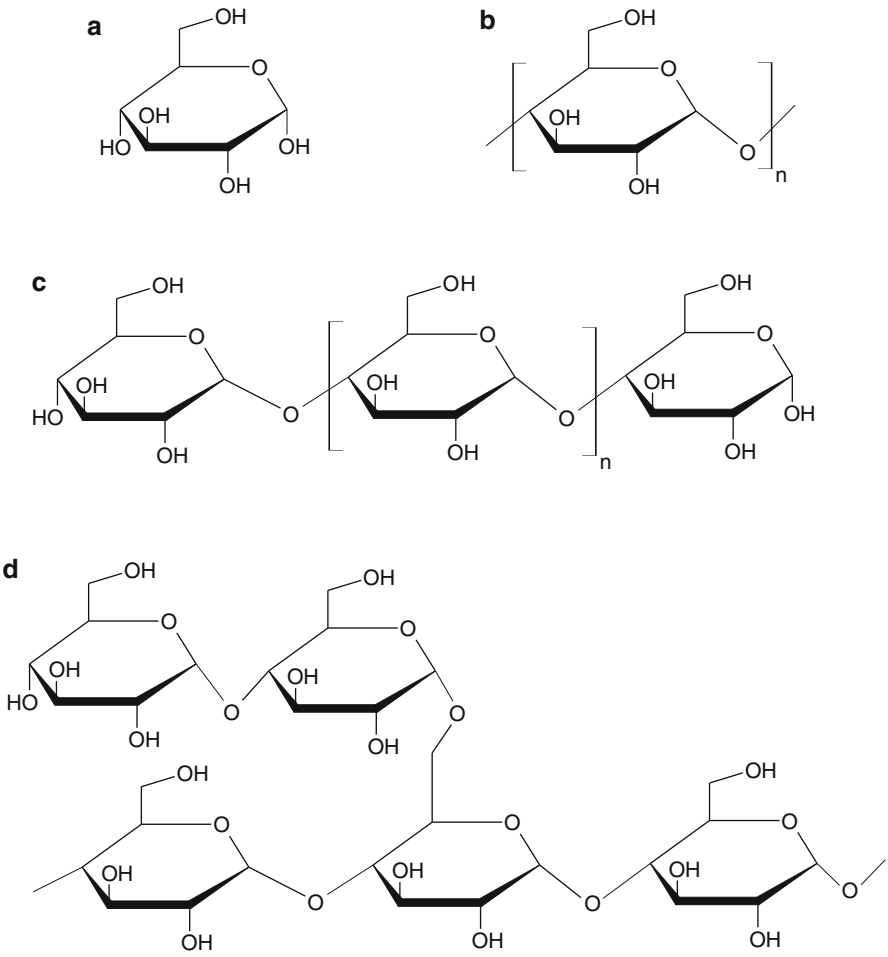


Fig. 2 Molecular structure of starch: (**a**) glucose monomer; (**b**) anhydroglucose unit – AGU; (**c**) amylose chain; (**d**) branching point of amylopectin

Chang et al. 2009a, b) and potato starch (Koroskenyi and McCarthy 2002) has been successfully carried out using microwaves. As a catalyst, tin(II) octoate was used. During the research no comparison to conventional conditions was done; however the total reaction time for PCL grafting was about 3 min (255 W). The structure of the obtained polymer was proven by means of detection of ester (carbonyl) signal formation observed using FTIR. Due to simple reaction setup (no group protection in this case; see chitosan grafted with PCL), the substitution degree and localization in starch chain remains unknown, but as in the case of all starch modifications, all three hydroxyls may be involved in this process.

On the other hand, many of the acrylic derivatives were applied to modify starch by means of free radical grafting (see Fig. 4) (Singh 2007; Singh et al. 2006;

Fig. 4 Acrylic monomers used for starch grafting at microwaves

Zheng et al. 2005; Xu et al. 2005; Chen et al. 2002). All those reactions were carried out in a very short time, i.e., 60 and 70 s for acrylamide and acrylonitrile, respectively. For sodium acrylate and acrylamido-2-methyl-propanosulfonic acid, the observed reaction time was a little bit longer and takes 10 and 7 min, respectively. In the case of acryloamide, the obtained material may be characterized by grafting percentage of about 160 %, while in the case of acrylonitrile, the value of 225 % was obtained. In those two experiments soluble starch was a starting material. Sodium acrylate and acrylamido-2-methyl-propanosulfonic acid were

grafted on corn starch. In those examples the superabsorbent products were obtained with the swelling ratio of about 520–620 g/g (for starch-*g*-sodium acrylate). On the other hand, only the branched fraction of starch, i.e., amylopectin, was grafted using acrylamide with shortening of the reaction time and grafting yield when compared with conventional conditions using cerium salts (Adhikary and Krishnamoorthi 2013). In other research the sago starch was grafted with acrylamide under microwave conditions as well (Singh and Nath 2013). The resulting polymer was successfully used as a controlled release polymeric carrier for drug delivery.

Acrylamide was also used in cationic starch modification in microwaves (Wang et al. 2011; Wang et al. 2012), while the corn starch was also modified using butyl methacrylate (Da-Wei et al. 2011). Generally speaking acrylamide is one of the most common grafting monomer. Under microwave condition it was used also for grafting polysaccharide blends containing starch, chitosan, and alginate (Sorour et al. 2013). In the last case the specific process environment was used that was called rheological phase reaction. The grafting occurs in microwaves, but the starch was first pregelatinized in high temperature of about 60 °C. In fact, the rheological phase reaction method is a kind of process in which products are formed in a solid–liquid rheological mixture in which the solid particles and liquid substance are distributed uniformly (Sun et al. 1999). Such kind of process environment in the presence of microwaves may result in a bigger influence of Maxwell–Wagner effects on interphase polarization. Experiments conducted by the authors show the phenomenon of radiation time on the viscosity of the grafted starch. The longer the radiation time was, the lower the viscosity of the product was observed. Additionally microwaves have also an influence on grafting efficiency with the maximum radiation time of 3.5 min, initiator content of 4.55 %, at which the grafting ratio reached 19.57 %.

Interesting research on starch grafting was also performed using ethyl acrylate (Singh and Maurya 2010). The authors have shown that however the efficiency of grafting without initiator is quite high, the presence of potassium persulfate–ascorbic acid initiating system improves grafting yield. The starch grafting may be also performed on starch derivatives including carboxymethyl starch grafted by acrylamide (Sen and Pal 2009). Additionally it was shown that polysaccharide blends containing starch (corn), chitosan, and alginate may be successfully grafted with acrylamide using combined microwaves and UV irradiation (Sorour et al. 2013). Obtained grafted blend may be treated as a new hydrogel with a swelling affected by pH due to ionic interactions between highly polar groups incorporated in the grafted material or by an external hydronium ion concentration.

The mechanism of acrylic polymer grafting on starch under microwave irradiation was proposed by Banerjee et al. (2012; Mishra et al. 2011). According to the authors highly electrophilic cerium ions may attack the lone pair of oxygen in the hydroxyl group. In anhydroglucose unit, the attack can be at the secondary C_2–C_3 or at the C_6 hydroxyl. Under conventional condition, C_2–C_3 attack is preferred because of higher electron density. On the other hand, when microwave irradiates the sample, the exothermic option is less preferable and binding at

C_6 hydroxyl occurs. According to that in conventional conditions, the cleavage of the carbon–carbon single bond occurs at C_2–C_3. Grafting of the acrylic monomer takes place at one of those carbons, while the second one is only oxidized to the form of carbonyl. At microwaves it takes place at the C6 position without any changes in the glucopyranose skeleton.

4.2 Seaweed Polysaccharides

Seaweed and seaweeds polysaccharide are paid a lot of attention by means of its commercial utilization in many branches of industry. In fact, most of them are well known and applied since ages, especially in the Far East Asian countries. But today there is a growing interest to apply them in many branches of science and industry. Very often the properties of the native polysaccharide do not meet the requirements of application. In those cases modification allows the change of properties. The most common plant polysaccharides acquired from the sea are alginates, agar, and carrageenan.

The term "carrageenans" describes a family of linear biopolymers obtained by water or alkali solution extraction from red seaweed found on the coast of North and South America, Asia, and Africa (Fig. 5). At the beginning of the last century, they were called as Irish moss extract (BeMiller and Whistler 2007; Glicksman 1986).

There are three main carrageenan fractions – fractions ι and κ, forming gels, and λ fraction, which does not gel at all. All these fractions are composed of D-galactose and 3,6-anhydro-D-galactose units, further esterified with sulfuric acid. Carbohydrate units are alternately connected by α-(1,3) and β-(1.4) bonds. Fractions κ and ι have similar compositions except that the fraction ι, except sulfate groups at the fourth carbon atom of D-galactose, has also a sulfate group at the second carbon atom of the 3,6-anhydro-D- galactose. On the other hand, λ fraction does not contain a 3,6-anhydro-D-galactose unit, and the sulfate groups are attached to every second unit of D-galactose, at the position of C_2 and C_6 (BeMiller and Whistler 2007; Thành et al. 2002; Necas and Bartosikova 2013). On the other hand, agar is a polymer composed of agarose and agaropectin. Agar consists of a mixture of agarose and agaropectin. Agarose, the predominant fraction, is a linear polymer, composed of anhydrogalactose and 3,6-anhydro-L-galactopyranose units.

Agaropectin fraction occurs in lesser amounts and is made up of alternating units of anhydro-D-galactose and anhydro-L-galactose heavily modified with such side groups as sulfate and pyruvate.

In recent research both polymers, i.e., carrageenan and agar, were successfully grafted with different side groups. At microwave conditions the most common grafting polymer for seaweed polysaccharide is polyvinylpyrrolidone (PVP). Hydrogels of carrageenan-g-PVP and agar-g-PVP were obtained at neutral pH with 125 % and 131 % of grafting, respectively (Prasad et al. 2006a). Both reactions have been carried out using potassium persulfate as radical initiator for about 2 min at 95 °C. As it was proved using HNMR and CNMR analysis, the grafting occurs simultaneously with cross-linking of polysaccharide chains using PVP bridges.

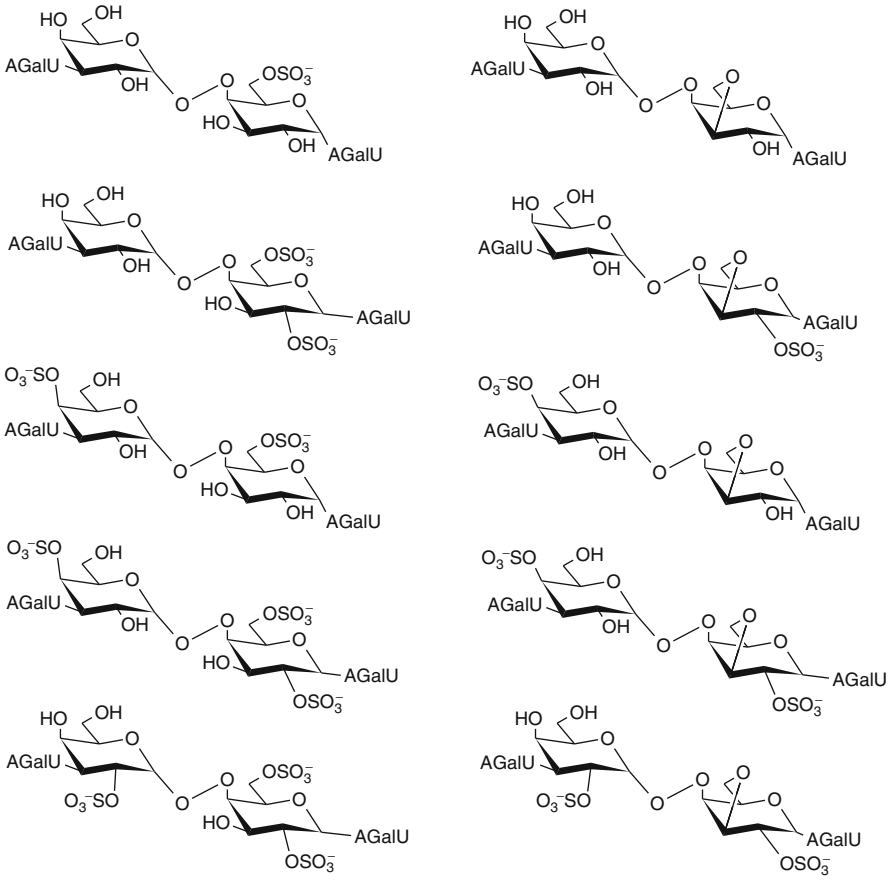

Fig. 5 Carrageenan family

As a result a higher water-holding capacity for grafted polymers was observed when compared with starting carbohydrate polymers. Microwaves were also applied for methyl methacrylate grafting on the carrageenan backbone (Prasad et al. 2006b, 2008; Meena et al. 2006). As a result a hydrophobic material was obtained with interesting improved barrier properties. As it was described for PVP grafting, methyl methacrylate is also able to cross-link two or more carbohydrate chains (Prasad et al. 2006b); however the presence of oxygen, "peroxide-like" bridges has not been proved by the authors. Meena et al. have also synthesized a carrageenan grafted methacrylate using microwaves, but in this case no specific molecular structure has been shown (Meena et al. 2006). It is also worthy to point out those specific short chains or low molecular organic compounds may also be grafted on carrageenan and agar forming interesting polysaccharide derivatives. Microwave may also be useful in this case as it was shown for the nucleobase cytosine (Oza et al. 2012a). In the reaction potassium persulfate was used as an initiator.

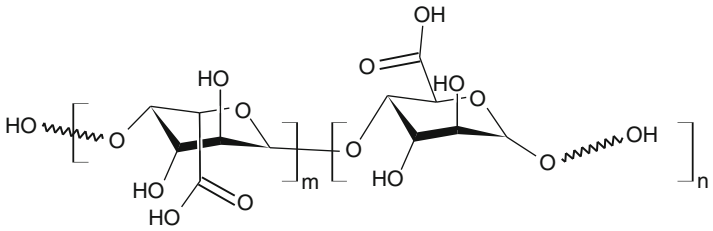

Fig. 6 Alginic acid structure

The reaction was carried out in water solution for about 3 min at 85 °C. Obtained products exhibited good fluorescence emissions. Similar results were obtained when adenine was grafted on carrageenan and agar in the microwave-assisted reaction performed in 2 min (Oza et al. 2012b).

Alginates are the group of seaweed polymers with different molecular constitutions when compared to carrageenan and agar. In this group sodium alginate is one of the most principal commercial water-soluble salts of alginic acid. Alginates are block copolymers of two carbohydrate subunits (Fig. 6).

Those building blocks are D-mannuronopyranosyl and L-guluronopyranosyl units. The ratio of those subunits is the key factor determining the alginate properties. As in the case of other polysaccharides, grafting of alginate skeleton may lead to a new group of polymers with designed properties. Some of those modifications have already been performed at microwave conditions. In fact, most alginates are grafted using acrylic polymers including methyl methacrylate (Rani et al. 2013), acrylamide (Sorour et al. 2013; Rani et al. 2013), or *N*-isopropylacrylamide (Işıklan and Küçükbalcı 2012). Methyl methacrylate has been grafted on agar using ceric ammonium nitrate. Microwave irradiation of about 800 W was used periodically in order to not exceed the temperature of 65 °C (g-PMMA 5, SAG-g-PMMA 6). During the research it was stated that the grafting process occurs in a most effective way at methyl methacrylate concentration of 7.5 g/1 g of alginate. The ceric ammonium nitrate concentration should be fixed as of 8 mg per 1 mL of the reaction mixture, and microwave power is maintained at 800 W (Rani et al. 2013). Obtained alginate-g-polymethyl methacrylate with highest observed intrinsic viscosity has been shown to possess a good flocculation efficacy against standard coal suspension. Alginate-g-acrylamide was obtained in water solution of alginate with no chemical initiator. The reaction conditions were set to 900 W of microwave power and the temperature do not reach the 70 °C. The total reaction time was 1–4 min; however the highest grafting efficiency was observed at 3 min (Sen et al. 2010b). Interesting results were obtained when *N*-isopropylacrylamide was grafted on alginate using different chemical initiators (Işıklan and Küçükbalcı 2012). The product of modification at microwaves was a pH- and temperature-responsive polymer that (in one case) exhibited temperature-induced phase transition behavior. It was proposed to apply alginate-g-*N*-isopropylacrylamide as an active drug-release matrix.

Besides acrylic polymers grafted on alginate, also an *N*-vinyl-pyrrolidone was successfully applied for grafting at microwave conditions (Yiğitoğlu et al. 2014). As in a former case, the resulted copolymer was shown to be able to play a role of a drug-release system, e.g., ibuprofen as a standard active substance. In described research azobisisobutyronitrile was used as an initiator. The process was carried out with a broad range of time from 2 min up to 2 h. It was shown that grafting yield and efficiency are rising with time and reach 57 % and 25.6 %, respectively. On the other hand, the viscosity average molecular mass of the product decreases about two times with time.

4.3 Gums

Gums belong to the group of polymers obtained mostly from the so-called higher plants or microorganisms. There are several gums that are important by means of technological application. In the group a variation in chemical constitution is observed. As a result different properties and industrial functions of those hydrocolloids may be detected. Due to chemical differences also the grafted polymers will vary by means of synthetic route and final properties.

4.3.1 Xanthan Gum

Xanthan gum is produced by microorganisms and has a complicated structure (Fig. 7). The macromolecule of xanthan is built from a cellulosic backbone in which the individual repeating units are combined together by β-1,4 glycosidic bonds. Every second unit, however, is substituted with short side chains of mannopyranosyl-D-(2→1)-β-D-glucuronic acid-(4→1)-β-D-mannopyranose which is linked to the main chain using α-1,3 glycosidic bond (Palaniraj and Jayaraman 2011). About 40 % of the terminal mannose groups form a cyclic ester of pyruvic acid (at positions 4, 6), and the inner mannose unit in most cases is acetylated at position C^6.

With the aid of microwaves, several xanthan grafted derivatives were obtained. Acrylamide was grafted on xanthan by Kumar et al. (2009). Xanthan-g-poly(acrylamide) was prepared employing microwave-assisted grafting and ceric-induced grafting. It was shown that relative grafting efficiency increases about three times (conventional method vs. 100 W of microwaves operating for 100 s) together with yield of grafting (more than three times for the same conditions). It is worthy to point out that a domestic microwave oven was used during experiments. The obtained polymer was characterized and used as a matrix for drug release. The study revealed faster release of the drug from graft copolymer matrix tablets as compared with the ungrafted gum. The release rate increased with the increase in percentage grafting (Kumar et al. 2009). Similar experiments on grafting were performed with ethyl acrylate (Pandey and Mishra 2012). During the research the comparison was done on the influence of microwaves on grafting. Microwave-assisted processes conducted in a domestic microwave were compared with a conventional one (water bath). In both cases as a result of the experiment, a series

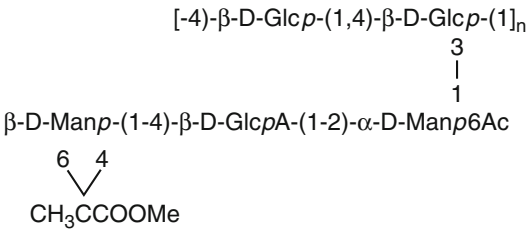

Fig. 7 Simplified xanthan gum structure

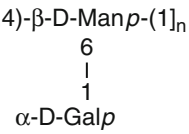
of grafted xanthan was obtained; however at the same monomer concentration, higher %G could be obtained under microwave conditions indicating grafting of more/larger monomer. The optimum %G was obtained by exposing a reaction mixture (25 mL) containing ethyl acrylate to microwaves for 15 s. During the research it was shown that microwave-assisted chemical grafting of the xanthan gum increased the adsorption capacity of lead ions from aqueous solution more than four times compared to the native xanthan gum.

4.3.2 Guar Gum

Guar gum is a polysaccharide that is extracted from plant seeds. Guar or cluster bean is the only source of that polysaccharide. Guar gum is an example of galactomannan, which is widely distributed in the plant kingdom (Cerqueira et al. 2011). Galactomannans are heterogeneous polysaccharides in which the backbone is built of mannopyranose units to which some galactopyranose units are attached as side groups. Various galactomannans found in nature differ in mannose/galactose ratio (Mulimani and Prashanth 2002). By means of chemical structure, the single macromolecule of guar contains anhydrogalactose and anhydromannose units. The backbone of the polymer is a linear chain of β-1,4-linked anhydromannose to which galactose residues are linked at C_6 position. The galactose units are presented at every second anhydromannose and forming short side branches (Srivastava and Kapoor 2005). As a result mannose/galactose ratio is about 2:1 (Fig. 8).

Guar gum has been widely used as a matrix for grafting acrylic monomers in microwaves including acrylonitrile (Singh et al. 2004), acrylamide (Pal et al. 2011; Sen et al. 2010; Shahid et al. 2013; Singh et al. 2004), ethyl acrylate (Singh et al. 2009), methyl methacrylate (Mishra and Sen 2011; Mundargi et al. 2006), etc. In the case of acrylonitrile, it was shown that grafting efficiency as well as percent of grafting is higher when microwaves are applied during the synthesis. It clearly shows the advantages of microwaves for grafting on guar; however there was a big difference in temperature observed at conventional and microwave-assisted processes (35 °C vs. 95 °C). Comparing polyacrylonitrile grafting guar is controversial in this case. During the described research it was also shown that grafting with microwaves results in higher molecular mass and viscosity of the product. It may be the result of shortening of the reaction time from 90 to 1.66 min. Also the factor of water absorption increases significantly when microwaves are applied. During the described research the mechanism of microwave-assisted

Fig. 8 Simplified guar gum structure



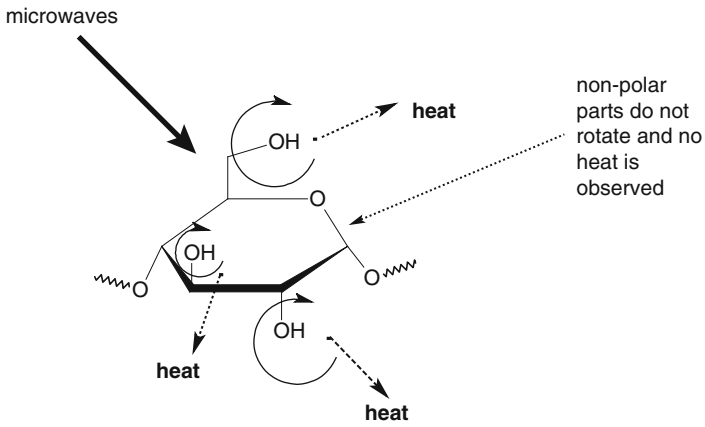


Fig. 9 Mechanism of microwave heat generation on polysaccharide chain

grafting onto guar gum was also proposed as an example of a polysaccharide matrix possessing high concentration of highly polar hydroxyl groups. According to that it was believed that dielectric (microwave) heating may be involved in rapid energy transfer from those "antennas" to neighboring molecules, i.e., monomer and solvent and water. In the polysaccharide chains there are large numbers of –OH groups (at least three for each anhydroglucose unit), so the energy dissipated to the environment seems to be crucial for the process (Singh et al. 2004) (Fig. 9).

Microwave-assisted grafting of acrylamide on guar gum has been performed in several studies (Table 2). Comparing all those data one can see that ternary initiating system allows to obtain the product with highest percent of grafting and grafting efficiency. The temperature of the processes does not exceed 70 °C and the total reaction time 4 min.

It is worthy to emphasize that under conventional conditions, no grafting product was observed in the absence of an initiator even when at high temperature. It clearly shows that radicals in the reaction system are of "microwave origin" (Singh et al. 2004). Except research on grafting and product characterization, also some application for acrylamide grafted guar gum has been proposed including flocculation processes (Pal et al. 2011) and drug release (Sen et al. 2010). The same application as well as synthetic protocol was used to graft guar gum with methyl methacrylate (Mishra and Sen 2011).

Microwaves were also employed in guar gum grafting using ethyl acrylate (Singh et al. 2009). In this case a microwave-induced emulsion copolymerization was performed in a very short time (15 s.). By varying with the ratio of gum and

Table 2 Grafting of guar gum using acrylamide

[a]Power density

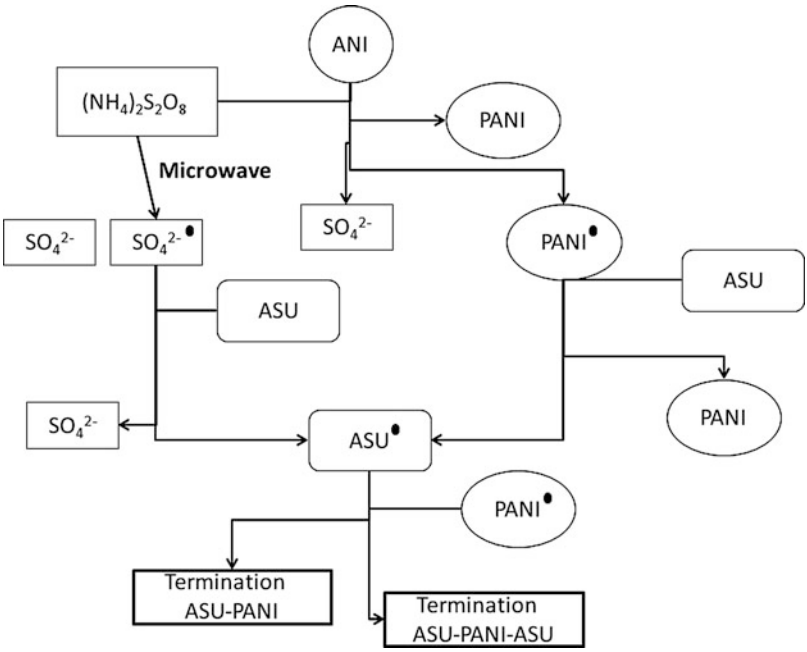

Fig. 10 Oxidative polymerization of aniline and grafting of polyaniline on polysaccharide backbone (*ANI* aniline, *PANI* polyaniline, *ASU* repeating unit of polysaccharide)

acrylate, a series of products was obtained with different grafting percents that reach up to 295 %G. The process was done in the absence of any redox initiator. Obtained copolymers were shown as capable to bind and remove cadmium ions from water solution (Singh et al. 2009).

Despite the most popular xanthan and guar gum, also some other gums have been successfully grafted in the presence of microwaves. During an interesting study acacia gum (gum Arabic) was grafted using polyaniline (Tiwari and Singh 2008). Arabic gum, in fact, is a complicated and undefined mixture of polysaccharides and glycoproteins (Phillips and Williams 2000). Although there is no strict information on the direct place where polyaniline chain is grown, the comparison between the conventional and microwave-assisted process clearly shows that grafting is more efficient when microwaves are operating especially by means of shortening of the reaction time. Because the polymerization of aniline is not only a radical process but a so-called oxidative polymerization, the mechanism of grafting looks different.

According to Tiwari et al., the primary radicals are generated from peroxydisulfate ions under the action of microwaves (Fig. 10). On the other hand, secondary radicals are forming on growing polyaniline chain. The grafting process is a result of the recombination of two macroradicals, i.e., the free radical on polysaccharide chain and secondary radical on polyaniline backbone (Tiwari and Singh 2008). Because polyaniline is one of the promising examples of conducting

polymers, the described synthetic protocol shows that microwaves may also be involved in natural compound modification that led to conductive substances. The obtained material is interesting also due to the phenomenon of pH switching conducting behavior that was dependent on the grafting extent. The occurrence is typical for polyaniline polymers but rather untypical in the case of biopolymers or polysaccharides. The observed controlled multifunctional electronic properties of the material might be usefully exploited for many technological applications.

Another example of gum grafting is ghatti gum that has been grafted using acrylamide (Rani et al. 2012). Ghatti gum is one of the oldest gums known. It is composed of L-arabinose, D-galactose, D-mannose, D-xylose, and D-glucuronic acid in a molar ratio of 10:6:2:1:2 and traces of 6-deoxyhexose (Whistler 1973). During the research ceric ammonium nitrate was used as an initiator and the process was performed in water solution. Microwave irradiation of the reaction mixture takes about 3 min at 800 W of microwave power. In order to avoid overheating of the reaction mixture, irradiation was done in cycles of heating (irradiating) and cooling. The obtained product was shown to serve as an effective flocculent for purifying water (Rani et al. 2012).

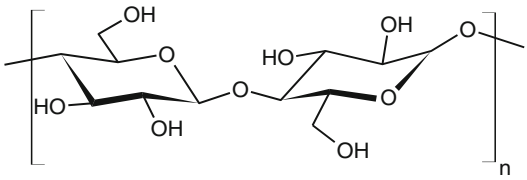
Additionally it is also worthy to point out that some rare gums have also been investigated as matrixes for grafting at microwave conditions. It includes gum kondagogu-g-poly(acrylamide) (Malik and Ahuja 2011), marginata gum (Singh et al. 2007, 2008, 2010), or *Cassia javanica* (Singh et al. 2010).

5 Cellulose

Cellulose is a naturally occurring polymer and is one of the most common organic polymers representing about 1.5×10^{12} tons of the annual biomass production. Additionally it is a very promising material due to its plenitude, availability, and low cost of acquisition. Cellulose is a linear polysaccharide and consists of β-D-glucopyranose units joined together by β-1,4 linkages (Fig. 11). In each repeating unit there are methylol and two hydroxyl groups as functional groups. In the structure of cellulose, there are no side chains or branching; therefore chains of polymer can exist in very ordered structure resulting in the existence of semicrystalline structure. In fact, the structure of cellulose is represented by areas of both high order (crystalline) and low order (amorphous). Although it is a linear polymer and contains a large amount of hydrophilic groups, e.g., two primary and secondary hydroxyl groups in each β-D-glucopyranose unit, it does not dissolve in water and in many organic solvents. It is caused by the existence of extensive hydrogen bonding system and van der Waals forces that are between polymer chains (Klemm et al. 2005).

The chain length of cellulose, expressed as the number of constituent units, varies with the origin and treatment of the raw material. In the case of wood, typical values are between 300 and 1,700, cotton and other plant fibers are in a 800–10,000 range. Partial chain degradation occurs on regenerating cellulose fibers (Phillips and Williams 2000).

Fig. 11 Cellulose formula



Cellulose has many crystal forms: cellulose I, which contains chains in a parallel orientation, and cellulose II, which is the most stable structure of cellulose and contains antiparallel-oriented chains. Cellulose has other polymorphic forms – cellulose III and cellulose IV (Klemm et al. 1998).

The properties of cellulose cannot be modified by conventional copolymerization methods, but they can be changed by some physical or chemical treatment, e.g., swelling in concentrated NaOH solution and then regeneration. During this process cellulose I is converted to cellulose II, and physical properties are changed. On the other hand, chemical properties of cellulose can be changed by (i) preparing ester or ether derivative cellulose, (ii) cross-linking cellulose chains, and (iii) grafting various monomers onto cellulose by copolymerization.

Graft copolymerization is among the widely used chemical modification methods for cellulose in order to improve its properties. During grafting, the side chains are covalently bonded to the main polymer structure to form a copolymer which has a branched structure. Graft copolymers have many useful properties different from those which each polymer has alone. There is extensive scientific literature available on the grafting modification of cellulose (Roy et al. 2009).

5.1 Microwave-Assisted Method

Cellulose has been modified to increase adsorption performance for copper(II) (Bao-Xiu et al. 2006). Partially neutralized acrylic acid (AA) and acrylamide (AAm) were grafted under microwave conditions. Potassium persulfate and sodium thiosulfate were used as initiators of radical reaction and *N*,*N*′-methylenebisacrylamide (MBA) as a cross-linker. Before grafting reaction cellulose was smashed into small particles and remains water immiscible and forms dispersion in the aqueous solution of vinyl monomers, cross-linker and initiator. Therefore grafting reaction takes place in heterogeneous conditions in the presence of redox system initiator. The radicals produced under microwave irradiation are generated more easily than in conventional heating conditions. Shortening of reaction time under microwaves is observed for several minutes at 360 W power. Alternatively reaction time for conventional heating was 10 h. Due to the presence of MBA in reaction medium, the resin obtained after grafting was also slightly cross-linked. The adsorption of Cu^{2+} by the optimum sample was 99.2 % and adsorption capability was 49.6 mg of Cu^{2+} per gram of grafted cellulose. Resin could be regenerated by using 8 % ammonia, regeneration ratio could achieve 85 %, and when recycled up to seven times adsorption ratio still kept 90 % after each cycle.

Graft copolymerization of *N*-isopropylacrylamide (NIPAM) and methyl acrylate (MA) on cellulose in heterogeneous conditions was carried out. Cellulose was dispersed in nitric acid, and an initiator system consists of cerium ammonium nitrate (CAN) and potassium persulfate (KPS). Series of reactions were done varying the microwave power as well as the reaction temperature to determine their influence on the grafting efficiency of polymers onto cellulose (Matahwa et al. 2007). The reaction time in microwave-assisted grafting was reduced to 10 min. The microwave power had only a small effect on grafting percentage, which was 36.86–49.14 %, depending on used microwave power. CAN/KPS initiation system is not suitable for microwave reactions in temperatures above 60 °C, only homopolymer is formed and cross-linking is highly enhanced.

Other sources of cellulose like mercerized cellulosic pine needles were used for grafting (Thakur et al. 2013a). Graft copolymerization synthesis of butyl acrylate (BA) was carried out in the presence of ferrous ammonium sulfate (FAS)/potassium persulfate initiator system. The reaction was carried out at selected doses of microwave radiation and for different time intervals. The optimum conditions for maximum percentage of grafting (28.18 %) were 90 mL of water, monomer 2.95×10^{-1} mol/L, time 400 s, FAS/KPS ratio 1:0.390, and microwave power 70 %. When reaction time is longer than 400 s, homopolymerization reaction dominates the graft copolymerization. When analyzing the influence of microwave power on grafting percentage, increasing of power up to 70 % causes increasing in grafting percentage, further increase in microwave power resulted in decreased grafting. In such high microwave power, homopolymerization reaction or decomposition reaction of graft copolymers occurs.

Bamboo cellulose was used in graft polymerization of methyl methacrylate (MMA); cerium ammonium nitrate was used as an initiator of polymerization reaction (Wan et al. 2011). Reaction was carried out under microwave radiation upon dispersion of cellulose in an aqueous medium in 3 min repeated period of time. The cellulose was pretreated with Ce^{4+} ions to form active reaction centers, and after that monomers were added. During pretreatment in the initiator of microwave-assisted grafting method, breaking of C–C bond in AGU unit occurs to form a carbonyl group and radical which is able to react with monomers to form grafted cellulose. The grafting reaction was confirmed with FTIR (characteristic band at 1,730 cm^{-1} corresponding to the stretch vibration of carbonyl group) and XRD spectra. Increasing of initiator concentration, grafting percentage (%G) and grafting efficiency (%GE) had the maximum at around 0.004 mol/L of the initiator, which caused more reaction sites on the cellulose backbone at low CAN concentration, and formation of the growing grafted chains or initiation of homopolymerization reactions at concentrations of CAN higher than 0.004 mol/L. %G and % GE initially increased with the increasing of microwave power up to 160 W, which is caused by more macroradicals generation. Whereas at microwave power higher than 160 W homopolymerization reaction is preferred, some decomposition of the graft polymer occurs. The maximum value of %G and %GE was reached after 9 min of reaction; further increasing of reaction time caused intensified interactions

between the initiator, monomer, and cellulose backbone and resulted in more generation of free radical sites both on the backbone and methyl methacrylate chains.

Microwave irradiation is one of the very effective methods for activating chemical reactions (Varma 1999; Elander et al. 2000; Perreux and Loupy 2001). Taking into consideration cellulose availability and biodegradability, glycidyl methacrylate grafted cellulose adsorbent for mercury was prepared, using microwave-initiated method (Kumar et al. 2013). Such initiation is possible due to the fact that during microwave irradiation, the localized rotations on an almost immobile OH group arising as a result of the dielectric heating involve energy transfer to solvent molecules, whereas the rupture/cleavage of the C–C bonds leads *t*o the formation of free radicals and then ensuing interaction with glycidyl methacrylate (GlyMA) to form grafted cellulose (Galema 1997). The grafting with GlyMA onto the cellulose backbone was confirmed with FTIR, XRD, and SEM analysis. FTIR spectra shows the O–H and C–H stretching peaks which appear at 3,343 and 2,895 cm^{-1}. Shifting of O–H and C–O peaks to 3,356 and 1,720 cm^{-1}, respectively, is observed after adsorption of mercury.

5.2 Microwave-Initiated Method

Microwave radiation was used to initiate grafting reaction. In that type of process, there were no other chemical substances which could initiate radical reaction. The nature of microwave radiation shows that the radiation beams cause "selective excitation" of only polar bonds, which results in their cleavage and leading to the formation of free radical sites. The C–C backbone of the polymer, which is relatively nonpolar, remains unaffected by the microwave radiation. Using this technique polyacrylic acid chains (PAA) were grafted on the carboxymethylcellulose (CMC) backbone. To initiate grafting reaction, microwave radiations that cause excitation of O–H bonds following free radicals were generated on the cellulose backbone. After that typical propagation reaction, with the participation of monomer (acrylic acid), according free radical mechanism occurs to build poly (acrylic acid) chain onto the CMC backbone. Authors suggests that in cellulose, free radical sites are expected to be generated at the primary hydroxyl group; however in carboxymethylated cellulose, part of those groups are unavailable due to the fact that they were substituted. Therefore when higher degree of substitution of cellulose, less of primary O–H sites will be available and hence and percentage grafting will be lower. To avoid competing homopolymer formation reaction and to prevent any thermal damage to the backbone polymer chain, the microwave irradiation was paused periodically whenever the reaction mixture starts boiling, i.e., at about 65 °C. The optimized reaction conditions have been determined, and it has been found that the highest grafting percentage (15.5 %) was at acrylic acid concentration of 10 g in the reaction mixture and 800 W of microwave power during 5 min.

Table 3 Optimized reaction conditions for microwave grafting of vinyl monomers onto flax fibers (Kaith and Kalia 2007, 2008; Kaith 2008)

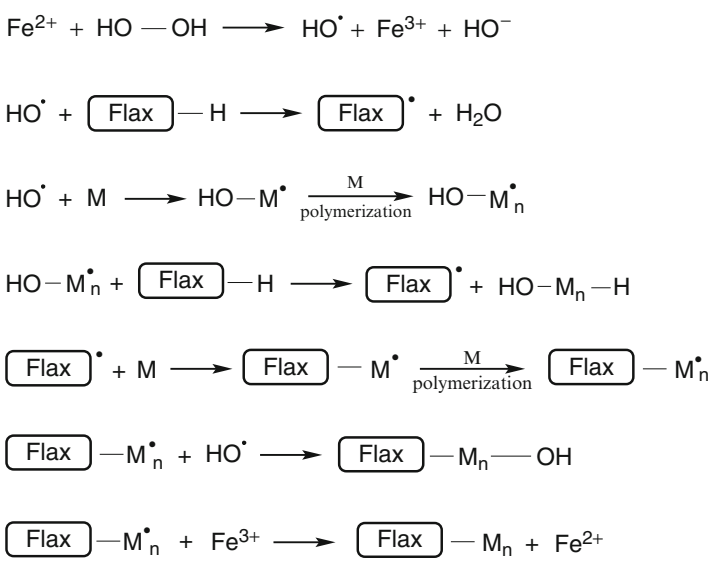
Monomer(s)	Monomer concentration $\times 10^3$ [mol/l]	% grafting
MMA	1.96	24.64
MMA/EA	2.3	51.2
MMA/AN	2.27	17.8
MMA/AA	2.91	12.08

5.3 Grafting onto Cellulose Fibers

Kaith et al. (Kaith and Kalia 2007; Kalia and Kaith 2008; Kaith 2008) report the grafting of methyl methacrylate or binary vinyl monomers such as MMA/ethyl acrylate(EA), MMA/acrylonitrile(AN), and MMA/acrylic acid onto flax fiber under different reaction conditions. In this technique of modification of natural fiber properties, the radiation technique reduces the extent of physicochemical stresses to which the fibers are exposed when modification occurs in conventional way. Properties of natural fibers treated under microwave radiation are even better than properties of fibers grafted through conventional technique (Freddi et al. 1996). Flax fibers grafted with vinyl monomers are excellent material as reinforcement to prepare of phenol-formaldehyde composites. Grafting reaction was carried out at microwave oven at 210 W microwave power, temperature not higher than 60 °C, reaction time 20–60 min. To initiate radical reaction Fenton reagent (ferrous ammonium sulfate/hydrogen peroxide) was used (Table 3).

The basis of the Scheme 1 hydroxyl radicals can be generated in the reaction between Fe^{2+} ions and hydroxy peroxide. OH radicals are able to react with flax fibers to form active sites onto the polymeric (cellulose in that case) backbone. Vinyl monomer can react with them to form graft copolymers as a concurrent homopolymerization reaction of vinyl monomer occurs. Percentage of grafting increases with increase on monomer concentration to about 2×10^{-3} mol/L (grafting percentage 24.64 %) for methyl methacrylate; further increase of monomer concentration prefers homopolymerization than graft copolymerization. Analyzing the influence of initiator concentration on grafting percentage, it was observed that maximum was observed when FAS–H_2O_2/monomer molar ratio was 1:6. Higher concentration of Fenton reagent could produce more Fe^{3+} ions, but they are rather consumed in termination reaction than in propagation reaction of copolymer chain. The optimum found reaction time was 30 min. Grafting reaction under microwave radiation results in less surface defects and crystal lattice of the fibers. The structure of fibers did not change very much during grafting which leads to better strength of flax-g-copolymer reinforced phenol-formaldehyde composites (Kalia and Kaith 2008).

Methyl methacrylate was grafted onto *Grewia optiva* fibers under microwave radiation where ferrous ammonium sulfate and potassium persulfate were used as a redox initiator system (Thakur et al. 2013b). *Grewia optiva* fibers consist of linear chains with repeating β-D-glucopyranose units joined together by β-1,4 linkages. To create free radical sites onto the cellulosic backbone, fibers were pretreated with



Scheme 1 Mechanism of grafting reaction onto flax fibers

initiator (FAS-H_2O_2). Generated free radicals may react with C_2, C_3, or C_6 hydroxy groups and C–H sites to form active sites for grafting of methyl acrylate. The optimum conditions for maximum grafting percentage (36.73 %) were as follows: solvent 110 mL, monomer (3.05×10^{-1} mol/L), time (350 s), FAS/KPS 1:0.250 mol/L, and microwave power at 70 %. The percentage of grafting increases with the increase in monomer concentration as initially more and more free radicals react with the cellulosic backbone of *Grewia optiva* fibers. However homopolymerization reaction dominates over graft copolymerization when monomer concentration is above optimum value resulting in decreasing of grafting percentage.

5.4 Hemicellulose

Another approach is to use tamarind kernel polysaccharide derived from the seeds of the commercially important tree in South Indian states and also in other Southeast Asian countries – *Tamarindus indica* (Ghosh et al. 2010). Tamarind seeds contain mainly xyloglucans, which have β-1-4-linked D-glucan backbone partially substituted with short side chains containing fucosyl, arabinosyl, galactosyl, and xylosyl residues (Fry 1989).

Tamarind kernel polysaccharide was grafted on acrylamide by three different techniques: (i) conventional technique with ceric ammonium nitrate as initiator, (ii) microwave-assisted method with the same initiator, and (iii) microwave-initiated method. When the third method was used, microwave energy was absorbed by the water molecules and then quickly transferred to the acrylamide causing dielectric

heating, which resulted in severing of double bonds in acrylamide, and producing of free radicals. The intrinsic viscosities and molecular weights of grafted products,were higher compared to the base polysaccharide. Such phenomenon was due to the presence of grafted polyacrylamide chains. As it was reported when microwave-initiated method is used, some grafting is observed, increasing molecular weight from 6.05×10^5 g/mol to 3.81×10^6 g/mol (grafting percentage 53 %); however it is not as effective as microwave-assisted method where molecular weight ranges to 5.12×10^6 g/mol and grafting percentage is 87 %.

6 Chitin and Chitosan

6.1 Chitin and Chitosan Chemistry

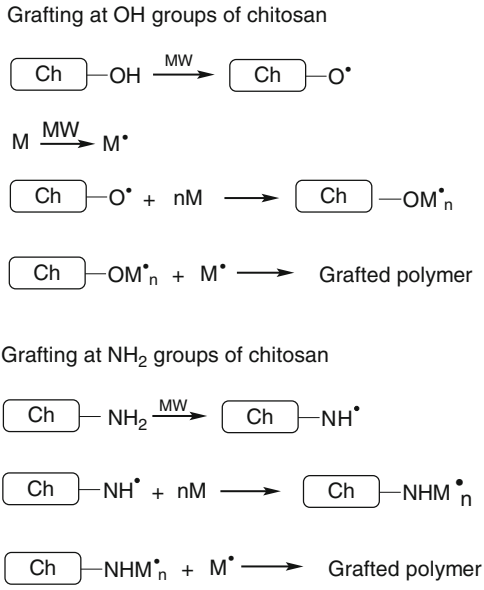
Chitin as a biopolymer is the most abundant organic compound of nitrogen in nature and is estimated to be at a level of about 10^{11} tons annually. It represents the major structural component of the skeletal material of invertebrates. At least 10^{13} kg of chitin is constantly present in the biosphere (Heinze 2005). It occurs in nature as ordered crystalline microfibrils forming structural components of exoskeletons, peritrophic membranes, and cocoons of insects. However only limited attention has been paid to chitin, mainly due to its intractable bulk structure, but chitin and its derivatives have high potential in many fields, e.g., pharmaceutical, cosmetics, agriculture, and environmental protection (Shahidi et al. 1999; Ravi Kumar 2000; Rinaudo 2006).

Chitin is structurally very similar to cellulose, but it has acetamide groups at the C-2 position. It is a highly ordered linear copolymer of 2-acetamido-2-deoxy-β-D-glucopyranose and 2-amino-2-deoxy-β-D-glucopyranose (Scheme 2). Chitin occurs naturally partially deacetylated; the occurrence of amino groups in chitin (5–15 %) is highly advantageous for providing biological reactions. The solubility of chitin is remarkably poorer than that of cellulose, because of high crystallinity supported by hydrogen bonds, which are formed mainly through the acetamido groups. Therefore chitin is insoluble in all the usual solvents. The insolubility is a major problem that confronts the development of processing and uses of chitin.

The most important derivative of chitin is chitosan (Fig. 12), obtained in two main processes: (i) (partial) deacetylation of chitin in the solid state under alkaline conditions (concentrated NaOH) or (ii) by enzymatic hydrolysis in the presence of a chitin deacetylase. Chitosan is the most important chitin derivative in terms of applications, due to fact that when the degree of deacetylation of chitin reaches about 50 %, polymer becomes soluble in aqueous acidic media. Therefore the degree of acetylation determines whether the polymer is called chitin or chitosan. Generally chitosan is used to name deacetylated chitin (deacetylation degree above 70 %). Chitosan, unlike chitin, is soluble in dilute acetic acid.

Taking into account the fact that chitin is poorly soluble and the reactions under heterogeneous conditions are accompanied by various problems, much attention had been paid to chemical modification of chitosan rather than chitin.

Scheme 2 Mechanism of copolymer grafting onto chitosan backbone under microwave irradiation



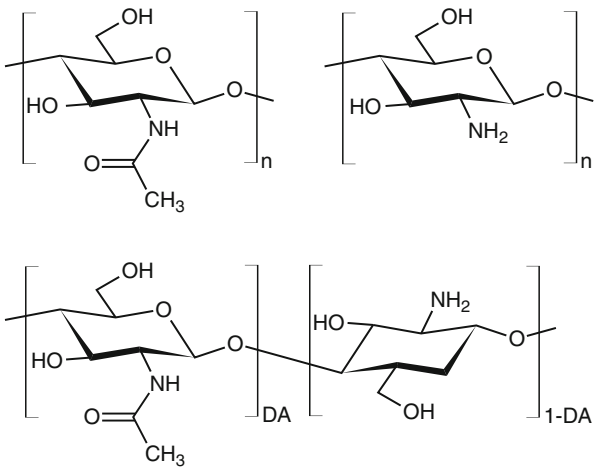


Fig. 12 Chemical structure of (**a**) chitin (**b**) chitosan (**c**) structure of partially acetylated chitosan

6.2 Graft Copolymerization of Chitosan

Graft copolymerization is expected to be the most promising approach to synthesize a wide variety of materials based on bio- and synthetic polymers. Vinyl grafted chitosan has many of its properties enhanced, and grafted chitosan materials behave as efficient flocculants (Hon and Tang 2000; Babel 2003; Chen and Park 2003; Guibal 2004), paper strengtheners, drug carrier (Calvo et al. 1997; Giunchedi et al. 1998; Wang et al. 2009; El-Sherbiny and Smyth 2010), etc. Most of the

chitosan copolymers are prepared through graft polymerization of vinyl monomers onto the polysaccharide backbone. But there are other approaches to synthesize grafted chitosans, e.g., cyclic monomers graft copolymerization via ring-opening method.

6.2.1 Vinyl Graft Copolymerization

Grafting reactions of vinyl monomers onto the chitosan backbone are mainly achieved by radical polymerization. In the beginning free radicals are generated on the polysaccharide backbone, and then they serve as macroinitiators for vinyl monomers, and propagation reaction of vinyl polymer onto the chitosan backbone occurs. Free radicals could be generated with microwave irradiation or with using different redox initiators, mainly ceric ions, potassium persulfate, and silver nitrate/potassium bromate.

Among different methods of initiation, the vinyl monomer graft copolymerization in microwaves onto chitosan *microwave initiation method* is the most frequently used (Table 4). In such conditions chitosan as quite a large molecule with pendant –OH and $–NH_2$ groups may interact with microwaves. Those groups anchored to an immobile backbone may rotate locally in the presence of microwaves, as a result dielectric heating of reaction medium is observed. In chitosan molecules there are large amounts of those pendant groups; therefore the amount of energy produced is expected to be very high, resulting in O–H and N–H bond breaking to produce radical sites on oxygen or nitrogen atoms of the chitosan molecule. Moreover as it was reported in literature, microwave irradiation may lower the Gibbs energy of activation of the reaction (Galema 1997). It was also reported (Singh et al. 2006a) that due to higher bond energy in hydroxyl group compared with N–H, more N · radicals will be produced; thus more grafting is expected at N–H sites.

Grafting of acrylamide (Singh et al. 2006a), methyl methacrylate (Singh et al. 2006b), and acrylonitrile (Singh et al. 2005) on chitosan has been done in the absence of any chemical initiator in aqueous conditions. Reactions were carried out in a very short time. In all abovementioned experiments, reactions were carried out in homogenous conditions, solution of chitosan in formic acid, in an open-glass vessel using domestic microwave oven without temperature control. The temperature in Table 4 was measured by inserting thermometer in the reaction mixture after the microwave exposure. Maximum MW power used was 80 % (960 W) due to the fact that further increase in microwave power leads to the decrease in grafting. This phenomenon was explained with increasing of homopolymerization process and partial degradation of the grafted polymer at such high microwave power.

During microwave-initiated grafting of acrylamide onto chitosan, it was found that the grafting percentage was increased with an increase in the initial concentration of monomer; thus more macroradicals were produced, which in turn may generate more grafting sites on chitosan (Singh et al. 2006a). When MW power was increased above 80 % (960 W), yield of the grafting starts decreasing due to the fact that some decomposition occurs and

Table 4 Reaction conditions and grafting parameters of vinyl polymers grafted onto chitosan with the use of microwave irradiation

homopolymerization reaction occurs. Under optimal grafting conditions for synthesis of chitosan-*graft*-poly(acrylamide), 169 %G was observed at 960 W microwave power after 70 s of reaction (Table 4).

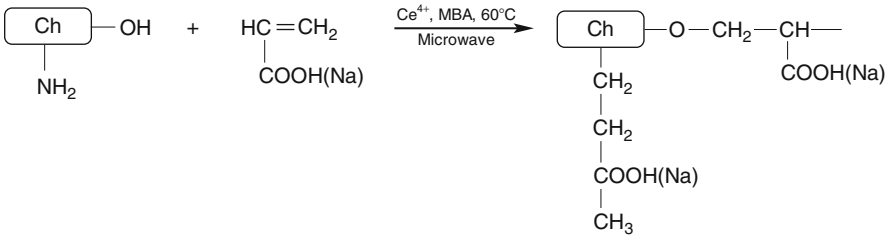
Grafting of acrylonitrile (Singh et al. 2005) was made in similar conditions and optimal parameters were found for grafting. When 960 W of MW power during 90 s was used, the copolymer sample having 170 %G was obtained. As it was in the case of acrylamide (Singh et al. 2006a) grafting, increasing of microwave power above 80 % (960 W) decreases grafting percentage and grafting efficiency.

Optimum conditions for microwave-initiated graft copolymerization of methyl methacrylate (MMA) on chitosan having 160 %G were as follows: under 80 % of microwave power after 2 min of exposure, using MMA in such amount, the concentration in the solution was 17×10^{-2} mol/L, 0.1 g of chitosan. It was found that in all cases mentioned above, grafting percentage was much higher and reaction time was much shorter, when compared with grafting in conventional way (redox initiator, without microwave irradiation) (Singh et al. 2005, 2006a, b).

Rajesh et al. tried to use a similar technique to graft *n*-butyl acrylate on chitosan in homogeneous conditions using microwave irradiation to initiate radical reaction (Santhana Krishna Kumar et al. 2014). They obtained grafted polymer after 3 min of reaction with 87.5 grafting percentage. Structure of copolymer was confirmed by FTIR spectra.

The microwave-assisted synthesis of partially neutralized acrylic acid grafted onto chitosan has been reported (Huacai et al. 2006). Cerium ammonium sulfate was used as an initiator in the presence of cross-linker *N*,*N*′-methylenebisacrylamide. Reaction was carried out in modified domestic microwave oven to control the temperature at 60 °C and radiated by microwave for 30 min. The grafting efficiency has been found to strongly depend on the amount of chitosan and, to a lesser extent, depends on the irradiation power. In optimum conditions 0.3 g of chitosan, 2.5 mL of 0.01 mol/L initiator, 5 mL of 0.01 mol/L of cross-linker, and microwave power 120 W over 30 min. were used, and grafting percentage was 89.6 % (Scheme 3).

The graft copolymerization of acrylamide on natural polysaccharide blend consisting of corn starch, chitosan, and alginic acid has been done (Sorour et al. 2013) in the presence of *N*,*N*′-methylenebisacrylamide that acts as a cross-linker and potassium persulfate as initiator. Reaction was carried out in domestic microwave oven without temperature control at different concentrations of acrylamide and polysaccharide blend. Due to the presence of cross-linker during grafting, cross-linking reaction occurs to form water-swelling hydrogel. Maximum swelling ratio was increased with increasing of acrylamide/blend weight ratio to reach a maximum value of 32 g/g. Such phenomenon is initially originating from the greater availability of monomer molecules in the vicinity of polysaccharide macroradicals; additionally higher acrylamide content enhances hydrophilicity of hydrogel. Further increasing of acrylamide/blend ratio causes decreasing of swelling ratio, due to intensification of homopolymerization reaction, increasing the viscosity of reaction medium and enhancing chances of chain transfer reaction to monomer molecules.



Scheme 3 Synthesis of microwave-assisted chitosan-*graft*-poly(acrylic acid)

6.2.2 Cyclic Monomer Graft Copolymerization: Ring-Opening Method

Graft copolymerization of ε-caprolactone onto chitosan has been done via three-step reactions involving (a) phthaloyl protection of amino groups of chitosan, (b) microwave-assisted graft copolymerization of ε-caprolactone in heterogeneous environment in the absence of solvent with the presence of tin(II) octoate as catalyst, and (c) deprotection to regenerate amino groups (Liu et al. 2005). The introduction of phthaloyl groups caused destruction of crystalline structure of chitosan as well as increasing of hydrophobicity of chitosan. This will cause better affinity of chitosan with hydrophobic ε-caprolactone and hydroxyl groups of chitosan (Koroskenyi and McCarthy 2002). At the microwave power 450 W, both the yield and grafting percentage were greatly improved, compared to conventional heating method. The optimum grafting percentage at level 120 % was found when feed ratio of ε-caprolactone monomer to phthaloylated chitosan was 1:2 and exposed for 12.5 min at 450 W microwave power. At MW power above 450 W, discoloration of the final product occurs due to overheating. Due to the fact that grafting reaction occurs only on hydroxyl groups of chitosan, after deprotection there are large amounts of free amino groups. Due to the presence of amino groups and hydrophobic polycaprolactone side chains, the obtained chitosan-*graft*-polycaprolactone could be used as degradable amphoteric material having extensive potential applications in biomedical materials (Fig. 13).

A similar procedure was used to synthesize thermoformable bionanocomposites based on chitin whisker-*graft*-polycaprolactone (Feng et al. 2009). Grafting of ε-caprolactone on chitin whisker was carried out through "graft from" strategy, to obtain long and dense "plasticizing" tails of polycaprolactone on chitin whisker surface, which are key issue of thermoforming. The reaction was carried out in the presence of tin(II) octoate under microwave irradiation of 255 W for 3 min. Authors observed that with an increase of polycaprolactone content, the strength and elongation as well as the hydrophobicity of the nanocomposites were increased.

Chitosan-*g*-poly(D,L-lactide) copolymers have been synthesized by ring-opening polymerization of D,L-lactide with the presence of tin(II) octoate as catalyst (Luo et al. 2012). Modified chitosan with pendant hydroxyl groups was used as the polymer backbone to weaken the intramolecular and intermolecular hydrogen bonds and to enhance reactivity of chitosan. The optimal conditions for the microwave-assisted copolymerization were as follows: 10 W of microwave

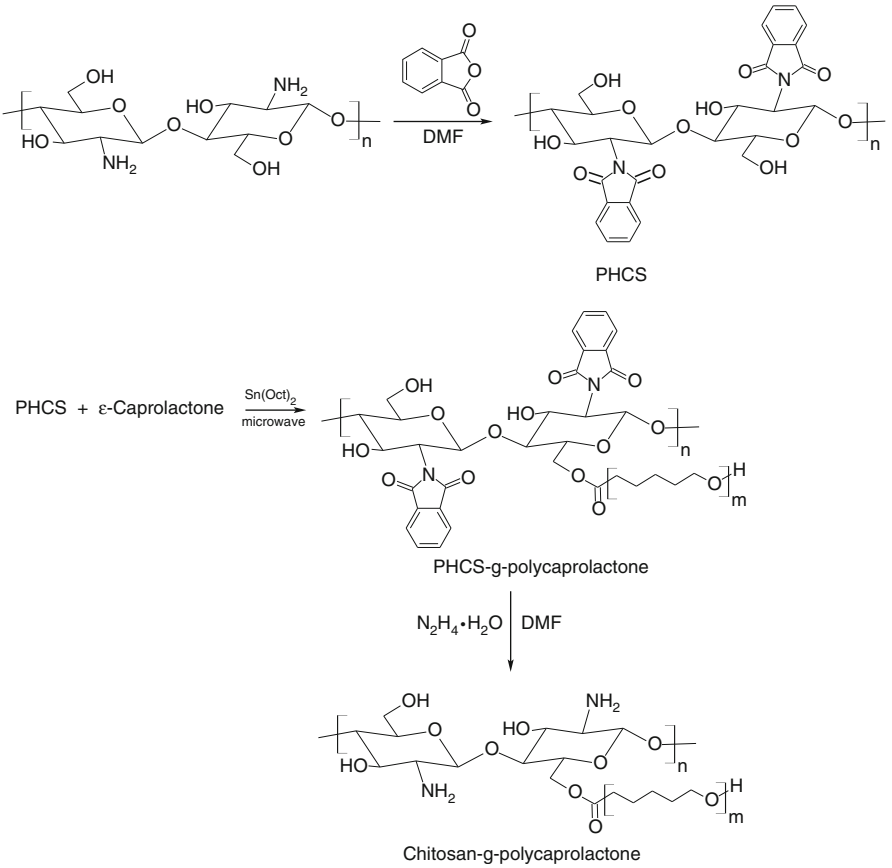


Fig. 13 Preparation of chitosan-g-polycaprolactone by ring-opening method with phthaloyl protection of amino groups

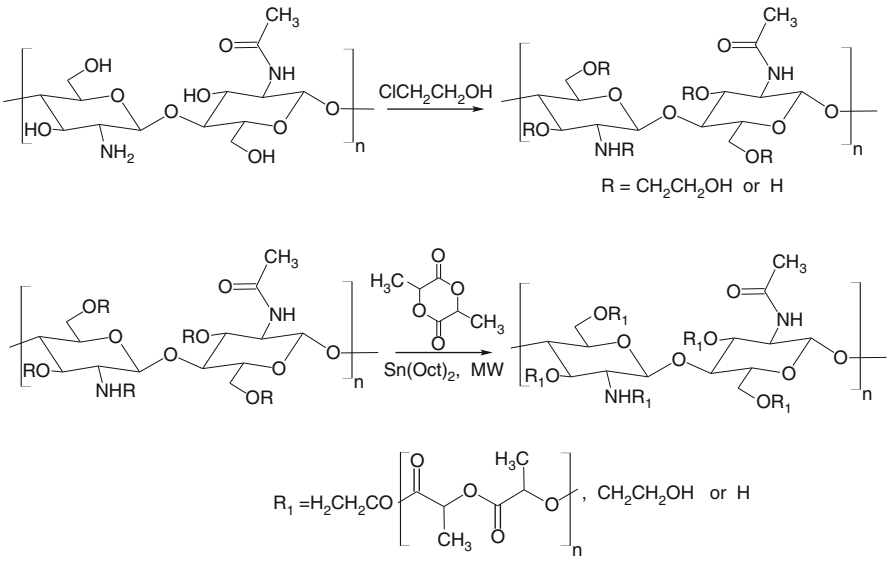
power for 15 min, reaction temperature 130 °C, and catalyst concentration 0.05 %. In those conditions grafting percentage reached 229.4 %. When microwave power is above 10 W, temperature higher than 130 °C, or reaction time longer than 15 min, the degradation of poly(D,L-lactide) side chains occurs, which led to a lower grafting percentage. The grafting percentage of the copolymer could be adjusted by control of the ratio of D,L-lactide to aminoglucoside units (Scheme 4).

7 Conclusions

Desirable properties can be imparted to natural polysaccharides through synthetic polymer grafting in order to obtain products with requirements needed in specialized applications. Polymer grafting under microwave irradiation is a clean method for altering properties of numerous biopolymer (polysaccharides) backbones and



Scheme 4 Synthesis of chitosan-*g*-poly(D,L-lactide) copolymer

can be a powerful strategy for the development of the valuable derivatives with diversified properties. It may also be used for various scientific and industrial applications. Microwave heating has many advantages over conventional thermal heating, and it offers an environmental friendly, cleaner, greener approach resulting in greater control and reproducibility of the final product, which is suitable for commercial production. There are some easy to see difficulties with commercialization of microwave synthesis of grafted polysaccharides, of which the most important could be the scale-up, because higher energy input is required for larger batch. Polysaccharide grafting reactions under microwave irradiation offers shortening in reaction time, solvent less/free or aqueous conditions, fast heating rate, and possibility of high-temperature reactions with modified selectivity. However microwave-based grafting reactions still require very careful control of reaction parameters to obtain polysaccharides with suitable properties and grafting efficiency. Current research in the area of polysaccharide grafting under microwave irradiation generated awareness that materials, with desirable properties using a natural polymers, can be produced through such processes with much simpler, cleaner, and quicker technologies than the conventional ones.

Analytical Methods for Lignocellulosic Biomass Structural Polysaccharides

39

Jason S. Lupoi

Contents

Abstract

The use of lignocellulosic biomass has been postulated as a potential pathway toward diminishing global dependence on nonrenewable sources of chemicals and fuels. Before a specific feedstock can be selected for biochemical conversion into biofuels and bio-based chemicals, it must first be characterized to evaluate the chemical composition of the cell walls. Polysaccharides, specifically cellulose and hemicellulose, are often the focal point of these appraisals, since these constituents are the dominant substrates converted into monomeric sugars like glucose and xylose. These monosaccharides can be transformed, using microorganisms like yeast, into substances such as ethanol. Plant species containing abundant polysaccharides are highly desirable, as higher quantities of sugars should translate into larger end-product yields. Given the vast pool of potential feedstocks, qualitative and quantitative analytical methods are needed to assess cell wall polysaccharides. Many of these tools, such as wet chemical and chromatographic techniques, have been ubiquitously used for some time.

Shortcomings in these analyses, however, prevent their usage in screening large sample sets for quintessential, high-yield, fuel-producing traits. This chapter briefly summarizes how analytical spectroscopy can lessen some of these limitations and how it has been utilized for polysaccharide analysis.

Keywords
Lignocellulosic biomass • Analytical instrumentation • Spectroscopy • Polysaccharides • Cellulose • Hemicellulose

1 Introduction

The analytical assessment of polysaccharides continues to be a prevalent research topic. Many applications previously developed for or applied to the food or textile industry have been transferred to the characterization of lignocellulosic biomass for the production of biofuels and other bio-based chemicals. This chapter seeks to provide an overview of the spectroscopic analytical methods employed for evaluating polysaccharides, encompassing qualitative (structural) and quantitative analyses applied to lignocellulosic biomass.

Lignocellulosic biomass conversion to biofuels is one possible pathway to supplanting global dependence on fossil fuels. In a 2011 supplement to the 2005 US Department of Energy *Billion Ton Report*, Perlack et al. projected that the existing biomass from agricultural and forest crops including wastes plus dedicated energy feedstocks, in the USA, is between 400 and 600 million tons priced at $60 per dry ton or less (Perlack 2005, 2011). Before a specific plant can be isolated for biofuel or bio-based chemical production, it must first be characterized using an array of analytical tools. Structural polysaccharides represent one of the dominant plant cell wall fractions evaluated in lignocellulosic biomass.

Structural polysaccharides are polymers of monosaccharides such as glucose or xylose and include cellulose, hemicellulose such as arabinoxylans, and pectin. Cellulose, the most abundant biopolymer on earth, comprising 15–30 % of primary walls and larger proportions of secondary walls, is a linear chain of β-D-glucopyranosyl units, connected via 1,4-glycosidic linkages. Hydrogen bonding between chains allows for the formation of tightly bound cellulose microfibrils. Measuring cellulose both qualitatively and quantitatively has been of considerable interest in the biofuel community, as higher cellulose contents provide a larger quantity of fermentable sugars following hydrolysis. Hemicelluloses are heteropolymers of arabinose, galactose, glucose, rhamnose, mannose, and xylose monomeric units and are classified as xyloglucans, xylans, mannans, glucomannans, and β-(1→3,1→4)-glucans (Scheller and Ulvskov 2010). They represent a supplemental source of cell wall sugars, in addition to cellulose, for conversion to biofuels and bio-based chemicals. The primary role of hemicelluloses is to strengthen the plant cell wall through interactions with cellulose and lignin (Scheller and Ulvskov 2010). Hemicellulose chains are long enough to interlace through the cellulose microfibrils, forming a complex network. Arabinoxylans are

similar to hemicelluloses in that they are predominantly chains of xylose, substituted with a few arabinose units. Pectin, considered to be the most structurally complex biopolymer, is a polymer of 1,4-linked α-D-galactosyluronic acid units (Mohnen 2008). Until recently, pectin had not received much attention as a potential feedstock for biofuels, despite the fact that pectin comprises approximately 2–35 % of plant primary walls depending on the type of tissue (Mohnen 2008; Edwards and Doran-Peterson 2012).

Analytical methods for characterizing polysaccharide structure and content include a variety of wet chemical degradation reactions and separation instrumentation such as capillary electrophoresis (CE) (Goubet et al. 2002; Suzuki and Honda 2003; Gamini et al. 2008; Persson et al. 2011; Li et al. 2013), high-performance liquid chromatography (HPLC) (Hausalo 1995; Rohrer 2003; Willfoer et al. 2009; Sluiter et al. 2010; Rohrer et al. 2013; Dvorackova et al. 2014), gas chromatography (GC) (Collings and Yokoyama 1979; Brummer and Cui 2005; Cui 2005; TAPPI 2009; Willfoer et al. 2009; Deutschmann and Dekker 2012; Sarossy et al. 2012), gel permeation chromatography (GPC) (White 1999), and size-exclusion chromatography (SEC) (Gillespie and Hammons 1999; Eremeeva 2003; Brummer and Cui 2005; Isogai and Yanagisawa 2008); mass spectrometry (MS) (Kelley et al. 2004; Cui 2005; Beecher et al. 2009; Ralet et al. 2009; Foston and Ragauskas 2012; Hounsell 2013); pyrolysis (py) (Kelley et al. 2004); thermogravimetric analysis (TGA) (Cozzani et al. 2008; Hatakeyama and Hatakeyama 2008; Serapiglia et al. 2008, Singh et al. 2009a; Carrier et al. 2011; Freda et al. 2012); spectroscopic tools such as mid-infrared (MIR) (Liang and Marchessault 1959a, b; Reeves 1997; Kacurikova et al. 1998; Kacurakova et al. 2000; Moore and Owen 2001; Workman 2001; Atalla and Isogai 2005; Choi et al. 2010; Coimbra et al. 2010; Persson et al. 2011; Reeves 2012; Lupoi et al. 2013; Xu et al. 2013), near-infrared (NIR) (Reeves 1997; Hames et al. 2003; Kelley et al. 2004; Poke and Raymond 2006; Ye et al. 2008; Hames 2009; Templeton et al. 2009; Wolfrum and Sluiter 2009; Liu et al. 2010; Tyson et al. 2010; Deutschmann and Dekker 2012; Reeves 2012; Lupoi et al. 2013; Xu et al. 2013), nuclear magnetic resonance (NMR) (Atalla et al. 1980; Atalla and VanderHart 1999; Ferrier et al. 2002; Maunu 2002; Atalla and Isogai 2005; Cui 2005; Beecher et al. 2009; Harris et al. 2010; Park et al. 2010; Persson et al. 2011; Deutschmann and Dekker 2012; Foston and Ragauskas 2012; Li et al. 2012; Kim et al. 2013; Lupoi et al. 2013; Nieto and Jiménez-Barbero 2013), Raman (Wiley and Atalla 1987a, b; Kenton and Rubinovitz 1990; Ona et al. 1997; Ona et al. 1998; Agarwal 1999; Schenzel and Fischer 2001; Workman 2001; Ona et al. 2003; Atalla and Isogai 2005; Schenzel et al. 2005; Agarwal 2008; Beecher et al. 2009; Schenzel et al. 2009; Agarwal and Atalla 2010; Agarwal et al. 2010; Choi et al. 2010; Foston and Ragauskas 2012; Agarwal et al. 2013; Kim et al. 2013; Lupoi et al. 2013), and ultraviolet/visible (UV/Vis) (Brummer and Cui 2005; Masuko et al. 2005; Chundawat et al. 2008; Foster et al. 2010; Lupoi et al. 2013); X-ray diffraction (XRD) (Segal et al. 1959; Thygesen et al. 2005; Beecher et al. 2009; Agarwal et al. 2010; Harris et al. 2010; Park et al. 2010; Foston and Ragauskas 2012; Agarwal et al. 2013; Kim et al. 2013); and microscopic methods such as atomic force microscopy (AFM) (Brant 1999; Abu-Lail and Camesano

2003; Stenius and Kolijonen 2008; Beecher et al. 2009; Funami 2010; Harris et al. 2010; Ding and Liu 2012; Foston and Ragauskas 2012) and scanning and transmission electron microscopy (SEM and TEM, respectively) (Atalla and Isogai 2005; Harris et al. 2010; Fazilova et al. 2011). Although this chapter will place emphasis on common or cutting-edge spectroscopic techniques for polysaccharide analysis, Table 1 provides a quick reference guide for a more complete breakdown of all methodologies. A recent review of how spectroscopic techniques have been employed for assessing lignocellulosic biomass illustrated the most contemporary and high-throughput methodologies (Lupoi et al. 2013).

1.1 Structural Analysis of Polysaccharides

1.1.1 Vibrational Spectroscopy

Raman spectroscopy is a noninvasive, nondestructive analytical tool that measures the scattering of photons when probed with an excitation source, commonly a laser (Carey 1982; Smith and Dent 2005). Approximately one per every one million photons will inelastically scatter with concomitant energy shift representing characteristic signatures of specific vibrational modes (Smith and Dent 2005). Thus, although Raman spectroscopy is a relatively weak phenomenon, it presents a versatile instrumental technique that has been routinely applied to measurements of polysaccharide structure, predominantly for cellulose analysis (Mathlouthi and Koenig 1986; Wiley and Atalla 1987a, b; Kenton and Rubinovitz 1990; Kacurikova et al. 1998; Agarwal 1999; Schenzel and Fischer 2001; Workman 2001; Atalla and Isogai 2005; Agarwal 2008; Schenzel et al. 2009; Agarwal and Atalla 2010; Agarwal et al. 2010; Choi et al. 2010; Foston and Ragauskas 2012; Agarwal et al. 2013; Lupoi et al. 2013). Infrared and Raman spectroscopies are often described as complementary techniques, due to the difference in selection rules. In infrared spectroscopy, a change in the dipole moment of a bond is necessary to be infrared "active," while in Raman spectroscopy, there must be a change in polarizability. The C-C and C-O bonds composing cellulose have high polarizabilities resulting in quality Raman spectra showcasing strong, spectrally resolved peaks.

The application of Raman spectroscopy was significantly advanced through the work of Atalla and coauthors in the 1970s and 1980s (Wiley and Atalla 1987a, b; Atalla and Isogai 2005). The innovative instrument combined an optical microscope with a standard spectrometer. By using a microscope, the excitation source could be focused down to a smaller spot size, facilitating morphological analysis. The authors analyzed a variety of cellulose preparations, including fibers extracted from algae, deuterated algal and bacterial fibers, and ramie cellulose. The excitation light polarization was varied to further elucidate key cellulose vibrational modes. This study demonstrated the utility of Raman spectroscopy for cellulose structural analysis and provided a foundation with which future researchers could progress upon.

Cellulose polymorphism was also evaluated using the Raman microprobe. Cellulose is known to have two major conformations, celluloses I and II.

Table 1 Methods for analyzing polysaccharides

Polysaccharide component	Wet chemical methods	Chromatographic methods	Thermochemical methods	Spectroscopic methods	Microscopy and others
Cellulose content	Acid hydrolysis (Cui 2005; Foyle et al. 2007; Hames 2009; Sluiter Justin et al. 2010)	CE (Persson et al. 2011)	MALDI-MS (Foston and Ragauskas 2012)	FTIR (Li et al. 2010, 2011; Reeves 2012; Lupoi et al. 2013)	Raman imaging (Lupoi et al. 2013)

Cellulose I is the native structure, while cellulose II is produced from mercerization or dissolution and subsequent regeneration of the fibers. To investigate whether cellulose I possessed internal polymorphism, dependent on the source, algal and ramie celluloses were measured. Spectral regions below 1,600 cm^{-1} were found to be most sensitive to conformational changes in the cellulose backbone, while the spectral contributions above 2,700 cm^{-1} were more sensitive to hydrogen bonding. By comparing the spectra of different native celluloses, the authors determined that any polymorphic structures belonging to cellulose I must be similar in conformational structure, as relatively few spectral differences were elucidated. The analysis of native celluloses at the higher wavenumber spectral regions revealed significant differences in cellulose hydrogen bonding. Schenzel et al. explored the use of Fourier transform (FT)-Raman spectroscopy to monitor the transformation of cellulose I into cellulose II and compared the Raman spectral data with that obtained using XRD and NMR (Schenzel and Fischer 2001; Schenzel et al. 2005, 2009). Raman microscopy can also be used to evaluate the deformation of cellulose (Hamad 2008). Shifts in characteristic Raman vibrational modes have been detected that coincide with the application of stress. For example, the 1,095 cm^{-1} mode has been measured to shift to lower wavenumbers and decrease in intensity as the strain on the cellulosic fibers increases.

Raman spectra of polysaccharides can be partitioned into distinct vibrational modes as depicted in Table 2. The most intense Raman peaks are typically near 1,091 and 1,117 cm^{-1} and correspond to C-C and C-O stretching (Wiley and Atalla 1987a, b; Agarwal 1999; Lupoi and Smith 2012). Other intense vibrational modes occur at 380, 435, 458, 520, 896, 1,002, 1,033, 1,074, 1,147, 1,268, 1,338, 1,376, and 1,460 cm^{-1}. Figure 1 depicts NIR, dispersive Raman spectra of microcrystalline cellulose and a commercially available hydrolytic lignin preparation (Lupoi and Smith 2012). A comparison of these spectra revealed that the main lignin vibrational modes are near 1,600 cm^{-1}, isolated from the aforementioned cellulose peaks. This can facilitate the analysis of solid biomass, at least in regard to the identification of peaks stemming from lignin and polysaccharides, as seen in Fig. 2, for a diverse assortment of potential biofuel feedstocks. In this figure, for example, a variety of hard- and softwoods and herbaceous feedstocks were grouped according to spectral similarity. Xylan structure has also been evaluated using FT-Raman spectroscopy (Kacurikova et al. 1998). As can be seen from Table 2, many of the vibrational modes of xylan and cellulose have overlapping or proximate peaks, due to their structural similarity. However, the analysis of the less intense vibrational modes of glucan and xylan can often reveal unique spectral signatures. Figure 3 illustrates this technique, as developed by Shih et al., depicting the simultaneous quantitation of glucose and xylose in a complex saccharification matrix, enabled by the identification of distinctive vibrational modes from the measurement of glucose and xylose standards using a spectral peak deconvolution method (Shih et al. 2011). The malleability of this method should allow its extension to the qualitative assessment of glucan and xylan polymers.

Raman imaging has enabled researchers to localize plant cell wall constituents such as cellulose and hemicellulose, as exemplified in Fig. 4, where black spruce

Table 2 Characteristic Raman vibrational modes for polysaccharides

Approximate peak location	Polysaccharide	Primary assignment
311	Cellulose II	CCO torsion (Schenzel and Fischer 2001)
329	Cellulose	CCC, CO, CCO, ring deformation (Schenzel and Fischer 2001)
331	Cellulose	Heavy atom bending (Wiley and Atalla 1987a, b)
344	Cellulose	Heavy atom stretching (Wiley and Atalla 1987a, b), CCC, CO, CCO, ring deformation (Schenzel and Fischer 2001)
352	Cellulose II	CCC, CO, CCO, ring deformation (Schenzel and Fischer 2001)
373	Cellulose II	CCC, CO, CCO, ring deformation (Schenzel and Fischer 2001)
376	Holocellulose	Holocellulose (Kenton and Rubinovitz 1990)
380	Cellulose	Heavy atom stretching (Wiley and Atalla 1987a, b), CCC, CO, CCO, ring deformation (Schenzel and Fischer 2001)
418	Cellulose II	CCC, CCO, ring deformation (Schenzel and Fischer 2001)
437	Cellulose	Heavy atom stretching (Wiley and Atalla 1987a, b), CCC, CCO, ring deformation (Schenzel and Fischer 2001)
458	Celluloses I and II	Heavy atom stretching (Wiley and Atalla 1987a, b), CCC, CCO, ring deformation (Schenzel and Fischer 2001)
503	Xylan	CCO (Kacurikova et al. 1998)
519	Cellulose	Heavy atom stretching (Wiley and Atalla 1987a, b)
521	Xylan	CCO (Kacurikova et al. 1998)
531	Xylan	CCO (Kacurikova et al. 1998)
553	Xylan	CCO (Kacurikova et al. 1998)
609	Cellulose	CCH torsion (Schenzel and Fischer 2001)
897	Celluloses I and II, holocellulose, xylan	Holocellulose (Kenton and Rubinovitz 1990), CH, ring (Kacurikova et al. 1998), C1-H (Schenzel and Fischer 2001)
904	Cellulose, xylan	CH, ring (Kacurikova et al. 1998; Schenzel and Fischer 2001)
910	Cellulose	HCC and HCO bending (Wiley and Atalla 1987a, b)
969	Celluloses I and II	CC and CO stretching (Wiley and Atalla 1987a, b), CH_2 (Schenzel and Fischer 2001)
977	Xylan	CO (Kacurikova et al. 1998)
995	Cellulose	CC and CO stretching (Wiley and Atalla 1987a, b)
997	Cellulose	CH_2 (Schenzel and Fischer 2001)
1,000–1,010	Cellulose, xylan	CC and COH (Kacurikova et al. 1998)
1,026	Xylan	CC and COH (Kacurikova et al. 1998)
1,037	Cellulose	CC and CO stretching (Wiley and Atalla 1987a, b)
1,057	Cellulose	CC and CO stretching (Wiley and Atalla 1987a, b)

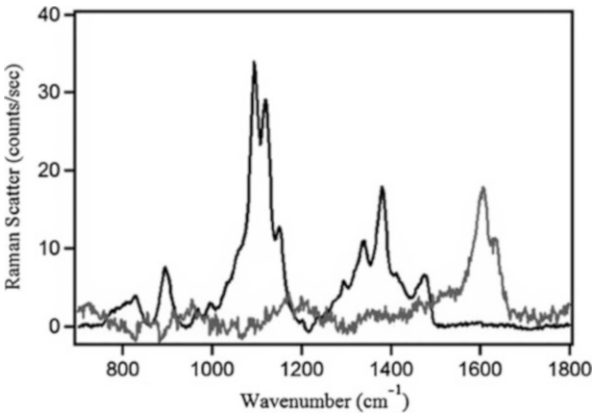

Fig. 1 NIR, dispersive Raman spectra of cellulose (*black*) and lignin (*gray*). The lignin spectrum has been multiplied by a factor of 10 to allow a better visual spectral comparison (Reprinted with permission from Lupoi and Smith 2012)

cell wall sections high in cellulose content were exposed (Agarwal 2006; Lupoi et al. 2013). These images and the corresponding Raman spectra (Fig. 5) reveal higher cellulose content in the secondary S2 region of the cell wall and a much lower cellulose fraction in the cell corners and compound middle lamella, areas known to contain more lignin. Imaging techniques have been utilized to monitor chemical pretreatments that render the biomass less recalcitrant to enzymatic hydrolysis. Recently, the deconstruction of feedstocks using ionic liquids (ILs) has been juxtaposed to acid and ammonia pretreatment strategies in corn stover and *Eucalyptus globulus* (Sun et al. 2010, 2013). Figures 6 and 7 illustrate the employment of Raman imaging for localizing cellulose content in tracheids (Fig. 6) and sclerenchyma cells (Fig. 7) before and during an IL pretreatment. This study demonstrated that while

lignin dissolution preferentially occurred in specific cell wall regions, there was no particular trend in cellulose dissolution. In general, Raman imaging techniques provide real-time evaluations of how plant cell walls are constructed and, more importantly, how efficient a projected pretreatment approach may be in diminishing the complex interlacing of cellulose, hemicellulose, and lignin. This live visualization is paramount for optimizing biomass-to-biofuel conversion efficiency. One of the major drawbacks in generating the images, however, can be long acquisition times due to the weak spontaneous Raman scattering phenomenon.

Coherent anti-Stokes Raman spectroscopy (CARS) and microscopy and stimulated Raman spectroscopy (SRS) have been employed to enhance spectral intensities, thereby alleviating a fundamental limitation of using spontaneous Raman scattering (Saar et al. 2010; Foston and Ragauskas 2012; Zeng et al. 2012; Pohling et al. 2014). Both techniques utilize two lasers that are overlapped spatially and temporally. When the frequency difference is resonated with a Raman-active frequency, the signal intensifies. The more intense spectra have facilitated more rapidly acquired images. Both techniques have the added benefit of reducing

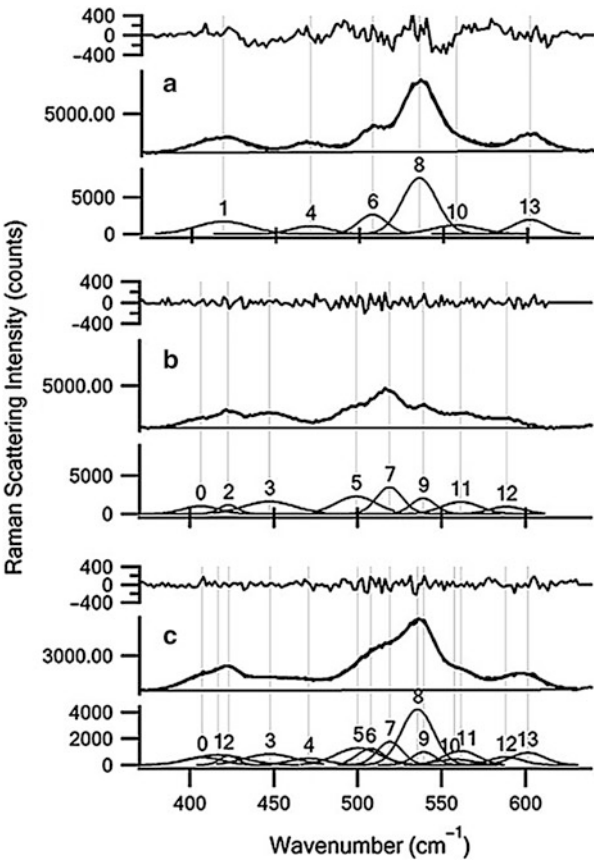

Fig. 3 NIR, dispersive Raman analysis of xylose (**a**) and glucose (**b**) standards in a simulated, complex saccharification matrix. Panel (**c**) represents a mixture of glucose and xylose. From the evaluation of the individual standards, and the mixture, vibrational modes at 519 and 536 cm^{-1} were selected for glucose and xylose analysis, respectively. In each panel, the top plot represents the amount of residuals left from the peak-fitting deconvolution, the middle panel depicts the raw spectra, and the bottom panel shows the peak deconvolution (Reprinted with permission from Shih et al. 2011)

intrinsic biomass fluorescence detrimental to spectra generated via spontaneous Raman scattering. SRS has been more successful for imaging cellulose as CARS suffers from photomultiplier limitations at the optimal acquisition parameters for cellulose detection (Zeng et al. 2012). Another benefit of SRS is the linear dependency of the signal on chemical concentration, like the signal generated using spontaneous Raman scattering. This means that the vibrational modes in a SRS spectrum can be defined using standard Raman peak assignments.

MIR spectroscopy, another nondestructive, noninvasive tool, provides complementary structural information to Raman spectroscopy due to the difference in the selection rules governing the criteria for obtaining MIR and Raman-active vibrational modes, as described above. A significant dissimilarity, however, is that in MIR spectroscopy, molecules are actually excited to higher energy levels, whereas in Raman spectroscopy, molecules are promoted to a short-lived "virtual" state, then quickly relax. Conjunctive use of both techniques can supply a more thorough qualitative structural analysis. Table 3 lists the main polysaccharide vibrational modes measured using MIR spectroscopy. The ratio of the vibrational modes at

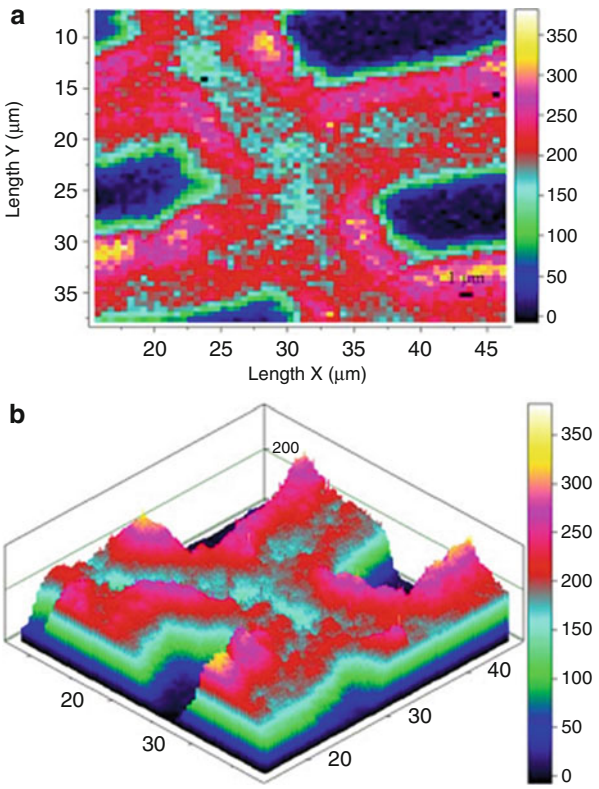

Fig. 4 False color two-dimensional (**a**) and three-dimensional (**b**) Raman images of cellulose distribution in the cell wall of *black* spruce. *Bright white* and/or *yellow* colors reveal cell wall areas high in cellulose, while *dark blue* and/or *black* regions show area very low in cellulose (Reprinted with permission from Agarwal 2006)

1,370 and 670 cm^{-1} enabled the estimation of cellulose I_α and I_β allomorphs in various biomass pulps (Akerholm et al. 2004). Specific bonds like hydrogen bonds in native cellulose or glycosidic linkages in polysaccharides have also been evaluated using MIR spectroscopy (Liang and Marchessault 1959; Nikonenko et al. 2000). For example, polysaccharides possessing 1→4 glycosidic bonds contain distinctive vibrational modes between 1,140 and 1,175 cm^{-1} (Nikonenko et al. 2000). In this same study, the authors presented a method for deconvoluting the spectra between 970 and 1,000 cm^{-1}, revealing multiple bands in the polysaccharides compared to one band when a correlative monomer was measured.

MIR spectroscopy has been extensively employed for evaluating polysaccharide structure and conformation, often subsequent to the chemical and/or physical pretreatment of the biomass (Liang and Marchessault 1959a, b; Mathlouthi and Koenig 1986; Kacurakova et al. 2000; Kacurakova and Wilson 2001; Moore and Owen 2001; Workman 2001; Cui 2005; Coimbra et al. 2010; Persson et al. 2011; Deutschmann and Dekker 2012; Reeves 2012; Lupoi et al. 2013; Xu et al. 2013). As mentioned above, ILs have been increasingly explored as environmentally friendly, deconstruction solvents capable of efficiently solubilizing cell wall constituents. The cellulose can be regenerated using an anti-solvent, such as water. Evaluations of cellulose before and after IL pretreatment of eucalyptus (Cetinkol et al. 2010)

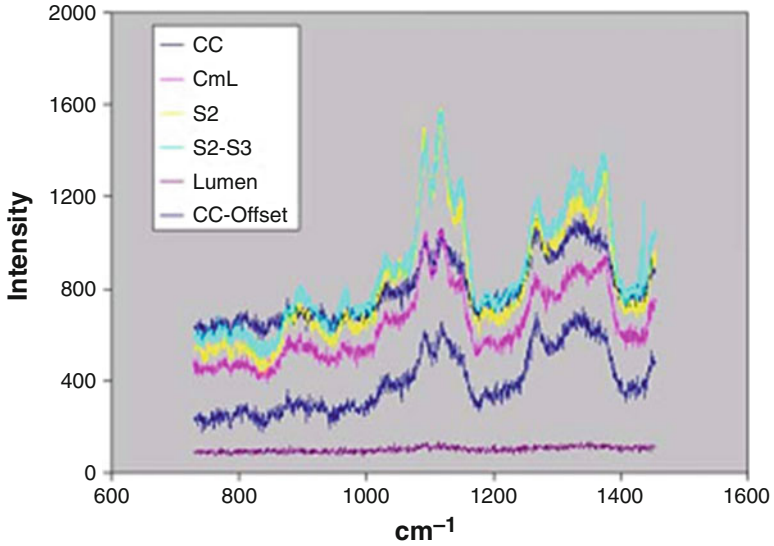

Fig. 5 Raman spectra acquired from various cell wall regions of *black* spruce. Spectrum CC offset (identical to CC) has been spatially offset to facilitate the spectral analysis. A higher cellulose concentration is indicated by more intense peaks at 1,098, 1,123, and 1,150 cm^{-1} (Reprinted with permission from Agarwal 2006)

and the ammonia fiber expansion pretreatment of corn stover (Li et al. 2011) using MIR spectroscopy have enabled researchers to determine if the native structure of cellulose is retained or is significantly altered after pretreatment. Figure 8 illustrates how IR spectroscopy enabled a comparison of *E. globulus* biomass before and after treatment with the IL 1-ethyl-3-methylimidazolium acetate [Cmim][OAc].

Specific bonds like hydrogen bonds in native cellulose or glycosidic linkages in polysaccharides have also been evaluated using MIR spectroscopy (Liang and Marchessault 1959; Nikonenko et al. 2000). For example, polysaccharides possessing 1→4 glycosidic bonds contain distinctive vibrational modes between 1,140 and 1,175 cm^{-1} (Nikonenko et al. 2000). In this same study, the authors presented a method for deconvoluting the spectra between 970 and 1,000 cm^{-1}, revealing multiple bands in the polysaccharides, juxtaposed to one band when a correlative monomer was measured.

In addition to the studies on cellulose, the structural evaluation of xylan has been explored using MIR spectroscopy (Kacurikova et al. 1998; Kacurakova et al. 2000; Kacurakova and Wilson 2001). Xylans reveal significant structural heterogeneity due to the diverse branching from the main polymeric chain. The spectra of β-(1→3)- and β-(1→4)-linked xylose groups show distinguishable signatures dependent on the degree of branching of the main chain and the type of substitutions. The analysis of complex mixtures of polysaccharides, including arabinoglucuronoxylan and galactoglucomannan or arabinogalactan and mannan, displayed at least one unique vibrational mode exclusive to each constituent (Kacurakova et al. 2000).

1.1.2 Fluorescence Imaging and Spectroscopy

When a molecule absorbs electromagnetic radiation from a light source, such as a lamp or laser, it can be excited to higher energy levels. The molecule will then relax back to a more stable energy state, often with a concomitant emission of radiation in the form of heat or light. When light is emitted, the phenomenon is termed fluorescence. Often, molecules that absorb light in the UV or higher-energy visible

region of the spectrum will emit strong, measurable fluorescence. Fluorescence instrumentation can provide 2–3 orders of magnitude more sensitive quantitation compared to UV/Vis spectrophotometry (Schmidt 2010; Lupoi et al. 2013). Fluorescence imaging and spectroscopy methods have been employed to study the interactions of cellulase enzymes with cellulose (Liu et al. 2009; Wang et al. 2010, 2012). Single molecule and fluorescence resonance energy transfer spectroscopy (SMS and FRET, respectively) are two such techniques that have provided a more fundamental understanding of how enzymes, or constituents of an enzyme, such as the carbohydrate-binding module, catalyze the hydrolysis of cellulose. FRET has often aided researchers in developing an understanding of the distance and interactions between two species, often an enzyme and its substrate (Wang et al. 2010). The FRET process occurs when a molecule labeled with a donor fluorophore transfers energy to a molecule labeled with an acceptor fluorophore, provided the two species are 10 nm or less apart. FRET can provide an in situ glimpse of the processivity of cellulase in real time (Wang et al. 2010). In this experiment, carboxymethylcellulose was labeled with the donor, while cellulase was labeled with the acceptor. In this fashion, real-time analyses of the enzyme kinetics can be studied, as well as the mechanisms of cellulase-cellulose interactions. Confocal fluorescence imaging has also been employed to localize cellulose in switchgrass and monitor changes in the structure of the cell wall during IL pretreatment (Singh et al. 2009b). Hydrogen bond disruption between cellulose fibrils was observed, followed by the subsequent dissolution of the entire cell wall. Figure 9 illustrates the use of confocal fluorescence imaging to monitor changes in corn stover stems and cell wall constituents before and during an IL pretreatment (Sun et al. 2013). The distortion and swelling of tracheids, parenchyma, and sclerenchyma fractions, with concomitant reductions in recalcitrance, can be visualized, illustrating the efficacy of ILs to deconstruct plant cell walls. Although cellulose itself does not fluoresce, fluorescence spectroscopy has been employed to identify molecules potentially causing fluorescence emission (Castellan et al. 2007). This phenomenon has been measured following the delignification of paper via chemical pulping and is hypothesized to result from the introduction of various fluorophores during the chemical processing of the biomass.

1.2 Nuclear Magnetic Resonance Spectroscopy

NMR has provided researchers with unparalleled structural information concerning lignocellulosic biomass (Atalla et al. 1980; Atalla and VanderHart 1999; Ferrier et al. 2002; Maunu 2002; Atalla and Isogai 2005; Cui 2005; Balakshin et al. 2008; Yelle et al. 2008; Persson et al. 2011; Yuan et al. 2011; Deutschmann and Dekker 2012; Foston and Ragauskas 2012; Foston et al. 2012; Li et al. 2012; Mazumder et al. 2012; Du et al. 2013; Lupoi et al. 2013; Miyagawa et al. 2013; Nieto and Jiménez-Barbero 2013; Du et al. 2014). In NMR, nuclei absorb radiation in the radio-wave region of the electromagnetic spectrum. Molecules are introduced to strong magnetic fields to split the electronic states, an essential occurrence, for the

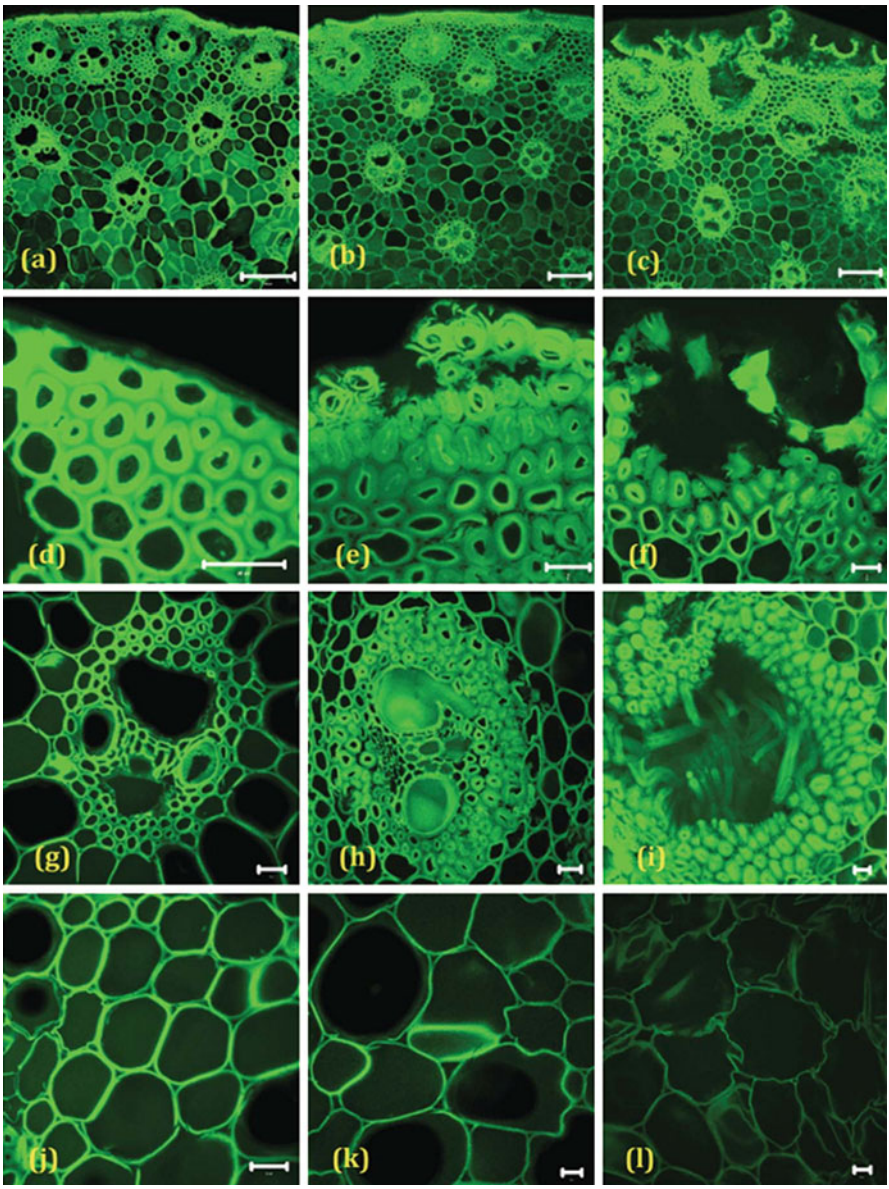

Fig. 9 Confocal fluorescence imaging of corn stover cell structures before and during pretreatment with an ionic liquid. Vertical columns indicate 0, 1, and 3 h of pretreatment, *left* to *right*. (**a**–**c**) Stem overview (100 μm scale bar), (**d**–**f**) sclerenchyma cells (20 μm scale bar), (**g**–**i**) tracheids (20 μm scale bar), and (**j**–**l**) parenchyma cells (20 μm scale bar) (Reprinted with permission from Sun et al. 2013)

absorption process to take place. NMR is a nondestructive, noninvasive technique, since low frequency of the excitation energy is not powerful enough to cause physical or chemical changes in the analyte. The dominant forms of NMR used for polysaccharide analysis include homonuclear techniques, such as proton (^{1}H), carbon-13 (^{13}C), and correlated spectroscopy (COSY), and heteronuclear methods like heteronuclear single quantum correlation (HSQC) 2D NMR. Homonuclear methods provide distinctive spectra for each polysaccharide studied but can often suffer from significant spectral overlap, especially when solely proton NMR is employed. For example, ^{1}H NMR provides a much more sensitive analysis, due to ubiquitous, naturally occurring proton abundance. The signals generated from the protons, however, are detected between 3 and 5 parts per million (ppm), resulting in overlapping peaks and necessitating a transition to 2D methods to resolve the signals (Cui 2005). Figures 10 and 11 show the assignments of key chemical shifts measured using ^{1}H and ^{13}C NMR, respectively. Although ^{13}C NMR does not have the strong signals present in proton NMR, the peaks correspondent to polysaccharides occur over a wider ppm range. Recent developments in both homonuclear (^{1}H-^{1}H) and heteronuclear (^{13}C-^{1}H) two-dimensional NMR spectroscopy have enhanced spectral sensitivity and resolution.

NMR studies can be performed on solubilized or solid biomass. Whole plant cell walls are predominantly insoluble in most customary NMR solvents, necessitating laborious extraction, isolation, and purification strategies. These techniques can potentially transform the chemical composition of the biomass, making their usage undesirable. Recent advances in sample preparation, involving the ball milling and subsequent swelling of the sample in perdeuterated dimethyl sulfoxide (DMSO-d_6), have provided an alternative method to preparing intact plant cell walls (Foston and Ragauskas 2012; Foston et al. 2012). Methods employing these preparatory steps have significantly improved the throughput of NMR experiments. ILs have also been employed as solvents, owing to the complete dissolution of biomass (Foston et al. 2012).

Solid-state NMR alleviates the need to develop efficient dissolution schemes by probing whole biomass. The analysis of cell wall pore size, ultrastructure, and the spatial orientation of the amorphous and crystalline cellulose, hemicellulose, and lignin fractions represent the diversity of solid-state NMR applications. Solid-state NMR has also been used for studying cellulose polymorphs. In fact, it was ^{13}C NMR that made the spectral resolution of cellulose I_α and I_β crystalline forms possible, as can be seen in Fig. 12 (Atalla et al. 1980; Harris et al. 2010). Figure 13 illustrates key spectral differences between crystalline and amorphous celluloses, using ^{13}C cross-polarization magic angle spinning (CP/MAS) NMR (Atalla et al. 1980). In Fig. 14, ^{13}C CP/MAS NMR spectra of pine, *Miscanthus*, and red clover are shown, along with the relative carbon abundance for each chemical shift. This technique can enable the semi-quantitation of specific analytes in biomass when compared against other species; in this example, however, the NMR spectra were used in conjunction with Raman spectroscopy to probe the sources of

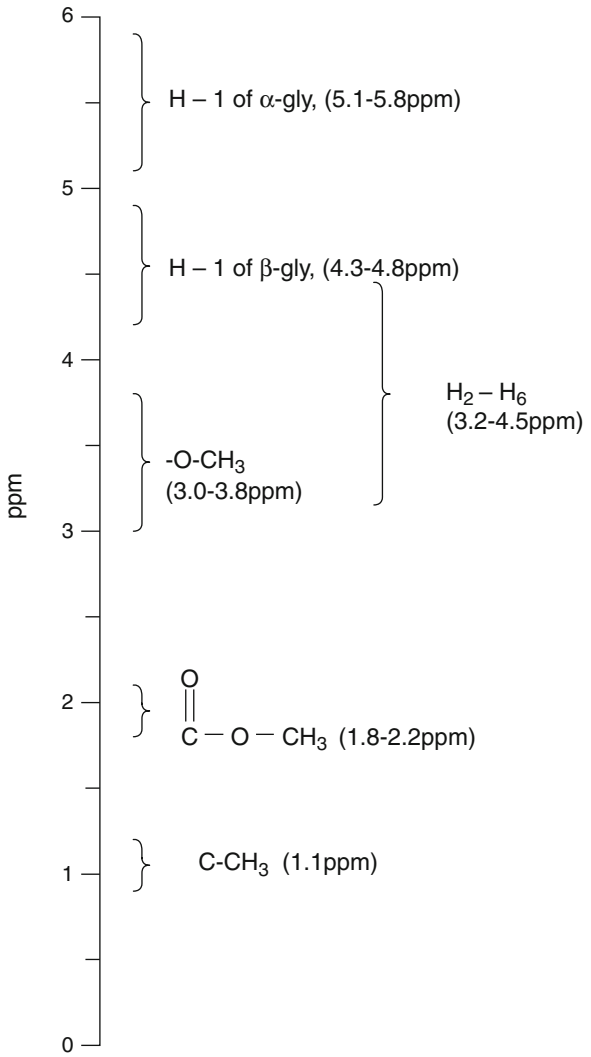

Fig. 10 Key chemical shifts measured using ^{1}H NMR (Reprinted with permission from Springer, from Cui 2005)

anomalous vibrational modes and provide an illustration of the employment of multiple analytical tools to elucidate structural information. Extractives in the herbaceous feedstocks were found to produce the inconsistent spectral peaks, thereby necessitating their removal via a Soxhlet extraction.

HSQC 2D NMR has been one of the most prevalently used techniques to evaluate the structure of lignocellulosic biomass. While many of the studies have focused on the evaluation of lignin, various applications have probed polysaccharides. The linkages responsible for the formation of lignin-carbohydrate complexes (LCCs) have been elucidated using a combination of ^{13}C NMR and HSQC 2D NMR (Balakshin et al. 2008; Yuan et al. 2011; Du et al. 2013). The cognition of

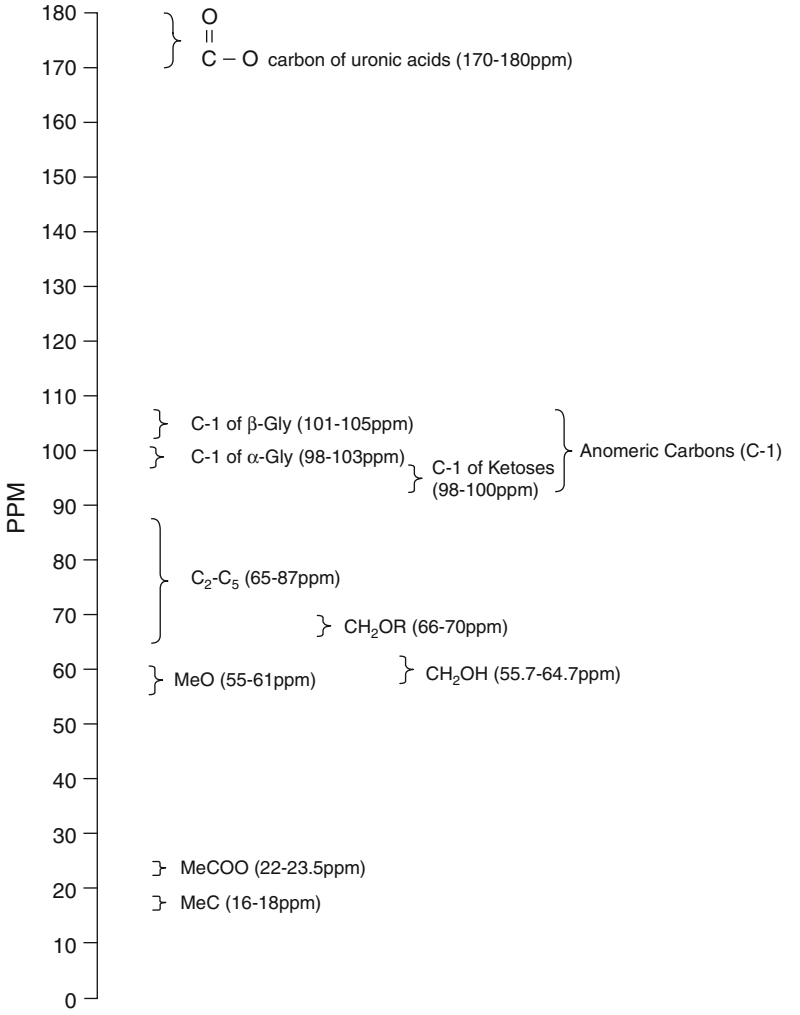

Fig. 11 Key chemical shifts measured using ^{13}C NMR (Reprinted with permission from Springer, from Cui 2005)

how the cell wall constituents are chemically interlaced is paramount for the development of key fractionation strategies for the isolation of each respective portion. For example, acetylated 4-*O*-methylgluconoxylan has been found to be intimately associated with lignin in ball-milled poplar wood (Yuan et al. 2011). β-*O*-4′ aryl ether, resinol, phenylcoumaran, phenyl glycoside, and benzyl ether linkages have all been quantified using ^{13}C NMR. Various studies have developed fractionation protocols to isolate glucan-lignin, glucomannan lignin, and xylan-lignin complexes to evaluate the specific linkages responsible for developing the intricate cell wall LCC networks (Miyagawa et al. 2013; Du et al. 2014).

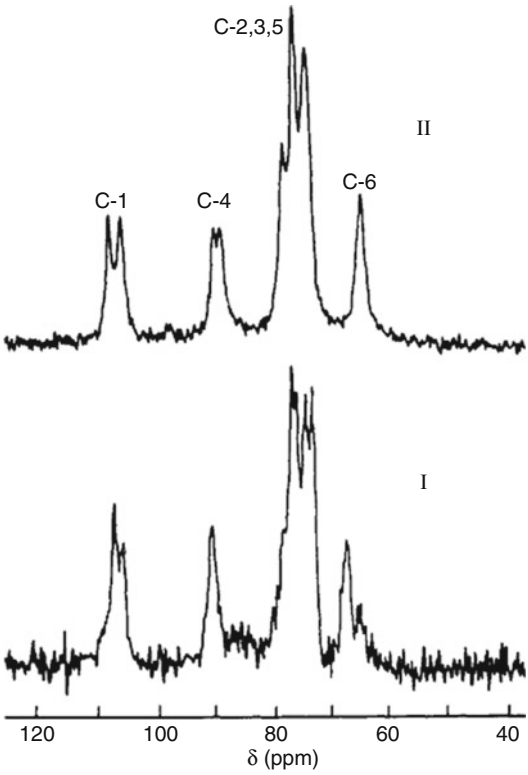

Fig. 12 CP/MAS ^{13}C NMR spectra of crystalline cellulose forms I (*bottom*) and II (*top*) (Reprinted with permission from Atalla et al. 1980)

HSQC 2D NMR has also been used to analyze biomass swelled using DMSO-d_6, permitting the analysis of intact cell walls (Hedenstroem et al. 2009; Rencoret et al. 2009). A combined IL/DMSO-d_6 solvent system coupled with HSQC 2D NMR has been found to appreciably decrease analysis time while simultaneously providing higher spectral resolution (Yelle et al. 2008). The spectral resolving power of HSQC 2D NMR has been conjoined with multivariate analysis (MVA) providing a formidable method for assessing changes in polysaccharide structure and composition between different feedstocks (Figs. 15, 16, and 17) (Hedenstroem et al. 2009). The evaluation of 2D spectral loadings plots in principal component analysis (PCA) can facilitate the nomination of important spectral regions without requiring researchers to rummage spectral regions containing significant overlapping peaks. Figure 15 depicts a typical 2D ^{13}C-^{1}H NMR HSQC spectrum illustrating the main polysaccharide constituents in aspen trees. Figure 16 demonstrates the PCA technique employed by the authors for reducing noise in the 2D NMR spectra and concomitantly elucidating key spectral features in the loadings plot. This method was applied to assess chemical differences between normal and tension aspen wood samples, as shown in Fig. 17. The cell wall constituents in lower or higher concentration in the two wood types could be determined using this

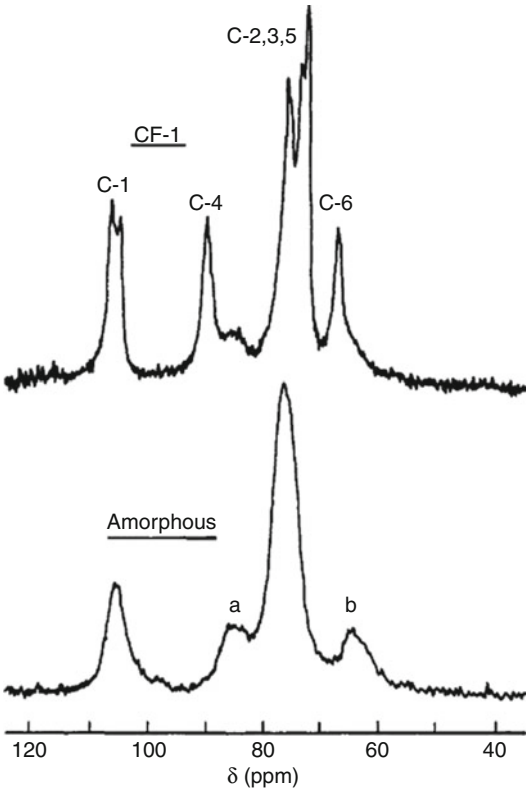

Fig. 13 CP/MAS ^{13}C NMR spectra of native (*top*) and amorphous cellulose (*bottom*) (Reprinted with permission from the American Chemical Society, from Atalla et al. 1980)

MVA technique, whereas traditional spectral analysis required the rummaging of overlapping peaks to expose key compositional differences.

2 Cellulose Crystallinity

Crystalline cellulose has been hypothesized as exhibiting greater recalcitrance to the enzymatic deconstruction of biomass when compared to the amorphous regions, although some studies have been inconclusive (Zhang and Lynd 2004; Hall et al. 2010). Therefore, knowledge of the cellulose crystallinity index (CrI) may assist researchers in developing more efficient degradative strategies. CrI measurements, however, have led to widely varying results. Although XRD remains one of the more prevalently employed analytical techniques for probing cellulose crystallinity (Segal et al. 1959; Thygesen et al. 2005; Beecher et al. 2009; Agarwal et al. 2010; Harris et al. 2010; Park et al. 2010; Foston and Ragauskas 2012; Agarwal et al. 2013; Kim et al. 2013), recent advances in vibrational spectroscopy and NMR have provided supplemental tools for measuring CrIs (Schenzel et al. 2005; Beecher et al. 2009; Agarwal et al. 2010, 2013; Harris et al. 2010; Park et al. 2010; Foston and Ragauskas 2012; Kim et al. 2013; Lupoi et al. 2013; Xu et al. 2013).

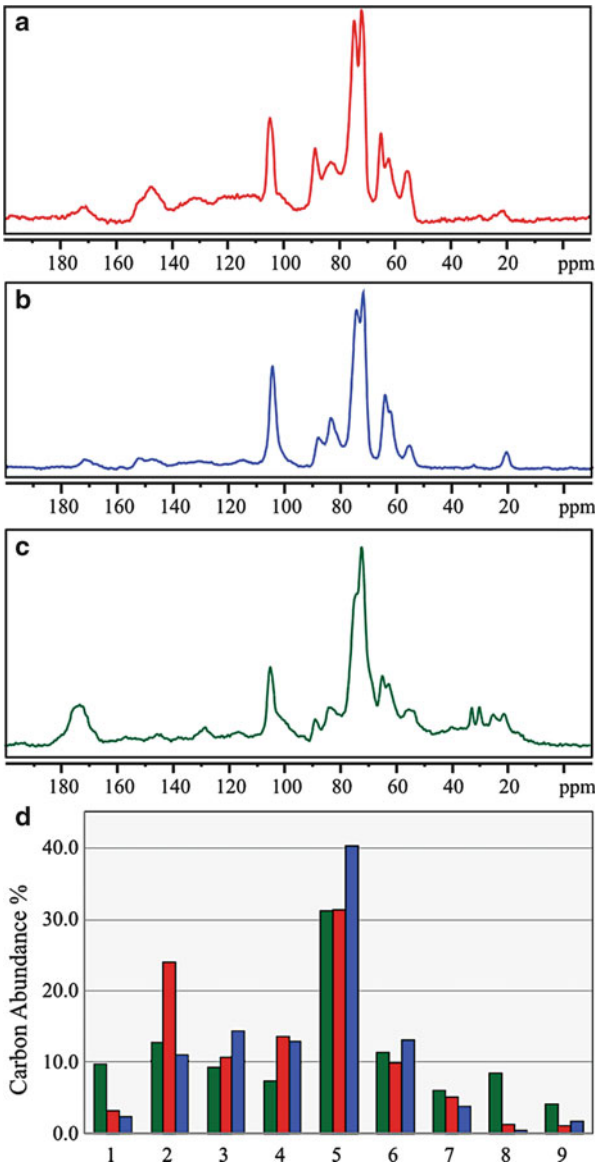

Fig. 14 ^{13}C NMR CP/MAS spectra of pine (**a**), *miscanthus* (**b**), and *red* clover (**c**). (**d**) The relative carbon abundance calculated from the integration ranges listed below. Relative intensities were found by dividing the individual integrated peak height by the total carbon intensity (sum of individual intensities). The integration ranges used and assignments were as follows (in ppm): *1* 180–163, carboxylate carbon in hemicellulose; *2* 158–110, phenyl carbon in lignin; *3* 109.8–100, carbon 1 in cellulose; *4* 92–80.5, carbon 4 in cellulose; *5* 80–68.4, carbons 2, 3, and 5 in cellulose; *6* 68–60.1, carbon 6 in cellulose; *7* 59–52, methoxy carbon in lignin, hemicellulose; *8* 42–27.5, aliphatic C–H; and *9* 24.1–18, methyl in hemicellulose (Reprinted with permission from Lupoi and Smith 2012)

2.1 Vibrational Spectroscopy

Techniques for measuring the CrI of cellulose using Raman spectroscopy have recently been developed (Schenzel et al. 2005; Agarwal et al. 2010, 2013; Kim et al. 2013). The ratio of the 380 and 1,096 cm^{-1} vibrational modes has been nominated for gauging the degree of cellulose crystallinity (Agarwal et al. 2010, 2013). Univariate and multivariate methods have been developed, both revealing

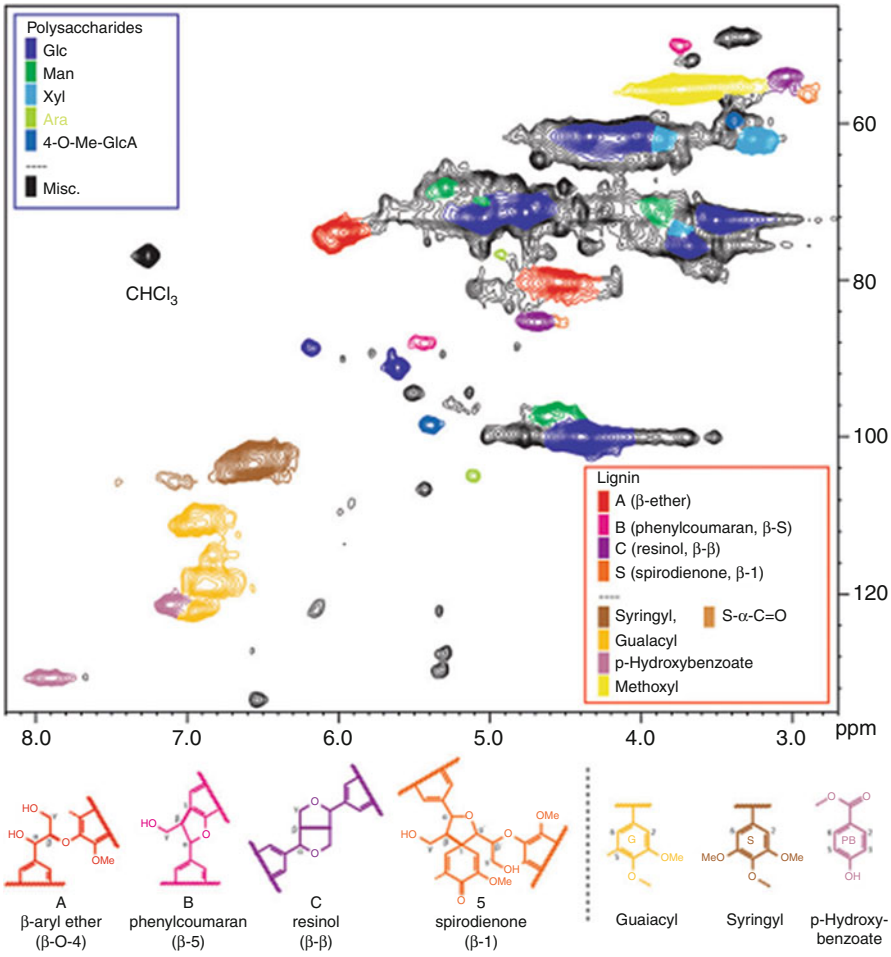

Fig. 15 2D ^{13}C-^{1}H HSQC spectrum of dissolved acetylated cell wall from poplar. Proton NMR chemical shifts are on the x-axis, while carbon NMR is on the y-axis. Spectral assignments are based upon the analysis of standard compounds and reported assignments from the literature. The polysaccharide abbreviations correspond to the following analytes: Glc, glucosyl; Man, mannosyl; Xyl, xylosyl; Ara, arabinosyl; and 4-OMe-GlcA, 4-*O*-methyl glucuronic acid (Reprinted with permission from Hedenström et al. 2009)

strong regression linearity. Another study determined the 1,481 and 1,462 cm^{-1} vibrational modes, assigned to crystalline and amorphous celluloses, respectively, providing a good measure of the CrI of cellulose I (Schenzel et al. 2005). These Raman techniques were optimized using pure cellulose samples, such as filter paper and Avicel. The measurement of the CrI of cellulose in biomass cell walls using vibrational spectroscopy can be complicated by overlapping peaks from hemicellulose, lignin, or other constituents. Thus, it becomes crucial to identify regions of the spectra that can be solely attributable to cellulosic vibrational modes.

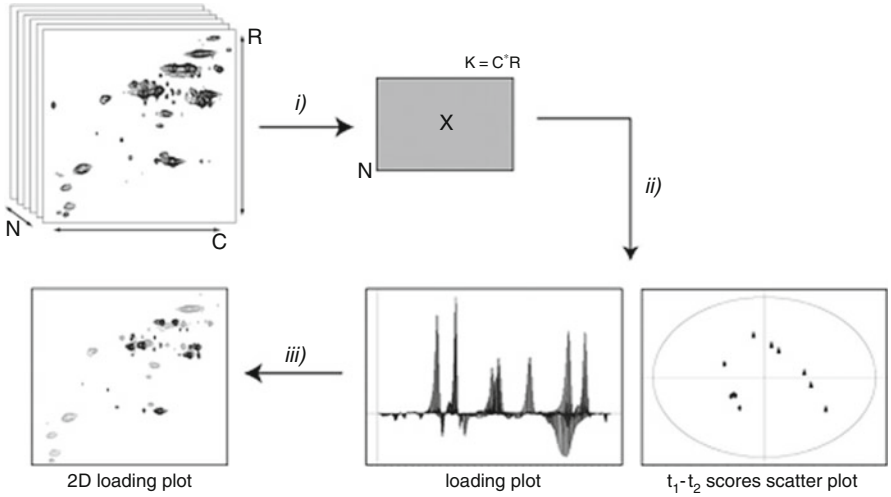

Fig. 16 This figure demonstrates how PCA can be used in conjunction with 2D NMR spectra. (**a**) 2D NMR spectra are converted to row vectors and inserted into data matrix X. Noisy spectral features were eliminated. (**b**) Scores and loadings plots are generated from the MVA analysis of the spectral data. This allows the elucidation of key latent structures with the spectra. (**c**) Loadings plots are unfolded back into 2D NMR spectra by reversing the order outlined in (**a**) (Reprinted with permission from Hedenström et al. 2009)

MIR spectroscopy has also been used to assess cellulose crystallinity (O'Connor et al. 1958; Akerholm et al. 2004; Siroky et al. 2010; Kljun et al. 2011; Xu et al. 2013). As with the Raman CrI measurements, MIR methods have entailed calculating the ratio of specific vibrational modes, such as 1,430 and 893 cm^{-1} to evaluate the lateral order index, which is proportional to crystallinity (O'Connor et al. 1958; Akerholm et al. 2004; Siroky et al. 2010; Kljun et al. 2011). The hydrogen bond index has also been used to indirectly measure cellulose crystallinity using the ratio of the 3,336 and 1,336 cm^{-1} modes (Siroky et al. 2010; Kljun et al. 2011). When juxtaposed to standard methods such as NMR, the MIR results have revealed good correlation.

2.2 Nuclear Magnetic Resonance

NMR has been a standard spectroscopic tool used for measuring the degree of cellulose crystallinity, as amorphous and crystalline celluloses produce different chemical shifts (Beecher et al. 2009; Foston and Ragauskas 2010, 2012; Park et al. 2010; Cao et al. 2012; Kim et al. 2013; Lupoi et al. 2013). The analysis of the C4 carbon has provided a direct way to evaluate crystallinity, as amorphous regions produce a broad peak between 80 and 85 ppm, while crystalline celluloses exhibit sharper peaks between 85 and 92 ppm (Beecher et al. 2009; Park et al. 2010; Foston and Ragauskas 2012). Figure 18 illustrates the use of ^{13}C CP/MAS NMR to quantify

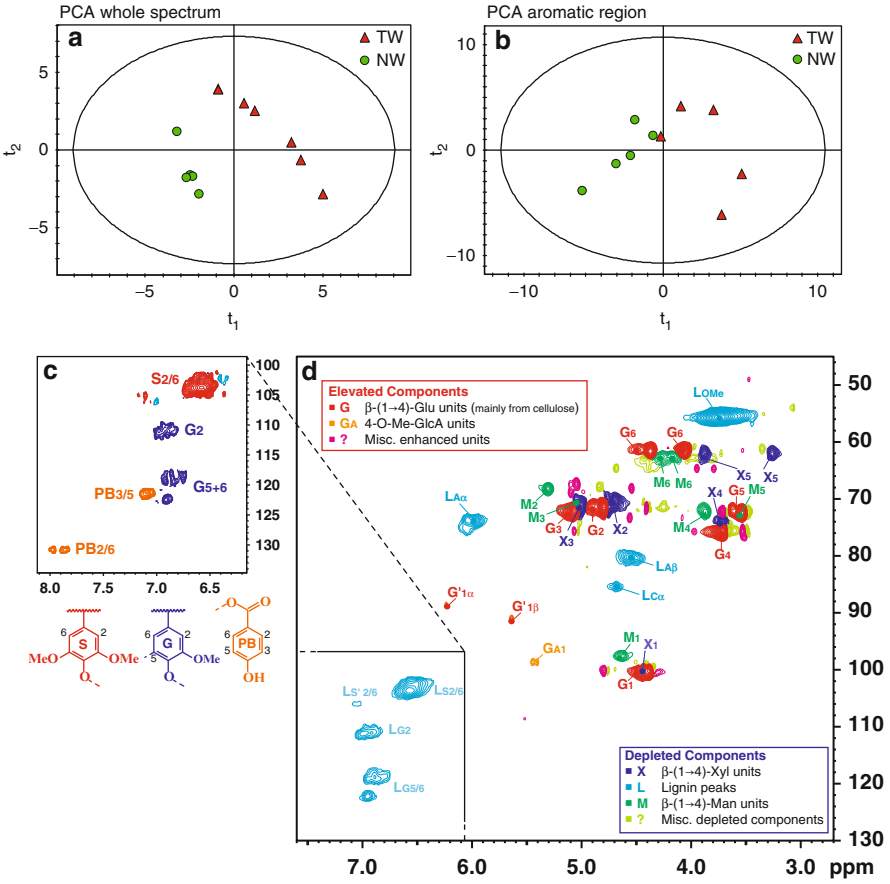

Fig. 17 PCA comparison of normal wood to tension wood. (**a**) PCA scores plot evaluating normal and tension wood using whole NMR spectra. (**b**) PCA scores plot evaluating normal and tension wood using only the aromatic region of the NMR spectra. (**c**) 2D NMR loadings plot explaining the variance along the first principal component in (**b**). S and PB lignin units are increased, while G lignin units are relatively decreased. (**d**) 2D NMR loadings plot derived from the PCA model in (**a**). *Red* and *orange* resonances depict the cell wall constituents in higher concentration in tension wood compared to normal wood. Those colored blue and green correspond to cellular components in higher concentration in normal wood. G′1α and G′1β refer to α- and β-conformations of the glucosyl anomeric units at the cellulose reducing end (Reprinted with permission from Hedenström et al. 2009)

the CrI of Avicel PH-101 (Park et al. 2010). The CrI can be calculated by deconvoluting the C4 signal into its two representative peaks. In Fig. 18, the crystalline cellulose region is labeled as x, while the amorphous fraction is labeled as y. The CrI can be found using the equation x/(x+y). The use of NMR has enabled researchers to evaluate cellulose structural changes resultant from various pretreatment strategies. For example, the changes in the degree of cellulose crystallinity following the dilute

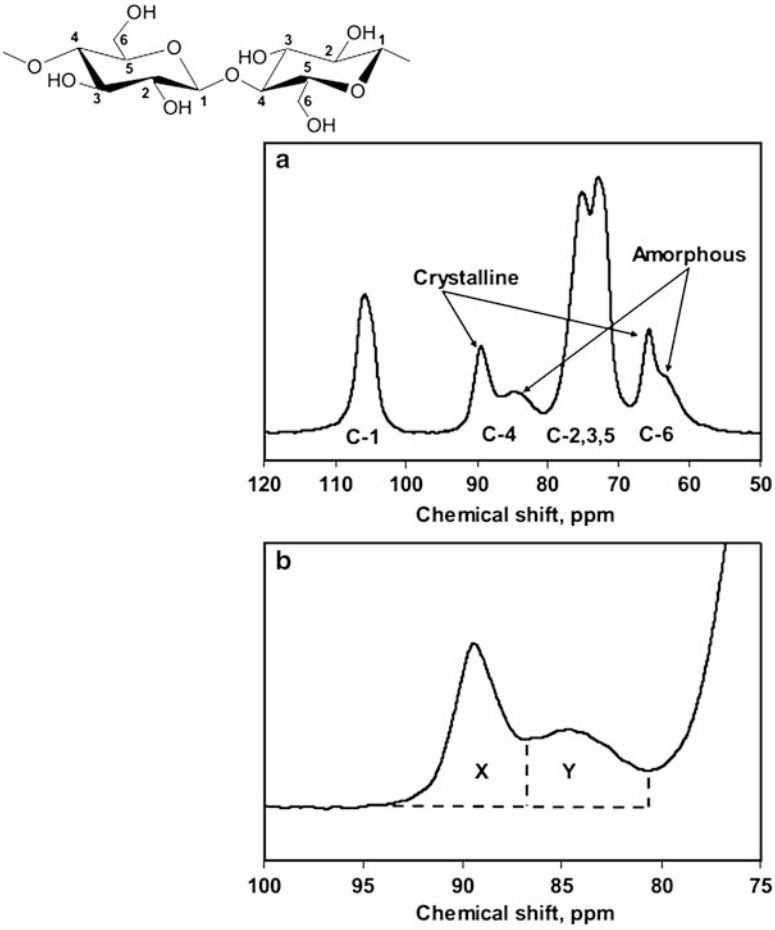

Fig. 18 ^{13}C NMR CP/MAS spectra of Avicel PH-101 used for calculating the cellulose crystallinity index (*CrI*). (**a**) Whole spectrum with the respective carbon peaks assigned using the glucopyranose unit. (**b**) C4 cellulose peak deconvolution elucidating the two peaks used for calculating the CrI (CrI = x/(x + y)) (Reprinted with permission from Park et al. 2010)

sulfuric acid pretreatment of poplar using shorter pretreatment durations proved to be insignificant, while at longer pretreatment times, a slow crystallization of amorphous cellulose was discovered (Foston and Ragauskas 2010; Cao et al. 2012).

3 Total Carbohydrates

Customary techniques for quantifying the total amount of carbohydrates in plant cell walls utilize wet chemical reactions such as the anthrone-sulfuric acid, phenol-sulfuric acid, trifluoroacetic acid (TFA), and the Van Soest methods (Van Soest 1963;

Van Soest and Wine 1968; Fengel and Wegener 1979; Brummer and Cui 2005; Masuko et al. 2005). Total carbohydrate measurements do not distinguish between the various types of sugars in the matrix, but rather provide an estimated quantity based upon the calibration curve of a reference analyte using UV/Vis spectrophotometry (Masuko et al. 2005; Foster et al. 2010). Fluorescence spectroscopy, although not prevalently used for the quantitation of biomass chemical composition, has been recently applied to red oak and yellow poplar woods exhibiting limited success when juxtaposed to NIR methodology (Nkansah and Dawson-Andoh 2010a, b).

Vibrational spectroscopy assessments of total carbohydrates have enabled the prediction of total carbohydrates using two approaches: total holocellulose (cellulose + hemicellulose) content or by quantifying all of the individual sugar producing polymers including glucan, xylan, galactan, mannan, and arabinan (see also Sect. 3.1). FT-Raman spectroscopy coupled with partial least squares (PLS) facilitated the prediction of raw and extractive-free holocellulose content in various eucalypts (Ona et al. 1997, 2003). MIR spectroscopy has also been evaluated for forecasting the total carbohydrate content in *Pinus radiata* using PLS and LC reference data (Meder et al. 1999). These two methods, however, have not been employed as frequently as NIR spectroscopy (Hames et al. 2003; Kelley et al. 2004; Ye et al. 2008; Templeton et al. 2009; Wolfrum and Sluiter 2009; Liu et al. 2010; Nkansah and Dawson-Andoh 2010a, b; Hou and Li 2011). While the analysis of the total carbohydrates using holocellulose may provide a fast way to screen through plant materials for the fermentable sugar content, partitioning the total carbohydrate content into its representative constituents can provide a better survey of potential biofuel feedstocks, as the different polysaccharides require specific enzymes for conversion to monomeric sugars and distinctive microorganisms for subsequent fermentation.

3.1 Cellulose and Noncellulosic Polysaccharide Content

Wet chemical and chromatographic protocols used for the determination of cellulose and noncellulosic polysaccharide content include the Updegraff (1969) (Van Soest and Wine 1968; Van Soest et al. 1991) methods, the two-step acid hydrolysis coupled with HPLC (Cui 2005; Hames 2009; Sluiter Justin et al. 2010), HP anion exchange liquid chromatography (Hausalo 1995; Rohrer 2003; Willfoer et al. 2009; Deutschmann and Dekker 2012), and quantitative GC analysis (Collings and Yokoyama 1979; Willfoer et al. 2009; Deutschmann and Dekker 2012; Sarossy et al. 2012). Although these standard techniques have been ubiquitously employed, they can require stringent reactants and time-consuming sample preparation steps, may destroy the sample, and can entail complex data processing. These limitations necessitate higher-throughput, nondestructive analytical methods, especially for screening large arrays of potential feedstocks to isolate those possessing the ideal phenotypic traits for biofuel and bio-based chemical production. Advances in vibrational spectroscopy have provided researchers with the tools to rapidly assess biomass for polysaccharide content (Lupoi et al. 2013). The coupling of vibrational

spectroscopy with MVA is one approach enabling researchers to diminish the experimental time and expense associated with the traditional protocols. To achieve this, a reference method is used to quantify analytes for a subset of samples, while the spectral data is obtained for all of the samples. The two data sets are correlated in MVA software, enabling a variety of chemometric assessments such as PCA for the classification of the analytes based on sample similarity or PLS regression for quantifying the variables of interest. PLS calibration models are constructed from the reference and spectral data. After the aggressive evaluation of models using validation data sets, where predicted and reference values are compared, the parameter(s) quantified using the reference method can be predicted in the unknown samples. This procedure has facilitated the screening of large pools of plant species for traits such as cellulose and hemicellulose content.

3.1.1 Vibrational Spectroscopy

The combination of vibrational spectroscopy and reference analytical techniques has been used to predict cellulose and hemicellulose content in a diverse assortment of biomass (Ona et al. 1997, 1998, 2003; Hames et al. 2003; Kelley et al. 2004; Poke and Raymond 2006; Ye et al. 2008; Hames 2009; Templeton et al. 2009; Wolfrum and Sluiter 2009; Liu et al. 2010; Tyson et al. 2010; Deutschmann and Dekker 2012; Reeves 2012; Lupoi et al. 2013; Xu et al. 2013). By far, the instrumental workhouse of these tools has been NIR spectroscopy. The spectra in NIR spectroscopy result from the measurement of C-H, N-H, O-H, and S-H bonds that stem from combination and overtone modes of the fundamental vibrations probed in MIR spectroscopy (Workman 1996; Workman et al. 2007). Table 4 lists the main NIR vibrational modes correlative to polysaccharides. Figure 19a depicts a typical NIR spectrum obtained for the measurement of biomass. The effect of differences in particle sizes is illustrated. Although NIR spectra reveal considerable similarity, with relatively broad peaks due to multiple bond vibrations, the coupling of NIR with MVA has led to a diverse assortment of applications regarding the HTP prediction of biomass phenotypes, like cellulose and hemicellulose content. NIR instrumentation provides a cost-efficient, robust tool that has field-portable capabilities. Many of the NIR methods for predicting cellulose and hemicellulose content combine the two-step sulfuric acid hydrolysis with processed NIR spectral data. The spectral processing usually involves the transformation of the spectra into their respective first or second derivative (Fig. 19b, c, respectively) and the application of methods such as standard normal variate (SNV) or multiplicative scatter correction to remove physical disparities, like particle size or path length variation, from the data, thereby honing in on chemical differences. Figure 20 demonstrates the spectral processing of NIR spectral data to diminish spectral contributions from nonchemical features. The raw spectra of *Acacia microbotrya*, a *Corymbia* hybrid, and *E. globulus* are depicted in the top panel. In this example, a second derivative, followed by an SNV transformation, was employed to isolate chemical differences (middle and bottom panels, respectively). Models constructed from NIR spectra have provided robust predictions of polysaccharide content in a diverse array of lignocellulosic feedstocks including corn stover, switchgrass, and eucalypts.

Table 4 Characteristic NIR vibrational modes of polysaccharides

Approximate peak location	Polysaccharide	Primary assignment
3,970–3,990	Cellulose	CO, CH, and CH_2 stretch (Bassett et al. 1963)
4,019	Cellulose	CH and CC stretch (Shenk et al. 2008)
4,063	Cellulose	CH and CC stretch (Osborne et al. 1993)
4,235	Cellulose	OH or CH deformation, CH or CH_2 stretch (Bassett et al. 1963)
4,252	Cellulose	CH stretch and deformation, 2nd overtone CH_2 bend (Shenk et al. 2008)
4,268	Cellulose	CH stretch and deformation and/or 2nd overtone CH deformation (Ali et al. 2001)
4,277	Cellulose	CH stretch and CH_2 deformation (Shenk et al. 2008)
4,281–4,283	Cellulose, hemicellulose	CH stretch and deformation (Tsuchikawa et al. 2005; Shenk et al. 2008)
4,288–4,296	Hemicellulose	CH stretch and deformation (Yonenobu and Tsuchikawa 2003)
4,365	Cellulose	CO and OH stretch, CH_2 bend and stretch (Bassett et al. 1963)
4,392	Cellulose	OH and CC stretch, CH stretch and deformation (Ali et al. 2001)
4,401	Hemicellulose	CH stretch and deformation (Osborne and Fearn 1986)
4,404	Cellulose, hemicellulose	CH stretch and deformation (Tsuchikawa et al. 2005)
4,405	Cellulose	CO and OH stretch (Shenk et al. 2008)
4,591, 4,608	Cellulose, hemicellulose	Not assigned (Schwanninger et al. 2011)
4,686	Hemicellulose	CH and C=O stretch (Schwanninger et al. 2011)
4,739	Cellulose	OH deformation and stretch (Ellis and Bath 1940)
4,760–4,780	Cellulose	OH deformation and stretch, CH deformation (Bassett et al. 1963)
4,795	Cellulose, hemicellulose	OH deformation and stretch, CH deformation (Bassett et al. 1963)
4,808	Cellulose	OH stretch, CH deformation (Osborne and Fearn 1986)
5,236, 5,245	Hemicellulose	2nd overtone CH stretch (Workman et al. 2007)
5,464	Cellulose	OH stretch and 2nd overtone CO stretch (Osborne and Fearn 1986; Fujimoto et al. 2007)
5,495	Cellulose	OH stretch and 2nd overtone CO stretch (Osborne et al. 1993; Workman et al. 2007)
5,577	Cellulose	1st overtone CH stretch (Ali et al. 2001)
5,587, 5,593	Cellulose	1st overtone CH stretch (Osborne and Fearn 1986)
5,618	Cellulose	1st overtone CH_2 stretch (Workman et al. 2007; Shenk et al. 2008)
5,776	Cellulose	1st overtone CH stretch (Barton and Himmelsbach 1993)

(*continued*)

Table 4 (continued)

Approximate peak location	Polysaccharide	Primary assignment
5,800	Hemicellulose	1st overtone CH stretch (Osborne and Fearn 1986; Fujimoto et al. 2007)
5,814, 5,816	Cellulose, hemicellulose, lignin	1st overtone CH stretch (Michell and Schimleck 1996; Schwanninger et al. 2011)
5,848	Hemicellulose	1st overtone CH stretch (Michell and Schimleck 1996; Yonenobu and Tsuchikawa 2003)
5,865	Hemicellulose	1st overtone CH stretch (Wust and Rudzik 1996)
5,872	Cellulose	1st overtone CH stretch (Ali et al. 2001)
5,950	Hemicellulose	1st overtone CH stretch (Wust and Rudzik 1996)

7,300	Hemicellulose	1st overtone CH stretch, CH deformation (Schwanninger et al. 2011)
7,315–7,321	Cellulose	1st overtone CH stretch, CH deformation (Ali et al. 2001)
7,400, 7,410	Hemicellulose, lignin	1st overtone CH stretch, CH deformation (Schwanninger et al. 2011)
8,160–8,250	Cellulose	2nd overtone CH stretch (Michell and Schimleck 1996)
8,450, 8,525, 8,540, 8,654	Hemicellulose	2nd overtone CH stretch (Wust and Rudzik 1996; Shenk et al. 2008)

Raman spectroscopy, although not utilized to the extent of NIR spectroscopy, has enabled the development of MVA predictive models for assessing polysaccharide content (Ona et al. 1997, 1998, 2003; Lupoi et al. 2013). The lack of abundant studies employing Raman spectroscopy could be due to higher instrumentation costs compared to NIR spectroscopy. One of the main spectroscopic instrumental challenges is obtaining high signal-to-noise (S/N) spectra. In NIR and MIR spectroscopy, this can be achievable by increasing the number of scans the instrument acquires, which reduces random noise in the spectra. Raman spectroscopy can have the added advantage of tunable excitation lasers. By increasing the laser power, spectral signals intensify, further elucidating subtle spectral differences between samples. The noise can be simultaneously diminished by acquiring more scans, thereby providing a two-pronged approach to increase S/N. Figure 21 illustrates the spectral processing of FT-Raman spectra for the development of predictive PLS models. Juxtaposed to the NIR spectra in Fig. 20, the Raman spectral data of the same feedstocks contains significantly more spectral information and a greater amount of spectral variance. MVA models flourish from the variance remaining once the average spectrum has been calculated and subtracted from all spectra, a process called mean centering. More diverse spectra should exhibit better partitioning between the samples, resulting in more accurate predictive models. Ona et al. have been one of the leading teams in applying FT-Raman spectroscopy and PLS to evaluate *Eucalyptus* for cellulose and hemicellulose content, as well as the monomeric sugars comprising hemicellulosic fractions (Ona et al. 1997, 1998, 2003). Although there have been recent advances in NIR, dispersive Raman instrumentation (Meyer et al. 2011), this arena remains relatively untapped for the development of MVA models.

Although typically used for biomass structural analysis, MIR spectroscopy has also been employed for the development of MVA predictive models for assessing

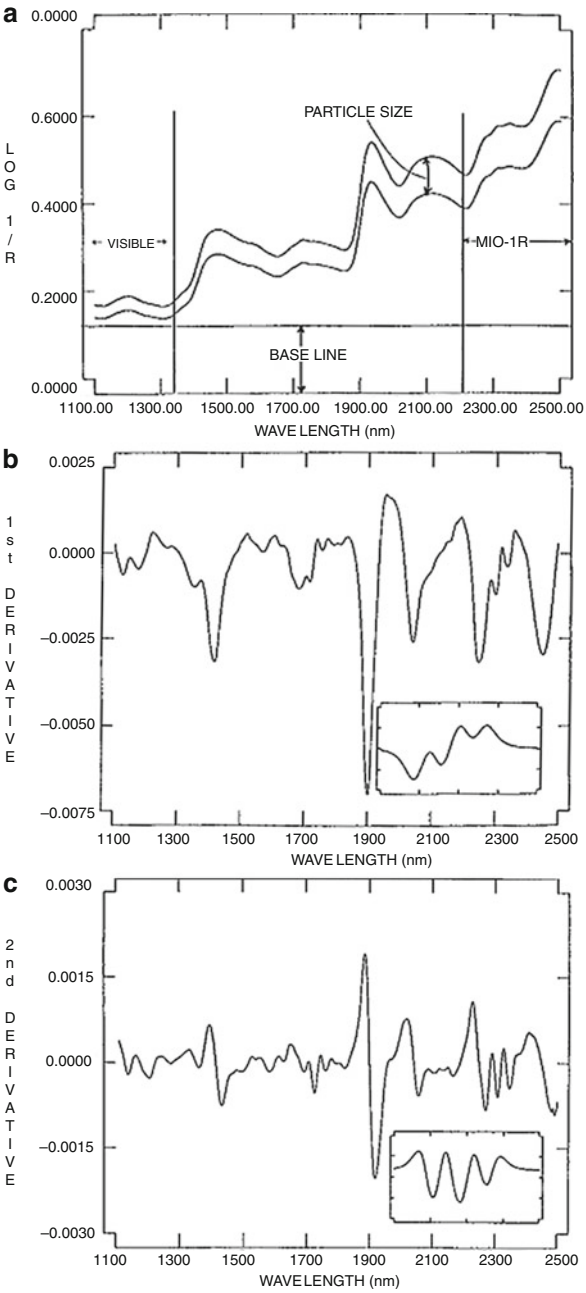

Fig. 19 (**a**) Demonstrative NIR spectral features from lignocellulosic biomass. (**b**) First-derivative spectrum of a forage product. (**c**) Second-derivative spectrum of a forage product (Reprinted with permission from Shenk et al. 2008)

polysaccharide content (Bjarnestad and Dahlman 2002; Jones et al. 2002; Reeves 2012; Lupoi et al. 2013). Since fundamental vibrational modes are being excited to higher energy levels in MIR spectroscopy, the spectral peaks are much more intense compared to those obtained in NIR spectroscopy. As described above for Raman

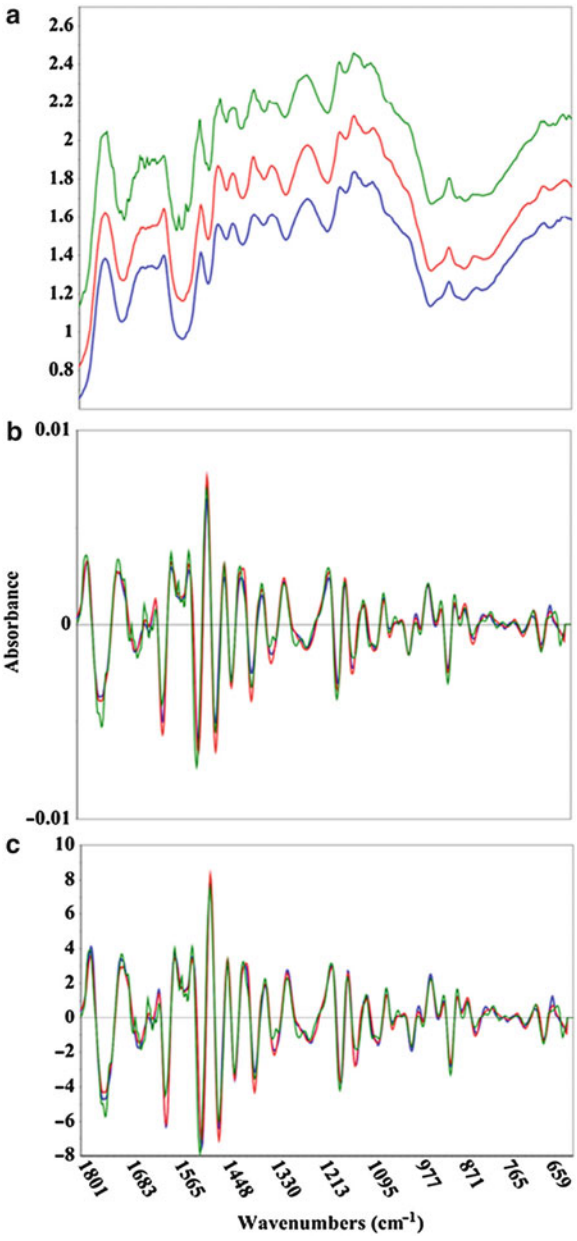

Fig. 22 Mid-infrared spectra of *Acacia microbotrya* (*green*), *Corymbia* hybrid (*blue*), and *Eucalyptus globulus* subspecies *maidenii* (*red*). The *upper panel* (**a**) shows the untreated spectral data, while the *middle* (**b**) and *bottom* (**c**) *panels* show the second-derivative and second-derivative + standard normal variate (SNV) spectral transformations, respectively. spectroscopy, MIR spectra are more diverse when contrasting different samples, presenting another option for the development of robust MVA models (Fig. 22). While MIR spectroscopy has been occasionally used for predicting the chemical composition of different feedstocks in a static environment, Jones et al. illustrated the viability of online thermal emission MIR spectroscopy to predict glucan and

hemicellulose in a moving process stream containing samples of 96 hard- and softwood chips (Jones et al. 2002). The ratio of the vibrational modes at 1,510 (lignin) and 900 cm^{-1} (cellulose) has been used to estimate the relative lignin-to-cellulose content of plant cell walls following different pretreatment strategies, such as dilute sulfuric acid and IL (Li et al. 2010, 2011). Variations of MIR spectroscopy, such as diffuse reflectance infrared Fourier transform (DRIFT) or photoacoustic FTIR spectroscopy, have also exhibited viability for the analysis of biomass (Meder et al. 1999; Bjarnestad and Dahlman 2002). These techniques, used for solid analyte analysis, require little to no sample preparation, can probe larger sample areas, and are not sensitive to sample morphology, significantly increasing the analytical throughput.

When endeavoring to construct robust MVA models based on vibrational spectroscopy, the methodical analysis of the regression coefficients used to build the model is essential. Regression coefficient plots illuminate which wavenumber locations have been critical in designing the model. These vibrational modes should correspond to the representative peaks established for the analyte of interest. Analyzing these plots is more straightforward when employing MIR or Raman spectra, since there are more discrete vibrational modes representative of the plant cell wall constituents. Although cellulose, hemicellulose, and lignin, for example, have common vibrational modes, leading to peak overlap in that portion of the spectrum, there are often specific peaks indicative of a sole analyte. This can be illustrated when comparing the spectra of microcrystalline cellulose to that of isolated lignin (see Fig. 1). The main peaks from lignin occur near 1,600 cm^{-1}, whereas cellulose does not contain vibrational modes in this region. The overlapping modes and broad peaks in NIR spectra complicate the determination of what is actually being predicted since correlating the developed models to spectral peaks is challenging.

3.1.2 Ultraviolet/Visible Spectrophotometry

UV/Vis spectrophotometry probes a molecule's electronic transition to higher energy levels when light is absorbed. Quantitative analysis can be achieved using Beer's law, in which the absorbance intensity is linearly proportional to the analyte concentration. By reading the absorbance value at a specific wavelength or wavenumber location for standard solutions with differing, known concentrations, a calibration curve can be developed. The equation of the trend line produced from the calibration curve can then be used to calculate the concentration of an unknown.

UV/Vis spectrophotometry has typically been employed in conjunction with wet chemical, often colorimetric, methods such as the phenol-sulfuric acid assay for carbohydrate quantitation (Masuko et al. 2005) or following the enzymatic transformation of key analytes such as glucose or xylose to derivative products with a concomitant side reaction, such as the reduction of NAD^+ to NADH, which can then be monitored at 340 nm (Bondar and Mead 1974; Selig et al. 2011). Crystalline cellulose content has also been measured spectrophotometrically by employing the Updegraff method (Updegraff 1969; Foster et al. 2010). Recent high-throughput techniques have enabled the rapid, nondestructive quantitation of glucan and xylan in a wide array of potential biofuel feedstocks, substantially diminishing analysis time (Selig et al. 2011).

4 Monosaccharide Content

The quantitation of monosaccharide content has typically involved wet chemical or chromatographic methodology such as methylation (Cui 2005), sulfuric acid or TFA hydrolysis (Collings and Yokoyama 1979; Fengel and Wegener 1979; Brummer and Cui 2005; Foyle et al. 2007; TAPPI 2009; Sluiter Justin et al. 2010; Lygin et al. 2011), derivatization followed by reductive cleavage (DRFC) coupled with GC (Lu and Ralph 1997; Brummer and Cui 2005), high-performance anion exchange chromatography (HPAEC) (Brummer and Cui 2005), HPLC (Sluiter Justin et al. 2010; Dvorackova et al. 2014), or CE (Goubet et al. 2002; Persson et al. 2011). Often these techniques are used to decompose the polysaccharides inside plant cell walls to their monomeric constituents. Then, the polymeric content can be calculated using stoichiometric conversion factors. The measurement of glucose and xylose release from the enzymatic saccharification of biomass is another way in which monosaccharide content is evaluated. This is an important step in the screening of potential biofuel feedstocks, as plants possessing greater cellulose content should translate into higher glucose yields for subsequent fermentation to bioethanol. One of the more customary detection techniques for monomeric sugar release is HPLC. One of the major impediments with HPLC, however, is the data collection run time associated with each sample. For the screening of large sample sets, higher-throughput methods are essential.

4.1 Vibrational Spectroscopy

Although vibrational spectroscopy has not been frequently exploited for the quantitation of monosaccharide content, a few recent developments are worth mentioning (Ona et al. 1998, 2003; Rodrigues et al. 2001; Smith-Moritz et al. 2011). FT-Raman spectroscopy has been used to predict which monomeric sugars comprised the hemicellulose fraction of *E. camaldulensis* and *E. globulus* (Ona et al. 1998, 2003). FTIR spectroscopy has been utilized for the characterization of monosaccharide content following the sulfuric acid hydrolysis of *E. globulus* (Rodrigues et al. 2001). In this study, both univariate and multivariate analyses were considered. Univariate analyses require the detection of a single vibrational mode that corresponds to the desired analyte(s). Due to the complexity of lignocellulosic biomass, and the similarity in the vibrational modes measured for cell wall polysaccharides, the experimental spectral resolution can substantially limit the use of univariate methods, as many bands will overlap. Univariate techniques, when viable, however, can significantly facilitate quantitative analysis. The integrated peak area or peak height of the distinctive vibrational mode can be used in conjunction with calibration curves from measured standards. NIR spectroscopy has enabled the screening of cell wall monosaccharide changes in wild-type and mutated *Arabidopsis* and rice (Smith-Moritz et al. 2011). As researchers attempt to develop biofuel feedstocks possessing more ideal phenotypic traits, high-throughput screens are paramount to the

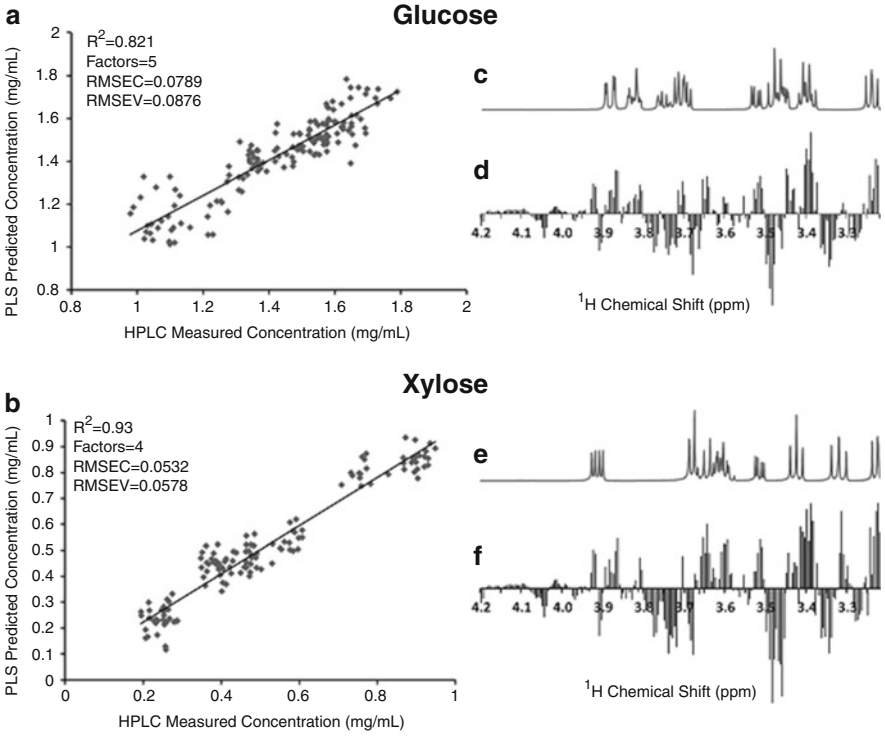

Fig. 23 PLS models constructed with ^{1}H NMR spectra and the HPLC analysis of (**a**) glucose and (**b**) xylose from multiple feedstocks. (**c**, **e**) show the NMR spectra and (**d**, **f**) show the regression coefficients for the glucose and xylose models, respectively (Reprinted with permission from Gjersing et al. 2013)

identification of successful mutations. In this study, the authors evaluated monosaccharide content variance in a rice mutant population containing thousands of unknown samples.

4.2 Nuclear Magnetic Resonance

A recent ^{1}H NMR analysis showcased the instrument's capability of quantifying monosaccharides in bamboo, eucalyptus, and sugarcane bagasse (Alves et al. 2010). The results showed a high correlation with those obtained using HPLC, especially for glucose and xylose. Another novel technique for assessing monosaccharide content coupled NMR spectral data with glucose, xylose, galactose, arabinose, and mannose concentrations measured with HPLC (Gjersing et al. 2013). PLS models were generated to predict multiple sugars simultaneously. Figures 23 and 24 illustrate the predictive capacity of the models. Although NMR

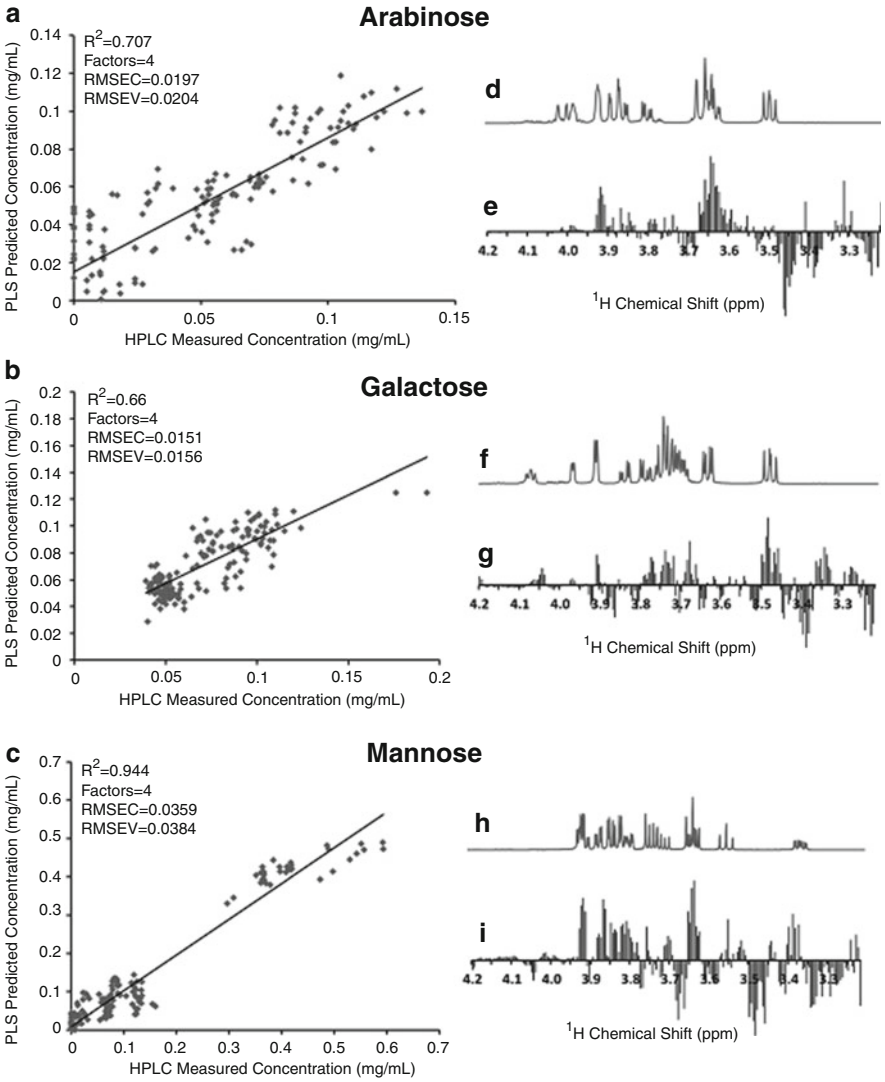

Fig. 24 PLS models constructed with ^{1}H NMR spectra and the HPLC analysis of (**a**) arabinose, (**b**) galactose, and (**c**) mannose. The R^2 for the validation set shows the linearity of the models. (**d**, **f**, and **h**) show the NMR spectra and (**e**, **g**, and **i**) show the regression coefficients for the arabinose, galactose, and mannose models, respectively (Reprinted with permission from Gjersing et al. 2013)

spectral data has not often been employed for the development of MVA models, perhaps due to the time-consuming nature of the technique, this study reduced the experimental time to one-third that required for the respective HPLC analysis, thereby significantly increasing the analytical throughput.

5 Conclusions

This chapter has provided a brief survey of how analytical spectroscopy has facilitated the qualitative and quantitative study of structural polysaccharides in lignocellulosic biomass. Techniques employing 2D NMR, such as COSY and HSQC, have allowed researchers to elucidate the labyrinthine entanglement between lignin and cell wall polysaccharides by the identification of key lignin-carbohydrate linkages. Developments in Raman and MIR spectroscopy have provided new methods for rapidly assessing cellulose crystallinity. Some of the most significant advances in the use of spectroscopy for polysaccharide analysis are the contemporary developments in Raman, MIR, and NIR spectroscopy that have enabled the progress of high-throughput methods for quantifying carbohydrates inside plant cell walls. This is paramount for the rapid screening of diverse arrays of naturally occurring or genetically designed plants to gauge their suitability for deconstruction to biofuels and bio-based chemicals. As the potential applications of analytical spectroscopy continue to be established, a more exhaustive comprehension of cell wall structural polysaccharides will be achieved, significantly facilitating the isolation of plants possessing high cellulose content, as well as the improvement of the degradative strategies paramount for efficient enzymatic hydrolyses.

Contents

Abstract

Raman spectroscopy is a long-established analytical technique that has now proliferated into a variety of research tools that are able to identify and characterize almost any type of molecule under most conditions. As such, Raman spectroscopies are well suited to the study of carbohydrates, from simple monosaccharides to the largest glycosaminoglycans and from industrial bioreactors to *in situ* measurements on living cells. This review covers a range of examples of how Raman techniques are addressing the questions of glycobiologists working on diverse aspects of this fascinating but poorly understood class of biomolecules.

Focus is placed on the application of Raman, surface-enhanced Raman, Raman optical activity, and related spectroscopies to characterizing carbohydrates of all types, with only a general introduction to the theory of the techniques themselves. Particular attention is also paid to the computational tools now regularly used by spectroscopists to analyze complex data. Although this review is aimed at the glycobiology community, the examples discussed also demonstrate to the expert spectroscopist how their techniques can impact on the exciting opportunities presented by working with carbohydrates.

1 Introduction

While the importance of carbohydrates to both the natural world and human society is clear, it is surprising how limited is our current understanding of the structural parameters that control the function and behavior of complex carbohydrates, particularly in contrast to proteins and DNA which are far better understood. While high-resolution structural techniques such as X-ray crystallography and nuclear magnetic resonance (NMR) have revolutionized biology through their ability to reveal detailed information on proteins and nucleic acids, they are less applicable to carbohydrates. Most glycoproteins and polysaccharides do not form diffractable crystals, while their typical combination of large size and low sequence complexity often prevents the acquisition of well-resolved NMR spectra. The development of our understanding of how sugars, glycans, and polysaccharides behave therefore requires the use of other biophysical techniques.

Raman spectroscopy, which measures the vibrational motions of molecules induced through the inelastic scattering of light, possesses several characteristics that makes it particularly suitable as an analytical technique for carbohydrates. Raman spectra can be obtained from samples in any physical state, which is particularly significant considering that complex carbohydrates are commonly found in solution, solid, and gel states; the technique is noninvasive and nondestructive; there is no size limit to the samples that can be studied, allowing studies on high molecular weight polysaccharides and large glycoproteins; and the spectra contain information about all levels of biomolecular structure. There are also a number of variants of conventional Raman spectroscopy that have been used to provide important new insights into carbohydrate structure. Surface-enhanced Raman scattering (SERS) exhibits a significant boosting of Raman bands due to surface plasmons generated by specific metal surfaces, thereby increasing sensitivity to even trace levels of biomolecules and forming the basis for a new generation of biosensors. Raman optical activity (ROA) is the chirally sensitive form of Raman scattering and displays an exquisite sensitivity to stereochemistry and conformational dynamics. These complementary Raman techniques together form a valuable toolkit for glycobiology, and this review presents an introduction to each of these methods and examples of their application to carbohydrates. We also discuss the capabilities of density functional theory (DFT) modeling and chemometrics for revealing further structural information about carbohydrates from these spectra.

The purpose of this review is not to exhaustively cover all previous research in this field but to illustrate to glycobiologists, through the use of relevant examples, how different Raman techniques can generate new information on carbohydrates and their behavior.

1.1 Raman Spectroscopy

Photons interact with matter in a number of ways including through absorbance and reflection. A proportion of photons will be scattered from molecules, and most of these elastically scatter, with no energy transfer, which is called Rayleigh scattering. However, a small proportion of the scattered photons (around 10^{-7} of the incident photons) will undergo a transfer of energy, either from the photon to the molecule, so raising it to an excited vibrational state (Stokes scattering), or from a molecule in an excited vibrational state to the photon, thus returning it to a lower energetic state (anti-Stokes scattering). In Raman spectroscopy, monochromatic radiation is used to excite Raman scattering, and, most typically, the Stokes-scattered photons are collected and analyzed as this leads to the optimum signal intensity as Boltzmann averaging dictates that there are more molecules in the ground vibrational state than in excited states. The differences in energy between the Raman-scattered and incident photons will correspond to vibrational motions of the molecule, which depend upon the atoms involved in the vibrational mode and their local environments. There are 3n–6 vibrational modes of a nonlinear molecule (where n is the number of atoms), with many, or most, of these potentially giving rise to Raman transitions. Therefore, the Raman spectrum of any molecule is an information-rich fingerprint of the molecule and any structural changes induced by the experimental conditions, e.g., through changes in temperature, pH, and binding interactions, or any other chemical or physical factor. Many different types of Raman spectrometer can be found, with these being optimized for different purposes, with Raman microscopes being particularly popular for studies on solids, including cells and tissues. For biological samples, care may have to be exercised in selecting the most appropriate type of Raman instrument. This is particularly true in terms of the competing factors of scattering efficiency, which is related to the excitation wavelength (λ) by λ^{-4} and so is higher at shorter wavelengths, and fluorescence, which can overwhelm a Raman spectrum and is more intense at shorter visible wavelengths. In the case of pure samples of carbohydrates, fluorescence is not typically a serious problem; however, for biofluids and tissues, this may be an issue.

A typical Raman spectrum of a simple carbohydrate is shown in Fig. 1, in this case for D-ribose in water at ~20 °C. Characteristic band patterns related to the functional groups of the saccharide are evident over the presented range of 300–1,800 cm^{-1}. Although they are not shown in this figure, other spectral regions can also be studied, particularly the C–H stretching region from ~2,800 to 3,100 cm^{-1}, N–H stretching region from ~3,200 to 3,600 cm^{-1}, with O–H stretching modes usually appearing ~3,600–3,700 cm^{-1}, and carboxylic acids

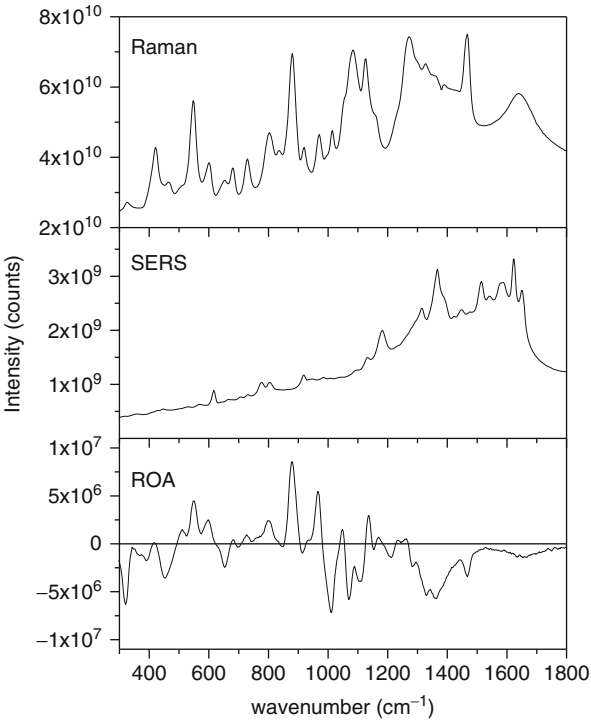

Fig. 1 Raman (*top*), SERS (*middle*), and ROA (*bottom*) spectra of D-ribose in solution. The Raman and ROA spectra were recorded at a concentration of 2.66 M for 237 min and with laser power at the sample of 625 mW. The SERS spectrum of D-ribose was measured with a concentration of 1.67 mM, for 20 min with 100 mW laser power. For the SERS measurement, silver citrate-reduced colloids and 20 mM K_2SO_4 as the aggregating agent were used (Figure was adapted from Ostovar Pour et al. 2011)

generating additional bands between 2,500 and 3,200 cm^{-1}. Detailed analysis of the functional group origins of these Raman bands can be found elsewhere (Ostovar pour et al. 2011), but in general many of the Raman modes of sugars over this range tend to involve complex combinations of molecular vibrations, with many of the Raman bands presented here for D-ribose from 700 to 1,100 cm^{-1} originating from various C–C and C–O stretching motions, sometimes with coupling to O–H deformations. Raman bands of carbohydrates from 1,300 to 1,600 cm^{-1} generally arise from CH deformations, and below 700 cm^{-1} can be seen bands signifying deformation modes of the skeletal ring backbone. The anomeric ratio can also be directly characterized from Raman bands in the region of ~630–700 cm^{-1} (Mathlouthi et al. 1983; Carmona and Molina 1990). The complex band patterns of carbohydrate Raman spectra make them useful fingerprints of identity and functional group composition, as well as the effects on structure induced by the local environment.

1.2 Surface-Enhanced Raman Scattering (SERS)

Although Raman spectroscopy is now widely used in the chemical, biological, and even medical sciences, it still is generally viewed as a relatively weak effect. One solution to this problem is the use of plasmon resonance enhancement mechanisms to greatly reduce detection limits and increase spectral intensities, which leads to

surface-enhanced Raman scattering (SERS). There are many detailed reviews on the origin and potential applications of SERS (Anker et al. 2008; Schlucker 2009, 2014; McNay et al. 2011; Larmour and Graham 2011; Kitahama et al. 2012; Ringe et al. 2013; Yamamoto et al. 2014), and so we present only a brief summary here of the relevant aspects.

While the first observation of SERS, of pyridine on an electrochemically roughened silver surface, was made by Fleischmann et al. (1974), it was in 1977 that two other groups suggested mechanisms for the enhancement process that are today widely accepted as being correct (Jeanmaire and van Duyne 1977; Albrecht and Creighton 1977). Considerable debate has been generated on the relative importance of different contributing factors to the SERS effect, but it is generally recognized that there are two main effects involved. The electromagnetic (EM) mechanism describes how an incident light wave can excite localized surface plasmons in the vicinity of roughened or geometric features on the surface of certain metals, with the most commonly used being silver or gold. The greatly enhanced local electric field then leads to an increase in Raman intensity. Both the Raman incident and emitted fields may be enhanced, generally by different amounts. The nature of the metal surface will affect the plasmon resonance frequency, so changing the SERS response. In general, silver surfaces give strongest enhancements for visible excitation frequencies, while gold surfaces work best at near-infrared excitation frequencies.

Although the EM mechanism is thought to be responsible for much of the observed SERS spectrum, it does not explain the whole process, and an additional contribution comes from the chemical enhancement (CE) mechanism. The CE mechanism involves charge transfer between the chemisorbed analyte molecule and the metal surface. It can be generalized that while the EM mechanism is responsible for most of the signal enhancement observed, the CE mechanism gives rise to the selective band enhancement that makes the SERS spectrum distinctive and different to the parent Raman spectrum. In Fig. 1, the SERS spectrum of D-ribose clearly has a different profile to the corresponding Raman spectrum due to the chemical enhancement of selected Raman bands. Although establishing the molecular origins of SERS bands is a subject of ongoing research for many group, most SERS bands measured for carbohydrates are not yet assigned in the literature. These SERS spectra are therefore commonly used as spectral fingerprints for the detection of specific sugars under conditions of low concentration and laser power. We note that the principal bands shown in the SERS spectrum for D-ribose are between 4 and 5 orders of magnitude stronger than the corresponding Raman features, on a per molecule basis. Such enhancement factors are commonly obtained, verifying the sensitivity of SERS as a bioanalytical tool.

1.3 Raman Optical Activity (ROA)

Raman optical activity (ROA) measures a small difference in the intensity of Raman scattering from chiral molecules using right- and left-circularly polarized

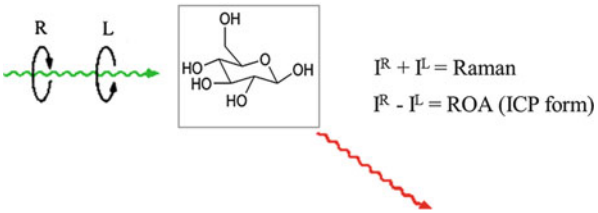

Fig. 2 Schematic of the ROA scattering process, specifically showing the incident circular polarization (*ICP*) form. If the scattered radiation was circularly polarized instead, this would correspond to the SCP form. The SCP form is most widely used, but in the absence of resonance effects, the ICP and SCP forms are equivalent and generate the same spectra (Figure is adapted from Barron et al. 2000)

light; see Fig. 2. ROA was first predicted in 1969 by Atkins and Barron (1969) and then observed experimentally in 1972 by Barron et al. (1973). Until recently, ROA spectroscopy was only used in a handful of laboratories around the world as it is a weak effect which requires careful measurement, with ROA scattering intensities typically being 10^{-3} to 10^{-5} of the corresponding Raman scattering. Although still a niche technique, at the time of writing, ROA was now available in around 30 laboratories globally, in both universities and pharmaceutical companies.

As is shown in Fig. 2, the circular polarization may be in either the incident light, leading to incident circular polarization (ICP) ROA, or the scattered light, leading to scattered circular polarization (SCP) ROA, or even in both, which gives rise to dual circular polarization (DCP) ROA. Most early ROA measurements, until around 2004, were made with the ICP form, but since then SCP ROA is the most common. However, this does not present a problem for comparing spectra measured with the different forms of ROA as in the far-from-resonance limit they give the same spectra. As can be clearly seen in Fig. 1, as ROA is a difference measurement, the spectrum is bisignate, with both positive and negative features. The ROA bands observed originate from the Raman bands, but as ROA spectral features derive from not only the electric polarizability but also the magnetic polarizability and the quadruple moment, ROA features display different intensities and bandshapes to the corresponding Raman features. They can also present both mono- and bisignate features. This is apparent for several of the ROA bands of D-ribose, shown in Fig. 1. Further details of the sensitivity of ROA bands to the local stereochemistry and structure of carbohydrates are discussed in this review, below.

The ROA measurement can be represented quantitatively by the circular intensity difference (CID), defined as:

$$\Delta = \left(I^R - I^L\right)/\left(I^R + I^L\right) \tag{1}$$

where I^R and I^L are the scattered Raman intensities in right- and left-circularly polarized incident light, respectively. If the R and L labels were subscripted, this would denote right- and left-circularly polarized scattered light intensities. As was mentioned above, in the absence of electronic enhancement, which is the typical

case for ROA studies on carbohydrates, the incident and scattered CID expressions are equivalent. For readers interested in the theory of ROA or its general application to other classes of molecules, we recommend any of several comprehensive reviews (Blanch et al. 2003; Barron et al. 2003, 2004; Barron and Blanch 2009).

2 Studies on Simple Carbohydrates

Early Raman studies on mono-, oligo-, and polysaccharides were mainly conducted on crystalline samples; see, e.g., Cael et al. (1974), Mathlouthi and Koenig (1986), Wells and Atalla (1990), and Dauchez et al. (1994a, b). These studies established that many of the vibrational modes of monosaccharides are complex and involve greater mixing of internal coordinates than is generally found for peptides and amino acids. Although this can make detailed analysis of the vibrational modes of sugars more challenging than for other biological molecules, the results from these studies indicated that characteristic spectral fingerprints could still be identified. Thus, the ability of Raman spectroscopy to differentiate between different monosaccharides, and so serve as a sensitive probe of carbohydrate identity, has been known for some time. Kačuráková and Mathlouthi (1996) found that they could use the Raman profiles to distinguish between a selection of simple sugars (D-glucose, D-galactose, lactose, maltose, melibiose, maltotriose, raffinose, and trehalose) in solution. These authors also found that distinctive Raman bands of the monosaccharides could be detected in the spectra of several of the disaccharides as the conformations of the individual sugars were very similar to those of the corresponding subunits. This contrasted with the larger changes observed in the spectra of melibiose and trehalose, as a result of the larger structural differences induced by formation of the glycosidic linkages. Similarly, Arboleda and Loppnow found that their Raman spectra of each of nine different monosaccharides were unique (Arboleda and Loppnow 2000). These monosaccharides were *O*-methylated to block racemization of the anomeric carbon. The authors found that they could even distinguish between the α- and β-anomers of several of these monosaccharides. They also reported that such distinctions could be made on samples of less than 0.1 mg, though typically larger amounts are generally used in most studies. Arboleda and Loppnow were also able to use Raman marker bands to identify the monosaccharide components of unknown disaccharide samples (Fig. 3).

Although carbohydrates do not display as well-defined coordination properties as many other natural ligands, they do bind transition metal ions. The large number of electronegative functional groups and well-defined stereochemistries of sugars makes them attractive synthons for the synthesis of more complex structures. The mode of coordination of metal ions with the different hydroxyl groups of sugars is a subject of importance for guiding new syntheses, but quantitative characterization of the anomeric and conformational species of the carbohydrates involved in these complexes is difficult. Cerchiaro et al. used Raman spectroscopy and electron paramagnetic resonance (EPR) to investigate complexes of Cu(II) ions with D-glucose, D-fructose, and D-galactose (Cerchiaro et al. 2005). They found that

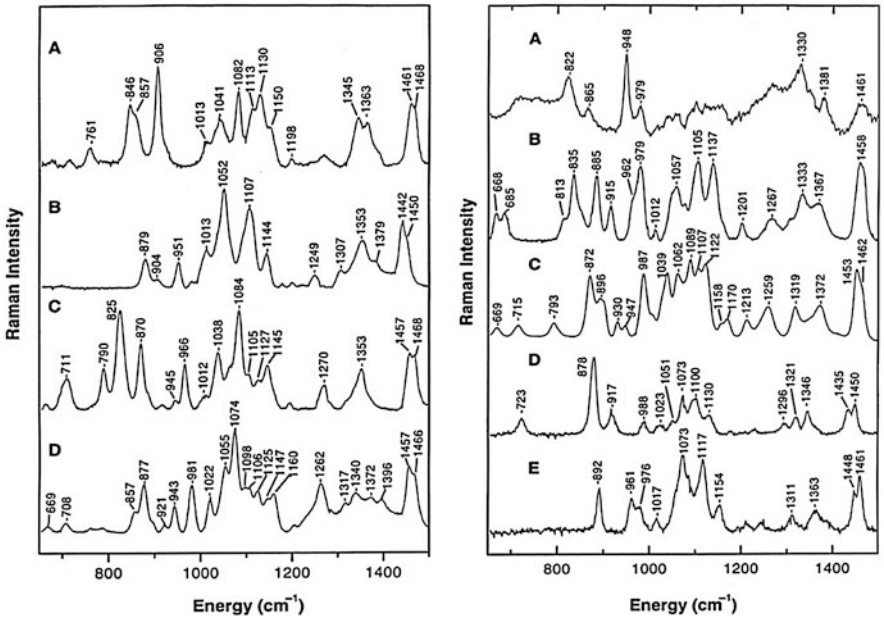

Fig. 3 Raman spectra of 1-*O*-methyl-monosaccharides. *Left-hand panel*: (*A*) 1-*O*-methyl-α-D-glucoside, (*B*) 1-*O*-methyl-β-D-glucoside, (*C*) 1-*O*-methyl-α-D-galactoside, and (*D*) 1-*O*-methyl-β-D-galactoside. *Right-hand panel*: (*A*) 1-*O*-methyl-α-D-*N*-acetylgalactosamine, (*B*) 1-*O*-methyl-α-D-mannoside, (*C*) 1-*O*-methyl-β-D-mannoside, (*D*) 1-*O*-methyl-α-D-xyloside, and (*E*) 1-*O*-methyl-β-D-xyloside. All spectra were measured with 2 W of 514.5 nm light. Note that the label of the ordinate axis used here, "energy," means the same as the more common "wave number" and "Raman shift" labels (Figure is Adapted from Arboleda and Loppnow 2000)

the β-anomer was the dominant form of D-glucose when complexed, but both α- and β-anomers were found in the complexes of D-galactose. For the complexes of D-fructose, both furanose and pyranose forms were detected, with furanose being the major one. Specific hydroxyls and oxygens were also identified as being coordination sites for the Cu(II) ions, from changes in their signature Raman bands upon complexation.

Mixtures of simple sugars are commonly found, and overlap of Raman bands from these sugars can yield complex spectra. However, standard analytical tools can successfully resolve the differences between the Raman spectral signatures and hence the identities and relative contributions of each. A nice illustration of this is a teaching experiment designed by Wang and colleagues (2009), who used principal component analysis and regression models (PCA/PCR) from the Raman spectra to quantify the relative compositions of three sugars (D-(−)-fructose, D-(+)-glucose, and D-(+)-galactose) in a solution mixture. It is particularly noteworthy that in this study undergraduate students were able to use this approach to obtain accurate results.

Previously, Mrozek et al. had used both Raman and SERS spectroscopies to differentiate between two sugars, maltotetraose, and stachyose (Mrozek et al. 2004). Their reported SERS spectra, following a procedure developed by

Mrozek and Weaver to measure SERS of several monosaccharides (Mrozek and Weaver 2002), were very similar to the corresponding Raman spectra, but apparently with enhancement factors of 2–3 orders of magnitude, so significantly reducing detection limits. These authors also considered the question of separating and quantifying the spectral signatures of each of the two sugars in a binary mixture and found this could be achieved accurately using PLS algorithms.

As previously stated, one advantage of SERS as an analytical technique is that it does not require an extrinsic label. However, in cases where even higher signal enhancements are sought, facilitating even down to attomolar detection, a widely used strategy is to chemically link a chromophoric reporter group, typically a dye compound, to either the analyte molecule or the metal surface. This further electronic resonance enhancement gives rise to the technique of surface-enhanced resonance Raman scattering or SERRS. Vangala et al. adopted this approach and coupled rhodamine tags to three different sugars: glucose, lactose, and glucuronic acid (Vangala et al. 2010). These tagged carbohydrates were shown to increase sensitivity for not only Raman detection but also for fluorescence and mass spectrometric analysis as well.

All sugars are chiral, making Raman optical activity (ROA) an obvious technique for investigating their solvated conformations. The Barron group in Glasgow undertook a number of studies on small sugars and found that detailed and informative spectra could be measured (Bell et al. 1994a, b, 1995; Macleod et al. 2006). Most significantly, Wen et al. (1993) verified that ROA can determine the absolute configuration about each chiral center of a carbohydrate and differentiate between α- and β-anomeric linkages; that large ROA spectral differences can be observed between epimers; that ROA spectra can also discriminate between homomorphic sugars, which have the same stereochemistry around each chiral carbon but different substituents, though these spectral differences are weaker than those found for epimers; and finally, that ROA can infer the relative conformations of CH_2OH groups, which are important for intramolecular hydrogen bonding and for stabilizing backbone conformations.

Further studies were conducted on cyclodextrins (Bell et al. 1997; Barron et al. 1990), and these established that ROA can provide detailed information about the conformational dynamics of oligosaccharides. The first ROA spectra of glycoproteins were, again, first reported by the Glasgow group (Bell et al. 1994c; Smyth et al. 2001; Zhu et al. 2005), who then subsequently demonstrated that ROA could simultaneously probe the structural complexity of both the protein and glycan components of a glycoprotein (Johannessen et al. 2011).

3 Conformational Studies on Polysaccharides and Glycoproteins

Raman and ROA spectroscopies have also been used to characterize the conformations and behavior of complex polysaccharides. One notable example of this is the study by Yaffe et al. on hyaluronan (HA), a nonsulfated glycosaminoglycan (GAG)

composed entirely of repeating disaccharides of glucuronic acid (GlcA) and *N*-acetyl-glucosamine (GlcNAc) linked by alternating β-1,3 and β-1,4 glycosidic bonds (Yaffe et al. 2010). Hyaluronan is found in all vertebrate tissues as a high molecular mass polysaccharide and performs a wide range of biological functions, leading to its widespread use in medicine, tissue engineering, and cosmetics. However, we understand relatively little about the structural parameters that regulate hyaluronan organization and function. Yaffe et al. were able to use the stereochemical sensitivity of ROA in order to monitor characteristic intersaccharide interactions in a short hyaluronan subunit (the HA_4 tetramer) but then found that there were no signs of extensive interchain interactions being formed in a much longer HA chain (see Fig. 4). In this way, the authors were able to conclude that there was no extensive tertiary structure formation in the HA polymer, in agreement with several NMR studies (Kaufmann et al. 1998; Blundell et al. 2006).

Rudd et al. have also reported the Raman and ROA spectra for several glycosaminoglycans (Rudd et al. 2010), further emphasizing the potential of the technique in glycobiology.

Recently, Ashton et al. have used both Raman and ROA spectroscopies to investigate the interactions between mucin glycoproteins (Ashton et al. 2013). Mucins are highly glycosylated, high molecular weight proteins which perform diverse roles in the formation of mucosal gels in metazoans. Mucins are important for determining the physical properties of gastrointestinal and salivary mucus, and they function as mesh-like, size, and charge exclusion barriers. Most mucins have a block copolymer structure with nonglycosylated domains at both termini that are separated by an extended glycosylated domain which is rich in serine, threonine, and proline residues. O-Linked glycosylation occurs through conjugation of *N*-acetylgalactosamine (GalNAc) sugars to the hydroxyl moieties of the serines and threonine side chains, giving rise to the so-called hinge region that is thought to be important for molecular control of the formation of the mucosal mesh. Using 2D correlation analysis with both Raman and ROA spectra, the authors were able to distinguish the order of conformational changes occurring over concentration ranges relevant to the formation of the gastric mucosal layer. They found that at mucin concentrations from 20 to 40 mg/ml, these GalNAc moieties underwent conformational changes, with other saccharides changing conformation above 40 mg/ml, together with other structural transitions observed in the protein core, specifically the formation of β-structure. In this way, Raman and ROA were able to monitor the formation of transient entanglements formed by what are thought to be brush–brush interactions between the oligosaccharide combs of mucin molecules.

One particular great challenge for glycobiology is to map and understand the expression patterns of component sugars in the glycan components of glycoproteins. With most techniques it is difficult to determine linkage types and between oligosaccharides with similar compositions. Johannessen et al. examined yeast invertase from *S. cerevisiae*, a high-mannose glycoprotein that is widely used in the sugar industry as a biocatalyst, and a number of its component oligosaccharides. Structures of these sugars are shown in Fig. 5 along with the Raman and ROA spectra of the mannose monosaccharide and three disaccharides. Unsurprisingly,

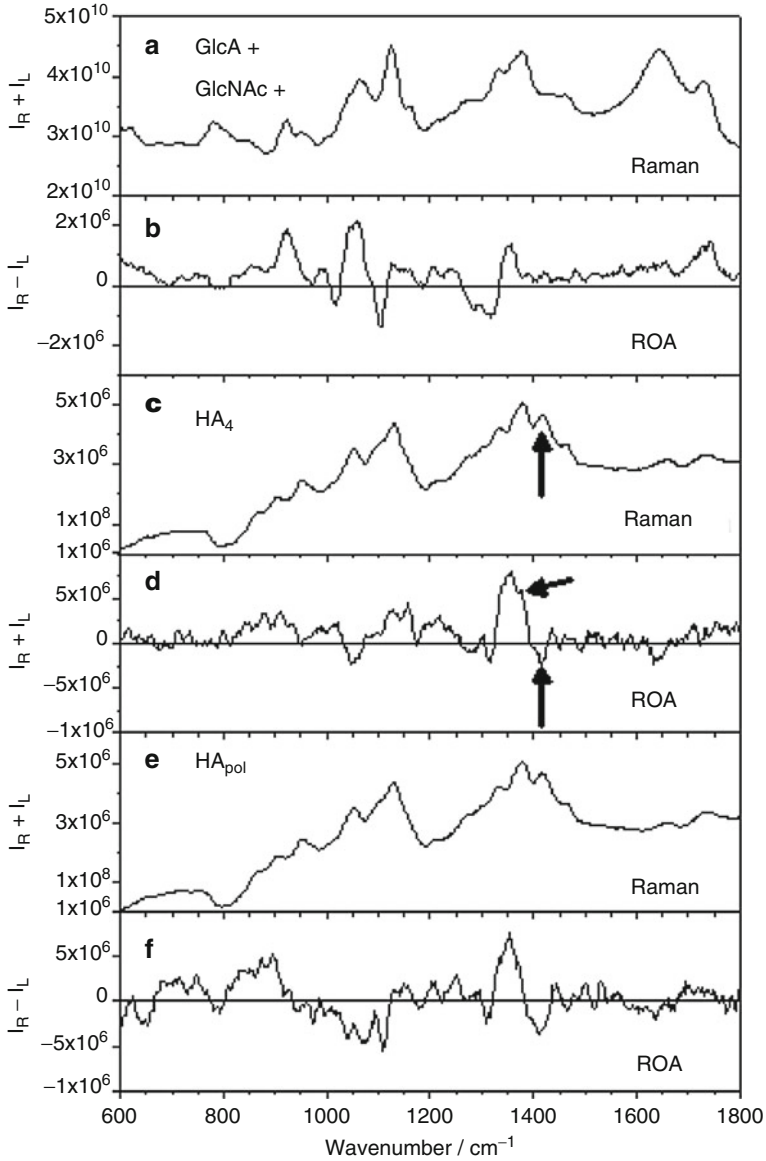

Fig. 4 Raman ($I_R + I_L$) and ROA ($I_R - I_L$) spectra, respectively, of a 1:1 stoichiometric mix of GlcA and GlcNAc (panels *A* and *B*), HA_4 tetramer (panels *C* and *D*), and the HA_{pol} polymer (panels *E* and *F*). Secondary structure marker bands are shown with *arrows*. The large differences between the ROA spectra shown in panels *B* and *D* reflect the formation of secondary structure-type interactions between saccharides, while the strong similarity between the ROA spectra for HA_4 and HA_{pol} (panels *D* and *F*) indicates that no significant tertiary interactions are formed in the polymer (Figure is taken from Yaffe et al. 2010)

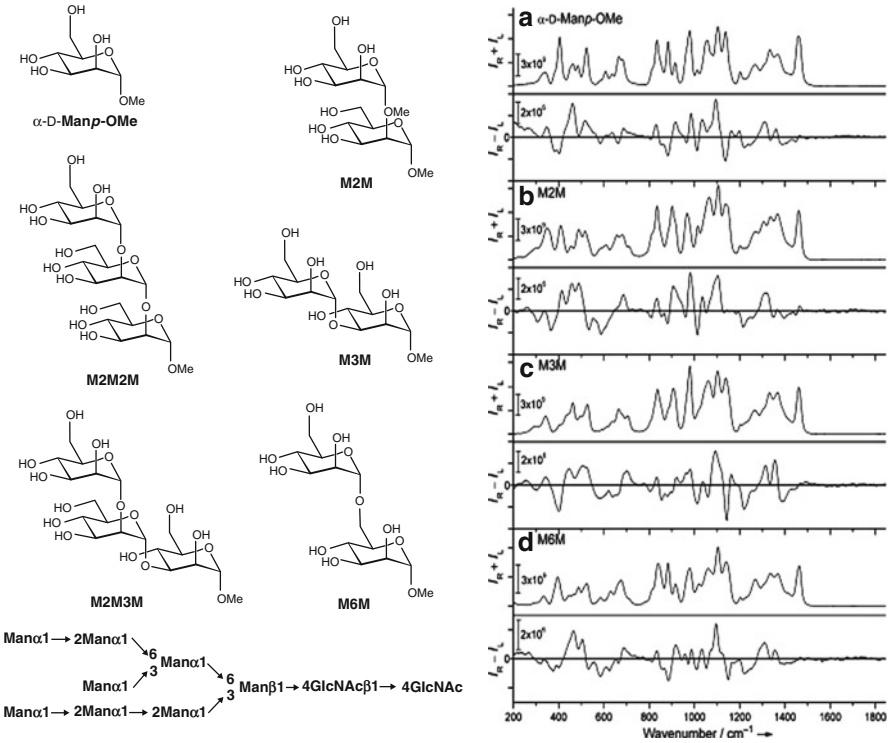

Fig. 5 Shown on the *left* are the structures of mannose oligosaccharides found in yeast invertase, along with the linkage scheme of the $Man_8GlcNAc_2$ unit. On the *right* are the corresponding Raman and ROA spectra for the mannose mono- and disaccharides (Figure is taken and adapted from Johannessen et al. (2011))

the four Raman spectra are all similar, though with some differences in detail. Far more significant differences can be observed between their corresponding ROA spectra. The obvious changes in ROA band profiles and intensities originate from the different glycosidic linkages and the resulting effects on conformation and dynamics of the component sugars.

Further differences between the ROA spectra were observed for the two mannose trisaccharides, labeled as M2M2M and M2M3M, and measured by Johannessen et al., as is shown in Fig. 6. Most strikingly, the complex ROA band structures from ~250 to 700 cm^{-1}, shown by shading, present in the spectra of M2M2M and M2M3M are also clearly apparent in the ROA spectrum of the yeast invertase. The authors concluded that this band pattern originated from the α-(1 → 2)- and α-(1 → 3)-glycosidic linkages, possibly with some minor contributions from α-(1 → 6)-linkages. As the authors stated, this close similarity in ROA band patterns also indicated that the conformations around these glycosidic links in the glycoprotein are very similar to those of the free mannose trisaccharides in aqueous solution. Although the use of Raman spectroscopies for studying protein

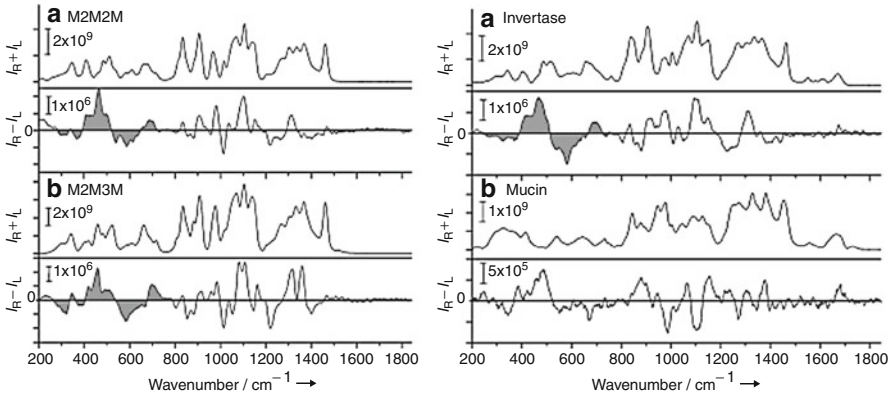

Fig. 6 Shown on the *left* are the Raman and ROA spectra for the mannose trisaccharides α-D-Man*p*-(1 → 2)-α-D-Man*p*-(1 → 2)-α-D-Man*p*-OMe (M2M2M) and α-D-Man*p*-(1 → 2)-α-D-Man*p*-(1 → 3)-α-D-Man*p*-OMe (M2M3M). Presented on the *right* are the Raman and ROA spectra of (*a*) yeast external invertase and (*b*) bovine submaxillary mucin in water. The shaded ROA band pattern in the low-wave number region of the invertase spectrum is very similar to the shaded patterns in the ROA spectra of the trisaccharides M2M2M and M2M3M (Figure is taken and adapted from Johannessen et al. 2011)

structure lies outside the purposes of this review, it should be noted that Raman spectroscopies, including ROA, can simultaneously probe both the protein and carbohydrate moieties of a glycoprotein. Johannessen et al. were able to determine from the absence of protein structural ROA marker bands that invertase was completely disordered, presumably due to the glycan content, similarly to a commercial sample of the highly glycosylated bovine submaxillary mucin.

Recently, this group extended their study on glycoproteins to ribonuclease B (RNase B). As already described, RNase B has the same protein sequence as RNase A as well as a single N-linked glycan with two GlcNAcs and a variable number of mannose residues. These researchers were able to reconstruct the Raman and ROA spectral signatures for this glycan component, as shown in Fig. 7, by subtracting the protein spectral signatures measured for the nonglycosylated RNase A (Mensch et al. 2014). Although there is insufficient information yet to analyze the glycan spectra in detail, this work demonstrates the future potential for Raman spectroscopies for investigating the structures of the glycan moieties of glycoproteins in situ.

4 Probing Hydration Interactions of Sugars

The dynamics of water molecules have long been thought to play important roles in the behavior and properties of carbohydrates. Water is a weak Raman scatterer so making Raman measurements on aqueous solutions easier than when using infrared spectroscopy. However, Raman spectra of solutes, including carbohydrates, are

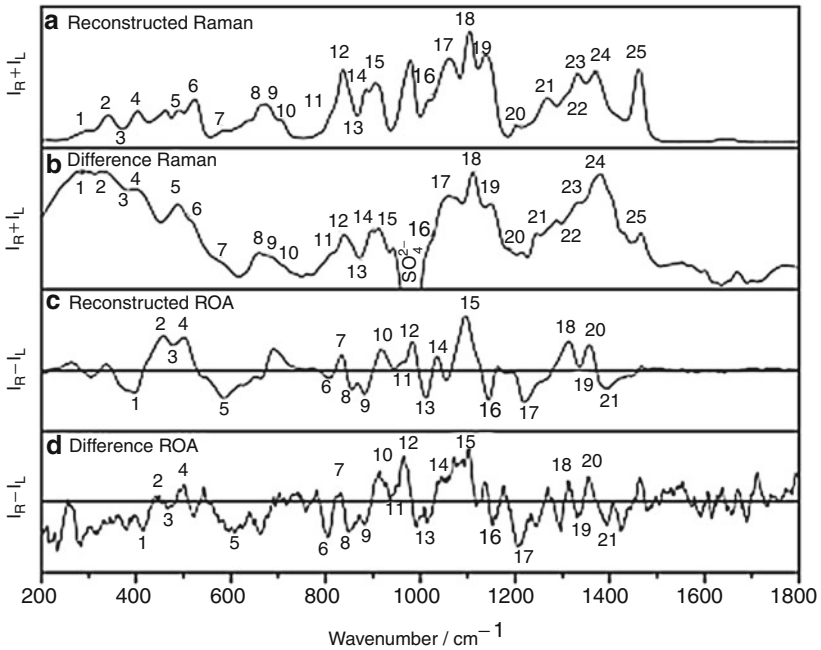

Fig. 7 Reconstructed Raman (*A*) and ROA (*C*) spectra of the glycan moiety from RNase B from the constituent disaccharide spectra and difference Raman (*B*) and ROA (*D*) spectra of RNase B after subtraction of the respective RNase A spectra. Particular bands are numbered (Figure is taken from Mensch et al. 2014)

sensitive to interactions with water molecules. Soderholm et al. investigated the sensitivity of specific Raman bands to hydration for samples of glucose and fructose (Soderholm et al. 1999). In their study of honey samples, de Oliveira et al. found that Raman bands of the component saccharides showed subtle changes in relative intensity as a function of water content (de Oliveira et al. 2002). Paola Sassi and colleagues in Perugia have performed a number of studies on hydration interactions with carbohydrates using different biophysical techniques including Raman spectroscopy (Fioretto et al. 2007; Paolantoni et al. 2007). They have shown that Raman bands from solvent water molecules are sensitive to the disordering of tetrahedral water structures by sugar molecules (Gallina et al. 2006; Perticaroli et al. 2008), with glucose and fructose appearing to have a different effect on bulk water structure than trehalose and dextran.

Irradiation of foods is now a widely used method for controlling microbial and insect contamination and can also extend the shelf life of fruits and vegetables by delaying ripening and inhibiting sprouting. However, ionizing radiation can, of course, cause chemical damage, and in the case of carbohydrates, this can lead to both the direct breaking of chemical bonds and indirect effects from formation of reactive hydroxyl radicals from water molecules within the foodstuffs.

5 Characterizing the Chemical Modification of Sugars

Raman spectroscopies show particular promise for the identification of chemical modifications in carbohydrates, particularly of sulfation. The vibrational modes of the sulfonyl group are typically intense and sharp and so are often easy to distinguish from the many other vibrational modes of carbohydrates, as was shown many years ago (Bansil et al. 1978; Cabassi et al. 1978). More recently, a number of other research groups have further explored the capabilities of Raman techniques for studying the sulfation of glycosaminoglycans. Matsuhiro and colleagues (2012) combined Raman and SERS spectroscopies in addition to FTIR and NMR to investigate the composition of material extracted from a sea cucumber (*Athyonidium chilensis*). They found that the SERS spectra were more informative than the corresponding Raman spectra, and their collective experiments characterized the glycosaminoglycan composition of the extract, with chondroitin 4,6-disulfate substituted at position O-3 of glucuronic acid and partially 2,4-disulfated-fucopyranosyl residues being found.

6 Industrial and Healthcare Applications

One of the greatest challenges currently facing the pharmaceutical sector is the characterization of posttranslational modifications (PTMs) of protein pharmaceuticals, with the most common of these being glycosylation. The stability, immunogenicity, and pharmacokinetics of a protein drug can all be affected by glycosylation, but detection and characterization of the glycan content typically require complex, destructive, or time-consuming methodologies. Raman spectroscopy has the potential to meet the requirement for a fast, noninvasive, and quantitative technique for the characterization of the glycan content of protein pharmaceuticals. Brewster et al. demonstrated that Raman spectroscopy coupled with multivariate data analyses could differentiate between the nonglycosylated ribonuclease A (RNase A) and the glycosylated ribonuclease B (RNase B, which has an identical amino acid sequence but also a single N-linked glycan containing two GlcNAcs and from three to nine mannoses), as well as deglycosylated versions of RNase B (Brewster et al. 2011). The Raman spectra shown in Fig. 8 display significant differences, highlighted in purple, due to glycosylation. Using the first principal component from the resulting PCA analysis performed on these Raman spectra, the authors were able to clearly distinguish between the glycosylated (RNase B) and nonglycosylated (RNase A) proteins.

Raman bands are quantitative, and the authors were also able to use another chemometrics technique, principal least squares regression (PLSR), to show that this methodology could accurately determine the amount of carbohydrate in a glycoprotein. In their results, presented in Fig. 9a, we observe the strong correlation between the predicted and known proportions of RNase B in mixtures of RNase A and B. Although this was a proof-of-principle experiment on a simplified system, this work is a good exemplar of the use of Raman for quantitative glycobiology.

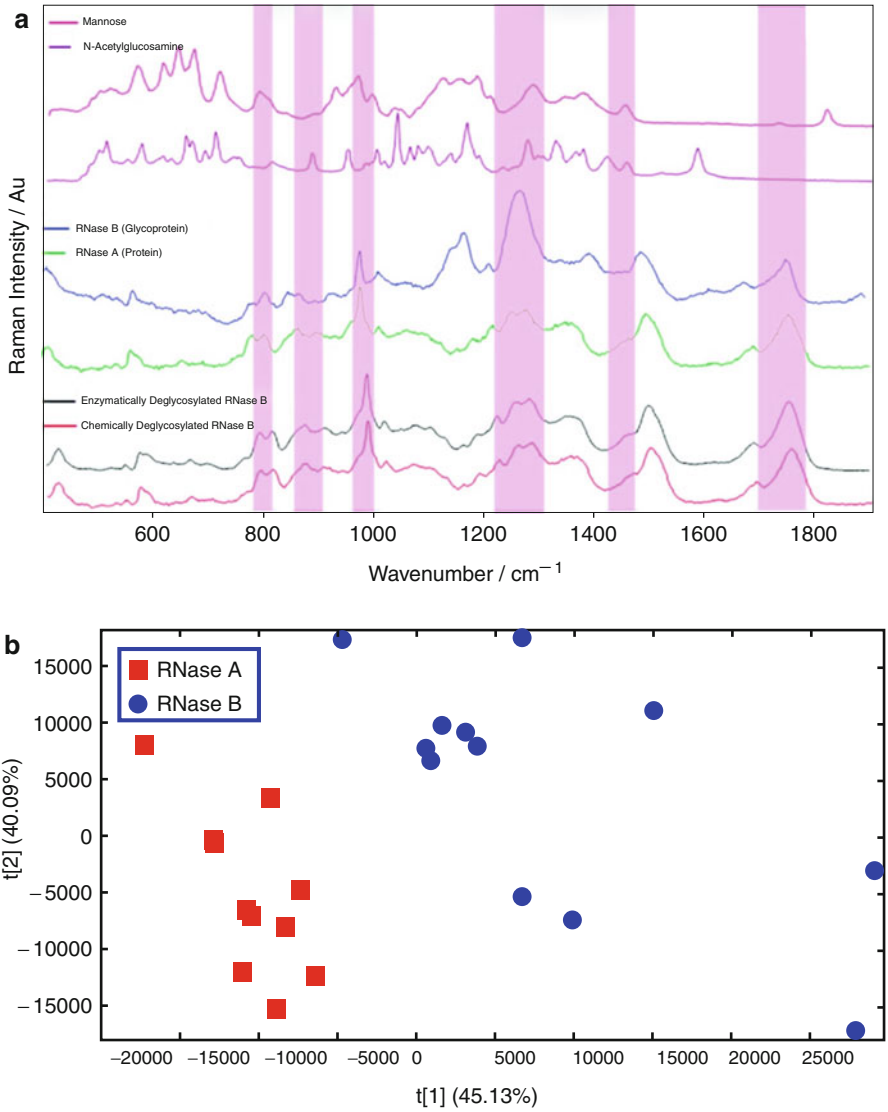

Fig. 8 Panel (**a**) shows averaged Raman spectra of mannose, GlcNAc, ribonuclease A and B, and chemically and enzymatically deglycosylated ribonuclease B, measured at 785 nm. Areas highlighted are regions of significance, as indicated by the PLS loading in panel (**b**), which presents the PCA scores plot (PC1 vs. PC2) of the ribonuclease data, showing ribonuclease A and B spectra resolved into separate clusters allowing separation of the glycosylated and nonglycosylated forms (Figure is taken from Brewster et al. 2011)

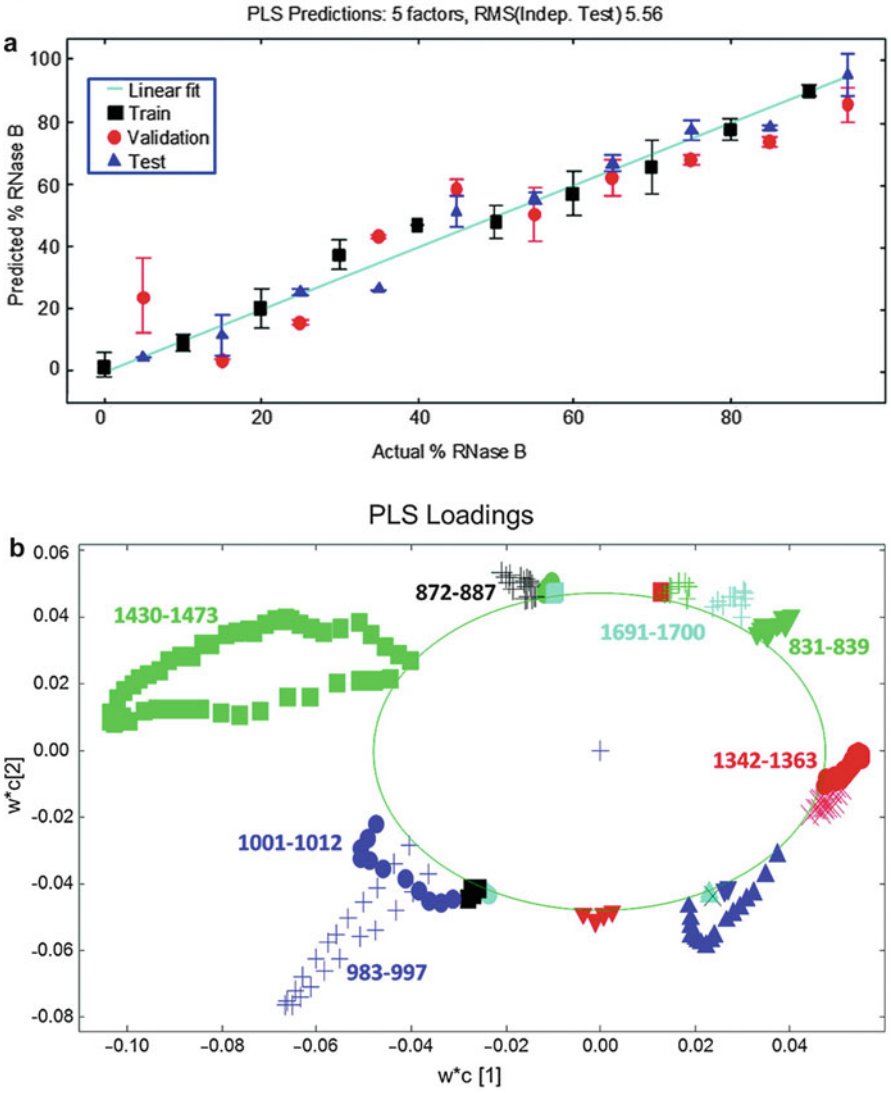

Fig. 9 (**a**) PLS predictions from Raman data of RNase mixtures (mean predictions (from $n = 5$) are plotted with standard error bars). (**b**) PLS loading plot of the first two latent variables (LVs; w_c[1] vs. w_c[2]); the *green circle* indicates the 95 % confidence limit. *Numbers* shown refer to Raman peak positions (Figure is taken from Brewster et al. 2011)

Furthermore, chemometrics analyses can also reveal greater structural detail from complex Raman spectra. Panel (b) of Fig. 9 shows the PLS loading plot from this study, with the first two latent vectors, which were responsible for most of the variance in this data, being sensitive to relative changes in selected marker bands from the regions highlighted in Fig. 8a.

A long-standing bioanalytical challenge is the detection and control of glucose levels in the bloodstream, for the control of diabetes mellitus. Among many other techniques, Raman spectroscopies have been applied to this problem. In particular, the van Duyne group at Northwestern University has developed nanolithographic surfaces as SERS-based sensors for monitoring glucose levels (Schafer-Peltier et al. 2003; Lyandres et al. 2005). More recently, this group has used a specialized spatially offset form of SERS for transcutaneous monitoring of glucose within living rats (Yuen et al. 2010; Ma et al. 2011). An alternative approach to monitoring glucose levels directly has been explored by Barman et al. who propose the detection of glycated hemoglobin (HbA1c), which is known to display a strong correlation with bloodstream glucose levels and is an approved target for screening diabetic and prediabetic conditions (Barman et al. 2012). These researchers coupled Raman excitation at 785 nm with drop coating deposition (DCD), which is a relatively new but popular analytical Raman technique (Ortiz et al. 2006). In brief, DCD uses special hydrophobic surfaces to preconcentrate the analytes in dried solution samples, so greatly increasing signal intensity. Analytes tend to coalesce into a coffee-ring pattern, and this phenomenon is still a subject of investigation, particularly with reference to the homogeneity of material deposited within the ring. Through their experiments on both HbA1c and nonglycated hemoglobin (Hb), Barman et al. found that DCD Raman combined with PCA and PLS informatics could distinguish spectra signatures of HbA1c that provided a limit of detection (LOD) of as low as 3.8 μM. This compares very favorably with clinically determined concentrations of HbA1c (60 μM and higher). Figure 10 shows how the PCA scores plot generated from their DCD Raman data could directly differentiate between the glycated HbA1c and nonglycated Hb. Although this paper by Barman et al. was another proof-of-principle experiment, they also consider in some detail the potential of this approach for clinical application, and we direct interested readers to their paper as well as a similar study on glycated albumin (Dingari et al. 2012).

The long-term and widespread prevalence of carbohydrates in foods and beverages makes the food and drink industry an obvious sector of interest for Raman spectroscopies. The rapid, noninvasive, and label-free nature of Raman scattering makes it well suited to many situations in food science and agriculture, though the complexity of spectra from food samples often requires the use of informatics during data analysis. Such a strategy was followed by Delfino et al. in their use of a standard Raman microscope to quantify glucose content in different commercial sports drinks (Delfino et al. 2011). They collected Raman spectra with a simple He–Ne laser and 50× optical objective on droplets of sample, with example spectra being shown in Fig. 11. Interval partial least squares (iPLS) was then employed to identify key marker bands and construct calibration models that allowed accurate determination of glucose concentration, within experimental error of the results from enzymatic assays.

Although the result from each Raman analysis had a higher experimental uncertainty than for the corresponding enzymatic (biochemical) assay, as is apparent in Fig. 12, this work shows that accurate quantitative analysis of sugars can be

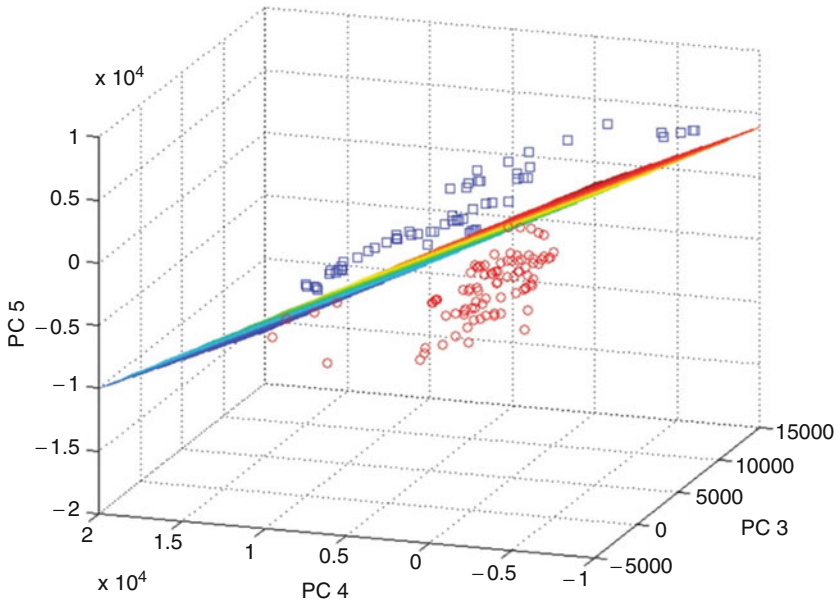

Fig. 10 Three-dimensional scores plot corresponding to principal components (*PCs*) 3, 4, and 5 for the Raman dataset acquired from single-protein Hb and HbA1c drop-coated rings. Hb samples are indicated by *red circles* and HbA1c by *blue squares* (Figure is taken from Barman et al. 2012)

obtained using relatively standard Raman equipment and multivariate analytical tools and a simple calibration model. As such Raman analyses of carbohydrates in food and beverage samples could be made rapidly and without specialist sample preparation, there is great potential for such techniques in on-site quality control and characterization of foodstuffs and beverages.

7 Applications in Virology

Glycoproteins play critical roles in the mechanisms of viral infection, such as membrane fusion, with conformational changes in these glycoproteins being important for driving these mechanisms. As already mentioned, conventional structural techniques are often difficult to apply to this problem. In the requirement for rapid clinical diagnosis of viral infection, the time constraint becomes increasingly important. The fast data acquisitions inherent to Raman technologies, coupled with the wealth of structural information that can be obtained, are leading to their application in structural virology, including the roles of glycoproteins in viral infection and cell–cell fusion. Lu et al. (2013) have used a confocal Raman microscope, along with chemometrics, to discriminate glycoproteins on the surfaces of virions and viruslike particles (VLPs) of Nipah virus (NiV). NiV is an

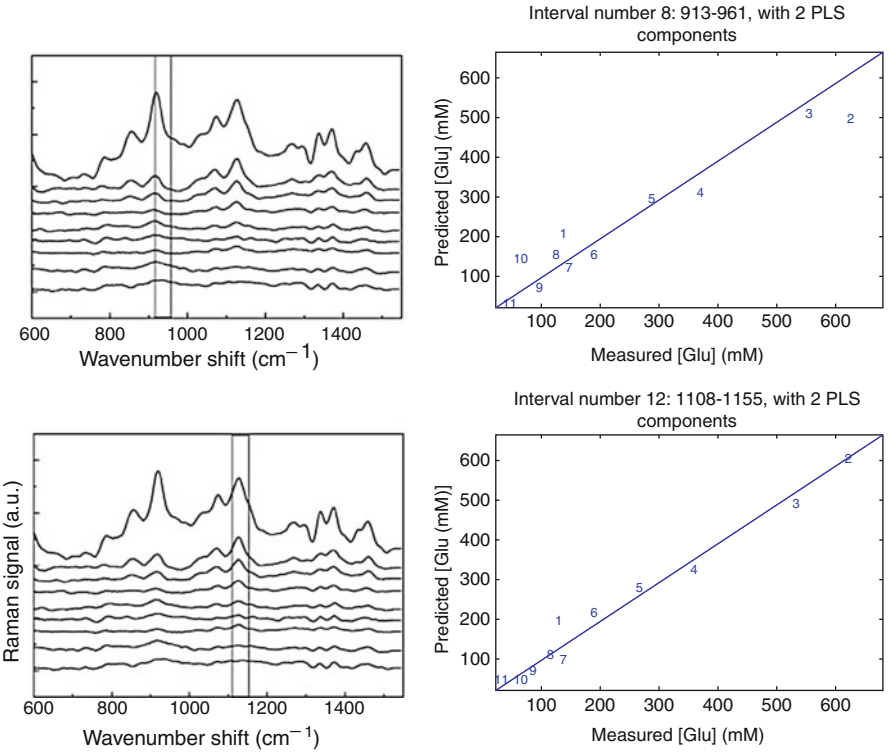

Fig. 11 Selected spectra intervals used in the iPLS model (*left panels*) for Raman spectra of solutions of different glucose concentrations with the corresponding predictions of concentration obtained using single spectral intervals (*right panels*, from 913–961 cm^{-1} (*top*) to 1,108–1,155 cm^{-1} (*bottom*)). Characteristic Raman marker bands for the α- and β-anomers are found at 919 and 1,128 cm^{-1}, respectively. *Numbers* represent the identities of individual measured spectra (Figure is taken from Delfino et al. 2011)

enveloped virus from the *Paramyxoviridae* family and zoonosis that is a disease that crosses species barriers and that causes severe illness in humans (encephalitis and respiratory disease) with a 40–75 % mortality rate and no approved therapy. Its relative aerosol stability and propensity for cross-species infection make NiV a potential bioterrorism agent and a priority pathogen for the National Institutes of Health and other healthcare authorities. In NiV, the F- and G-glycoproteins are required for membrane fusion during cell entry and pathognomonic cell–cell fusion. Figure 13 shows Raman spectra collected by Lu et al. for various NiV VLPs and pseudovirions expressing the F- and G-glycoproteins, as well as the matrix (M) protein.

A commonly used method for differentiating between similar Raman spectra such as those shown in Fig. 14 is to take the second derivative, with these derivatives being shown for NiV-M, NiV-G, and NiV-F in Fig. 14, panels (a) and (b). Second-derivative Raman spectra are very sensitive to differences in identity and

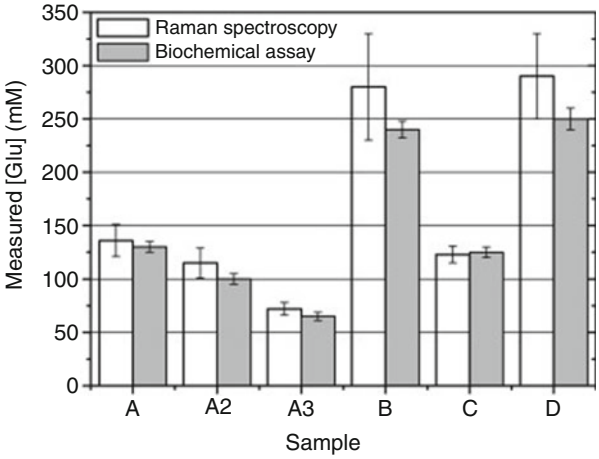

Fig. 12 Measured glucose concentrations for the investigated commercial beverage samples as obtained by iPLS analysis of Raman spectra, benchmarked against the enzymatic (biochemical) assays (Figure is taken from Delfino et al. 2011)

composition, and Lu et al. were able to utilize these for constructing a PCA model, shown in panel (c) of Fig. 14, which could clearly differentiate between the three VLPs based on the glycoproteins expressed. The rapid capability of Raman spectra to characterize viruses and identify structural changes makes it a viable real-time diagnostic technique for virology and vaccine development.

Raman spectra are sensitive to the specific vibrational modes that characterize changes in the structure of biomolecules, so making it an increasingly important biophysical technique. An example of this is presented here from the Lu et al. paper in Fig. 15, where they used the second derivatives of the measured Raman spectra in order to increase spectral sensitivity and remove the effects of baseline variations. Panels (a–c) display characteristic spectral changes induced by receptor binding to the F- and G-glycoproteins attached to the NiV pseudovirions. The authors suggested that they were probably monitoring the formation of a prehairpin intermediate. Note that no conformational change occurs in panel (d), and the two traces overlap perfectly. This work illustrates both the applicability of Raman spectroscopies to studying large biomolecular complexes, such as virions, and the sensitivity of specific marker bands to conformational changes, in this case in glycoproteins.

8 Studies on Carbohydrates Within Living Cells

Raman spectra can also be readily obtained from living single cells, such as bacteria and yeast, using microscope systems. Standard methods used for monitoring the uptake and metabolic flux of nutrients, such as sugars, typically involve isotopic labeling combined with biophysical methods such as chromatography or mass spectrometry. These approaches are complex and time-consuming and require bulk cell populations and experiments performed on cell extracts, so potentially losing information about the effects of cellular variation and dynamics.

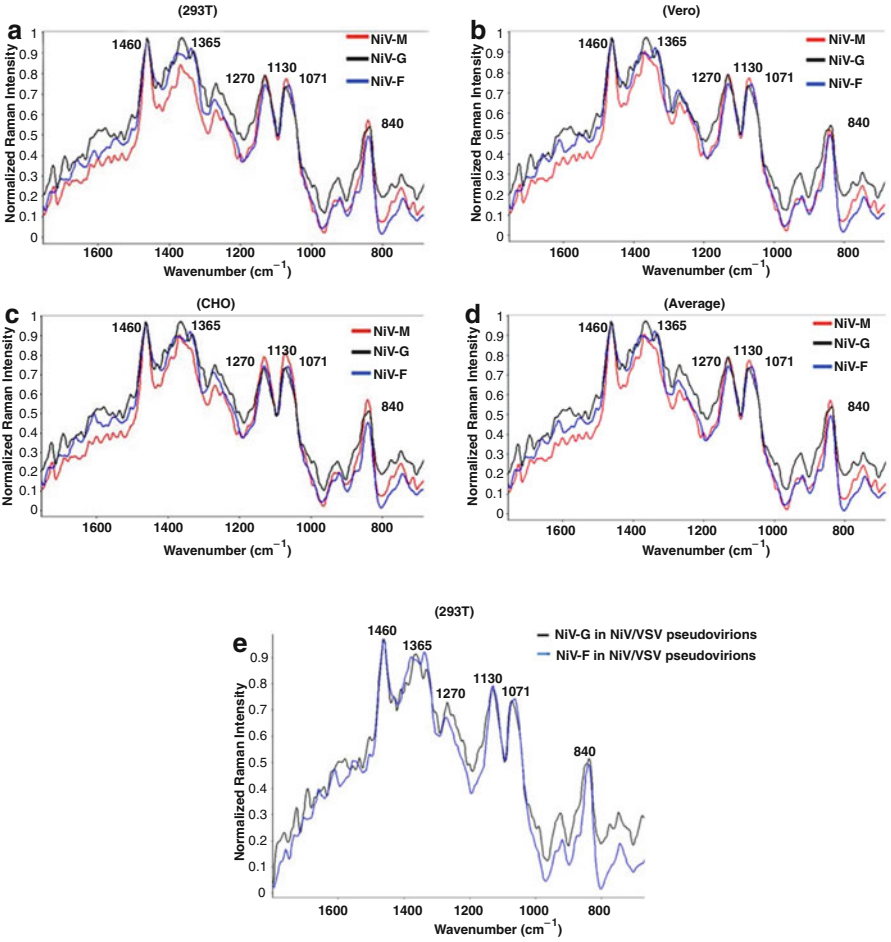

Fig. 13 Raman spectral features of M-, F-, and G-proteins on NiV VLPs cultivated in three different cell lines (panels **a**–**c**), the average of VLP signals produced from three distinct cell cultures (panel **d**), and NiV-G and NiV-F spectra from pseudovirions (panel **e**) (Figure is taken from Lu et al. 2013)

While fluorescent labels and stains can reveal useful information about sugar uptake and metabolism, this approach introduces potential problems due to the size and chemistry of exogenous fluorophores affecting the structure and behavior of the investigated biomolecules, issues of inhomogeneous expression and distribution, as well as photobleaching reducing signal intensity and reproducibility. The ability of Raman microscopy to measure detailed chemical and structural information from intrinsic vibrational motions of carbohydrates, without the requirement of a fluorescent label being added, makes it a more widely applicable and label-free probe of carbohydrate biochemistry in living cells. A recent demonstration of this can be found from the work of Avetisyan et al. (2013). This group used laser

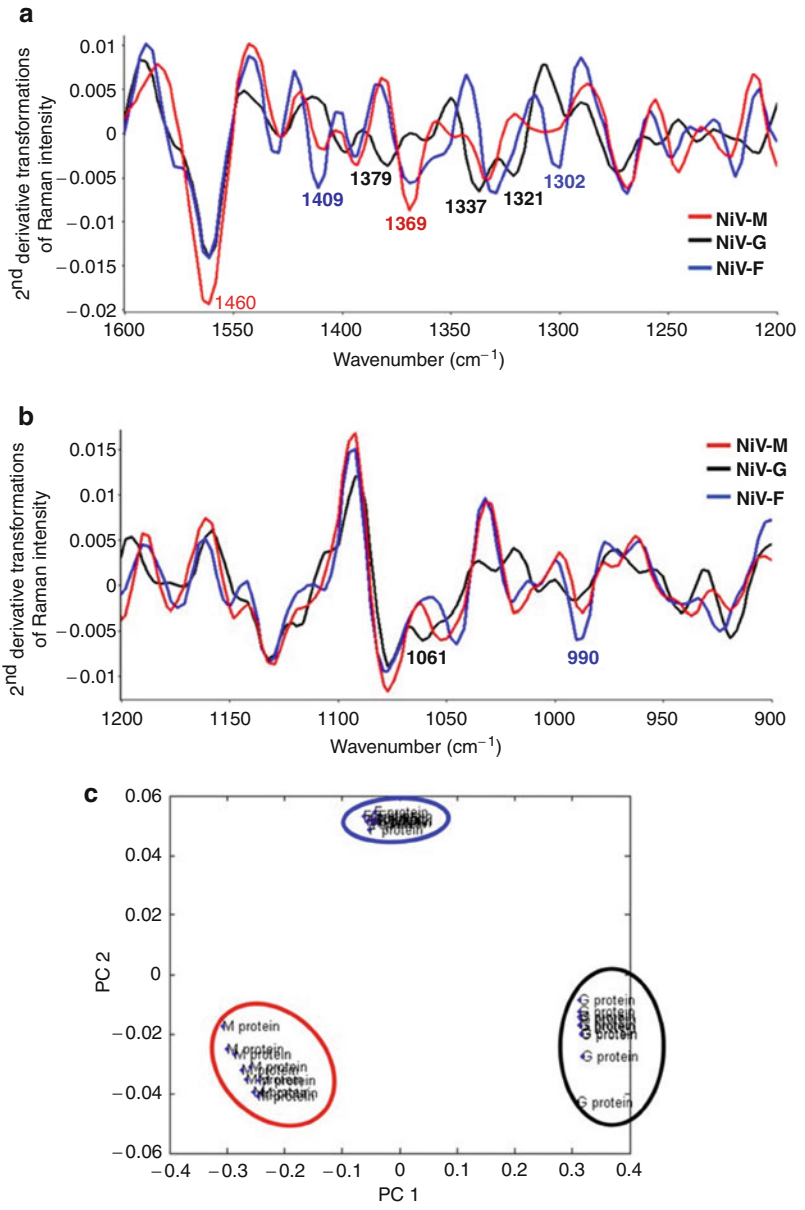

Fig. 14 Second-derivative analyses of Raman spectral features showing specific M, F, and G spectral peaks. Panel (**a**) shows the second-derivative transformation of Raman spectra (1,500–1,200 cm^{-1}) of the M-, F-, and G-proteins on NiV VLPs (from the *Vero cell line*). Panel (**b**) shows the same as for panel (**a**) but for the range of 1,200–900 cm^{-1}. Panel (**c**) shows a representative PCA classification model established and cross-validated to differentiate NiV proteins (*n*_4), with data points being circled as *blue*, F-protein; *black*, G-protein; *red*, M-protein (Figure is taken from Lu et al. 2013)

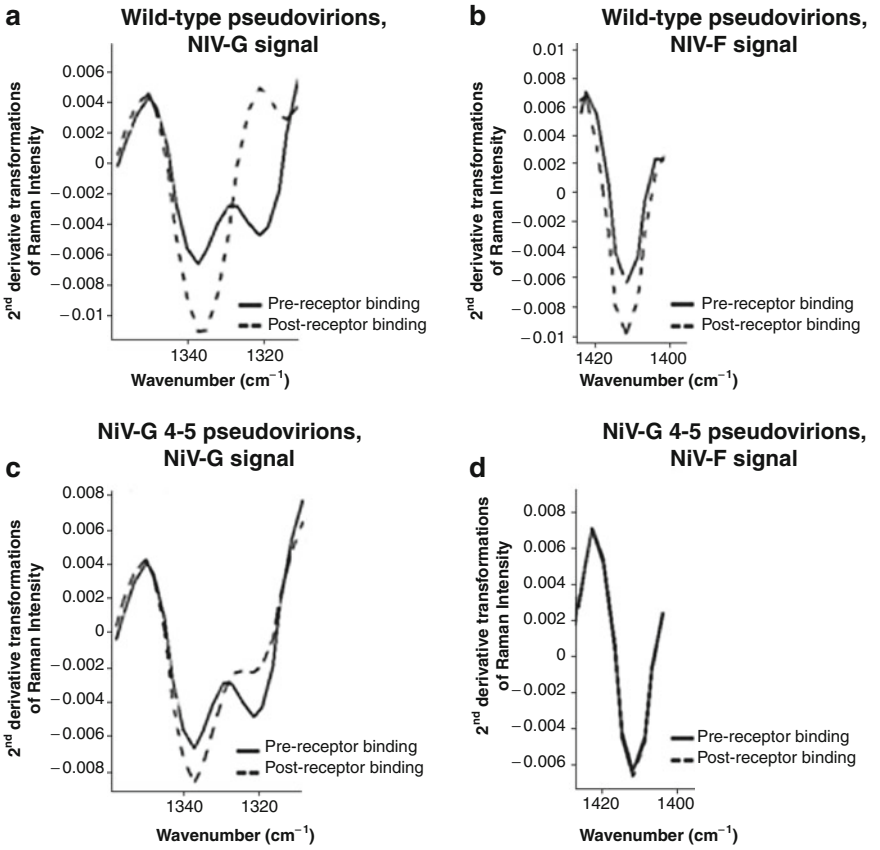

Fig. 15 Examples of Raman spectral changes (from the second derivative) corresponding to receptor-induced conformational changes in the NiV-F and NiV-G-glycoproteins. In panels (**a**–**c**) conformational changes are monitored but not in panel (**d**) (For specific details of these experiments please refer to Lu et al. 2013)

tweezers to isolate and localize single *Sinorhizobium meliloti* cells, a soil bacterium, and then collected Raman spectra at 785 nm to investigate the uptake of trehalose. This approach is also referred to as laser tweezers Raman spectroscopy (LTRS).

Figure 16 shows the sensitivity of Raman spectra to a small chemical difference in the disaccharide trehalose, in this case substitution of a single hydroxyl with a carbonyl moiety. Through following such changes in characteristic marker bands, Avetisyan et al. could monitor uptake and metabolism of trehalose by individual *S. meliloti* cells, as is shown in Fig. 17. Although care must be taken to minimize the risk of photodegradation, the use of longer-wavelength lasers (in this case 785 nm) and short spectral acquisition times (as low as 10 s in this study) can achieve this. The authors were able to quantitatively follow the metabolism of trehalose in situ, determining that intracellular concentrations of the disaccharide were an average of

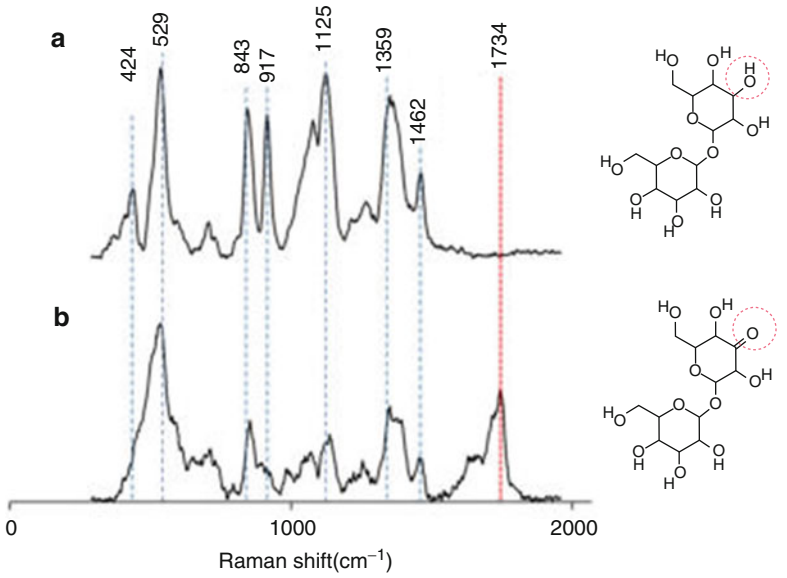

Fig. 16 Chemical structures (*right*) and Raman spectra (*left*) of a 5 % (w/v) aqueous solution of trehalose (*A*) and 3-ketotrehalose (*B*). Significant spectral differences are observed between the two closely related sugars, such as the carbonyl stretching vibration at 1,734 cm^{-1} distinguishing 3-ketotrehalose from trehalose. Key Raman peaks are labeled (Figure is taken from Avetisyan et al. 2013)

22 mM but varied from 18 to 65 mM. As the authors point out, their approach could be readily adapted for studies on carbohydrate metabolism, utilization, or production in a wide range of microorganisms.

Raman imaging is now a widely used technique in biomedical and materials research as it allows the direct visualization of the chemical complexity of surfaces and living material. To date, there have been few developments in the imaging of carbohydrates, but one relevant paper is that of Åkeson et al. who used coherent anti-Stokes Raman (CARS) spectroscopy to image both glucose fluxes in lipid bilayer vesicles and the metabolic responses to a glucose pulse by living yeast cells (Åkeson et al. 2010). Examples of their results on yeast cells are shown in Fig. 18, with a specific Raman vibration at 2,870 cm^{-1} being used to generate the images. For readers new to Raman spectroscopic imaging, please refer to more extensive reviews of this topic, e.g., Dochow et al. (2011), Chan (2013), Diem et al. (2013), Galler et al. (2014), Xu et al. (2014), but the key conceptual difference to fluorescence imaging is that in the various Raman imaging techniques images of a picture or map can be generated using any of the spectral marker bands measured. In this way, the chemistry of the sample, or changes in its chemical profile, is directly observed and spatially resolved, providing a powerful means to investigate the biochemistry of living cells and tissues in situ and in real time. In this case, Åkeson et al. were able to probe metabolic changes throughout all regions of a living cell induced by the glucose pulse.

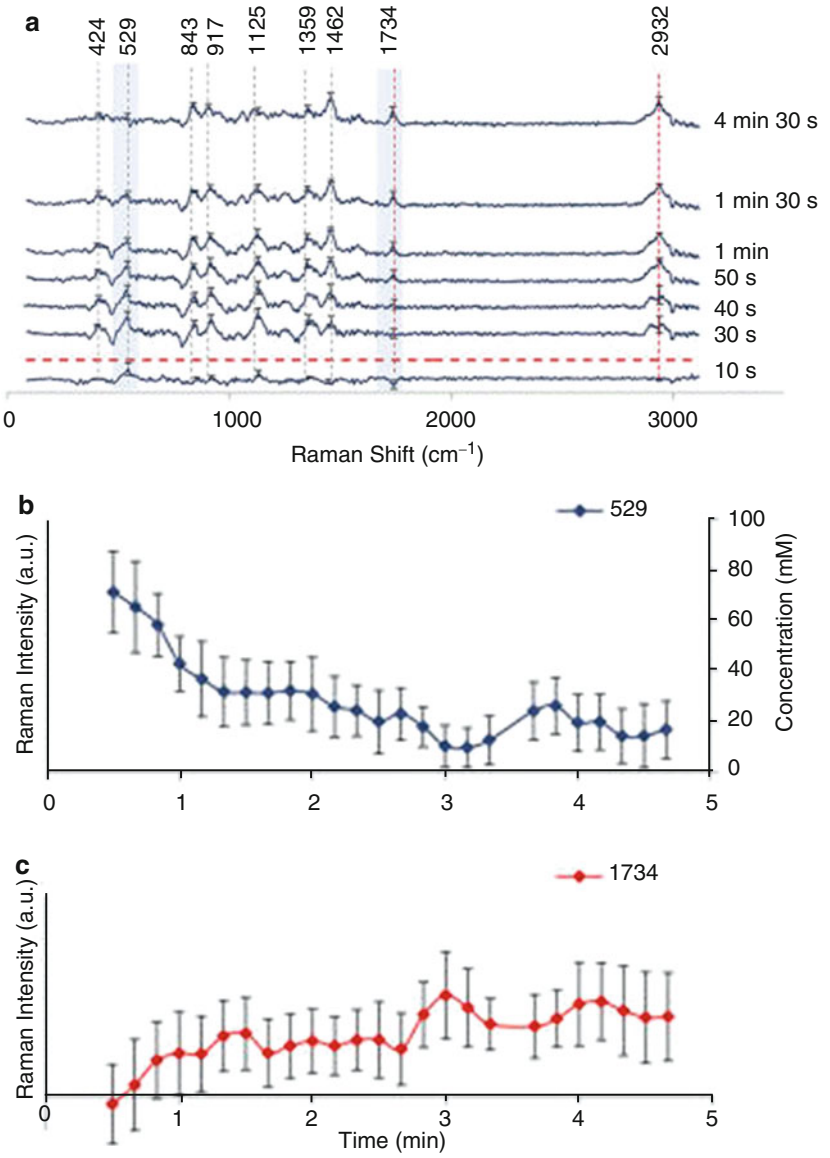

Fig. 17 (**a**) Time dependence of trehalose uptake and metabolism in single *S. meliloti* cells. Spectral average with standard error represents three different cells. Note that the acquisition time for each spectrum was 10 s (excitation power of 30 mW at 785 nm). Data are presented as continuous acquisitions of a single cell for 4 min and 30 s where the initial cell spectrum, i.e., at $t = 0$ s, was subtracted. *Dashed gray* and *red lines* show the peaks present and absent in the trehalose standard, respectively. Decrease of the peak at 529 cm^{-1} and appearance of the band at 1,734 cm^{-1} are due to conversion of trehalose to 3-ketotrehalose. The intensity changes of peaks occurring from 30 s to 4 min and 30 s with standard errors ($n = 3$) are presented in (**b**), for peak at 529 cm^{-1}, and (**c**) for peak at 1,734 cm^{-1}) (Figure is taken from Avetisyan et al. 2013)

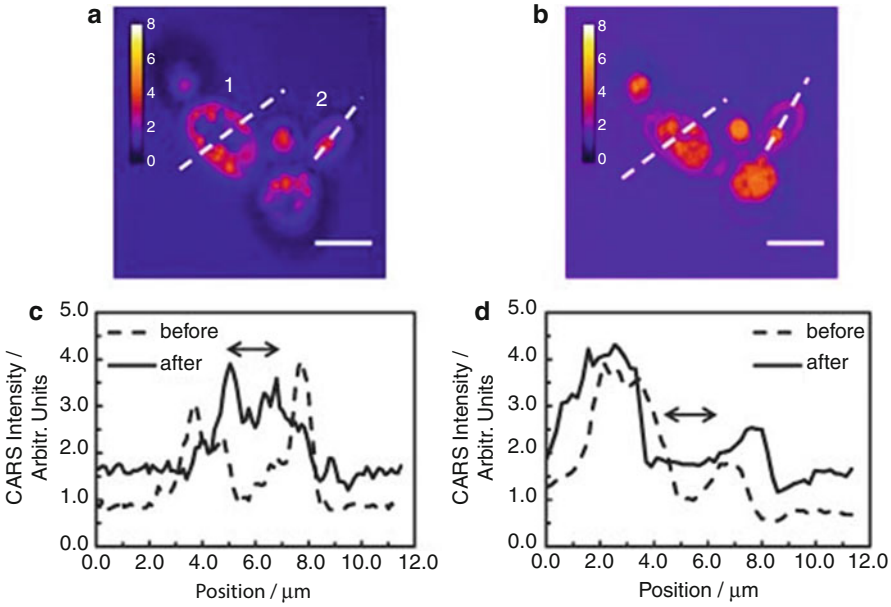

Fig. 18 CARS images (from the band at 2,870 cm^{-1}) of yeast cells before (**a**) and after (**b**) glucose addition. For the cells labeled *1* and *2*, the accompanying intensity profiles corresponding to the *dashed white lines* are shown in (**c**) and (**d**), respectively. After addition of glucose, increased CARS signals are observed both in the surrounding medium and within the cells. In addition, reduced cell size and a redistribution of organelles can be observed. The *horizontal arrows* above the graphs highlight the cytosol regions in the cells, characterized by higher CARS signal after addition of glucose compared to before. Image size is 25 × 25 µm (scale bar 5 µm), integration time 20 s (Figure is taken from Åkeson et al. 2010)

9 Computational Raman and ROA Spectroscopies

As shown above, experimental Raman and ROA spectroscopies can offer a great insight into the structure of carbohydrates. While a large amount of important data can already be elucidated in these cases, an even greater understanding can be exposed from using quantum chemical simulations.

This area of spectroscopy is one where there is a useful complement between the experimentally obtained data and computationally simulated spectra. It is possible to determine structural features, assign absolute configurations, or obtain otherwise unavailable vibrational data and structural dynamics. While early ab initio calculations of Raman intensities date back to the 1970s (Janosche 1973), the first reported ROA calculations came as late as 1989 (Bose et al. 1989), and following several important advancements in theory (Liegeois et al. 2007; Ruud and Thorvaldsen 2009) and computing, it is now possible to routinely simulate spectra of small- to medium-sized molecules.

ROA spectroscopy is a very powerful chiroptical technique and due to its treatment of chiral molecules makes it particularly useful for analyzing carbohydrates. Although while the combination of calculated and experimental data makes this method ideally suited to study these molecules, especially in light of shortcomings of other structural biology techniques, there are very few publications in this area. This is in part due to the difficulty of carrying out accurate calculations. Carbohydrates exhibit strong solvent effects requiring accurate treatment of water as well as exhibiting high conformational flexibility, meaning multiple calculations are needed to simulate the conformational dynamics. With these complications, the calculations can be computationally expensive, with full quantum simulations usually difficult on molecules larger than a few monosaccharides.

The computational treatment of carbohydrates using ROA spectroscopy is still very much an up-and-coming field, and as such much of the work referenced within this section focuses on understanding the structure of monosaccharides, and no work has been reported on larger molecules. As such the higher-order structure of carbohydrates has yet to be explored in this way. However, with refinements to the techniques, it is possible to get very accurate representations of experimental spectra with future aims to increase the size and scope of the research being carried out in this area.

9.1 Calculation of Raman and ROA Spectra

When carrying out the calculation of Raman and ROA intensities, it is important to use a suitable method and basis set. The early reported calculations utilized Hartree–Fock or multi-configurational self-consistent field methods with relatively small basis sets, and due to computational constraints at the time, only very small molecules could be studied (Polavarapu 1990; Barron et al. 1991a, 1992; Helgaker et al. 1994). Advancements in the theory as well as computation mean that DFT methods are now considered the standard in this area, and as such several benchmark studies have been carried out to find the most suitable functional and basis sets.

Early benchmark studies examined the importance of the basis set used for calculation of ROA. Pecul and Rizzo found that diffuse functions are an essential part of the basis set (Pecul and Rizzo 2003), and a more rigorous investigation by Zuber and Hug yielded a highly rarefied basis set called rDPS, constructed from 3-21++G with semi-diffuse p functions on all hydrogens that offered excellent results for ROA intensities when compared to much larger basis sets (Zuber and Hug 2004). In the basis set studies, Reiher et al. (2005) also examined the DFT method needed, finding that generalized gradient approximation and hybrid methods perform to a similar level, and both outperform local density approximation methods. In general several DFT functionals show potential but one of the most suitable choices is that of B3LYP, which exhibits a reasonable compromise between accuracy and cost (Ruud et al. 2002).

The most recent benchmark study published by Cheeseman and Frisch examined not only the basis set requirements for calculation of ROA and Raman intensities but also the requirements for optimization and calculation of the force field (Cheeseman and Frisch 2011). There are two different algorithms that can be used for simulation of the spectra: the one-step algorithm, where the force field and ROA invariants are calculated at the same level of theory, and the two-step algorithm, where the force field and ROA invariants are calculated at different level of theories. The authors offer suggested schemes for calculations of differing size systems; for small systems, the one-step procedure can be used, and the basis sets aug-cc-pVDZ and aug(sp)-cc-pVDZ are ideal. The two-step procedure however is more efficient and as such offers the ability to carry out calculations on larger systems. The recommend basis sets for medium to large systems are a combination of cc-pVTZ or 6-31G* with aug(sp)-cc-pVDZ or rDPS for the calculation of the force field and ROA tensors, respectively.

As mentioned above, the calculation of ROA spectra can be very time-consuming and computationally expensive, and as such calculations are limited to small- to medium-sized systems, meaning it can be difficult to get information about higher orders of structure of carbohydrates. To be able to expand calculations to larger systems, further approximations need to be made, and several have been suggested (Luber and Reiher 2009a; Ghysels et al. 2007) with one of the most popular being the Cartesian coordinate tensor transfer (CCT), proposed by Bour et al. (1997). This approach aims to calculate property tensors for large molecules by using values of overlapping smaller fragments. While some errors have been reported for this approach (Yamamoto and Bour 2011), it offers the scope of getting a greater structural understanding of larger carbohydrate molecules.

Due to the strong solvent effects that carbohydrates undergo, it is important to include an aqueous environment within calculations. There are three approaches that can be used to fulfill this: implicit solvent models, a small number of explicit solvent molecules treated at the quantum level, or a large number of explicit solvent molecules in a hybrid quantum mechanical/molecular mechanical (QM/MM) treated with a force field method. Implicit solvent models are the cheapest computationally but are also the least accurate by only modeling solvent as a dielectric continuum and foregoing any interactions with the solute. A small number of explicit solvent molecules are a more accurate approach and can be used alongside implicit models, but this approach fails to show information about solvation layers as a whole. The hybrid QM/MM approach is likely the most suitable when studying carbohydrates as it allows water molecules numbering in the hundreds to be included in simulations, and therefore multiple solvation shells can be included.

9.2 Structural Investigation of Carbohydrates Using ROA Spectroscopy

The first reported computational ROA study of carbohydrates was carried out by Macleod et al. (2006) who studied hydrated and isolated glucose, galactose, and

lactose in the gas phase and in aqueous solution. In experimental measurements of Raman and ROA spectra in aqueous solution at 298 K, infrared ion-dip spectroscopy was conducted at low temperatures. Gas phase calculations of the low-lying conformational structures, at the B3LYP/6-31+G* level of theory, were used to give sets of computed spectra, which in turn were used to create weighted sums in an attempt to approximate the experimental spectra recorded in solution. These calculations were compared with estimates based upon NMR measurements as well as molecular mechanics and molecular dynamics simulations (MD), giving results deemed surprisingly successful. The singly hydrated complexes of the two monosaccharides studied showed altered conformational preferences in the gas phase experiments, which were sustained in aqueous solution. These results supported the view that explicit hydration has a strong influence on aqueous phase conformations.

Luber and Reiher calculated the Raman and ROA spectra of the carbohydrate molecule 1,6-anhydro-β-D-glucopyranose (Luber and Reiher 2009b), to offer a deeper insight into an earlier published experimental ROA spectrum (Barron et al. 1991b). Boat and chair conformations of the monosaccharide were studied as well as rotamers arising from the three hydroxyl groups, giving rise to 54 conformers. These calculations exhibited the great sensitivity of ROA by showing large variations of peak intensity between rotamers. The need for solvent in calculations was treated in two ways, the implicit solvation model COSMO was used initially, and then the molecule was explicitly hydrated using several water molecules. The implicit model gave rise to minor alterations in ROA bands, but the inclusion of explicit solvent resulted in a markedly different spectrum, showing the large effect hydrogen bonding can have on the results. Final spectra were constructed by weighting individual conformers using three approaches: electronic energies, Gibbs free energies, and no weighting. The agreement with experiment was good for all types of weighting; however, it was noted that on the route to better experimental agreement, combined MD and QM/MM approaches would offer better prospects at modeling solvent effects and conformational dynamics.

Kaminsky et al. (2009) used Raman and ROA calculations coupled with MD simulations as well as the CCT transfer technique to interpret the experimental spectra of a sugar derivative, the gluconic acid anion. This linear carbohydrate exhibits large conformational flexibility due to ten dihedral angles that if carrying out mapping of the conformational space at 120° intervals would result in close to 60,000 conformers, an unfeasible number to be able to calculate a spectrum for each. To circumvent this, the authors carried out MD simulations to get a 1,000 structures and took a small sample of geometries from these simulations and calculated force fields, polarizability, and optical activity tensors at the B3LYP/6-31 + G**/CPCM level of theory. The CCT transfer technique was used with the DFT-calculated results to generate a spectrum from the MD library that reproduced most of the experimental features. It is also noted that despite a high level of spectral averaging, it is still possible to identify characteristic vibrational normal modes such as C–H and O–H bending.

One of the more recent publications in this field by Cheeseman et al. (2011) shows the future potential of the Raman and ROA calculations of carbohydrates,

by incorporating MD simulations with explicit solvation alongside QM/MM calculations. Studying the monosaccharide methyl-β-D-glucose, a selection of MD snapshots was used as the starting point for ONIOM calculations, where optimizations and force field calculations were carried out at the B3LYP/6-31G* level of theory for the monosaccharide and AMBER for the water. Calculation of Raman and ROA tensors was carried out at the HSEH1PBE/rDPS level of theory for the monosaccharide and AMBER for the water, using the two-step procedure. By incorporating the conformational dynamics and explicit solvation from the MD simulations with the quantum calculation of the ROA spectrum, excellent agreement with experiment is achieved, especially when compared to gas phase or implicit solvent calculations of the same molecule. The authors also note that this combined approach solves problems associated with the inability to model the sensitivity of ROA spectra, and it surpasses all previous approaches to include hydration in these calculations.

9.3 Structural Investigation of Carbohydrates Using Raman Spectroscopy

Due to the chiroptical nature of ROA, it makes it particularly useful in the study of carbohydrates particularly when combined with calculations, much more so then the non-chirally sensitive analogous technique Raman spectroscopy. As such there is also a lack or reported research using only Raman spectroscopy, with the only publications occurring only in the last few years.

Brizuela et al. (2012) reported one of the first examples of using computational modeling of Raman spectra to study carbohydrates in 2012, by offering a complete characterization of the Raman and FTIR spectra of the disaccharide sucrose in the solid state. They had a particular interest in structural properties including bond order, charge transfer, and topological properties of the monosaccharide rings studied using DFT calculations, natural bond orbital (NBO) analysis as well as atoms in molecules (AIM) analysis. Calculations at the B3LYP/6-31G* and B3LYP/6-311++G** levels of theory gave results that were in good agreement with experimental data and resulted in a complete assignment of the normal vibrational modes of this molecule.

A similar study to the one presented above was also carried out by Brizuela et al. (2014) on sucrose but in an aqueous medium instead of the solid phase. Self-consistent reaction field calculations were used to model the presence of solvent, and full assignment of the normal vibrational modes was achieved as well as confirming the presence of pentahydrate and dihydrate sucrose species in aqueous solution.

Quesada-Moreno et al. (2013) studied the conformational preference of the carbohydrates D-ribose and 2-deoxy-D-ribose in the aqueous and solid phase. Experimentally IR and Raman measurements were taken as well as another chiroptical technique, vibrational circular dichroism (VCD). Calculations at several levels of theory were used in this study, including MP2, B3LYP, and M06-2X, with the PCM implicit solvation model and in some calculations

a single explicit water molecule. The combination of the two approaches allowed the dominant configurations of the carbohydrates in question to be elucidated as well as discovered that for 2-deoxy-D-ribose, there are different conformer populations between solution and the solid phase.

9.4 Guidelines for Raman and ROA Calculations of Carbohydrates

In calculation of Raman and ROA spectra, several things need to be taken into account. Choice of method and basis set is important, as already shown above, but it is also important to account for the presence of all important conformers, especially when carrying out calculations on carbohydrates that exhibit high conformational flexibility.

Firstly, the structure of the molecule of choice must be constructed, and then a search of this molecule's conformational space must be undertaken. This can be carried out in several ways, such as manually exploring the angular degrees of freedom of the molecule. Although this approach is more suitable for small rigid molecules than carbohydrates, as such a better approach would be to use MD simulations, which also offers the advantage of being able to include explicit solvent molecules. The MD trajectories can then be used to obtain snapshots as starting points for Raman and ROA calculations as well as giving conformational population analysis.

Selected snapshots are used as starting points for optimization and these optimized structures are used for calculation of the force field and Raman and ROA intensities. Spectra can be plotted from these intensities using Lorentzian or Gaussian curves with ranging half-peak widths, although for most applications 10 cm^{-1} is recommended. The spectra of the individual snapshots can then be used to create a final spectrum be carrying out weighted averages, either based on Boltzmann distributions or using the population analysis from MD simulations. These computationally obtained spectra can then be compared to experimentally obtained data (Fig. 19).

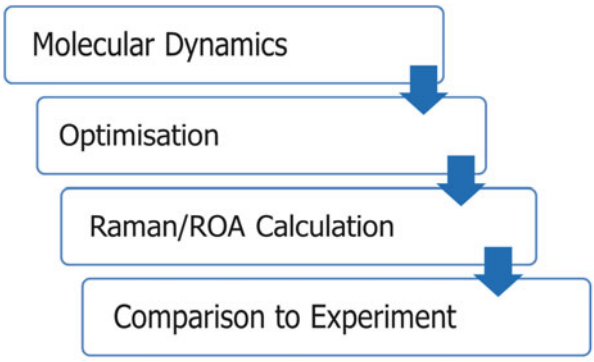

Fig. 19 Scheme showing the approach for the calculation of Raman and ROA spectra of carbohydrates

10 Conclusion

Carbohydrates present, arguably, the greatest challenge for structural biology today, not least because of their flexible natures and their heterogeneous compositions (in the case of glycoproteins) or limited complexity sequences (a significant issue for NMR studies on glycosaminoglycans). Raman spectroscopies now comprise a highly adaptable toolkit of analytical techniques that are able to provide detailed information about carbohydrates, their structures and behavior. The ability to collect such information noninvasively from environments as disparate as living cells, bioreactors, and foodstuffs can allow Raman spectroscopies to make a significant impact in glycobiology, not only in research but also in the industrial and biomedical sectors. Although this review has presented examples from a number of Raman techniques (Raman microscopy, SERS, ROA, CARS), this is not an exhaustive list, and other Raman methods are likely to prove valuable in the future. For example, the capability of tip-enhanced Raman (TERS) (Bailo and Deckert 2008) to combine the chemical sensitivity of Raman with the site specificity of atomic force microscopy has already created great interest for studies on proteins and nucleic acids (Kurouski et al. 2012; Rasmussen and Deckert 2006). The potential of TERS to provide detailed site- or region-specific information about the glycosylation patterns of individual glycoproteins would open new opportunities for researchers of these important but poorly understood systems. As we have discussed, Raman spectroscopy can be readily combined with other technologies, and hyphenated variations in the form of a single instrument package, such as Raman-mass spectrometry, are likely to prove useful in this field in the future. In parallel with technological developments, it is also likely that chemometrics will become a routine data processing step due to the already demonstrated ability of both clustering and regression algorithms to extract information about carbohydrates of any form. The many modeling tools being developed for systems biology are well suited to mining the rich detail of carbohydrate Raman spectra. Finally, the exquisite sensitivity of quantum and molecular mechanics to the vibrational modes of molecules can provide the atomic resolution level of understanding that we currently lack for most carbohydrates.

We hope that this review provides our glycobiology colleagues with an insight into how the family of Raman spectroscopies can help them understand this fascinating class of biomolecules. We encourage them to contact their local Raman experts to explore the many opportunities available for doing some new and exciting science. And to our fellow Raman spectroscopists, the future is indeed looking sweet.

Contents

Abstract

In view of the increase in global energy requirements, pyrolysis of lignocellulosic biomass gains significant impetus as a promising source of renewable energy and valuable chemicals. This pyrolysis oil is a complex mixture of simple organic, inorganic, and macromolecular compounds formed as a result of thermochemical breakdown of lignocellulosic biomass. It has high oxygen content and consequently a very low calorific value which renders it useless for fuel applications. As a result, appropriate upgrading is essential to make it a viable alternative to petroleum fuels. Analytical chemistry plays a key role in revealing compositional important information and helps in developing molecular-level understanding. Bio-oil production and upgrading research aimed at building up of commercial production and refining units concerns monitoring of quality and stability of initial and final products which rely strongly on analytical approaches. In the ensuing discussion, fundamental and practical aspects of

1 Introduction

Energy requirements across the globe are incessantly increasing due to fast growths in population and economies especially in China, India, Latin America, the Middle East, and Russia. Extensive use of fossilized organic substances such as coal, oils, and gases for energy generation and production of chemicals has resulted in massive carbon dioxide generation which is responsible for global climate change. Fast-expanding transportation sector demands huge energy which is currently met through fossil fuels. Power generation heavily relies on either coal or natural gases in large parts of the developed as well as developing world. Diminishing geological reserves and grave environmental concerns have necessitated the exploration of new and renewable sources of energy (Sorrell et al. 2010). One such approach is the conversion of biomass to biofuels and chemicals through thermal degradation in an integrated refining process (Ragauskas et al. 2006).

As shown in Fig. 1, biomass is the most abundant and renewable source from which fuels and chemicals may be obtained in reasonable yields, shorter span, and ecological and environmentally friendly manner. First-generation biofuels essentially comprise ethanol which is produced from edible biomass such as food grade agricultural produce and crops. Carbohydrates (sucrose, starch, cellulose, etc.) undergo microbial fermentation to give bioethanol, and this technology is quite ancient. Nowadays bioethanol is a very popular biofuel worldwide especially in Brazil and the USA where its blending of up to 25 % in gasoline is prevalent. Bioethanol production and consumption statistics in terms of cost, feedstocks, plant operational variables, and manufacturing processes has been reviewed (Demirbas 2011). Ethanol can be used in gasoline-driven engines in the form of blended fuel in any proportion. Although ethanol has lower calorific value than hydrocarbons, its high octane rating is used to increase the octane rating of gasoline which is an important parameter for petrol-powered engines. The limitation associated with ethanol use as fuel or a replacement of gasoline is its production from food grade crops and high cost in current scenario where gasoline is available. In addition, its low energy content requires larger fuel tanks as compared to conventional fuels, and water solubility leads to corrosion of engine parts. Butanol has promising potential for being utilized in fuel applications due to higher energy density and lesser water content. Biosynthesis of butanol was carried out through ABE

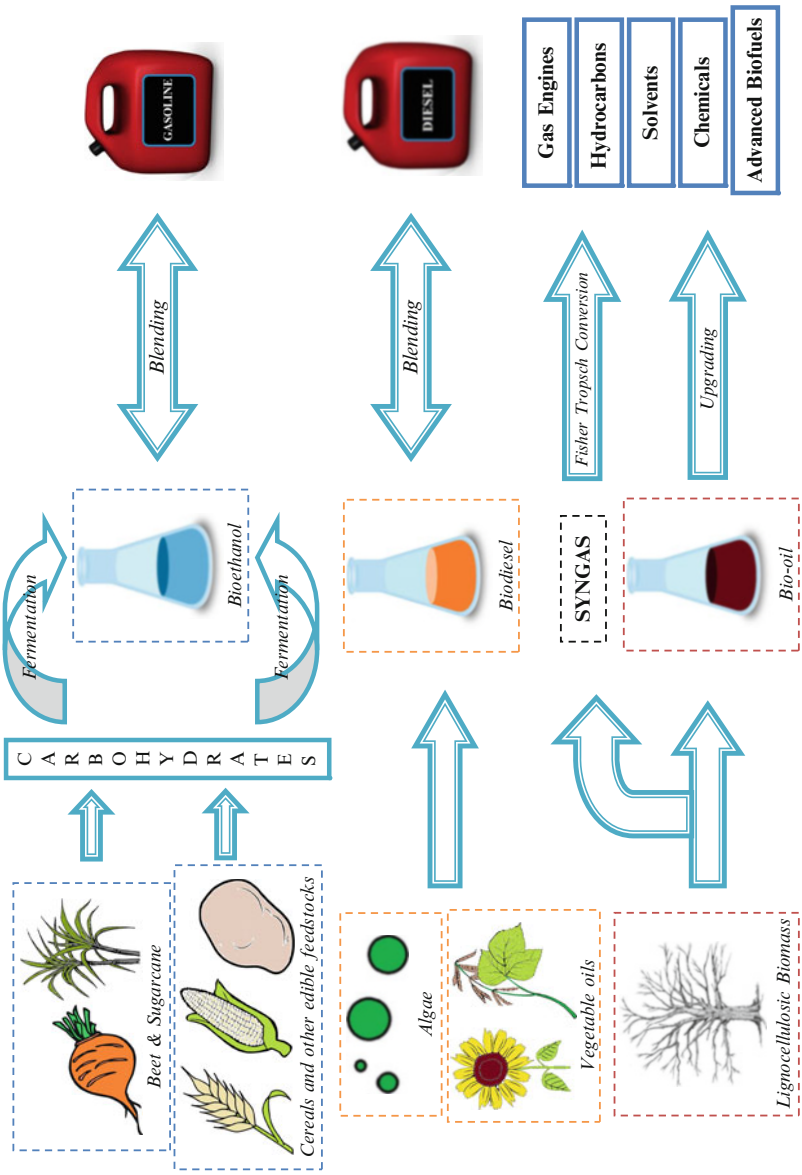

Fig. 1 Schematic presentation for the utilization of biomass to biofuels and other value-added products through pyrolysis

(acetone–butanol–ethanol) with the help of bacterium from *Clostridium* species; however, the process was abandoned commercially after the 1960s. Recently, microbial fermentation of substrates of sustainable origin to produce higher alcohols, short-chain alkanes, free fatty acids, fatty esters, and fatty alcohols as gasoline substitutes has been explored by several scientists (Atsumi et al. 2008; Choi and Lee 2013). First-generation biofuels also comprise biodiesels and green diesels which have gained popularity due to their close similarity with conventional diesel. Biodiesel is readily obtained from oils or fats of plant or animal origin through transesterification. It is primarily composed of methyl esters (or some ethyl), fatty acids (if derived from vegetable oils), and triglycerides of fatty acids (if derived from animal fats such as tallow or lard). Biodiesel is nontoxic, biodegradable, and used as diesel additive to reduce levels of particulates and other toxic emissions (Ma and Hanna 1999). Essential feedstocks for biodiesel production are animal fats, soybean, sunflower, rapeseed, corn, cottonseed, palm, *Jatropha*, *Pongamia*, algae, and many more.

In contrast, second-generation biofuels or advanced biofuels are derived from abundant, renewable, and nonedible biomass comprising wood and agricultural residues broadly called as lignocellulosic biomass. Throughout the human evolution, lignocellulosic biomass has been extensively exploited as a primary renewable energy resource. By the end of the eighteenth century, fossilized energy sources started replacing biomass utilization as a result of increased urbanization, industrialization, and improved lifestyles. Mitigation of environmental pollution, global warming, and other limitations associated with fossil fuel use requires biomass-based economical energy. At the beginning of the twentieth century, a large number of industrial materials such as solvents, dyes, fibers, etc. were obtained from wood biomass/trees and agricultural crops. By around the 1960s and after it, such products were readily obtained from petroleum. Biomass gasification is popular and pretty prevalent as it leads to the formation of *syngas* (also termed *producer gas*) in controlled conditions. It is an important development since the evolved gases may be utilized in several ways such as in gas engines to produce energy and in producing methanol or converted into synthetic fuel via Fischer–Tropsch process. Biomass gasification, however, is associated with the production of tar in variable quantities irrespective of the gasifiers utilized. Pervasive research in this area has improved our understanding and know-how related to chemical and physical properties of biomass and derived products. Engineering solutions were provided from time to time on the basis of outcomes from longitudinal observations which are considered necessary part of process development. Tars have either been recycled or disposed through fractionation or chemical and biological transformations. A simple illustration of the utilization of agricultural and plant biomass for biofuel production and other applications is presented in Fig. 1.

2 Pyrolysis and Lignocellulosic Biomass

Pyrolysis of wood biomass was known to ancient societies where tars and condensates were used for various applications. Ancient Egypt people used pyroligneous acid (wood vinegar) from hardwood as embalming fluids (Austin 1984). In the

olden times, pyroligneous acid was known for its strong sterilizing properties in addition to its widespread use as deodorizer, preservative, and flavoring substance. Since the early 1990s, it has also been used in agriculture as a fertilizer and growth-promoting agent. Wood pyrolysis liquids have always been considered as a wealthy source of essential oils and biopesticides. Detailed chemical characterization of products obtained after thermal decomposition of wood biomass remained unknown for quite some time. Later on fractionation and identification of liquid pyrolysis condensates aimed at developing refining methods were started with the use of available tools of analytical chemistry (Soltes and Elder 1981).

Lignocellulosic biomass is a promising renewable resource for biofuels and numerous value-added chemicals. Pyrolysis is a widely adopted process for the thermal breakdown of biomass feedstocks in the absence of oxygen which leads to the fragmentation of macromolecules and rearrangement of smaller reactive chemicals into stable molecules. The pyrolysis of biomass is either fast or slow and produces gaseous, liquid, and solid products (Goyal et al. 2008). The distribution of formed chemical species among the obtained products usually depends upon utilized feedstocks and pyrolysis parameters such as reactor, residence time, and employed temperatures. Before the middle of twentieth century, the liquid obtained as a result of thermal decomposition (i.e., partial oxidation, steam reforming, or pyrolysis) which is popularly termed *pyrolysis oils* or "*bio-oils*" was considered as an offshoot of these processes, and its uses were restricted to larger extent due to unavailability of efficient procedures of handling and utilization. On the contrary, biomass gasification had larger end use earlier due to the complex chemical composition of bio-oils. Despite several advantages and popularity, biomass gasification is accompanied with tar formation, loss of C–C bond, and eventually energy wastage (Bridgwater 2003). However, as the research progressed in this area, tremendous prospect of bio-oil utilization and upgrading into fuel and chemical production were realized. Major limitations associated with bio-oil utilization, handling, storage, transportation, and refining have been significantly surmounted.

Pyrolysis is a process of thermochemical decomposition of organic matter at high temperatures in the absence of oxygen that leads to changes in chemical and physical properties of the pyrolyzed substance. Pyrolysis of biomass yields bio-oil for which considerable efforts are being continuously put in to develop and improve the upgrading strategies to transform it into prospective engine fuel applications within an integrated bio-oil refinery. Energy content of lignocellulosic biomass feedstocks can be effectively and economically utilized in stationary energy applications such as boilers (or steam generators) in power plants and other utility sectors like commercial or domestic heating purposes. For all other energy requirements, especially fuel related, gaseous as well as liquid pyrolyzed products from lignocellulosic biomass have been explored and put forward. Pyrolysis also produces fuel gases and leads to four- to sevenfold concentration in energy density in bio-oils as compared to raw biomass. On the basis of employed temperatures, heating rates, and residence time, pyrolysis is broadly classified into three types, viz., slow, fast, and flash. The adopted procedure of pyrolysis and employed parameters extensively govern the quality and amount of formed bio-oil.

The demarcation between slow and fast pyrolysis is solely observed on the basis of employed heating rates and vapor residence times. In slow pyrolysis, vapor residence times vary from few minutes to half an hour, whereas in fast pyrolysis, extremely less time (<2 s) is employed. The heating rate in slow pyrolysis usually ranges between 0.1 and 1 °C/min^{-1}, and the pyrolysis temperature varies around 300–700 °C. In contrast, fast pyrolysis typically involves heating rates of 1,000 °C/s or more and pyrolysis temperature up to 1,000 °C. In slow pyrolysis, long vapor residence times inside the reactor provides opportunity to the gaseous products to react, rearrange, and stabilize, thereby producing considerable amounts of char.

During fast pyrolysis, fast heating rates facilitate the formation of small reactive chemical from thermolabile biomass constituents. The formed chemical species instantly condense as a consequence of short vapor residence time which maximizes yields of liquid. In a typical fast pyrolysis process, nearly 60–75 wt% of bio-oil is formed along with solid char and noncondensable gases (in almost equal proportions). The quantity of bio-oil, char, and gases is largely governed by the nature of biomass feedstock. Since the pyrolysis process takes place at fast pace, the reaction kinetics, high heat transfer, thermal stability, and phase separation of formed chemicals determine the overall product distributions. Among several pyrolysis processes, fluidized bed reactors and circulating fluidized bed reactors are efficient and easy to operate. Flash pyrolysis is an improved format of fast pyrolysis which utilizes very high heating rates, generally more than 1,000 °C s^{-1}, and lesser reaction times. In addition to the reactors used in fast pyrolysis, others such as vacuum pyrolysis, rotating cone, entrained flow, ablative, vortex, and twin screw reactors are widely used. However, entrained flow (fluidized bed) reactors are quite widespread.

Pyrolysis leads to significant thermochemical changes within biomass that always depends on how fast and efficiently thermodynamic equilibrium is achieved within a very small time scale. It also governs the chemical reaction kinetics during thermochemical transformations. During pyrolysis, heat is transferred to biomass which leads to the commencement of thermal breakdown of biomass constituents to release volatiles which move rapidly to the cooler region of the reactor and collide with unpyrolyzed biomass and may condense over it to form char. Shorter residence times also allow volatiles to move out and condense. The pyrolysis then proceeds autocatalytically to form other chemicals and intermediates simultaneously along with the formation of volatiles and gases. During the progress of pyrolysis, thermal degradation, rearrangement, dehydration, and so many other chemical processes take place. The biomass pyrolysis process is highly endothermic due to which several ways of transferring heat to biomass are in practice. Combustion of biomass is a process with poor energy generation leading to char formation. Prominent reactor designs which have been employed for biomass fast pyrolysis are based on fixed beds, entrained flow, augers, ablative, rotating cone, fluidized beds, and circulating and bubbling fluidized bed reactors. The pyrolysis of lignocellulosic biomass has been reviewed by several eminent researchers in this area (Bridgwater 1999, 2003, 2004; Bridgwater et al. 1999, 2001; Bridgwater and Peacocke 2000; Peacocke and Bridgwater 1996; Meier and Faix 1999; Vamvuka 2011; Mohan et al. 2006).

These reviews are very much informative and explore fundamental aspects of pyrolysis process, reactor designs, process scale-up, and commercialization. Wide-ranging biomass comprising agricultural and forest scrap have been extensively used for pyrolysis. These include barley straw and hulls, rice husk, wheat straw, corn plant (stalks, leaves, and husks), coconut shells, peanut shells, fruit pulps, woods (waste furniture, eucalyptus, pine, etc.), forage crops, tea waste, bagasse, and many more. In addition to the lignocellulosic feedstocks, sewage sludge, swine manure, and more interestingly waste plastic and printed circuit boards from used computers have also been utilized to produce pyrolysis oil. Algae being a rich source of energy owing to its higher photosynthetic efficiency than trees are a promising feedstock for bio-oils and valuable chemical (Amin 2009).

The lignocellulosic biomass is primarily composed of three major components: cellulose, hemicellulose, and lignin (Fig. 2). Other minor constituents of wood are fats, mucilage, wax, alkaloids, terpenoids, etc. The presence of substantial amount of oxygen in lignocellulosic biomass differentiates it from fossil fuels and significantly lowers its heating value. The proportion of the three major constituents differs from one species of wood to the other. The usual distribution of cellulose,

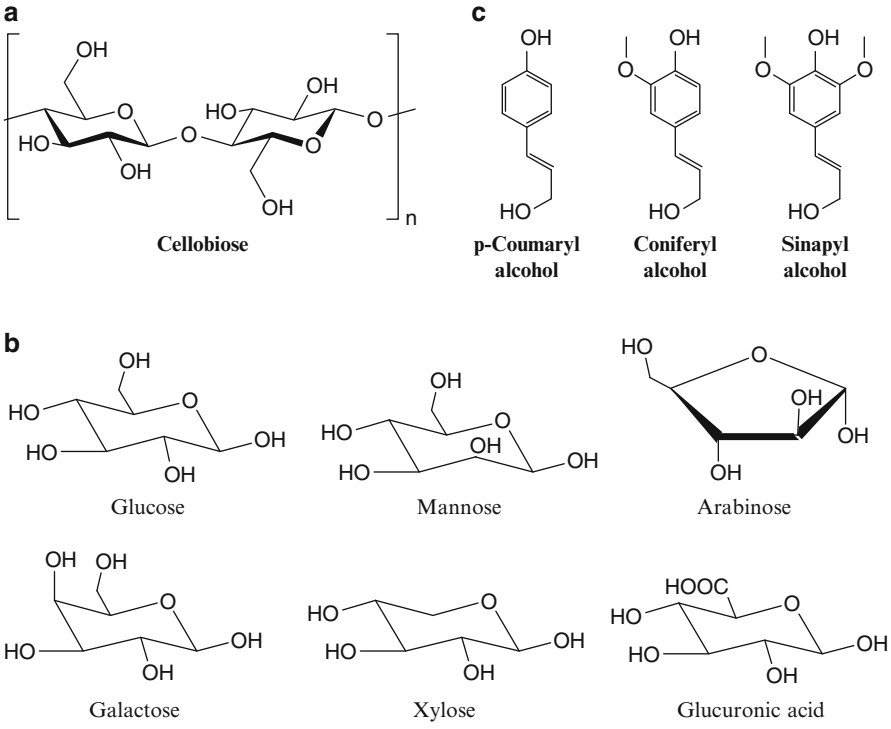

Fig. 2 Chemical structures of (**a**) cellulose, (**b**) hemicellulose monomers, and (**c**) lignin precursors

hemicellulose, and lignin across biomass samples (e.g., softwood, hardwood, straw, husk, stalk, leaves, etc.) roughly ranges between 24–51 %, 16–39 %, and 12–53 %, respectively (Demirbas 1997). Cellulose ($C_6H_{10}O_5$) is a polysaccharide and a prominent constituent of lignocellulosic biomass which is comprised of linear chains of β(1 → 4)-linked D-glucose units as shown in Fig. 2a. Cellulose is the most abundant organic polymer which is biosynthesized naturally and is typically present in cell wall of plants and many other organisms (e.g., algae). In angiosperms, cellulose is the chief component of reaction wood (tension wood). It has several important commercial applications like paper, textile fibers (cotton), filtration and chromatography (thin layer chromatography), conversion to biofuels, etc. Cellulose fibers provide mechanical strength to the wood and comprise considerable dry weight of wood. The fibrous nature of cellulose is due to long chains of glucose units bonded to each other by a long network of hydrogen bonds which exists within the same chain and also across several chains. Cellulose thermal degradation begins at around 240 °C and produces levoglucosan, levoglucosenone, furfural, substituted furans, and several other small molecules comprising aldehydes and ketones.

Hemicellulose is the second major constituent of lignocellulosic biomass and is composed through the combination of several monosaccharides as glucose, mannose, galactose, xylose, arabinose, 4-*O*-methyl glucuronic acid, and galacturonic acid residues. The chemical structures of important hemicellulose constituents (monomers) are shown in Fig. 2b. Unlike cellulose it has a random (branched), amorphous structure with little strength and consists of shorter chains (500–3,000 monosaccharide units) as compared to cellulose (with 7,000–15,000 glucose units). Hemicellulose pyrolysis occurs at temperatures ranging between 200 °C and 260 °C, leading to the formation of volatile organic compounds and smaller amounts of levoglucosan. Deacetylation of hemicellulose leads to the formation of acetic acid which is responsible for acidic nature of derived bio-oils. Lignin on the other hand is the third most abundant constituent of lignocellulosic biomass, and it is mainly concentrated in the compression wood in conifers. It acts as binder for cellulosic components and also provides protection against microbial damage. It is covalently linked to hemicellulose and acts as a strong cross-linker between plant polysaccharides, thereby imparting mechanical strength to the plant. Lignin has a very complex and highly branched chemical structure which contains phenolic, hydroxy-, and methoxy-substituted phenylpropane units. It plays a crucial role in the transportation of water across the plant through stems. During lignin biosynthesis, three common alcohols, viz., paracoumaryl, coniferyl, and sinapyl alcohols (Fig. 2c), undergo oligomerization and polymerization to give lignin whose structure varies depending upon the wood (hardwood and softwood). Lignin decomposes when heated above 280 °C, and its pyrolysis produces phenols and methoxyphenols of which monolignols (guaiacol and syringol) are prominent. Lignin is one of the major sources of phenol-containing species in bio-oils. The pyrolytic products originating from cellulose, hemicellulose, and lignins are schematically shown in Figs. 3 and 4.

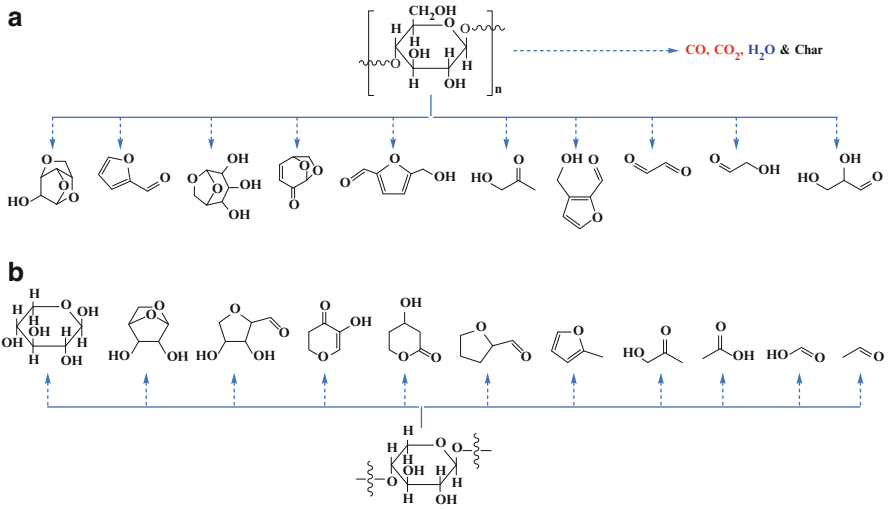

Fig. 3 Prominent pyrolytic products from (**a**) cellulose and (**b**) hemicellulose

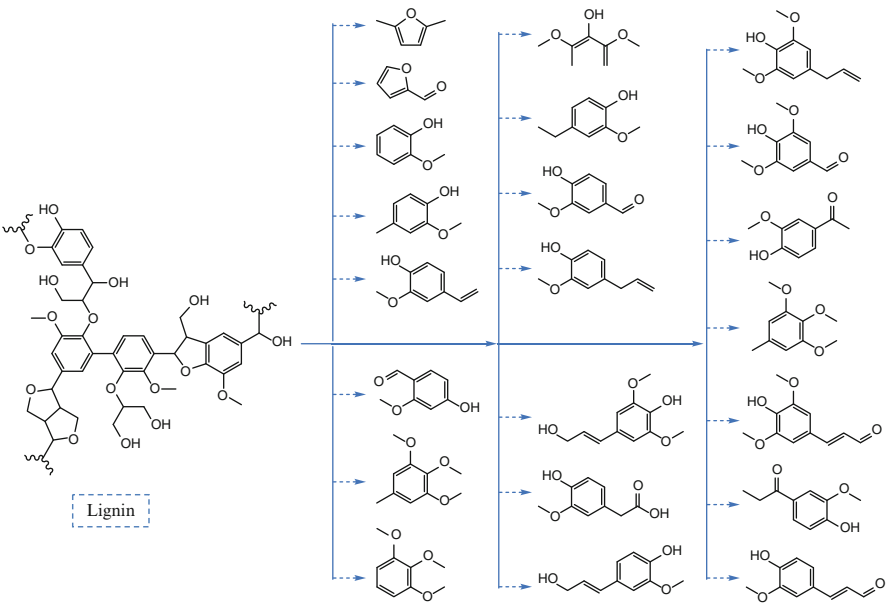

Fig. 4 Pyrolytic degradation of lignin (only important chemicals which typically form during lignin pyrolysis are shown above and do not cover the complete list)

3 Bio-oil

Bio-oil is a dark-colored liquid comprising mixture of organic compounds that serves as mother liquor to a large number of valuable chemicals. It is a complex assemblage of chemicals arising from the pyrolysis involving depolymerization, fragmentation, and rearrangement of cellulose, hemicellulose, and lignin with increase in temperature. Shorter residence times of the formed organic species inside the pyrolysis reactors lead to their condensation to give bio-oil. However, the presence of many highly reactive species results in unusual change in the stability and properties of bio-oils. Chemically, bio-oil comprises water, guaiacols, catechols, syringols, vanillins, substituted furans, furancarboxaldehydes, isoeugenol, pyrones, organic acids, hydroxyaldehydes, hydroxyketones, sugars, and phenolics. Bio-oil physically behaves like microemulsions in which the continuous phase is an aqueous solution solubilizing highly polar components of all origin and dispersed phase that is largely composed of pyrolytic lignin macromolecules and compounds derived from it. Stabilization of the continuous and discontinuous phases is mainly achieved through hydrogen bonding and micelle formation. The complex composition of bio-oils has been explained as multiphase due to the presence of char particles, waxy materials, aqueous droplets, droplets of different nature, and micelles formed of heavy compounds in a matrix of holocellulose-derived compounds and water (Garcia-Perez et al. 2006). The presence of reactive chemicals as acids, aldehydes, ketones, intermediates, etc. causes instability of bio-oil which causes gradual change in the phases due to several organic reactions (oxidation, hydrolysis, substitution, elimination, and rearrangements). Upon prolonged storage, bio-oil undergoes series of chemical reactions triggered by organic acids and intermediates in addition to the re-polymerization of reactive olefinic compounds. Aging reduces bio-oil quality and increases its viscosity which ultimately leads to the separation of continuous and dispersed phases. The presence of substantial amounts of organic acids is the sole cause of bio-oil acidity whose pH ranges between 2 and 4. As a consequence, storage, handling, and transportation of bio-oils become very difficult and challenging. In view of several challenges associated with bio-oil use involving upgrading and value addition, large amount of research has been witnessed in this area. Thorough analytical investigations are essential in every aspect related to bio-oil upgrading to prospective refining applications to yield fuels.

4 Bio-oil Upgrading

Bio-oil upgrading is essential for its value addition and involves series of chemical and engineering processes to overcome drawbacks associated with its use. Bio-oils are useless as fuels except for direct boiler and related applications, e.g., for some turbine or large diesel applications after necessary modifications. Since bio-oil is a source of valuable chemicals and advanced biofuels, its reliable scale-up and refining promise its economic viability and usage at par with conventional fossil fuels. In this direction, upgrading implicitly involves removal of bio-oil acidity

caused by free organic acids (formic, acetic, propionic acid, etc.). Additionally, upgrading is needed to increase thermal stability and reduce volatility and viscosity through oxygen removal and molecular weight reduction. Adequate upgrading of bio-oil is also essential in order to blend it with petroleum fuels. Catalytic cracking, decarboxylation, decarbonylation, hydrocracking, hydrodeoxygenation, and hydrogenation are some important approaches of upgrading biomass pyrolysis oils (Jacobson et al. 2013). Apart from these widespread approaches, organic solvents addition is also utilized for phase separation to improve the bio-oil quality. The role of additives in lowering the viscosity of bio-oils has been investigated to see its effect in imparting storage stability. For this purpose, ethyl acetate, methyl isobutyl ketone, methanol, and several others were screened. Additionally, accelerated aging tests were also conducted at 90 °C to measure the effect of these additives on the studies' parameters (Diebold and Czernik 1997).

Catalytic cracking is a prevalent upgrading process for bio-oils which requires an acidic and hydrophobic catalyst, typically ZSM-5 to produce H_2O, CO_2, or CO under atmospheric pressure. The high temperature employed in this process facilitates cleavage of bonds in large molecules and decarbonylate/decarboxylate the compounds present in biomass pyrolysis oils to form hydrocarbons. The mechanism is similar to reforming of heavily oxygenated bio-oils. One of the key approaches of upgrading also involves the removal of free organic acids (formic, acetic, propionic acid, etc.) through esterification. It is achieved through various catalysts such as solid catalysts, acidic ionic liquid catalysts, acidic ion-exchange-based zeolites (HZSM-5), H-mordenite, H-Y, silicalite, aluminum silicate catalysts, propyl-sulfonated mesoporous silica, etc. Unlike the hydroprocessing processes used for petroleum fuels (hydrotreating, hydrodesulfurization, hydrodenitrification, etc.), hydrodeoxygenation is widely applicable for bio-oils since it lacks nitrogen or sulfur but abundant in oxygen. The catalysts efficiency (in catalytic cracking or hydrodeoxygenation) is adversely affected by the deposition of oligomeric species (derived largely from lignins) present in bio-oil. It has been overcome by co-feeding hydrogen donors such as methanol, tetralin, and decalin. These co-feeds promote cracking as well as hydrogenation reactions and simultaneously dilute the lignins, thereby decreasing polymerization at high temperatures (Gayubo et al. 2009). Various aspects of hydrodeoxygenation and zeolite cracking of bio-oils to engine fuels have been reviewed by researchers and focused upon updates on catalyst development, their performance evaluation, and optimization of efficiencies. Other aspects such as reaction mechanisms, kinetics of crucial reaction parameters, and prospects of process commercialization have also been explored in detail (Mortensen et al. 2011).

5 Bio-oil: Physical Properties

As we discuss about the prospective application of lignocellulosic biomass-derived pyrolysis oil for engine fuel applications, a comparison of bio-oils and petroleum-based fuels becomes obvious. Differences in physical properties of both the liquids depend upon their chemical compositions. Bio-oils derived from all kinds of biomass

(hardwood, softwood, straw, agricultural residues, etc.) are distinctively high in water content, pyrolytic lignins, organic acids, and high oxygen content as a result of which possess very low heating values. Fuel oil qualities and chemical composition are important parameters for fuel engine applications or combustion and rely on some crucial physical properties as stability, homogeneity, heating value, viscosity, liquid density, solid content, and many more. Chemical composition is the fundamental consideration which largely governs all the listed physical properties and ultimately a measure of suitability of the liquid for being used as either boiler/turbine or engine applications. ASTM provides certain guidelines and specifications of pyrolysis liquid produced from biomass. It also specifies about the estimation of a number of physicochemical properties for such liquids for which normative references of the standards developed for characterization of petroleum and lubricants have been given. VTT, Finland, has been carrying out systematic research in this area for more than the past two decades and presented detailed physical properties of pyrolysis oils and methods to determine them (Oasmaa et al. 2005). The detailed guidelines provided have been rigorously formulated after huge analytical work and several round robin exercises in bio-oil analysis. Physical properties of biomass pyrolysis oils are extensively studied and very well documented in the scientific literature.

The lower heating value of bio-oils (18 MJ/kg) remains around 60 % of that of hydrocarbon fuels due to the presence of 50 wt% oxygen (approximately 40 wt% of dry matter) as revealed through proximate analysis of the former. Bio-oils are readily miscible with polar organic solvents (lower alcohols) that demonstrate the presence of high amounts of oxygenated species in it. The presence of more than 300 oxygen-containing chemicals has been reported in bio-oils of which hydroxyaldehydes, hydroxyketones, sugars, carboxylates, and phenolates are prominent (Soltes and Elder 1981). The measurement of physicochemical properties is an important analytical activity for biomass pyrolysis liquids and aimed at ascertaining its usefulness as fuels. The International Energy Agency and European Union jointly conducted several round robin tests for comparing the accuracy of chemical and physical characterization methods for fast pyrolysis liquids (Oasmaa and Meier 2005). During these tests, the measurement of critical properties as water content, viscosity, solid content, pH, stability, elemental analysis, and pyrolytic lignins was carried out. It was, however, realized after the tests that liquid sample handling and accurate estimation of water and density were precise whereas oxygen determination by difference remained variable even as its direct determination was poor. In addition, high variations were obtained for nitrogen, viscosity, pH, and solid measurements. Generally, large variability in the determination of such properties always exists due to complex scenarios. A list of applicable ASTM methods along with the brief detail is given in Table 1.

6 Sample Preparation

Sample preparation plays a crucial role in chemical analysis through instrumental techniques and implies how samples are treated prior to analysis. It is applicable to all the disciplines of chemical and biochemical investigations (Chen et al. 2008).

Table 1 Overview of ASTM standard methods of physicochemical and chemical analysis as applicable for the estimation of bio-oil properties

S. no.	Estimation parameter	Standard method (ASTM)	Basis of determination
1.	Ash content	D482	Thermogravimetry
2.	Boiling range fractionation	D2887	Boiling range distribution by gas chromatography
3.	Carbon residue	D189	Destructive distillation method of carbon residue determination
		D4530	Micromethod (gravimetric analysis at 500 °C under inert nitrogen atmosphere)
4.	Density	D1298	Hydrometer method
		D4052	Digital density meter
		D369 (withdrawn)	Specific gravity by pycnometer method
5.	Elemental analysis	D5373	Estimation of CO_2, H_2O, and NO_x (oxidization of sample containing C, H, and N)
		D5291	Determination of gases obtained after conversion from their respective elements
6.	Fixed carbon/ash content of biochar	D3174	Gravimetric analysis under controlled environment
7.	Flash point	D93	Flash point by specified rate of heating
		D3828	Small-scale cup test in which sample is placed and ignition spark is created
8.	Heating value	D3286 (withdrawn)	Gross calorific value of coal and coke by isoperibol bomb calorimeter
		D240	Heat of combustion by bomb calorimeter method
		D4809	By bomb calorimeter method
9.	Lubricity	D2783	Load under one ball is measured against three fixed balls covered by sample
10.	Pour point	D97	Specified cooling of a heated sample with monitoring of sample movement
11.	Sulfur analysis	D4239	Infrared determination of SO_x after combustion of sample
		D4294	Energy dispersive X-ray fluorescence spectrometric method
		D2622	Wavelength dispersive X-ray fluorescence spectrometric method
12.	Surface tension	D971	Measurement of interfacial tension by the movement of a platinum ring from the surface of fluid with higher surface tension
13.	Solid content	D2276	Particulate contaminant by line sampling (filtration through membrane)
14.	Total acid value	D974	Color-indicator titration
		D664	Potentiometric titration method
		D3339	Semimicro color indicator titration

(*continued*)

Table 1 (continued)

S. no.	Estimation parameter	Standard method (ASTM)	Basis of determination
15.	Viscosity	D88	Saybolt viscosity by viscometer method
		D445	Capillary method through viscometer
		D2170	Flow of liquid through calibrated glass capillary method
16.	Volatiles in biochar	D3175	Weight loss through gravimetric analysis under controlled conditions
17.	Water content	D1744 (withdrawn)	Karl Fischer method–volumetric method
		D95	Distillation method
		E203	Karl Fischer reagent through volumetric method

Mainstream analytical techniques require adequate pretreatment procedures to obtain a suitable sample form which can be analyzed. Sample preparation is often performed to achieve selectivity and/or specificity in analyte identification. It tends to eliminate matrix interferences which may suppress signals from the analyte of interest and removes artifacts encountered in analysis. The selection of a sample preparation method is dependent on the analytical technique being employed for analysis, nature and background of matrix (sample), chemical nature of target analyte, and background material present in the sample. It may sometimes become extremely labor intensive and time consuming yet unavoidable. For bio-oils, sample preparation is indispensable due to its chemical complexity; hence enormous literature reports are available for adopting an appropriate procedure which comprises filtration, centrifugation, phase separation, LLE, SPE, and several others. An overview of available sample preparation methods for chemical analysis of bio-oils is given in Table 2. Every class of naturally occurring biomolecules present in biomass degrades pyrolytically to give simpler organic molecules containing varied functional groups. This complex mixture of extremely polar to nonpolar chemicals presents a tough analytical scenario which can be handled by adopting an adequate cleanup strategy and analytical technique. Important approaches of sample preparation before contemporary chemical analysis may be summarized as follows:

6.1 Chromatography

Adsorption chromatography is widespread among all other chromatographic separations. It is used to obtain various fractions of bio-oil containing chemicals on the basis of polarity. Column chromatography is a prominent method in which the mixture of chemical species is separated over stationary phase held in a tubular column. In bio-oils, column chromatography plays significant role since large number of chemicals (>400) may be present in such complex matrices.

Table 2 Overview of sample preparation methods and their application to bio-oil analysis

S. no.	Sample preparation	Mechanism
1.	***Mechanical phase separation***	
A.	Filtration	Size of particulate matter; difference in solubility
B.	Centrifugation	Separation of solids from continuous phase
C.	Phase separation through water addition	Separation of phases due to difference in polarity
2.	***Solvent extraction***	
A.	Liquid–liquid extraction (LLE)	Difference in solubility between two immiscible liquids
B.	Single-drop microextraction (SDME)	Same as above but with high enrichment factors
3.	***Chromatography***	
A.	Column (normal and reversed phase)	Difference in rate of movement of solutes through stationary phase in column
B.	Solid-phase extraction (SPE)	Adsorption of solute over adsorbent through normal or reversed phase approach
C.	Ion exchange	Interaction of solute with ion-exchange (anion or cation) resins
D.	Size exclusion	Difference in molecular size
E.	High performance thin layer chromatography (HPTLC)	Difference in the rate of movement of solutes through stationary phase on planar support
F.	Solid-phase microextraction (SPME)	Adsorption of analyte over adsorbent fiber followed by thermal desorption
4.	***Electrophoresis***	
A.	Capillary electrophoresis (CE)	Difference in migration of charged species in electric field

The adsorption chromatography can be normal or reversed phase and more applicable to the organic fraction of bio-oils. Close to ASTM D2549 test method for high-boiling petroleum distillates, pentane-soluble fraction of bio-oils can be easily separated over normal phase adsorbents. In the same way, moderate to heavy polar bio-oil organic or aqueous fractions can be segregated on reversed phases (Venter et al. 2006). The miniaturized mode like SPME and HS-SPME are equally popular (Pan and Pawliszyn 1997). In a research work, volatiles from eucalyptus bio-oil and its vacuum-distilled residual product were extracted through HS-SPME (Araujo et al. 2010).

SPE, due to its versatility, efficiency, and simplicity, is an extensively used sample pretreatment tool in almost all the areas of basic and applied science. It is a usual and highly convenient method of choice for sample preparation of complex matrices prior to analysis with sensitive spectroscopic techniques. In the literature, enormous details related to bio-oil pretreatment through SPE involving normal phase, reversed phase, and ion exchange are available. Reversed phase (C_{18}) SPE has been reported for extraction of oxygenates, whereas normal phase was used for polycyclic aromatic hydrocarbons. Other equally important modes of chromatography include ion-exchange and size-exclusion chromatography. Anion exchange and cation exchange have their applications in trapping anions (carboxylates, phosphates,

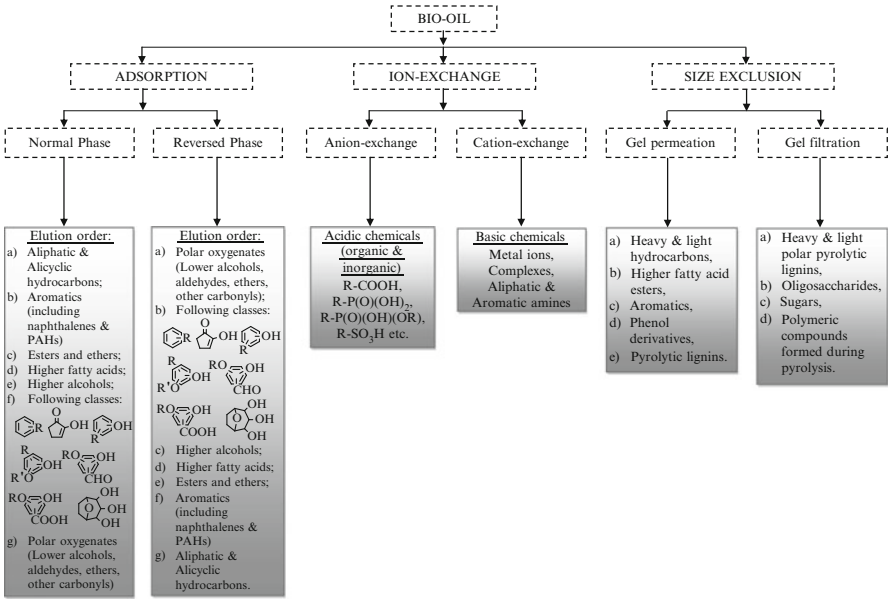

Fig. 5 Schematic presentation of the chromatographic methods of bio-oil fractionation

phosphonates, sulfonates, etc.) and cations (metal ions, cationic complexes, amines, etc.) present in bio-oils. Bio-oil fractionation through ion-exchange and size-exclusion chromatography to segregate components on the basis of their polarity and pK_a is reported. GPC is a popular size-exclusion approach and has been used in the removal of pyrolytic lignins in bio-oil samples (Andersson et al. 2000; Mullen and Boateng 2011). The chromatographic approach of bio-oil fractionation is represented in Fig. 5.

6.2 Liquid–Liquid Extraction

LLE is an efficient method of bio-oil fractionation and allows ionization suppression through pH manipulation and Soxhlet extraction. Optimization of extracting solvent is essential in maximizing the enrichment of target compounds in LLE extracts. Broadly bio-oils need to be separated between two phases, aqueous and organic, by addition of water if necessary. The aqueous phase presumably contains most of the small polar organic chemicals which may be extracted with water immiscible solvents in order of their polarities. Hexane, dichloromethane, chloroform, ethyl acetate, diethyl ether, etc. are some solvents which fractionate the entire bio-oil aqueous portion. Partitioning of analytes is generally governed by factors such as solvent polarity, nature of analytes, functional groups within the compounds, pK_a, and types of physical and chemical interactions (Garcia-Perez et al. 2007). Pyrolysis oils have been fractionated into distinct fractions, i.e., *n*-pentane soluble and insoluble which were further separated chromatographically

over activated silica gel column and eluted successively with pentane, toluene, and methanol to produce aliphatic, aromatic, and polar fractions, respectively (Ozbay et al. 2006).

SFE with CO_2 is also used for thermally labile compounds and serves the same purpose. SDME, SLE, and extraction mediated by advanced material-based adsorbents (carbon nanotubes, graphenes, nanomaterials, molecularly imprinted polymers) appear attractive in the modern research. These methods are considered green due to the miniaturized formats and associated with high enrichment factors. They also offer efficiency with the requirement of very little sample size. However, limited or very scarce information is available on such approaches due to the complexity/nonuniformity of sample matrix and restricted applications at higher scale. HPTLC has also been shown to separate anhydrosugars (levoglucosan, cellobiosan, glucose, arabinose, xylose, cellobiose, etc.) (Tessini et al. 2011). Ion-exchange methods are widely used for the removal of bio-oil acidity which involves elimination of organic acids (acetic and formic acids) formed during the thermal breakdown of lignocellulose. Anion-exchange resins (e.g., Dowex-22) are convenient options in addition to the ionization suppression caused by pH change. Neutralization of such acids with calcium oxide followed by filtration of the precipitate has also been used. Inorganic contents of bio-oil comprise of metals, their oxides, and complexes with several ligands and ions. Solvent-based extraction method for bio-oil is shown in Fig. 6. AAS and AES through ICP are highly

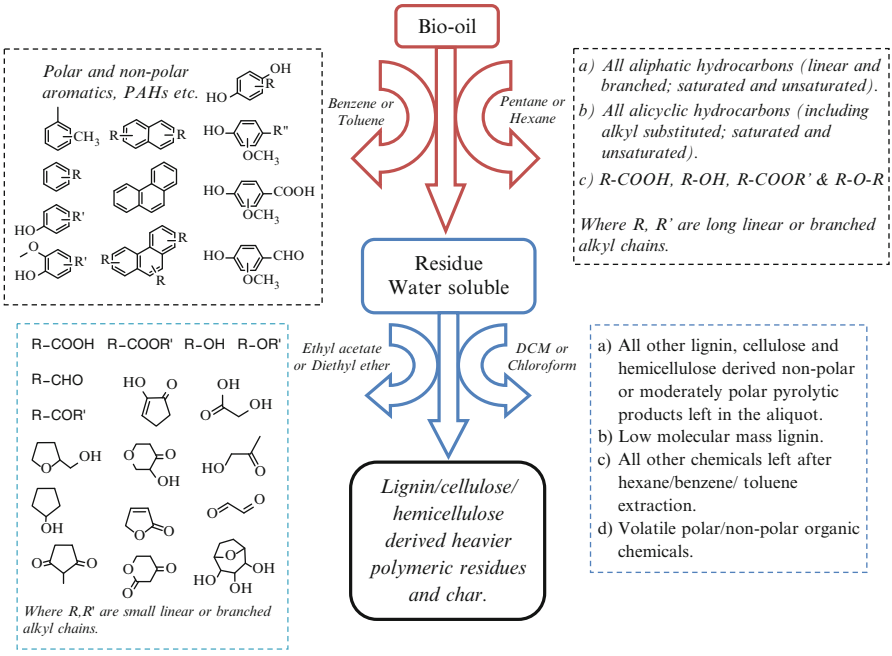

Fig. 6 Schematic presentation of liquid–liquid extraction plan for fractionation of bio-oil chemical components

appropriate instrumental procedures of analysis. Its sample preparation usually involves acid digestion and alkali fusion followed by dissolution.

Chemical derivatization is an essential aspect of sample preparation and highly crucial especially for chromatographic methods. The goal of derivatization is to primarily impart thermal stability to the labile (and polar) compounds which thereby enhances their chromatographic properties. Besides chromatographic applications, other purpose of derivatization is to improve the sensitivity of certain detection techniques. These techniques include mass spectrometry (especially soft ionization based) and NMR analysis with certain nuclei. Derivatization may sometimes become tedious and time consuming and often introduces error in the quantitative estimations. It is a potential source of unwanted artifacts in certain analytical methods. In bio-oil analysis, all the conventional and nonconventional methods of sample preparation are widely applicable due to the availability of varied chemical species into it. However, literature still lacks rigorous sample preparation for the characterization of complex matrices such as bio-oils unless extensive upgrading research is involved.

7 Chemical Characterization of Bio-oils

Chemical characterization of bio-oils remained a challenge before the early 1990s, due to the complex nature of matrix. Highly viscous nature due to macromolecules produced from lignins and sugars and highly polar chemicals caused difficulty in the complete analysis. Drastic variations in the chemical composition of biomass feedstocks are imperative in understanding chemical nature of the formed pyrolysis liquid. Adequate sample pretreatment is absolutely essential in view of the presence of a large number of chemicals arising due to pyrolysis. Furthermore, monitoring of upgrading approaches implies understanding of chemical processes and reactions at molecular levels. Due to these reasons, the need for complete chemical characterization of bio-oils is crucial in understanding the involved processes at molecular levels. Tools of analytical chemistry provide comprehensive solutions in this field and engage all the aspects like thermogravimetry, electroanalytical methods, volumetry, and spectroscopy. Separation processes act as backbone for the entire chemical analysis and encompass most of the activity covered in sample preparation. Typically, analytical techniques which have been widely employed for bio-oil analysis are GC, GPC, GC $\times$ GC, HPLC, GC–MS, LC–MS, FTIR, NMR, and TGA. Bio-oil analysis unequivocally involves synchronization in results obtained from several analytical techniques and methods. In other words, analytical data should complement each other, leading to unambiguous identification and quantification of any chemical component. GC-based detection inevitably requires volatility of analytes so that gases, non-polars, and chemical derivatives of polar organic compounds present in bio-oils are largely amenable to this technique. To deal with moderately polar to highly polar thermolabile compounds, HPLC-based detection is generally more common. Molecular weight distribution of compounds within a sample is reliably estimated with GPC. Mass spectrometer

being a very powerful detector to the chromatographic systems is ideal for identification, quantification, behavior studies of molecules, and advanced gaseous phase reactions.

Hyphenated analytical techniques as GC–MS, LC–MS, and GC-FTIR immensely contribute in the area of bio-oil analysis as witnessed through the huge amount of literature reports which started appearing since the early 1990s. FTIR reveals the presence of functional groups in the sample which helps in narrowing down on present chemical compounds and establishing molecular structure. NMR essentially determines the nature and types of covalently bonded nuclei (hydrogen or carbon) within a molecule. It provides an estimated number of such nuclei in a sample under observation through peak area integrations. Thus, spectroscopic analysis offers valuable structural insights of such complex matrix. In contrast, physicochemical characterization of bio-oil largely relies on bulk property measurements and is expressed as functions of respective chemical properties. Bio-oil production and upgrading research require monitoring of the progress and fate of chemical reactions that is very useful in developing molecular-level understanding of bio-oils and upgraded products.

7.1 Thermal Analysis

Biomass thermal profiling is highly crucial in ascertaining the quality of bio-oil for which thermoanalytical techniques represented by TGA and DTG are commonly used. TGA helps in determining plausible thermal behavior of the biomass feedstocks and products derived from it. It involves change of sample mass against time or temperature which is monitored at a specified rate of heating. Valid thermodynamic values can be concluded by the application of Arrhenius equation corresponding to separate slopes of constant loss of mass for a sample. The abundance of particular lignocellulosic components in the biomass samples governs bio-oil properties which can be reliably predicted by analyzing TGA profiles of employed biomass feedstock. It has been observed generally that the lower the parent biomass lignin content, the better is the quality of obtained bio-oil. Bio-oil and its organic fractions have some volatility, and its vapors comprise collection of true vapors and minute droplets (aerosols) along with a large number of nonvolatile compounds formed during or along with vapor condensation in an irreversible manner. Through TGA, estimation of properties such as evaporation, thermal decomposition, and combustion becomes easy. It is known that volatile and lighter product is considered better for combustion; hence TGA data of biomass and bio-oil is useful in optimizing pyrolysis conditions, improving bio-oil quality and energy content, since the measured mass losses are related to the volatility and molar masses of fractions under investigation. TGA/DTG has been extensively used in comparing evaporation and cracking behavior of bio-oils derived from different feedstocks (Vitolo and Ghetti 1994).

Thermal analysis of various biomass samples and bio-oils derived from them typically shows three major steps of weight losses:

(i) Loss of water at around 100 °C
(ii) Loss of volatiles and smaller organic compounds (from lignin pyrolysis) at 250–350 °C
(iii) Complete combustion of all kinds of organic matter at 350–500 °C

These losses provide valuable information about sample reactivity which shows that wood with lower lignin showed higher reactivity. They also suggest amounts of tar which one should expect from pyrolysis of dissimilar biomass samples. TGA coupled to FTIR is an essential technique in determining the composition of biomass sample in terms of the presence of functional groups and change in composition during or after pyrolysis. Roughly, 65–70 % (w/w) volatiles, 27–29 % (w/w) fixed carbon, and around 3 % (w/w) ash content have been estimated in biomass samples which is subject to moderate variations depending upon the nature of plant biomass (Kanaujia et al. 2013, 2014). The yield of pyrolysis liquids, sometimes, has been reported to be influenced by ash content in the feedstocks, and it has been reported that the higher the ash concentration, the lower is the yield of bio-oil. Apart from feedstock analysis, thermal stability of bio-oil has been monitored systematically by Adjaye et al. in 1992 where fresh bio-oil sample was distilled at different temperatures under vacuum and its physicochemical properties (density, viscosity, distillation characteristics, composition, etc.) were measured. The important observations of this study were related to yields of oxygenated compounds, such as acids, ethers, alcohols, and volatile aliphatic hydrocarbons with moderate thermal stability, which decreased with increase in temperatures above 200 °C. In contrast, concentration of aromatic hydrocarbons, naphthenes, aldehydes, and ketones remained at maximum at around 175 °C (Adjaye et al. 1992). Qiang et al. compared TGA and DTG curves for bio-oil analyzed in nitrogen and air and compared its thermal behavior. The similarities in combustion profiles were observed in nitrogen as well as air at temperature less than 400 °C, while burning of char residues occurred in air above 400 °C. DTG curves of bio-oil heated in nitrogen and air showed two and three distinct peaks, respectively, which indicated that first two peaks corresponded to the loss of volatiles in both the atmospheres whereas third peak in the latter was due to burning of char residues (Lu et al. 2008). It is largely observed that DTG curves serve as good indicators of boiling point distribution and overall composition of bio-oils. In addition, a very interesting application of TGA exists for catalyst characterization in which it determined the amounts of deposits over bio-oil upgrading catalysts. These catalysts, as discussed previously, have been employed to upgrade and obtain a variety of value-added end products from bio-oil by various processing methodologies.

7.2 Fourier Transform Infrared Spectroscopy

Infrared spectroscopy is one of the most conclusive and simple methods of structure elucidation which is extensively utilized to reveal the presence of various functional groups in molecules. It has significance in light of the examination of the

Table 3 Typical FTIR peak assignments for biomass pyrolysis oils and its fractions

S. no.	Wave number (cm^{-1})	Vibrations	Functional group assignment
1.	1,100–1,000	C–O stretch	Carboxylic acid, ester, ethers, and alcohols
2.	1,200–900	C–O and C–O–C stretch	Polysaccharides (pyrolytic cellulose and hemicelluloses)
3.	3,100–2,850	C–H stretch	Aliphatic and olefinic hydrocarbons
4.	3,300–3,400	O–H stretch	Bonded or nonbonded hydroxyl groups and water
5.	1,600–1,800	C=O stretch	Carboxylic acids, esters, aldehydes, and ketone groups
6.	1,600–1,450	C–C stretch	Aliphatic and aromatic species
7.	1,640–1,600	C=C stretch	Olefinic and aromatic species
8.	700–850	C–H bend out of plane	Aromatic ring structure
9.	2,350–2,000	C≡C stretch	Alkynes

fundamental vibrations and associated rotational–vibrational structure within a molecule. FTIR is highly useful in the qualitative and quantitative component analysis, thermal deterioration, aging, and QA/QC studies in almost all areas of contemporary chemical and biological research. A huge number of literature information indicates enormous applications of FTIR in every aspect of bio-oil research. The interpretation of IR spectra is straightforward and generally shows peaks above 3,050 cm^{-1} corresponding to C–H stretching vibration for the presence of aliphatic hydrocarbons. Peak above 3,100 cm^{-1} indicates C–H stretch for olefinic compounds, between 3,300 and 3,400 cm^{-1} corresponding to O–H stretching vibrations caused by carboxylic acids and/or alcohols. Peaks between 1,450 and 1,600 cm^{-1} indicate a C–C stretching vibration caused by aliphatic or aromatic structure. The C=O peak is seen between 1,600 and 1,800 cm^{-1}, indicating either carboxylic acid/ester or aldehydes/ketone groups. C–O stretching peak (in acids, esters, ethers, and alcohols) is seen between 1,000 and 1,100 cm^{-1}. Aromatic rings are also determined by the presence of C–H "out of plane" bands in the range of 700–850 cm^{-1}. The details of important FTIR vibrations and their functional group assignments are shown in Table 3.

TG-FTIR, as discussed in the previous section, is a useful hyphenated tool for determining online changes in the chemical composition within a bio-oil during its formation or upgrading. It has been used widely to predict and optimize factors which influence pyrolysis (Kanaujia et al. 2014). Pyrolysis of wheat straw and other agricultural residues including coconut shell, sugarcane bagasse, corn stalks, peanut shell, etc. has been explored with TG-FTIR (Souza et al. 2009). Bio-oils from other feedstocks such as rapeseed cake, apricot, peach pulp, pine wood, linseed, etc. have been analyzed to divulge usual functional groups. Characterization of bio-oil fractions with organic solvents shows usual functional group distribution and suggests oxygen content and their distribution. In one of the studies, bio-oils obtained from subcritical and supercritical water liquefaction of wood biomass

largely contained heavy oils among other compounds such as hydrocarbons, aldehydes, ketones, hydroxybenzenes, and esters (Qian et al. 2007). In another well planned pyrolysis and upgrading study, bio-oil was produced from soybean stalk (and deoxy-liquefied in a closed reactor) was shown to possess low oxygen content, high H/C ratio, and high heating value. In this study, dissociation of O–H and recombination of C–H bonds into hydrocarbons were proposed which was accompanied by the release of CO and CO_2. This bio-oil was analyzed with FTIR and typical oxygenates were observed. Upgrading of this bio-oil yielded final product which was distilled and decolorized over activated clay to obtain high-quality biofuel (Li et al. 2008). The existence of -NO_2 and N–H functional groups with signals between 1,550 and 1,490 cm^{-1} has been identified in bio-oil obtained from rice husk (Lu et al. 2008). Analysis of bio-oil from lignin pyrolysis in attenuated total reflectance (ATR) mode revealed the predominance of hydrocarbon structures in addition to small amounts of phenols and carboxyl groups. Fiber optic-based near IR system working on reflection–absorption phenomenon has been used for predicting water content in bio-oils by applying multivariate analysis to the spectral information containing different water content.

The reactivity of various carbonyl functionalities in bio-oils has been predicted on the basis of FTIR analysis and considered important for upgrading process. Carbonyl distribution in bio-oil is a function of composition of feedstock (hemicellulose, cellulose, and lignin) and an indicator of aging. FTIR is important in ascertaining the aging of bio-oils since reactive organic species that form during pyrolysis have a strong tendency to repolymerize, rearrange, or fragment to form stable products. It leads to deterioration of quality which creates difficulty in bio-oil storage, handling, transportation, and upgrading. FTIR is employed to monitor this transformation effectively, and several studies have been carried out in this direction. In one such experiment, bio-oil quality during thermal treatments or long-term storage at ambient temperatures was evaluated which showed the presence of C–H out of plane deformation vibration of terminal olefins (signal at 880 cm^{-1}) indicating commencement of thermal deterioration process (Xu et al. 2011). Increase in C–O stretch (phenols, carboxylic acids, esters, and ethers) and C=O (carbonyl) functional groups suggests aging for which accelerated aging studies have been carried out to establish the stability of bio-oils. Upgraded bio-oils have also been emulsified with biodiesel and monitored for stability through FTIR. Biochars obtained after pyrolysis can be routinely analyzed with FTIR to determine its nature which usually comprises N–H, C–H, C–C, and C–O–C bonds. In this way, FTIR finds immense application in all aspects of bio-oil research due to its simple, straightforward, and conclusive nature that is useful in process scale-up.

7.3 Gas Chromatography

GC is a highly versatile separation technique extensively employed for volatile and thermally stable organic compounds. Widespread utilization of a variety of available detectors has exponentially expanded the dimensions of GC, mass selective

detection being one of the most popular. Regular modifications to this technique have led to the evolution of other efficient formats such as GC × GC, static headspace extraction-GC, and fast GC. In itself, GC is a vast area of contemporary research including petroleomics. Since bio-oils contain a large number of chemicals with varying volatility and polarity, GC employs several variables that cater requirements for their analysis. Polar organic compounds often require chemical derivatization prior to GC-based analysis, and bio-oils contain numerous such chemicals which originate from thermal degradation of lignins, hemicelluloses, and celluloses. GC-FID is generally used for estimating biomass pyrolysis/gasification condensates as well as other formed organic components. In an interlaboratory proficiency test conducted by the International Energy Agency and European Union, GC analysis was included as a primary technique for bio-oil characterization. In this round robin activity, bonded cross-linked mid-polar capillary column containing 14 % cyanopropyl-phenyl was the recommended stationary phase. In the same test, participating laboratories reported GC-FID analysis of organic acids, aldehydes, ketones, alcohols, sugars, phenols, and PAHs (Oasmaa and Meier 2005). Analyses of acetic acid, aldehydes, sewage sludge pyrolysis liquid, bio-oil fractions, etc. have been carried out with GC-FID. Bio-oil extracts obtained with LLE, SPE, and column chromatography have also been analyzed showing that GC-FID is a method of choice for bio-oil characterization. Similarly, gases evolved during pyrolysis are easily identified and quantified with GC-TCD. These uncondensed gases comprise CO, CO_2, CH_4, H_2, C_2H_4, C_2H_6, C_3H_6, C_3H_8, C_4H_8, and C_4H_{10}, and their analysis is largely preferred by GC-TCD or GC-FID.

Group-type analysis of oxygenated organic compounds in bio-oils is conveniently accomplished with GC × GC with usual detectors. Recently, GC × GC has progressed quickly and emerged as a powerful analytical tool for analysis of organic compounds. It offers discrete separations of the sample components which are separated firstly in one dimension (column) and then subsequently separated in second dimension (column) with the help of modulators. In other words, the separation occurs on a long nonpolar column where the components are separated on the basis of their boiling points. The separation on this column is assisted by another column through a modulator which collects the effluents in a defined elution range and then inject this fraction over another short (polar or intermediate polar) column which helps separate the components on the basis of their polarities under isothermal conditions. Excellent results are obtained if the two or more separation mechanisms are independent of each other. It is for this reason the technique is termed multidimensional GC or GC × GC. This technique is valuable in the separation of large number of compounds with very close boiling points such as in bio-oils. Pyrolytic products from lignocellulosic biomass along with the upgraded products have been analyzed with GC × GC-FID and GC × GC-HRMS. Time of flight mass spectrometer (TOFMS) is the detector of choice for GC × GC which is helpful in identifying components having close molecular weights. Pyrolytic products obtained from biomass have been analyzed with GC × GC-TOFMS to reveal more than 100 (or 300) chemicals which vary from one feedstock to other (Sfetsas et al. 2011).

7.4 Nuclear Magnetic Resonance

The NMR is essentially employed in monitoring experiments on solid, liquid, and gaseous samples, over a wide temperature span. NMR plays a remarkable role in the structural characterization of petroleum fractions and a crucial tool for carrying out group-type analysis which directly measures aromatic and aliphatic carbon (^{13}C) and hydrogen distributions (^{1}H). It provides vital information on the structural layout of carbon and hydrogen groups within a molecule with standard methods of ^{13}C NMR studies on coal and asphaltenes being its important applications. In the area of bio-oil research, the advantage of using NMR is that whole bio-oil can be dissolved and analyzed in a suitable solvent, and qualitative assessment of the oxygen-containing functionalities can be determined from the integration of appropriate regions of the ^{13}C and ^{1}H spectra.

Bio-oils are largely studied with ^{13}C NMR particularly due to large chemical shift regions. ^{13}C and ^{1}H NMR offer reasonable trade-off between functional group identification and analytical measurement effort. Accuracy, however, depends upon the selection of chemical shift regions, baseline compensation, and correction for incomplete longitudinal relaxation effects. NMR had been used in the past to provide confirmation of chemical functional groups in bio-oil. In the 1980s, the concern was the solubility of components in deuterated acetone or chloroform along with the poor quality of ^{13}C spectra owing to low signal-to-noise ratio and imperfect baseline attenuation. The presence of high molecular weight compounds also remained a challenge in NMR analysis. Several studies were carried out in the past which provided a lot of information on pyrolytic lignins and bio-oils. Evaluation of pyrolysis conditions and changes in product formation profile has been performed through ^{1}H NMR which helped in optimizing pyrolysis parameters and manipulating the yields of components such as aromatics, paraffins, and olefins. Chemical species present in bio-oils derived from lignin pyrolysis have been identified through NMR with ^{1}H, ^{13}C, and ^{31}P to determine the extent of lignin degradation. Polar functionalities present in bio-oils are comprised mainly of hydroxyl and carboxyl groups that can be quantified using ^{31}P NMR after derivatizing them with phosphorus-containing reagent such as 2-chlorophosphalone or 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane. In an investigation, ^{31}P was used for determining three principal forms of phosphitylated phenolic hydroxyls present in lignins (*p*-hydroxyphenyl, guaiacyl, and syringyl structures) along with other groups such as hydroxyls, carboxylic acids, and two diastereomeric forms of arylglycerol-beta-aryl ether units. ^{31}P NMR has advantage over other nuclei due to the absence of the interference of peaks from other nuclei and can be studied in a wide chemical shift scale. DEPT NMR is useful in the quantitative classification of carbon and hydrogen. DEPT quantifies protons and carbon atoms in off-resonance-decoupled ^{13}C spectra to extract information on the types of molecules that are found in the matrix. In a study, biomass fast pyrolysis oils were characterized with ^{13}C and DEPT NMR to determine functional group compositions related to their energy content. The spectra were compared with gasoline and diesel and divided into distinct regions

according to the chemical shift ranges appropriate for various functional groups. The spectral intensities of each region were quantified, and carbon–proton substitution numbers were determined. Additionally, chemometrics was used to extract more useful information from spectra (Strahan et al. 2011).

Several NMR studies related to bio-oil analysis have been carried out with ^{13}C NMR which suffers from low sensitivity due to its low natural abundance and long relaxation times. Few important observations have thrown light on the process part of bio-oil production on the basis of ^{13}C NMR experiments. It has been proposed on the basis of ^{13}C NMR analysis that carbohydrate fraction decreases and aromatic fraction increases as the pyrolysis temperature is increased in a fluidized bed reactor. It has also been observed that pyrolysis oil from kraft lignin showed removal of aliphatic hydroxyl, carboxyl, and methoxyl groups during pyrolysis. On the other hand, ^{1}H NMR is sensitive and essential for determining hydrogen distributions in crude bio-oil obtained from various biomass feedstocks. Thermal stability of whole bio-oil, its ether-soluble fraction, and biodiesel blends are reported in addition to monitoring of structural changes in the blends measured with ^{1}H and ^{13}C NMR experiments, respectively (Jiang et al. 2011). Interestingly, it has been proposed that the presence of very broad peak in the spectra results due to the presence of polymeric material with slow molecular motions (Mullen and Boateng 2011). Proton NMR was also used for water estimation in bio-oil at par with conventional methods like Karl Fischer titration and azeotropic distillation. Heteronuclear single quantum correlation NMR (HSQC-NMR) has been shown to provide chemical shift assignment for 27 different types of C–H bonds present in bio-oils and indicated the presence of two different types of methoxyl groups in samples. Levoglucosan, furfurals, and phenols were the major components in all samples; however, most aliphatic and aromatic C–H bonds were produced from lignin component (Ben and Ragauskas 2011).

7.5 Mass Spectrometry

Mass spectrometry (MS) provides unequivocal elemental and structural composition of chemical species. Quadrupole mass analyzers are affordable, rugged, and commonly available and, hence, are used extensively in the unambiguous analysis of liquid pyrolysis products. A wide range of ionization modes and analyzers have expanded the scope of mass spectrometry, which is applicable to all the areas of chemical and biological research. Briefly, among the available ionization techniques, EI in positive mode and at 70 eV is largely used for characterization purposes due to the existence of huge mass spectral database. Soft ionizations such as CI, ESI, APCI, FI, FAB, and MALDI are used for thermolabile molecules. Other less common one is DESI which is manifested by DART-based mass spectrometers. Tremendous possibilities exist in the area of chemical and biochemical analysis with the available analyzers and ionization methods in mass spectrometry. A wide range of analyzers such as magnetic sector, quadrupole, time of flight, ion traps, orbitrap, and ICR are being used currently.

Py–GC–MS is highly useful in understanding the process of biomass pyrolysis and obtained products. It comprises thermal decomposition of biomass feedstocks under defined conditions followed by GC–MS analysis. There are two formats of Py–GC–MS, namely, online and offline methods. In online pyrolysis, the pyrolytic products directly enter into the GC inlet where they are analyzed after being separated. On the contrary, offline pyrolysis involves trapping of the formed pyrolytic products on adsorbents, after which it is eluted with solvents before introducing into the GC columns. The online method is good and provides valuable information on the formed pyrolytic products, but it is associated with challenges such as deterioration of liners and columns due to high molecular weight polar products. It often leads to artifacts and imprecise/inaccurate analytical data. Offline method on the other hand is advantageous because it enables analyst to adopt suitable column and sample pretreatment steps (including derivatization) and leads to accurate results. A large amount of work has been carried out with Py–GC–MS in which upgrading of bio-oils and determinations of bio-oil compositions of different pyrolytic lignins obtained from different feedstocks are involved (Johnson et al. 2009).

Low-resolution mass spectrometry exhibited by quadrupole-based instruments has been widely used for chemical identification for bio-oil analysis and upgrading. It is highly suitable for the characterization of small molecular weight organic compounds from aliquots obtained after sample preparation. GC is used for sample introduction and separation followed by data acquisition in EI mode. The prerequisite for GC–MS analysis is the extraction of the liquid condensate with suitable organic solvents (LLE) or SPE. Bio-oil characterization and stability analysis have identified more than 100 individual compounds including oxygenates and hydrocarbons. Oxygenated compounds mostly included acids, cyclic alcohols, aliphatic alcohols, aldehydes, cyclic ketones, substituted furans, ethers, and alkyl-substituted methoxy phenols. Hydrocarbons consisted mainly of long-chain paraffins, olefins, aromatics, cycloparaffins (non-condensed and condensed), and polycyclic aromatic hydrocarbons (Adjaye et al. 1992). Carbon range distributions have also been estimated in pentane soluble bio-oil fraction which showed the presence of *n*-alkanes, *n*-alkenes, and branched hydrocarbons with the majority of linear hydrocarbons being distributed in the range of C_{11}–C_{29}. Semiquantitative estimation of hydrocarbon distribution showed roughly 72.87 % *n*-alkanes, 16.44 % *n*-alkenes, and 1.84 % branched hydrocarbons. Bio-oil from cyclone reactor has been analyzed with GC–MS and found to contain: (i) holocellulose-derived compounds, viz., propanol, acetic acid, propanone, and furfural; (ii) lignin-derived compounds, viz., phenol, cresol, guaiacol, xylenol, methyl guaiacol, ethyl guaiacol, syringol, vanillin, and eugenol; and (iii) PAHs such as pyrene, fluorene, naphthalene, phenanthrene, biphenyl, and anthracene (Lede et al. 2007). Other PAHs which have been identified by several other researchers include alkylated benzofurans, indenes, and naphthalene-dominated PAHs. Around 63 PAHs have been confirmed to be found in bio-oils among which some of them were also quantified. Bio-oil derived from algal biomass has also been characterized with GC–MS (Zhou et al. 2010).

ESI-based mass spectrometers are typically used as LC–MS in order to obtain molecular weight information of polar and thermolabile molecules. Molecular mass distribution and all polar chemicals present in bio-oil obtained from lignocellulosic biomass have been reported with LC–MS. Positive and negative ESI-MS have revealed around 320 peaks in a bio-oil sample with mass distribution ranging between 100 and 1,100 mass units complemented through size-exclusion chromatography (Harris et al. 2011). Chemometrics along with the LC–MS is generally preferred for fingerprinting of bio-oil components and petroleum products. MALDI-TOFMS, LDI-TOFMS, and temperature-resolved analytical pyrolysis field ionization mass spectrometry Py-FI-MS are also used for this purpose.

HRMS is a valuable analytical approach of mass spectrometry which is expensive and more sophisticated and, hence, is not very common. HRMS plays a significant role in accurate mass measurement which deconvolutes molecular information from complex matrix like petroleum where as much as 250 chemicals have been known to have same nominal masses. It is the mass analyzer which is responsible for resolving the power of the mass spectrometer which refers to the ability to separate two mass spectral peaks differing by accurate masses. Analyzers which help in achieving high resolving power are double-focusing magnetic sector, TOF, and FT-ICR. Excellent reviews have been written in this area dealing with the fundamentals and basic into advanced applications of HRMS in various R&D sectors (Burlingame et al. 1996). Bio-oils have high degree of compositional complexity; hence the resolving power of MS to extract accurate molecular-level information is useful. HRMS has been employed to evaluate bio-oil composition using LDI and linear ion trap–orbitrap analyzer. Comparison of high-resolution data obtained from orbitrap and FT-ICR-MS has been performed to establish the minimum resolution required for unambiguous detection of analytes. Furthermore, the orbitrap analyzer was reported to provide sufficient resolution which could determine chemical compositions for over 100 compounds (Smith and Lee 2010). Similarly, high-resolution orbitrap, quadrupole TOF (QTOF), and FT-ICR-MS in negative ESI modes were also compared. Heteroatom class distribution and double bond equivalence have also been performed with FT-ICR-MS to obtain clearly distinguished phenols derived from lignin. Analysis of bio-oil at 8,000 resolution with TOF at different electron beam energies provided molecular weight distribution. Inorganic mass spectrometry for the determination of common elements in the biomass ash is preferred with ICP-based technique such as AES, AAS, and MS. ICP-MS is preferred over others and is used for a variety of applications in bio-oil characterization and upgrading including algal biomass-derived liquids (Jena and Das 2011).

7.6 Other Analytical Techniques

Owing to the diversity and complexity of lignocellulosic biomass pyrolysis oils, there are very limited literature applications of other instrumental analytical techniques besides those discussed above. Only few studies have been undertaken for

bio-oil characterization with such techniques which have proven capabilities in other areas of modern research. Micellar electrokinetic chromatography is similar to capillary electrophoresis and has been used for the analysis of phenolic fraction of bio-oil. In capillary electrophoresis, components of a sample are separated by differential partitioning between micelles (pseudo-stationary phase) and a surrounding aqueous buffer solution (mobile phase). HPLC analysis with retention index and ultraviolet detection is reported, for polar bio-oil components such as aldehydes after derivatization with suitable reagents, in addition to multidimensional LC which is optimized for estimation of phenols (Andersson et al. 2000). Size-exclusion chromatography with ultraviolet and retention index detector has been used to obtain average molecular weight, dispersity, and molar mass at maximum peak height. Laser-induced fluorescence has been used to simulate and monitor the effect of ultraviolet exposure on the chemical stability of bio-oil produced from pine lumber, pine bark, oak bark, and oakwood. It was proposed that phenols present in the bio-oil showed chemical instability by giving time-dependent fluorescence intensities (Tripathi et al. 2010). Other less used analytical techniques include XRD and SEM which have been used for biochar characterization.

8 Conclusion

The presence of a very large number of compounds with varied functional groups in bio-oils has necessitated the development of universal extraction and analytical protocols. Widespread utilization of advanced analytical methods has enhanced our understanding about the composition and correlation of several variables associated with quality, upgrading, and stability. Feedstock, pyrolysis process, reactor design, pressure and temperature conditions, etc. are responsible for overall quality and stability of the bio-oil. The research in this direction is academic in nature; however, huge investment across the globe has promising prospects. The European Committee for Standardization is developing quality standards for pyrolysis products for the development of necessary test methods to determine relevant properties. Finland along with other countries has already invested in developing an integrated pyrolysis and upgrading refinery which would take shape in the coming years. Analytical insights have simplified overall bio-oil understanding that ranges from compositional revelations to modeling and chemometric approaches in the process optimizations. Chromatography and spectroscopy offer various approaches of instrumental analysis of which sample preparation is extremely crucial. Nanomaterials exhibit extraordinary physical, chemical, mechanical, and electrical properties and therefore have ample scope in sample pretreatment and catalyst formulations. In sample preparation, their enormous adsorption potential can be utilized as such or with covalent/non-covalent modification of surfaces. Magnetic nanoparticles with or without functionalization are useful in selective extractions and other desired sample pretreatments. Principles of immunoaffinity chromatography in the form of molecularly imprinted polymers may be explored for specific refining applications.

A concerted effort involving funding bodies, industry, and academy is absolutely essential for bio-oil value addition and to circumvent the increasing burden on limited petroleum reserves. Tools of analytical chemistry offer unequivocal identification and quantitation of target analytes and the matrix as well. Spectroscopic analysis provides vital structural insights and dominates over others, whereas determination of physicochemical properties is based on the classical methods of analysis. Discussion on all the aspects of bio-oil characterization is presented to emphasize and enumerate important findings plus the importance of correlation between feedstock nature and bio-oil quality. Unstable chemical species in bio-oils are revealed by TGA points toward the development of efficient extraction protocols which must be adopted for further production, processing, and storage of bio-oil. Ongoing use of mass spectrometry for bio-oil analysis is apparent by the presence of enormous literature and has necessitated the need for interlaboratory proficiency testing (round robin) so that uniform analytical guidelines and results evaluation criteria evolve in due course of time. Since mass spectrometric results provide conclusive evidence of compounds in fresh and aged bio-oil samples, therefore storage and stability issues associated with it must be appropriately addressed. Other techniques like NMR, FTIR, and chromatography have already simplified the analysis not only in this area but modern research as a whole.

HPLC Method for Microanalysis and Pharmacokinetics of Marine Sulfated Polysaccharides, Propylene Glycol Alginate Sodium Sulfate

42

Yi-Ting Xue, Chun-Xia Li, Xia Zhao, and Hua-Shi Guan

Contents

Abstract

With the development of glycobiology and glycochemistry, bioactive polysaccharides are more and more widely used in the clinical area due to their anticoagulation, antitumor, immune regulation, antivirus, and other activities. As a marine sulfated polysaccharide, propylene glycol alginate sodium sulfate (PSS) has been commonly used as a heparinoid drug for the treatment of ischemic cerebrovascular and hyperlipidemia diseases in China for nearly 30 years. The reliable high-performance liquid chromatography (HPLC) with pre-column derivatization and post-column fluorescence derivatization methods is developed for the determination of the β-D-mannuronic acid (M)/α-L-guluronic acid (G) ratio of PSS and microanalysis of PSS in rat plasma, respectively. These methods provide the basis of the quality control, qualitative, and quantitative analysis. Especially, these methods can be used for microanalysis of other polysaccharide drugs in vivo and pharmacokinetic study.

UVD	Ultraviolet detector
Vd	Volume of distribution

1 Introduction

PSS is a marine sulfated polysaccharide composed of (1→4) linked β-D-mannuronic acid (M) and its C-5 epimer α-L-guluronic acid (G) (Fig. 1), which is prepared by hydrolysis, esterification and sulfation of sodium alginate from brown seaweeds (Guan 1999; Rahelivao et al. 2013). PSS is a heparinoid-active drug and has good anticoagulant, hypolipidemic, hypoglycemic activities, and other

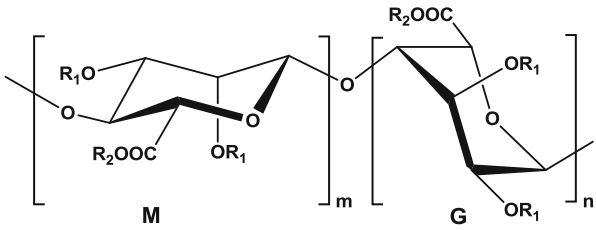

Fig. 1 Chemical structure of PSS, $R_1 = H$, SO_3Na, $R_2 = Na$, or $CH_2CH(OH)CH_3$

functions (Li et al. 2011, 2014). In the 1980s, it was first authorized for clinical application in China, and it is mainly used for the prophylaxis and treatment of ischemic cardiovascular and cerebrovascular diseases.

The previous work has shown that the bioactivities of PSS are mainly related with uronic acid composition (M/G ratio), degree and pattern of sulfation, and weight-average molecular weight (Lin et al. 2007; Fan et al. 2011). Among them, M/G ratio of PSS is one of the most important structural factors (Wu et al. 2014) for its activities and identification. There is an urgent need to develop a reliable and sensitive method for determination of the M/G ratio of PSS for quality control and clinical purposes.

Pharmacokinetics is usually carried out by studying the absorption, distribution, metabolism, and excretion (ADME) of drugs in vivo and in vitro. It is essential to guide the clinical administration including dose regulation, regimens, plasma concentration monitoring, and evaluation of the interactions among medicines (Zeng et al. 2013). Pharmacokinetic study plays an important role in making objective evaluation of existed drugs, designing new drug delivery systems, optimizing dosing regimen, and directing clinical medication (Liu and Sun 1999; Zhong 2000).

With the development of polysaccharide drugs, it is a great challenge for the analysis of polysaccharide drugs in vivo due to their structural complexity and heterogeneity (Wang 2007; Lv 2008). The pharmacokinetic analysis and microanalysis of polysaccharide drugs in biological samples of polysaccharide drugs have become huge obstacle in the pharmaceutical analysis field. The reasons are mainly elaborated in the following aspects. Firstly, the chemical structure of polysaccharide is complex. The lack of chromophoric and fluorophoric groups reduces specific ultraviolet absorption; therefore, it is difficult to use conventional sensitive detectors to analyze. Secondly, polysaccharide has large molecular weight, and it is often composed of multiple components. Hence it is difficult to use specific standardization methods to make quantitative detection. In addition, there are many endogenous polysaccharides in the organism to interfere with analysis of polysaccharide drugs. These offer great obstacle in pharmacokinetic study of polysaccharide drugs. In this chapter, a reliable HPLC with pre-column derivatization and post-column fluorescence derivatization methods was developed for the determination of the M/G ratio of PSS and microanalysis of PSS in rat plasma, respectively. These methods provide the basis of the quality control, qualitative, and quantitative analysis. Especially, the HPLC methods can be used for microanalysis of polysaccharide drugs in vivo and pharmacokinetic study.

2 The Pre-Column Derivatization Method for Analysis of M/G Ratio of PSS

Nuclear magnetic resonance (NMR) has been widely used in determining the M/G ratio of alginate (Heyraud et al. 1996; Buranaosot et al. 2009; Aida et al. 2010). However, it is not suitable for the analysis of sulfated alginate derivatives because the presence of sulfate groups affects the resolution of anomeric proton signals. The method for M/G ratio determination of alginate by anion exchange liquid chromatography (Gacesa et al. 1983) is also not suitable for the microanalysis of PSS, alginate sulfated derivatives, because the lactone forms of uronic acids interfere with the quantification of M and G.

A reversed-phase HPLC method using 1-phenyl-3-methyl-5-pyrazolone (PMP) as a pre-column derivatization reagent for the separation and analysis of M and G was developed by our group. This method is rapid, accurate, and sensitive for determination of the M/G ratio in PSS, and it is suitable for quality control and microanalysis of PSS.

The pre-column derivatization method refers to samples reacting with derivatization reagents into derivatives with chromophoric and fluorophoric groups in advance, following chromatographic separation and detection. This method mainly applies the sensitive ultraviolet detector (UVD) and the fluorophotomeric detector (FD).

2.1 Degradation of Samples

Polysaccharide degradation includes chemical degradation (such as $NaNO_2$ degradation, acid degradation, and oxidative degradation), physical degradation (ultrasonic method and radiative method), and biodegradation (specific enzyme hydrolysis and nonspecific enzyme hydrolysis) (Chen and Wu 2008).

For the determination of M/G ratio, PSS should be hydrolyzed into monosaccharides primarily. The average molecular weight of PSS is about 10 KDa, and it is usually hydrolyzed by chemical degradation methods. Wu et al. (2014) studied four methods of hydrolysis of PSS, including dilute sulfuric acid (0.1 mol L^{-1}) degradation (at 120 °C for 4 h), trifluoroacetic acid (TFA, 2 mol L^{-1}) degradation (at 110 °C for 6 h) (Wang et al. 2009), microwave degradation (1,600 W at 130 °C for 15 min) (Hu et al. 2013), and conventional acid hydrolysis method (with 80 % H_2SO_4 at 20 °C for 18 h and then 2 mol L^{-1} H_2SO_4 at 100 °C for 6 h) (Haug and Larsen 1962). Comparing with the results of ^{1}H-NMR analysis, the M/G ratios of PSS degraded by the microwave method or dilute sulfuric acid method were approximate with a low loss of uronic acid. But the microwave method showed the poorest repeatability. Dilute sulfuric acid hydrolysis was selected as the best method for the hydrolysis of PSS, with low uronic acid loss and good repeatability.

The dilute sulfuric acid hydrolysis method is carried out as follows: 600 μL PSS solution (8 mg mL^{-1}) is added in a sealed glass ampoule, adding 200 μL water and

200 μL dilute sulfuric acid (0.5 mol L^{-1}), hydrolyzed in 120 °C for 4 h, and then neutralized with 500 μL NaOH (0.4 mol L^{-1}) after it is cooled to room temperature. In the last, PSS hydrolysates are kept at −50 °C until used for derivatization and analysis.

2.2 Derivatization of Samples

Due to the strong polar, similar structure, and lack of optical activity in polysaccharide, gas chromatography (GC) was applied to determine the composition of polysaccharide previously. But more and more researchers focus on the HPLC method for the qualitative and quantitative analysis. Usually monosaccharide derivatization with ultraviolet or fluorophotomeric groups is required for separation and detection by HPLC (Bao et al. 2002; Xing et al. 2011). Currently, monosaccharide derivatization reagents include PMP (Honda et al. 1989), *p*-aminobenzoic acid (Hao et al. 2007), *p*-anisidine (Ma et al. 2012), 2-aminopyridine (Tomiya et al. 1987), and so on.

The majority of derivatization is based on the reductive amination reaction. In this process, acid was added to catalyze the reaction for a long time which prompted the growing unstable products and influenced the next analysis (Suzuki et al. 2001). PMP can react with reducing sugars in mild conditions without the addition of acid, and the derivative products have strong absorption in 245 nm. Therefore, PMP has been widely used in the analysis of polysaccharide composition.

Wang et al. (2009) optimized the derivatization conditions for PSS, PMS, and PGS, three marine drugs with different uronic acid components. With the development of analytical techniques, the derivatization method of PSS was further improved (Wu et al. 2014).

The PMP derivatization method is carried out as follows: 100 μL of 0.3 mol L^{-1} NaOH is added in 100 μL of PSS hydrolysate and the mixture is blended. One hundred twenty microliter methanolic solution of PMP (0.5 mol L^{-1}) is added and blended and then the final mixture is heated to 70 °C and incubated for 1 h. After the reaction mixture is cooled to room temperature, it is neutralized with 100 μL of 0.3 mol L^{-1} HCl and then extracted with chloroform (500 μL each) for four times. The aqueous layer is filtered through a 0.22 μm micron membrane filter before HPLC analysis.

2.3 HPLC Analysis of Samples

After PSS was hydrolyzed and derivatizated with PMP, it was separated at the optimal chromatographic conditions by HPLC to determine the M/G ratio. The M/G ratio of PSS was calculated by comparing the peak area values of M or G to each calibrated standard curve. Calibration curves of M and G were constructed by plotting the peak areas against the concentrations of their monosaccharide standards.

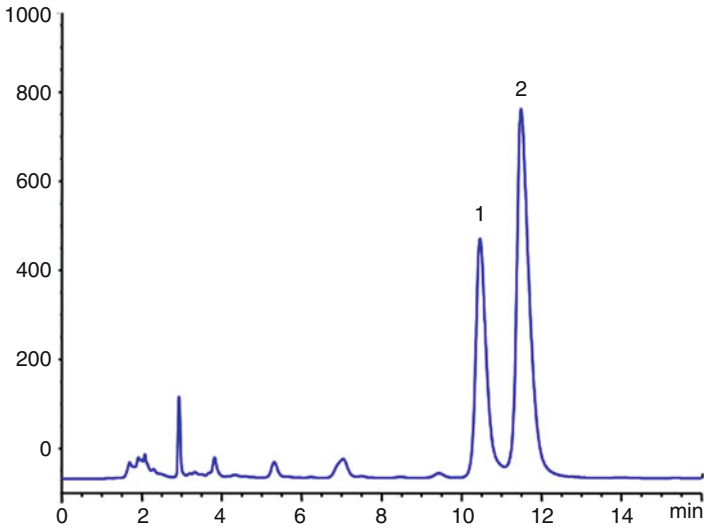

Fig. 2 The chromatogram of M/G ratio of PSS, 1-guluronic acid (*G*), and 2-mannuronic acid (*M*)

The separation conditions of M and G derivatives were investigated by changing the pH value of the phosphate buffer, the proportion of acetonitrile, the flow rate, and loading quantity of the sample (Wu et al. 2014). The chromatogram was shown in Fig. 2.

The optimal chromatographic separation of derivatives is carried out as follows: A HPLC system with UVD and a C18 column (150 × 4.6 mm, 5 μm) is used for HPLC analysis. Chromatographic separation of PMP derivatives is carried out using 0.1 mol L^{-1} phosphate buffer (pH = 7.0) and acetonitrile at a ratio of 83:17 (v/v, %) as a mobile phase at a flow rate of 0.8 mL min^{-1}. The temperature of the column is maintained at 30 °C and detected by UVD at 245 nm.

To demonstrate that the proposed HPLC method is optimal, we employed a desulfurization strategy (Falshaw and Furneaux 1998) to overcome the influence of the sulfate group on the resolution of anomeric proton signals. We determined the M/G ratio of PSS by the NMR technique using its intermediate (low-molecular-weight alginate) and desulfurization products. Results showed that the M/G ratios of PSS determined by the HPLC method were in good accordance with those obtained by the traditional nondestructive ^{1}H-NMR method using desulfurization products (Wu et al. 2014).

This showed that the HPLC method is accurate in determining the M/G ratio of PSS. The M/G ratio results for PSS samples that were collected from different manufacturers in China were shown in Table 1 (Wu et al. 2014). There were obvious differences in the M/G ratios for the ten PSS samples, which likely resulted from the differences in raw material alginates. This means it is necessary to strengthen the quality control of PSS.

Table 1 M/G ratios of PSS samples that were collected from different manufacturers in China

Sample	Peak area (average, mAu*min)		Peak area ratio	M/G ratio	RSD(%) ($n = 3$)
	G	M			
1	76.49	181.91	2.38	1.26	1.62
2	68.90	164.98	2.39	1.26	0.83
3	72.71	165.44	2.28	1.21	1.60
4	128.18	224.39	1.75	0.93	1.81
5	127.01	240.08	1.89	1.00	1.34
6	132.81	238.29	1.79	0.95	1.10
7	112.84	233.91	2.07	1.10	0.74
8	124.35	204.55	1.65	0.87	1.54
9	106.58	227.59	2.14	1.13	0.63
10	89.94	174.61	1.94	1.03	0.53

3 The Post-Column Derivatization Method for Pharmacokinetic Analysis of PSS

For pharmacokinetics of polysaccharide, the analytical methods include isotope labeling method (Laforest et al. 1991), immunoassay (Wang et al. 2011), bioassay (Mischke et al. 2012), chromatography (Lin et al. 2010), and mass spectroscopy (MS) (Pan et al. 2009). PSS possesses few chromophoric or fluorophoric groups. The sensitivity of analysis of PSS in biological samples by measuring the refractive, scattering indexes or using colorimetric assays is relatively poor. Due to the limitations of traditional analysis techniques and methods, there are not many suitable methods to study the pharmacokinetic characteristics of PSS. The labeling method of tritium (^{3}H) was firstly applied to early pharmacokinetic study of PSS (Liu et al. 1990). However, taking into account the radioactivity of ^{3}H, it was not applied to pharmacokinetic study in the human body. We also developed a fluorescent labeling method to microanalyze PSS and study its pharmacokinetic parameters with fluorescein isothiocyanate (FITC) (Li et al. 2014). The fluorescent labeling method was of high sensitivity and safety with relatively low cost. However, this method was complicated and time-consuming and also could not be applied to pharmacokinetic studies in human body.

The post-column derivatization method refers to add reagents into the liquid chromatographic effluent to increase detection sensitivity of sample bands or to enhance sensitivity with respect to interfering bands which overlap sample bands of interest, using one or more hollow fibers immersed within mobile reagent which is permeated through the walls of the fibers and, thus, ultimately diffused into the column effluent (Davis 1985). The post-column HPLC system was showed in Fig. 3. This method has advantages of convenience, good reproducibility, continuous reaction, and is easy to realize automatic analysis (Yang 2008).

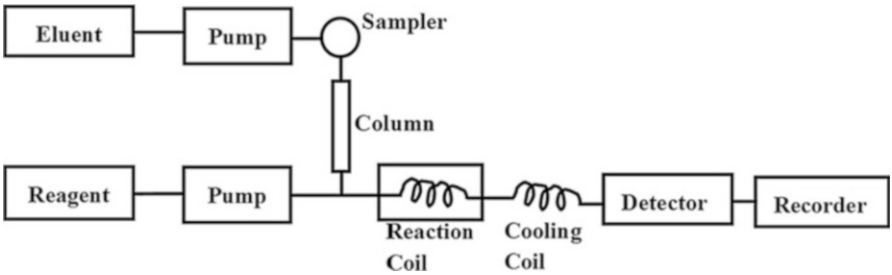

Fig. 3 The flow diagram of the post-column HPLC system

The post-column fluorescence derivatization reagents mainly include aliphatic amines, guanidines, amidines, and so on (Sun 2008). Nozal et al. employed post-column derivatization of carbohydrates with ethanolamine-boric acid prior to their detection by HPLC (Nozal et al. 1992). Coquet et al. realized trace level detection of reducing saccharides using HPLC by selective post-column fluorogenic reaction with benzamidine (Coquet et al. 1991). Sun et al. (2012) selected guanidine as a fluorometric reagent for the determination of oligosaccharide HS203 in beagle dog blood plasma by HPLC post-column fluorescence derivatization method. In 2013, Li et al. (2013) also chose guanidine hydrochloride as a post-column derivatizing reagent to detect PSS in rat plasma by HPLC method.

Based on the above research work, a highly sensitive and effective HPLC method with post-column fluorescence detection was developed to determine PSS in rat plasma. This method, using guanidine hydrochloride as the fluorescence derivatization reagent, was validated to have high accuracy, precision, and reproducibility. Plasma samples were prepared by a simple and fast ultrafiltration method. Isocratic chromatographic separation was performed on a TSKgel G2500PWxL column with the mobile phase of 0.1 M sodium sulfate. Analyte detection was achieved by FD at 250 nm (excitation, λex) and 435 nm (emission, λem).

3.1 Animal Administration and Sampling

Healthy Wistar rats (male and female, 1:1), 200–220 g in body weight, were used for the study of pharmacokinetics of PSS.

Rats were randomly divided into two groups, the oral administration group of PSS and the intravenous injection group of PSS. All the rats were fasted overnight prior to dosing. PSS was dissolved in sterile saline and administered to the rats by a single oral gavage (50 mg kg^{-1}) and a single injection via the tail vein (25 mg kg^{-1}).

The blood samples (about 0.3 mL) collected from the tip of the tail at predetermined time intervals up to 48 h after oral administration and 24 h after intravenous injection were placed into sodium citrate microcentrifuge tubes. The blood samples were centrifuged at 3,000 rpm for 15 min and the separated plasma (100 μL) was stored at −50 °C until analysis.

3.2 Pretreatment of Blood Sample

Except for the drugs, biological samples contain many endogenous substances, including protein, polypeptide, fatty acids, pigments, and lipids. These interfering substances with larger molecular weight cannot only plug the column (Masuda et al. 1996) but also influence the determination of drugs if the separation of drugs with these macromolecular substances is not good. Accordingly, pretreatment of biological samples (serum, tissue, urine, etc.) is deemed the foundation of pharmacokinetic study. Pretreatment of biological samples should fully consider the physicochemical properties, the chemical composition, the protein binding rate, the type of matrix interference, the stability, the pollution of pretreatment process, the suitable solvents of chromatographic system for the tested samples, and so on (Masuda et al. 1996; Danielson et al. 1999).

Pretreatment of biological samples is mainly to remove protein. In order to quantitatively analyze drugs in biological samples, the combination between protein and drugs must be destroyed and drugs can be collected as much as possible (Nojiri et al. 2000). Sun et al. (2012) carried out the ultrafiltration method to remove protein of oligosaccharide HS203 blood samples, established a simple and convenient method of oligosaccharide pharmacokinetics.

In 2013, Li et al. (2013) carried out the ultrafiltration method to remove protein of PSS blood samples, laying the foundation of polysaccharide pharmacokinetics. In the pretreatment procedure, PSS was released completely from the blood plasma and almost all plasma proteins were retained in Ultra-0.5 centrifugal filter (30 kDa, MWCO). The method involving centrifugal ultrafiltration was convenient, reproducible, and high recoverable, and the endogenous substances in the plasma did not interfere the detection of PSS in HPLC analysis. Since PSS is a kind of uronic acid derivative, D-glucuronic acid was selected as IS due to its high recovery, suitable retention time, and similar structure to the analyte.

This pretreatment of centrifugal ultrafiltration method is carried out as follows: To a 100 μL portion of plasma sample, 50 μL of water and 10 μL D-glucuronic acid (IS, 3.0 mg mL^{-1}) solution are added. Then the mixtures are vortexed for 3 min and transferred into a 30 KD Ultra-0.5 centrifugal filter device. After centrifugation at 12,000 rpm for 20 min, the aliquot (20 μL) of the supernatant is submitted to the HPLC system.

3.3 HPLC Analysis of Samples

To explore high-sensitivity detection method for PSS, the derivatization conditions were optimized, including the selections of columns and the fluorescence derivatization reagents, and the IS was carried out to determine the analytes in the plasma (Li et al. 2013).

The column selection was based on the properties of PSS and relevant literature of similar polysaccharide drugs. Based on size exclusion and distribution, TSKgel G3000PWxL and TSKgel G2500PWxL columns were tried, which are different in

the exclusion limits of molecular weights. The glucose in the plasma was separated excellently from PSS and IS by the TSKgel G2500PWxL column, so it was chosen as the analytical column. Sodium sulfate (0.1 M) was chosen as the appropriate mobile phase after testing several mobile phases, and the appropriate flow rate was established at 0.5 mL·min^{-1}.

Then benzamidine and guanidine hydrochloride were selected as fluorescence derivatization reagents as a check. The experiments showed that guanidine hydrochloride had high sensitivity compared with benzamidine. Therefore guanidine hydrochloride was used as the fluorescence derivatization reagent.

In order to improve the sensitivity of the method, three derivatization reaction factors were tested: the concentration of guanidine hydrochloride, the reaction temperature, and the concentration of sodium hydroxide. As a result, 0.1 M guanidine hydrochloride, 120 °C, and 0.5 M sodium hydroxide were chosen as the optimal reaction conditions.

The post-column HPLC analysis was performed on a Dionex UltiMate™ 3000 HPLC system, which was equipped with a pump (DGP-3600SD), an autosampler (WPS-3000SL), a column compartment (TCC-300RS), and a fluorescence detector (FD-3100). The chromatogram of blood sample was shown in Fig. 4.

The optimal chromatographic separation is carried out as follows: A HPLC system with FD and TSKgel G2500PWxL column is used for HPLC analysis. The chromatographic separation is performed on a TSKgel G2500PWxL column (300 × 7.8 mm, 7 μm) at 30 °C. The mobile phase is 0.1 mol·L^{-1} Na_2SO_4 at a flow rate of 0.5 mL min^{-1}. In the post-column procedure, a 0.5 mol L^{-1} NaOH solution containing 0.1 mol L^{-1} guanidine hydrochloride is passed through polytetrafluoroethylene (PTFE) reaction coil (0.5 mm i.d. × 10 m) thermostated at 120 °C and then the mixture is added to the column effluent at a flow rate of 0.3 mL min^{-1}. Subsequently, a 0.5 mol L^{-1} NaOH solution at a flow rate of 0.3 mL min^{-1} is added

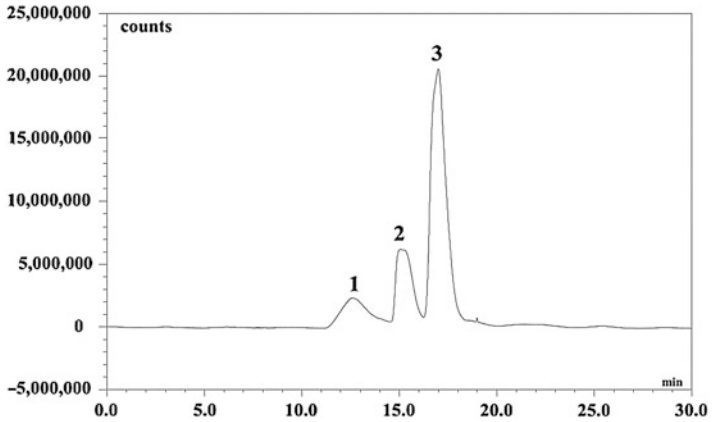

Fig. 4 The chromatogram of blood sample, 1-PSS, 2-D-glucuronic acid, and 3-glucose in the plasma

Table 2 Pharmacokinetic parameters ($n = 7$) of PSS after a single oral gavage (Ig) and a single intravenous injection (i.v.) of PSS, respectively

	PSS	
Pharmacokinetic parameters	i.v.	Ig
T_{max} (h)	–	0.50 ± 0.00
C_{max} (μg·mL^{-1})	1217.21 ± 361.74	22.91 ± 4.67
$T_{1/2}$ (h)	3.11 ± 0.62	35.96 ± 16.65
$AUC_{0\text{-}t}$ (h*μg·mL^{-1})	1315.52 ± 314.33	251.22 ± 30.25
Vd (mL·kg^{-1})	0.087 ± 0.021	5.59 ± 1.96
CL (mL*kg·h^{-1})	0.020 ± 0.0039	0.12 ± 0.032
MRT (h)	2.59 ± 0.71	55.96 ± 23.30
F (%)	9.55	

to cool down the mixture in another PTFE coil (0.25 mm i.d. × 3 m) with an ice bath. Fluorescence detection is carried out at λex of 250 nm and λem of 435 nm.

The validated method described above was successfully applied to the determination of PSS in rat plasma. Calculations were performed with the pharmacokinetic program PKSolver. The pharmacokinetic parameters of PSS were characterized and the limit of lowest detection (LLOD) was 250 ng mL^{-1} which indicated that this method was of high sensitivity. The pharmacokinetic parameters and concentration-time curve were shown in Table 2 and Fig. 5.

All the pharmacokinetic parameters in this study were similar to those obtained previously by the fluorescent labeling method (Li et al. 2014). Taking into account the simplicity of the method and the suitability for human pharmacokinetic study, the HPLC method with post-column fluorescence detection was shown to be the optimal method to determine PSS and to study its pharmacokinetic characteristics in biological samples.

4 Conclusion

With the deep development of chemical glycobiology, the research and development on carbohydrate-based drugs attract more and more attention, especially the bioactive polysaccharides. Because of the structure complexity and interference of endogenous glycan, the microanalysis of polysaccharide drugs in vivo and in vitro is a big challenge. Although the development of modern analytical techniques offers favorable support for pharmacokinetic study of polysaccharide, the current pharmacokinetics of polysaccharide is still lacking of comprehensive, systematic, and in-depth study. The reported study related with pharmacokinetics of polysaccharide is relatively few. The isotope labeling method is once most widely used, and biological method is also explored. Currently chromatography has been becoming more and more important in pharmacokinetics study with its sensitivity, simplicity, non-toxicity, and other characteristics. However, new suitable HPLC method is demanded for the microanalysis of polysaccharide drugs. In this chapter, HPLC with pre-column derivatization and post-column fluorescence derivatization

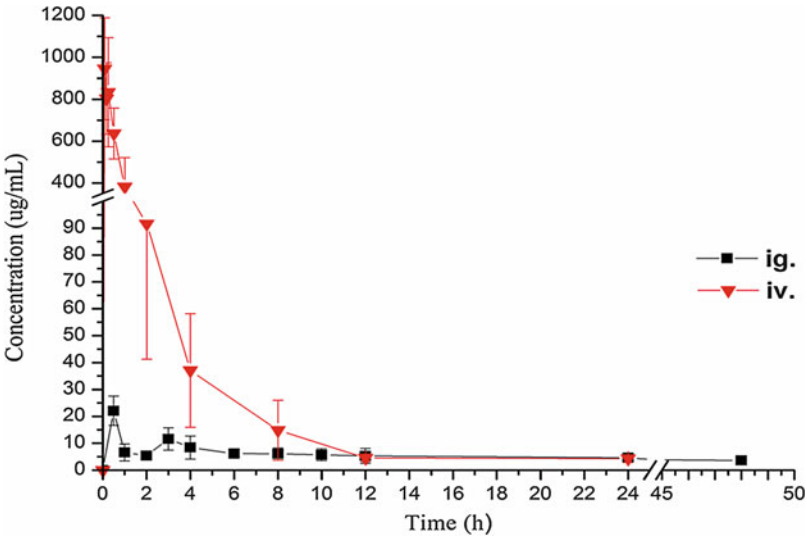

Fig. 5 The concentration-time curves of PSS in rats after a single oral gavage (ig) and a single intravenous injection (i.v.) of PSS, respectively. Each data point represents the mean ± sd ($n = 7$)

methods was developed for the determination of the composition of PSS and microanalysis of PSS in rat plasma. These methods provide the basis of the quality control, qualitative, and quantitative analysis for polysaccharide drugs.

But these methods cannot answer all the problems of microanalysis of polysaccharide drugs, especially the pharmacokinetics. Taking into account the accuracy sensitivity, simplicity of the methods, and the suitability for human pharmacokinetic study, innovative methods are still demanded for the detection and quantification of polysaccharide drugs.

Determination of Must and Wine Polysaccharides by Gas Chromatography-Mass Spectrometry (GC-MS) and Size-Exclusion Chromatography (SEC)

43

Zenaida Guadalupe, Belén Ayestarán, Pascale Williams, and Thierry Doco

Contents

Abstract

Polysaccharides are one of the major classes of macromolecules found in wines. They play a critical role in stabilizing other molecules in solution and thus are able to modify both the wine processing and organoleptic properties. Detailed analyses of these polysaccharides are essential to know their physicochemical properties and biological functions.

We present analytical techniques not only to define the fine chemical structures of individual wine polysaccharides but also to estimate the overall polysaccharide composition of must and wines. The procedure covers the preparation of the sample, together with gas chromatography-mass spectrometry-based methods, for both the analysis of monosaccharides as their volatile trimethylsilyl methyl glycoside derivatives and methylation analysis to determine linkage positions between monosaccharide residues as their volatile partially methylated alditol acetate derivatives. We also provide a protocol for estimating the global

content of wine polysaccharides by using size-exclusion chromatography with refractive index detector (SEC-RID). This is a rapid and simple method that can be used routinely in a reasonably equipped laboratory. Analysis complexity and time will vary depending on the method used, and the duration ranges from 2 days for a global polysaccharide estimation to 2 weeks for a carboxyl reduction/methylation linkage analysis.

1 Introduction

Polysaccharides are one of the main groups of macromolecules in wines. They can be present in concentrations ranging from 200 to 1,500 mg L^{-1} depending on winemaking stage, winemaking practices, vintage, variety, and *terroir*.

Wine polysaccharides originate both from grapes and microorganisms acting during the winemaking. Major wine polysaccharides include (i) polysaccharides rich in arabinose and galactose (PRAG), which comprise arabinans, arabinogalactans, and arabinogalactan proteins (AGP) and originate from grape berry cell walls; (ii) rhamnogalacturonans types I and II (RG-I and RG-II), which also arise from grape berry cell walls; and (iii) mannoproteins (MP) and glucans (GL) which are released by yeast during fermentation and during the aging of wines on lees. Therefore, Vidal et al. (2003) found that the polysaccharides from a Carignan Noir wine were composed of 42 % AGP, 35 % MP, 19 % RG-II, and 4 % RG-I, and Guadalupe and Ayestarán (2007) found values of 50 % AGP, 30 % MP, and 15 % RG-II in young red Tempranillo wines and 37 % AGP, 45 % MP, and 15 % RG-II in Tempranillo wines aged in oak. In a recent study, values of 35 % PRAG, 35 % MP, and 25 % GL were found for white and rosé sparkling wines made from different grape varieties (Martínez-Lapuente et al. 2013).

Wine polysaccharides play a critical role in stabilizing other molecules in solution, preventing or limiting aggregation and flocculation and thereby haze formation (Waters et al. 1994; Moine-Ledoux and Dubourdieu 1999; Dupin et al. 2000; Lomolino and Curioni 2007; Schmidt et al. 2009) and tartrate salts crystallization (Gerbaud et al. 1997; Moine-Ledoux and Dubourdieu 2002). Wine polysaccharides have also been described for their detrimental role in filterability (Belleville et al. 1991, 1992; Vernhet et al. 1999), their influence on the fermentation flora (Guilloux-Benatier et al. 1995; Guilloux-Benatier and Chassagne 2003), and their interaction with aromatic compounds (Dufour and Bayonove 1999; Chalier et al. 2007) and other molecules responsible for wine flavor, color, and foam (Riou et al. 2002; Vidal et al. 2004; Poncet-Legrand et al. 2007; Martínez-Lapuente et al. 2013). However, it has been shown that not all polysaccharides have the same behavior with respect to wines. Their influence on wine processing and sensory properties will depend not only on their quantity but also on the type of

polysaccharide. It has been shown that AGP have greater influence on the filtration procedures than MP (Ribéreau-Gayon et al. 2006) which are more efficient at reducing protein haze in white wines (Waters et al. 1994; Moine-Ledoux and Dubourdieu 1999; Dupin et al. 2000). RG-II is a stronger accelerator of hydrogen tartrate crystallization than RG-I, accelerating crystallization at low concentrations and inhibiting it at high concentrations (Gerbaud et al. 1996). AGP, on the other hand, have no effect on this phenomenon (Ribéreau-Gayon et al. 2006). Among the MP classes present in wine, some have been found to act as protective factors with regard to tartrate salts precipitation (Gerbaud et al. 1997; Moine-Ledoux and Dubourdieu 1999), and it has also been described that MP can adsorb toxic ochratoxin A from wines (Bejaoui et al. 2004; Baptista et al. 2004; Ringot et al. 2005; Caridi et al. 2006) and that the dimer RG-II /boron can form complexes with di- and trivalent cations which could reduce the level of toxic cations in wines (Pérez et al. 2003). There are also important differences with regard to the effect of wine polysaccharides on the organoleptic properties of red wines. It has been shown that RG-II, MP, and AGP have different influences on the aggregation of proanthocyanidins (Riou et al. 2002; Mateus et al. 2004; Carvalho et al. 2006; Poncet-Legrand et al. 2007) and, therefore, have varied influences on the wine gustatory structure, fullness, and body (Vidal et al. 2004; Quijada-Morín et al. 2014). Interactions between aroma compounds and MP have also been described (Dufour and Bayonove 1999; Chalier et al. 2007). In the case of sparkling wines, some authors have correlated the foam properties of grape juices, base wines, and sparkling wines with the polysaccharide content (Andrés-Lacueva et al. 1996, 1997; López-Barajas et al. 1998a; Girbau-Sola et al. 2002a, b). A connection between the molecular weight and composition of polysaccharides and foaming characteristics has also been shown (Moreno-Arribas et al. 2000; López-Barajas et al. 2001), and some authors have identified the yeast MP released during autolysis as the molecules responsible for the improvement of foaming properties (Nuñez et al. 2005, 2006; Abdallah et al. 2010; Coelho et al. 2011). However, it has been shown that not all mannoproteins have the same behavior (Nuñez et al. 2006; Coelho et al. 2011). Moreover, MP plays other roles in sparkling wines since they contribute to the flocculation of yeast strains (Caridi 2006) and improve their elimination from the bottle during disgorging.

Considering all the potential effects of wine polysaccharides in both wine processing and quality, several attempts have been done during the last years in order to increase their content into the wines. The amount of polysaccharides released in red wines depends on the winemaking process, and low temperature techniques during the winemaking (cold prefermentative maceration, dry ice addition, grape skin freezing) have been applied in order to degrade the cell walls and achieve greater extraction of polysaccharides (Apolinar-Valiente et al. 2013, 2014). The efficiency of using commercial pectinases to increase the extraction of wine polysaccharides and oligosaccharides has also been studied (Ayestarán et al. 2004; Guadalupe et al. 2007; Doco et al. 2007; Ducasse et al. 2010a, 2011; Apolinar-Valiente et al. 2013). The effect of adding commercial mannoproteins or other yeast extracts and autolysates in the winemaking has also been studied in literature

(Comuzzo et al. 2006; Guadalupe and Ayestarán 2008; Pozo-Bayón et al. 2009; Guadalupe et al. 2010; Del Barrio-Galán et al. 2011). Moreover, many types of these products are currently used as technological adjuvants in the enological industry in order to increase the content of mannoproteins in the wines and thus improve their overall stability, modify the mouth-fell properties and color of red wines, and improve the aromatic intensity of white wines or the foam properties of sparkling wines. Taking into account the growing tendency in the use of these commercial products, different studies have focused on the evaluation of methodologies to increase the content of mannoproteins into the wines. The effect of the addition of mannoprotein overexpressing yeast strains during the alcoholic fermentation of still wines was analyzed by Guadalupe et al. (2007, 2010); thermosensitive autolytic mutants of *S. cerevisiae* made to increase the release of polysaccharides have been employed during the alcoholic fermentation (Giovani and Rosi 2007) and the secondary fermentation of sparkling wine production (González et al. 2003; Nuñez et al. 2005); and different technological approaches have been applied to accelerate the autolytic process during wine aging on lees (Doco et al. 2003a; Nuñez et al. 2005; Pati et al. 2010; Fernández et al. 2011).

In conclusion, many groups have focused their research on wine polysaccharides during the last decade, trying to isolate and characterize them; studying their evolution from grape to wine and during the winemaking and aging; analyzing their functions, mechanisms of action, and factors affecting their content; or trying to modulate their content into the wines. However, many of these researches have shown contradictory results, and there are still many aspects regarding polysaccharide structural characterization, functions, and mechanisms of action that still remain unknown. The difficulty in separating and purifying all of these compounds has resulted in them being less studied than other wine compounds such as polyphenols, polypeptides, or proteins. Therefore, the simple study of wine polysaccharides is difficult and time-consuming, and an adequate determination of the different polysaccharide families requires analytical methodologies which involve complex multistep procedures.

To determine the content of grape, must, or wine polysaccharides, all the methods proposed begin with an extraction step by direct precipitation with either ethanol acid, concentration-precipitation, dialysis, or ultrafiltration. After the extraction step, two alternatives can be chosen to analyze the polysaccharides in the extract: (i) using rapid and simple methods to estimate the global content of polysaccharides and (ii) using more complex and time-consuming methods to quantify specific families of polysaccharides. Direct quantification of wine polysaccharides is usually based on the precipitation of total wine colloids, followed by traditional colorimetric assays (Segarra et al. 1995) or by the determination of peak areas by size-exclusion chromatography (Dubourdieu et al. 1986; López-Barajas et al. 1998b; Guadalupe et al. 2012). However, these global methods do not allow the quantification of the different families of polysaccharides present in wines, which can only be estimated by assessing its monosaccharide profile. Several methods have been proposed for the identification and quantification of grape and wine monosaccharides: high-performance anion-exchange chromatography with

pulsed amperometric detection (HPAEC-PAD) (Arnous and Meyer 2009), Fourier transform infrared spectroscopy (FTIR) (Coimbra et al. 2005; Boulet et al. 2007), and gas chromatography (GC). When GC is used, two different detectors have been used: flame ionization detector (FID) and mass spectrometry detector (MS). Undoubtedly, gas chromatography coupled with mass spectrometry (GC-MS) after hydrolysis and monosaccharide silylation is of general acceptance due to its high sensitivity combined with its ability to achieve efficient separation of complex mixtures and structural characterization.

We present in this chapter analytical techniques to quantify must and wine polysaccharides. We provide a simple and rapid protocol for estimating the global content of wine polysaccharides by using of size-exclusion chromatography with refractive index detector (SEC-RID). We also present more complex techniques not only to define the fine chemical structures of individual wine polysaccharides but also to estimate the overall polysaccharide composition of must and wines. The procedure covers the preparation of the sample, together with gas chromatography-mass spectrometry-based methods, for both the analysis of monosaccharides as their volatile trimethylsilyl methyl glycoside derivatives and methylation analysis to determine linkage positions between monosaccharide residues as their volatile partially methylated alditol acetate derivatives. Firstly, an understanding of the structure of the different polysaccharide families is essential.

2 Wine Polysaccharides: Origin and Structure

Wine polysaccharides are grouped in two families according to their origin: those originating from grape berry cell walls and those released by microorganism, which include yeast, bacteria, and fungal grape contamination such as *Botrytis cinerea*. Exogenous polysaccharides such as arabic gum and carboxymethyl cellulose could also be present in several commercial wines as they are authorized as additives. This origin diversity leads to polysaccharide families that are different in composition and structure, and a deep knowledge of their composition is essential for their quantification. Hence, during the past decade, many works have focused on the isolation and structural characterization of polysaccharides from different must and wine matrices.

Grape polysaccharides include polysaccharides rich in arabinose and galactose (PRAG), which comprise arabinans, type I arabinogalactans and type II arabinogalactan proteins (AGP), rhamnogalacturonans type I (RG-I) and type II (RG-II), and homogalacturonans (HL). These polysaccharides are released from the pectic network of berry cell walls under the action of several endogenous and exogenous enzymes during the earlier stages of winemaking (Guadalupe and Ayestarán 2007). The cell wall of grape skins is built of three general layers: (i) the middle lamella, which binds the cell together and is mainly composed of pectin, (ii) the primary cell wall, and (iii) the secondary cell wall. Figure 1 shows a model of a primary plant cell wall, which consists of several interconnected matrices composed of structural proteins and polysaccharides, which make up about 90 % of the dry weight of primary cell walls. Such matrices include a

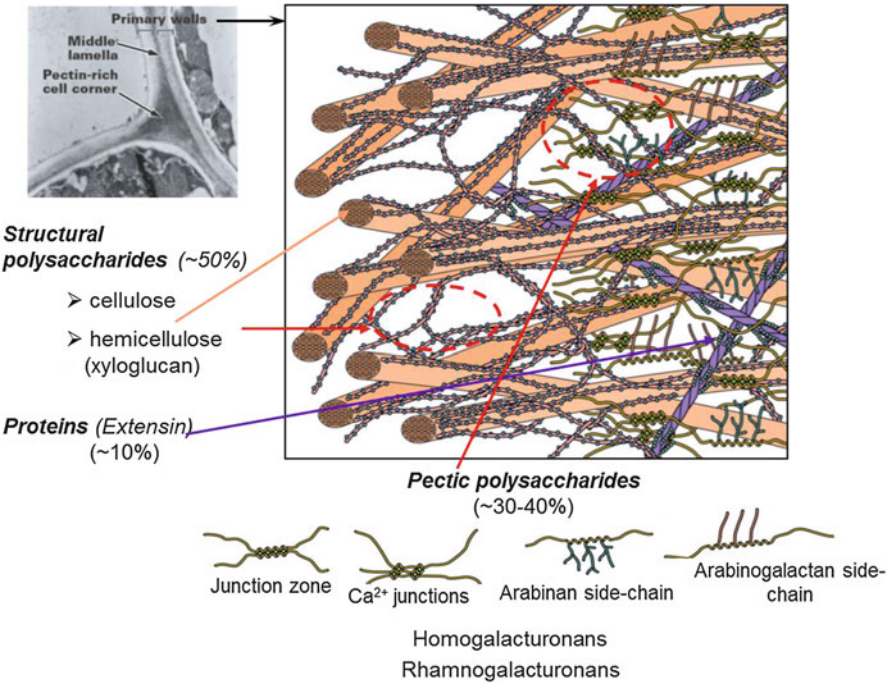

Fig. 1 Model of a primary plant cell wall. The percentage of the dry weight of each compound is shown

cellulose and associated hemicelluloses framework that is embedded in a matrix of the pectin polysaccharides composed of homogalacturonan, rhamnogalacturonan II, and rhamnogalacturonan I, with a diverse range of arabinogalactan and arabinans side chains (Vidal et al. 2003). The secondary cell wall is largely made of cellulose microfibrils (40–80 %) and also contains hemicelluloses and some lignin (Pinelo et al. 2006).

Cellulose is composed of α-(1–4)-linked D-glucose. In grape cell walls, hemicellulosic polysaccharides consist mainly of xyloglucans whose structures are based on a β-(1–4) D-glucan backbone in which about 75 % of the glucose residues carry β-D-Galp-(1 → 2)-α-D-Xylp(1 → 6) or α-L-Fucp(1 → 2)- β-D-Galp-(1 → 2)-α-D-Xylp(1 → 6) side chains (Doco et al. 2003b; Pinelo et al. 2006). Although these structural glucosyl polysaccharides are major in both the skin and pulp cell wall of grape berries (Vidal et al. 2001), and they are found in important amounts in must samples (Guadalupe and Ayestarán 2007), they are detected in very low quantities in wine samples as they precipitate during the winemaking (Guadalupe and Ayestarán 2007). Homogalacturonans, which are linear chains of α-(1–4)-linked D-galacturonic acid (Fig. 2), can make up to 80 % of the pectic polysaccharides in grapes, but they are also present in wines in very low amounts (Guadalupe and Ayestarán 2007) as they are probably fragmented by polygalacturonases during winemaking (Vidal et al. 2001). RG-I molecules are characterized

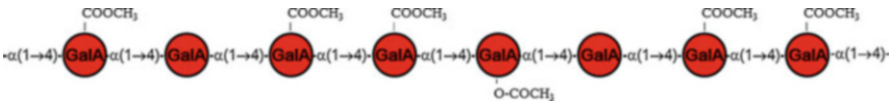

Fig. 2 Chemical structure of the homogalacturonan (HL). *GalA* galacturonic acid

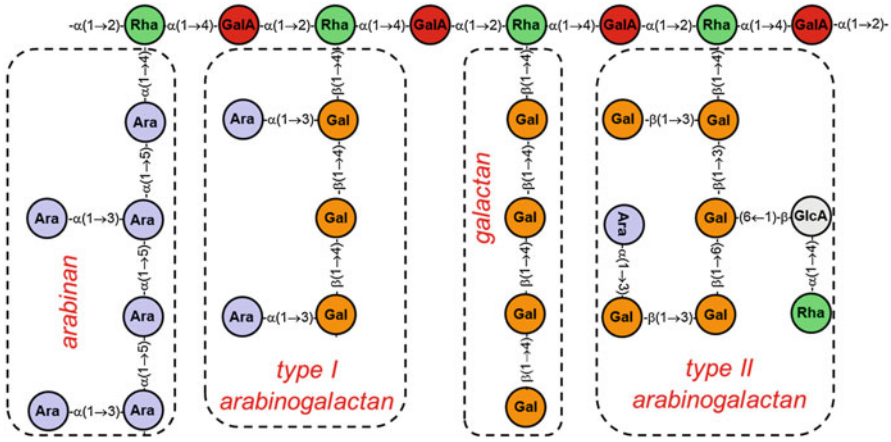

Fig. 3 Chemical structure of the type I rhamnogalacturonan (*RG-I*). *Ara* arabinose, *Gal* galactose, *GalA* galacturonic acid, *GLcA* glucuronic acid, *Rha* rhamnose

by a backbone of alternating galacturonic acid and rhamnose residues and side branches that are arabinans, galactans, and arabinogalactans (Fig. 3). These polysaccharides are also abundant in grape berries, but they are also insignificant in wines due to their poor solubility (Vidal et al. 2001). RG-I isolated from grapes show mainly arabinans and type II arabinogalactan side chains (Vidal et al. 2001). However, RG-I isolated from wines, with molecular weights ranging from 45 to 50 kDa, contain side chains of type I and II arabinogalactans and only a small proportions of arabinans (Vidal et al. 2003). RG-II structure is largely conserved along plant species and consists of a short (1 → 4)-α-D-galacturonan backbone branched with four different side chains containing primarily rhamnose, arabinose, and galactose and also different rare sugars such as aceric acid or 3-*C*-carboxy-5-deoxy-L-xylose, apiose, Dha or 3-deoxy-D-lyxo-2-heptulosaric acid, Kdo or 3-deoxy-D-manno-octulosonic acid, and 2-*O*-methyl-fucose and 2-*O*-methyl-xylose (Fig. 4), which allow for its identification and quantification. RG-II, which accounts for less than 3 % of the berry cell wall (Vidal et al. 2001), is one of the major polysaccharides in musts and wines (Vidal et al. 2003; Guadalupe and Ayestarán 2007), where it is mainly found in the form of dimmers cross-linked by borate-diol esters, with an average molecular weight of around 10 kDa. As previously described, arabinans and arabinogalactans are side chains of the RG-I backbone arising from their degradation by pectinases. Type I arabinogalactans have a backbone of (1 → 4)-β-D-galactan and are not present in wine polysaccharides

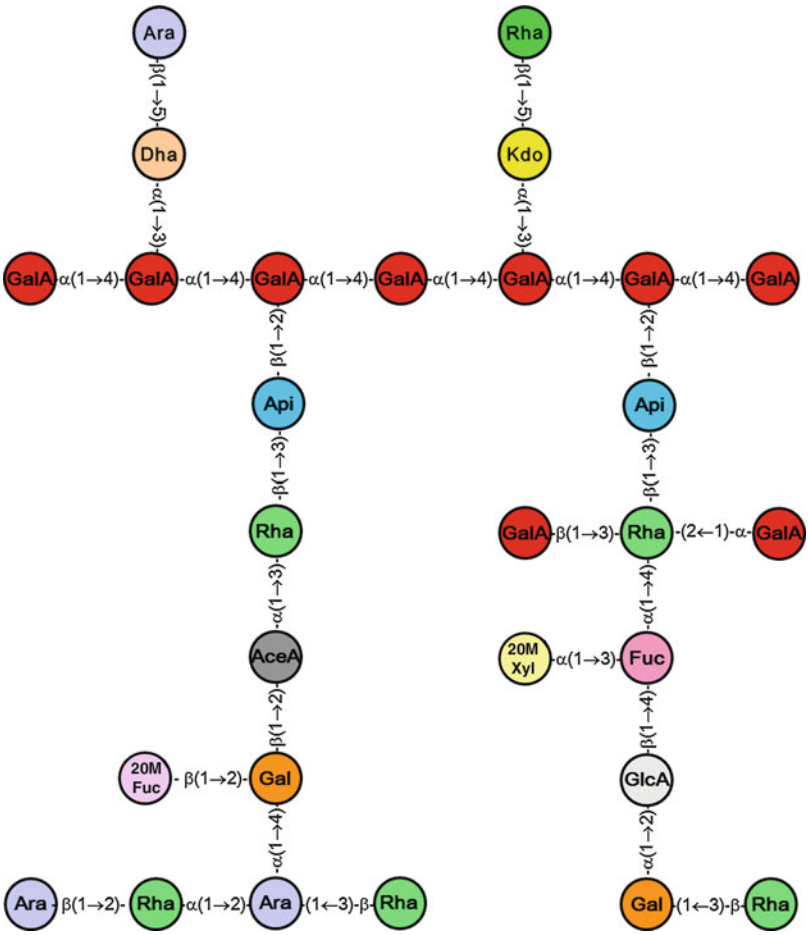

Fig. 4 Chemical structure of the type II rhamnogalacturonan (*RG-II*). *AceA* aceric acid (3-C-carboxy-5-deoxy-L-xylose), *Ara* arabinose, *Api* apiose, *Dha* 3-deoxy-D-*lyxo*-2-heptulosaric acid, *Fuc* fucose, *Gal* galactose, *GalA* galacturonic acid, *GlcA* glucuronic acid, *Kdo* 3-deoxy-D-manno-octulosonic acid, *Rha* rhamnose, *2OMFuc* 2-*O*-methyl-fucose, *2OMXyl* 2-*O*-methyl-xylose

(Doco and Williams 2013). Type II arabinogalactans are in fact arabinogalactan proteins (AGP) and represent more than 35 % of total red wine polysaccharides (Pellerin et al. 1995; Vidal et al. 2003; Guadalupe and Ayestarán 2007). Their common structural feature is a (1 → 3)-β-D-galactan backbone with (1 → 6) linked β-D-galactan side chains highly substituted by arabinofuranosyl residues (Fig. 5). Typical AGP isolated from wines commonly contain less than 5 % protein and show a molar mass from 50 to 260 kDa (Pellerin et al. 1995; Vidal et al. 2003; Doco and Williams 2013). AGP are localized in soluble forms within the cell walls and can be membrane anchored although this has not been demonstrated in the cell wall of grape berries (Doco and Williams 2013).

Polysaccharides from yeasts include mannans and mannoproteins (MP) and glucans (GL). They arise from the cell wall of *Saccharomyces cerevisiae*, and they can account for up to 90 % of the dry weight of their cell wall (Fig. 6). Mannoproteins produced by yeasts are the second most abundant family of polysaccharides in wine (Vidal et al. 2003; Guadalupe and Ayestarán 2007). These polysaccharides, which can account for up to 50 % of the cell wall dry mass of *S. cerevisiae*, are located in the outermost layer of the cell wall, where they are linked by β-1,3 glucan chain to the innermost, fibrous layer formed of β-1,3 glucan chains and chitin (Klis et al. 2006). These polymers, with highly variable sizes, are glycoproteins, often highly glycosylated, with carbohydrate fractions consisting mainly of mannose (>90 %) and glucose (Fig. 7). Two classes of mannoproteins have been described in wines. The first group is released by the action of a β-1,3 glucanase upon the wall during aging of wine on lees in the presence of nonmultiplying cells (autolysis); the second group is released by yeast when actively growing during alcoholic fermentation of grape must. These last compounds, with highly variable sizes from 5 to more than 800 kDa (Doco et al. 2003a),

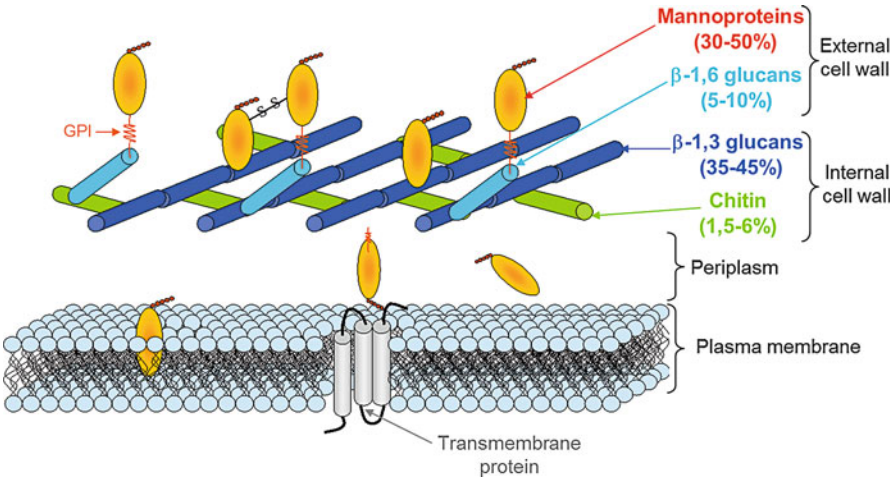

Fig. 6 Model of a yeast cell wall. The percentage of the dry weight of each compound is shown

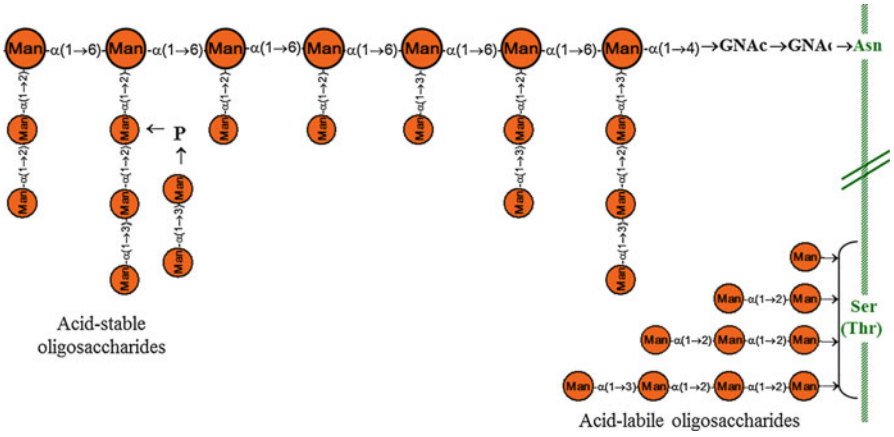

Fig. 7 Chemical structure of yeast exocellular mannoproteins. *Asn* asparagine, *GNAc N*-acetyl-glucosamine, *Man* mannose, *P* phosphate, *Ser* serine, *Thr* threonine

are similar to those from yeast cell walls, except for a lower protein content (Saulnier et al. 1991; Rosi et al. 2000). Glucan molecules are polysaccharides of D-glucose monomers linked by β-(1 → 3) and β-(1 → 6) glycosidic bonds, the β-1,3 glucans being the most abundant. These compounds, with a molecular weight ranging from 25 to 270 kDa (Klis et al. 2006), are only major polysaccharides in sparkling wines (Martínez-Lapuente et al. 2013) and wines aged on lees (Fernández et al. 2011).

3 Methods of Sample Preparation

In this section, we will only describe the methodologies for obtaining polysaccharides from musts, juices, or wines. We will not present the protocols carried out to obtain the polysaccharides from the cell walls of grape berries, which have already been described recently by other authors (Apolinar-Valiente et al. 2010).

Many studies have dealt with soluble polysaccharides present in must, grape juices, or wines, but they differ in the procedures used for the preparation of the samples, polysaccharide recovery, and the analytical methods for the quantification of polysaccharides (Table 1). According to the most often reported procedures, musts are usually obtained at the laboratory scale by grinding berries in a Waring commercial blender or from industrial processes in wineries where free-run juices are obtained by crushing or pressing grapes. Wines are usually obtained from wineries or experimental wine cellars and sometimes from microvinifications carried out in research laboratories. Moreover, polysaccharides have been isolated either from turbid and clarified musts, even during fermentation, or from wines at all stages of the winemaking process: during alcoholic fermentation, post-maceration, malolactic fermentation, wine aging in oak, wine aging in bottles, wine aging on lees, or second fermentations in sparkling wines.

3.1 Isolation of Polysaccharides from Musts and Wines

To determine the content of must or wine polysaccharides, all the methods begin with an extraction step by direct precipitation with ethanol acid, concentration-precipitation, dialysis, or ultrafiltration.

The ultrafiltration membranes covering a wide range of molecular weight cutoffs (MWCO) that overlap the molecular weight distribution of wine polysaccharides make this operation particularly appropriate to separate the wine polysaccharides. Applications of ultrafiltration membranes in enology have been described in the review of El Rayess et al. (2011). However, dialysis is a method of choice in comparison to the ultrafiltration methods because there is no problem of membrane fouling which affects the operating costs and limits the application of the filtration membranes. Whether for dialysis or ultrafiltration membranes, the most important parameter is the pore size of the membrane, whose MWCO should be at around 10 kDa to retain the carbohydrate macromolecules and remove small sugars, salts, monomeric polyphenols, etc.

The most common method used to extract polysaccharides in must and wine samples are the alcohol precipitation in an acidic medium (Segarra et al. 1995; López-Barajas et al. 1998b; Vidal et al. 2003; Ayestarán et al. 2004; Doco et al. 2007; Guadalupe et al. 2007, 2012; Apolinar-Valiente et al. 2014). Factors affecting the yield of polysaccharide precipitation have been studied in detail by Ayestarán et al. (2004) and Guadalupe et al. (2012), who optimized the conditions regarding the temperature and time of precipitation. Moreover, the concentration of

the sample prior the precipitation with ethanol acid was found to be critical to ensure the quantitative precipitation of all soluble polysaccharides since some polysaccharide families such as RG molecules or HL precipitated only partially in non-concentrated samples. They concluded that it was necessary to concentrate must samples three times and wine samples five times to ensure the adequate extraction of all polysaccharide families. Therefore, wine samples are firstly concentrated five times under reduced pressure or using centrifugal evaporators. Thereafter, precipitation of polysaccharides is carried out by adding four volumes of cold 96 % ethanol containing HCl (0.3 M), and samples are kept for 18 h at 4 °C. Samples are centrifuged, the supernatants discarded, and the pellets obtained washed by absolute ethanol several times to remove interfering materials. The precipitates are finally dissolved in ultrapure water and freeze-dried. These precipitates contain the total polysaccharide extract.

Although the methodology described above constitutes a simple and rapid procedure to obtain polysaccharides and it has shown very good values of repeatability in both wine and must samples, i.e., 3.02 % and 2.89 %, respectively (Ayestarán et al. 2004), other chemical compounds present in the samples can complicate the further analysis by GC-MS. In general, the complexity of the method used to obtain the polysaccharide extract will depend on the type of starting material and on the purpose of the analysis. For musts or grape juices, a preliminary step is usually carried out to remove the great excess of sucrose present, and total colloids are firstly recovered from musts or juices by different extraction procedures such as dialysis or ultrafiltration membranes (Vidal et al. 2000). For red wine samples, and depending on the aim of the analysis, the polysaccharide extract (or directly the wine prior the precipitation step) has to be depigmented to remove the interference of anthocyanins. It is important to take into account that the amount of glucose residues present in the extract originates not only from the polysaccharides but also from other molecules such as condensed anthocyanins, which are present in red wines in quite important amounts. Therefore, if we want to use the content of glucose to estimate the content of glucans, a previous depigmentation by decolorization of the sample is needed, which can be achieved by the use of polyamide columns. Finally, our objective could be to achieve a further separation of polysaccharides from oligosaccharides or even a separation of the different polysaccharide families. In this sense, a method has been recently proposed in order to isolate any complex carbohydrate present in musts, juices, or wines. Firstly, the *contaminant molecules* are removed by a separation mechanism mainly based on hydrogen bonds, and then the polysaccharides are fractionated according to their molecular sizes (Ducasse et al. 2010a). Wines are first partially depigmented onto a column of NN polyamide SC6 previously equilibrated with NaCl 1 M. Neutral and acidic polysaccharides and oligosaccharides are eluted with 2 bed volumes of 1 M NaCl, while polyphenolic materials are retained in the column. The eluted fraction is then concentrated under vacuum. Polysaccharides can be then separated in different fractions according to their molecular weight by high-resolution size-exclusion chromatography on a Superdex 75-HR column (1.3 × 30 cm) or a Superdex-30 HR column (1.6 × 60 cm) equilibrated at 1 mL min^{-1} with 30 mM

ammonium formiate pH 5.6. The elution of polysaccharides is followed by refractive index detector, and the different polysaccharide fractions (Ayestarán et al. 2004; Guadalupe and Ayestarán 2007) or oligosaccharide fractions (Ducasse et al. 2010a) are collected according to their elution times (Fig. 8). The isolated fractions are freeze-dried, redissolved in water, and freeze-dried again for three times to remove the ammonium salt.

3.2 Purification of the Different Families of Wine Polysaccharides

The isolation and purification of the different families of wine polysaccharides (PRAG, RG-I, RG-II, MP, and GL) is essential to know their chemical structures and to determine their physicochemical properties. However, these studies are limited due to the diversity of wine polysaccharides, their relatively low concentration, the recovery of sufficient amounts, and the time-consuming methods needed to obtain purified and well-defined polysaccharides.

Most methodologies to obtain purified wine polysaccharides have been based on gel permeation chromatography, ion-exchange chromatography, or affinity-exchange chromatography techniques alone or in combination. Few studies describe the fractionation and purification of *pure* polysaccharides (Villetaz et al. 1981; Llaubères et al. 1987; Brillouet et al. 1990; Doco and Brillouet. 1993; Pellerin et al. 1993, 1995, 1996; Waters et al. 1994; Ciezack et al. 2010; Vidal et al. 2003; DOCO and Williams 2013. Vidal et al. (2003) summarize the techniques of fractionation and purification to obtain a collection of wine polysaccharides in sufficient amounts to allow the determination of their structural characterization and intrinsic properties (Fig. 9).

The most common method used to purify polysaccharides is size-exclusion chromatography (SEC), in which macromolecules in solution are separated by their size and, in some cases, their molecular weight. Sephacryl-S400 HR or Sephacryl-S200 HR (cross-linked copolymer of allyl dextran and *N*,*N*′-methylene bisacrylamide) gel permeation columns equilibrated in 50 mM sodium acetate buffer pH 5 are used to obtain different fractions of wine polysaccharides. However, in most cases, a first step of anion-exchange chromatography is performed before SEC in order to separate charged and non-charged wine polysaccharides. Briefly, in cation-exchange chromatography, positively charged molecules are attracted to a negatively charged solid support, while in anion-exchange chromatography, negatively charged molecules are attracted to a positively charged solid support. To separate polysaccharides of musts, juices, and wines, the anion-exchange chromatography techniques are used with different medium gels. In Vidal et al. (2003), the support was a Fractogel EMD DEAE 650 (M) equilibrated with 50 mM sodium citrate buffer pH 4.6. An unbound fraction was recovered, and the bound polysaccharides were eluted by stepwise gradient of NaCl (10, 50, 150, and 250 mM in the starting buffer). For some

The hatched area corresponds to the oligosaccharide fraction and the non-hatched to the polysaccharide fraction. Fraction S1 corresponds to AGP and MP with an average molecular weight of 110 kDa; fraction S2 corresponds mainly to RG-II dimers with an average molecular weight of 10 kDa and smaller AGP and MP

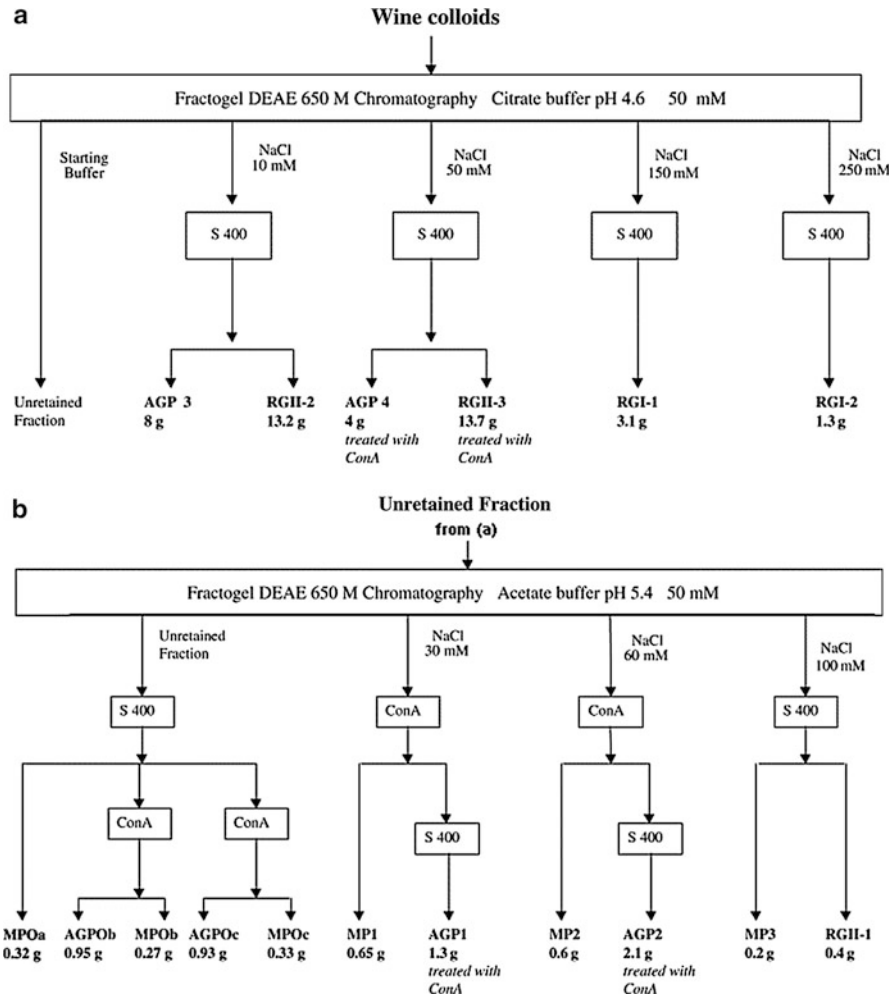

Fig. 9 Scheme of fractionation of the totality of wine polysaccharides by anion-exchange, affinity, and size-exclusion chromatography according to Vidal et al. (2003)

polysaccharides, such as rhamnogalacturonans, the steps of ion-exchange and gel permeation chromatography are sufficient to obtain purified polysaccharides. But for others like PRAG or MP, these two steps are not sufficient, and further separation by affinity-exchange chromatography is needed. Mannoprotein fractions can be obtained using their ability to bind to concanavalin A lectin immobilized on a Sepharose column. Concanavalin A lectin binds molecules that contain α-D-mannopyranosyl, α-D-glucopyranosyl, and sterically related residues with available C-3, C-4, or C-5 hydroxyl groups. Therefore, mannoprotein fractions are loaded on the column equilibrated in 50 mM sodium acetate buffer pH 5.6 containing 150 mM NaCl, 1 mM $NaCl_2$, 1 mM $MgCl_2$, and 1 mM $MnCl_2$. The desorption of the wine

mannoproteins is carried out using two bed volumes of the same buffer containing 100 mM of methyl-α-D-mannopyranoside.

The comprehensive fractionation of wine polysaccharides described by Vidal et al. (2003) has allowed obtaining the major classes of polysaccharides present in musts and wines, including xyloglucans, mannoproteins, arabinans and type I and II AGP, and type I and II rhamnogalacturonans. The characterization performed on the purified, isolated polysaccharides in order to know their chemical fine structure by the analysis of the monosaccharide composition and glycosidic linkages by GC-MS is described below.

4 Methods of Analysis

In general, the method used will be dependent on the purpose of the analysis: (i) to know the polysaccharide composition of must or wine samples by quantifying the content of specific polysaccharide families (see Sect. 4.1), (ii) to know the chemical fine structures of concrete polysaccharides isolated from musts or wines (see Sect. 4.2), and (iii) to estimate the global content of polysaccharides in a must or wine sample (see Sect. 4.3).

4.1 Quantification of Polysaccharide Families by GC-MS After Methylation and Derivatization Analysis

4.1.1 Methylation and Derivatization Analysis

The different families of polysaccharides can only be estimated by assessing its monosaccharide profile. The monosaccharide composition of the polysaccharide extracts can be determined both quantitatively and qualitatively by their conversion to their trimethylsilylated methyl glycoside derivatives (TMS) obtained after acidic methanolysis and derivatization.

Methanolysis, which yields methyl glycosides, is a useful technique for determining neutral, acidic, and amino sugars simultaneously. Thereafter, the conversion of methyl glycosides to volatile derivatives can be done by the formation of methyl ethers, acetates, and trimethylsilyl ethers (TMS). TMS derivatization after methanolysis has proven to be simple, quantitative, and suitable for hydrocolloids which have uronic acids. Resolution of multiple peaks of TMS derivatives has been significantly improved by the use of fused-silica capillary columns in the GC system. In the procedure we describe, all the free hydroxyl groups of the polysaccharide are methylated, and, following hydrolysis of the methylated polysaccharide, the partially methylated sugars released are derivatized to convert the methyl glycosides to their TMS derivatives to increase their volatility (Fig. 10). This conversion will result in the formation of several components (derivatives of the α- and β- and pyranose and furanose forms) for each sugar. Finally, TMS can be analyzed by GC with MS detection and the monosaccharides identified by their spectra and retention time relative to the internal standard. We typically use *myo*-inositol as the internal standard as it is not expected to be in the sample.

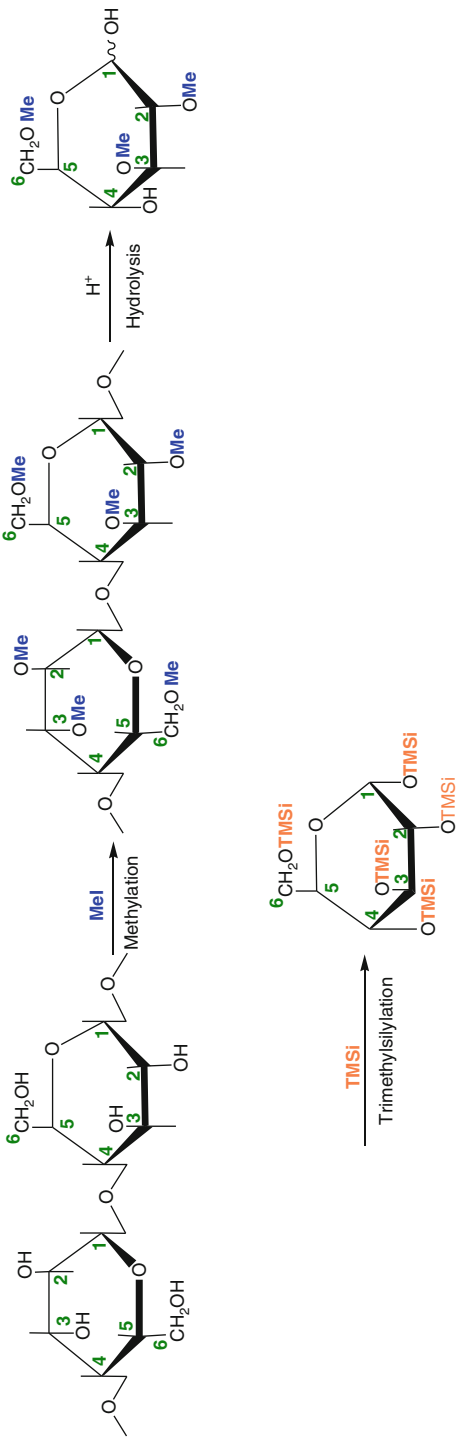

Fig. 10 Methylation and derivatization reactions to obtain trimethylsilylated methyl glycoside derivatives (*TMS*). The methylation positions of the free hydroxyl groups in the polysaccharides are shown (for simplicity, H atoms have been omitted from the top diagram). After acid methanolysis, the methyl glycosides are converted to volatile derivatives by the formation of trimethylsilyl ethers

The hydrolysis and derivatization conditions used are crucial to achieve a complete hydrolysis and TMS conversion. The protocol is described in detail by Guadalupe et al. (2012). Therefore, the polysaccharide fractions are treated with the methanolysis reagent (MeOH containing HCl 0.5 M), and the reaction is conducted in nitrogen atmosphere at 80 °C for 16 h. Thereafter, the excess of reagent is removed using a stream of nitrogen gas. The conversion of the methyl glycosides to their TMS derivatives is performed by adding a mix of pyridine, hexamethyldisilazane, and trimethylchlorosilane (10:2:1 v/v) to the dried material. The reaction is carried out at 80 °C for 30 min and the reagent removed using a stream of nitrogen gas. A solution of derivatized *myo*-inositol is then added as internal standard, and the derivatized residues are extracted with hexane. GC-MS is performed with these solutions, and samples are injected in duplicate. Standard carbohydrates are also converted to their corresponding TMS derivatives and analyzed by GC-MS in order to obtain patterns for identification and the standard calibration curves.

The chromatographic column used is a Teknokroma fused-silica capillary column (30 m × 0.25 mm × 0.25 μm) of phase 5 % phenyl and 95 % methylpolysiloxane. The oven program starts at an initial temperature of 120 °C which was increased at a rate of 1 °C min^{-1} to 145 °C and then to 180 °C at a rate of 0.9 °C min^{-1} and finally to 230 °C at 40 °C min^{-1}. The GC injectors are equipped with a 3.4 mm ID and maintained at 250 °C with a 1:20 split ratio. The carrier gas is helium (99.996 %) at a flow rate of 1 mL min^{-1}. Ionization is performed by electron impact (EI) mode at 70 eV. The temperatures used are 150 °C for the MS Quad, 230 °C for the MS Source, and 250 °C for the transfer line. The identification of the peaks is carried out by comparing retention times and mass spectra with those obtained by injections of pure standards.

Typical GC-MS chromatogram for a wine polysaccharide extract is shown in Fig. 11. MS fragmentation patterns reported in Doco et al. 2001 can be used to identify those monosaccharides for which no commercial standards are available. Calibration curves of L-fucose, L-rhamnose, 2-*O*-methyl D-xylose, L-arabinose, D-xylose, D-galactose, D-glucose, D-mannose, Kdo, D-galacturonic acid, and D-glucuronic acid are used for quantification; 2-*O*-methyl fucose, aceric acid, Dha, and apiose can be quantified using the 2-*O*-methyl xylose calibration curve. The different monosaccharides are quantified in selected ion monitoring (SIM) mode, selecting the appropriate number of ions for each compound (*m*/*z*) in one segment from 3 to 65 min. D-galacturonic acid, L-rhamnose, L-fucose, D-galactose, D-glucose, D-mannose, and D-xylose are quantified with 204 ion; D-glucuronic acid, L-arabinose, Kdo, 2-*O*-methyl-L-fucose, Dha, and aceric acid with 217 ion; 2-*O*-methyl D-xylose with 146 ion; apiose with 191 ion; and *myo*-inositol with 305 ion. For all the spectra, these ions show the highest signal/noise ratio and are selected for recording SIM mode chromatograms.

The methodology described above has provided good values of quantification and detection limits and suitable values of repeatability, reproducibility, and overall recoveries. Repeatability and reproducibility values ranged from 1 % to 14 %. Limits of detection were below 1.0 μg for all monosaccharides, and limits of

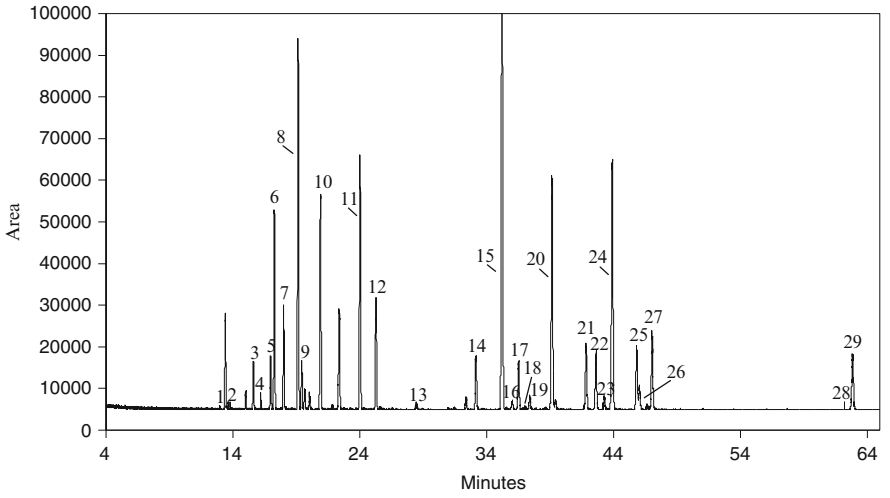

Fig. 11 GC-MS chromatogram obtained for a wine polysaccharide extract obtained after methylation and derivatization analysis. Peak identification: aceric acid (*peak 1*), 2-*O*-Me-fucose (*peak 2*), 2-*O*-Me-xylose (*peak 3*), apiose (*peak 4*), arabinose (*peak 5, 6, 7, 10, 11*), rhamnose (*peak 8*), fucose (*peak 9*), xylose (*peak 12, 13, 14*), mannose (*peak 15, 19*), galacturonic acid (*peak 16, 23*), Dha (*peak 18*), galactose (*peak 20, 21, 22*), glucose (*peak 24, 26*), glucuronic acid (*peak 25, 27*), Kdo (*peak 28*), *myo*-inositol (*peak 29*)

quantification were below 1.8 μg. Moreover, a recovery study of the whole method, including sample preparation, provided absolute recoveries between 81 % and 116 % for different wine samples, very good values taking into account the multistep procedure. The comparison of the results obtained by GC-MS with those obtained by GC-FID (GC coupled to flame ionization detector) revealed that both methods were suitable for determining the content of monosaccharides in wine samples, but MS detector showed to be more sensitive and selective than FID, allowing lower detection limits which may be useful when quantifying rare RG-II monosaccharides which are present in musts and wines in very low concentrations. A further advantage of the MS detection is that it provides unambiguous identification and quantification of the complex mixtures of monosaccharides present in grape-derived beverages.

4.1.2 Polysaccharide Composition Estimation

The content of each polysaccharide family can be estimated from the concentration of their individual glucosyl residues which are characteristic of structurally identified wine polysaccharides. The PRAG, mainly arabinogalactans, arabinogalactan proteins, and arabinans, can be estimated from the sum of galactose and arabinose residues. All of the mannose content can be attributed to yeast mannoproteins, and the content of glucans can be estimated from the content of glucose residues if the anthocyanins have been previously removed in the polysaccharide extract. The RG-II content can be calculated from the sum of its diagnostic monosaccharides, which represent approximately 25 % of the RG-II molecule. Taking into account

the molar ratios of the RG-II described by Pellerin et al. (1996) and Vidal et al. (2003) (1 residue of 2-*O*-methyl fucose, 3.5 rhamnose, 2 arabinose, 2 galactose, 1 glucuronic acid, and 9 galacturonic acid), the remaining part can be attributed to the presence of PRAG in the case of arabinose and galactose, and the remaining galacturonosyl residues can be used to estimate the content of oligomers of homogalacturonans (HG). The content of total polysaccharides can be estimated from the sum of PRAG, MP, GL, RG-II, and HG.

4.2 Structural Characterization of Polysaccharides by the Analysis of Glycosyl-Linkage Composition

Must and wine polysaccharides are known to be heterogeneous with respect to their chemical fine structure and size. Information obtained from isolated and purified polysaccharides enables us to deduce their fundamental structures. We will describe in this subsection analytical techniques to deduce the chemical fine structure of concrete polysaccharides isolated from musts and wines.

The analytical procedure to elucidate the chemical structures of the polysaccharides begins with methylation. Methylation analysis provides information about the linkage position on the sugar sequence. In this procedure, all the free hydroxyl groups of the polysaccharide are methylated, and, following hydrolysis of the methylated polysaccharide, the partially methylated sugars released are reduced and acetylated to yield partially methylated alditol acetates (PMAA). These volatiles can be separated, identified, and quantified by GC-MS. The linkage position (s) of each individual sugar in the parent polysaccharide is deduced by identifying PMAA, but it is not possible to work out the position or anomeric configuration of these residues in the polymer (Pettolino et al. 2012).

Complete methylation results in the methylation of all free hydroxyls not involved in the glycosidic linkage (Fig. 12). After acid hydrolysis, the partially methylated monosaccharides that are released are reduced with $NaBD_4$, which simultaneously opens the sugar ring to form the alditol and tags the anomeric C atom (C1) with a deuterium atom. However, information on the anomeric configuration (α/β) of the glycosyl residue is lost during this reduction step. To increase the volatility of the derivatives for GC separation, the partially methylated alditols are acetylated with acetic anhydride. In this way, C atoms were involved in the glycosidic linkage, and the ring carries acetyl groups (Fig. 12). Finally, the PMAA sugar derivatives are injected directly into a GC-MS system, wherein diagnostic fragmentation is generated by electron impact ionization.

Two of the most common reagents for methylation for monosaccharide linkage are methylsulfinyl carbanion in DMSO (Hakomori 1964) and the solid sodium hydroxide (NaOH) in DMSO method of Ciucanu and Kerek (1984). Both methods involve the preparation of very powerful bases for the ionization of the high-pKa hydroxyl groups of monosaccharide residues. Once ionized, the polysaccharide is treated with CH_3I, which results in the methylation of the hydroxyl groups. Once all free hydroxyl groups in the sugar are protected by persistent blocking with methyl

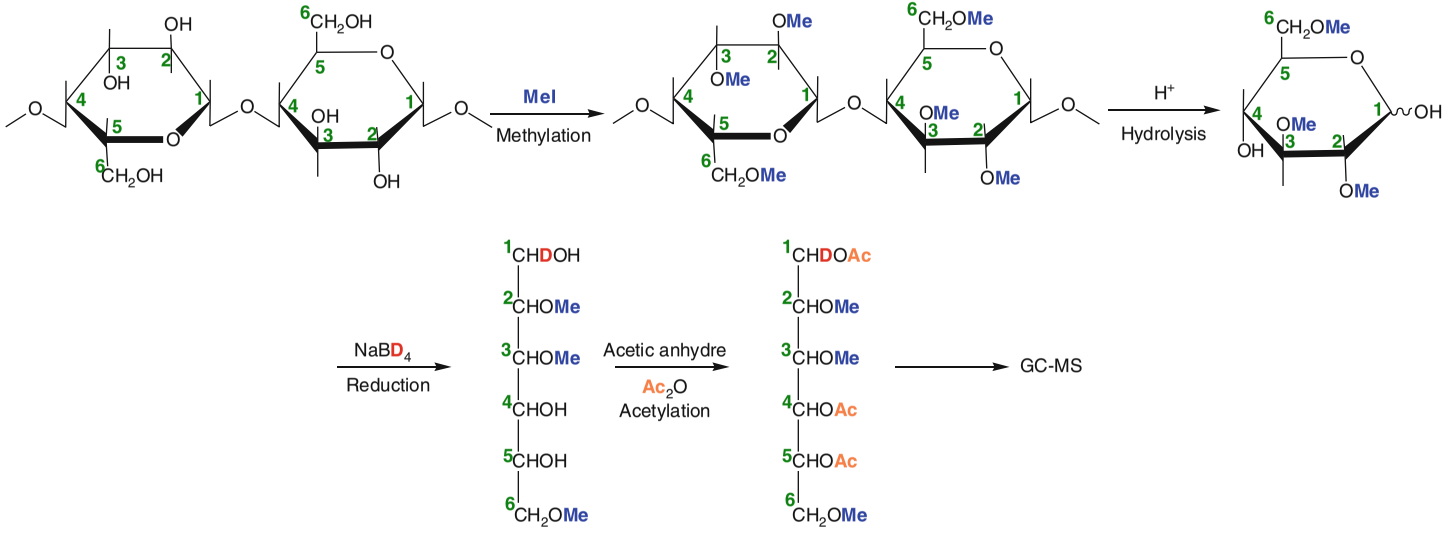

Fig. 12 Methylation reactions to obtain partially methylated alditol acetates (*PMAA*). The methylation positions of the free hydroxyl groups in the polysaccharides are shown (for simplicity, H atoms have been omitted from the top diagram). Thus, hydroxyls not involved in the glycosidic linkage are methylated. After acid hydrolysis, the partially methylated monosaccharides that are released are reduced with $NaBD_4$, which simultaneously opens the sugar ring to form the alditol and tags C atom number 1 with a deuterium atom. To increase the volatility of the derivatives, the partially methylated alditols are acetylated with acetic anhydride and separated by GC

group, the hydrolysis is carried out either with trifluoroacetic acid, which is volatile and therefore easily removed, or sulfuric acid. Hydrolysis conditions are crucial and can vary depending on the nature of the sample and its component sugars.

When polysaccharides contain uronic acids, methylation analysis becomes more difficult. The alkaline conditions used for methylation analysis could cause β-elimination. Glycosidic linkages adjacent to uronic acids are difficult to hydrolyze efficiently/quantitatively, and hence the uronic acids are not detectable as alditol acetates unless they are prereduced to their neutral sugar counterparts. This problem is resolved by a chemical reduction of the carboxyl group by lithium triethylborodeuteride or carbodiimide. Among acetylation methods, the addition of acetic anhydride to form alditol acetates is commonly used.

A method for classical elucidation of the chemical structures of polysaccharides isolated from wines and grapes is summarized below. The polysaccharide fractions are submitted to the reaction of per-*O*-methylated, and the methyl-esterified carboxyl groups are then reduced with lithium triethylborodeuteride prior to hydrolysis, reduction, and acetylation. For the methylation reaction, the fraction of polysaccharide dissolved in DMSO is methylated using methyl sulfinyl carbanion and methyl iodide (Hakomori 1964). Half of the methylated sample is then carboxyl reduced with lithium triethylborodeuteride (Pellerin et al. 1995). Thereafter, both methylated and carboxyl-reduced samples are hydrolyzed with 2 M trifluoroacetic acid (75 min at 120 °C). The released methylated or carboxyl-reduced monosaccharides are converted to their corresponding alditols by treatment with $NaDH_4$ to obtain the PMAA (Harris et al. 1984). PMAA are finally analyzed by GC-MS using a DB-1 capillary column (30 m × 0.32 mm i.d., 0.25 μm film); temperature program starts at 135 °C for 10 min, then 1.2 °C min^{-1} to 180 °C, with H_2 as the carrier gas (Vidal et al. 2001). The identity of each methyl ether is confirmed by electron ionization MS (EI-MS), and their areas are corrected by response factors. Figure 13 shows the fragmentation of PMAA during EI-MS (Pettolino et al. 2012).

It is important to stand out that methylation analysis provides only information about the linkage position on sugar sequence. Complete structures should be built up with additional analytical results obtained with modern techniques such as fast atom bombardment mass spectrometry (FAB-MS), matrix-assistant laser desorption ionization (MALDI-MS), electrospray ionization spectrometry (ESI-MS), and one and two (multi)-dimensional NMR spectroscopy.

4.3 Estimation of the Content of Total Polysaccharides by SEC-RID

Size-exclusion chromatography (SEC) is the technique commonly used to determine the molecular distribution of must and wine polysaccharide extracts according to their molecular mass. On the other hand, some authors have also used this procedure to obtain an estimation of the content of total polysaccharides in must or wine samples (López-Barajas et al. 1998b; Guadalupe et al. 2012).

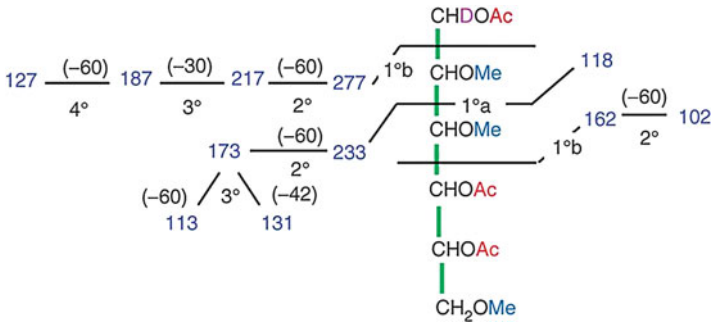

Fig. 13 Fragmentation of *PMAA* during electron ionization MS. Primary fragmentation of *PMAA* occurs in a particular order of preference, namely, (i) between two methoxylated carbons (either fragment carries the charge), (ii) between a methoxylated carbon and an acetoxylated carbon (the methoxy fragment carries the charge), and (iii) between two acetoxylated carbons. Secondary fragmentation results in the following fragments: acetic acid (H_3C-COOH) $m/z = 60$, methanol (CH_3OH) $m/z = 32$, ketene ($CH_2 = C = O$) $m/z = 42$, and formaldehyde (H_2CO) $m/z = 30$ (Pettolino et al. 2012)

The size-exclusion chromatography system is formed by an isocratic pump and two serial exclusion columns connected to a refractive index detector (RID). The size-exclusion columns more frequently used in literature for separating polysaccharide extracts coming from musts and wines are two serial 250 and 500 Ultrahydrogel columns (López-Barajas et al. 1998b, 2001; Palomero et al. 2007, 2009) and two Shodex OHpak SB-803 and SB-805 columns (Doco et al. 1996; Guadalupe and Ayestarán 2007; Guadalupe et al. 2012; Gil et al. 2013), which differ in their exclusion limit. Shodex and Ultrahydrogel columns are different in both their packing material and exclusion limits. Therefore, the Shodex OHpak SB columns are made of polyhydroxymethacrylate gel, while the Ultrahydrogel columns consist of a gel of a cross-linked hydroxylated polymer and contain some residual carboxyl. Both packing materials are suitable for the analysis of aqueous-soluble samples such as oligosaccharides, polysaccharides, and cationic, anionic, and amphoteric polymers and proteins. It is expected that samples or standards are separated in these columns according to their molecular weight. However, López-Barajas et al. (1998b) observed ionic interactions between anionic compounds, such as pectins and polyacrylic acids standards, and the cross-linked hydroxylated polymer of the columns. In order to eliminate these interactions, an eluent with a greater ionic strength must be used, ranging from 0.01 to 0.1 M $NaNO_3$ (Palomero et al. 2007). When the Shodex OHpak KB columns are chosen, the eluents most commonly used are 0.1 M $LiNO_3$ with a constant flow of 1 mL min^{-1} (Guadalupe and Ayestarán 2007; Apolinar-Valiente et al. 2013, 2014) or NH_4HCO_2 (from 30 mM to 50 mM) at 0.6 mL min^{-1} (Gil et al. 2013; González-Royo et al. 2013).

The apparent molecular weights (Mw) of polysaccharide extracts in the SEC chromatograms are compared with those of known pullulan standards of different molecular weights, and the calibration equation is then deduced as log Mw = a − b

Table 2 Retention times and calibration curve equations constructed with dextran (Ds), polyacrylic acids (PACs), and pectins (PECs) pullulan standards using two serial 250 and 500 Ultrahydrogel columns, according to López-Barajas et al. (1998b)

	M_r	T_R mean[a] (min)
Dextrans (Ds) y = 1E + 24x − 11, 78	D-580000	37,08
	D-267000	37,27
	D-150000[b]	39,90
	D-71000	41,36
	D-39000	43,61
	D-11000	49,29
Polyacrylic acids (PACs) and pectins (PECs) y = 5E + 18x − 89, 037	PAC-450000[c]	35,7
	PEC-82000	36,9
	PEC-34000[d]	37,74
	PEC-17000	38,5
	PAC-8000[e]	47,71
	PAC-5100	49,43
	PAC-2000	51,46

x = retention time (min)
y = molecular mass
[a]Mean was obtained with $n = 6$
[b]Reference standard for response factors of dextrans (*Ds*)
[c]This standard was not included in the calibration curve
[d]Reference standard for response factors of pectins (*PECs*)
[e]Reference standard for response factors of polyacrylic acids (*PACs*)

(t_r = column retention time at peak maximum, a = intercept, b = slope). Table 2 shows the calibration curve equations made with dextrans, pectins, and polyacrylic acids (López-Barajas et al. 1998b). It can be observed that the retention times of both pectins and polyacrylic acids standards differ from those expected, which is attributed to the ionic interactions.

Figure 14a shows the SEC-RID chromatograms of the polysaccharides produced in a model medium by autolysis of a non-Saccharomyces wine yeast using two serial Ultrahydrogel 250 and Ultrahydrogel 500 columns. The retention times of pullulan dextran standards of different molecular weight are also shown: P-5, Mw = 5.9 kDa; P-10, Mw = 11.8 kDa; P-20, Mw = kD kDa; P-50, Mw = 47.3 kDa; P-100, Mw = 112 kDa; P-200, Mw = 212 kDa; P-400, Mw = 404 kDa; and P-800, MW = 788 kDa. Figure 14b shows the chromatograms of the polysaccharide extracts from three wine samples using the serial columns OHpak KB-803 and KB-805 (Guadalupe et al. 2012). These authors describe that the first fraction corresponds to molecules with an average molecular weight higher than 47.3 kDa (average of 212, 112, and 50 kDa), attributed to a complex mixture of high-molecular-weight AGP from grape berries and high-molecular-weight MP from yeasts. The polysaccharides with an average molecular weight of 12 kDa (P10), eluting in the second fraction, correspond to grape RG-II dimers and lower-molecular-weight AGP and MP. Signals eluting after P5 correspond to a molecular weight of less than 6 kDa, and they are attributed to oligosaccharides and small

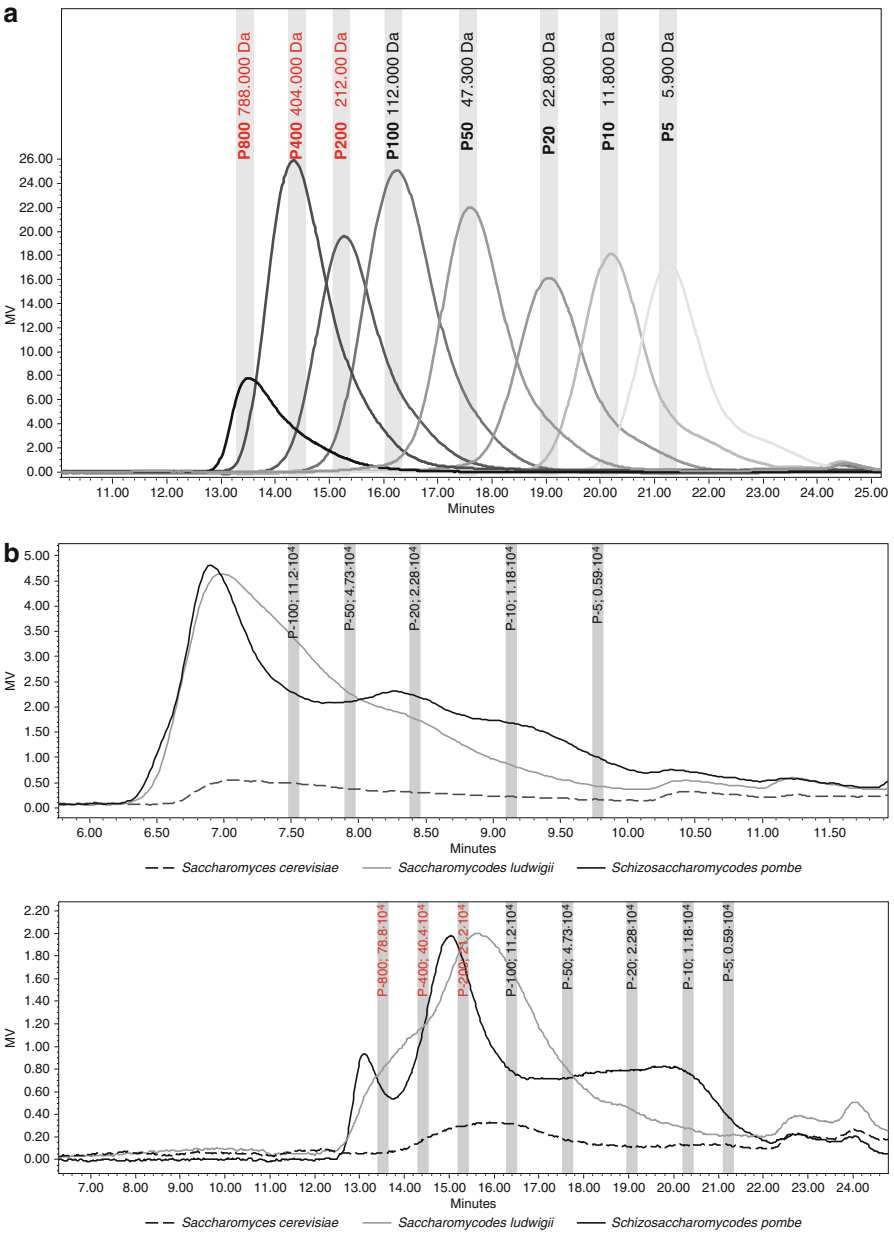

Fig. 14 SEC-RID chromatograms obtained for a wine polysaccharide extract on (**a**) Ultrahydrogel 250 and Ultrahydrogel 500 columns and (**b**) Shodex OHpak KB-803 and KB-805 columns. (**a**) SEC-RID chromatograms of polysaccharides produced by *Saccharomyces cerevisiae* G3(7) (*dashed black line*), *Schizosaccharomyces pombe* (*continuous black line*), and *Saccharomyces ludwigii* (*continuous gray line*) at 58 days of aging over lees. Chromatogram obtained using two serial Ultrahydrogel 250 and Ultrahydrogel 500 columns (Palomero et al. 2009). The retention

fragments of AGP, MP, and RG-II monomers. On the other hand, the chromatogram obtained by the Ultrahydrogel columns shows an early elution peak that corresponds to biopolymers of over 788 kDa (Fig. 14a). It is important to stand out that this chromatogram corresponds to a model media, and these high-molecular-weight signals are not usually obtained in wine samples.

The detailed protocol to quantify the amount of total polysaccharides on the basis of the peak areas from the SEC-RID chromatograms is described in detail by Guadalupe et al. (2012). In this procedure, signals eluting after P5 are not taken into account, and total polysaccharides are estimated from the sum of signals with a higher molecular weight higher than 6 kDa. Polysaccharide contents are estimated using calibration curves constructed with dextran pullulan standards whose peaks best match with those obtained for the samples. It is important to point out that the quantity of polysaccharides obtained by SEC-RID is just an estimation because the polysaccharide extract is not pure and there may be other contaminants such as salts, proteins, or phenolics. These compounds elute together with polysaccharides when these SEC columns are used. Therefore, Guadalupe et al. (2012) observed that the polysaccharide content estimated by SEC was considerably lower than that obtained with GC-MS. However, a good correlation was found between the two methods ($r = 0.746$, $p < 0.05$), indicating that the former could serve as a rapid and simple method for total wine polysaccharide estimation. It is important to notice that SEC-RID provided almost half of the value obtained by the GC-MS method, and thus it led to an underestimation of real wine polysaccharides, although it could be valid for comparative purposes.

5 Conclusions

Polysaccharides play a critical role in both the wine processing and quality, and their influence depends on their structure, composition, and distribution. Detailed analyses of these polysaccharides are essential to know their chemical, physicochemical, and sensory properties. Many researches have focused on wine polysaccharides during the last decade, trying to isolate and characterize them; studying their evolution from grape to wine and during the winemaking and aging; analyzing their functions, mechanisms of action, and factors affecting their content; or trying to modulate their concentrations into the wines. However, these studies are limited due to the diversity of wine polysaccharides, their relative low concentration, the recovery of sufficient amounts, and the time-consuming methods needed for their analysis. The difficulty in separating, purifying, and quantifying all of these

Fig. 14 (continued) times (*bands*) for the pullulan standards are shown. (**b**) SEC-RID chromatograms of total soluble polysaccharides in three wine samples. Chromatogram obtained using two serial Shodex OHpak KB-803 and KB-805 columns (Guadalupe et al. 2012). Elution times for pullulan standards are shown

compounds has resulted in them being less studied than other wine compounds such as polyphenols, polypeptides, or proteins. Therefore, an adequate determination of the different polysaccharide families requires analytical methodologies which involve complex multistep procedures.

We present in this chapter analytical techniques that are useful for the study of must and wine polysaccharides. We describe procedures not only to define the fine chemical structures of individual wine polysaccharides but also to estimate the overall polysaccharide composition of must and wine samples. The procedure covers the preparation of the sample, together with gas chromatography-mass spectrometry-based methods, for both the analysis of monosaccharides as their volatile trimethylsilylated methyl glycoside derivatives and methylation analysis to determine linkage positions between monosaccharide residues as their volatile partially methylated alditol acetate derivatives. We also provide a protocol for estimating the global content of wine polysaccharides by using of size-exclusion chromatography with refractive index detector (SEC-RID). This is a rapid and simple method that can be used routinely in a reasonably equipped laboratory. Analysis complexity and time will vary depending on the method used, and the duration ranges from 2 days for a global polysaccharide estimation to 2 weeks for a carboxyl reduction/methylation linkage analysis. In general, the complexity of the method used will depend on the type of starting material and on the purpose of the analysis: (i) to know the polysaccharide composition of must or wine samples by quantifying the content of specific polysaccharide families, (ii) to know the chemical fine structures of concrete polysaccharides isolated from musts or wines, and (iii) to estimate the global content of polysaccharides in a must or wine sample.

NMR Spectroscopy for the Determination of Mucoadhesive Properties of Polysaccharides

44

Gloria Uccello-Barretta, Federica Balzano, and Federica Aiello

Contents

Abstract

Applications of nuclear magnetic resonance (NMR) spectroscopy to the structural characterization of polysaccharides with mucoadhesive characteristics are described together with some limited cases of uses in the detection of affinity to mucin. Structural characterization spans from quantification of monomeric units of polysaccharides following degradation procedures to the development of reliable analytical protocols directly on the intact polymeric materials. In these last cases several problems can be solved such as the identification of derivatization sites on monosaccharide units and determination of average length of derivatizing pendants. For non-covalent modifications, the more difficult aspect is the detection of conformational changes. Mucoadhesivity can be determined by exploiting the possibility to detect changes of affinity to mucin of small probe molecules due to the mucin–polysaccharide interaction.

1 Introduction

The role of NMR spectroscopy in the field of structural, conformational, and stereochemical characterization of high and low molecular weight compounds and their supramolecular aggregates is definitely well recognized, and its potentials can be fully exploited in the field of the characterization of new materials of proved mucoadhesivity. Polysaccharides, in particular, come from natural sources and, therefore, require accurate preliminary characterizations. Furthermore, many of them can be subjected to covalent or non-covalent modifications aimed to improve their mucoadhesivity: in the first case the derivatization degree needs to be defined together with the distribution of derivatizing groups on the different sites of repeating units. Non-covalent modifications constitute a useful alternative approach

to the enhancement of mucoadhesion, which exploits the strong sensitivity of polysaccharide conformation to aggregation processes with other polymeric materials or specific excipients. The use of NMR spectroscopy in all these areas is almost always resolutive and gives quite accurate structural information, which may contribute to the comprehension of the complex phenomenon of mucoadhesion at a molecular level.

The application of spectroscopic techniques for the in vitro evaluation of mucoadhesivity is even more challenging and usually relies on the detection of supramolecular aggregation processes of potentially mucoadhesive materials with mucin.

Based on abovesaid premises, the subject of the present review is not only very complex but also very articulate since it covers applications areas of NMR spectroscopy, which are too wide to be exhaustively reviewed all together. Therefore, although fully aware that in the literature there are many valuable contributions regarding the topics which will be discussed, however we selected just a limited number of examples which are better suited from the illustrative point of view.

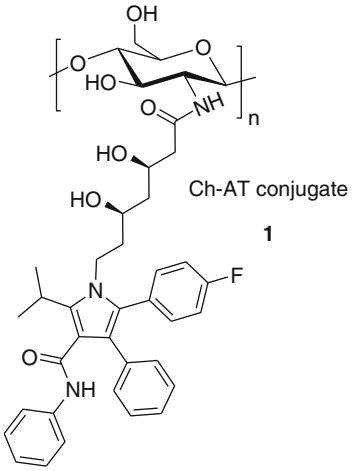
2 Characterization of Polysaccharides and Their Derivatives

A common approach to the accurate quantitative determination of the monomeric composition of polysaccharides is based on chemical degradation processes followed by NMR quantitative analysis. However, the concomitant degradation of monosaccharides could affect reliability of the quantitative analyses. An elegant approach to solving this problem has been recently proposed by de Souza et al. (2013), who described a universally applicable method for the hydrolysis of several kinds of polysaccharides, based on the Saeman hydrolysis, followed by NMR quantification. The hydrolyzed mixture was analyzed by ^{1}H NMR with maleic acid as internal standard for the quantitative analysis, comparing the integrated areas of the maleic acid protons and the anomeric proton resonances. A correction for degradation of monosaccharides was then applied by subjecting a standard mixture represented in the polymer and containing a known amount of glucose, galactose, mannose, glucosamine, xylose, and arabinose to the same conditions. This correction resulted in a very accurate and reproducible method with relative deviations down to 1 %.

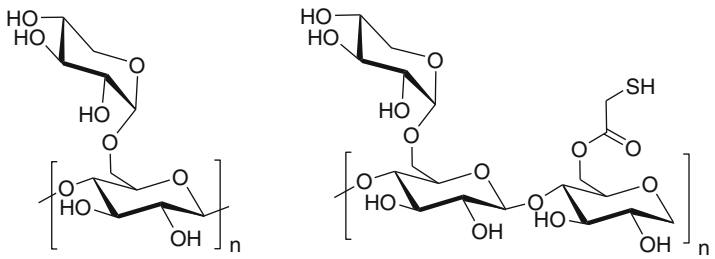
The application of NMR spectroscopy to covalent modifications of polysaccharides ranges from the simple detection of the derivatization process to the development of accurate analytical protocols for the identification of the degree and location of derivatizing pendants on each repeating unit.

As an example, for the development of a new chitosan–atorvastatin (Ch–AT, **1**) conjugate, a coupling reaction was exploited, by formation of amide linkages, the presence of which was very simply checked in the ^{1}H NMR spectra by means of the

appearance of a new amide signal at 9.89 ppm (Anwar et al. 2011). In this case NMR spectroscopy was also employed to prove that no chemical changes occurred during nanonization processes since the ^{1}H NMR spectrum of Ch–AT nanoconjugate was superimposable to the corresponding spectrum of Ch–AT conjugate.

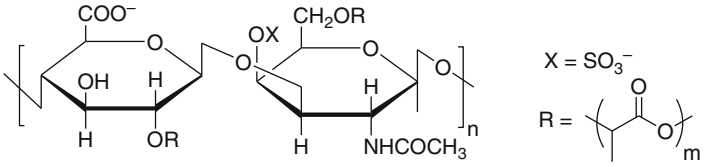


Thiolation of polysaccharides by means of esterification with thioglycolic acid represents a common way to enhance bioadhesive potential of polysaccharides, as described (Mahajan et al. 2013) for a xyloglucan. In this case the modification was confirmed on the basis of the comparison of the ^{1}H NMR spectra of parent xyloglucan (**2**) and thiolated xyloglucan (**3**). NMR spectra were quite superimposable with the exception of an additional signal at 3.27 ppm, which was attributed to the resonance of SH protons.



In the development of new biodegradable brushlike amphiphilic poly(L-lactide)-grafted chondroitin sulfate copolymers **4**, with specific mucoadhesion or receptor recognition abilities, poly(L-lactide) (PLLA) was grafted onto chondroitin sulfate (CS) (Lee et al. 2007). The degree of substitution, the degree of polymerization, and the chondroitin sulfate content (from 1.1 % to 15.4 %) all

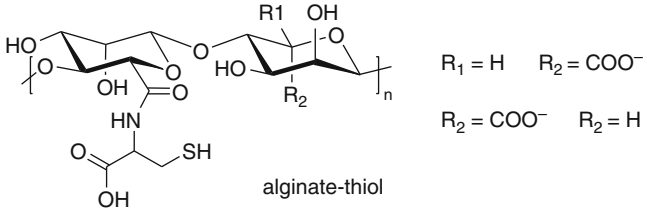
were established by ^{1}H NMR. In particular, the degree of substitution was calculated based on the area ratio of signals from methine protons of PLLA segments at 5.2 ppm (one proton) and methyl proton of CS at 1.9 ppm (three protons). This value corresponds to the average number of hydroxyl groups on the disaccharides of CS that have been reacted with L-lactide. The degree of polymerization of L-lactide was calculated based on the area ratio of the terminal methine proton signal of PLLA at 4.1 ppm to the internal methine proton signal of PLLA segments at 5.2 ppm, which gives the average length of every PLLA branch.



4

Attempts have been made to improve the mucoadhesive properties via covalent bonds such as disulfide bridges between the polymer to the mucin (Bernkop-Schnürch et al. 2003). Therefore, new mucoadhesive polymers, termed thiomers, have been proposed as drug delivery carriers able to adhere to the mucous layer.

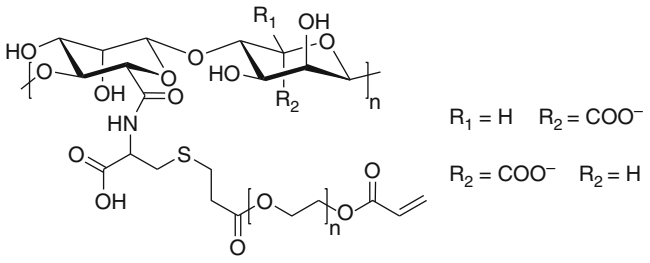
In 2009 Davidovich-Pinhas described the synthesis of a model thiomer, alginate-thiol **5**, which was characterized by NMR (Davidovich-Pinhas et al. 2009). The synthesis was carried out by reacting alginate with L-cysteine. By comparing the NMR spectra of modified alginate and parent alginate, several new signals were detected, supporting molecular structure changes. However, besides expected additional peaks due to cysteine conjugation, eight more resonances were detected. In this case the simple spectral analysis was not sufficient to identify the products, and 2D scalar correlation experiments were carried out, which allowed authors to establish that some units of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride, employed to activate the carboxylic acid groups of the polymer, remained attached to the polymer backbone.



5

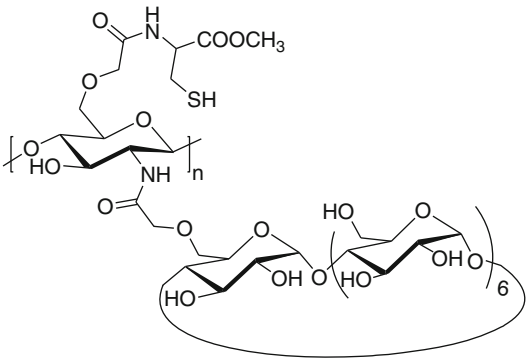
The same author also reported (Davidovich-Pinhas and Bianco-Peled 2011) a novel mucoadhesive alginate–polyethylenglycol acrylate conjugate (alginate–PEGAc, **6**),

which was synthesized from alginate-thiol **5**. The conjugate **6** was characterized by polyethylenglycol chains with one acrylate end group connected to the alginate backbone via the cysteine spacer. This polymer combined the strength, simplicity, and gelation ability of alginate with the mucoadhesion properties of polyethylenglycol. In order to assess the occurrence of derivatization, the native, intermediate (**5**), and final (**6**) products were compared using ^{1}H NMR spectroscopy.



6

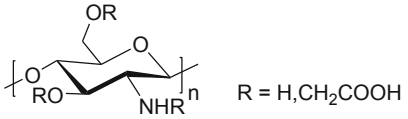
Even though thiomers mimic the natural mechanism of secreted mucous glycoproteins and, hence, show enhanced mucoadhesivity, however their poor interaction with hydrophobic drug molecules often negatively affects their potential applications in pharmaceutical fields. In order to expand potential applications of thiomers as mucoadhesive drug delivery carrier with controlled drug release capability, a thiolated carboxymethyl chitosan-*g*-carboxymethyl-β-cyclodextrin (CMCh-*g*-CM-β-CD, **7**) was proposed (Prabaharan and Gong 2008): firstly carboxymethyl chitosan (CMCh) was prepared from chitosan and chloroacetic acid. From the relative peak intensities between the protons of the carboxymethyl groups (4.4 ppm) at the C6 position of the CMCh and the protons at C2 of monosaccharide residue (3.0 ppm), the degree of substitution of carboxymethyl groups on the primary hydroxyl sites of the modified chitosan CMCh was determined as 35 % using ^{1}H NMR. Carboxymethyl-β-cyclodextrin (CM-β-CD) was obtained from β-CD and chloroacetic acid, with a substitution degree on the primary hydroxyl sites estimated as 14 % using ^{1}H NMR; then it was grafted onto CMCh in the presence of suitable condensing agents and finally conjugated with L-cysteine methyl ester hydrochloride (CMEH). The bases of quantitative determination mainly were the methylene protons of CMEH appearing in the spectrum of thiolated CMCh-*g*-CM-β-CDs. From the relative peak intensities of anomeric protons of CMCh (4.8 ppm), CM-β-CD (5.0 ppm), and methylene protons of CMEH (2.65 ppm), the degree of substitution of CM-β-CD in thiolated CMCh-*g*-CM-β-CDs was estimated as ≈ 77 %. The degree of substitution of CMEH in two different thiolated CMCh-*g*-CM-β-CDs was determined as about 20 %.



Thiolated CMCh-*g*-CM-β-CD

7

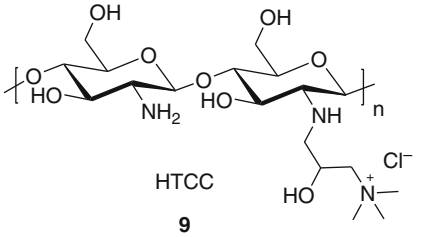
In another preparation of water-soluble 6-*O*-carboxymethyl derivative of chitosan (OCM-Ch, **8**) (Shinde et al. 2013), the ^{13}C NMR spectroscopy was exploited for the characterization of the products; the signals for –COOH substituted on –OH and –NH were detected at 173.4 and 170.1 ppm, respectively. Chemical shifts at 70.9, 69.1, and 48.3 ppm were assigned to methylene carbon of $–CH_2COOH$ groups substituted on O-6, O-3, and N-2, indicating that there were three possible sites for the carboxymethylation of Ch. On account of the signal intensity, it was concluded that the OH-6 was the major site for carboxymethylation of Ch.



OCM-Ch

8

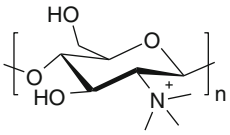
An oral insulin delivery system (*N*-(2-hydroxyl)propyl-3-trimethylammonium-chitosan chloride, HTCC, **9**) was obtained (Sonia and Sharma 2011) by coupling glycidyl trimethylammonium chloride to chitosan in aqueous medium, and the modification of chitosan was assessed by the appearance of intense ^1H NMR peaks at 3.1 ppm, which were attributed to the presence of methyl groups in the quaternary nitrogen atoms.



HTCC

9

In some cases modifying groups may enter in different sites of repeating units and also originate pendants with different lengths, as in the case of ammonium quaternization of chitosan, which represents an efficient way to the improvement of solubility of parent polysaccharide, by affecting strongly its bioavailability and mucoadhesivity. In 2009 Mourya reviewed the synthesis, characterization, and applications of *N*,*N*,*N*-trimethylchitosan (TMCh, **10**) (Mourya and Inamdar 2009). Methylation of amino groups in chitosan can be achieved with methyl iodide in different experimental conditions by obtaining strongly variable degree of quaternization depending on the number of reaction steps or reaction time or using different deacetylation grades of chitosan. At higher degrees of quaternization, *O*-methylation on the 3 and 6 hydroxyl groups of chitosan may occur, which leads to less soluble products. In this regard there is a strong need to have in hand a robust and reliable analytical protocol.



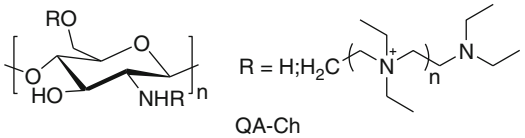
TMCh

10

Mourya (Mourya and Inamdar 2009) reviewed an analytical protocol based on the individuation of well-defined spectral regions of the ^{1}H NMR spectra of TMCh including specific resonances of the glucopyranose rings and derivatizing groups (Sieval et al. 1998; de Britto and Assis 2007). In particular, NMR spectra include signals at 3.4 ppm for quaternized amino group and a peak at 2.5 ppm for dimethylamino group, as well as at 3.36–3.56 ppm for *O*-methylated group. Between 4.5 and 5.0 ppm, anomeric protons are detected, the signal at 3.18 ppm is assigned to H_2 protons, whereas the 3.4–4.0 ppm region includes the other ^{1}H NMR nuclei on the carbon atoms 3, 4, 5, and 6 of the glucopyranose unit; finally acetamido groups give resonances centered at 2 ppm. Therefore, the quaternization degree was established from the ratio of integrated areas of quaternized trimethylamino group and anomeric protons.

It was also reported that mucoadhesion, which is a key element of TMCh polymers for being effective as absorption enhancers at mucosal surfaces, is strongly affected by the increase of molecular weight (Di Colo et al. 2004). Therefore, novel quaternary ammonium chitosan derivatives QACh (**11**) containing different percentages of pendant quaternary ammonium groups were obtained by reacting chitosan with 2-diethylaminoethyl chloride (Zambito et al. 2006). Very complex NMR spectra were obtained with extensively superimposed broad NMR signals, making quite difficult the spectral attribution also in consideration of the fact that some alkylammonium signals are superimposed to ring protons. For this reason the attribution required the combined analysis of scalar and dipolar 2D NMR maps, with a particularly useful contribution from long-range ^{1}H–^{13}C scalar

correlations. Several different kinds of methylene groups were distinguished, i.e., isolated ethyl groups bound to neutral nitrogens (methyls resonating between 0.90 and 1.10 ppm) and ethyl groups bound to quaternary nitrogens (methyls resonating between 1.10 and 1.40 ppm). Other two different clusters of methylene protons were found, which corresponded to methylene groups joining neutral nitrogen atoms to quaternary nitrogen atoms or quaternary nitrogen atoms to the derivatization sites on the glucopyranose ring and, finally, methylene protons on the primary sites of the glucopyranose rings. The presence of strong dipolar correlations due to spatial proximity of H_2 protons with ethyl groups bound to neutral and quaternized nitrogens points to the 2-site on the glucopyranose ring as the preferential substitution site. On the basis of the described spectral characterization, the ratio between quaternary and neutral groups in the pendant chain, which is indicative of chain growth, was calculated. The degree of acetylation was obtained by comparing the proton unit of the acetyl group to the proton unit of the glucopyranose ring. The total degree of substitution can be obtained by comparing the proton unit of the terminal methyl groups linked to the neutral nitrogen to the proton unit of the glucopyranose ring.



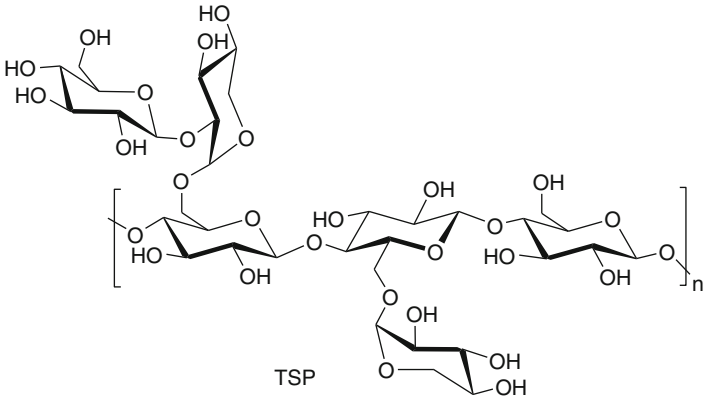
QA-Ch

11

Maestrelli and coworkers (Maestrelli et al. 2006) conjugated mucoadhesive chitosan with cyclodextrins which were composed in nanoparticulate structures in order to develop new mucoadhesive drug release systems. Later different cyclodextrins were incorporated (Trapani et al. 2008), the architectural assembly of which was investigated by NMR. 1D-water-LOGSY experiments (Dalvit et al. 2001) led to detect through space dipole–dipole interactions between the external water phase and other molecules in close contact with it. Through this experiment cyclodextrin component was not detected to indicate that its protons are not in contact with the external water phase (Trapani et al. 2008). By contrast some Ch resonances are observed and hence a fraction of chains of this polymer interacted with the external water phase. Importantly, NMR diffusion experiments (diffusion-ordered spectroscopy, DOSY, Morris 2010; Macchioni et al. 2012) confirmed that Ch is attached to the nanoparticles (NPs) and does not diffuse as free molecules in solution (Trapani et al. 2008). On the basis of the abovesaid results, authors concluded that some chains of the Ch polymer were located on the external side of NPs and exposed to the aqueous medium. On the other hand, the cyclodextrin was entrapped into the NP polymeric network.

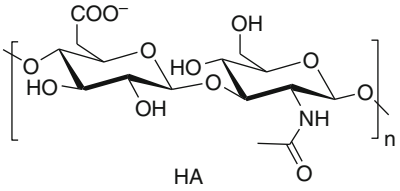
Non-covalent modifications by supramolecular aggregations of potentially mucoadhesive materials may be very attractive from an economic and practical point of view and have been exploited for the development of eye drops based on

mixtures of two polysaccharides: tamarind seed polysaccharide (TSP, **12**), a non-ionic, neutral, branched polysaccharide, and hyaluronic acid (HA, **13**), a polyanion alternating 2-acetamide-2-deoxy-β-D-glucopyranose and β-D-glucopyranuronic acid residues (Uccello-Barretta et al. 2010). TSP has a cellulose-like backbone carrying xylose and galactoxylose substituents.



TSP

12



HA

13

In such a kind of application, NMR contributed to face two problems: the detection of interpolymer interactions demonstrating their supramolecular aggregation and the evaluation of the mucoadhesivity of pure polysaccharides in comparison to their mixtures, depending on the mixture composition, which will be described in the following paragraph. Taking into account that we are dealing with high molecular weight polymers, which originate very broad signals, it cannot be expected to obtain detectable chemical shift changes, due to interpolymer interactions, in the mixtures relative to single polymers. A possible chance is to measure relaxation parameters, i.e., spin–lattice relaxation rates (R_1), giving the recovery time of the longitudinal magnetization, and spin–spin relaxation rates (R_2), which measure the decay of transverse magnetization. Such a kind of NMR parameters is strongly sensitive (Hills et al. 1991; Cowman et al. 1996) to conformational changes and slowing down of molecular motions due to intermolecular interactions. Regarding TSP/HA interaction processes, spin–spin transverse relaxation rates of anomeric protons of 2-*O*-galactosylxylose (Xyl), terminal xylose (Xyl_t), and all of the glucose and galactose (GluGal)

residues were remarkably sensitive to TSP/HA molar ratios and total concentration (Uccello-Barretta et al. 2010). In particular, at constant TSP concentration, relaxation rate parameters of Xyl and Xyl_t anomeric protons of TSP underwent a fourfold and sevenfold decrease (for Xyl and Xyl_t, respectively) in the 1:4 TSP/HA mixture relative to pure TSP. Importantly, viscosity effects on relaxation parameters could be ruled out as they would have produced opposite changes, i.e., an increase of relaxation rates. By adding further amounts of HA, relaxation rates progressively increased reaching a maximum for the 3:2 TSP/HA ratio, to indicate the formation of stable aggregates at well-defined TSP/HA ratios. Response of glucose backbone and galactopyranosyl side chain (GluGal) units was opposite, as relaxation rates of their anomeric protons underwent an initial sensible increase in the presence of HA, but remarkably decreased with increasing TSP/HA ratio till the limit ratio of 3:2. By contrast, relaxation parameter of GluGal anomeric protons of unmixed TSP was not sensitive to concentration changes. Regarding HA, its acetyl protons constituted the probe of the TSP/HA interaction. The spin–spin and spin–lattice relaxation parameters of acetyl moiety of pure HA reflected the changes of repulsive electrostatic interactions due to changes of HA total concentrations. In the mixtures containing TSP, the effect is significantly lower, to indicate that TSP interacted with HA thus contributing to minimize repulsive electrostatic interactions among the chains of the latter. Another sensitive probe of interpolymer interactions is transverse relaxation rate of solvent molecules, which is strongly responsive both to conformational changes and aggregation processes (Hills et al. 1991) as confirmed for TSP/HA mixtures where the R_2 values of the solvent (water) at the TSP/HA 3:2 ratio were remarkably higher than the sum of the values for the single polymers. This fact indicates that the formation of the TSP–HA supramolecular aggregate strongly affects the nature of polysaccharide interactions with water molecules.

3 Mucoadhesivity Determinations by NMR

Going to the problem of using NMR spectroscopy as an in vitro method for assessing mucoadhesivity, mucin–polysaccharide interactions should be detected, which represents a challenging task as both components produce very broad signals. An alternative approach could be using low molecular weight probes in order to detect changes in their mucin affinity imputable to the presence of polysaccharides and, hence, attributable to supramolecular aggregation between the polymeric materials.

Several NMR techniques may be exploited for the investigation of the drug to macromolecule affinities, which have been exhaustively reviewed by several authors (Shapiro 2002; Zartler et al. 2003; Fielding et al. 2005; Fielding 2007; Viegas et al. 2010; Cala et al. 2014). Here we will focus on selected methods, which have been used in polysaccharide applications.

The fundamental needed premise is that a large excess of a low molecular weight component with respect to the macromolecular system must be typically used in

order to obtain its observable signals in solution, where the total concentration is kept to values, which are suitable for obtaining homogeneous solutions without significant viscosity effects. Furthermore, the drug to macromolecule interaction may originate slow- or fast-exchange conditions. In the first case, signals due to bound and free drug are different, and therefore, in principle, affinity effects could be quantified simply by integrating the two signals. Unfortunately, in the operative conditions of very large excess of ligand with respect to macromolecule, it is difficult to detect the signals of very low amount of bound species.

In fast-exchange conditions, only one set of signals is detected and NMR parameters (P_{obs}) are the weighted average of the ones in the free and bound states (Eq. 1):

$$P_{obs} = P_b x_b + P_f x_f \tag{1}$$

where x_b and x_f are the molar fractions in bound and free state, respectively.

The bound state contribution to the observed parameter is very low, and therefore, NMR parameters strongly responsive to drug to macromolecule interactions must be selected. Such a kind of parameters is proton selective relaxation rates (Valensin et al. 1986).

It has been shown that the selective relaxation rate (${R_1}^s$) of the ligand is a more sensitive indicator of binding than the nonselective rate (${R_1}^{ns}$). In fact, methods based on the determination of the selective relaxation rates take advantage of the favorable dependence of ${R_1}^s$ on the reorientational correlation time (τ_c) in the region of slow molecular motions, in which the small molecule is forced by the interaction with the macromolecule. In the fast motion region ($\omega\tau_c \ll 1$, $\omega =$ Larmor frequency), both the selective and nonselective relaxation rates increase progressively with increasing τ_c. When the molecular motion of the ligand is slowed down to the $\omega\tau_c \gg 1$ region as a consequence of the interaction with the macromolecule, ${R_1}^s$ shows a sharp increase, whereas ${R_1}^{ns}$ reaches a maximum for $\omega\tau_c \cong 1$ and then decreases with further increasing $\omega\tau_c$.

Selective relaxation rates are measured by using the standard inversion recovery sequence by selectively inverting one spin and leaving unperturbed all the other spins and measuring the recovery of the magnetization in the time.

Such a kind of sensitive NMR parameters was exploited (Uccello-Barretta et al. 2011) for gaining some insight on the tamarind seed polysaccharide (TSP, **12**) to bovine submaxillary mucin (BSM) interaction in comparison with a water-soluble arabinogalactan (AG), by using ketotifen fumarate (KT) as low molecular weight probe for mucoadhesivity. Preliminarily, the affinity of KT for TSP was evaluated by measuring the proton selective relaxation rates of aromatic protons of pure KT and evaluating the effect of the presence of TSP (Uccello-Barretta et al. 2008). A twofold increase of selective relaxation rates was detected in the mixtures containing TSP, demonstrating the good affinity of the drug for the polysaccharide. The affinity of KT for mucin was even stronger as more than a twentyfold increase of relaxation rates was detected for KT protons (2 mM) in the

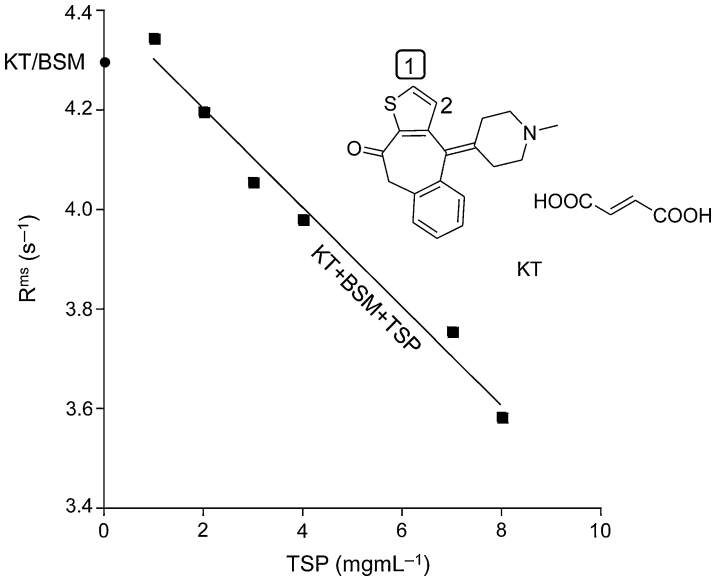


Fig. 1 Plot of mono-selective relaxation rates (R_1^{ms}) of proton H_1 of KT (2 mM) in the presence of BSM (4 mg mL^{-1}) and variable amounts of TSP

presence of 8 mg mL^{-1} mucin, i.e., at concentration levels for which the effect of viscosity changes on the NMR parameters could be ruled out (Uccello-Barretta et al. 2011). By adding increasing amounts of TSP to the binary mixture KT (2 mM)/BSM (4 mg mL^{-1}), concomitant progressive decreases of KT relaxation rates were detected to indicate the mucoadhesive properties of TSP (Fig. 1): the tamarind seed polysaccharide formed stable adducts with mucin and, hence, displaced KT from it. Interestingly, very low changes of relaxation rates of KT protons were detected in the presence of arabinogalactan, which pointed out the lower affinity of the drug for AG. The same polysaccharide did not affect the KT/BSM interaction, as the relaxation rates of KT were nearly unchanged in the binary KT/BSM and ternary KT/BSM/AG mixtures. In this way the minor mucoadhesivity of AG was pointed out in comparison with TSP (Uccello-Barretta et al. 2011). Interestingly, rheological measurements on the mucoadhesive properties of TSP and AG (Burgalassi et al. 2007; Di Colo et al. 2009) gave controversial results.

In another application, both ketotifen fumarate (KT) and diclofenac sodium salt (DS) were employed as mucoadhesivity probes for polysaccharide mixtures containing tamarind seed polysaccharide and hyaluronic acid (Uccello-Barretta et al. 2010). KT, which showed good affinity for TSP (Uccello-Barretta et al. 2008), did not show any propensity to interact with hyaluronic acid as its proton selective relaxation rates remained nearly unchanged in binary mixtures KT/HA in comparison to pure KT. The response of relaxation rates of KT in the

ternary mixtures KT/HA/BSM in comparison to binary mixtures KT/BSM and KT/HA suggested that HA interacted with mucin to a low extent. In the quaternary mixtures KT/TSP/HA/BSM, remarkable decreases of relaxation rates of KT were measured with respect to the values measured in the KT/BSM mixtures, to indicate that TSP/HA mixtures formed stable aggregates with mucin thus displacing KT from it. The abovesaid effect was strongly dependent on the TSP/HA ratio. In particular, TSP/HA mixtures with ratios between 2:3 and 3:2 showed the maximum ability to displace KT from mucin. The formation of stable TSP to HA aggregates with enhanced mucin affinity was confirmed by the values of the cross-relaxation parameters (σ_{ij}) for selected proton pairs *ij* of KT (Uccello-Barretta et al. 2010).

Cross-relaxation term σ_{ij} (Valensin et al. 1986; Uccello-Barretta et al. 1991), which describes the magnetization transfer between the proton pair *ij*, is a function of the reorientational correlation time τ_c of the vector connecting the two spins *i* and *j* and of their distance r_{ij} (Eq. 2):

$$\sigma_{ij} = f\left(r_{ij}^{-6}, \tau_c\right) \tag{2}$$

The cross-relaxation parameters can be determined in a very simple way by measuring the proton mono- (R_i^{ms}) and bi-selective (R_{ij}^{bs}) relaxation rates, which are determined by inverting together the proton pair *ij* and following the recovery of *i* in the time (Fig. 2). On subtracting R_i^{ms} from R_{ij}^{bs}, the cross-relaxation rate σ_{ij} can be calculated (Eq. 3), and hence, the σ_{ij} values for proton pairs at fixed distances can be usefully correlated to the reorientational correlation time, which is a parameter very sensitive to the drug–macromolecule interaction. In particular, in fast motion region, which is typical of low molecular weight molecules, positive values of σ_{ij} are expected (Eq. 4), whereas in the slow motion region, which is typical of macromolecule bound ligands, negative σ_{ij} values are obtained (Eq. 5), and hence, a decrease of σ_{ij} with respect to the free value must be expected, the extent of which depends on the bound molar fraction.

$$\sigma_{ij} = R_{ij}^{bs} - R_i^{ms} \tag{3}$$

$$\sigma_{ij} = 0.5\gamma^4\hbar^2 r_{ij}^{-6}\tau_c \tag{4}$$

$$\sigma_{ij} = -0.1\gamma^4\hbar^2 r_{ij}^{-6}\tau_c \tag{5}$$

In the investigation of mucin affinity of TSP/HA mixtures, the proton pair H_1–H_2 of KT (Fig. 1) was selected being at the fixed distance of 2.94 Å, and its cross-relaxation parameters σ_{12} were calculated on the basis of the corresponding mono-selective relaxation rate (R_1^{ms}) and bi-selective relaxation rate (R_{12}^{bs}). Pure KT showed a low and positive value of σ_{12} (0.04 s^{-1}), which remarkably decreased to -1.83 s^{-1} in the presence of mucin, to indicate that the interaction with mucin forced the small molecule to the slow motion region. In the quaternary mixtures

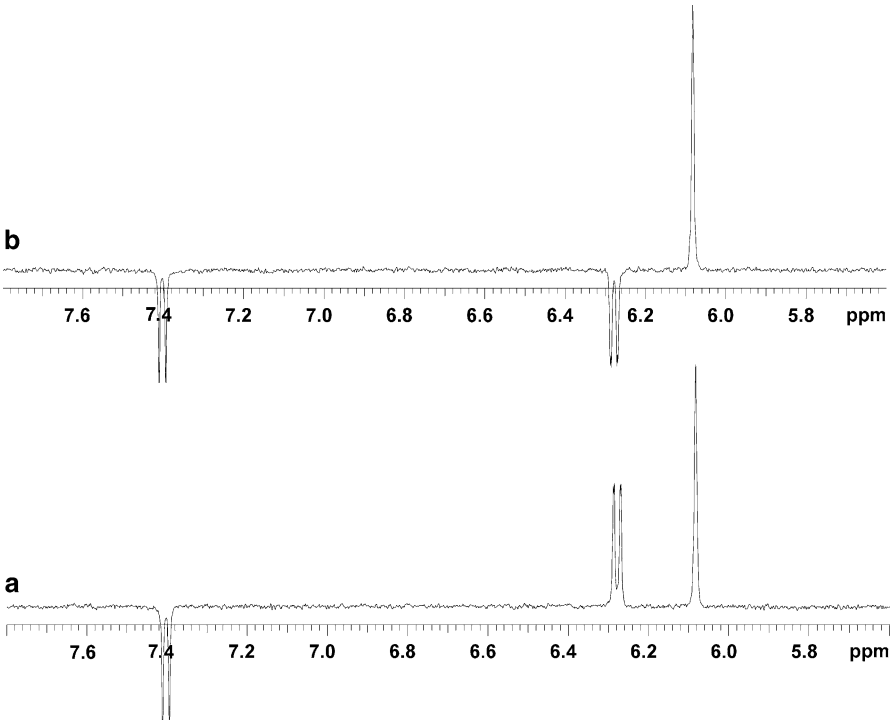

Fig. 2 Example of (**a**) mono- and (**b**) bi-selective proton inversions

KT/TSP/HA/BSM, an increase of the relaxation parameter was detected, the amount of which strongly depended on the TSP to HA ratio.

Diclofenac sodium salt (DS) constituted an alternative low molecular weight interaction probe with negligible propensity to interact both with TSP and HA, whereas its mucin affinity was remarkable (Fig. 3), as about fiftyfold increases of selective relaxation rates of DS were detected in the presence of mucin (Uccello-Barretta et al. 2010, 2013). TSP/HA mixtures produced relevant decreases of DS relaxation rates in quaternary mixtures DS/BSM/TSP/HA with respect to DS/BSM binary mixtures (Fig. 4), confirming the mucoadhesion properties of TSP/HA aggregates.

Such a kind of promising results suggested to extend the NMR approach also to the in vitro evaluation of mucoadhesivity of nanoparticles obtained from quaternary ammonium chitosan conjugates QA-rCh (analogues of QACh, but prepared from chitosan with reduced molecular weight) and QA-rCh-SH (**14**) (Uccello-Barretta et al. 2014). Particularly interesting was the comparison between the polymers and their nanoparticulate aggregates, by using dexamethasone 21-phosphate (DP) as mucoadhesivity probe. The enhanced affinity of the drug for the nanoparticles was assessed with respect to the parent polymer on the basis of responses of relaxation rates of DP in binary mixtures containing the polymer or the nanoparticles; more

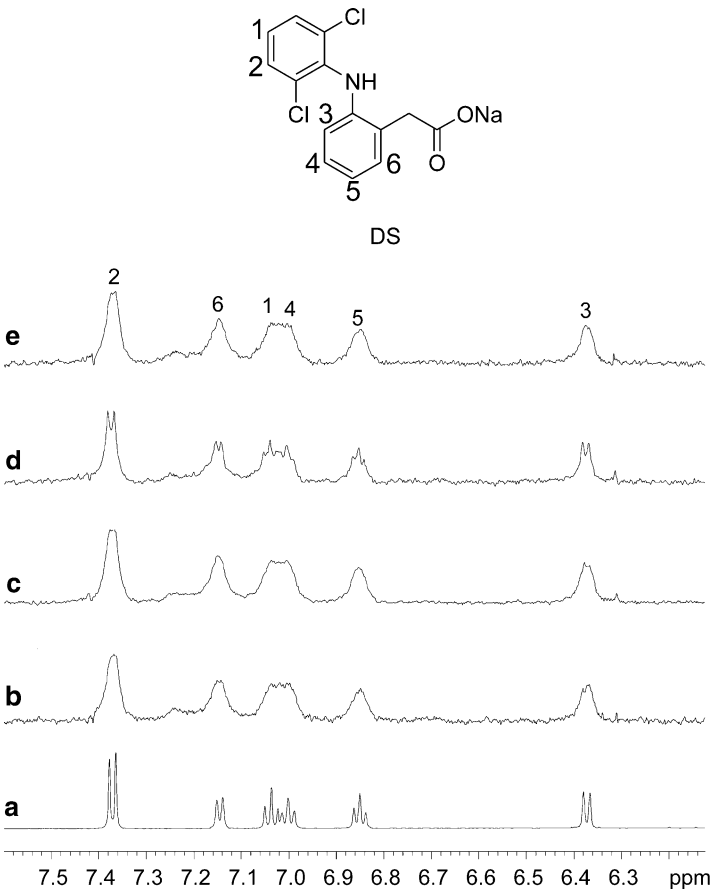

Fig. 3 ^{1}H NMR (600 MHz, D_2O, 25 °C) spectra of DS (2 mM) (**a**) in the presence of BSM (10 mg mL^{-1}) (**b**) and in the quaternary mixtures DS/BSM/TSP/HA at different TSP/HA molar ratios (total concentration 3 mg mL^{-1}): 5:1 (**c**), 1:1 (**d**), 1:5 (**e**)

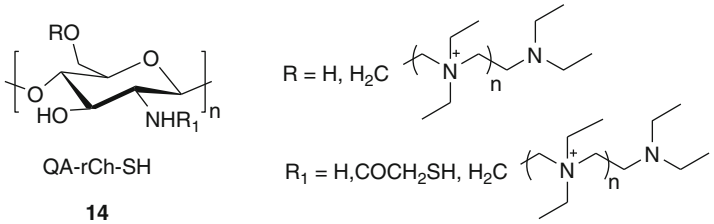
importantly, the relaxation rates of the drug in the ternary mixtures dexamethasone/nanoparticles/mucin were not additive with respect to the binary mixtures drug/mucin and drug/nanoparticles, to indicate that nanoparticles formed stable aggregates with mucin.



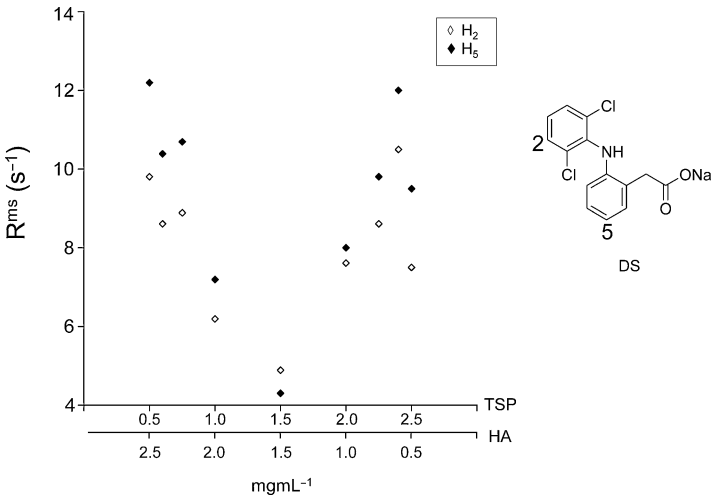


Fig. 4 Dependence of mono-selective relaxation rates of protons H_2 and H_5 of DS (2 mM) in quaternary mixtures with BSM (10 mg mL^{-1}) and TSP/HA at different molar ratios (total concentration 3 mg mL^{-1})

4 Conclusion

NMR spectroscopy has been largely exploited in the field of structural characterization of polysaccharides with proven mucoadhesivity, thus giving a fundamental support to synthetic procedures. On the contrary, in vitro evaluation of their mucoadhesion properties by NMR, although very attractive in terms of noninvasiveness, is still rather limited, but large room is left to future improvements also in view of possible simultaneous applications to the problem of the controlled release properties of mucoadhesive polysaccharide materials in the form of nanostructured aggregates.

Transition-Metal-Catalyzed Transformation of Monosaccharides and Polysaccharides

45

Zuzana Hricovíniová

Contents

Abstract

The exploitation of transition metals in carbohydrate chemistry has achieved considerable developments in the last decades. This contribution gives an overview of transition-metal-catalyzed transformations of various mono- and polysaccharides into enantiopure compounds, fine chemicals, and building blocks suitable for industrial application. These recent applications in this area have made this field of chemistry very attractive. The utilization of carbohydrate–transition-metal complexes have become a powerful tool for forming and breaking of the carbon–carbon bonds. Particular attention is given to recent developments and advances in the use of Mo(VI) ions as highly stereospecific catalyst in carbohydrate synthesis, highlighting the representative examples from the last decade. In the second part, the review describes transition-metal catalytic systems that are involved in the of transformation natural polysaccharides (cellulose, starch, xylans) into important organic intermediates (5-hydroxymethylfurfural, furfural). It is shown that particularly the application

1 Introduction

Carbohydrates are the most abundant biomolecules in Nature and important structural components of biological systems. They play essential roles in living organisms as energy sources and building blocks and are involved in a number of fundamental biological processes (such as cell–cell communication, cell growth and differentiation, bacterial infections, autoimmune disorders, etc.) (Feizi 1993; Dwek 1996; Rudd et al. 2001). In addition, naturally occurring polysaccharides are bio-resources and renewable feedstock that can be used in nutrition and as raw materials. Carbohydrates occur as monosaccharides, oligosaccharides, polysaccharides, as well as components of glycoconjugates. From the chemical point of view, carbohydrates are unique due to their structural diversity having multiple stereocenters and numerous functional groups. Each monosaccharide unit possesses multiple attachment sites and can be linked in a variety of linear or branched forms. These structural features make carbohydrates one of the most complex classes of organic compounds. The study of carbohydrates in biological systems has focused mostly on glycoconjugates, such as glycoproteins or glycolipids. Carbohydrate-containing biopolymers are among the major components of the living cell where they provide the normal course of highly specific biological processes. Some glycosylated natural products have been used as antimicrobial agents, as biological probes for clinical diagnosis, and in recent years as promising anticancer drugs (Kim and Varki 1997; Freeze and Aebi 2005; Geyer and Geyer 2008). However, many functions of carbohydrates and glycoconjugates in living organisms remain still unknown. In order to understand all details of carbohydrate roles and preparation of drug candidates, chemists and biochemists focus their efforts not only on analysis of their functions (e.g., chiral molecules as single-enantiomer chemical intermediates serve as tools for biological studies) but on preparation and testing new carbohydrates and their derivatives as well. To achieve this goal, there is a need for development of new chemical methods for targeted synthesis of complex carbohydrates and glycoconjugates. Particularly, chemist's efforts have been aimed at utilization of unconventional energy sources, novel activating reagents, or

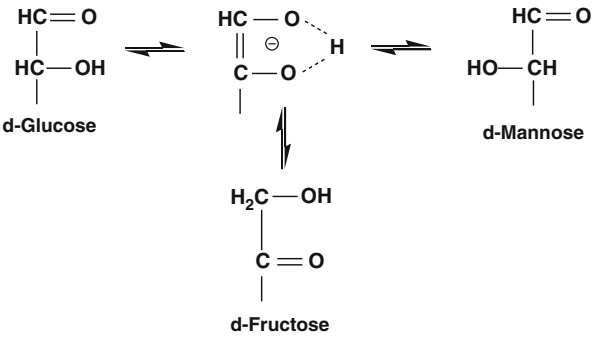
introduction of new effective catalysts. Several reviews have been published in this field (Pratt and Bertozzi 2005; Lichtenthaler 2010).

Catalysis plays central role in many chemical and biochemical processes and has been subject of numerous studies. Crucial role of catalytic functions of enzymes has been recognized long time ago and, together with transition-metal complexes, belongs to the most efficient asymmetric catalysts. However, the inorganic catalysts are usually more stable, readily available, and less expensive and can be applied in demanding reaction conditions. Consequently, catalytic role of metallic ions in saccharide transformations can significantly simplify complex synthetic procedures, and this approach belongs to the most promising synthetic methods at present. Transition-metal complexes of carbohydrates exhibit unique and outstanding properties, which have been discussed in several reviews (Yano 1988; Angyal 1989; Alekseev et al. 1998). The complex formation between sugar molecule and metal ion contributes to superior atom efficiency, usually avoiding several protection and deprotection steps. This strategy allows direct synthesis of structurally complex molecules in a relatively simple way, thus transition metal-catalyzed carbon–carbon bond-forming reactions have become widely used in organic synthesis.

The aim of this review is to describe reactions based on Mo(VI)-catalyzed skeletal rearrangement of carbohydrate backbone. Particular attention will be given to recent advances in the use of Mo(VI) ions as highly stereospecific catalyst in carbohydrate synthesis, highlighting the representative examples from the last decade, especially, to the recent applications of this interesting transformation. In the second part, discussion will be presented on recent progress in the direct transition-metal-catalyzed transformations of polysaccharides which has facilitated access to rare sugars and useful platform chemicals.

2 Isomerization Reactions of Reducing Saccharides

The isomerization of sugars is an important reaction in various essential metabolic pathways and industrial processes. The isomerization of the most common sugar, D-glucose to D-fructose, can be performed under mild conditions using either biological or chemical catalysts. In vivo, these rearrangements are catalyzed by enzymes with high regio- and stereoselectivity. The glucose is converted to fructose, the sweetest one of the natural sugars, through isomerization reaction. Fructose syrups from this process compete with saccharose (beet or cane sugar) in many food applications because they are less expensive than saccharose. In industrial production of these natural sweeteners, starch is hydrolyzed with hydrolase enzymes that convert it into glucose syrup. In order to produce fructose syrups, the glucose is further processed in the presence of isomerase enzymes, which convert D-glucose into its isomer, D-fructose (Schomburg and Salzmann 1990). However, as all biological catalysts, isomerases require very specific reaction conditions (precise control of process variables, such as pH, temperature, etc.) that make biochemical processes relatively costly. Several different ways are presented in the literature for



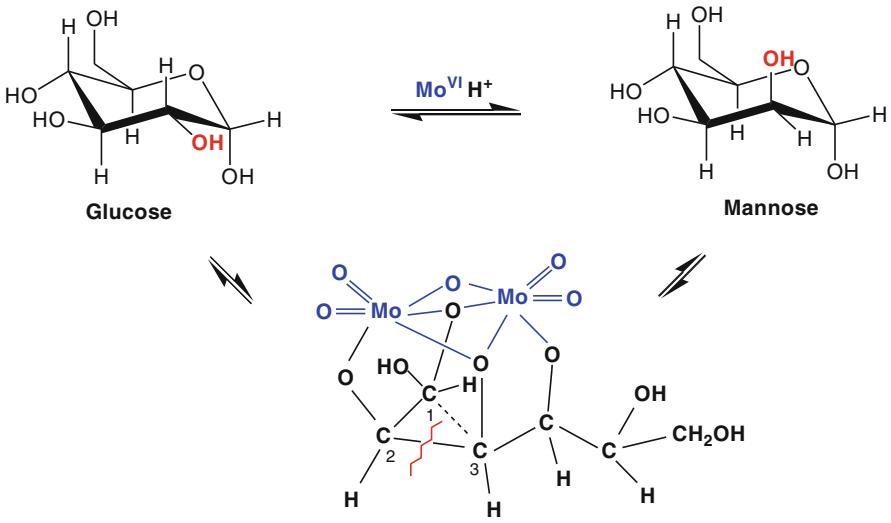
Scheme 1 The Lobry de Bruyn–Alberda van Ekenstein reaction. Equilibrium mixture of glucose–mannose–fructose with 1,2-enediol. *Cis*-form is much more stable, because it is stabilized by an intramolecular hydrogen bond

chemical conversion of saccharides to their isomers besides the enzyme technology. Reducing sugars in open-chain forms can undergo enolization to form different isomers. The reaction is favored in alkaline solutions but can also take place under acidic conditions. This conversion is known as the Lobry de Bruyn–Alberda van Ekenstein rearrangement (Speck 1958; Angyal 2001) and occurs via the base-catalyzed 1,2-enolization of an aldose or ketose to enediol, followed by isomerization. The most investigated case is the glucose–mannose–fructose system, where these three sugars are in equilibrium with 1,2-enediol (Scheme 1).

The Lobry de Bruyn–van Ekenstein reaction has been used for the synthesis of many sugars, and its mechanism has been extensively studied. This reaction can be of preparative use in favorable cases, especially when structural features of starting sugar and products minimize competing reactions (Lichtenthaler and Ronninger 1990). A good example is the preparation of D-psicose from D-allose (Steiger and Reichstein 1936) and preparation of 6-*deoxy*-L-fructose from L-rhamnose (Ennifar and El Khadem 1989) that proceeds in good yields. This reaction was the simplest method for the synthesis of rare monosaccharides for a long period. However, the epimeric aldose is usually obtained in a smaller yield than the ketose, so Lobry de Bruyn–van Ekenstein reaction is not a very practical method for the preparation of epimeric aldoses. The reason for that is that beside the aldose–ketose isomerization a series of side reactions proceed such as aldose–aldose epimerization, inversion of configuration C-3 carbon, or degradation reactions followed by aldol condensation, or another concurrent reactions. In order to minimize these side reactions, the reaction time has to be considerably shortened and, consequently, the equilibrium mixture is seldom reached.

The interactions between saccharides and metal ions have been studied for a long time. The examination of the carbohydrate carbon skeleton upon the formation of metal complexes is an interesting area of the coordination chemistry. It was observed that isomerization reaction proceeds at C-2 carbon without ketose formation when transition metals are used as catalysts. With the development of newer methods, the Lobry de Bruyn–van Ekenstein transformation is of interest only for synthesis of ketoses from aldoses.

One of the best examples of this kind of isomerization reactions was described by Bílik in 1972 when he presented highly stereospecific C-2-epimerization



Scheme 2 Mo(VI)-catalyzed epimerization of aldoses (Bílik reaction)

reaction of aldoses catalyzed by molybdate ions (Bílik 1972a, b, c; Bílik et al. 1972). He found a simple way to use inorganic catalyst in place of the enzymes to generate pure sugar epimers. The Mo(VI)-catalyzed mutual interconversion of epimeric aldoses became a crucial achievement in preparative carbohydrate chemistry. Extensive studies on this catalyzed transformation have been performed using a wide range of epimeric pairs of aldoses to map the scope and limitations of this unique stereospecific carbon-skeletal rearrangement. This rearrangement involves a C-1/C-2 interconversion within the carbon skeleton, wherein the bond between C-2 and C-3 carbon is cleaved and a new bond between C-1 and C-3 is formed. Consequently, the C-2 position has an inverted configuration (Scheme 2).

It was concluded that treatment of an acidic aqueous solution of aldose, in the presence of a catalytic amount of molybdic acid for several hours, gives rise to an equilibrium mixture of two epimeric aldoses without formation of the complementary ketose. The epimeric aldose with lower value of conformational instability is prevailing in the thermodynamic equilibrium mixture, and this equilibrium is the same independently of whether aldose is used as starting material. This stereospecific mutual transformation is applicable for all aldoses in both D- and L-series. Epimerization of aldoses catalyzed by molybdate ions, named after its discoverer (Bílik reaction), become soon the simplest and the most convenient general method for the widespread production of rare monosaccharides. Implementation of the Bílik reaction into practice has made rare aldoses efficiently available. Starting from the less-expensive, more accessible aldoses, it is possible to prepare in one-step reaction rare sugars (e.g., D-talose, D-lyxose, L-ribose, L-glucose, D-mannose, D-altrose, etc.) (Bílik 1972a, b, c; Petruš et al. 2001). Later, other catalytic

systems have been described allowing similar interconversions of aldoses. However, all these catalytic systems have not been as widely exploited as the reaction catalyzed by Mo(VI) ions.

The formation and catalytic effect of transition-metal complexes (Ni^{2+}, Co^{2+}, Ca^{2+}, and Sr^{2+}) on the epimerization reaction depends mainly on their structure (Ishida et al. 1989; Osanai 2001; Tanase et al. 2001). Though glucose–mannose epimerization can be achieved by Ni(II)–tetramethyl-ethylenediamine complex, the yields are lower than those obtained by Mo(VI) catalyst. The mechanism of Ni(II)-catalyzed transformation was extensively studied (Yamauchi et al. 1990; Osanai et al. 1991). The epimerization reaction catalyzed with Ca(II) complexes proceeds via a different mechanism. The results obtained with various aldoses clearly showed that the "mannose-type" aldoses are not isomerized in Ca(II)-tetramethyl-ethylenediamine system (Yamauchi et al. 1990), but Ca^{2+} ions in methanol alone (Yanagihara et al. 1997) lead to epimerization without the ketose formation. According to Angyal (Angyal 1980), these results can be explained by the stability of the various complexes formed between aldoses and Ca^{2+}ions. Reaction between D-glucose and several metal hydroxides in water demonstrate that isomerization proceed only with calcium hydroxide with the formation of all three isomers (Glc/Man/Fru) (Sowden and Schaffer 1952; Angyal and Mills 1979).

3 Microwave-Assisted Reactions in Carbohydrate Synthesis

As mentioned in Introduction, chemists' efforts have been focused also on utilization of unconventional energy sources to improve the conventional methods of organic synthesis. In this respect, microwave-assisted chemistry has gained much popularity as it is very efficient and environmentally friendly technique.

Microwave heating (MW) is based on the interaction of electromagnetic field (wavelengths in the microwave region) with the matter. Molecules having permanent dipole moment tend to align to the applied electromagnetic field. As the field alternates, molecules with dipole moments rotate in order to align with the field. These molecular motions (rotations and collisions) lead to a heat generation (called also dielectric heating) (Caddick 1995; Lidström et al. 2001). The dielectric heating depends mainly on the polarity of molecules (electrical dipole moment). Typically, water and carbohydrates are molecules exhibiting dipole moments. As water is fairly polar molecule, it efficiently "absorbs" MW energy. Consequently, the energy transfer is quite efficient to the absorbing reactants during the MW heating in aqueous solutions. Microwave heating offers several advantages over conventional heating, such as noncontact heating, energy transfer instead of heat transfer (radiation), material effective heating, and fast start-up and stopping.

Dielectric heating generally shows large difference on reaction times, higher yields, and purities of products compared to conventional conditions. Moreover, in many cases the MW synthesis is considered as environmental friendly since the reactions are more efficient and less wasteful than traditional methods. Since microwaves can transfer energy directly to the reactive species, they can promote

transformations that are currently not possible. This is especially in cases when conventional methods require demanding chemical conditions, sensitive reagents, or prolonged reaction times. The advantages of using MW dielectric heating were soon realized and resulted in the increased number of published scientific papers. Microwaves were effectively applied to diverse fields of chemistry, such as organic synthesis (Loupy 2002; Kappe and Stadler 2005), nanotechnology (Tompsett et al. 2006; Taylor et al. 2009), biochemistry (Lill et al. 2007; Nesatyy et al. 2007), and medicinal chemistry/drug discovery (Kappe and Dallinger 2006; Collins and Leadbeater 2007).

Carbohydrate chemistry is special area that can benefit from MW radiation. Carbohydrates because of their complexity, arising from their stereochemistry and multifunctionality, are difficult synthetic targets. Furthermore, as many complex carbohydrate molecules are heat sensitive, chemical reactions preparing or modifying carbohydrates are particularly suitable for application of MW heating. For example, rearrangement reactions represent very useful approach for the stereospecific production of isomeric structures leading to diverse natural products. In this case, high demands in activation energy in the reactions, especially isomerization processes, can be completed in a short time applying MW irradiation. The beneficial effect of MW irradiation, which is direct, fast, selective, and controllable, has been employed to accelerate various organic reactions, including alkylations, condensations, nucleophilic substitutions, cycloadditions, protection, and deprotection reactions with the optimal use of material and energy. The intrinsic advantages of MW irradiation in chemical transformations, the impact, and future potential are illustrated in a number of articles and reviews (Das 2004; Richel and Paquot 2012; Corsaro et al. 2013).

4 Mo(VI)-Catalyzed Transformations of Saccharides

Monosaccharides form various types of complexes with molybdate ions in aqueous solutions. Types of the complexes depend on the solution pH and steric arrangement of the hydroxyl groups (Porai-Koshits and Atovmyan 1974). Structures of molybdate complexes of reducing sugars have been extensively studied in aqueous solution mainly by ^{1}H, ^{13}C, and ^{95}Mo NMR spectroscopy. Data showed that saccharides can create bidentate, tridentate, or tetradentate complexes (Matulová and Bílik 1990a, b; Sauvage et al. 1992; Matulová and Bílik 1993; Sauvage et al. 1996; Matulová and Hricovíniová 2002). A few structures have also been determined by X-ray crystallography (Hedman 1977; Taylor and Waters 1981; Ma et al. 1989). Epimerization of aldoses is based on the ability of molybdate ions to catalyze stereospecific rearrangement that proceeds via acyclic dimolybdate–saccharide complexes. The acyclic hydrated aldehyde forms of aldoses are linked in the binuclear molybdate core as tetradentate ligands via their hydrated carbonyl group and three adjacent hydroxyls (bound on carbons C-2, C-3, and C-4 (Fig. 1)). Only these complexes are considered as catalytically active and can mediate the stereospecific rearrangement. The formation of the molybdate complex influences the

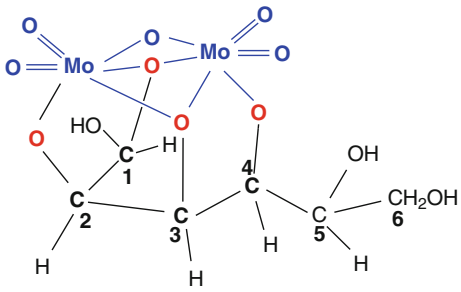


Fig. 1 The acyclic form of aldose linked in the binuclear molybdate core as tetradentate ligand via hydrated carbonyl group C-1 and three hydroxyl groups attached to carbons C-2, C-3, and C-4

development of the thermodynamic equilibrium for epimeric pairs of corresponding aldoses that can be reached in very different periods of time. The most advantageous pH range for epimerization reaction is pH 2.5–3.0.

Recent reports showed that the epimerization of aldoses can be facilitated by combined action of Mo(VI) catalyst and MW irradiation (Hricovíniová 2006). Such approach has much greater potential than would correspond to two independent processes and leads to the considerable improvement in activity and selectivity of the isomerization reaction. This remarkable transformation proceeds by unusual stereospecific rearrangement of carbohydrate skeleton and thus opens up exciting opportunities for the production of various rare sugars using Mo(VI) catalyst. In addition, molybdate ions were further examined as stereospecific catalyst associated with C–C bond-forming reactions. New methodology was successfully applied for the preparation of various sugar derivatives and led to the efficient synthesis of epimeric aldoses (Hricovíniová 2006), ketoses (Hricovíniová 2008a), *deoxy*-aldoses (Hricovíniová 2009), 6-*O*-aryl-aldoses (Hricovíniová et al. 2010), 2-*C*-branched-chain aldoses (Hricovíniová-Bíliková et al. 1999), and 3-*C*-branched-chain aldoses (Hricovíniová and Hricovíni 2013). This approach was also effective in the case of aldoses bearing nitrogen in the branch (Hricovíniová 2010). Transformation proceeds very efficiently, and investigation of Mo(VI)-catalyzed interconversions was therefore further extended to several disaccharides (Hricovíniová 2008b) and polysaccharides (Hricovíniová 2011, 2013).

4.1 Mo(VI)-Catalyzed Isomerization of 2-*C*- and 3-*C*-Branched Aldoses

Branched saccharides occur in nature and have been the subject of intense biochemical studies. Despite their low natural abundance, they have enormous potential in several important applications. They often serve as essential biosynthetic precursors, structural elements, biological probes, pharmaceuticals, etc. Higher-carbon saccharides have been particularly interesting because of the fact that they can be used as non-metabolized analogues of oligosaccharides or components of antibiotics (Grisebach and Schmid 1972; Weizman and Tor 2003). Several enzymatic methods toward preparation of higher-carbon sugars have been developed

(Izumori 2002; Beerens et al. 2012), but the complex nature of biochemical processes makes them very costly.

Epimerization of aldoses catalyzed by molybdate ions has become an effective method for preparation of C-2 epimers (Bílik et al. 1975; Hayes et al. 1982; Petruš et al. 2001). Based on the current knowledge of Mo(VI) complexes of monosaccharides, one could expect the similar mutual interconversion between 2-ketoses and 2-*C*-(hydroxymethyl)-aldoses. The possibility of extension of this approach for the synthesis of other rare, biologically active carbohydrates has been verified on Mo(VI)-catalyzed mutual interconversions of 2-ketoses and 2-*C*-(hydroxymethyl)-aldoses. It was shown that treatment of 2-*C*-(hydroxymethyl)-D-glucose and 2-*C*-(hydroxymethyl)-D-mannose (Hricovíniová et al. 1998a) and D-fructose (Hricovíniová et al. 1998b) with Mo(VI) ions results in dramatic structural changes. Mechanistic studies with the isotopically substituted saccharides have shown that the interconversion of 2-ketoses and 2-*C*-(hydroxymethyl)-aldoses, with mutually inverted positions of hydroxyl groups at their carbon atoms C-2 and C-3, is a consequence of a highly stereospecific carbon skeleton rearrangement. In this respect Mo(VI)-catalyzed isomerization of 2-ketoses and 2-*C*-(hydroxymethyl)-aldoses is very similar process to the mutual interconversion of epimeric aldoses. Two 2-*C*-(hydroxymethyl)-branched-chain aldohexoses are rearranged stereospecifically and reversibly to D-*manno*-heptulose and D-*gluco*-heptulose, respectively. Accordingly, D-fructose provided an equilibrium reaction mixture with its isomer 2-*C*-(hydroxymethyl)-D-ribose (D-hamamelose) under identical reaction conditions. The carbon skeleton rearrangement during this transformation was confirmed by ^{13}C and ^{1}H NMR analysis of D-(2-^{13}C) fructose conversion to D-(2-^{13}C) hamamelose (Hricovíniová-Bíliková et al. 1999). This new, one-step approach was examined on several other pairs of isomers, starting from 2-pentuloses to 2-nonuloses. The equilibria in all cases strongly favored 2-ketoses, and the isomeric ratios in thermodynamic equilibrium mixtures were established by NMR spectroscopy (Table 1).

Table 1 Equilibrium mixtures of Mo(VI)-catalyzed mutual isomerization of 2-ketoses and 2-*C*-(hydroxymethyl)-branched aldoses obtained under conventional conditions

Equilibrium mixture of 2-ketose and corresponding 2-*C*-(hydroxymethyl)-aldose	
D-Ribulose/2-*C*-(hydroxymethyl)-D-threose	11:1
D-Xylulose/2-*C*-(hydroxymethyl)-D-erythrose	10:1
D-Fructose/2-*C*-(hydroxymethyl)-D-ribose	14:1
6-*Deoxy*-L-fructose/2-*C*-(hydroxymethyl)-5-*deoxy*-L-ribose	10:1
L-Sorbose/2-*C*-(hydroxymethyl)-L-lyxose	32:1
D-Tagatose/2-*C*-(hydroxymethyl)-D-xylose	19:1
D-*Gluco*-heptulose/2-*C*-(hydroxymethyl)-D-mannose	12:1
D-*Manno*-heptulose/2-*C*-(hydroxymethyl)-D-glucose	26:1
D-*Altro*-heptulose/2-*C*-(hydroxymethyl)-D-allose	12:1
D-*Ido*-heptulose/2-*C*-(hydroxymethyl)-D-gulose	36:1
7-*Deoxy*-L-*gluco*-heptulose/2-*C*-(hydroxymethyl)-L-rhamnose	9:1

The transformation is initiated by the formation of catalytically active molybdate complexes that promote this unique stereospecific rearrangement. A possible mechanism of the isomerization of 2-*C*-(hydroxymethyl)-branched aldose to 2-ketose has been suggested on the basis of the known capability of molybdate ions to form complexes with monosaccharides. Effective, stereospecific transformation occurs in the case of 2-*C*-(hydroxymethyl)-branched aldoses with C-2–C-3 bond cleavage and transposition. The transformation proceeds via acyclic dimolybdate–saccharide complexes (Scheme 3). The formation of the dimolybdate complex with the carbonyl-oxygen atom C-1 and the adjacent three hydroxylic oxygen atoms at C-2, C-3, and C-4 of the 2-*C*-(hydroxymethyl)-branched aldose (Scheme 3a) leads to the transition state (Scheme 3b) in which branched saccharide function as bidentate ligand bound to the metal center. The design of ligand is the key issue for the catalytic process. The critical C-2–C-3 and new C-1–C-3 bond is formed stereospecifically. Dissociation of the complex produces either the starting 2-*C*-(hydroxymethyl)-branched aldose or the isomeric 2-ketose (Scheme 3c) generated by the stereospecific rearrangement. The thermodynamic equilibrium favors in this case the 2-ketoses (Hricovíniová-Bíliková et al. 1999).

4.2 Mo(VI)-Catalysis in Preparation of Rare Ketoses

2-*C*-(Hydroxymethyl)-branched aldoses with the C-2, C-3 *erythro* configuration are easily accessible via the base-catalyzed aldolization of their 2,3-*O*-isopropylidene derivatives with formaldehyde (Ho 1978). Treatment of 2-*C*-(hydroxymethyl)-branched aldose with the catalytic amount of molybdic acid in microwave field afforded the thermodynamic equilibrium mixture of the starting branched-chain aldose and the corresponding 2-ketose in several minutes (Scheme 4).

It was observed that the reaction proceeded efficiently with excellent yields and the reaction rates were dramatically enhanced. The same reaction under conventional conditions took 5–8 h to afford comparable yields. Due to easily accessible 2-*C*-(hydroxymethyl)-aldoses, the method is especially advantageous for the one-step preparation of rare higher ketoses. The scope and generality of this stereospecific transformation was illustrated on various 2-*C*-(hydroxymethyl)-branched aldoses (Table 2).

The comparison of these results clearly shows that MW irradiation markedly accelerates the isomerization process and also causes the differences in equilibration of reaction mixtures. As indicated from the data in Table 2, the effect of MW irradiation increases the yields of 2-ketoses up to 10 %, but the beneficial effect of microwaves is significant mainly from the point of view of the reaction kinetic of studied transformation. The reaction time decreased from hours to minutes, that is, up to 160-fold shorter than in the case of conventional oil-bath heating and, at the same time, obtaining the better yields of cleaner products without the formation of

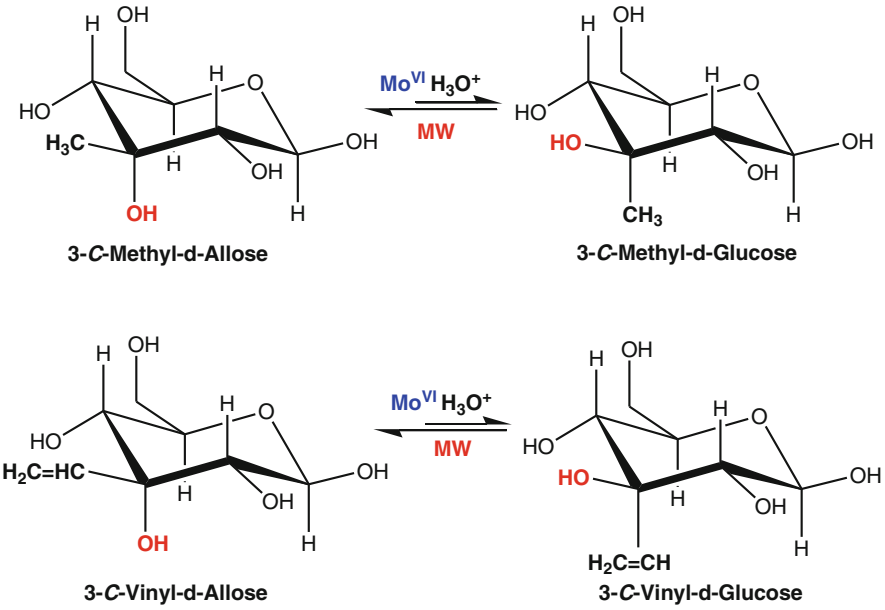
Table 2 The comparison of the Mo(VI)-catalyzed isomerization of 2-*C*-(hydroxymethyl)-branched aldoses to 2-ketoses in microwave field and under conventional conditions

		MW filed		Conventional heating	
2-*C*-(hydroxymethyl)-branched aldose	Product 2-ketose	Time (min)	Yield (%)	Time (min)	Yield (%)
2-*C*-(hydroxymethyl)-D-glucose	*Ido*-heptulose	3	86	420	83
2-*C*-(hydroxymethyl)-L-rhamnose	7-*Deoxy*-*gluco*-heptulose	3	85	360	77
2-*C*-(hydroxymethyl)-D-mannose	*Gluco*-heptulose	3	85	120	80
2-*C*-(hydroxymethyl)-D-*gulo*-heptose	*Ido*-octulose	3	46	480	40
2-*C*-(hydroxymethyl)-D-*talo*-heptose	*Galacto*-octulose	3	65	360	59
2-*C*-(hydroxymethyl)-D-*manno*-octose	*Gluco*-nonulose	3	76	300	61

side products. Performing this reaction under MW conditions leads to respectable yields (46–86 %) in several minutes (Hricovíniová 2008a).

The rate enhancement under MW irradiation may be attributed to the absorption of more energy by the polar media, which generates sufficient heat energy to promote this demanding isomerization process. As these reactions occur with high stereoselectivity, there must be high enough difference in activation energy for processes leading to two stereoisomers. The method was tested on preparation of D-*ido*-heptulose (Hricovíniová 2001), 7-*deoxy*-L-*gluco*-heptulose (Hricovíniová 2009), D-*gluco*-heptulose (Hricovíniová et al. 1998a), D-*glycero*-D-*ido*-octulose (Hricovíniová et al. 2001), D-*glycero*-L-*galacto*-octulose (Hricovíniová 2002), and D-*erythro*-L-*gluco*-nonulose (Hricovíniová 2007). The method is universal and leads to rare ketoses in a single step. This approach is suitable also for preparative purposes because both isomers can be very effectively separated by chromatography. In addition, it provides useful alternative in chemical synthesis of rare or biologically active carbohydrates with scarce natural occurrence.



Scheme 5 The Mo(VI)-catalyzed mutual isomerization of 3-*C*-branched alloses and glucoses in MW field

Apart from the C-2 isomerization, which yields C-2 isomeric products, a new type of rearrangement has also been described very recently (Hricovíniová and Hricovíni 2013). In this case, C-3 isomers of 3-*C*-branched aldoses were prepared in a simple way without formation of side products. This type of reaction was demonstrated on selected model 3-*C*-branched-chain aldoses. For example, 3-*C*-methyl-D-allose and 3-*C*-vinyl-D-allose were rapidly interconverted to their isomers, 3-*C*-methyl-D-glucose and 3-*C*-vinyl-D-glucose (Scheme 5).

The structure of 3-*C*-methyl-D-glucose was confirmed by NMR chemical shifts, proton–proton coupling constant, and NOE spectra as well as theoretical analysis. ^{1}H NMR spectrum (Fig. 2) of the reaction mixture contained new doublets at 5.18 and 4.66 ppm, respectively, which were assigned to the pyranose anomeric protons H-1 of the 3-*C*-methyl-D-glucose.

Theoretical analysis (using DFT calculations) agreed with experimental data and supported $^4C_1$ β-pyranose form of glucose derivative. The presence of the methyl group at C-3 was confirmed not only by the characteristic ^{1}H resonance (originating from the CH_3 resonance linked to C-3) but by two-dimensional NOE spectra as well.

As it was explored, a specific catalytically active molybdate complex is formed producing isomeric 3-*C*-methyl-branched aldose. According to the data, the structure of the ligand seems to be a key issue for the catalytic process: Aldoses epimerize at C-2 carbon producing *epi*-aldoses (Scheme 6a). Aldoses bearing hydroxymethyl-substituent at C-2 carbon isomerize under the formation of 2-ketoses (Scheme 6b).

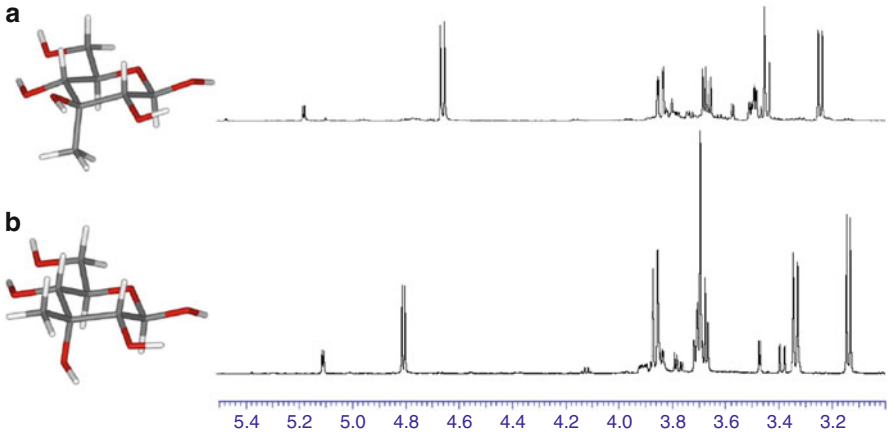


Fig. 2 High-resolution 600 MHz ^{1}H NMR spectra of 3-*C*-methyl-D-allose (**a**) and 3-*C*-methyl-D-glucose (**b**) at 25 °C in D_2O. Insets show DFT-optimized structures of these branched aldoses

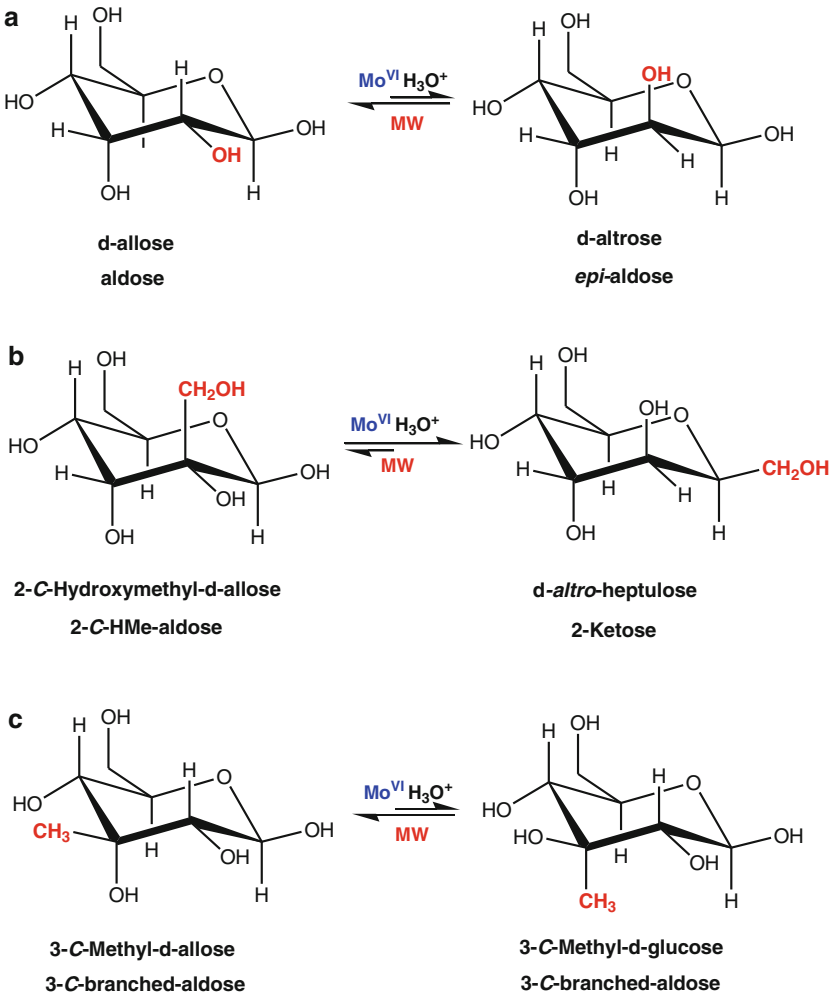
3-*C*-branched aldoses with sterically accessible substituents (such as methyl or vinyl) isomerize at C-3 carbon (Scheme 6c), whereas bulky substituents (e.g., phenyl, nitromethyl) linked to C-3 carbon prevent any isomerization.

This new type of rearrangement allows preparation of isomeric products of 3-*C*-methyl- and 3-*C*-vinyl-branched-chain aldoses via C-3 isomerization utilizing the synergic effect of Mo(VI) ions and MW field. The reaction leads to rare saccharides in a single step and provides excellent alternative to conventional methods in chemical synthesis of rare carbohydrates. It also provides insight into the development of other stereoselective transformations used in the synthesis of natural products.

4.3 Mo(VI)-Catalysis in the Preparation of Amadori Ketoses

Amino sugars are another important class of bioactive compounds having broad spectrum of applications in biochemical and pharmaceutical fields (Collins and Ferrier 1995). The substitution of a hydroxyl function by an amino group may alter the properties of the sugar molecule significantly in terms of its solubility, hydrogen-bonding properties, and electronic distribution. The most abundant example is D-glucosamine (2-*amino*-2-*deoxy*-D-glucose), but various amino sugars are frequently occurring components of biological systems. As a consequence, amino sugars play important physiological roles in many glycoconjugates and are of interest for the development of new drugs, biological substrates, and reference standards (Pelyvas et al. 1988; Stütz 1999). Particularly carbohydrates bearing azido functions have emerged as valuable intermediates. Their chemical stability and easy reduction make them attractive compounds for obtaining the corresponding amino derivatives. There are numerous approaches for the synthesis



Scheme 6 The comparison of Mo(VI)-catalyzed epimerization/isomerization reactions of aldoses (**a**) 2-*C*-(hydroxymethyl)-branched aldoses (**b**) and 3-*C*-(methyl)-branched aldoses (**c**)

of amino sugars. Most of them are based on naturally occurring carbohydrates and involve several protecting group manipulations as well as other synthetic steps (Nicotra et al. 2008). An important concept of preparation of amino sugars as synthetic intermediates for glycoarray synthesis is Amadori rearrangement (Amadori 1931). Reaction between α-hydroxy aldehydes and suitable amines leads to α-amino ketones. When applied to aldoses, it allows the introduction of the amino group at position C-1 with concomitant isomerization leading to 1-*amino*-1-*deoxy*-ketoses (Amadori ketoses). The rearrangement is known as an initial step of the Maillard reaction cascade. The dark-colored rearrangement products formed in this reaction are responsible for the nonenzymatic browning

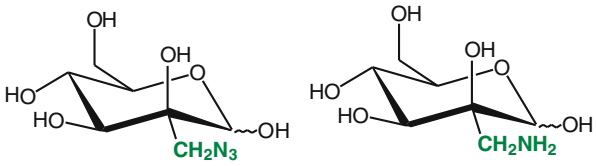


Fig. 3 2-*C*-Azidomethyl-D-mannose and 2-*C*-aminomethyl-D-mannose

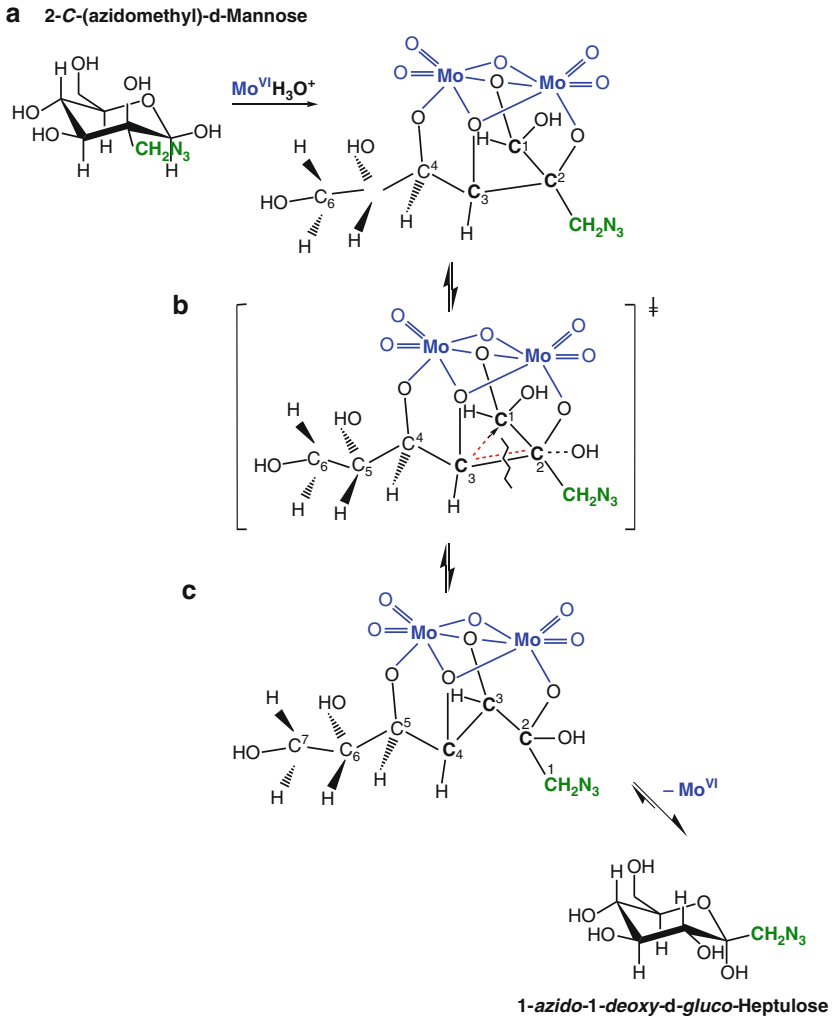
of food (Maillard 1912; Yaylayan et al. 1994). The Amadori rearrangement allows a simple introduction of the amino moiety to C-1 position of a carbohydrate. However, the preparative use of this rearrangement is rather limited as several reversible steps occur during the isomerization as well as a number of side and degradation products. Only a few preparatively useful examples are known owing to their difficult isolation from the obtained reaction mixture. Especially aliphatic glycosylamines are very sensitive to hydrolysis and give the rearrangement products only under very specific conditions. According to the relevance of Amadori ketoses in biological processes, several investigations of their roles in the pathological effects of diabetes and ageing processes were conducted (Raabe et al. 1996; Posthuma et al. 2001). Some authors have suggested that blocking of the ketone group in Amadori compounds and their autoxidation might prevent the formation of glycation end products and thus avoid their pathological effects as a result (Asif et al. 2000; Adrover et al. 2008). Additionally, synthesis and evaluation of biological activities of such compounds are of growing interest.

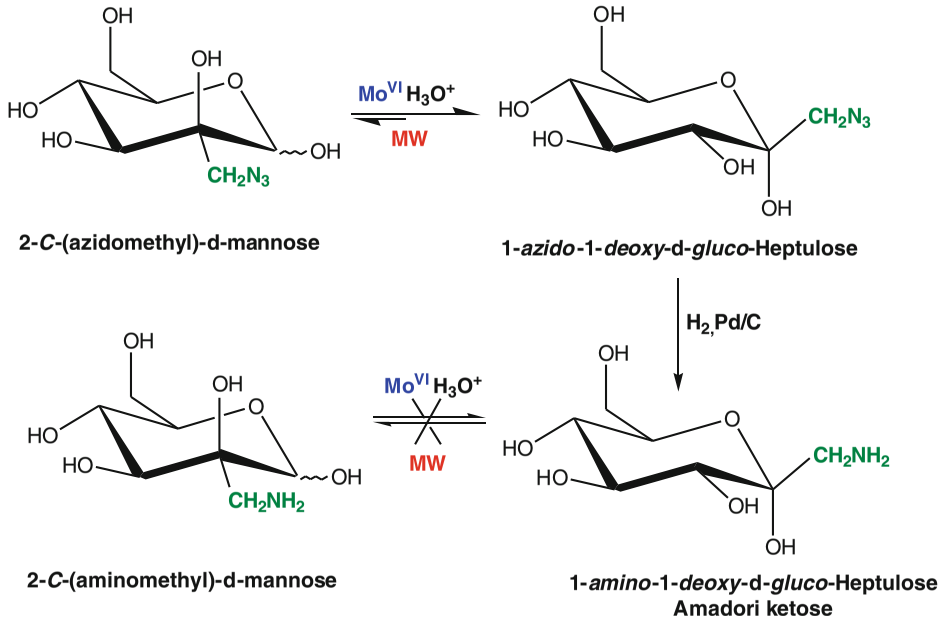
Based on the concept that utilizes the catalytic effect of molybdate ions, an efficient and stereodivergent synthesis of Amadori ketoses was developed (Hricovíniová 2010). The branched-chain aldose bearing azido group at position C-2 provides access to the corresponding 1-*azido*-1-*deoxy*-ketoses and 1-*amino*-1-*deoxy*-ketoses in a single step through a stereospecific isomerization reaction. The transformation was studied using nitrogen-bearing branched-chain saccharides. 2-*C*-azidomethyl-D-mannose and 2-*C*-aminomethyl-D-mannose were selected as the model compounds for examination of the reaction conditions for Mo(VI)-catalyzed rearrangement of carbon skeleton (Fig. 3).

The stereospecific transformation involves the formation of molybdate complexes of branched saccharides bearing azido function. Branched-chain aldose 2-*C*-azidomethyl-D-mannose was subjected to react with a catalytic amount of molybdic acid in acidic aqueous solution. A smooth isomerization reaction took place in MW field and gave the desired product in excellent yield. The equilibrium mixture was reached very fast, and the starting branched aldose was converted to 1-*azido*-ketose in almost quantitative yield (98 %). The same equilibrium mixture can be obtained using conventional heating (oil bath at 80 °C). The mechanism for the isomerization of 2-*C*-(azidomethyl)-D-mannose into 1-*deoxy*-1-*azido*-D-*gluco*-heptulose was suggested (Hricovíniová 2010). The transformation, as in previous cases, proceeds via acyclic dimolybdate–saccharide complexes. Based on studies with isotopically labeled sugars and stereochemical rules of molybdate complexes, the mechanism of the molybdic acid-catalyzed mutual interconversion of the 2-*C*-(azidomethyl)-D-mannose and 1-*azido*-1-*deoxy*-D-*gluco*-heptulose is shown in Scheme 7.



Scheme 7 The Mo(VI)-catalyzed isomerization of 2-*C*-(azidomethyl)-branched aldose (**a**), transition state (**b**), and 1-*azido*-1-*deoxy*-ketose (**c**)

As the isomerization reaction with the 2-*C*-azidomethyl-branched D-mannose progressed flatly in MW field, 2-*C*-aminomethyl-D-mannose acted quite differently (Scheme 8). Intramolecular isomerization did not take place in the case of second model compound. 2-*C*-aminomethyl-D-mannose did not isomerize to corresponding 1-*amino*-1-*deoxy*-D-*gluco*-heptulose even under much stronger reaction conditions. Possible explanation of this fact was based on the theoretical DFT analysis of the α-anomer of 2-*C*-aminomethyl-D-mannose structure. The obtained data showed that the pyranose ring adopts the chair $^4C_1$ form having hydroxymethyl and aminomethyl groups in equatorial positions. Calculations also revealed the



Scheme 8 Mo(VI)-catalyzed transformation of 2-*C*-azidomethyl- and 2-*C*-aminomethyl-branched D-mannose in MW field

strong intramolecular hydrogen bond between OH-2 proton and amine nitrogen. Such types of hydrogen bonds are rather frequent in glycoconjugates (Luisi et al. 1998; Mukherjee et al. 2005). Other two intramolecular hydrogen bonds are located between OH-4...O-6 and OH-3...O-2. These strong hydrogen bonds stabilize structure in the form that prevents formation of catalytically active complex with Mo(VI).

Experimental results demonstrate that molybdate ions can form catalytically active complexes with 2-*C*-azidomethyl-branched sugars and promote the isomerization process leading to 1-*azido*-1-*deoxy*-ketoses in a single step. Although 2-*C*-aminomethyl-D-mannose did not directly isomerize to 1-*amino*-1-*deoxy*-D-*gluco*-heptulose, desired Amadori ketose is easily accessible via catalytic hydrogenation from stable azido derivative. Thus, catalytic hydrogenation of 1-*azido*-1-*deoxy*-D-*gluco*-heptulose afforded quantitatively the corresponding 1-*amino*-1-*deoxy*-D-*gluco*-heptulose (Scheme 8). Preparative use of this approach leading to Amadori ketoses is not limited as it is in the case of Amadori rearrangement. There are no difficulties with reversible steps, formation of side products, and isolation of desired product in excellent yields.

5 Chemical Transformations of Polysaccharides

Carbohydrates, mostly present in polymeric forms, are classified among the most intensively studied precursors with a wide range of properties and applications. The use of environmentally friendly processes for the preparation of various chemical compounds from annually renewable biomass is very important today (Anastas and Warner 2000). Decreasing fossil fuel reserves calls for the development of new, long-term, and sustainable chemical sources. Fossil-based carbon resources can be replaced by carbohydrates that are renewable in nature. Carbohydrates are abundant all over the world as a product of the light-induced fixation of carbon dioxide in plants via photosynthesis. The product, D-glucose, as energy-rich organic molecule can be further transformed into other more complex organic compounds. In this regard, polysaccharides like starch, cellulose, lignocelluloses, or xylans could be the primary target resources for the sustainable chemical industry.

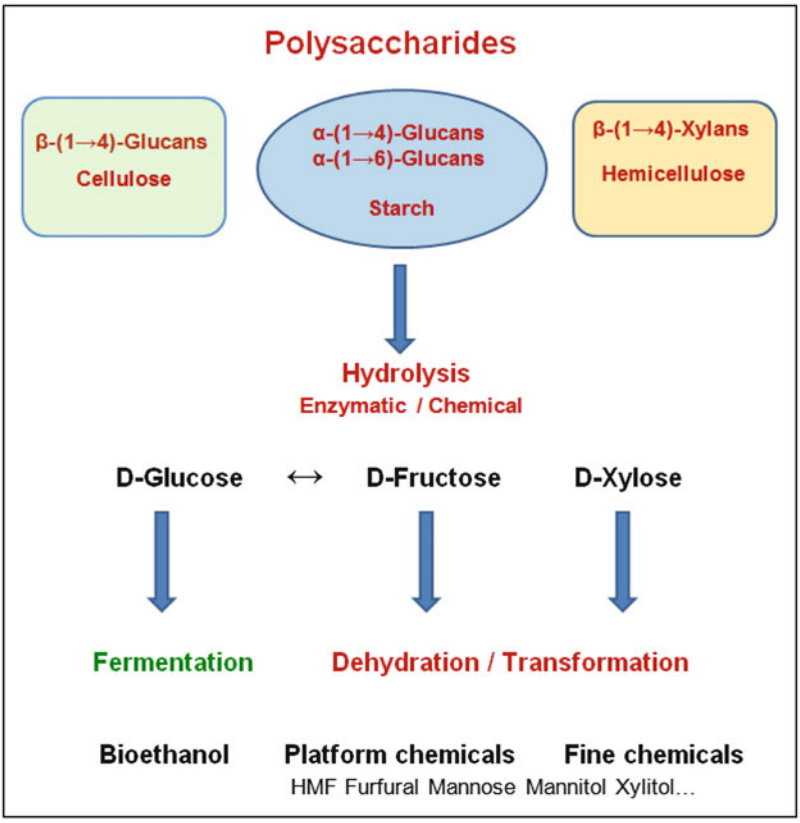
Carbohydrates in their oligomeric and polymeric forms can be easily converted to a wide range of useful intermediates by enzymatic or chemical processes (Belgacem and Gandini 2008). The rate of hydrolysis of a polysaccharide is a function of its structure. In general, α-glycosidic linkages are hydrolyzed more readily than β-glycosidic linkages. Polysaccharides, such as arabans and fructans, whose monosaccharide units occur as furanosides, can be rapidly and completely hydrolyzed under mild acidic conditions. Polysaccharides consisting of pentose units in pyranose form are more resistant. More concentrated mineral acids, especially hydrochloric acid, decompose the pentoses to furfural. Stronger hydrolytic conditions are necessary for polysaccharides composed of hexopyranoside units. The treatment with sulfuric or hydrochloric acid at 100 °C is usually sufficient, but more drastic conditions are necessary in some cases.

Considerable efforts have been done in order to achieve efficient polysaccharide depolymerization and utilization of the obtained monosaccharides (e.g., glucose, fructose, xylose) as a source for synthesis of many industrial chemicals. Dehydration reactions of carbohydrates are important in pulping, in food industry (Maillard reaction) (Saltmarch and Labuza 1982; Ledl and Schleicher 1990), and in the production of bulk chemicals. Extensive research has been initiated worldwide to convert carbohydrates into valuable products, such as ethanol, furfural, 5-hydroxymethylfurfural, and levulinic acid (Huber et al. 2006; Corma and Iborra 2007; El-Zawawy et al. 2011). It is clear that many methods are now available for converting biomass to biofuels and that biomass conversion processes will continue to have industrial interest. In recent years, an increasing effort has been devoted to find cheap and effective methods for the production of furan derivatives which are readily usable for industrial scale-up. Two basic nonpetroleum chemicals are accessible from renewable resources: furfural (2-furaldehyde) arising from the acid-catalyzed dehydration of pentoses and hydroxymethylfurfural (5-hydroxymethyl-2-furaldehyde, HMF) arising from the acid-catalyzed dehydration of hexoses. These compounds are suitable starting materials for the preparation of further monomers required for polymer applications, such as polyamides, polyesters, and polyurethanes. From the commercial point of view, furfural is currently produced on an industrial scale using mineral acids as catalysts, but HMF is not yet a high-volume chemical, partly due to the currently high production costs (Lewkowski 2001; Chheda et al. 2007; Binder et al. 2010). Both HMF and furfural are strategic compounds, which can be derived from agricultural waste products composed from polysaccharides. Thus these versatile and multifunctional compounds are good starting material for the production of useful organic intermediates, fine chemicals, pharmaceutical precursors, polymers, solvents, surface-active agents, and fuels (Scheme 9).

5.1 Transition-Metal-Catalyzed Transformation of Cellulose

Cellulose, hemicelluloses, and starch are the major natural polymers in the world. This widely abundant and renewable carbohydrate biomass is a valuable alternative resource. It mainly consists of oligo- and polysaccharides that can be hydrolyzed to monosaccharides (e.g., glucose, xylose, mannose, galactose, arabinose) by various methods. Monomeric carbohydrates are the most important materials that can be directly used as feedstock for the production of many bio-based chemicals.

Cellulose is a natural polysaccharide that is insoluble in water. The molecules of this straight-chain polymer are composed from two D-glucoses linked uniformly by β-1→4-glycosidic bonds. Breakage of these glycosidic linkages by acids leads to the hydrolysis of cellulose polymers. The first step for cellulose utilization is to depolymerize it into soluble oligosaccharides and monomeric glucose. Unfortunately, the natural polymer forms a robust crystal structure with high chemical stability, thus making the depolymerization processes difficult. The crystallinity of cellulose results from a complex network of intra-strand and



Scheme 9 Transformation of polysaccharides

inter-strand hydrogen bonds (Nishiyama et al. 2003). In order to dissolve cellulose, a solvent must compete for these intermolecular hydrogen bonds. Consequently, acid-catalyzed cellulose hydrolysis is a complex heterogeneous reaction that involves physical factors as well as the hydrolytic chemical reaction (Ott et al. 1965; Zugenmajer 2008).

Multiple conditions are now established to facilitate cellulose hydrolysis. It can be hydrolyzed enzymatically by cellulases into fermentable products. However, there are many factors affecting cellulase accessibility to cellulose, such as high microcrystallinity of cellulose, extensive intermolecular hydrogen bonding, and van der Waals forces (Zhang et al. 2010; Hosseini and Shah 2011).

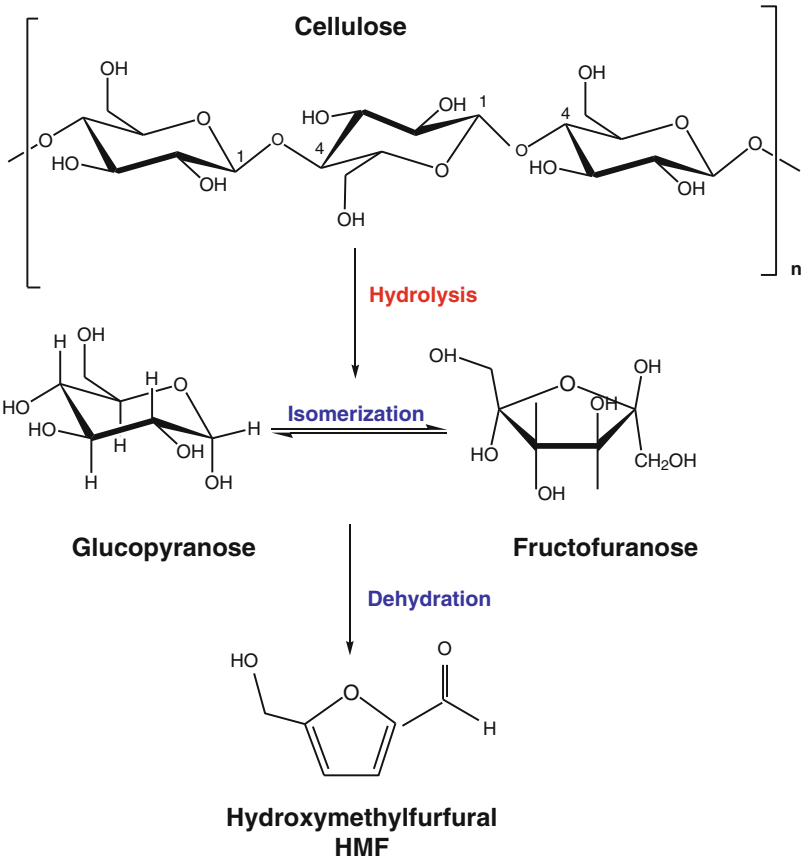
Much work has been devoted on the hydrolysis of cellulose to glucose with mineral acids, such as sulfuric acid (H_2SO_4) or hydrochloric acid (HCl). However, the large-scale use of acid suffers from several problems such as reactor corrosion and catalyst recovery and requires treatment of the acid residue, producing lots of waste (Camacho et al. 1996; Kim et al. 2001). Recently, the increasing attention has gained the application of solid acids for cellulose hydrolysis (Vigier and Jérôme 2010).

The main advantage of solid acid catalysts is that they reduce the pollutants, the product separation is easier, they are recyclable, and they cause less damage to the reactor. Although cellulose hydrolysis has been developed with solid acids toward the greener synthesis of sugars, the reaction efficiency and selectivity still need to be improved. The introduction of ionic liquids was the further step that improved cellulose dissolution and allowed the reaction to proceed more easily under milder conditions. The mechanism of dissolution by ionic liquids is accomplished by disruption of the hydrogen-bonding network forming the electron donor–electron acceptor complexes with the hydroxyl groups of cellulose. As ionic liquids are charged species, they efficiently de-aggregate the polymer strands allowing effective dissolution (Pinkert et al. 2009; Zakrzewska et al. 2010).

As mentioned above, cellulose can be hydrolyzed to glucose and then further transformed into the platform chemicals. HMF is probably one of the most important biomass-derived platform molecules. Actually, it can be prepared through the catalyzed dehydration of glucose or fructose and transformed into highly valuable intermediates. HMF is suitable for the preparation of liquid biofuels, alternative polymers, and macrocyclic compounds or for precursors of pharmaceuticals (Vigier and Jérôme 2010; Rosatella et al. 2011). While HMF can currently be made from fructose and glucose, the ability to synthesize HMF directly from natural cellulose would remove a major barrier to the development of a sustainable HMF platform (Scheme 10).

Thirty years ago, van Dam (van Dam et al. 1986) and Cottier (Cottier et al. 1989) showed that both aqueous and nonaqueous dehydration processes lead to around 37 % yield of HMF. They found that the reactions performed in the aqueous solution increase the degradation of HMF. Furthermore, the polymerization of HMF occurs in both aqueous and nonaqueous media. The acid-catalyzed dehydration of hexoses (D-glucose and D-fructose) to HMF in aqueous media has received considerable attention, but there are still many problems associated with the selectivity and yields of this transformation. The dehydration rate of glucose is about 40 times lower than that of fructose, and much lower is also the product yield. Kinetics studies show that the initial glucose or fructose concentration, the acidity of the aqueous medium, and the presence of various catalysts are factors that influence the conversion of the sugars to HMF (Kuster and van der Baan 1977; Kuster 1990). Fructose has been selected by many researches as the preferred feedstock for the production of HMF. Excellent yields of HMF have been readily achieved applying various methods. The dehydration of D-fructose can generally be catalyzed by protonic acids as well as by Lewis acids. Sulfuric, phosphoric, and hydrochloric mineral acids are the most commonly used to catalyze the transformations of carbohydrate materials (Feather and Harris 1973).

Kuster and van Bekkum reported an exhaustive study of all parameters influencing the course of dehydration of fructose in water as the most convenient solvent (Van Dam et al. 1986). Some improvements were obtained when using acidic ion-exchange resins in water instead of mineral acids. However, any significant selectivity improvement in production of HMF was achieved in this case (Mercadier et al. 1981). The highest selectivities in HMF have been obtained in



Scheme 10 Catalyzed transformation of cellulose

dimethyl sulfoxide (DMSO) as the solvent. Fructose was selectively and quantitatively converted into HMF in the absence of catalyst as well as in the presence of ion-exchange resins. It has been suggested that DMSO preferentially stabilizes the furanoid structure of fructose (five-membered ring) to the pyranoid form (six-membered ring), indicating that the dehydration of fructofuranose is more HMF selective. The advantage of DMSO as the solvent is that it is the dipolar aprotic solvent and prevents the formation of levulinic acid and humins. Its disadvantage is the separation of DMSO, HMF, and water formed and the formation of toxic by-products arising from the decomposition of the solvent (Musau and Munavu 1987).

However, it should be noted that D-fructose is not abundant in nature because it mainly exists as a part of oligosaccharides, in fruits and honey. Moreover, fructose is very expensive because its manufacturing process is very complicated. Glucose which is the monomeric unit of various polysaccharides (mainly cellulose and starch) is a better candidate for this purpose. With its low cost and vast availability,

the conversion of D-glucose to HMF has attracted increasing interest in recent years. However, it is difficult to obtain high yields of HMF from glucose in water (Feather and Harris 1973), organic solvents (Rasrendra et al. 2012), or biphasic systems (Yang et al. 2012), because glucose tends to form a stable six-membered pyranoside structure that is unfavorable to HMF formation. Thus, the effective transformation of D-glucose into HMF remains a challenge. Extensive research efforts are currently performed to develop efficient and sustainable methods to prepare HMF. However, there is still no intensive commercial production of HMF from inexpensive carbohydrates up to now.

To overcome this disadvantage, the use of organic and inorganic salts in the synthesis of HMF in aqueous solution was the subject of numerous works. An interesting catalytic pathway was revealed for the rapid conversion of cellulose to sugars and further to HMF in a single-step process. Recent studies showed that D-glucose can be converted to HMF in good yields in nonaqueous systems using transition-metal elements as the catalysts. The reaction from D-glucose to HMF is generally assumed to involve isomerization of D-glucose to D-fructose followed by dehydration to HMF (Scheme 9). Recently, some significant progress for the metal-catalyzed dehydration of hexoses has been reported (Zhao et al. 2007; Yong et al. 2008).

Transition-metal oxides have catalytic activity for cellulose hydrolysis, and when used as solid acid catalysts, they are reusable and easily separated from reaction products. Mesoporous transition-metal oxides, such as Zr-TMS (transition-metal oxide mesoporous molecular sieves) (Chidambaram et al. 2003) Nb_2O_5, WO_3 (Tagusagawa et al. 2010a), TiO_2 (Kondo et al. 2005), and Ta_2O_5-WO_3 (Tagusagawa et al. 2010b), are widely studied as heterogeneous acid catalysts (Takagaki et al. 2008). Metal oxides are widely used as catalyst supports because of their thermal and mechanical stability, high specific surface area, and large pore size. Sulfonated metal oxides, such as SO_4^{2-}/Al_2O_3, SO_4^{2-}/TiO_2, SO_4^{2-}/ZrO_2, SO_4^{2-}/SnO_2, and SO_4^{2-}/V_2O_5, can supply many acidic species because they operate the same as H^+ for cellulose hydrolysis (Yang et al. 2011; Delaney et al. 2011). The catalysts are active in heterogeneous liquid–solid systems and are recoverable and reusable. However, one limitation of these types of solid catalysts is that the acidic sites become leached from silica surfaces under hydrolytic conditions.

Metallic chlorides in ionic liquids were reported to be an exceptional system capable to convert glucose into HMF in high yield. Zhang and coworkers (Zhao et al. 2007) developed the application of metal salts in 1-ethyl-3-methylimidazolium chloride ([EMIM]Cl) as the solvent. The yields of 60–70 % for HMF prepared from glucose were reported when applying $CrCl_2$/EMIMCl as catalytic system (Pidko et al. 2010). The efficiency of the catalytic system is attributed to its ability to isomerize glucose to fructose, which is more easily dehydrated. Similar results were obtained by Hu et al. using $SnCl_4$ as the catalyst in a series of ionic liquids (Hu et al. 2009). It was found that $SnCl_4$ could efficiently convert glucose to HMF in 1-ethyl-3-methylimidazolium tetrafluoroborate ([EMIM]BF_4). The authors proposed that the formation of the five-membered ring chelate complex of the Sn

atom and glucose plays a key role for the HMF formation. The highest yield of HMF in $SnCl_4$/[EMIm]BF_4 system was about 60 %.

Chou and coworkers used $MnCl_2$ in the acidic ionic liquid 1-(4-sulfonic acid) butyl-3-methylimidazolium hydrogen sulfate ([SA-BMIM]HSO_4) to transform cellulose to HMF (Tao et al. 2011). Ionic liquids combined with lanthanide-based catalysts were also applied for the direct conversion of glucose into HMF. Stahlberg et al. reported only moderate yields (up to 32 %) when a lanthanide salt ($YbCl_3$) was used as catalyst (Stahlberg et al. 2010). Zhao and coworkers used germanium salt ($GeCl_4$) as catalyst in ionic liquid [BMIM]Cl with HMF yield of about 38 % (Zhang et al. 2011). Very recently, the addition of other chlorides, $NbCl_5$, $TaCl_5$, and VCl_3, were applied in ionic liquids to dehydrate D-fructose in HMF (Mittal et al. 2012). The highest yield in HMF production was reported over $NbCl_5$ catalyst. The authors suggested that the remarkable HMF selectivity obtained with these chlorides was due to their weak Lewis acidity, while strongest Lewis acids would favor side reactions.

It was observed that paired ($CuCl_2$/$CrCl_2$) catalysts in [EMIM]Cl exhibited remarkably high activity for hydrolytic cellulose depolymerization. Cellulose depolymerization occurs at a rate that is about one order of magnitude faster than conventional acid-catalyzed hydrolysis. In contrast, single metal chlorides showed considerably less activity under similar conditions. Thus a single-step conversion of cellulose to HMF has been successfully performed with a pair of metal chlorides $CuCl_2$/$CrCl_2$ in [EMIM]Cl solvent, and a 55–59 % yield of HMF was obtained (Su et al. 2009).

Direct transformation of cellulose and sugarcane bagasse into HMF was carried out using single or combined metal chloride catalysts in *N*,*N*-dimethylformamide (DMF) as a solvent. Binder and Raines used $CrCl_2$ and $CrCl_3$ in a solvent mixture of *N*,*N*-dimethylacetamide (DMA)–LiCl and [EMIM]Cl (Binder and Raines 2009). In this solvent system, glucose was transformed into HMF in comparable yields (62 % using $CrCl_2$ and 67 % using $CrCl_3$). Moreover, the system was suitable for cellulose dissolution, and by using $CrCl_3$ a moderate yield of HMF (48 %) was obtained from the corn stover biomass material, along with a 37 % yield of furfural. Though promising, the use of metal salts in ionic liquids has limitations due to the relatively high price of ionic liquids, requiring very efficient recycling strategies. Zhang and coworkers successfully used a pairing of $CrCl_3$ with ammonium halides to transform sucrose, glucose, and fructose into HMF. Application of NH_4Br in DMA afforded conversion to HMF in 87 %, 74 %, and 92 % yields (Wang et al. 2012). The lanthanide metals have been found to serve as Lewis acids in their ionic forms to catalyze the conversion of various saccharides into HMF. The high yields of HMF (>90 %) could be obtained from fructose using the lanthanide chlorides in DMSO (Seri et al. 2000). Another study has shown that the lanthanide (III) ions could dehydrate hexoses in water without rehydration to levulinic and formic acids (Seri et al. 2001).

It was shown recently that both chromium and aluminum salts promote the isomerization of D-glucose to D-fructose in water (with only marginal yields of HMF 10 %). Recently, good yields of HMF were obtained from fructose, glucose,

sucrose, and inulin (60 %, 31 %, 43 %, and 46 %, respectively) using $CrCl_3$ as catalyst (Ilgen et al. 2009). Among several metal chloride catalysts studied, combined catalyst $Zr(O)Cl_2/CrCl_3$ was the most effective enabling conversion to HMF 57 % from cellulose fiber. $Zr(O)Cl_2/CrCl_3$ catalyst was also effective for the conversion of sugarcane bagasse to HMF and 5-ethoxymethyl-2-furfural (EMF) another promising biofuel (Dutta et al. 2012). Indium trichloride was also used as catalyst for the conversion of monosaccharides into HMF and levulinic acid (LA) in aqueous media. It was found that $InCl_3$ could not only catalyze the isomerization of glucose to fructose but also have the positive effects on the dehydration of monosaccharides. Li et al. found that $InCl_3$/acidic ion-exchange resin/ionic liquid catalytic system was effective for the conversion of cellulose to HMF. However, the expensive ionic liquid restricted its extensive application. The application of $InCl_3$ catalyst for the conversion of biomass in aqueous media was also tested (Li et al. 2013; Shen et al. 2014). Several examples of metal catalysts used for the transformation of saccharides into HMF are illustrated in Table 3.

Examples of various transition-metal catalysts used in the transformation of saccharides into HMF in ionic liquids or organic solvents.

5.2 Transition-Metal-Catalyzed Transformation of Starch

Plants store polysaccharides as a food reserve. The most important of these reserves are starches, fructans, mannans, and galactomannans. Starch is the most abundant carbohydrate reservoir in plants and can be found in the grains of all cereal crops including rice, wheat, maize, barley, tapioca, etc. The structure of starch varies widely between plant species and differs in chemical composition as well. Starch granules are largely composed of carbohydrates but also contain minor constituents (fatty acids, minerals, phosphorus), which may influence the properties of the granules. Starch is the second most abundant biopolymer in Nature after cellulose. In particular, because starch is available at relatively lower cost than other sugars (such as fructose and glucose), it could be a cost-effective biomaterial for their mass production. Starch possesses valuable properties like biodegradability, lower environmental contamination, adhesive properties, ability to make layers, etc. High amounts of starch are used in food, textile, and papermaking industries (Steve 2004; Belgacem and Gandini 2008).

Starch varieties contain primarily two structurally different polysaccharides. One is a linear molecule termed amylose, and the other is branched structure termed amylopectin. Both are composed of D-glucopyranose units. Amylose is primarily a linear macromolecule forming predominately single chain. In amylose, 250–300 units are uniformly linked by α-1→4-glucosidic linkages. Such structure tends to induce a spiraling of the molecule in a helix-like fashion. In amylopectin the majority of the units are connected 1→4 with α-links, but there are α-1→6-glycosidic bonds at the branch points. Amylopectin makes up 70–80 % of most starch varieties and so is the major component, strongly influencing the physiochemical characteristics of starch (Bertolini 2010).

The present overview was conducted to examine the effect of metal salts on the acid hydrolysis and other transformations of starch using various reaction conditions. It has already been demonstrated that starches form Werner-type complexes with the non-transition- (Lai et al. 2001) and transition-metal (Ciesielski et al. 2003) cations. Acetates, nitrates, and chlorides of Co(II), Cu(II), Fe(III), Mn(II), and Ni(II) were ligated with starch, and the formation of polycenter Werner complexes was widely studied by Tomasik et al. (Tomasik et al. 1989). The coordination of starch to central metal ions influenced the thermal decomposition of starch and resulted in the slower decomposition compared to the decomposition of non-coordinated starch. Stepwise decomposition of starch potentially provides series of novel dextrins. Thus, properly understood effect of coordination upon the course of thermolysis might lead to custom-made dextrins of a wide range of application (Ciesielski and Tomasik 2003).

Considerable efforts have been done to achieve efficient starch depolymerization and utilization of the obtained monosaccharides for synthesis of many chemicals. Starch can be easily converted by enzymatic hydrolysis or chemical catalytic processes to a wide range of chemical intermediates and useful products used in the food and pharmaceutical industries (Östergård et al. 1988; Quignard et al. 2010). It can be hydrolyzed to glucose and other oligosaccharides by acid

catalysis and further transformed by thermal dehydration. As a starting biomaterial for sustainable synthesis of HMF, starch has a higher viability than other biopolymers, such as cellulose, because the depolymerization process of starch is much easier than that of cellulose.

The effect of MW heating has been widely studied in chemistry of polysaccharides (Corsaro et al. 2013). Microwave reactors produce efficient heating by direct transfer of MW energy to molecules (solvents, reagents, or catalysts) present in the reaction mixtures. Microwave dielectric heating is a very efficient process and results in higher rate of polysaccharide depolymerization. There are several reports describing the use of MW heating in the degradation of starch from different sources, such as wheat, rice, potato, and corn starches (Khan et al. 1979; Lewandowicz et al. 2000). Treatment or degradation of starch using microwaves usually use water or dilute mineral acid (such as HCl or H_2SO_4) as a reaction medium. The reported concentration of starch suspension varied from 1 % up to 50 % in most of studies, but usually 10 % of starch suspension was used. Yu et al. showed that 10 % starch solution in dilute HCl was completely hydrolyzed within several minutes of MW irradiation without the formation of colored by-products (Yu et al. 1996). In contrast, the retrograded starch in similar solutions has not hydrolyzed when conventional methods were used. Thus MW irradiation not only increases the rate of energy transfer but can also change the structure (or conformation) of the reactant accelerating the reaction times.

The addition of inorganic salts is another factor that can enhance the starch hydrolysis. It is known that addition of salts to solvents can increase their conductivity and the solution of substance is heated up more rapidly than by other convective–conductive heating sources, such as oil bath. Furthermore, it was observed that different kinds of salts manifest different effects during starch hydrolysis (Mingos and Baghurst 1991; Kunlan et al. 2001). It was found that starch could be hydrolyzed to D-glucose completely in a short time in the presence of metal halides. The maximum yield of D-glucose was reached using metal halides LiCl, $BaCl_2$, and $FeCl_3$, with 120–180 s of MW irradiation. The difference between metal halides and sulfate salts illustrate that the properties of the salts are very important in affecting the hydrolysis reaction in a MW field. Results showed that Na_2SO_4, $MgSO_4$, and $ZnSO_4$ did not accelerate the acid hydrolysis of starch, and the highest yield of D-glucose was only 12.6 % in the presence of Na_2SO_4. However, when $Ce(SO_4)_2$ was employed, the yield of D-glucose reached 88.9 %, and thus $Ce(SO_4)_2$ facilitates hydrolysis of starch more than other sulfates in a MW field. These results suggest that the catalytic activities of sulfates are lower than metal halides, and the presence of sulfates, such as Na_2SO_4, $MgSO_4$, and $ZnSO_4$, even inhibits the acid hydrolysis of starch. The reason is probably that sulfate buffers the pH and decreases the acidity of HCl because the hydrogen sulfate ion is a weak acid (Kunlan et al. 2001).

The acid-catalyzed dehydration of glucose to HMF in aqueous solution is possible without a catalyst both by conventional and MW-assisted heating. However, the effect of a catalyst results in increase of the dehydration rate significantly. Several recent studies have demonstrated the HMF production in substantial

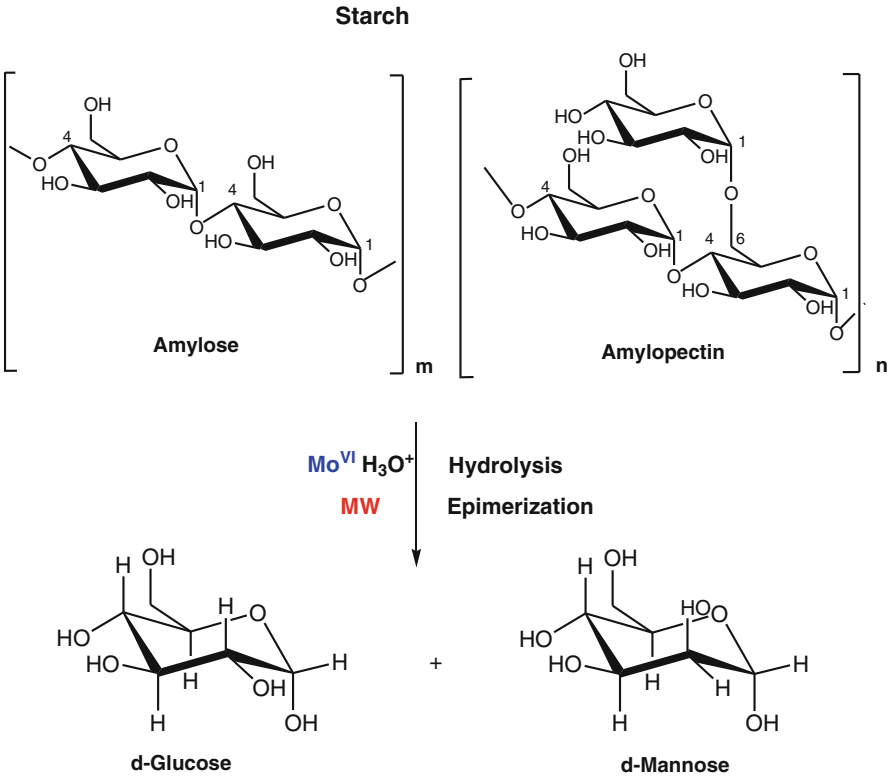
amounts using fructose and glucose by modifying its synthetic processes in the presence of ionic liquids. Recently, Chun et al. published a simple method of producing HMF from various starches using ionic liquid, 1-octyl-3-methylimidazolium chloride ([OMIM]Cl), and $CrCl_2$ as transition-metal catalyst. The addition of $CrCl_2$ to the reaction mixture significantly affected the yields of HMF. The yields of HMF increased approximately twofolds on average in the presence of this catalyst. Among eight starch sources (corn starch, wheat starch, rice starch, potato starch, sweet potato starch, tapioca starch, acorn starch, and kudzu starch) the highest yields of HMF were achieved in tapioca starch (75 %), showing that this starch is most suitable for production of HMF compared with other ones (Chun et al. 2010).

Data from literature consistently pointed out that use of MW irradiation is powerful tool in the field of polysaccharide chemistry. The first goal could be achieved by facilitating reactions under bulk conditions. Reactions can proceed even when the reagents do not absorb the radiation by selecting an appropriately absorbing solvent or by adding ionic liquids. However, since MW equipment has been designed for use in the laboratory, it often limits the scalability of the process and demanding batch reactions using in industrial processes.

5.3 Mo(VI)-Catalyzed Transformation of Starch: Preparation of Mannose and Mannitol

One of the important features of current chemistry methods is the effective preparation of enantiomerically pure compounds from naturally occurring sources. Recent research showed that starch is strongly affected by MW irradiation and has different properties compared to conventionally heated reactions. Several papers have reported the hydrolysis of starch in MW field (Lewandowicz et al. 2000; Palav and Seetharaman 2007; Bhat and Karim 2009). Microwave-assisted transformations are attractive due to short reaction times, high selectivity, and improved yields. As mentioned previously, the presence of ions can also enhance effects of dielectric loss, and MW coupling could produce superheating (Mingos and Baghurst 1991; Kunlan et al. 2001). Molybdate salts were examined in order to increase the efficiency of MW heating together with their catalytic properties. It was observed that in the presence of Mo(VI) ions, the process of starch hydrolysis proceeded much faster and simultaneous epimerization of obtained D-glucose to commercially interesting D-mannose was considerably improved (Hricovíniová 2011).

The effects of starch sources on the yields of D-mannose were compared using three different starches (potato starch, rice starch, and corn starch). In the optimized reaction conditions, a 5 % solution of starch in aqueous solution of HCl with a catalytic amount of sodium molybdate was exposed to MW irradiation. Homogenous blue solutions were obtained indicating completion of the complex formation. Selected reaction conditions lead to complete depolymerization of starch and high conversion by means of D-glucose and D-mannose content (2:1). It was observed



Scheme 11 Reaction scheme of starch hydrolysis and simultaneous Mo(VI)-catalyzed epimerization of obtained D-glucose to D-mannose

that transformation occurs with full selectivity and equilibrium reaction mixture was reached within minutes. The reaction scheme of the combined starch hydrolysis and simultaneous epimerization reaction of obtained D-glucose to D-mannose is illustrated in Scheme 11.

The ratio of sugars present in equilibrium reaction mixture with respect to the production of D-mannose was determined by ^{1}H NMR spectroscopy. The efficiency of the method was demonstrated also in the semi-preparative scale yielding mixture of glucose and mannose (Table 4). Starch hydrolysis is predominantly determined by acid concentration, but the simultaneous mutual interconversion of glucose and mannose is governed by highly stereospecific isomerization reaction catalyzed by molybdate ions.

The microwave-heated samples of starch were compared with the samples prepared by conduction heating. In the latter case, the equilibrium reaction mixtures were obtained after long heating (40 h). The NMR analysis indicated that starch was completely hydrolyzed and converted to the equilibrium mixture (3:1) of glucose and mannose. The formation of D-mannose started after 6 h, and the maximum was reached in about 35–40 h. The final equilibrium mixture is comparable to that found

Table 4 Comparison of MW-assisted and conventional starch hydrolysis and simultaneous epimerization reaction of obtained D-glucose to D-mannose. Both partial and full conversions are shown for both approaches to demonstrate vast differences in reaction kinetics and amounts of D-mannose formations

	MW filed		Conventional		Heating	
Starch	Time (min)	Starch/Glc/Man (%)	Time (h)	Starch/Glc/Man (%)	Time (h)	Starch/Glc/Man (%)
Potato starch	3	0/65/33	10	52/35/7	40	0/73/24
Rice starch	3	0/63/31	10	55/31/6	40	0/73/22
Corn starch	3	0/62/30	10	56/32/6	40	0/74/24

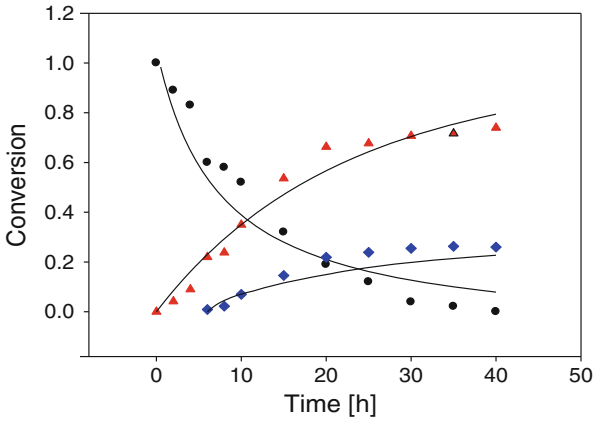


Fig. 4 Conversion of potato starch (●) to D-glucose (▲) and D-mannose (◆) as a function of time under conventional, oil-bath heating. Formation of D-mannose starts about 6 h after starch hydrolysis to D-glucose

in previous studies of Glc/Man epimerization (Bílik 1972a). The composition of the reaction mixture in terms of starch, glucose, and mannose content as a function of time is depicted in Fig. 4. Different reaction kinetics and thermodynamics were observed using MW heating. Starch hydrolysis and the molybdic acid-catalyzed isomerization reached thermodynamic equilibrium already after 3 min under the identical reaction conditions (concentrations, temperature) as used for conventional heating (Fig. 5).

The rearrangement of obtained D-glucose to D-mannose was accomplished after acid hydrolysis of starch in MW field using Mo(VI) ions as catalytically active species. In this respect, D-glucose isomerization is a crucial step in the efficient production of D-mannose. The mechanism of this stereospecific transformation is based on the coordination of glucose with the dimolybdate anion, and, consequently, the creation of catalytically active complexes leads to isomerization of

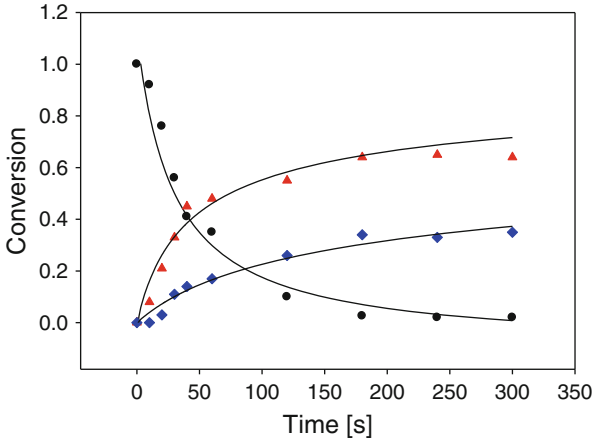

Fig. 5 Conversion of potato starch (●) to D-glucose (▲) and D-mannose (◆) as a function of time in MW field

D-glucose to D-mannose (Bílik 1972a; Petruš et al. 2001; Hricovíniová 2006). The comparison of the results clearly shows that MW irradiation markedly accelerated the isomerization process (by two orders of magnitude compared to conventional heating) and that MW field also caused the differences in the equilibration of the reaction mixtures. The obtained data suggest that the synergistic coordination ability of the catalyst used under the given reaction conditions enables simultaneous efficient starch depolymerization and formation of new compound D-mannose in a single step. Thus, unlike to conventional heating, D-mannose is formed virtually simultaneously with D-glucose using microwaves. The presented approach opens way for the preparation of many interesting sugar derivatives. It should be also noted in this respect that the presence of molybdate ions improves efficiency of energy absorption and thus reaction proceeds faster compared to that without the presence of this catalyst. The Mo(VI) ions thus perform a double role in the presented reaction: the first role is the improvement of the dielectric properties of the solution, leading to high energy transfer to solution from a MW source; secondly, Mo(VI) acts as an efficient catalyst that enables stereospecific conversion of glucose to mannose. These twofold roles of molybdate ions make them a unique catalyst for the isomerization reactions of carbohydrate molecules.

D-Mannose and D-mannitol are widely used in food and pharmaceutical industry (De Guzman 2005; Ghoreishi and Shahrestani 2009). It is only half as sweet as sucrose, which makes mannitol applicable as sweetener in the so-called "light" foods. Mannitol is metabolized independently of insulin, and thus it is also applicable in diabetic food products. Besides applications in the food industry, mannitol is also used in human medicine to decrease cellular edema (excessive accumulation of fluid) and increases the urinary output. Moreover, it is also chemically inert. These properties make mannitol very useful in production of tablets and granulated powders. Furthermore, its sweet cool taste is used to mask the unpleasant taste of

many drugs. The reduction of D-mannose with sodium borohydride leads to D-mannitol in a good yield (78 %); hence the production of pure D-mannose is needed in sufficient amounts. At present, D-mannitol is mainly produced by reduction of D-fructose from less-expensive glucose–fructose syrups which leads to a mixture of D-mannitol and D-sorbitol (1:1). Mixtures of mannitol and sorbitol are also produced enzymatically from fructose with different microorganisms (Peterson and Fred 1920; Soetaert et al. 1999). The main problem is that D-mannitol is difficult to separate from its stereoisomer D-sorbitol. Compared to enzymatic production, chemical catalysis employing inorganic materials for isomerization of reducing sugars could offer attractive advantages, as it is environmentally friendly and inexpensive. Furthermore, the isomerization process can be completed in very short reaction time, which makes transformation more efficient. The application of this methodology provides an attractive way in the field of MW-assisted metal-catalyzed reactions in aqueous media. MW irradiation in combination with Mo(VI) catalyst proved to be an efficient method for the hydrolysis of starch and isomerization of the obtained D-glucose to D-mannose. The short reaction times and good conversions in combination with the easy performance and work-up make this method attractive and applicable also in semi-preparative scale.

5.4 Transition-Metal-Catalyzed Transformation of Hemicellulose

Hemicellulose is, after cellulose and starch, the third most abundant biopolymer. Hemicellulose is a complex branched heteropolysaccharide composed of linear polymers with short branched chains. This plant cell wall polymer is mainly found in woods, grasses, algae, and cereals. The major constituents of hemicellulose chains are xylans, polysaccharides formed by β-(1→4)-linked D-xylopyranoside monomer units. The xylose units of the β-(1→4)-linked backbone chain can be substituted with *O*-acetyl groups at O-2 and/or O-3 or branched with L-arabinose (arabinoxylans) or D-glucuronic acid (glucuronoxylans) (Deutschmann and Dekker 2012). Hemicellulose biomass is widely available renewable low-cost raw material suitable for the production of biofuels and value-added organic products. It is rich in pentosans present in agricultural waste, such as rice husks, oat hulls, cottonseed, hull bran, almond husks, etc. (Akpinar et al. 2009; Amiri et al. 2010; Ren et al. 2012). Conversion of this source of biomass utilizing various chemical methods is an important process mainly due to the development of renewable platform chemicals, mainly furfural (Scheme 9). Furfural applications range from the raw furan-based chemical compounds to solvents. Industrially, furfural is used as a building block for polymers (polyester, polyurethane), thermosetting copolymer resins or high-molecular-weight plastics (polyvinylfurfural). Bulk chemicals such as tetrahydrofuran, tetramethylene chloride, furfuryl alcohol, and pyridine are also obtained from furfural (Moreau et al. 2004).

Furfural is produced through the dehydration of pentoses (mainly from D-xylose). Consequently, the acid-catalyzed dehydration of polysaccharides has been the subject of many studies (Antal et al. 1991; Vásquez et al. 2007).

Pentose dehydration reactions are currently carried out at high temperatures using the acid catalysts. In industrial process, furfural is produced by the homogeneous reaction catalyzed by mineral acids (such as sulfuric acid, hydrochloric acid, acetic acid, or phosphoric acid). These catalysts are effective and give furfural yields of 40–60 %. However, the utilization of mineral acids has serious drawbacks of extreme corrosion, toxicity, and excessive waste disposal. This process causes environmental problems due to the large quantity of wastewater needed to dilute the acid and difficulties arising from separation and recycling (Zeitsch 2000). Furthermore, the process can also produce many secondary reactions that contribute to selectivity losses, including the condensation of furfural and the production of other undesirable by-products. For this reason, it is necessary to develop selective low-cost processes and environmentally friendly methods for the conversion of hemicellulose biomass into furan derivatives.

A number of highly efficient catalysts were developed in the last decade. Among them, inorganic oxides (Corma 1995), heteropolyacids (Dias et al. 2005, 2006), ion-exchange polymer resins (Agirrezabal-Telleria et al. 2011), zirconium phosphate (Weingarten et al. 2011), vanadium phosphate (Sádaba et al. 2011), sulfated metal oxides (Shi et al. 2011; Suzuki et al. 2011), and zeolites (Lima et al. 2008; Lessard et al. 2010) have been reported to be active in the dehydration of xylose to furfural. Indeed, zeolites and related materials can be used as highly selective and active catalysts. The structural properties of these materials, acidic and basic sites, as well as their hydrophilic and hydrophobic properties, make them applicable as efficient solid heterogeneous catalysts. Furthermore, the oxides or pillars could be converted into active sites with different levels of acidity, depending on the characteristics of the cations incorporated. Thus, metal cations such as Al, Zr, Hf, and Ce have been evaluated for a wide range of reactions (Campos et al. 2008). Al–Hf pillared clays were investigated as promising catalysts for the dehydration of pentoses in water, producing furfural with an average conversion up to 78 %. The conversion rates achieved with Al–Hf catalyst using water as a solvent were comparable to those obtained with other catalysts, such as zeolites, which yield conversions ranging from 45 % to 80 % under similar reaction conditions (Lima et al. 2008) Nevertheless, these reactions were carried out in water/organic solvent mixtures, such as water/toluene (Lima et al. 2010) and water/DMSO (Dias et al. 2005). The application of solid heterogeneous catalysts is the promising alternative to strong mineral acids, such as concentrated sulfuric acid, due to their high activity, stability, and simple separation from the reaction products.

Alternative investigations have already been implemented which focus on the conversion of pentoses into furfural by thermochemical processes. Recent processes involve the use of inorganic salts, metal oxides, as well as solid acids instead of mineral acids (Choudhary et al. 2013). The aqueous phase is more favorable from the economic and environmental view for the industrial production. However, the efficiency is very low due to further rehydration of furfural in aqueous solution and the formation of oligomeric species. Organic solvents, such as DMSO and DMF, which favored the formation of furan compounds, have been proven to depress effectively side reactions in the dehydration reactions of D-fructose and

D-xylose (Brown et al. 1982). However, monosaccharide, polysaccharide, and biomass can be only dissolved in a few types of organic solvents to form a homogeneous system. Moreover, the use of organic solvents gives rise to environmental pollution leading to costly recycling procedures.

Ionic liquids with desirable properties of negligible vapor pressures and high thermal stabilities have been proven to be effective solvents in pentose dehydration. The catalyzed conversion of xylan into furfural in ionic liquids in the presence of metal chlorides as catalysts under MW irradiation was studied. Zhang and Zhao demonstrated that $CrCl_3$ in ionic liquids could promote biomass (cornstalk, rice straw, and pine wood) conversion to produce furfural in yields of 23–31 % under MW irradiation (Zhang and Zhao 2010). Zhang et al. studied the catalyzed conversion of xylan in [BMIM]Cl with metal chlorides as catalysts in MW field. Among catalysts, $AlCl_3$ in [BMIM]Cl resulted in the highest furfural yield (84.8 %). The yields of furfural from untreated corncob, grass, and pine wood were in the range of 16–33 % (Zhang et al. 2013). Catalytic system $AlCl_3$/[BMIM]Cl could be recycled for four runs with stable catalytic activity. Moreover, the use of ionic liquid as a reaction medium has not generated any toxic wastewater. However, the high cost of ionic liquids has kept them from being applied in a large-scale furfural production.

One of the promising strategies for furfural production is the continuous extraction of the target product from the aqueous solution utilizing organic solvents. Biphasic systems (water/organic solvent) were introduced as an ecologically viable catalytic pathway for furfural production without the addition of mineral acids. This approach reduces the formation of degradable side products through the consecutive polymerization reactions. Biphasic system using the solid acid catalyst SO_4^{2-}/TiO_2-ZrO_2/La^{3+} in different kinds of aprotic organic solvents (DMSO, DMF) in water phase was used for the production of furfural from xylose. The addition of DMSO, DMF, and 1,3-dimethyl-2-imidazolidinone (DMI) to the aqueous phase of the biphasic system can greatly improve the furfural yield, especially for the DMI solvent (Li et al. 2014).

Very recently, niobium phosphate (NbP) and niobium oxide (Nb_2O_5) were used for the dehydration of xylose to furfural in biphasic solvent system. Xylose conversion and furfural yield and selectivity were tested over different solid acid catalysts (such as zirconium phosphate, sulfated zirconia, H-beta (SiO_2/Al_2O_3=25) and H-Y (SiO_2/Al_2O_3=4) zeolite catalysts) in toluene/water system. Results have shown that among all catalysts tested, NbP exhibited the best catalytic performance. Moreover, NbP showed good stability, and no obvious deactivation of Nb could be observed after six continuous recycles. On the other hand, only moderate yield of furfural (22.5 %) was obtained. The acid-catalyzed xylose conversion and furfural yield over the mesoporous Nb_2O_5 were found up to 90 % and 50 %, respectively (Pholjaroen et al. 2013; García-Sancho et al. 2014).

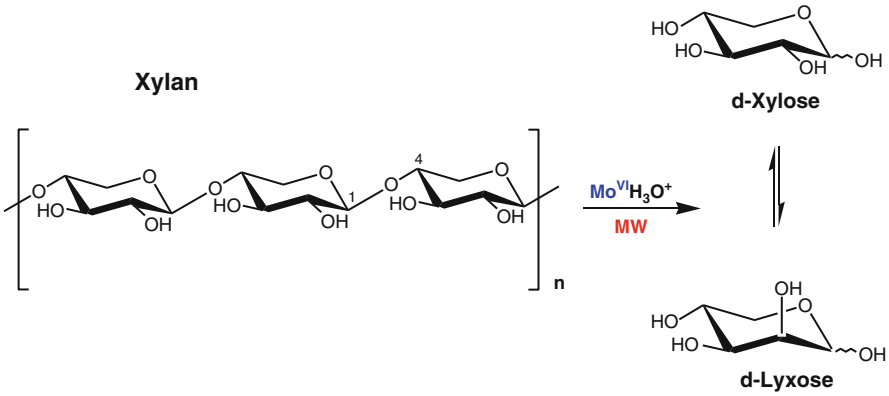
Many research groups are focusing their efforts on finding more economical ways of producing xylan-related chemical intermediates for different applications. The production of chemicals based on xylans is still a challenging task and requires extensive research depending on the source and the desired final products.

Application of new methodologies, careful modification of the reaction conditions, and the accurate and reliable analyses of polysaccharide resources could significantly improve the utilization of hemicellulose biomass.

5.5 Mo(VI)-Catalyzed Transformation of Xylan: Preparation of Xylose, Lyxose, Xylitol, and Furfural

A number of chemical technologies are known and several studies have appeared that describe the transformation of hemicellulose in a MW field. Some polysaccharides require harsh conditions to degrade. While cellulose is crystalline and strongly resistant to hydrolysis, hemicellulose containing predominantly D-xylose units has an amorphous structure with little strength (Binder and Raines 2009). MW irradiation is able to enhance the hydrolytic cleavage of its macromolecular chains. It was shown that the application of microwaves in combination with hexavalent molybdenum catalyst is the efficient method for the production of commercially interesting chemicals from starch. Several experiments were designed for exploitation of this catalytic system to improve xylan hydrolysis with subsequent epimerization of D-xylose monomer. Beechwood xylan was selected as the model compound for determination of the influence of MW-induced Mo(VI)-catalyzed conversion of hemicelluloses to epimeric pentoses. Appropriate reaction conditions led to complete depolymerization of xylan and high conversion to D-xylose and D-lyxose. The analysis of ^{1}H NMR spectra confirmed that xylan was completely hydrolyzed and converted to the equilibrium mixture of D-xylose and D-lyxose (1.6:1) in several minutes. The hydrolysis of xylan and simultaneous epimerization of obtained D-xylose to D-lyxose is illustrated in Scheme 12.

The yields of D-xylose/D-lyxose were compared using three different xylan substrates (beechwood, birch wood xylan, and 4-*O*-methyl glucuronoxylan).



Scheme 12 Reaction scheme of xylan hydrolysis and simultaneous epimerization of obtained D-xylose to D-lyxose

Table 5 Comparison of MW-assisted and conduction-heated xylan samples during combined hydrolysis and simultaneous epimerization reaction of obtained D-xylose to D-lyxose. Vast differences are seen in xylan/xylose/lyxose conversions and reaction kinetic of two heating techniques

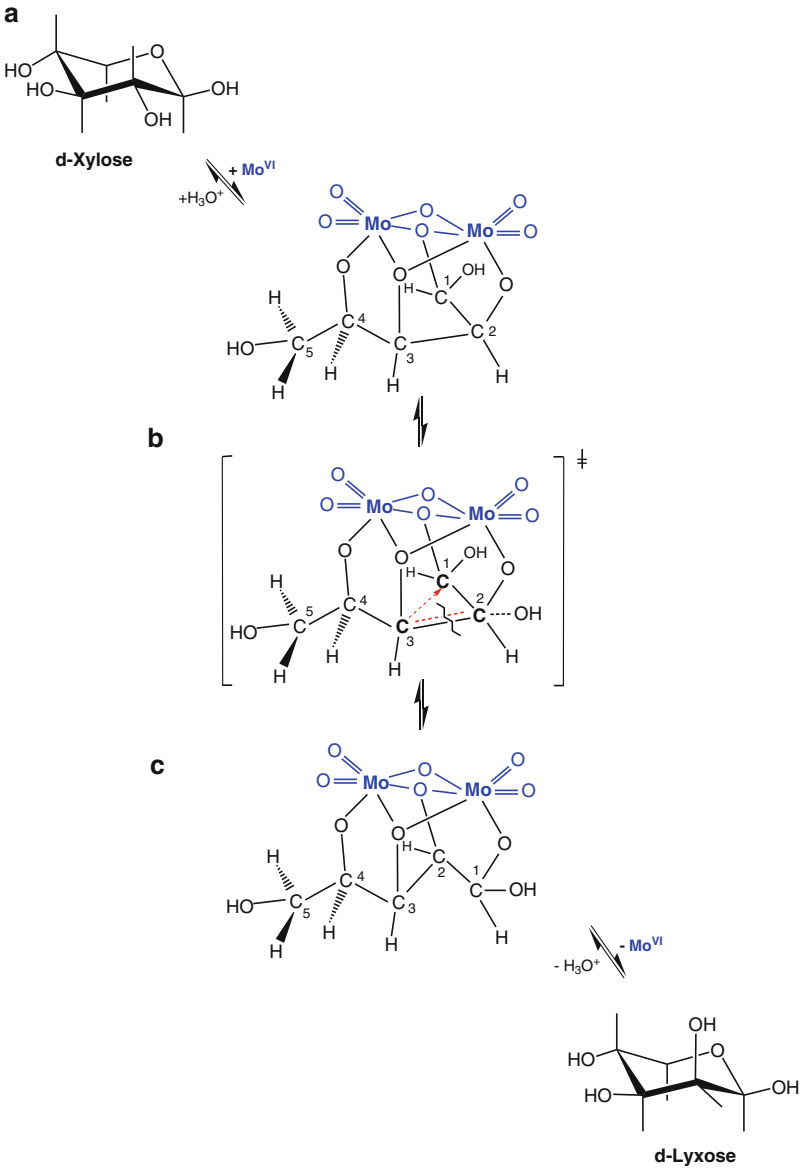
	MW field		Conventional		Heating	
Xylan source	Time (min)	Xylan/Xyl/Lyx (%)	Time (h)	Xylan/Xyl/Lyx (%)	Time (h)	Xylan/Xyl/Lyx (%)
Beechwood	3	0/62/38	10	6/68/25	20	0/70/30
Birch wood	3	0/63/37	10	7/68/24	20	0/69/31
4-*O*-Me-gluX	3	0/61/39	10	7/67/25	20	0/68/32

The ratio of sugar components present in the equilibrium reaction mixture was determined by ^{1}H NMR spectroscopy. The transformation occurs in 3 min affording pure epimers of D-xylose and D-lyxose in good yields. Table 5 summarizes the data obtained for various xylan samples heated in MW field and by conventional heating. It should also be noted that the increasing amount of catalyst did not influence the product composition.

The mechanism of this stereospecific transformation, as in the case of starch, is based on the formation of catalytically active Mo(VI) complexes of D-xylose monomer and through rearrangement of the carbohydrate carbon skeleton which led to the formation of equilibrium reaction mixture of D-xylose and D-lyxose. The accepted mechanism is depicted in Scheme 13. The first step is formation of the binuclear molybdate complex with the acyclic hydrated form of D-xylose (Scheme 13a). This rigid framework holds the acyclic carbohydrate skeleton in required conformation for stereospecific carbon backbone rearrangement. The rearrangement occurs through a transition state (Scheme 13b). Bond formation between C-2 and C-3 regenerates the starting D-xylose, while bond formation between C-1 and C-3 produces the 2-epimer, D-lyxose (Scheme 13c).

The kinetics and composition of the reaction mixture under microwave and conventional conditions are depicted in Figs. 6 and 7. As shown in Fig. 6, more than 80 % of xylan is hydrolyzed to D-xylose monomers in MW field after 25 s. Epimerization of xylose to lyxose starts in 30 s, simultaneously with the hydrolysis of xylan. Results indicate that 3 min is sufficient reaction time for the epimerization of D-xylose to D-lyxose, whereas prolonged duration might lead to the occurrence of side reactions. The traces of furfural were also observed after 3 min. Under conventional conditions about 45 % of xylan is hydrolyzed to D-xylose monomers after 2 h. As seen from Fig. 7, formation of D-lyxose started after 2 h. The ratio of xylose/lyxose was 2.7:1 after 10 h of heating, and the equilibrium mixture of xylose/lyxose 2.2:1 was reached after 20–25 h of heating.

The results obtained by application of two heating techniques show that MW irradiation caused the differences in the equilibration of the reaction mixtures. The different ratios of stereoisomers as a function of time were observed owing to differences in the mode of energy transfer. The reaction equilibrium was shifted in both cases to the aldose with the lower value of conformational instability, thus a larger amount of D-xylose was present in reaction mixture. MW approach allows



Scheme 13 Reaction mechanism of the Mo(VI)-catalyzed epimerization of D-xylose to D-lyxose

faster product formation (min) compared to conventional conditions (20–25 h) (Hricovíniová 2013).

Xylose and lyxose were obtained from various xylan samples in a one-pot transformation. Lyxose occurs rarely in Nature, and its higher amounts can be obtained only by chemical synthesis (Bílik and Caplovic 1973; Giudici and Griffin

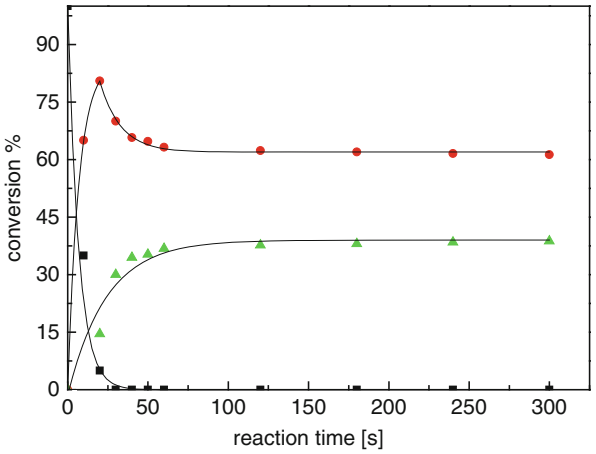


Fig. 6 Conversion of beechwood xylan (■) to D-xylose (●) and D-lyxose (▲) as a function of time in microwave field

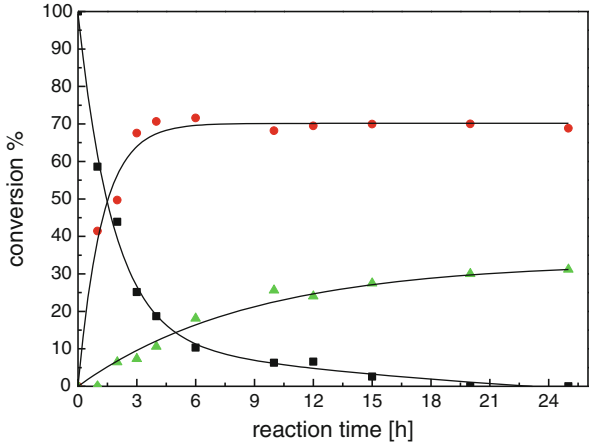

Fig. 7 Conversion of beechwood xylan (■) to D-xylose (●) and D-lyxose (▲) as a function of time under conventional conditions

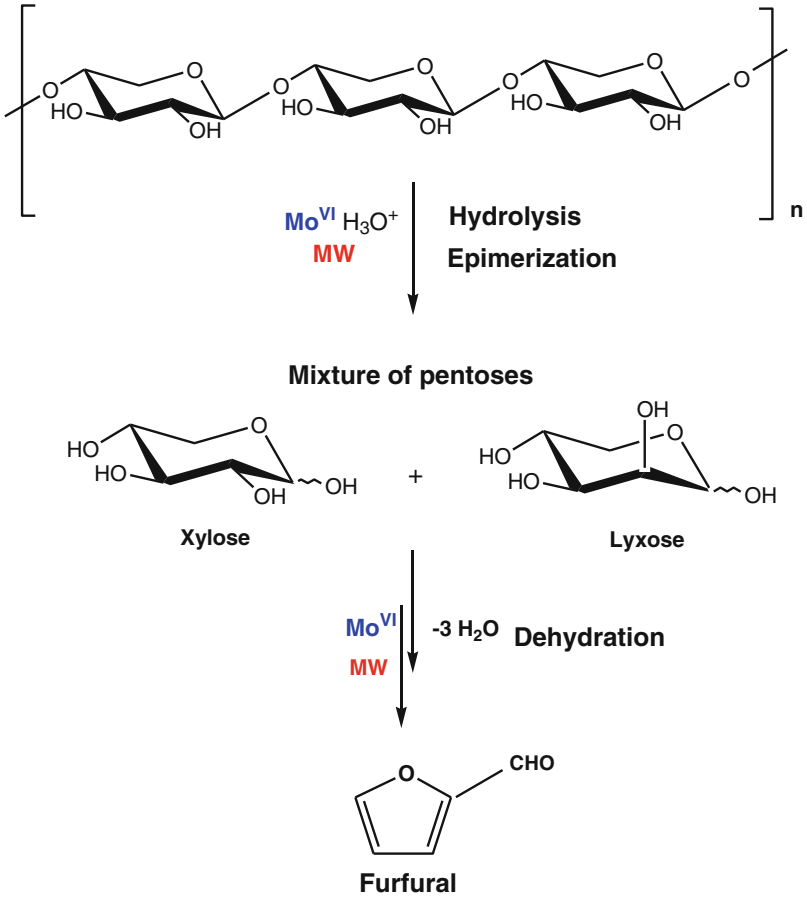
1974). Xylose is an important compound mainly for its conversion to xylitol with its wide variety of applications. It metabolizes easily in the human body and produces the same amount of energy. Xylitol, with its high sweetening power (matching that of saccharose), is applicable as a sugar substitute in the food processing industry. It can be used as in diabetic foods, beverages, and pharmaceuticals (Kontiokari et al. 1995; 1998; Granström et al. 2007). Industrially, it is produced by catalytic hydrogenation or by enzymatic reduction of xylose. However, industrial bioconversion of detoxified hemicellulosic hydrolysate by yeast strains to xylitol is complicated by inhibitory effects of the often detected phenolic by-products

(Wisniak et al. 1974; Zhang et al. 2012). Compared to enzymatic production Mo (VI)-catalysis could offer attractive alternative. Utilizing an efficient catalytic system and water as the solvent has many advantages. Xylitol and lyxitol can be prepared by the simple reduction of corresponding aldoses.

The direct conversion of xylan to furfural in the presence of molybdate ions has also been studied. The hydrolysis of xylan proceeds much faster than the dehydration reaction, but the use of microwaves in the dehydration of pentoses revealed notable effect on the reaction rate. The combined xylan hydrolysis, epimerization reaction, and dehydration of obtained mixture of pentoses to furfural are illustrated in Scheme 14.

The analysis of furfural formation in the molybdate-catalyzed transformation of xylan in MW field has shown that the single-step process provided higher amounts of furfural (53 %) compared to reaction without Mo(VI) catalyst (42 %).



Scheme 14 Mo(VI)-catalyzed one-step transformation of xylan to furfural in MW field

The interaction of molybdate ions with monomeric D-xylose promotes the stabilization of its acyclic form that is quickly equilibrated with its furanose and pyranose forms. The less stable pyranose ring leads via 2,5-anhydride in dehydration pathway to furfural (Antal et al. 1991). The preparation of furfural from xylan was compared with conventional oil-bath heating, but maximum yield of furfural was only 28 %. Longer reaction times and nonselective heat transfer at the surface of reaction vessels resulted in the loss of furfural due to secondary reactions and undesired by-products that decreased its final yield.

The molybdate salts thus play an important role in the presented reaction. Mo(VI) acts as special catalyst for stereospecific conversion of xylose to lyxose. Moreover, Mo(VI) catalyst is also efficient in the transformation of mixed source of pentoses to furfural, where three simultaneous steps (hydrolysis, epimerization, and dehydration reaction) are combined in the one-pot reaction. Mo(VI)-catalyzed isomerization reactions thus provide an interesting alternative toward preparing platform chemicals from renewable natural lignocellulosic polymers.

6 Methods of Analysis

The structure of synthesized saccharides is analyzed by various methods. Nowadays, fast and nondestructive methods, such as NMR, are essential for the compositional analysis of reaction mixtures. They provide information that is necessary for possible optimization or changes of reaction conditions. Depending on the nature of the sample, the analysis may need several steps of pretreatment.

Mixtures of mono-, oligo-, and polysaccharides are separated by several chromatographic methods and analyzed by various analytical techniques. Monosaccharides and their derivatives can be separated by ligand-exchange liquid chromatography. The formation of a donor–acceptor complex between the cations immobilized on the ion-exchange resins and the carbohydrate hydroxyl groups makes this separation method very effective (Caruel et al. 1991). High-performance liquid chromatography (HPLC) equipped with a refractive index detector and utilizing aqueous mobile phase is widely used in the analysis of mono- and oligosaccharides. Different types of columns may require also other solvents. When mono- and oligosaccharides are present together in one sample, solvent mixtures in gradient mode are usually used. Beside HPLC several other methods for sample analysis are used. The oldest one is a colorimetric method for the determination of total carbohydrate content with phenol-sulfuric acid reagent in combination with paper chromatography (Dubois et al. 1956). The other one is based on the gas chromatography–mass spectrometry (GC-MS) analysis of derivatized monosaccharides. Each sugar constituent of polysaccharide is derivatized to alditol acetate or per-*O*-trimethylsilyl derivative (Sawardeker et al. 1965; Ciucanu and Kerek 1984; Merkle and Poppe 1994). Both methods have several disadvantages (in terms of long-time analysis or time-consuming derivatization steps) compared to HPLC method. In carbohydrate analysis simpler spectroscopic methods might be used. Colored products obtained after

acid-catalyzed degradation of pentoses (e.g., furfural) have characteristic absorption in UV spectroscopic region (Douglas 1981; Martinez et al. 2000). Infrared spectroscopy (IR) could be useful to assess chemical composition of polysaccharides (Kelley et al. 2004).

High-resolution nuclear magnetic spectroscopy (NMR) is the most powerful analytical method used for determination of the structure of monosaccharides and polysaccharides. NMR allows primary and secondary structural analysis of pure saccharides in solution from determination of chemical shifts and coupling constants (Bock and Pedersen 1983; Angyal 1984; 1994; Shin and Cho 2008; Mittal et al. 2009). Conformation and dynamics of saccharides can be studied by relaxation measurements and measuring dipolar interactions (employing NOESY or ROESY experiments). Analysis of mixtures of products obtained by synthesis or by degradation of polysaccharides is provided by diffusion-ordered spectroscopy. NMR techniques thus enable detailed analysis of composition (determination of individual monosaccharide units and the type of linkages) of branched polysaccharides without necessity of their degradation. Furthermore, the anomeric ratio or composition of polysaccharides can be quantitatively determined by integration of proton and carbon resonances in ^{1}H or ^{13}C NMR spectra. Both one-dimensional (1D) and two-dimensional (2D) NMR spectroscopy experiments are mostly used for carbohydrate structural analysis. The proton and carbon chemical shifts in aqueous solutions are usually referenced to internal TSP (trimethylsilyl propionate) or DSS (4,4-dimethyl-4-silapentane-1-sulfonic acid) calibration standards. The combination of 2D COSY, HSQC, and HMBC is routinely used for the determination of ^{1}H and ^{13}C chemical shifts. These three experiments are mostly sufficient to determine chemical shifts. In more complex molecules, however, other experiments can also be performed, such as 1D or 2D TOCSY, 2D NOESY, HSQC-TOCSY, etc. Nonuniform sampling type of experiments can also be useful for structural analysis of polysaccharides. Proton–proton coupling constants are usually determined directly from proton spectra; in some cases 1D TOCSY or COSY spectra can also be used. One-bond proton–carbon coupling constants can be retrieved from 2D HSQC-coupled spectra.

Further details on carbohydrate molecular structures can be obtained from molecular modeling (MM). MM is necessary for interpretation of solution NMR spectra when analyzing 3D molecular structures. Molecular mechanics methods are simple methods that can give data for large molecular structures (large oligosaccharides) without demands on computer time and memory. However, this approach may not always give reliable data due to application of force fields that are not optimized for given carbohydrate structures. More general are quantum chemical methods. Density functional theory (DFT) approach is frequently used at present as it represents a good compromise between demands on computer hardware and accuracy of structures and computed energies. Solvent effect can also be modeled by various methods; the most usual is a continuum model. More rigorous is explicit solvent model which is also more time-consuming especially when computing large saccharide molecules.

7 Conclusion and Future Perspectives

An increasing interest of chemists in carbohydrates originates from the fact that these molecules are not only the most abundant biomolecules in Nature, but, perhaps even more importantly, carbohydrates belong to very few renewable energy and material sources. Carbohydrates can be obtained from various natural sources but also from agricultural waste, thus through the recycling processes. In the present, there are strong incentives to convert such carbohydrate resources into valuable products via environmentally friendly and effective processes, ideally by one-pot transformations. Many research groups try to find simple and economical ways to chemically modified saccharides with special properties for the requirements of various areas of life.

Numerous technologically important compounds can be prepared from renewable polysaccharides through the catalytic transformations. Acid-catalyzed hydrolysis of polysaccharides coupled with dehydration reaction afforded important platform chemicals in good yields. Solid catalysts, bearing both Brønsted and Lewis acid sites, have great potential for efficient transformation and can replace many conventional liquid acids. They can be reused several times and operate at low temperatures. Ionic liquids applied as reaction solvents and as catalytic reagents gave also promising results. Dissolution of hardly soluble compounds in highly ionic solvents at lower temperatures improves the selectivity, but the use of ionic liquids for the industrial processing, especially for cellulose, is not optimal solution. On the other hand, water as cheap and environmentally friendly reaction medium is useful only in high-temperature processes to achieve good conversions. In this respect, one-pot transformations of polysaccharides using direct extraction into biphasic system are inspiring examples. Application of biphasic systems can significantly improve the production of furans and avoid their destruction.

Significant interest has been directed toward the use of solid heterogeneous catalysts in combination with transition metals. They have several advantages over other catalytic systems, because they can work at high temperatures, facilitate the separation of product, and can be recycled several times. Combination of metal salts and ionic liquids lead to improved depolymerization of polysaccharides and transformation of obtained monomers to attractive chiral raw materials and fine chemicals. Introduction of MW irradiation to carbohydrate chemistry provides an interesting alternative. It is possible to alter the selectivity in many reactions under controlled MW heating. The effect of MW irradiation on transformation of polysaccharides, using various catalytic systems, leads to improved yields and cleaner reaction profiles in reduced timescale.

Application of transition-metal catalytic systems in combination with microwaves offers interesting improvements in yields and selectivity. Among them, microwave-assisted Mo(VI)-catalyzed isomerization of sugars in water represents a useful synthetic method in synthetic carbohydrate chemistry. The application of Mo (VI) catalyst in MW field offers a remarkable synergic effect with the great potential. The employment of this catalytic system represents the innovative approach with

processing advantages, especially where the extended conventional heating can cause degradation reactions. Numerous carefully controlled experiments were performed to evaluate the scope and limitations of this approach. The usefulness of this method was demonstrated in highly stereospecific, rapid, and efficient transformation of various reducing monosaccharides, oligosaccharides, and polysaccharides.

Each of the mentioned methods has important advantages and disadvantages. Considerable efforts are now directed toward the improvement of methods of selective transformation of saccharides by deeper understanding of their structural properties. In addition, modification of the reaction conditions and introduction of more efficient chemo- and stereoselective routes will allow several reaction steps to be finished in one reactor and thus allow easier access to various valuable compounds. Further progress in synthetic carbohydrate chemistry will be greatly supported by introduction of new methods and techniques. Developing of efficient synthetic methodologies will have in longer term significant impact in diverse areas of natural sciences, medicine, and industry.

Surface Properties of Polysaccharides

46

Yi Wang and Gary A. Dykes

Contents

Abstract

Polysaccharides are used in a wide range of applications across the medical, food, and material science spheres. Their applicability is in part a consequence of their specific surface properties and the nature of their interactions at interfaces. Intensive research into polysaccharide surface properties and methods to investigate these has been undertaken for decades. Due to the complicated structural, chemical, and physical features of polysaccharides, however, fully understanding their surface properties and developing effective methods for studying these properties are still challenging tasks. In this chapter methods frequently used for polysaccharide surface characterization, including sample preparation and surface analysis, are described and critically discussed. In addition to the traditionally used methods, several novel techniques of preparing polysaccharide model surfaces and description of advanced

1 Introduction

Polysaccharides are critical components of a great diversity of fundamental processes and structures in all forms of life including plants, animals, and microorganisms. Cellulose, for example, the most abundant of all polysaccharides, occurs as a structural component of plant cell walls in combination with other biopolymers. It is, however, also produced by some bacteria as an extracellular mat which is thought to act as a floatation platform to increase bacterial access to oxygen. The surface properties of polysaccharides and their mechanism of interactions with water and other macromolecules need to be thoroughly studied in order to understand their roles in food and biological systems and consequently to use them for industrial applications.

Investigations into the structural, morphological, physical, and chemical properties of polysaccharides have been undertaken for many years. Despite the

development of new methods and techniques over the years, the characterization of polysaccharide surfaces is still challenging and time consuming. Difficulties associated with this analysis are often related to sample preparation and the selection of appropriate methods. For example, common methods for obtaining polysaccharides from their original sources such as enzymatic, chemical, and physical extractions (Ahola et al. 2008a; Lu and Hsieh 2010; Man et al. 2011) are often unable to preserve their inherent properties or structure intact. The selection of methods for surface analysis is based on the state and structural features of the sample (e.g., crystalline or amorphous, dry or swollen) which affect the levels of accessibility of solvents and the functionalities of the hydroxyl groups on the polysaccharide chains (Lin et al. 2012). Using only one method to investigate a particular polysaccharide is therefore often not sufficient, and employing a combination of different methods is sometimes necessary to thoroughly describe a surface property. For these reasons, polysaccharide model surfaces with well-defined structural and physicochemical features are often prepared for research purposes. In fact, some frequently used methods for surface characterization can only be applied to model surfaces as opposed to real systems because of the restrictions of the methods (Stana-Kleinschek et al. 2012).

The specific surface properties of polysaccharides which impact on features such as mechanical strength, environmental friendliness, electrostatic properties, and structural features have led to them finding a wide range of applications in the fields of medical, food, and material sciences. The application of polysaccharides is, however, limited by a variety of factors such as their adaptability to different systems (e.g., solubility, compatibility) and sensitivity to environmental factors (e.g., pH, temperature). Research has therefore focused on using their surface properties, with potential physical and chemical modification, to improve their mechanical, interfacial, chemical, and biological performance.

This chapter describes the methods used for surface characterization of polysaccharides in modern research. Specifically, methods often used for sample preparation including preparation methods for polysaccharide model surfaces are presented. In addition, different methods for analysis of surface properties are discussed and compared. Finally, several examples of how surface modification of polysaccharides measured using these methods may be practically applied are also discussed.

2 Methods of Sample Preparation

Over the past 20 years, substantial work has been conducted on the purification and characterization of polysaccharides, and especially cellulose, for studies of surface interactions and properties. A major challenge of this work is the difficulty in the preparation of samples directly from plant/animal sources for these studies. For example, it is very difficult to measure surface properties of cellulose in plant cell walls or to quantify specific interactions between cellulose and other molecules using plant cell wall as the sample. Consequently, model polysaccharide systems

have been used to study these properties and provide knowledge that cannot be obtained directly from plant cell walls. Additionally, model systems provide an excellent way to study the chemical, physicochemical, and morphological changes during various processes, such as interactions with water (swelling) and surface chemical modification, involving polysaccharides. Here several commonly used methods for polysaccharide extraction as well as preparation of model surfaces are described.

2.1 Extraction of Native Polysaccharides

2.1.1 Acid Extraction

Acid is often used to extract cellulose from native samples and produce cellulose nanocrystals. Nanocellulose is important for surface property studies due to its nanoscale dimensions, high surface-to-volume ratio, low density, unique morphology, unique optical and chiral properties, and high mechanical strength.

Nanocellulose is prepared by acid hydrolysis of cellulose fibers such as cotton, algae, and wood. A fiber suspension is treated with a strong acid, followed by a series of cleaning and purification procedures before solvent evaporation to obtain the final product (Lu and Hsieh 2010). During treatment with strong acids, crystalline regions in cellulose structures are hydrolyzed slower than amorphous regions, and the resultant nanoparticles are mainly crystalline. The geometric dimensions and properties of nanocellulose vary depending on the source and hydrolysis conditions (e.g., the type of acid used, the time and temperature of treatment). Commonly used acids are sulfuric acid, hydrochloric acid, and hydrobromic acid. If sulfuric acid is used, the hydroxyl groups on the particle surfaces are esterified with sulfate groups, and consequently the nanoparticles are electrostatically stabilized. If on the other hand hydrochloric acid is used as the hydrolyzing agent, the ability to disperse the resulted nanocellulose is limited (Araki et al. 1998). The shapes of the final particles can be identified by scanning electron microscopy (SEM) and atomic force microscopy (AFM) to be rod-, sphere-, or network-shaped, but they cannot be easily separated from each other (Lu and Hsieh 2010).

Due to the high surface-to-volume ratio of nanocellulose, its functionality as compared to that of other forms of cellulose is greatly enhanced as more hydroxyl groups are accessible for further modification including esterification, etherification, silylation, and polymer grafting. These functions and advantages enhance its potential application in the food and medical industries for use as nanocomposite films and in drug delivery, protein immobilization, and metallic reaction templates (Peng et al. 2011).

A significant challenge of developing cellulose nanocrystals and for further applications is their tendency to form large aggregates during solvent evaporation, which greatly limits their advantage and functionality. During drying a high number of hydrogen bonds form and cause aggregation which poses significant problems in the distribution and re-dispersion of the particles in solvents. To solve this problem, different methods to isolate the nanoparticles need to be developed. One potential

way to overcome this problem is to employ freeze drying (Lu and Hsieh 2010). The hydrolyzed product is quickly frozen with liquid nitrogen to keep the particles separated and fixed in the solidified ice, followed by freeze drying under strong vacuum to dry the sample without formation of hydrogen bonds. Another problem that limits the applicability of acid-extracted cellulose is the toxicity of the concentrated acids, which restricts its use in food industries.

2.1.2 Enzymatic Extraction

Enzymatic treatment of polysaccharides, such as cellulose, is generally designed to degrade them into fermentable sugars. The conversion of lignocellulosic material to monomeric sugars is a more complex process, however, and is difficult to achieve. The process is influenced by the chemistry, heterogeneity, crystallinity, and surface area of the substrate, all of which can strongly affect the kinetics of enzymatic conversion (Ahola et al. 2008a). For this reason these incomplete enzymatic degradations of lignocellulose are often used to extract cellulose from its natural sources.

Commonly used enzymes are endoglucanases, which randomly attack and hydrolyze the amorphous region of polymers; exoglucanases, which attack cellulose polymer chains from either the reducing or nonreducing ends; and cellobiohydrolases, which attack cellulose at the C-1 or C-4 positions (Filson et al. 2009). The enzymatic reactions are accelerated by microwave heating, and the degraded cellulose particles are purified by filtration, solvent evaporation, and freeze drying. This method has been used to collect cellulose from pulp samples (Ahola et al. 2008a; Filson et al. 2009). A problem with this method is the difficulty in controlling the sizes of the cellulose products.

2.1.3 Ionic Liquid Extraction

Ionic liquids, which are organic salts with low melting points that form liquids at temperatures below 100 °C, are good solvents for polysaccharides. For example, 1-butyl-3-methylimidazolium chloride and 1-butyl-3-methylimidazolium hydrogen sulfate dissolve cellulose (Swatloski et al. 2002; Man et al. 2011), while 1-allyl-3-methylimidazolium bromide at a high concentrations dissolves chitin (Kadokawa et al. 2011). The polysaccharide content in a natural sample is dissolved in the ionic liquid, while the impurities are filtered away. The dissolved polysaccharide is sedimented and dispersed by a series of heat and solvent treatments. It is then purified by vacuum evaporation and freeze drying (Kadokawa et al. 2011; Man et al. 2011). The products are usually in the form of a film of nanowhiskers.

The advantages of using ionic liquids as solvents to extract polysaccharides are based on their properties, including their chemical and thermal stability, nonflammability, low vapor pressures, and ability to design their characteristics for specific uses (Earle and Seddon 2000). In addition, ionic liquids are not consumed during the extraction processes and are therefore reusable. A limitation of using ionic liquids is that the thermal stability of the resultant products drops after the extraction as compared to their native forms (Man et al. 2011). Furthermore, small amounts of the ionic liquid may remain in the product and are difficult to removed

due to the formation of hydrogen bonds between the polysaccharide and the solvent (Kadokawa et al. 2011).

2.2 Model Polysaccharide Surface

Model polysaccharide surfaces are often used to study the surface properties of natural polysaccharides. The most common model surface used for surface property studies is cellulose. Compared to natural polymers, model surfaces can be prepared more rapidly and reproducibly and have defined supramolecular structures, defined surface morphologies, and defined thicknesses. In addition, model surfaces allow surface interactions, such as adsorption and desorption, which are difficult to study in natural polymers, to be measured.

2.2.1 Model Cellulose Films

In contrast to natural polysaccharide samples, model cellulose films are ideal for surface interaction studies due to their well-defined surfaces. Adsorption, wettability, electrostatic interactions, surfactant activities, bioactivities, as well as surface characterization are easier to perform on cellulose model films because of their homogeneity.

Cellulose films are usually prepared using the Langmuir–Blodgett (LB) technique by spin coating or dip coating an LB film onto an inert solid substrate (Schaub et al. 1993; Hitrik et al. 2011). Cellulose LB films can be prepared by homogenizing a cellulose ether, such as trimethylsilyl cellulose (TMSC), in an organic solvent (e.g., *n*-hexane or chloroform). After coating the TMSC film on a solid substrate (e.g., gold, silicone, or indium tin oxide), the film is hydrolyzed by HCl vapors to cleave the TMS side groups. The thickness of a film can be controlled by the number of layers that are coated on the substrate (Hitrik et al. 2011). The hydrolysis process can generate free OH groups on the film surface, which decreases the surface hydrophobicity and consequently the surface free energies. Carefully controlling the hydrolysis reaction conditions allows the tailoring of the wettability and thickness of the film (Mohan et al. 2012a, b).

The selection of solvent systems for LB film preparation is crucial because some solvents can react with cellulose to a certain extent. For example, 1-alkyl-3-methylimidazolium can react with cellulose at its reducing end (C-2) and form a carbon–carbon covalent bond (Ebner et al. 2008) which results in a lack of purity of the cellulose phase. In addition, salts (e.g., LiCl) added to the solvent to break up the hydrogen-bonded network may lead to rough model surfaces.

Using model cellulose films for studies of polysaccharide surface properties is, however, not always ideal. For instance, model films consist only of cellulose II (the crystalline state) which do not represent other supramolecular cellulose structures. Conclusions drawn from cellulose films are therefore not generally applicable to other polysaccharide surfaces, although cellulose II is the most common cellulose allotrope present in manufactured products (e.g., regenerated cellulose fibers). For this reason cellulose I (the amorphous state) films have been

synthesized and characterized in some surface property studies (Habibi et al. 2007; Ahola et al. 2008b). It should also be noted that due to the well-defined surface morphology of model cellulose films, results of analysis of surface structure are more meaningful for natural polysaccharide samples than for model films. For this reason the intended application of model cellulose films needs to be defined before choosing them for surface property studies. For example, model films are useful for studies of surface interactions, such as adsorption, wetting, hydrophobicity, and electrostatic interactions, which are strongly dependent on surface morphology and chemical composition (Notley and Wågberg 2005; Eriksson et al. 2007).

2.2.2 Bacterial Cellulose (BC) Films

Cellulose produced by bacteria (e.g., *Gluconacetobacter*) has a specific network structure, high crystallinity, high mechanical strength, and high water retention ability. For these reasons it has been suggested to be a potential model of cellulose in native plant cell walls. Plant cell walls have been extensively studied in terms of their chemical properties, structural properties, surface properties, and interactions with the external and internal plant environment. The part of plant cell walls which contribute most significantly to these properties is the primary cell wall which consists of a polysaccharide matrix. This polysaccharide matrix is in a network structure consisting of approximately 30 % cellulose acting as the backbone of the network, 50 % pectin, and 20 % hemicelluloses (e.g., xyloglucan) filling in the pores of the network (Cybulska et al. 2010). Work has been conducted on isolation and characterization of cell wall materials from natural plant tissues. Current methods for isolation, however, do not allow the acquisition of cell wall fragments of sufficient size to perform many tests (e.g., mechanical tests, bacterial interaction tests). Bacterial cellulose has a similar chemical composition, similar network structure, similar physicochemical properties, and comparable mechanical strength as native cell walls and is therefore an ideal substitute for conducting such studies (Cybulska et al. 2010; Mikkelsen et al. 2011).

BC is produced by growing *Gluconacetobacter xylinus* in Hestrin–Schramm broth containing 2 % glucose (Mikkelsen et al. 2011). The bacteria synthesize uridine diphosphoglucose from glucose and polymerize it into long and unbranched chains of cellulose. The chains then assemble into a network and form a film on the top of the broth. The resultant BC films have been repeatedly shown to have similar structural and mechanical properties as native plant cell wall samples (e.g., apple tissues, wheat) (Quero et al. 2010; Mikkelsen et al. 2011). Images (SEM) of a BC network are shown in Fig. 1a. It is clear that the cellulose chains form a web-like network and cells of *Gluconacetobacter xylinus*, which can be removed by NaOH treatment, are trapped inside. In order to further imitate native plant cell walls, other cell wall polysaccharides, such as pectin and xyloglucan, can be added to the network by mixing them with the broth prior to inoculating the bacteria. The resultant BC composites will have these polysaccharides incorporated into the network (Fig. 1b) and have been shown to have a similar chemical composition as native plant cell walls (Cybulska et al. 2010).

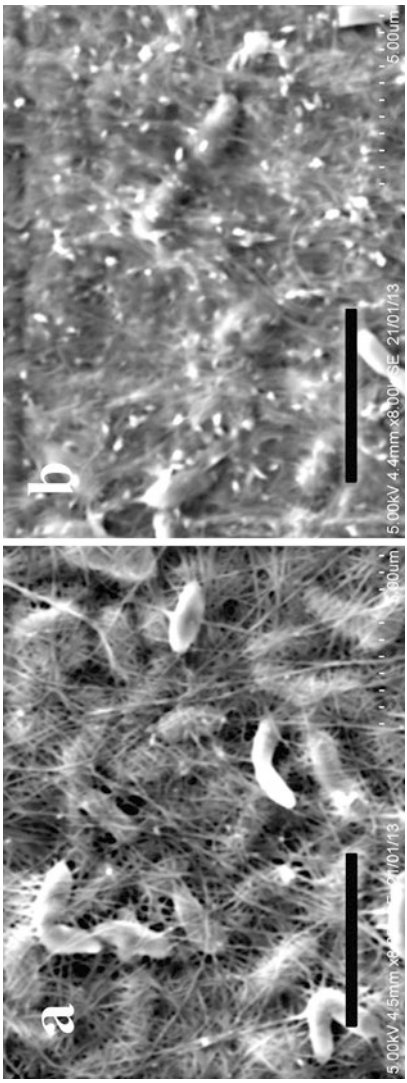

Fig 1 Scanning electron microscopy images of (**a**) bacterial cellulose and (**b**) bacterial cellulose composite with pectin and xyloglucan incorporated into it

Bacterial cellulose has been widely used in research for different purposes. The first attempt to use BC as a model of plant cell walls for studies of surface interactions with bacteria was carried out by Tan et al. (2013). The attachment of *Salmonella* Enteritidis, *Salmonella* Typhimurium, and *Listeria monocytogenes* to BC with pectin and xyloglucan incorporated in them was investigated and was compared to apple tissues in terms of the number of attached bacteria and the rate of attachment. Results analyzed by a multifactor ANOVA model showed that this plant cell wall model can well represent apple tissues with respect to bacterial surface interactions.

2.3 Surfaces of Natural Polysaccharides and Regenerated Fibers

Model surfaces cannot always represent natural polysaccharides and regenerated fibers (e.g., textile fibers, pulp fibers, and foils) since their surface properties are strongly dependent on surface structures such as surface topography, chemical composition, networking, and crystalline/amorphous state. For example, natural cellulose (e.g., cotton, flax, ramie) contains ~10-15 % of non-polysaccharide compounds such as proteins, pigments, and minerals, which gives them different surface morphology, chemical networking, and side groups on the surface and consequently different levels of charge, hydrophobicity, and water-retaining abilities. Differences also exist between different types of cellulose, for instance, foils exhibit extremely hydrophilic characteristics due to their relatively low surface roughness, despite having the same chemical composition as other types of cellulose (Stana-Kleinschek et al. 2012). In addition, the degree of crystallinity and amorphousness of cellulose results in different surface properties. For example, as compared to pulp fibers, modal fibers are more crystalline resulting in different morphologies and higher surface energy (Krässig 1996) and lower zeta potential (which is a result of a relative lower amount of acidic groups on the surface of modal fibers) (Jacobasch et al. 1985). Amorphous fibers also have a higher reactivity and a different adsorption activity. Model polysaccharide surfaces are therefore not always ideal representation of natural polysaccharides due to their homogeneity which does not occur in nature. Careful consideration is therefore required for sample selection and preparation of polysaccharides for analysis of surface properties.

3 Methods of Analysis

In the characterization of polysaccharide surfaces, interfaces, and interactions with compounds in the liquid phase, some surface properties such as morphology, chemical composition, surface tension/hydrophobicity, charge, and adsorption are of particular importance. Methods for studying these properties are briefly described in this section and summarized in Table 1.

Table 1 Frequently used methods for surface characterization of polysaccharides

Surface property	Methods	Notes	References
Surface chemical composition	XPS	Careful sample preparation required	(Johansson et al. 2005)
	MALDI-TOF	Provides 2-D maps, limited by "matrix effect"	(Belu et al. 2003)
Surface morphology	SEM	Specific sample preparation required	(Tan et al. 2013)
	AFM	Expensive and time consuming; no specific sample preparation required	(Katsikogianni and Missirlis 2004)
Surface layer thickness	Sarfus	Real-time visualization, provides 3-D maps	(Ausserre and Valignat 2006)
	Ellipsometry	Allows in situ analysis, allows measurements of multilayers	(Losurdo et al. 2009)
Hydrophobicity and surface energy	Contact angle measurements	Results can be affected by surface morphology and wetness	(Yasuda and Okuno 1994)
	AFM	Expensive and time consuming; results can be affected by surface charge	(Ducker and Senden 1992)
Surface charge	Charge titration	Quantifications of immobile charges	(Fras et al. 2004)
	ZP measurements	Measurements of the electric potential at Debye layer, ZP values are converted from electrokinetic measurements	(Bellona and Drewes 2005)
Surface adsorption	QCM	Real-time measurement; high sensitivity	(Marx 2003)

3.1 Surface Chemical Composition

The presence and number of specific functional groups on the surface of polysaccharides result in particular surface properties. For example, acid groups give the surface negative charges and hydroxyl groups contribute to hydrophilicity. It is therefore of interest to identify and quantify functional groups on the surface of polysaccharides.

3.1.1 X-ray Photoelectron Spectroscopy (XPS)

X-ray photoelectron spectroscopy (XPS) can be used to determine the atomic composition of the outermost few nm of a solid surface (Gray et al. 2010). A surface will emit photoelectrons when exposed to X-ray photons. The binding energies of the emitted photoelectrons are then measured and compared to those of elements, and their oxidation states, with known values. The intensity of the emitted photoelectrons directly correlates to the atomic distribution of elements on a surface. It is a quantitative indicator of the relative atomic composition and

stoichiometric ratio of the elements. The resultant spectrum graph is a plot of intensity against binding energy which provides information on elemental composition on the surface, thickness of the surface layer, electronic state of the elements, and material density. The detectable range of XPS covers most elements except hydrogen. The XPS technique has been applied to a range of cellulose samples, such as pulp and paper, to study their surface chemistry and morphology (Maximova et al. 2001; Gustafsson et al. 2003; Johansson and Campbell 2004; Johansson et al. 2005).

A major challenge of the XPS technique is that the detectable depth is limited to the top few nm on the surface. Samples must be prepared very carefully since minor amounts of contamination can spoil the results.

3.1.2 Matrix-Assisted Laser Desorption/Ionization and Time-of-Flight Mass Spectrometry (MALDI-TOF)

The XPS technique provides proportional measurements of atomic composition but does not allow determination of the spatial distribution of atoms or chemical groups on the surface. The MALDI-TOF technique, which determines the type and quantity of ionizable chemical groups at different tilts on the sample surface, has been used in combination with XPS and/or imaging technology to provide an insight into the gradients and distributions of elements in the surface layer (Belu et al. 2003).

The MALDI technique involves application of a laser beam of primary ions to the sample surface, the energy of which is absorbed by matrix molecules and transferred to the macromolecules on the surface. This causes ionization of the macromolecules which then emit secondary ions. The emitted ions are separated according to their mass-to-charge ratio in a mass spectrometer which then plots a spectrum of signal intensity against mass-to-charge ratio. MALDI-TOF also provides two-dimensional chemical maps to aid imaging and allows depth profiling, which can be used to establish surface homogeneity (Belu et al. 2000; Pan et al. 2007).

A major limitation of the MALDI-TOF technique is the so-called matrix effect where the intensity of a given fragment can, in some cases, be highly dependent on its surrounding environment and therefore not directly related to its concentration on the surface. For example, oxygen and cesium enhance the yields of positive and negative ion, respectively, emitted by other elements by several orders of magnitude (Delcorte 2006). Fortunately for most polymeric biomaterials such as proteins and polysaccharides, the matrix effects are minimal.

3.2 Surface Morphology

3.2.1 Scanning Electron Microscopy (SEM)

The use of SEM allows visualization of the surfaces of biomaterials at submicron scales. An SEM emits a high-energy electron beam which is scanned over the sample surface and receives secondary electrons released from the atoms on the surface. The surface topography of the specimen is imaged from the received

secondary electrons. The sample surface must be electrically conductive or, for most biological samples, be sputtered by powdered conductive materials (e.g., Au, Pd). The SEM technique has been used for surface analysis of many polysaccharides such as pectin, cellulose, and carrageenan (MacArtain et al. 2003; Andrade et al. 2009; Tan et al. 2013).

3.2.2 Atomic Force Microscopy (AFM)

Atomic force microscopy is a method that can be used to profile surfaces and to measure their roughness at a sub-nm scale (Katsikogianni and Missirlis 2004; Warning and Datta 2013). An AFM scans a surface using a sharp tip attached to a cantilever with a curvature of several nm. The deflection of an inclined cantilever tip is measured with a laser beam reflected from the back of the cantilever and is used to construct a topographic image.

For hard surfaces, the cantilever makes direct contact with the sample surface, and the deflection of the tip is measured as a feedback signal. For soft surfaces, the tip gently taps on and scans over the surface. The tapping is gentle enough for soft biomaterials, even in a liquid medium. Using this method, the surface morphology of different samples can be visualized, and the surface roughness can be measured. The AFM technique can also be used to measure surface physicochemical forces (e.g., van der Waals, dipole–dipole, dispersion, electrostatic) using a noncontact mode. When scanning a surface, the tip is oscillating above, but not in direct contact with, the surface. The forces between the tip and the surface change the oscillation which is measured and expressed as a force–distance curve. Using this technique a force map of the surface can be obtained.

Two major advantages of the AFM technique are that it can profile a diverse type of surfaces in three dimensions at high resolutions and that it does not require specific sample pretreatments and can therefore be used to investigate biological samples under in situ conditions.

3.3 Surface Layer Thickness

3.3.1 Sarfus

Sarfus is an optical technique for determining surface layer thickness by measuring the change of the polarization of light reflected from a specific support (surf) caused by the thickness of the sample layer (Ausserre and Valignat 2006). The surfs amplify the contrast of light but do not change the polarization after reflection. The polarization is changed only by the sample surface mounted on the surf and is affected by the sample thickness. This technique has been used for thickness analysis of chitosan and cellulose (Mohan et al. 2011; Spirk et al. 2013).

An advantage of the sarfus technique is that it visualizes thin films directly in real time requiring no vacuum conditions and provides three-dimensional presentations which also allow measurements of surface roughness. The measurable range of thickness is, however, limited to 70 nm.

3.3.2 Ellipsometry

Ellipsometry is an optical technique employed to determine the thickness of thin layers by measuring their dielectric properties (Losurdo et al. 2009). It analyzes the dielectric function tensor by determining the polarization of light reflected from the sample surface. It can be used to measure the thickness of single layers or multilayers ranging from sub-nano to micron scales. Ellipsometry is a nondestructive, nonintrusive, noninvasive, and contactless optical technique used for the characterization of surface structures, interfaces, and composites of bulk materials and thin films.

An advantage of ellipsometry is that specific sample preparation or surface modification is not required which allows real-time in situ analysis of biomaterials. It is, however, limited by the need for establishing reference surfaces for measurement purposes.

3.4 Hydrophobicity and Surface Energies

3.4.1 Contact Angle Measurements

Contact angle measurement is the most commonly used method to determine hydrophobicity, surface tension, and total surface energy of a solid substrate. These properties are, in general, a direct function of the contact angle of a liquid with known surface tension energies and can be calculated from the contact angle data using Young's equation (van Oss et al. 1988). Contact angles cannot, however, be directly correlated to surface tension which is contributed to by both Lifshitz–van der Waals (LW) and Lewis acid-based (AB) interaction energies. The total surface energy, which represents the hydrophobicity of a solid substrate, is obtained by calculating the components of the two interaction energies (1. LW component of surface tension, 2. electron acceptor parameter of the AB component of surface tension, and 3. electron donor parameter of the AB component of surface tension) using contact angle data (Wang et al. 2014). As a consequence of having three unknown factors to determine the total surface energy, contact angles of three liquids with different and known surface tension energies are deposited on a substrate and measured. In addition to the information derived from static contact angle measurements, the determination of contact angle hysteresis, which is the difference between the advancing contact angle and receding contact angle, gives insights into the dynamics of the interactions (Yasuda and Okuno 1994). The contact angle method has been used for characterization of surface tensions of different polysaccharide gels and surface coatings (Yasuda and Okuno 1994; Morra and Cassineli 1999).

Contact angle measurement is an inexpensive, rapid, and simple method which allows the contributions of different surface tension parameters to be distinguished. It is, however, limited by discrepancies in the results caused by surface morphology (e.g., roughness) and the wetness of the sample surface.

3.4.2 Surface Force Measurements Using AFM

As mentioned above in addition to measuring surface roughness, AFM can also be used for measurements of surface forces between the cantilever tip and a surface, which represent hydrophobicity, at a nanoscopic scale. It can be applied to different polysaccharide films to measure and compare the surface forces. Alternatively, the forces between a polysaccharide sphere fixed to the cantilever tip and standard surfaces (e.g., silica, metal) can also be measured using this technique (Ducker and Senden 1992). The surface forces are determined as a function of the displacement of the cantilever. This method is, however, expensive and time consuming, and the results can be greatly affected by the surface charge of the material.

3.5 Surface Charge

3.5.1 Charge Titration

It is of interest to quantify the immobile charges, contributed by weak acid groups, located on the surfaces of polysaccharides. High-precision titration techniques designed to determine complex equilibriums in solutions are often used for quantification of surface charge of dispersed polysaccharides (Fras et al. 2004). Titration methods are diverse and various indicators can be used (e.g., pH, conductivity, streaming potential).

For example, the potentiometric titration method determines the concentration of hydrogen ions dissociated from weak acid groups on the sample surface after the stepwise addition of NaOH. The concentration of hydrogen ions represents the electrical potential of the sample surface. The titration process is performed in an electrochemical cell, the potential of which is premeasured in order to determine the proton concentration. This method has been used to measure the charge of different fibers and pulp products (Laine et al. 1996; Lindgren and Öhman 2000; Räsänen et al. 2001).

Instead of the concentration of hydrogen ions, conductometric titration measures the conductance which is an additive function of the concentration and equivalent conductance of each type of ion present in the solution. The conductance of a solution is dominated by the two most conducting ions, namely, hydrogen and hydroxyl ions. This method has also been widely used for polysaccharides (Fras et al. 2004).

Another titration method for charge quantification is polyelectrolyte titration. This technique uses charged polyelectrolytes as the titrant and streaming potential as the indicator. A counter-charged substance is added to the sample solution and is absorbed on the sample molecules. The unadsorbed part is titrated by a polyelectrolyte until charge neutralization is achieved and the charge of the sample can be determined. For surface charge measurements, high molecular weight polyelectrolytes which neutralize the surface charges only are used. For total accessible charge measurements, low molecular weight polyelectrolytes that can neutralize both surface and interior charges are used. This method has been used for a range of polysaccharides (Wågberg et al. 1989; Zhang et al. 1994).

3.5.2 Zeta Potential (ZP) Measurement

The electrostatic charge density on a surface is usually expressed ZP. The ZP is defined as the difference in the electric potential between the surface double layer and the mobile liquid phase. This is the primary interaction area for substances diffusing from the liquid bulk phase toward the solid surface. The level of ZP depends on the chemical and physical properties of the surface as well as the liquid medium and is therefore a parameter describing the interaction properties of a solid surface in contact with a liquid. The ZP is often used to estimate the effect of surface charge on different physicochemical processes such as aggregation, adsorption, and dispersion.

Direct measurements of ZP are not experimentally feasible, and it is therefore necessary to employ indirect means such as electrokinetic methods (e.g., electrophoresis). For example, the electrophoretic mobility method determines the mobility of reference colloid particles in an electric field generated by the surface charges of the solid sample (Bellona and Drewes 2005). The result (mobility) can be converted into ZP.

Streaming potential measurement is also widely used for determinations of surface charge. It measures the potential induced when an electrolyte solution flows across a stationary and charged surface (Childress and Elimelech 1996). A limitation of these methods is that results can be greatly affected by surface morphology (roughness and topography). Similar methods for charge measurements, such as sedimentation potential and electroosmosis assays, are also used.

3.6 Surface Absorption: Quartz Crystal Microbalance (QCM)

Adsorption of polysaccharides at solid–liquid interfaces is of interest with respect to technological and biomedical applications. Use of the QCM is a promising technique that provides direct information on solid–liquid interactions. It gives information about adsorption/desorption processes at the solid–liquid interfaces. The QCM detects a sub-monolayer of adsorbate on the surface by measuring the change of the oscillating frequency of a piezoelectric quartz crystal device upon mass loading (Marx 2003). Real-time measurements of the frequency change and energy dissipation caused by mass changes and viscoelastic properties give information about the absorbed layer. This technique has been used for adsorption studies of different polysaccharides such as cellulose and chitosan (Indest et al. 2008; Lee et al. 2014).

An advantage of this method is its sensitivity that allows the detection of small amounts of adsorbate (at the ng level) in situ. A disadvantage is that it does not measure the adsorbed mass directly. The results need to be approximated using Sauerbrey equation (Marx 2003) to calculate the adsorbed mass.

4 Potential Applications: Surface Engineering

While they are widely used across a range of industries, the applicability of polysaccharides is, in some cases, limited by their surface properties. For example, chitosan is a good candidate for food packaging materials due to its nontoxicity,

biodegradability, and antimicrobial activity. Its applicability is, however, limited by its low mechanical strength. In order to overcome these limitations, characterization and measurement of polysaccharides by the above techniques, and subsequent directed surface chemical and physical modification techniques to improve their features for specific applications, can be used.

4.1 Charge Modification

The strength of the surface charge on polysaccharides is dependent on the surface chemical composition and affects surface chemical and physical interactions. Modification of surface charges of polysaccharides can greatly alter their surface properties and interactions and consequently change or enhance their research and industrial applicability. Both cations and anions can be induced on polysaccharide surfaces.

A common method for charge modification is surface ionization via induction of chemical groups. Anions on polysaccharide surfaces are contributed by acid groups which can ionize the surface without changing the pH to extreme values. Methods for inducing acid groups are diverse and include but are not limited to: oxidation which uses hydrogen peroxide, nitrogen dioxide, or ozone to oxidize hydroxyl groups on polysaccharide chains to charged carboxyl groups (Zeronian and Inglesby 1995); addition of sulfonic acid groups to fibers to produce sulfoxine cellulose (Zih-Perényi et al. 1998); and carboxymethylation, which replaces the proton on a hydroxyl group with a carboxymethyl group (Song et al. 2012). The increases in charge and acid groups on polysaccharide surfaces are usually determined by charge titration methods in combination with XPS. These chemical processes not only modify polysaccharides with respect to surface charges but also their structural, mechanical, and biofunctional properties. A good example of such a product is carboxymethyl cellulose (CMC) which is often used as an adsorbent for cotton to improve its functionality. After being adsorbed by cotton, CMC facilitates higher water adsorption of the cotton and improves its ability to adhere to moist surfaces, its biodegradability and biocompatibility, and its antimicrobial activity.

The cationic functionalization of polysaccharides is also of great importance in industry. The most common cationized polysaccharide is nitrogen-coated cellulose. Water-soluble cellulose coupled with tertiary amino groups, which is prepared by the interaction of cellulose acetate with *N,N*-diethylepoxypropylamine, has been extensively studied for its application in industry (Liesiene 2010). Due to its increased charge, this cationic cellulose can be used as a flocculant for wastewater treatment, as an additive in paper making, as a thickener for mineral processing and oil recovery, and as a conditioner in personal care formulations (Finch 1996).

While charge modification is widely used to enhance the applicability of polysaccharides, it should be noted that the chemical treatments used to modify charges may also result in undesirable changes in physical and chemical properties such as texture, surface morphology, rigidity, and toxicity. Precautions and a thorough

investigation of the characteristics of charge-modified polysaccharides need to be taken before employing them, especially in food industry.

4.2 Polysaccharide Hybrid Materials

The specific properties of individual polysaccharides are frequently used in industry and research. The application of a single polysaccharide is, in some cases, not sufficient due to the limitations of the nature of the polysaccharide itself. For example, cellulose nanoparticles can be used as a bionano reinforcement for formulating biobased nanocomposites (Samir et al. 2005) because they are a renewable and environmentally friendly material with low density, high mechanical strength, and a nonabrasive nature. This applicability is, however, limited by a low compatibility with other materials that does not allow acceptable dispersion in nanocomposites. Chitosan composites represent an example of this. Chitosan is a very abundant material in nature and is characterized by nontoxicity, biocompatibility, biodegradability, and antimicrobial activities. These features make it suitable for various biomedical applications such as drug delivery, tissue engineering, wound healing, and food packaging (de Mesquita et al. 2010). Its water sensitivity and relatively low mechanical strength limit its use for a wider range of applications, especially in moist environments. To overcome these limitations, hybrid materials of two or more polysaccharides or of a polysaccharide and a non-saccharide material have been developed for industrial and research purposes. A hybrid polysaccharide material of cellulose and chitosan has been intensively studied in recent years. Due to the presence of glucosamine monomer units, chitosan is chemically compatible with a number of polysaccharides and in particular with cellulose. The adsorption of chitosan onto cellulose surfaces involves the protonation of the primary amine groups on the surface of chitosan and is therefore irreversible. The amine groups also increase the charge levels of cellulose by cationizing the surface. Čakara et al. (2009) established a chitosan–cotton model and found a relationship between pH and the increase in charge using potentiometric titration. de Mesquita et al. (2010) developed a new biodegradable nanocomposite using layer-by-layer assembly of nanocellulose and chitosan. Potentiometric titration and ZP measurements were performed to determine the charge of the product, and SEM was used to visualize the surface morphology. The surface was relatively smooth and negatively charged. Nanocellulose was incorporated into chitosan layers in high amounts resulting in a dense and homogeneous distribution. After the incorporation of nanocellulose, chitosan displayed a significantly increased mechanical strength and excellent thermal stability and water resistance.

Development of organic-inorganic hybrid materials provides another approach to improve surface physicochemical properties of polysaccharides. For example, introduction of silica into polysaccharides can affect the oxygen permeability, hydrophobicity, and mechanical and thermal properties (Suzuki and Mizushima 1997; Tian et al. 1997; Liu et al. 2004). Liu et al. (2004) combined chitosan and silica at different ratios using sol–gel chemistry and determined the properties of

the products. It was found that an increase in silica–chitosan ratio resulted in a decrease in water contact angle, an increase in thermal stability, and a decrease in mechanical strength. This shows that the physicochemical properties of hybrid materials can be manipulated by adjusting the ratio of precursors.

Hybrid materials are able to combine the advantages of different polysaccharides and/or non-saccharide materials, which can greatly enhance their applicability in different areas. This approach is limited by the compatibility of the components in terms of solubility and different reaction conditions such as pH and temperature. Careful consideration must be given to material selection based on the conditions of under which the materials will be produced and used.

4.3 Chemically Modified Polysaccharide Surfaces With Bioactivities

Chemical modification of polysaccharides may provide bioactivities that can be used in the industrial and medical spheres. A well-known example is the derivatization of the hydroxyl groups of cellulose that provides specific bioactive properties. A research area of growing interest is the synthesis of sulfated polysaccharides that possess antithrombotic features. Polysaccharides often used for sulfation are cellulose, chitosan, and galactoglucomannans. Negatively charged sulfate groups are introduced to these polysaccharides, usually at the C-6 position, in different solvents based on their solubility. For galactoglucomannans organic solvents are used, whereas chitosan is only soluble under acidic conditions and cellulose requires very specific solvent systems. When sulfating chitosan consideration must be given to the fact that the NH_2 group at C-2 needs to be preserved during the process for further reactions. Important characterization techniques for sulfated polysaccharides include infrared spectroscopy (IR), nuclear magnetic resonance spectroscopy (NMR), and inductively coupled plasma mass spectroscopy (ICP-MS) (Fasl et al. 2010).

The antithrombotic activities of sulfated cellulose, chitosan, and galactoglucomannans were determined and compared to their original forms as well as heparin, a well-known anticoagulant, using activated partial thromboplastin time (APTT), free hemoglobin, and QCM methods (Doliška et al. 2012a, b). Results showed that the sulfated form of the three polysaccharides exhibited high antithrombotic activities. These polysaccharide sulfates can effectively prevent blood from clotting and are therefore excellent examples of how surface engineering can improve the biocompatibility of artificial polymers.

Another example of the chemical modification of polysaccharide surface characteristics is carboxymethylation of lacquer polysaccharide (LP) isolated from the sap of the lac tree, which enhances bioactivity against leukopenia induced by cyclophosphamide (Yang and Du 2003). LP was carboxymethylated using monochloroacetic acid, and the product was characterized using gel permeation chromatography (GPC), Fourier transformation infrared spectroscopy (FT-IR), and NMR. The bioactivity assay was performed in mice, and the results showed that

carboxymethylated LP exhibited a significantly higher activity against leukopenia as compared to its unmodified form.

5 Conclusions and Outlook

This chapter aims to provide an overview on methods and instrumentation used to study surface properties of polysaccharides and to provide examples of surface modification of polysaccharides measurable by these techniques that are applicable in the medical, food, and material science. An overview of this information allows a better understanding of the methods used to investigate interfacial processes in polysaccharides and provides insight into future polysaccharide material development and processing. There are a number of challenges with respect to research into, and future applications of, the methods used to characterize surfaces of polysaccharides. First, development of methods for sample preparation that can effectively extract polysaccharides from the natural source while preserving the chemistry, structural features, and inherent properties is still beyond reach. Second, analytical methods for one property are often unable to eliminate interference from other properties (e.g., results obtained from contact angle measurements are often affected by surface morphology and wetness, hydrophobicity and charge often affect the determination of each other). Third, the surface properties and molecular/supermolecular structure of polysaccharide in the dry state are already well described and understood, while these properties in the wet state, where most technological and natural processes take place, are still barely known. Knowledge of the chemical/physical interactions between polysaccharides and liquid media, such as the swelling processes and the kinetics of penetration, is very limited. Future research on polysaccharide surfaces and the development of methods associated with this are challenging and require effort from multidisciplinary expertise in areas such as surface chemistry, engineering, and instrumentation.

Acknowledgment We would like to acknowledge Michelle Sze-Fan Tan for the preparation of the bacterial cellulose composites for SEM.

Computerized Models of Carbohydrates

47

Alfred D. French

Contents

Abstract

Some history of computerized modeling is furnished to set the stage for modern work, including the development of the justification for using flexible monosaccharide residues. Modeling studies of mono- and disaccharides, primarily by the author and colleagues, have been reviewed and additional analyses were furnished that relate the conformations found in crystal structures to the adiabatic energies through a Boltzmann-like distribution. Those decreases in the numbers of observed crystal structures with increasing energy, discussed earlier by Dunitz and coworkers, suggest that the consequences of crystal packing forces are equivalent to the distribution of structures that would be found at about 500 K for non-crystalline molecules. A closing study of a large oligosaccharide, a cycloamylose with 26 glucose residues (CA26), revealed the extent to which energy minimization studies could retain molecular features found in crystal structures of a large carbohydrate. As also done for the disaccharides, both empirical force fields (molecular mechanics) and density functional theory

(quantum mechanics) were employed. Some intrinsic features of the CA26 were reproduced, but the detailed results from the different modeling methods diverged. Results from the CA26 calculations based on normal termination criteria changed significantly when tighter criteria were employed; it was not practical to tighten the criteria for the quantum calculations.

1 Introduction

Carbohydrates are chiefly composed of carbon, hydrogen, and oxygen, with occasional substitution of the oxygen atoms with nitrogen, sulfur, and other atoms. Included are mono-, di-, oligo-, and polysaccharides. Structural knowledge of a polysaccharide logically includes the knowledge of the smaller units, so it might seem ironic that the earliest computer model of a carbohydrate was of the cellulose polysaccharide. That model was intrinsic to the fiber diffraction study of Jones (1960), who used the Manchester University Mark I and DFUCE electronic computers. His efforts sought a model that would be satisfactory from a stereochemical standpoint and satisfy the X-ray intensities on the fiber diffraction pattern. At that time, there were just a few relevant crystal structures to provide approximate positions of the carbons and all but one of the oxygens of the glucose monomer.

Shortly afterwards, Ramachandran et al. (1963) and his modeling method captured the collective imagination of the biopolymer field because his approach was focused on predicting the most likely shapes of a molecule through conformational analysis. That goal is more widely held than Jones' need to account for a diffraction pattern from a reasonably well defined molecular shape. Conformational analyses are founded on the Boltzmann relationship that states that the most probable shapes will have the lowest energies. Thus, a conformational analysis evaluates the relative energies of the various potential molecular shapes that might occur, with the shapes having the lowest energy being most probable. In early studies (Rees and Skerrett 1968; Goebel et al. 1970; Lemieux et al. 1980), the geometry of individual monomers was assumed and not varied (although different authors assumed slightly different structures); the very first "energies" were based on interatomic contact distances. They were rated as allowed (low enough), partially allowed, or disallowed (too high in energy).

In analogy with Ramachandran's work on peptides and proteins, it was understood that the energy of a disaccharide would depend on the values of the torsion angles describing the amount of rotation about the bonds to the jointly held glycosidic oxygen atom. The conformations of two-bond-linked disaccharides were studied by systematically calculating the energy for all of the combinations of two torsion angles now widely named ϕ and ψ. The standard visualization of the

results is a ϕ-ψ map. If the dipeptide or disaccharide linkage conformation was being studied as a model for the polymer, then all linkages of the polymer were assumed to have the same geometry, resulting in a regular helix. In discussions of the exact shapes, a helical cavity is not required for a helix to exist. The only requirement is for screw-axis symmetry, and the helix can have nonintegral numbers of residues per turn. The relationship between ϕ and ψ values and the helix descriptors of number of residues per turn (**n**) and the advance per monomer along the helix axis (**h**) was worked out by Shimanouchi and Mizushima (1955). Thus, a disaccharide's ϕ-ψ map can also depict the **n** and **h** values for the related polysaccharide with a given monomeric geometry and glycosidic linkage bond angle.

When studying proteins or polysaccharides, it is also necessary to account for the excluded volume principle, namely to avoid conflict with more distant parts of the molecule and also to recognize any attractive interactions. Thus, while useful information is available from the simple allowed, marginally allowed, and disallowed ratings of the earliest computer models (Ramachandran's earliest models were physical!), the many forces in play gave a strong impetus to incorporation of quantitative energy calculations.

During the ensuing decade, it was realized that carbohydrates have special needs that are less important or even inapplicable when modeling proteins or other organic molecules. With the abundance of hydroxyl groups of carbohydrates, hydrogen bonding is a major complication and the still-controversial anomeric effects (including the exo-anomeric effect) are another (Grindley 2008). Departures from established understanding continue to be called "effects" even after they become part of the conventional thinking. Several other effects that affect carbohydrates are described by Allinger (2010).

What wasn't initially appreciated was a third item, the flexibility of the monomeric unit. In the case of ring-form carbohydrate monomers, there is a substantial variability among the positions of the ring atoms, even if all rings being considered can be described as having a chair form. The detailed variability is indicated by the different values of the endocyclic torsion angles. This variability can radically affect the relative disposition of the bonds to the inter-monomeric linkage oxygens. To fully appreciate the effects of monomer flexibility, it is useful to think in terms of connecting particular individual glucose monomers with given glycosidic bond angle and ϕ and ψ linkage torsion angles. In the case of models of the amylose component of the starch polysaccharide that has α-(1,4)-linked glucose residues, many monomers with feasible structures can be taken from the extensive literature of crystal structures. The shapes of the model starch molecules will depend importantly on the particular monomer shape. Because each of the glucose monomer shapes from crystal structures had been experimentally observed, it must be considered as a potential monomer shape in an oligosaccharide or polysaccharide.

While the distance between the C1 and C4 atoms of α-glucopyranose is relatively constant, the O1–O4 distance varies over a range of more than 0.8 Å (French and Johnson 2011), with roughly 15° ranges each for the C4–C1–O1 and C1–C4–O4 virtual bond angles in either α- or β-glucopyranose. These ranges were found with a new search of the Cambridge Crystal Structure Database

(Groom and Allen 2014) that was conducted for this review. The virtual torsion angle O1–C1–C4–O4 in α-glucose $^4C_1$ rings have values ranging from −14° to +22° (French and Johnson 2007). The resulting variations in polymer shape are important in that some observed polymer shapes cannot be modeled unless the correct monomer shape is incorporated. Of course, the problem of variable monomer geometry is magnified when an overall shape, such as a chair, cannot be assumed and other ring shapes must also be considered.

The variability of the O1–O4 distance has strong implications for the shape of some model oligomers of the amylose component of starch. Because of the relatively constant C1′–O–C4 glycosidic bond angle, the oligomers with short O1–O4 distances lead to helices with small values of the helical parameters **n** and **h**. Longer residues lead to helices with larger values of **n** and **h** (French and Murphy 1973). Cyclic model oligosaccharides such as cyclomaltohexaose (α-Schardinger dextrin) have **h** = 0.0. Stereochemically correct models of the cyclomaltodextrins can be built with five to nine residues that have increasing O1–O4 distance of the constituent residues. Goebel et al. (1970) reported a maximum of six residues per turn for amylose when modeled with one glucose geometry and nine residues per turn when another geometry was used, without attributing the difference to any particular geometric feature of the glucose residues. The O1–O4 distance variability is discussed further in Sect. 4.

A second manifestation of the need to consider flexible residues was less obvious. A clear example of this need was given by a Ramachandran analysis to understand the range of observed variation in torsion angles of the glycosidic linkages in the crystal structures of molecules that contained sucrose moieties (Ferretti et al. 1984). Their computer models were based on rigid monomer geometries from crystalline sucrose. Their calculated energy for the sucrose moiety in the raffinose trisaccharide, relative to the sucrose conformation in its own crystal, exceeded 100 kcal mol^{-1}. A relative energy of 10 kcal mol^{-1} indicates severe problems for an observed structure, let alone 100 kcal mol^{-1}. Ferretti et al. observed that the extremely high energy was probably an artifact due to the use of rigid residue models. Subsequent calculations that allowed the monomer geometries to relax during energy minimization reduced that energy to 8–10 kcal mol^{-1}, and a hybrid quantum mechanics/molecular mechanics (QM::MM) calculation in the same paper reduced the relative energy to about 3 kcal mol^{-1} (French et al. 2000a).

Conformational energy calculations for reducing disaccharides that had been based on energy minimization with MM had been reasonably predictive of the observed conformations. Therefore, it was hypothesized that the parameterization for the linkage torsion angle energies was insufficient for nonreducing sugars. When both carbon atoms of the glycosidic linkage serve as anomeric centers, there could be an overlapping exo-anomeric effect that was mentioned earlier by Schleifer et al. (1990). Such effects may be modeled more reliably with QM.

At first glance, the emphasis on Ramachandran mapping of disaccharides might seem excessive, considering that there are other carbohydrate conformation questions of interest. For example, the shapes of five-membered furanosyl rings are important, as there is substantial variability potentially present and modeling could

assist understanding of the properties of molecules having these small rings. The six-membered pyranosyl rings are usually found in a chair form with the maximum number of equatorial substituents, but a few sugars, especially idose, are found in both chair forms (Angyal and Pickles 1972) and a skew-boat form (Snyder and Serianni 1986). Idose chair forms have mixtures of axial and equatorial substituents. The study of the shapes of the various rings, however, required development of potential energy functions that could be considered reliable. In the early work, therefore, it was more attractive to try to explain the polysaccharide shapes based on monosaccharide geometries that were known with some confidence.

By the early 1990s, there was a wider range of carbohydrate modeling studies. Rigid-residue modeling had been mostly discarded as a viable approach and was replaced with relaxed-residue energy mapping. In addition to empirical potential energy functions, electronic structure theory (quantum mechanics) methods were being applied to small molecules such as five-membered rings (Garrett and Serianni 1990). Models of crystals were also being studied, including attempts to solve the crystal structures for simple polysaccharides such as cellulose Iα, which has only one chain with two glucose residues per unit cell (Aabloo and French 1994). Computer software was expanded to handle such large problems, and increases in processor performance and memory size enabled these advances.

One of the most important divisions was the development of molecular dynamics (MD) methods. MD has numerous capabilities that are not available in energy minimization methods. Although MD is usually carried out with empirical (often called molecular mechanics or MM) force fields, it is also possible to use electronic structure theory (quantum mechanics, QM) methods to compute the energy of the system at each increment of time. The first advantage of MD is that entropy is explicitly considered. A molecule may possibly spend more time in a conformation with slightly higher enthalpy because the range of allowed variation is larger than for a structure with a lower enthalpy but a small allowed range. The time spent in each conformation is equivalent to its relative probability, and the probability is a function of the free energy. Thus, information on free energy is available. Another advantage is that the orientations of exocyclic groups of carbohydrates are varied "naturally" because of thermal motion. However, it is still important to make sure that the necessary variations are sampled during the dynamics.

Perhaps the biggest reason for MD studies is the ability to explicitly incorporate water molecules. By placing the solute molecule inside a "box" that is filled with hundreds or thousands of water molecules, the influence of water on the properties of the carbohydrate can be studied. Because the addition of thousands of water molecules adds considerably to the computational expense (the amount of time and computer memory capacity used), the added water molecules are treated with their own specific parameters. These parameters are combined to produce SPC (Berendsen et al. 1981), TIP3P (Jorgensen et al. 1983), or a number of other water models. Some observed properties of carbohydrate molecules are apparently the result of changes in the structure of the water around the carbohydrate; MD studies can test those ideas (Liu and Brady 1996; Mason et al. 2005). Another important function of MD modeling is the study of the effects of temperature

change, for example calculation of the glass transition temperatures for polysaccharides (Caffarena and Grigera 1997, Mazeau and Heux 2003), as well as other temperature-based phase changes.

With the current ability to do multi-nanosecond or even microsecond simulations for models of reasonable sizes, the Boltzmann equation makes it possible to back-convert the populations (or probabilities) of the various increments of geometry to give an energy map. When the MD studies also include water explicitly, the calculated population distribution depends on both the intrinsic forces as well as the forces from the water and the effects of the water on the intrinsic forces. The conversion of the populations gives a "potential of mean force" that is plotted on free-energy versions of Ramachandran maps. Simulations by Hatcher et al. (2011) have been able to determine energy values as high as 6 kcal mol^{-1}. Thus, reliable populations were obtained for structures that were only 0.000045 as probable as the global minimum structure.

With this list of MD's important attributes comes an impressive list of extra challenges. One important challenge is the degree of sampling needed to assure that all of the important conformations are given due consideration. The structures can remain trapped inside of local wells and never access the global minimum structure because of high barriers. There are several schemes for overcoming this "multiple minimum" problem, with examples in Perić-Hassler et al. (2010), Spiwok et al. (2010), and Campen et al. (2007). This problem also exists with energy minimization methods. Methods for overcoming the problem with MD could be said to add to the complexity of MD methods.

Another MD problem is that the methods of calculating the energy are usually compromised because of a need for rapid calculations. The empirical force fields used are based on simple potential energy functions to speed up the calculation, and the most widely used force fields are specific to narrow classes of molecules. The force field is usually refined to work with a particular water model, and the force field may then not be optimal for other environments.

At present numerous topics in carbohydrate chemistry are under study with various modeling methods. With the worldwide interest in sustainable bioenergy, much effort is expended on the study of cellulose. Of particular interest is the so-called biomass recalcitrance, i.e., the resistance of the biomass to degradation to individual fermentable glucose residues. That recalcitrance is usually attributed to the crystallinity of the cellulose. Therefore, crystal modeling is the subject of many studies. The resulting models are tested by the calculation of numerous observables, including FT-IR (Fourier transform infrared), Raman, and NMR (nuclear magnetic resonance) spectra (Kubicki et al. 2013), crystal dimensions and retention of proposed hydrogen bonding schemes (Matthews et al. 2006; Yui et al. 2006; Nishiyama et al. 2008), and X-ray diffraction patterns (Nishiyama et al. 2012).

Another fairly new area is the study of the weak interactions within or between molecules with either Natural Bond Order (NBO) methods or Bader's Atoms-in-Molecules theory. NBO methods have been used to study the anomeric effect, based on various interactions (Takahashi et al. 2007; Cocinero et al. 2011). AIM has been exploited to a limited extent for detecting in an objective manner the various

atomic interactions in both experimental X-ray diffraction studies and purely theoretical QM calculations, as well as studies that use both theory and experiment (Jaradat et al. 2007; Stevens et al. 2010; French et al. 2014).

This chapter will touch on modeling studies in order of molecular size, avoiding, with apologies, as much as possible the numerous areas in which the author has little or no first-hand experience. A general thought is that the arc of modeling progress bends towards fewer assumptions, but the effort involved increases exponentially with the loss of each assumption.

2 Monosaccharides

2.1 Acyclic Sugars

Over the years little effort has been spent on acyclic monosaccharides. When a hexose is acyclic there are many variables that have complete freedom. For example, all the torsion angles have surmountable barriers to full rotation so a complete determination for the hexose chain would have three backbone torsions plus five hydroxyl group torsions to consider. This would result in some 3^8 (6,561) conformers for which the energy is calculated, assuming that the low-energy forms would correspond to, or be accessible from, one of the three staggered conformations. Such a project, involving the added torsion angle in D-glucaramide (3^9 or 19,683 starting structures), was completed using the empirical force field program MM3 (Allinger et al. 1990) in batch mode on a Windows PC that was considered obsolete in 2002 (Styron et al. 2002). One complication, often encountered in MM projects (either MD or energy minimization), was the need to develop torsion angle parameters. In the glucaramide case, parameters were needed for the N–C–C–O sequences. That was done with the aid of HF/6-31G* QM calculations. Another complication is simply the bookkeeping that is needed for so many thousands of calculations. Follow-on work involved a Monte Carlo method running under Linux to more efficiently search for the low-energy forms (Dowd et al. 2011). The method is also applicable to larger structures, but since an explicit search of all possibilities had been conducted for glucaramide, it was a good target for validation.

2.2 Ring-Form Sugars

Monosaccharides of greatest interest often have ring shapes. As in the case of the acyclic structures, bond-length variations are not considered to be meaningful for describing ring shapes, nor are conventional bond angle differences. Torsion angles are again the major factor in conformational change, although changes in torsion angles will result in some variation in the bond lengths and bond angles. Because there are too many endocyclic torsion angles to mentally monitor, however, conformational analysis is based on the fact that ring formation results in a structure for which there is a meaningful mean plane. Deviations of the atoms from that plane

result in different descriptors for the ring shape, and the descriptors indicate the position(s) of maximum deviation from the plane as well as the extent of the deviation. If just the exocyclic torsions are considered for an aldohexose, there are $3^6 = 729$ conformations to consider for each ring shape. A brief study (French and Johnson 2011) showed that only 150 combinations of exocyclic orientations were stationary for α-glucopyranose when it was in the $^4C_1$ shape. Of these, 125 were true minima at the B3LYP/6-31+G(d,p) level and the remaining 25 were saddle-point structures. The range of energies for these structures was 13.8 kcal mol^{-1} in the vacuum calculations.

2.3 Ring Puckering

Although many studies ignore variations of ring shape, it is critical to understand it. The simplest important form is the furanose ring. Many aspects of conformational analysis can be illustrated with furanose rings and they are small enough that fairly complete analyses can be carried out with minimal assumptions. The conformations of furanose rings were recently reviewed in great depth by Taha et al. (2013).

Furanose rings. Figure 1 shows both an aldofuranose, ribose, and a ketofuranose, fructose, with the carbohydrate-specific numbering of the atoms. Because three points define a plane, a conformational analysis of furanose rings can be carried out by driving the starting structure into different shapes by moving the remaining two atoms perpendicular to the plane. Then, a determination of the resulting ring shape is performed. Five-membered rings are described as having either Envelope (E) or Twist (T) shapes. E shapes have one atom that is either above or below the plane formed by the other four atoms, with a total of ten different E shapes. T shapes have two adjacent atoms deviating in opposite directions from a plane formed by the other three atoms, and in characteristic T shapes, the two deviating atoms will be the same absolute distance from the plane. The 10 T shapes are intermediates between the adjacent E forms. For example, the $^3T_2$ form would be a transition shape between the ^3E and the E_2 forms.

Consider a furanose ring with conventional ketose numbering (Fig. 1a). If the C2, C3, and C5 atoms are fixed in a plane with z-coordinates of zero, the ring oxygen and C4 can be fixed at different distances from that plane, for example in increments of 0.1 Å up to ± 1 Å. Of course, this particular procedure depends on the modeling software to have the facility to fix the coordinates of the atoms in one dimension, but not in the others. Although the ring oxygen can be moved by itself to create starting models for energy minimization, movement of C4 requires coordinated movement of its attached exocyclic groups (H4 and O4–H). Thus, substituents on C4 will require the varying C4 z-coordinate value to be added to their original z-coordinate value. Movements of the atoms from the plane would more naturally follow arcs, so when puckered ring shapes are initially constructed by simply adjusting the z-coordinates of the deviating atoms, very strained rings occur. However, energy minimization will quickly relieve that strain. The process of giving 21 values of the z-coordinates to the O5 and C4 atoms (for a total of

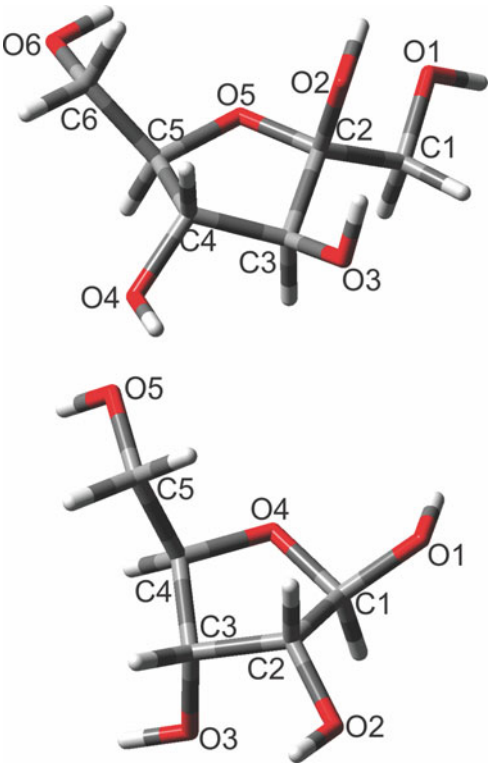

Fig. 1 β-D-Fructofuranose (*above*) and β-D-ribose (*below*). The fructose ring has the $^{4}T_{3}$ shape, and the ribose ring is $^{2}T_{3}$ in this drawing

441 structures) generates a reasonably complete range of furanosyl ring conformations (French and Dowd 1994).

Numeric values can be associated with the deviation from planarity for furanoid molecules because there are 10 E forms, interspersed with 10 T forms for a total of 20 characteristic (or canonical) conformations. In the case of cyclopentane, the E and T forms are nearly isoenergetic, and the equilibrium state is dynamic in solution or the gas phase as the structures interconvert, with different atoms being out of plane. The process is called pseudorotation, as one E form converts to a T form and then on to another E form. For example, the ring form can easily change from ^{1}E to $^{1}T_{2}$ to E_{2} and then to $^{3}T_{2}$. Thus, the location of "puckering" moves around the ring. For a five-membered ring, numeric values can be given to describe the puckering. Namely the characteristic conformations are spaced 18° (360°/20) apart on a "conformational wheel," allowing intermediates to the characteristic conformers to be designated with an intermediate numeric value. Figure 2 illustrates conformational wheels for both aldoses and ketoses, and in both the Altona and Sundaralingam (1972) and the Cremer and Pople (1975) puckering nomenclature. Additionally, the broad North–South-East–West classifications are indicated, as well as the obsolete "endo" and "exo" notation. Further, the amplitude of deviation from the mean plane can be expressed in distance units such as Å. A useful, if not rigorous, conversion between the Altona-Sundaralingam and Cremer-Pople

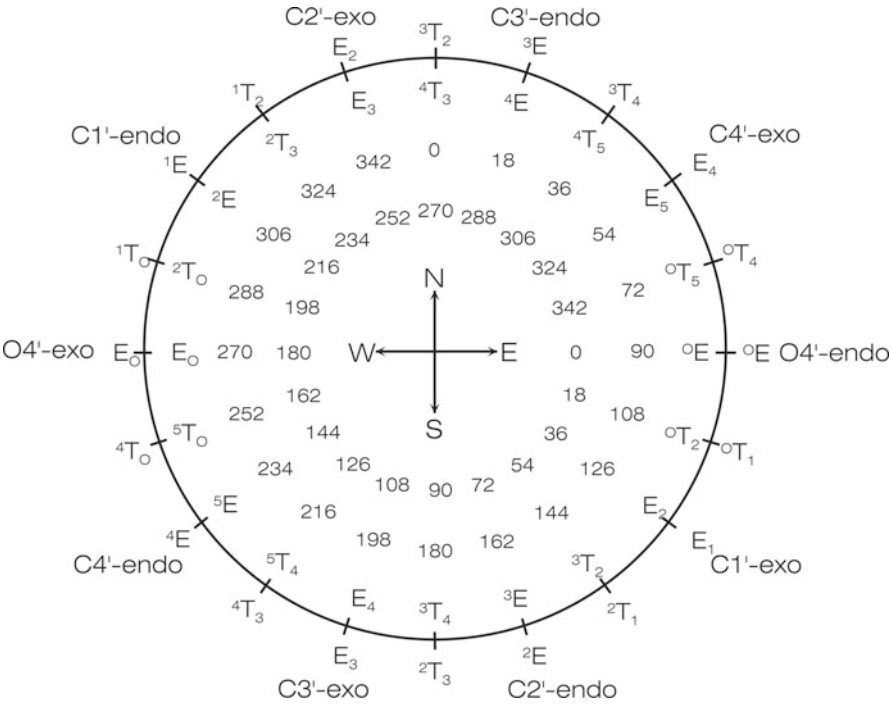

Fig. 2 Conformational Wheel for aldo- and keto-furanose rings. The outer designations apply to the aldofuranoses and the inner ones to ketofuranoses. The inner ring of puckering phase angles applies to the Altoona-Sundaralingam puckering parameters; the outer ring to Cremer-Pople phase angles. The obsolete endo and exo notation is also given for the aldofuranoses

nomenclatures is to just add 90° to the Cremer-Pople phase angle (Φ) and multiply the Cremer-Pople amplitude (q) by 100.

Unlike cyclopentane, the various conformers of furanosyl sugars have ranges of energy values so it is of interest to conduct a conformational analysis based on the puckering parameters. One way to carry out such an analysis is to calculate the energy at each of the 441 points mentioned previously (30 points corresponded to very distorted structures and were not included). One "small" problem is that the orientations of the exocyclic groups affect the calculated energy. Hexafuranosyl sugars such as fructofuranose have seven different exocyclic bonds about which groups can be rotated. So an "adiabatic" conformational energy surface can be calculated by finding the lowest of the 2,187 energies for each of the 441 points, i.e., while holding the ring in the prescribed shape with the O5 and C4 atoms held at different distances from the z = 0 plane held by the other three carbon atoms. The puckering parameters for the 441 ring shapes are determined by software provided by Cremer (Ring 88), or other suitable routines, e.g., PLATON (Spek 2009). Because most plotting software is not able to provide plots for the plane polar coordinates that describe the puckering, they are converted to Cartesian coordinates, after attending to the need to actually plot the coordinates based on 360°-Φ so

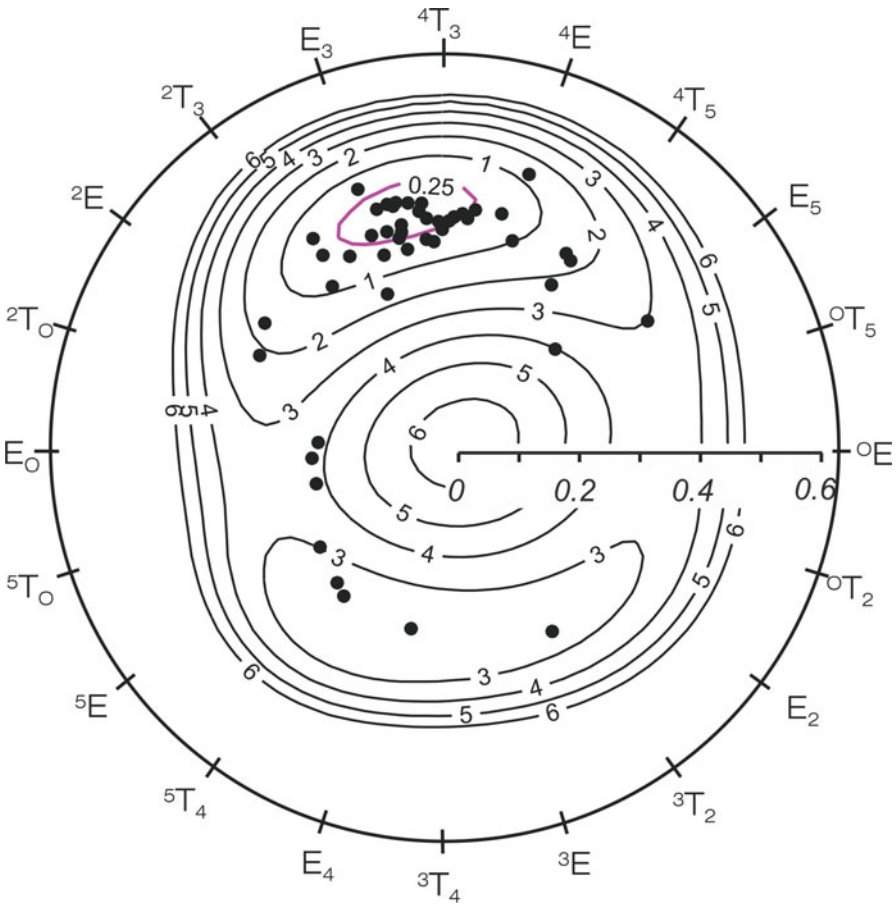

Fig. 3 MM3 energy contours for β-D-fructofuranose plotted on conformational wheel. The Cremer-Pople puckering amplitude is shown by the *horizontal line* from the *center* of the pattern to the ^{O}E conformation. Observed ring conformations from crystal structures for many fructose-related compounds are shown as *large dots*

that a clockwise system results. That allows the plot to correspond to the ring shape when the ring is oriented according to the convention, as in Fig. 1.

The Cartesian coordinates for 441 different conformations and their associated energies can then be fed into a surface contouring routine. The Surfer program (Golden Software, Golden, Colorado) has most of the necessary facilities, and its output is shown in Fig. 3 for β-fructofuranose. In this plot, the energies were calculated with MM3 at a dielectric constant of 4.0 (French et al. 1997) and the points representing the experimental puckering parameters from a new survey of the Cambridge Crystal Structure Database (CSD) are displayed. The plot shows the puckering amplitude scale as well. All but six of the 47 different conformations fall into the northern, global minimum, with the southern structures generally having

smaller puckering amplitudes than the northern ones. This decrease in amplitude for the lowest-energy southern structures is also indicated by the energy contours, which have their local minimum closer to the center of the wheel.

It is not universally agreed that such an analysis can be expected to predict the conformations found in crystal structures. Crystal neighbors deform the ring shape in different ways and this is shown in Fig. 3. Chemical substitution seems to have less influence on the variation than does crystal packing. The 'rules' for inclusion of a particular structure from the CSD were that there be no rings involving the exocyclic groups that would hold the ring in a particular shape. But there are substantial chemical differences, with sucrose octaacetate and sucrose octasulfate both included as well as numerous hydroxyl-bearing oligosaccharides. Conformations of the furanose rings in the trisaccharide, 1-kestose are $\Phi = 254.4°$, $Q = 0.417$ Å and $\Phi = 100.6°$, $Q = 0.298$ Å. Thus it has both northern and southern rings in the same molecule. They are about as different as the rings in the two substituted sucrose molecules (for the octaacetate, $\Phi = 302.7°$, $Q = 0.328$ Å; for the octasulfate $\Phi = 129.2°$; $Q = 0.280$ Å).

The hypothesis that the puckering of furanose rings can be predicted from isolated-molecule calculations for native, substituted, and complexed crystal structures is subject to quantitative tests. Previously, a similar proposal for another set of conformational indicators, the linkage torsion angles for disaccharides, was tested by examining the distribution of conformational energies that corresponds to the observed conformations. To be a successful prediction, the frequencies of the corresponding energy values should decrease in an exponential manner as the energies increase (Bürgi and Dunitz 1988).

Figure 4 shows a "cumulative frequency" plot of the corresponding energies for the puckering parameters from the crystallographically determined fructose structures in Fig. 3. Those energies are obtained with the "residual" function of the Surfer software. Cumulative frequency plots perform the function of a histogram, but are much more suited to small data sets. Although the *y*-axis is labeled

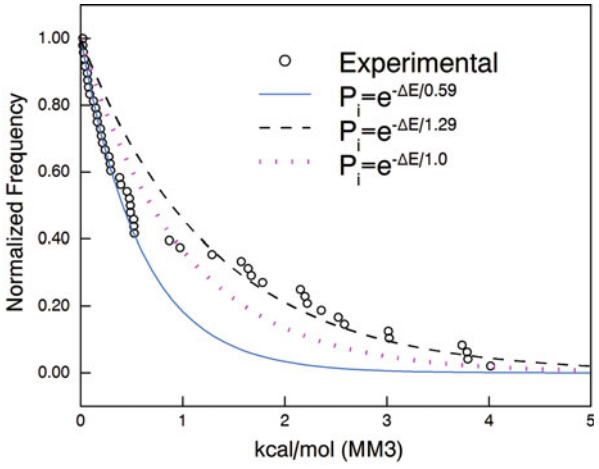

Fig. 4 Cumulative frequency plot for observed crystal structures of fructofuranose, with corresponding energies taken from Fig. 2. *Ideal lines* of probable frequency (P_i) are plotted for different temperatures, with the exponent's denominators of 0.59, 1.0, and 1.29 being the products of multiplication of the universal gas constant (R), × 298°, 505°, and 651°K

normalized frequency, the actual value plotted is cumulative frequency, or "1.0 – (position in a sorted list/number of points)." Three lines are shown, all based on $P_i = e^{-\Delta E/RT}$ with RT (the universal gas constant R, 1.98 kcal (mol^{-1}), times a temperature in Kelvin). When RT = 0.59, the line represents the exponential decay expected at room temperature. When RT = 1.0, the line corresponds to 505 K, and RT of 1.29 corresponds to a temperature of 651 K. The latter value was derived by fitting an exponential function to the data, forcing the function to have a value of 1 at 0 kcal using a spreadsheet program.

Although there is not perfect agreement between any of the lines and the experimental data, it is clear that the number of points decreases as the energy increases. The fitted line with RT = 1.29 appears to give too much weight to the high-energy structures, while the arbitrarily selected room temperature line (RT = 0.59) does not explain the structures above 0.5 kcal mol^{-1} well. The equally arbitrary RT = 1.0 line appears to be a compromise. It is important to not overanalyze this result. For one thing, the limited number of structures is spread over a wide range of conformations. More crystallographic results could change the perceived distribution. For another, Fig. 3 is a very complex hypersurface and errors of 1.0 kcal mol^{-1} could dramatically alter the graph in Fig. 4. Another factor is that the arrangement of the hydroxyl groups found for minimum-energy isolated molecules is almost never the same as found in crystal structures (French and Csonka 2011).

Digressing to further discuss the cumulative frequency plots, French et al. (2000a) showed an example (Fig. 3b in that work) of a cumulative frequency plot for sucrose structures, with corresponding energies from a simplified model compound that did not have the primary alcohol group at C2 of the furanose moiety. That omitted group resulted in a cumulative frequency plot that was not predictive. A different cumulative frequency plot in that work (its Fig. 3a) was based on hybrid energies with a dielectric constant of 3.5 for the full sucrose molecule. Compared with Fig. 4 of this work, that plot has a somewhat better fit, with RT of 1.16, equivalent to 585 K. In cumulative frequency work with disaccharides (French et al. 2000b), the 153 corresponding energies from eight disaccharides were pooled. Combining the corresponding energies when they were all calculated with the same method makes it possible to judge the validity of a force field when the data for any single molecule are limited. Three different dielectric constants were employed as well. At $\varepsilon = 1.5$, the fitted line corresponded to 942 K; at $\varepsilon = 3.5$, to 480 K, and at 7.5 to 419 K.

When the energy is lowered by formation of hydrogen bonds in some locations on Ramachandran's surfaces but not in others, the surfaces generally become flatter (and more predictive) as the dielectric constant is elevated (French et al. 2000b; French 2012, Fig. 10). The same phenomenon was observed with quantum mechanics calculations for the cellobiose disaccharide when a continuum solvation model was added (French et al. 2012). In turn, this flattening of the surface should reduce the effective temperature of a cumulative frequency analysis. When combined with a visual examination of the energy surfaces to see whether all of the low-energy regions are suitably populated (French et al. 2000b), the cumulative frequency

analysis can be a useful tool to judge the quality of the conformational analysis. It is significant that the distortions in crystals of the primary conformational variables correspond to conformational distributions that would be observed in the vapor phase at about 500 K, at least according to the present calculations and two previous studies.

Pyranose rings. There are three puckering parameters for pyranose rings: an amplitude, Q, the phase angle, Φ, and another angular variable, θ . When a chair-form pyranose ring is viewed from the side, the choice of the word "puckering" (a gathering into small wrinkles) to represent the ring shape becomes obvious. Instead of a 2-dimensional conformational wheel, a 3-d sphere is appropriate. The amplitude is represented by the distance from the center of the sphere to the surface, whereas the Φ angle corresponds to the longitude on a globe. The θ parameter is equivalent to the latitude. This conformational space can be represented by a 3-dimensional solid that encloses all structures with an energy less than a certain value, or perhaps more conveniently, the amplitude can be ignored and the space is therefore only 2-dimensional. The amplitude, or deviations from a mean plane, systematically varies depending on the ring shape. For example, if a chair form ring is constructed with alternating torsion angles for the ring atoms of ±59°, its amplitude will be about 0.60 Å, but a boat with two torsion angles of 0° and the others with ±59° will have an amplitude of about 0.82 Å. These differences occur despite having kept the bond lengths constant between the two rings. Thus, the amplitude of a chair is inherently less than a boat so amplitude is primarily of interest in comparing different examples of the same ring shape. For example, a molecule subjected to energy minimization in isolation might have somewhat greater puckering amplitude than one found in the crystal structure. Also, the two chairs for a given pyranose may have interesting differences in the puckering because of the interactions of the exocyclic groups in axial or equatorial dispositions.

There is some disagreement on the most correct and convenient way to calculate the ring puckering. Although the work of Cremer and Pople is the de facto standard, Haasnoot (1992), Bérces et al. (2001), Ionescu et al. (2005), and Hill and Reilly (2007) are among the numerous authors who have proposed alternate algorithms. Barnett and Naidoo (2010) adopted the Hill-Reilly approach, which reports the puckering in terms of the angles of three rotatable planes to a central reference plane, in their comparison of several semiempirical methods for modeling both furanose and pyranose ring shapes. Incidentally, Barnett and Naidoo found that none of those methods (AM1, PM3, PM3CARB-1) were suitable for modeling carbohydrates.

Because the puckering space has been repeatedly described for pyranose rings (e.g., Jeffrey and Yates 1979; French and Brady 1990; Ernst et al. 1998; Babin and Sagui 2010) and the concepts for the furanose rings were already discussed herein, treatment in this chapter will be brief. The 38 characteristic or canonical conformations comprise two chairs, six boats, six skew boats or twists, 12 half-chairs and 12 envelopes. They have letter designations of C, B, S, H, and E, respectively. The relationship between the various letter designations and the Φ and θ parameters is shown in Fig. 5. The aldopyranose puckering can be obtained from Fig. 5 by subtracting one from the super- and subscripted numbers associated with the C,

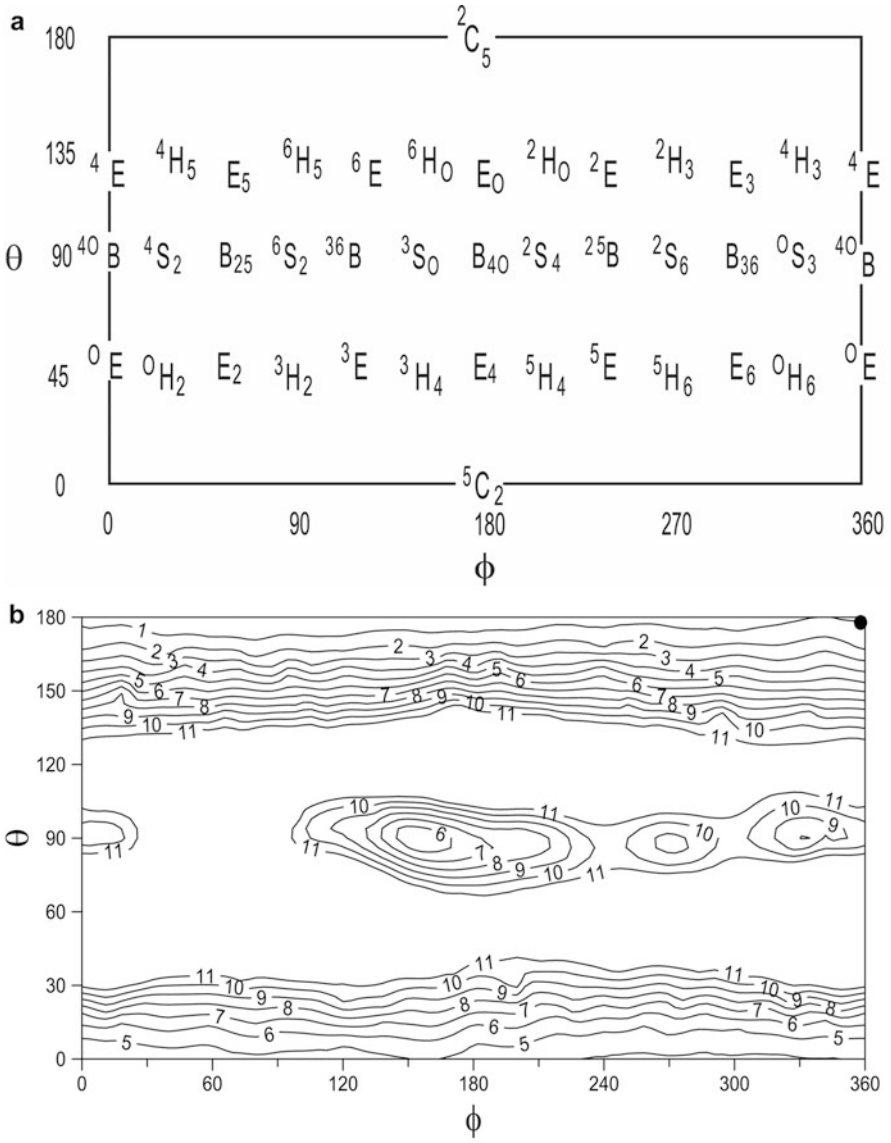

Fig. 5 (**a**) (*Upper*) Ketopyranose puckering chart, (*lower*) β-psicose energies. The designations of conformations are the same for the α- and β-anomers. The puckering for the crystal structure of psicose is plotted in the *upper right corner* of (**b**) as a *large dot*

B, S, H, and E letters. Note that the puckering maps will often reverse the θ axis, so that the $^{5}C_{2}$ (or $^{4}C_{1}$) chair is at the top of a depiction. Just as at the north or south poles of a globe where longitude is meaningless to describe the position, values of Φ are irrelevant for all structures having θ values of 0° or 180°.

In a manner analogous to the study of fructofuranose described previously, an energy surface can be created for pyranosyl sugars on the surface described in Fig. 5a. However, that 2-dimensional surface ignores the puckering amplitude values. This is a reasonable compromise because the amplitude depends on the θ values. Such a surface is again typically a hypersurface that depicts the lowest energy value at each increment of ring shape variation but does not reveal other information such as the variation of the exocyclic group orientations and puckering amplitude. Of course that information is available during such a study if desired. In our studies there were 4,913 ring shapes based on 0.1 Å vertical shifts from -0.8 to +0.8 Å for three alternating ring atoms (e.g., O5, C2, and C4 for an aldopyranose). For the 16 aldohexapyranoses (Dowd et al. 1994), psicose (French and Dowd 1994) and fructopyranose (French et al. 1997) the 729 combinations of staggered exocyclic group orientations were only evaluated for the 38 characteristic conformations. An updated example from that body of work is shown in Fig. 5b. The subject molecule, β-psicose, is of special interest because it was thought to be impossible to crystallize due to a complex equilibrium in solution. More recently (Kwiecień et al. 2008), psicose was crystallized; its $^{2}C_{5}$ puckering is consistent with the prediction. Note that the energies in Fig. 5b are somewhat different than shown in the 1994 paper. In that work the energy map lacks periodicity in the Φ puckering direction because of a lack of data points at $\Phi = 360°$. However, the calculated values at $\Phi = 0°$ were copied and used at $\Phi = 360°$ to make the new map.

The pentopyranoses xylose, lyxose, and arabinose only have four rotatable exocyclic side groups and so all 81 combinations of staggered orientations were tested at each of the 4,913 ring shapes (Dowd et al. 2002). Deoxy- (L-fucose, D-quinovose, and L-rhamnose) and dideoxyhexapyranoses (D-digitoxose, abequose, paratose, and tyvelose) were also studied exhaustively with 81 or 27 combinations of exocyclic group orientations (Rockey et al. 2001). Ribose and deoxyribose have also been studied exhaustively (Dowd et al. 2000). In all of these studies, there were hundreds of thousands of starting structures for each molecule. Because they were done with the MM3 empirical force field, the computer time, while considerable, was not the only obstacle to completing the work. The bookkeeping for that many structures required planning and organization.

Given the advances in computational resources since that time, it has been possible to begin to repeat this work with QM (Mayes et al. 2014). In that work, all staggered combinations of exocyclic group orientations for each of the 38 characteristic conformers were evaluated at the M06-2X/6-31G(d) level for the two anomers of glucose and β-mannose, as well as 972 for β-*N*-acetylglucosamine, 81 for β-xylose, and one of oxane. The major difference is that the puckering amplitude was not a variable in the screening work, whereas in the work of Dowd et al., the 4,913 ring shapes included the 38 conformations of Mayes et al. and many other variations such as intermediates and various puckering amplitudes. Mayes et al. assumed that vacuum calculations would mimic the electrostatic environment similar to the interior of a glucosyl hydrolase enzyme, on the grounds that the dielectric constant of the protein-carbohydrate complex would be around 4.0. However, a change from 1.0 for the vacuum to 4.0 for the complex amounts to a

fourfold reduction in the strength of the electrostatic contribution to a hydrogen bond. As calculated from the data in Řezáč et al. (2011, see more below), the electrostatic contribution to the dimerization energy of methanol in vacuum is nearly 4.1 kcal mol^{-1}. Reducing it to one fourth to account for the reciprocal relationship of the dielectric constant to electrostatic stabilization would yield a value of 1.0 kcal mol^{-1} as the appropriate amount of stabilization for the complex. A dielectric constant of 78, as for water, would reduce the electrostatic contribution to just 0.05 kcal mol^{-1}. Still, 1.0 kcal is closer to 0.05 kcal than it is to 4.1 kcal at dielectric 1.0. Therefore, use of an aqueous solvent model in the calculations would have been more appropriate if some solvent model with an intermediate dielectric constant were not deemed more appropriate.

Because of the large number of calculations involved in the semi- or fully-exhaustive energy minimization approach and the inability to explicitly account for solvation and free energy, molecular dynamics approaches have also been utilized. One example is the study of methyl glucuronic and iduronic acids by Babin and Sagui (2010) mentioned in the context of puckering calculations. Their work used a combination of Adaptively Biased Molecular Dynamics and Replica Exchange protocol along with Amber and the Glycam06 force field for carbohydrates and was presented on Hammer-Aitoff equal-area projections of puckering space. Preliminary implicit solvation calculations were used along with TIP3P explicit solvation in the production simulations.

At nearly the same time as Babin and Sagui's paper, Spiwok et al. (2010) published a force field comparison with the metadynamics extension of the GROMACS software (Van Der Spoel et al. 2005) (Fig. 6). The molecule studied was β-D-glucopyranose. The modification to GROMACS is called GROMETA 2.0 (Camilloni et al. 2008), and the Glycam06, GROMOS 45a4, and OPLS force fields were evaluated by both vacuum and solvated calculations. Again, the dynamics simulation is forced by a bias to sample the puckering space. The results were

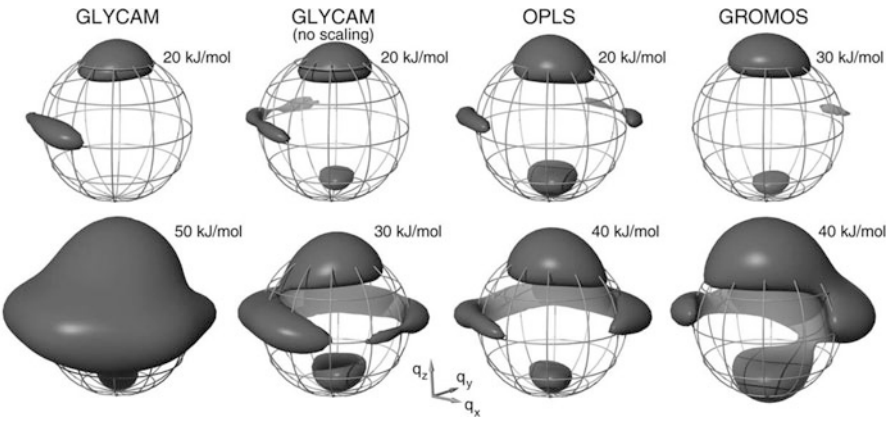

Fig. 6 Puckering surfaces for β-D-glucopyranose from GROMETA/Glycam metadynamics (From Spiwok et al. (2010), used with permission)

compared to glucose conformations observed in structures found in the Protein Data Bank. In crystals of small molecules, β-glucose residues are invariably in the $^4C_1$ conformation, but there are a number of examples in enzyme complexes where the glucose residues are distorted as part of the hydrolytic cleavage of the polysaccharide. Interestingly, a few examples of α-glucose with ring shapes other than $^4C_1$ have been observed residues in substituted cyclodextrins having seven glucose monomers per cycle (Steiner and Saenger 1998; Anibarro et al. 2001; French and Johnson 2007). Just as the complexation of the carbohydrate substrate at the catalytic site of an enzyme can result in distortion of the pyranosyl ring (Phillips 1966), a crumpling of an empty derivatized cyclodextrin because of van der Waals forces can make it advantageous to the system for one of the rings in the cyclodextrin to take an alternative form.

Somewhat earlier, Biarnés et al. (2007) carried out quantum mechanics studies of β-glucopyranose with the Car-Parrinello molecular dynamics (CPMD) method that incorporated metadynamics. Again, the molecular dynamics simulation was forced to explore various ring shapes, although in this case only conformations having puckering θ values of less than 90° were considered. In that work, the authors utilized a diagram published by Stoddart (1971) that represented the same conformational space that they explored with CPMD. This diagram is also widely used in studies of glucoside hydrolases, but it has some misleading implications. For example, Envelope conformations are not included, and the indicated interconversion pathways go directly through a canonical Half-chair form to a particular ring form on the Boat/Skew itinerary where $\theta = 90°$. The canonical or characteristic conformations are only descriptive landmarks in conformational space and too much significance should not be attached to them.

Limitations in that work included a very short simulation (44.4 ps, whereas a microsecond is sought in current MD simulations with empirical force fields) as well as the lack of consideration of the $^1C_4$ form and conformation space leading to it. Their energies based on plane wave basis functions and the PBE density functional theory (DFT) method were compared with results from calculations by a more frequently used DFT method, B3LYP, and the /6-31+G* Pople basis set. The differences of ±0.6 kcal mol^{-1} did not change the order of the preferred conformers. Their values for a ^2S_O structure were 4.12 and 3.0 kcal for ΔE and ΔG, which were also compared with literature values of 4.75 and 3.4 kcal mol^{-1} from Appell et al. (2004) who used B3LYP/6-311++G**. Dowd et al. (1994) reported a relative MM3 energy for a ^2S_O structure of 6.5 kcal mol^{-1}, but that calculation involved an elevated dielectric constant to account for a condensed phase while the other calculations were for the gas phase.

2.4 Electron Density Analyses

Descriptive analysis of the electronic structure in terms of the electron density (instead of orbitals) is being applied to carbohydrates. The electron density can be probed by both experiment and QM calculations. Although not applicable to

carbohydrates because of their nonplanar structure, specialized Atomic Force Microscopes with a carbon monoxide molecule on the tip have produced images of the bonding structure at both the covalent and hydrogen bonding levels (Gross et al. 2012; Zhang et al. 2013). High-resolution X-ray crystallography also can yield information on the electron density because the X-rays are scattered by the electrons (Koritsánszky and Coppens 2001). Although the diffraction patterns are normally solved by assuming the atoms to be spherical, for electron density studies they are assumed to take a shape described by a combination of mono-, di-, quadra-, octa-, and hexadecapoles. Experimental X-ray diffraction studies of electron, or charge, density can use "difference density" methods in which the electron density as modeled by the multipole method is compared with the usual spherical density for the atoms. For example, this data can provide resolution of the lone pairs of electrons on oxygen, for example (Longchambon et al. 1985; French et al. 2014).

The work of Bader (1990) has added topological analysis to quantitative studies of electron density with X-rays and QM. In Bader's Atoms-in-Molecules (AIM) analysis, the molecular structure is described in terms of critical points, bond paths, and basins. For example, a point at which the electron density is a maximum in all three directions is a "nuclear attractor" or nucleus, and a point from which the electron density increases in all directions is a "cage critical point." "Ring critical points" are located where electron density is at a minimum in two directions but a maximum in the third. The last to be mentioned is the "bond critical point" (BCP) at which the electron density is at a minimum between two atoms but a maximum in a plane perpendicular to a line connecting the two atoms. A bond path connects the BCP to the nuclei in question. The bond path need not be straight. For example it is curved for C–C bonds in cyclopropane (Patai 1992). The sign of the Laplacian (the second derivative of the electron density at the BCP) indicates whether the bonding is covalent (negative values) or a weaker, "non-bonded" interaction (positive values). Another descriptor of the electron density at the BCP is the ellipticity, which can indicate the extent of π-bonding, for example. A depiction of the nuclei and bond paths constitutes a molecular graph, which usually looks like a "ball and stick" model.

Because the electron density extends to infinity around each atom, it is usual to use a cutoff of the electron density, perhaps at the 0.001 electron per atomic unit (a cubic bohr, which equals 0.14735 $Å^3$). Quantum chemists favor the atomic units and crystallographers favor $Å^3$. This cutoff distance is equivalent to the van der Waals surface of a molecule, defined by objective criteria for each atom. Each nucleus is said to exist in a basin defined by the minima in the surrounding electron density and the outer van der Waals surface. Thus the volume of each atom in a molecule can be calculated. Each basin can be said to contain the electrons associated with the particular nucleus, so the atomic charge on each atom is also defined. Unfortunately, the shapes of these basins make them generally unsuited for providing parameters for empirical force fields.

Figure 7 shows two different representations of QM-derived electron density for α-D-glucopyranose. The upper plot shows the 0.021 e/a.u. (darker green) and 0.018 e/a.u. (pea green) isodensity surfaces, rendered by the MOLISO software (Hűbschle

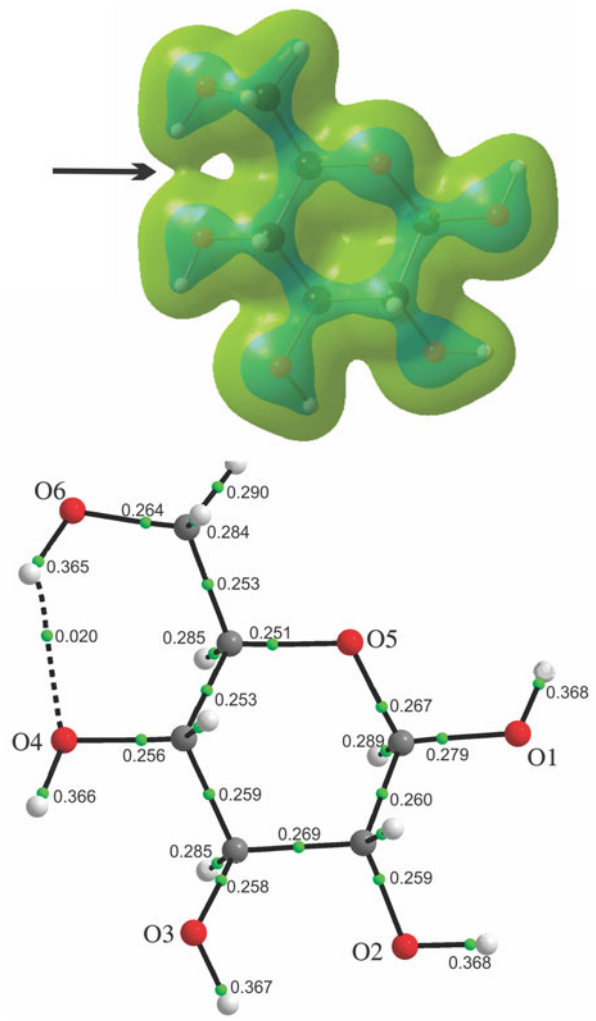

Fig. 7 Electron density analysis with 0.23 e/au isodensity surface (*upper*) and AIM critical point and bond-path analyses (*lower*). Electron densities are shown in the *lower* image for the sugar with the hydroxyl groups in the counter-clockwise orientations

and Luger 2006). The lower plot shows the rendition of the same structure by the AIM Studio software that is part of the AIMAll package (Keith 2013). This molecular graph shows the labels for the oxygen atoms and the values of the electron densities for the BCP. The electron density was derived from energy minimization at the B3LYP/6-31+G* level and the final electronic structure provided by B3LYP/6-311++G** theory.

Although depictions of bonds have been described as "cartoons," the darker green regions in the MOLISO plot clearly depict the concentrations of electron density that correspond to the molecule's covalent structure. Although it is not useful to compare the electron densities for bonds that involve different elements, for a given type of bond, the bond order (e.g., single or double) is related to the

electron density. The arrow points to the concentration of electron density that represents a hydrogen bond between the hydrogen on O6 and O4.

As previously indicated by Klein (2002), there is a hydrogen bond formed for this particular structure of glucose, with O6 in the experimentally rare *tg* orientation and the O4 hydroxyl group pointing counter-clockwise. This is despite the absence of hydrogen bonding for the other adjacent hydroxyl groups, reported initially by Csonka et al. (1997) and by Klein (2002). Although the secondary hydroxyl groups in Fig. 7 are all oriented in a counter-clockwise direction around the glucose ring, there are no bond critical points or bond paths to indicate hydrogen bonding. This is despite the fact that such an arrangement and its clockwise counterpart are routinely found to correspond to the minimum energy arrangements of the hydroxyl groups (French and Csonka 2011), leading to a claim of hydrogen bonding in many studies.

Investigation of this problem indicated that the proposed intramolecular hydrogen bonds between vicinal hydroxyl groups have O–H. . .O angles of less than 115° as well as H. . .O distances greater than 2.4 Å (Table 1). Quantum mechanics calculations for 1,2-dihydroxycyclohexane showed that there was a drop of about 2 kcal mol^{-1} when the "donor" hydroxyl group was in an optimal orientation vs. an increase of about 2 kcal mol^{-1} when oriented in an opposite direction (French and Csonka 2011). (A zero of relative energy was established subsequent to the 2011 work by placing the second hydroxyl group in a nonvicinal position.) Additionally, the 2 kcal mol^{-1} attraction was eliminated by calculations that added the SMD implicit solvation model. This evidence points to the idea that such vicinal hydroxyl hydrogen bonds, if they are to be called that, are based on only the electrostatic component of the hydrogen bond, whereas the AIM analysis depends on the dispersive or van der Waals component.

A breakdown of water-water, water-methanol, and methanol-methanol hydrogen bonds, all with optimal geometries, showed ratios of dispersive to electrostatic interactions of 0.29, 0.35, and 0.40 (Řezáč et al. 2011). The corresponding total ΔE values from that work were 4.92, 5.59, and 5.76 kcal mol^{-1} at the CCSD(T)/CBS level. The breakdown was achieved with Symmetry-Adapted Perturbation Theory (Jeziorski et al. 1994; http://www.physics.udel.edu/~szalewic/SAPT/index.html). Thus, the AIM calculations, which are not oriented towards finding electrostatic bonds, are failing to find a van der Waal component of the hydrogen bonding because of the geometry, but the QM calculation is finding the electrostatic component, albeit reduced because of the longer H. . .O distance that is a consequence of the vicinal geometry. Small changes in that geometry, such as for vicinal

Table 1 Interactions among hydroxyl groups in β-D-glucose of Fig. 7

Interaction	AIM HB?	H. . .O (Å)	O–H. . .O (°)	O. . .O–H (°)
O6–H. . .O4	Yes	2.06	134.8	31.1
O4–H. . .O3	No	2.40	106.5	54.3
O3–H. . .O2	No	2.50	102.7	58.1
O2–H. . .O1	No	2.55	99.7	60.9

hydroxyl groups on a septanoid ring, do allow the calculations to show a bond path and BCP (French and Csonka 2011).

While the AIM approach has been used to question one class of proposed hydrogen bonds, it has strengths in the detection of C–H. . .O and general van der Waals interactions. Particularly interesting was the detection of C–H. . .O interactions with complexed water in crystalline trehalose dehydrate by both crystallography and QM calculation (Stevens et al. 2010). Several C–H. . .O and van der Waals interactions in crystalline native cellulose were detected by AIM on QM calculations based on the coordinates proposed from fiber diffraction. Fiber diffraction does not provide sufficient data for electron density studies, but basing the AIM analysis on QM calculations on the fiber diffraction coordinates appears to be an effective way to detect weak interactions in such samples.

In overview, the AFM work dramatically illustrates and validates the work on charge density that has been underway in the crystallographic and QM communities at admittedly low levels of intensity for some 40 years. For carbohydrates, three approaches can be used: QM calculations alone, QM calculations based on crystal coordinates from a conventional determination, or analysis of the high-resolution X-ray data. Combination of the latter two approaches allows insights into the accuracy of the approximations at given levels of QM theory. Although Bader's book (1990) offers interesting examples such as detection of covalent bonds in propellane, perhaps AIM analyses are likely to be most fruitful in the carbohydrates arena for detection of weak interactions that are generally considered to be "non-bonded."

3 Disaccharides

The most critical subject in understanding polysaccharide structure has been the disaccharide linkage. This writer has written extensively on Ramachandran mapping studies based on energy minimization studies, including a methods chapter (French 2014) and a justification of methods that we have used (French 2011). Disaccharide maps for various force fields and QM maps are described at some length in French (2012). The present chapter will concentrate on results obtained with energy minimization, with some observations on some molecular dynamics efforts. This focus on energy minimization is justified from a similarity of results for a given method of calculating the energies, as indicated in Fig. 8. That work shows the explicit solvation Amber/Glycam Replica Exchange MD data from Shen et al., with results from energy minimization using dielectric constant 8 Amber/Glycam calculations on 150 different starting geometries.

For those wishing to create relaxed-residue Ramachandran maps of disaccharide energies, there are a few important guidelines. The first is that maps of the entire $\phi-\psi$ conformation space must be periodic, i.e., the values at the edges must be the same on opposite sides of the map. This will not generally be the case if "dihedral driver" or "scan" capabilities that are built into modeling software are used. Most of those utilities carry out an energy minimization at a certain conformation and then

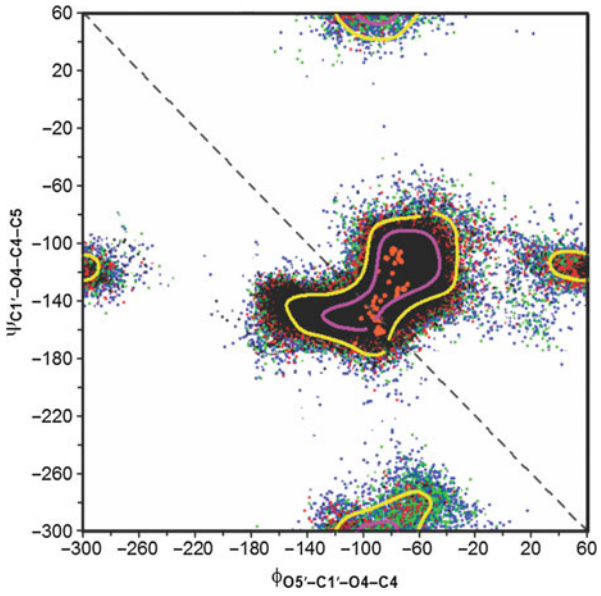

Fig. 8 Merged Replica Exchange MD and energy minimization plot (Modified from Shen et al. (2009) and French (2012)). Crystal structure conformations of molecules related to cellobiose are plotted as *large orange dots*. *Black dots* are for room-temperature structures, and *colored dots* indicate conformations accessed at progressively higher temperatures. The *contour lines* are from the dielectric 8.0 Amber/Glycam map (French 2012), with *magenta* and *yellow contour lines* for 1 and 2 kcal mol^{-1}, respectively. The *diagonal line* indicates conformations that would result in twofold screw-axis symmetry when applied to an infinitely long cellulose molecule

make a small change in the conformation and carry out another minimization for the next point on the Ramachandran grid. This does not work for carbohydrates because the structures are transformed by the energy minimization process and do not recover. Therefore, on an energy map from $-180°$ to $+180°$ with intermediate steps, the minimized structure at $-180°$ will not generally be the same as at $+180°$. So it is necessary to start each minimization with the intended starting structure (French 2011).

Another point is that a variety of starting geometries must be used if it is desired to find the global minimum. In a practical sense, this means that individual maps for the various combinations of the clockwise and counter-clockwise orientations of the exo-cyclic groups must each be calculated. The various combinations of primary alcohol group orientations are also needed. The desired adiabatic map can be generated by finding the lowest energy from all of the starting geometries at each increment of ϕ and ψ. Our recent QM adiabatic maps for cellobiose (French et al. 2012) consisted of energies from about 30 different starting geometries. A caution for those constructing adiabatic maps is that to be predictive in general, such maps must include some concession to a condensed phase, such as continuum solvation or an elevated dielectric constant.

When a method is in doubt, it would be useful to compare the results for the backbone of the disaccharide molecule having no hydroxyl groups with those from a HF/6-31G* QM study for analogs with various linkages (French et al. 2001). These analog energy surfaces are remarkably independent of the level of theory, although higher levels have been subsequently used for less specific models in the parameterization of the most recent CHARMM force field (Guvench et al. 2009).

Even when adhering to these rules it is possible to get results that do not seem predictive when using MM methods. Although our MM models of many disaccharides gave sensible results, one did not. For reasons that are not fully understood, modeling the sucrose disaccharide with MM was not satisfactory, based on the distribution of crystal structures on the Ramachandran map. However, a hybrid QM::MM hybrid method was reasonably predictive (French et al. 2000a). Another situation that was resolved with QM calculations involved the conformational preference of α,α-trehalose. Based on MD simulations with CHARMM in both vacuum and solvent, it was decided that the vacuum and solution conformations were very different (Liu et al. 1997; Engelsen and Pérez 2000). Taking advantage of the chemical symmetry of the molecule and a reduction in conformation space because of very high energies in some regions for an analog molecule stripped of hydroxyl groups (Tvaroška and Václavik 1987; French et al. 2001), mapping studies showed that the $\phi = 180°$, $\psi = 180°$ conformation had 7 or 8 kcal mol^{-1} higher energy despite a modeled hydrogen bond. This was the result from three different levels of QM theory. The $\phi = 60°$, $\psi = 60°$ conformation, which is in accord with the exo-anomeric effect had the lowest energy and was in full agreement with conformations of some 25 crystal structures. A dozen new crystal structures are also found in that same gauche-gauche energy well, once three determinations are corrected for the inadvertent reporting in as the mirror images of the correct structure. There was a substantial variation in energy surfaces because of the different levels of theory that were employed and a particular combination that was thought to underestimate hydrogen bonding energies (HF/6-311++G**// B3LYP/6-31G*) gave the best rationale for the observed crystal structures. In any case, the idea of a dramatic change in conformation from the gas phase to aqueous solution was refuted for trehalose by the QM studies.

More recently, such a solvent effect was supported by a much more extensive QM study of cellobiose (French et al. 2012). That work pointed out the critical role of the solvation model, as well as inclusion of a sufficient number of starting geometries. Although the preference for a conformation of cellobiose was indicated by several modeling studies, including the work of Appell et al. (2004), it was not until the QM-aided experimental work of Cocinero et al. (2009) that the idea of a very different vacuum conformation was widely accepted. A QM study by Schnupf and Momany (2011a) was based on 18 starting structures and attempted to build an adiabatic map based on energy studies around each of the local minima. Also, the COSMO continuum solvation model was used. Our following effort used the same QM computation strategy with the B3LYP method and mixed basis set for minimization, namely /6-31+G* for the oxygen atoms and 4-31G for the carbon atoms, with final energies by B3LYP/6-31+G*. However, we used the SMD solvation

model and some twenty more starting geometries, previously extracted (French and Johnson 2006, 2008) from HF/6-31G* studies. In the vacuum calculations, the $\phi = 60°$, $\psi = -120°$ conformation was favored by 3.5 kcal mol^{-1} but in solvent the $\phi = -100°$, $\psi = -140°$ form was favored by 2.0 kcal mol^{-1}.

Figure 9 shows the entire SMD energy surface as well as a close-up view of the central area where most of the crystal structures are located. The close-up view includes a diagonal line that corresponds to a twofold screw axis when applied to cellulose itself. The twofold screw conformation for cellulose has been controversial, with various MM software programs giving higher energy right along the line, owing to a short contact between H4 and H1′ on the linkage carbon atoms. That is not so much a problem with the levels of QM theory that have been applied (French and Johnson 2009).

A different set of crystal structures was plotted, based on a new survey of the CSD for this work. It discriminates between the crystal structures that are for molecules that have hydroxyl groups in the 2- and 3-positions so that inter-residue hydrogen bonds can form across the glycosidic linkage and those β-(1,4)-linked structures that are derivatized in those locations or missing the oxygen atom. On Fig. 9, there is considerable overlap between the two types of crystal structure, with the non-H-bonding structures slightly exceeding the range of the structures that can form hydrogen bonds, whether they do or not. Structures with ψ values greater than −130° do not form the classic 03-H. . .O5′ hydrogen bonds.

Using the same cumulative frequency analysis as previously used herein for fructofuranose, these all-inclusive and hydrogen-bonding ability only populations can be evaluated on the energy surface. (The heavily derivatized structure (Ernst and Vasella 1996) at the bottom of the map could not be included for technical reasons.) The cumulative frequency plots (Fig. 10) differ in a fairly subtle manner. However, the upper plot has an equivalent temperature of 533 K, and, according to the fitted exponential decay line, some 61 % of the structures should have energies less than 1 kcal mol^{-1}. The comparable figures for the structures that can form hydrogen bonds across the linkage are 413 K and 70 %. In a room temperature gas, 82 % of the structures would have energies of less than 1 kcal mol^{-1}.

This type of analysis must be kept in perspective. Selection of the crystal structures to plot is obviously important. In the case of the data set used herein, for example, the structures of cellotetraose and methyl cellotrioside are included. They alone contribute 14 different linkage geometries to the statistics, and once the molecule is in the flat-ribbon, twofold shape, crystal packing can be very efficient. The shapes of carbohydrates in complexes with enzymes are another matter. Not only are ring shapes distorted, but the glycosidic torsion angle values indicate that the linkage may be in a higher-energy shape (Johnson et al. 2009).

Another argument is that the exocyclic groups in the actual structures are involved in mostly intermolecular interactions, and the lowest-energy forms bear little similarity in that regard to the experimental structures. Still, the basic idea that a molecule in a crystal is perturbed in one direction or another from its ideal shape by crystal packing forces seems reasonable enough. When a sufficient number of different but closely related molecules are examined in their crystalline

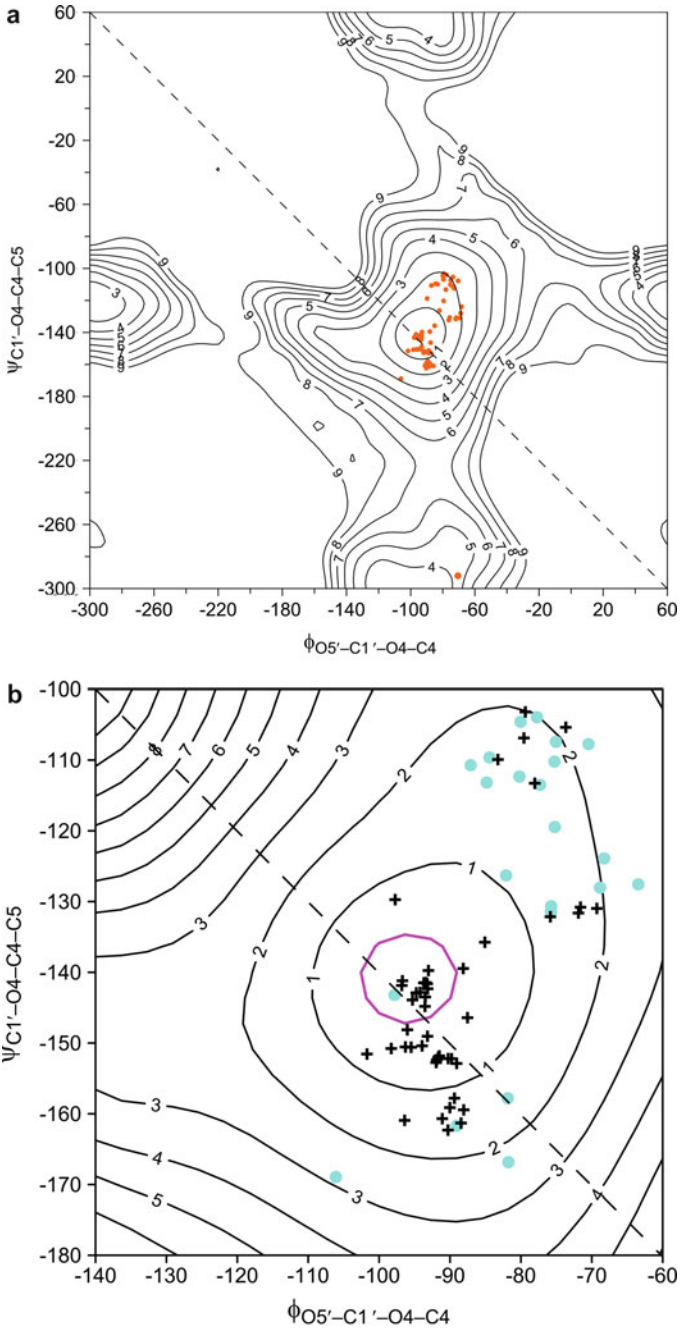

Fig. 9 (**a**) QM solvated cellobiose energy surface using the full 6-31+G* basis set. The *orange dots* represent conformations found in crystal structures of β-(1,4)-linked disaccharides such as

environments, the perturbations will appear random but have a distribution that approaches exponential decline with increasing corresponding energy. Even if the details are fuzzy, it seems that the information provided by crystal structures can provide useful information on the validity of a particular approach to modeling. It can also give valuable insights on the factors that determine conformation. Another point is that even with the structural diversity of the different crystal structures, they are confined to a relatively small portion of conformation space.

4 Oligosaccharides and Polysaccharides

The structures of simple oligosaccharides such as cellotetraose can be readily understood in terms of the material on monosaccharides and disaccharides, with just more linkages (Shen et al. 2009). The relative importance of MD simulations increases substantially, however, because exploration of the increased number of dimensions of conformation space is expedited by the fundamental basis for MD. Namely, thermal motion can overcome minor energy barriers.

The complex branched oligosaccharides that are on the surfaces of proteins or recognized by proteins, on the other hand, are a more complicated topic. Rather than try to address it here, the reader is referred to a substantial body of work in that area by the Woods groups, located at the University of Georgia and at the National University of Ireland in Galway. Among their papers that should be known among all carbohydrate modelers are generally applicable works such as a review of available carbohydrate force fields by Fadda and Woods (2010) and Foley et al. (2011). The description of the Glycam force field that they developed (Kirschner et al. 2008) should be of interest. One of the major drivers for the latest version of the Glycam force field is the ability to mix protein and carbohydrate structures. The Glycam web site is a potential resource for many users. http://glycam.ccrc.uga.edu/. Among the publications from that group and colleagues specifically on oligosaccharides and their binding to enzymes, readers can get an idea of the state of the art from reading Woods and Tessier (2010), DeMarco et al. (2010), Kadirvelraj et al. (2011), Nivedha et al. (2014), or Martin et al. (2014). Other efforts on the conformation of oligosaccharides include Widmalm (2013), Fernandes et al. (2010), and Wood et al. (2013).

This review will instead cover the conformation of a large cyclodextrin, a field that is less complicated but still quite challenging. The biosynthetic cyclomaltooligosaccharides and cycloamylose molecules comprise as few as five glucose residues (Nakagawa et al. 1994) up to hundreds and a number of them have

Fig. 9 (continued) cellobiose. The *dashed diagonal line* represents structures with twofold screw axes. Near the *line*, structures above the *line* are left-handed and below it they are right-handed. Energies taken from French et al. 2012. (**b**) QM solvated cellobiose energy surface, zoomed in view of (**a**). + *signs* represent crystal structure conformations for molecules that could (or did) form inter-residue hydrogen bonds, *cyan dots* show β-1,4-linked structures without that capacity

crystallized (Saenger et al. 1998). These molecules are made by the action of enzymes on the mostly linear amylose component of starch. The prediction of cyclodextrin structures with various molecular modeling approaches has been reasonably popular (Ivanov and Jaime 2004; Maestre et al. 2007). One of the most interesting is CA26 or cycloamylose with 26 glucose residues per cycle (Fig. 11). The interest in CA26 comes from its two helical segments that closely resemble some of the "V" polymorphic structures proposed from fiber and powder diffraction patterns for amylose (Rappenecker and Zugenmaier 1981), one of the two components of starch. Their helical cavities can host guest molecules and structures of crystalline complexes of CA26 with triiodide (Nimz et al. 2003), undecanoic acid, and dodecanol (Nimz et al. 2004). Those crystal structures are in addition to the triclinic and orthorhombic packings of the hydrated but otherwise empty carbohydrate (Gessler et al. 1999; Nimz et al. 2001). In all, eight crystallographically unique molecules are in the literature; two of the molecules have C2 symmetry but both halves of the molecule are all included in the analyses below.

The two helices are connected by two folding (or flipping) regions, where the ψ_H torsion angles take on values near 180° instead of about 0° taken by the other 24 linkages. Such folds were indicated by Manley (1964) from electron microscopy of amylose crystals but no details were provided. In solutions of CA26, the ^{13}C NMR spectrum shows only six unique chemical shifts, i.e., all glucose residues are

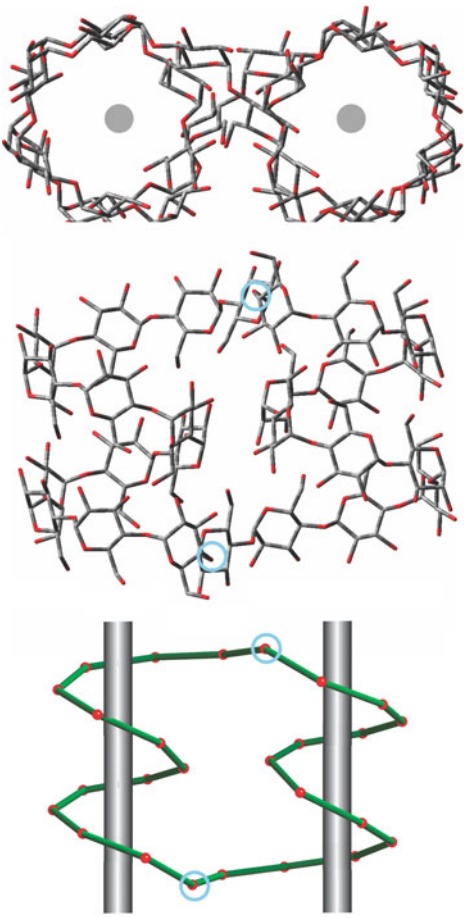

Fig. 11 CA26 molecule showing a schematic of two turns each of two six-residue/turn helices with helix axes (*lower*); atomistic drawing in same view (hydrogen atoms deleted, *middle* image) and looking down the helix axes (*upper* image). Disordered oxygen atoms were removed. *Light blue circle* indicate the two linkages where the amylose chain "flips" with ψ values very different from the other linkages

equivalent on the NMR timescale in water at 50 °C (Gessler et al. 1999). Therefore, there is an interconversion and the flipping linkages rapidly migrate through the molecule on the NMR timescale similar to pseudorotation in furanosyl rings.

Modeling studies of CA26 before the crystal structure was solved did not reveal the correct structure so further studies should be useful in improving modeling methods for large carbohydrates (Gessler et al. 1999). Figure 12 shows that the ϕ and ψ linkage conformations fall into the two major minima for the maltose disaccharide (the shortest amylose molecule), with the two flipping linkages from each of the eight molecules located within the secondary minimum surrounded by a 3 kcal·mol^{-1} contour. The energy contours on that surface were calculated with a composite, or hybrid, method. Energies for the backbone, a suitably linked pair of tetrahydropyran rings, were calculated with HF/6-31G* theory and remaining atoms were calculated with MM3 (Allinger et al. 1990) and a dielectric constant of 3.5. In this case, the dielectric constant was not critical to a successful modeling calculation as the other two maps in Johnson et al. (2007) would have also provided

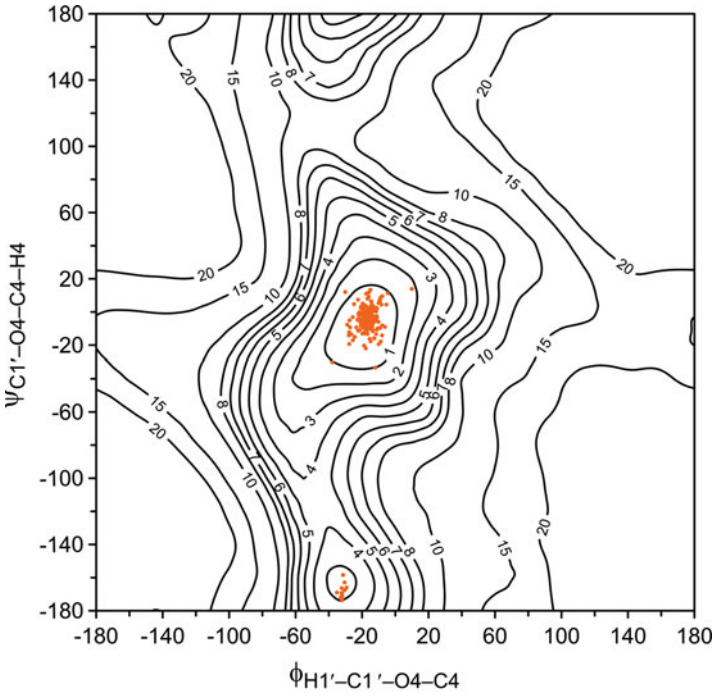

Fig. 12 Energy contours for maltose from MM3, dielectric constant 3.5 with HF/6-31G* correction for the tetrahydropyran rings and glycosidic linkage (Johnson et al. 2007), with crystal structure conformations from CA26 (Note that the torsion angles are defined with the hydrogen atoms, rather than our recent practice of using the ring oxygen and C5 atoms)

suitable energy wells for the CA26 conformations. In Johnson et al., however, an elevated dielectric constant was quite important to providing a low-energy region that matched the distribution of linkage conformations of the noncyclic di- and oligosaccharide crystal structures. While the HF/6-31G* correction of the hybrid map was crucial to successfully modeling the sucrose disaccharide (French et al. 2000a), it played a minor role in mapping for the maltose disaccharide (compare with maltose maps in Dowd et al. 1992). This map is very different from the vacuum CHARMM map of Hatcher et al. (2011) who made extensive use of QM in the parameterization. They found another significant ($<$2.0 kcal mol^{-1}) secondary minimum around $\phi_H = 180°$. Their solution map is similar to Fig. 12 and also to the QM::MM3 hybrid map at dielectric 7.5 (Johnson et al. 2007).

Although CA26 is a large oligosaccharide, some modeling studies can be carried out with DFT methods. Schnupf and Momany (2011b) evaluated several different methods with their mixed basis set that uses 4-31G for the carbon atoms and 6-31+G* for the oxygen atoms. Besides the widely used B3LYP method, B97D (the D is for dispersion) and the same method with PCM continuum (implicit) solvation were applied, based on the B3LYP geometry as a starting structure. A potentially interesting alternative quantum mechanical method (SCC-DFTB) that

has similarities to semi-empirical methods (Elstner 2006) was also evaluated. They also made a comprehensive comparison of the different CA26 crystal structures. One motivation of the work was to study the V-amylose helix based on the computed information starting with a half-segment of the CA26 structure. In that they found the polysaccharide to be reasonably stable under the calculations; a misleading point compared the average 7.9 Å pitch of single V helices to a value of 10.57 Å for the native starch B form (Takahashi et al. 2004). That 10.57 Å value is the crystallographic repeating distance for the double helix; the individual strands of the double helix repeat in 21.14 Å, so there is a much larger conformational change in transitioning from V amylose to B amylose, besides the mysteries of the double helix formation by amylose.

Despite the necessity of a continuum solvation model to model cellobiose crystal structure conformations (French et al. 2012), Schnupf and Momany found that the B3LYP method with their mixed basis set and no solvent gave the lowest Root Mean Square Deviation with the CA26 crystal structure that was used to derive the starting geometry. The preparation of the starting structure included deleting one of the disordered positions for several of the oxygen atom positions and adding hydrogen atoms that were not located crystallographically. The crystal structures were heavily hydrated but the water molecules were deleted before starting the calculations.

Given the approximations to the physical situation resulting from the preparation of the starting geometry, it is not surprising that the coordinates from the modeling calculation and from the crystal structure were not identical. The RMSD values for the B3LYP model were between 0.77 and 1.20 Å. However, that range was similar to the range of RMSD values among the various CA26 crystal structures, so comparison with experiment did not invalidate the modeling method.

For the present paper we essentially repeated their vacuum B3LYP calculation with the mixed basis set. However, we started with the other molecule in the original triclinic structure determination (Gessler et al. 1999). Our initial crystal structure was equivalent to Schnupf and Momany's molecule 1A (their starting structure was based on 1B), and we used different software to remove the extra atoms (Chem-X, no longer available) resulting from the disorder and to add hydrogen atoms (OpenBabel, O'Boyle et al. 2011). While Schnupf and Momany (2011b) used PM3 to adjust the hydrogen atom positions, we used MM4 (Allinger et al. 2003; Lii et al. 2003a, b, c, 2005) for energy minimization of all atomic positions. We then used that MM4 structure for the B3LYP calculations. We also carried out an MM3 minimization (Allinger et al. 1990) with the same input file as for MM4. The MM3 and MM4 calculations were done with the standard termination criterion based on energy change, and the B3LYP calculations used Gaussian 09 (Frisch et al. 2009) with the "Loose" keyword. Even with "Loose," the QM calculations required some 26 days using four processors. The initial MM3 and MM4 calculations were considerably more economical at 2 and 4 min, respectively. Both MM3 and MM4 calculations were done with a dielectric constant of 1.5. Note that a dielectric constant of 1.5 is designated for use in MM3 and MM4 for calculations on isolated molecules (in a vacuum, except for the molecule itself).

Because experimental values are known for the parameters that have been modeled, it is fair to question why such calculations are useful. There are several excellent reasons for this exercise. The first is to learn whether the geometric features that have systematic variation are predictable with theoretical calculations. Another way of asking that question is to find out whether there are features that are outside our understanding of the general principles of molecular structure. Similar to the case of branched oligosaccharides, the CA26 structures have a considerably wider range of inter-residue interactions than a disaccharide, and therefore constitute a more stringent test of the reliability of the computational methods. In particular orthorhombic CA26 has some short inter-helical contacts including a network of C–H. . .O hydrogen bonds (Nimz et al. 2001). Because of the similarity of the interactions within a CA26 molecule to those of oligosaccharides for which crystal structures are unavailable, the quality of the models of a known structure is of substantial interest. Another interesting question regards the symmetry of the CA26 molecule. Two of the crystal structures have C2 symmetry, i.e., the two halves are related by rotational symmetry. Is this the minimum energy condition, or is the asymmetric structure the preferred structure? Is the symmetrical condition a consequence of crystallization, or is asymmetry?

To rigorously address these questions for such a large, complex molecule with computations is difficult. The final energy hypersurfaces are likely to be fairly flat, with numerous variations on the global minimum structures that have small differences in energy. In this work, we have conceded that the starting structure is not likely to minimize to the global minimum. Another issue is whether the structure has actually completed the energy minimization? Has the termination criterion stopped the process before the geometric details are settled to a reasonable approximation? In the case of the QM calculation, the "Loose" keyword was a practical necessity. In the case of MM3 and MM4, however, a tenfold increase in computer time would not be an issue. Their default termination criterion is an energy change of 0.00008 kcal mol^{-1} times the number of atoms. That is appropriate for small molecules, but when there are 546 atoms, as in CA26, the energy is still changing by 0.0437 kcal mol^{-1} for each cycle. When evaluating different computational methods, it is important that the results for each method represent the capability of the method, so we did decrease the termination criterion by a factor of 10 for MM3 and 8 for MM4 (the difference was due to a local technical consideration). In general, the resulting longer minimizations would allow the atoms to move further from their starting positions. That makes comparison with the B3LYP calculation more difficult.

Table 2 shows the various RMSD values computed for structures minimized by various methods. The additional minimization time in the longer runs did increase the deviation from the starting structure, except for the MM4 determination of the glycosidic angle. Not revealed by the glycosidic angle data in Table 2 is that the MM3 values of the glycosidic angle decreased on average by about 1.9° and increased by MM4 by about 1.1°.

Another way to compare the effect of minimizing with the various methods is shown in Table 3. A fully minimized model should have parameters near to the

Table 2 RMS differences from starting structure

	RMSD values for various methods		
Parameter	MM3	MM4	B3LYP-r
$\phi_{\text{standard termination}}$	4.4°	3.9°	7.2°
$\phi_{\text{small termination (tight)}}$[a]	5.9°	6.8°	
$\psi_{\text{standard termination}}$	6.4°	4.2°	9.7°
$\psi_{\text{small termination (tight)}}$[a]	9.2	9.2°	
$O1–O4_{\text{standard termination}}$	0.054 Å	0.044 Å	0.103 Å
$O1–O4_{\text{small termination (tight)}}$[a]	0.071 Å	0.063 Å	
$C1–O–C4_{\text{standard termination}}$	1.7°	2.2°	1.2°
$C1–O–C4_{\text{small termination (tight)}}$[a]	2.4°	1.8°	

[a]"Tight" indicates termination criteria of 0.0546 and 0.0437 kcal mol^{-1} for MM3 and for MM4, respectively

average of the experimental structures. Table 3 compares the average, minimum, and maximum values of the four descriptive parameters. On a positive view, none of the modeled values are grossly outside of the range of observed experimental values. Average values of the modeled parameters were reasonably close to the experimental values, with the MM3 values for the glycosidic (C1–O–C4) angle being slightly low, as mentioned above. Several discrepancies merit comment. The two B3LYP studies are impressively dissimilar, considering that the same software was used for the final results. However, the initial crystal structures were not the same, and several different procedures were used to create the models that were minimized with B3LYP. The O1–O4 distance is an interesting case; the MM3 average was closest to the experimental average, with the MM4 and B3LYP methods being 0.05 Å longer. The ranges of minimized values, 0.51 Å and 0.55 Å for MM3 and MM4, respectively, were somewhat larger than the B3LYP ranges of about 0.47 Å, but all were smaller than the experimental range of 0.75 Å.

An overall assessment of the crystal structures and the models suggests that there is a substantial flexibility of the molecule. Still, as shown by Schnupf and Momany, there is a substantial similarity of the structures of the molecules in the crystals and the models are also all easily recognizable as having the same structure for chemical or biological purposes.

The questions of whether the minimized models tend towards a symmetric structure, and whether there is a coupling of parameters can be addressed graphically. Figure 13a shows the ϕ and ψ angles for two complete trips (residue numbers 1–27 and 27–53) around the final MM3 and MM4 models of CA26 to illustrate the degree of symmetry and coupling. The large spikes in the lower curve for the ψ angle are matched by smaller, downward spikes in the upper, ϕ angle line. These spikes occur for the "flipping" linkages. Smaller fluctuations between the peaks for the 1st and 14th (and 27th, 40th, and 53rd) residues are not so well matched, with four and five small "up" peaks in the two different intervals for the upper plot's ϕ values. On the lower curve's ψ values there are three, somewhat larger "up" peaks in each of the same intervals. One might conclude from the models that there is an atom-conflict based need for the ψ values to alternate even within the helical

Table 3 Comparison of experimental averages and ranges with those from minimized models

Parameter	Experimental (all crystal structures)[a]	MM3	MM4	B3LYP/r (our calculations)	B3LYP/r (Schnupf and Momany)[b]
$\phi_{average}$	102.3°	101.7°	100.2°	103.0°	101.6°

[b]Taken from values in Schnupf and Momany (2011b). These averages are based on their 25 reported values. Their ψ values were converted from C1′–O–C4′–C3′ to C1′–O–C4′–C5′ by addition of 120°

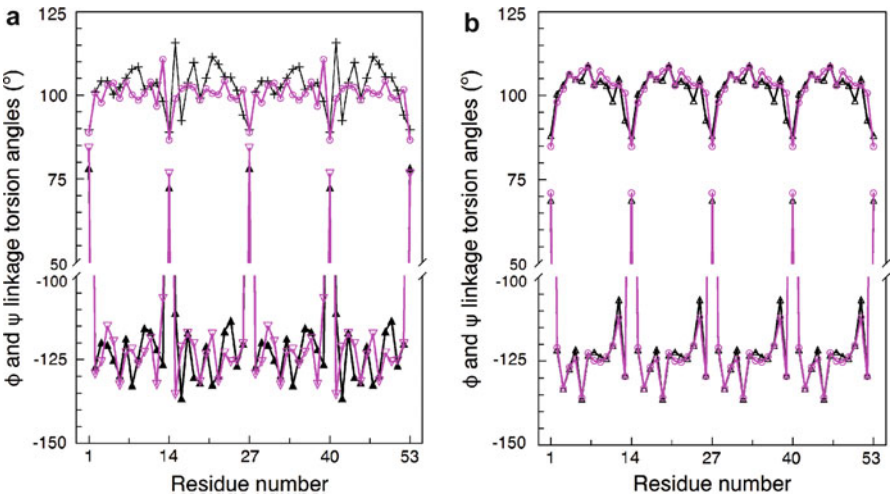

Fig. 13 ϕ and ψ torsion angles for CA26. (**a**) MM3 (*black*) and MM4 (*magenta*) values for ϕ (*upper graph*)/ψ (both parts of *split graph*) data on sequence plot. (**b**) Experimental structures from the symmetrical barium iodide and dodecanol crystals are shown in *black* and *magenta*, respectively. *Torsion angles* are ϕ (O5'–C1'–O4–C4) and ψ (C1'–O4–C4–C5). Two trips around the model (26 residues each trip) are shown to help visualize the periodicity and reproduction of intrinsic variation

portions of CA26. Figure 13b is a similar plot for the two symmetrical CA26 molecules [barium iodide complex II (Nimz et al. 2003) and dodecanol complex (Nimz et al. 2004)]. The ϕ oscillations are smaller and both molecules are quite similar. The ψ torsion angle values are similar for both experimental molecules, and their ranges of values, even when excluding the flipping linkages, are larger than for the ϕ torsions. There is reduced variation in ψ values for residues 7–9 (and 20–22, etc.); those groups of residues are on the inner sides of each helix. That observation of reduced variation possibly due to inter-helix forces is not confirmed by the models in Fig. 13a.

Figure 14a shows the O1–O4 distances for the MM3, MM4, and 14b shows values for the two symmetric experimental structures (see previous paragraph). In particular the MM4 plot indicates strong pseudo symmetry; the MM3 values are somewhat different between the two halves of the molecule (split at the flipping linkages). In the two experimental structures, which are nearly identical to each other, the variation is somewhat different in both the flipping regions (residues 1–3, 13–16, 26–29, etc.) and the helical regions (residues 4–12 and 17–25).

The values of the O1–O4 distance for the 16 residues that were considered to be part of the six-residue per turn helices in the MM3, MM4 our B3LYP structures are 4.33 Å, 4.38 Å, and 4.37 Å, whereas the average value from the eight crystal structures is 4.29 Å. That value is closest to the prediction of 4.25 Å for V_6 amylose in French and Murphy (1973) based on a variety of rigid-residue models. The average O1–O4 distance for the residues in the tetrasaccharide sections associated with the

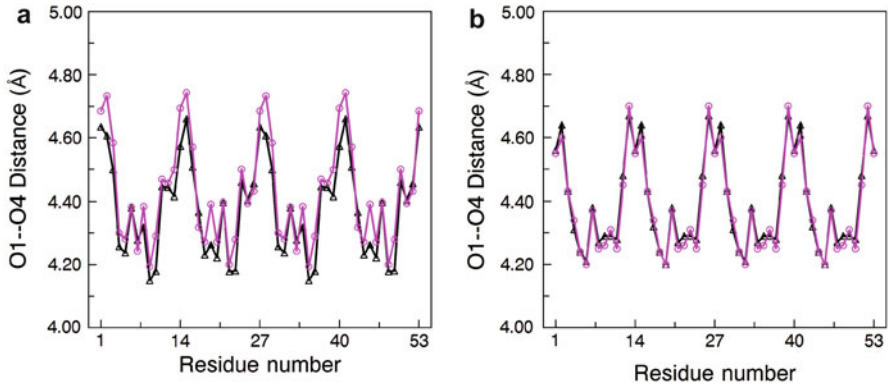

Fig. 14 O1–O4 distance for each residue number showing the stretching of the residues at the flip zones (residues 1, 14, 27, 40, and 53). (**a**) The *black line* is for the MM3 geometries, and the *magenta line* for the MM4 calculation. (**b**) The O1–O4 distances are shown for the symmetrical experimental structures. The *black line* is for the barium iodide complex with CA26, and the *magenta line* for the dodecanol structure. Two trips around the model are shown to help visualize the periodicity and reproduction of intrinsic variation

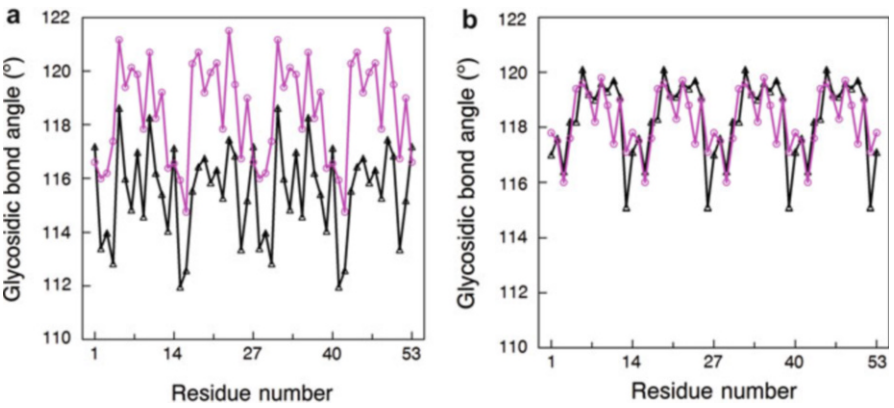

Fig. 15 C1–O4–C4 glycosidic bond angle for CA26. (**a**) MM3 (*black*) and MM4 (*magenta*) bond angles. (**b**) Values from the symmetric experimental structures, with the *black line* for the barium iodide complex and the *magenta line* for the dodecanol complex structure. Two trips around the model are shown to help visualize the periodicity and reproduction of intrinsic variation

flipping linkages was 4.56 Å. These values required an offset in the matching of the O1–O4 distance with tabulated linkage parameters in Table 1 of Nimz et al. (2001) for the orthorhombic structure to match with the groupings of Schnupf and Momany.

Figure 15a, b show the glycosidic bond angles (C1′–O4–C4) by MM3 and MM4 and the two symmetric CA26 molecules from crystal structure determinations. For the bond angle, the B3LYP method was superior (not shown), with the MM values being systematically low (MM3) or high (MM4), each by about a degree.

5 Conclusions

The material on CA26 provides a perspective on computerized modeling of carbohydrates, indicating both some successes and some remaining issues. It shows that there can be substantial intrinsic variation in molecular and linkage geometries for chemically identical moieties, and that modeling can reproduce numerous aspects of that variation. The relatively small set of methods had been shown in earlier parts of this chapter to perform credibly in reproducing features of precisely known crystal structures, such as the puckering of sugar rings and linkage geometries of disaccharides. In the original work it was already established that some acknowledgement of a condensed phase environment was needed to predict all of the known experimental geometries. The predictions were made objective by calculating a "temperature" that would give a comparable distribution of corresponding energies, with values in the neighborhood of 500 K. New calculations of corresponding energies from updated lists of crystal structures were made based on previously published energy surfaces.

In the CA26 study, it was not so convenient to construct a starting model from atoms or even glucose residues; it was far easier to take advantage of an existing crystal structure. Even so, the existing crystal structures required modification before calculations because of missing hydrogen atoms or disordered atoms that are in the coordinate lists twice. Because the limits of our capability to calculate many atom structures with quantum mechanics were being tested, the numerous water and other guest moieties such as iodide or dodecanol were deleted. In our work, the missing hydrogen atoms were added in an arbitrary manner. Most ironically, the acknowledgement of the condensed phase, established for either somewhat elevated dielectric constants or continuum solvation, was not employed in the CA26 calculations.

There are many simplifications or approximations in these calculations, but some conclusions can be tentatively drawn regarding the ability to model complex carbohydrate structures. The substantial variation in some of the critical properties of the experimental structures is met with a substantial variation in the same properties of the models calculated by different methods. However, the major intrinsic variations in linkage torsion angles and O1–O4 distances were retained by the models. There were no obvious differences that would affect the chemistry or biochemistry of this complicated molecule. The average values of the four major variable parameters were reasonably well predicted, but some of the modeled values were slightly outside of the range of the experimental structures. These were models, after all. A certain amount of tension in the structures, both experimental and modeled, was indicated by the persistent variation in parameters even in the helical regions, although the tension is resolved in different ways in the various models and actual crystal structures.

One important lesson is to pay attention to the termination criteria. When operating with a large molecule such as CA26 with 546 atoms, it was useful to continue the energy minimization beyond its default point. The structural details changed significantly afterwards when some ten times as much computer time was

used. With the empirical force fields, this increase was not a significant issue but it was not feasible to increase the precision of the "loose" B3LYP calculation. The B3LYP calculation that we did afford furnished results closer to experiment for only one of the four variables. As will be obvious to many readers, much work remains to be done for a comprehensive study of CA26, and the extensive computer time needed for the B3LYP calculations indicates that a more reasonable approach would involve empirical force fields when only basic structural information is needed. Studies starting with both the symmetric and the other asymmetric crystal structures and some acknowledgement of the condensed phase environment would be critical issues in a more comprehensive study. A molecular dynamics study would be especially interesting to learn whether the equivalency of all of the linkages on the NMR time scale can be reproduced. But this is a review, with some supplemental calculations, rather than a new computational effort.

Acknowledgements Many of the calculations in this effort were carried out by Michael Dowd, Glenn Johnson, and Monica Concha. Michael Dowd, Krystal Fontenot, and Michael Santiago Cintrón provided valuable pre-submission comments on the manuscript.

Abstract

Carbohydrates, like nucleic acids and proteins, are essential biological molecules. Owing to their intrinsic physicochemical properties, carbohydrates are capable of generating structural diversity in a multitude of ways and are prominently displayed on the surfaces of cell membranes or on the exposed regions of macromolecules. Recent studies highlight that carbohydrate moieties are critical for molecular recognition, cell-cell interactions, and cell signaling in many physiological and pathological processes, and for biocommunication between microbes and host species. Modern carbohydrate microarrays emerged in 2002 and brought in new high-throughput tools for "glyco code" exploration. In this section, some basic concepts of sugar chain diversity, glyco-epitope recognition, and the evolving area of glyco-epitomics and biomarker discovery are discussed.

Two complementary technologies, carbohydrate antigen arrays and photogenerated glyco-chips, serve as models to illustrate how to apply carbohydrate microarrays to address biomedical questions.

Keywords

Antibodies • Carbohydrates • Carbohydrate microarrays • Glycans • Glycoepitopes • Glycoconjugates • Glycome • Glycomics • Lectins • Oligosaccharides • Polysaccharides

Abbreviations

Ab	Antibody
Ag	Antigen
AGOR	Agalacto-orosomucoid
ANOVA	Analysis of variance
ASOR	Asialo-orosomucoid
BSA	Bovine serum albumin
DC-SIGN	Dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin (also known as CD209)
ELISA	Enzyme-linked immunosorbent assay
FACS	Fluorescence-activated cell sorting
GBP	Glycan-binding protein
Gn	GlcNAc
GNA	Galanthus nivalis lectin
Hi-D FACS	High-dimensional fluorescence-activated cell sorting
HIV	Human immunodeficiency virus
IgG	Immunoglobulin G
IgM	Immunoglobulin M
KLH	Keyhole-limpet hemocyanin
LAM	Lipoarabinomannan
LPS	Lipopolysaccharide
mAbs	Monoclonal antibodies
Man9	Man9Gn2Asn moiety
m-II	Multivalent type II chains
Neu5Ac	*N*-acetylneuraminic acid
OR	Orosomucoid
PAMPs	Pathogen-associated molecular patterns
PBMC	Peripheral blood mononuclear cells
P-Man	Yeast phosphomannan Y-2448
PHA-L	Phaseolus vulgaris-L lectin
RAR	Relative antibody reactivity
SARS CoV	Severe acute respiratory syndrome-associated coronavirus
SNA	Sambucus nigra I agglutinin
Stpv	Streptavidin
TI	T-independent

Tn	GalNAcα1→Ser/Thr
Tri/m-Gn	Tri-antennary and multivalent GlcNAc cores
Tri/m-II	Tri-antennary and multivalent type II chains
Tri-II	Tri-antennary type II (Galβ1→4GlcNAc) chains

1 Introduction

Cellular carbohydrates are present in multiple structural configurations, including mono-, oligo-, and polysaccharides, as well as various glycan-hybrid molecules. The latter include, but are not limited to, glycolipids, glycoproteins, proteoglycans, and glycosaminoglycans. Unlike proteins, which are composed of amino acids that are connected solely by one possible peptide bond, carbohydrates utilize many possible glycosidic linkages so as to extensively diversify their structures. For example, two amino acid residues, such as two alanines, can produce only one possible dipeptide; however, two molecules of glucose have the potential to generate 11 different disaccharides. A trimer of any of the nine common sugar residues of the human body theoretically can give rise to 119,736 different structural isomers; this is in striking contrast to the maximal construction of 8,000 tripeptides using 20 different amino acid residues. Theoretically, sugar chain structures can have unlimited variation.

In human and virtually all animal species, cell display of specific complex carbohydrates is characteristically associated with the stages or steps of embryonic development, cell differentiation, and transformation of normal cells to abnormally differentiated tumor or cancer cells (Feizi 1982; Hakomori 1985; Crocker and Feizi 1996; Focarelli et al. 2001). In plants, a highly complex set of polysaccharides are associated with structural proteins and lignin to form cell walls (Avci et al. 2012). Even in a given tissue or cell, cell wall layers and domains may have very different carbohydrate structures and express different glyco-epitopes (Albersheim et al. 2010; Avci et al. 2012). Many microbial organisms also carry unique glycosylation systems and produce specific sugar signatures for almost every microorganism in the living world (Dochez and Avery 1917; Heidelberger and Avery 1923; Ezzell et al. 1990; Robbins and Schneerson 1990; Mond et al. 1995; Wang and Kabat 1996). The term "glycome" has been recently introduced to cover the universe of carbohydrate moieties in all living organisms.

Importantly, multiple carbohydrate recognition systems are present in living species. For example, there are numerous anti-glycan antibodies produced by human and other animal species that play key roles in protecting a host from microbial infections (Behring and Kitasato 1890; Wang and Kabat 1998; Lucas et al. 2008) and families of lectin-like glycan-binding proteins (GBPs) that are evolved for carbohydrate-mediated cell-cell communication (Drickamer 1988; Sharon 2007; Varki 2009). The well-known GBPs that are associated with cell signaling and immunomodulation are the receptors of the innate immune system, such as Dectin-1 that recognizes fungal β-glucans (Brown et al. 2002), mannose
